The second type of inguinal hernia, referred to as direct or medial, is acquired. It is a result of stretching and weakening of the abdominal wall just medial to the inferior epigastric (IE) vessels. Looked at from within the abdominal cavity, there is a triangle referred to as Hasselbach's triangle, the three sides of which are the IE vessels laterally, the lateral edge of rectus abdominis medially and the pubic bone below (the iliopubic tract) (Figure 60.12). This area is weak because the abdominal wall here consists of only transversalis fascia covered by the external oblique aponeurosis. A direct, medial hernia is more likely in elderly patients. It is broadly based and therefore unlikely to strangulate. The medially placed bladder can be pulled into a direct hernia (Figure 60.13).

The third type of inguinal hernia is referred to as a sliding hernia. This is also an acquired hernia due to weakening of the abdominal wall, but occurs at the deep inguinal ring lateral to the IE vessels. Retroperitoneal fatty tissue is pushed downwards along the inguinal canal. As more tissue enters the hernia, peritoneum is pulled with it, thus creating a sac. However, the sac has formed secondarily, distinguishing it from a classic indirect hernia. On the left side, sigmoid colon may be pulled into a sliding hernia and on the right side the caecum. Surgeons need extra caution during repair because the wall of the large bowel may not be covered by peritoneum and can be damaged.

Occasionally, both lateral and medial hernias are present in the same patient (pantaloon hernia).

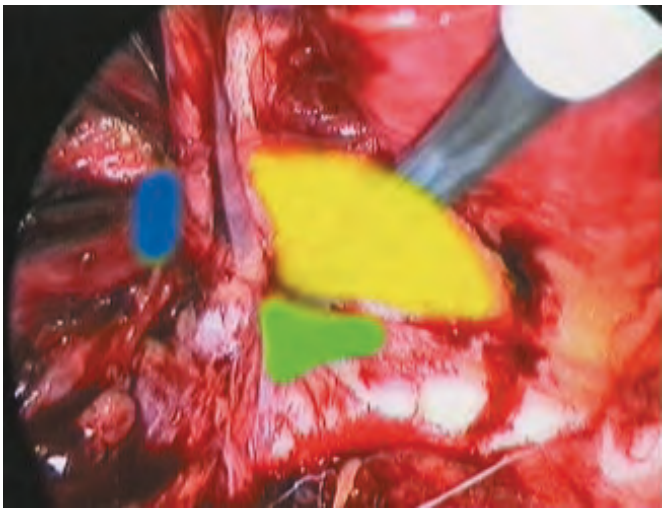

Figure 60.12 Laparoscopic view of the posterior inguinal region with hernia defects highlighted: yellow, medial inguinal; blue, lateral inguinal; green, femoral.

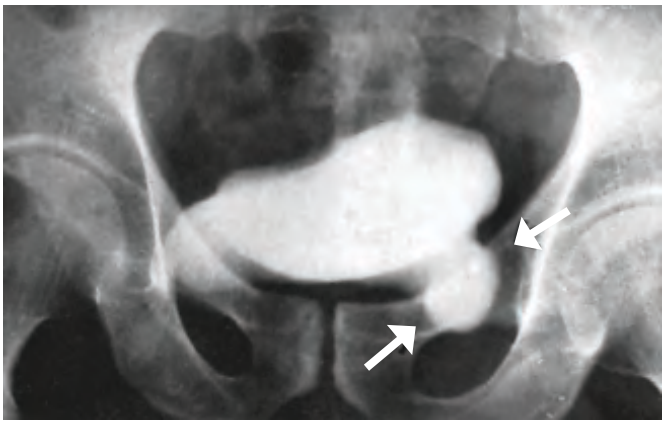

Figure 60.13 This cystogram shows the urinary bladder, part of which has descended into a left direct inguinal hernia (arrows).

Classification

Many surgeons over the past 100 years have attempted to classify inguinal (and femoral) hernias, including Casten, Halverson and McVay, Zollinger, Ponka, Gilbert and Nyhus. The European Hernia Society has recently suggested a simplified system of:

- primary or recurrent (P or R);
- lateral, medial or femoral (L, M or F);
- defect size in fingerbreadths assumed to be 1.5 cm.

A primary, indirect, inguinal hernia with a 3-cm defect size would be PL2.

Diagnosis of an inguinal hernia

In most cases, the diagnosis of an inguinal hernia is simple and patients often know their diagnosis because they are so common. Usually these hernias are reducible presenting as intermittent swellings, lying above and lateral to the pubic tubercle, with an associated cough impulse. Often the hernia will reduce on lying and reappear on standing. With the patient lying down, the patient is asked to reduce the hernia if it has not spontaneously reduced. If the patient cannot then the surgeon gently attempts to reduce the hernia. Once reduced, the surgeon identifies the bony landmarks of the anterosuperior iliac spine and pubic tubercle to landmark the deep inguinal ring at the mid-inguinal point. Gentle pressure is applied at this point and the patient asked to cough. If the hernia is controlled with pressure on the deep inguinal ring then it is likely to be indirect/lateral and if the hernia appears medial to this point then it is direct/medial. Other examination techniques have been suggested but even experienced surgeons find it difficult to distinguish lateral and medial hernias with certainty (**Figure 60.14**).

Figure 60.14 Oblique left inguinal hernia that became apparent when the patient coughed and persisted until it was reduced when he lay down.

Diagnostic difficulties

Confirmation of the diagnosis may not be possible when the patient describes an intermittent swelling but nothing is found on examination. Surgeons will often accept the diagnosis on history alone but re-examination at a later date or investigation by ultrasound scan may be requested.

If an inguinal hernia becomes irreducible and tense there may be no cough impulse. Differential diagnosis would include a lymph node groin mass or an abdominal mass (**Figure 60.15**). Such cases require urgent investigation by either ultrasonography or CT.

Large scrotal hernias may be misdiagnosed as a hydrocele or other testicular swelling. The surgeon should be able to identify the upper limit of a scrotal swelling but a large scrotal hernia has no upper limit because it extends back along the inguinal canal to the peritoneal cavity. In cases of doubt, ultrasonography should establish the diagnosis.

As inguinal hernia is so common, less-experienced clinicians might suggest this diagnosis when referring cases of femoral hernia or spigelian hernia. Also patients with a saphena varix may present with a swelling that increases in size on standing and with a definite cough impulse and be misdiagnosed as a hernia. The same can be true for a varicocele.

It is essential to examine the scrotal contents to exclude other pathologies and to check that the patient has two testes. It is important to examine the opposite side because contralateral hernia is common. Even if the contralateral side is weak, then bilateral repair should be recommended because the risk of contralateral recurrence is high. Of all patients 10% will present with bilateral inguinal hernias and up to 20% more will have an occult contralateral hernia on laparoscopic evaluation. A patient with a single hernia has a lifetime 33% risk of developing a hernia on the other side. Some surgeons have suggested that all patients should be offered bilateral repair, especially if laparoscopic surgery is planned, but this is not widespread practice at present.

Figure 60.15 Malignant mass of nodes.

Investigations for inguinal hernia

Most cases require no diagnostic tests but ultrasonography, CT and MRI are occasionally used. A herniogram involves the injection of contrast into the peritoneal cavity followed by screening which shows the presence of a sac or asymmetrical bulging of the inguinal anatomy.

Management of inguinal hernia

It is safe to recommend no active treatment in cases of early, asymptomatic, direct hernia, particularly in elderly patients who do not wish for surgical intervention. These patients should be warned to seek early advice if the hernia increases in size or becomes symptomatic. Surgical trusses are not recommended but may be required for occasional patients who refuse any form of surgical intervention.

Elective surgery for inguinal hernia is a common and simple operation. It can be undertaken under local, regional or general anaesthesia with minimal risk, even in high-risk patients.

HERNIOTOMY

In children who have lateral hernias with a persistent processus, it is sufficient just to remove and close the sac. This is called a herniotomy. In adult surgery, herniotomy alone has a high recurrence rate and some form of muscle strengthening is added (herniorrhaphy).

OPEN SUTURE REPAIR

In 1890, Eduardo Bassini described suture repair for inguinal hernia (**Figure 60.16**). This was a massive leap forward and has been the basis of open repair for over 100 years. The surgeon enters the inguinal canal by opening its anterior wall, the external oblique aponeurosis. The spermatic cord is dissected free and the presence of a lateral or a medial hernia is confirmed. The sac of a lateral hernia is separated from the cord, opened and any contents reduced. The sac is then sutured closed at its neck and excess sac removed. If there is a medial hernia then it is inverted and the transversalis fascia is suture plicated. Sutures are now placed between the conjoint tendon above and the inguinal ligament below, extending from the pubic tubercle to the deep inguinal ring. The posterior wall of the inguinal canal is thus strengthened.

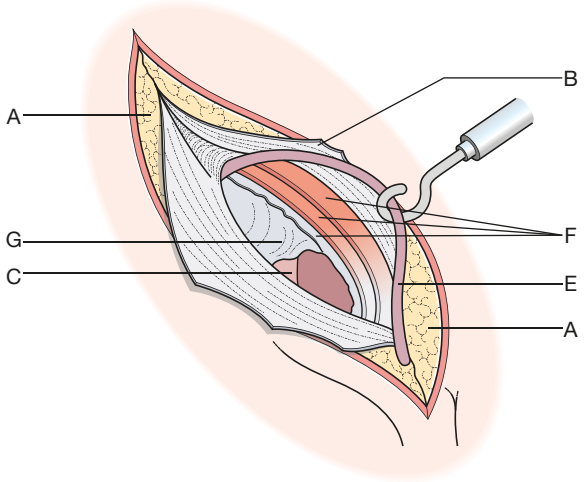

Figure 60.16 Bassini's original diagram. A, subcutaneous fat; B, external oblique; C, iliac vein; E, spermatic cord; F, nerves in inguinal canal; G, transversalis fascia.

Over 150 modifications to Bassini's operation have been described with little or no benefit except for the Shouldice modification. In this operation, the transversalis fascia is opened by a central incision from the deep inguinal ring to the pubic tubercle and then closed to create a double-thick, two-layered posterior wall (double breasting). The external oblique is closed in similar fashion. Expert centres have reported lifetime failure rates of less than 2% after Shouldice repair but it is a technically demanding operation which, in general hands, gives results identical to Bassini's repair.

Today, when a Bassini-type operation is done, most surgeons use a continuous, non-absorbable nylon or polypropylene suture which is darned between the conjoint tendon and inguinal ligament. This operation was described by Maloney, and recently published large randomised trials have reported excellent results when compared with mesh techniques. It is the most common operation performed in countries where mesh is too expensive.

Suture repair is still under development and, recently, Desarda has described an operation where a 1- to 2-cm strip of external oblique aponeurosis lying over the inguinal canal is isolated from the main muscle, but left attached both medially and laterally. It is then sutured to the conjoint tendon and inguinal ligament, reinforcing the posterior wall of the inguinal canal. As the abdominal muscles contract, this strip of aponeurosis tightens to add further physiological support to the posterior wall. This operation is currently being evaluated.

OPEN FLAT MESH REPAIR

Synthetic mesh has been used since the 1950s to reinforce hernia repair, and in the 1980s Lichtenstein described a tension-free, simple, flat, polypropylene mesh repair for inguinal hernia (**Figure 60.17**). The initial part of the operation is identical to Bassini's. Once the hernia sac has been removed and any medial defect closed, a piece of mesh, measuring 8 × 15 cm, is placed over the posterior wall, behind the spermatic cord, and is split to wrap around the spermatic cord at the deep inguinal ring. Loose sutures hold the mesh to the inguinal ligament and conjoint tendon. Two major advantages are claimed: lowered hernia recurrence rates and accelerated postoperative recovery. Randomised trials show that hernia recurrence within the first 2 years is lowered but acute pain scores are similar. Recent research comparing Lichtenstein's repair with laparoscopic surgery has identified chronic pain as the most common complication of open flat mesh repair with rates reported as high as 20%. Nevertheless, today, Lichtenstein's repair is the most common operation for inguinal hernia in resource-rich countries.

Eduardo Bassini, 1844–1924, Professor of Surgery, Padua, Italy, described this method of herniorraphy in 1889.

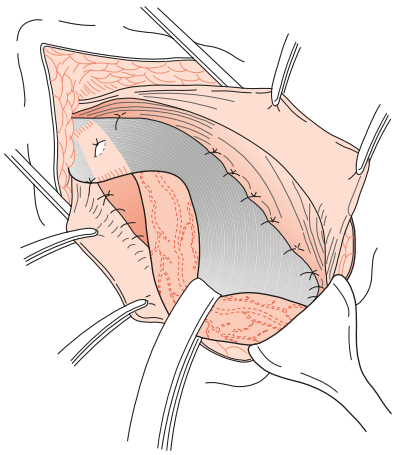

Figure 60.17 Lichtenstein's repair.

OPEN PLUG/DEVICE/COMPLEX MESH REPAIR

Surgeons and industry have been highly creative, attempting to improve on simple flat mesh repair. A surgeon in Europe has over 200 different products and techniques from which to choose. Shaped mesh plugs have gained much attention, being simple to insert into the defect and requiring little if any fixation. However, they can become solid (meshoma) and also migrate. Meshes have been designed to be placed beneath the transversalis fascia. The surgeon introduces a finger through the deep inguinal ring and bluntly (and blindly) opens the preperitoneal space deep to the inguinal canal into which a mesh is inserted. A two-layered mesh ('hernia system'), in which the inner layer is placed deep to transversalis fascia and the outer layer superficial to it, is also gaining popularity. To date, there is little evidence to show that any of these techniques is superior to Lichtenstein's operation.

OPEN PREPERITONEAL REPAIR

This approach was first described by Annandale in 1880, but was largely discarded until the 1950s when Stoppa, a French surgeon, described it with mesh reconstruction. It is useful when multiple attempts at open standard surgery have failed and the hernia(s) keeps recurring. It may now be superseded by the totally extraperitoneal laparoscopic approach, which is modelled on Stoppa's operation and first described by Ger, also French.

LAPAROSCOPIC INGUINAL HERNIA REPAIR

Two techniques are described and have been extensively studied in randomised trials. The totally extraperitoneal (TEP) approach is more widely used than the transabdominal preperitoneal (TAPP) approach. In both, the aim of surgery is to reduce the hernia and hernia sac within the abdomen, and then place a 10 × 15 cm mesh just deep to the abdominal wall, extending across the midline into the retropubic space and 5 cm lateral to the deep inguinal ring. The mesh covers Hasselbach's triangle, the deep inguinal ring and the femoral canal. In TEP, the surgeon is able to create a space just deep to the abdominal muscles without entering the peritoneal cavity whereas, in TAPP, the surgeon enters the peritoneal cavity then incises the peritoneum above the hernia defects, and reflects it away from the muscles, essentially entering the same space as in TEP. Once the hernia has been reduced, an identical mesh is inserted and the peritoneum closed over the mesh (**Figures 60.18 and 60.19**).

Over 60 randomised trials have compared laparoscopic surgery with Lichtenstein's repair. They show that, although the laparoscopic operation takes longer to perform, proven advantages are reduced pain both after surgery and up to 5 years later, more rapid return to full activity, and the reduced incidence of the wound complications of infection, bleeding and seroma. Laparoscopic surgery is of particular benefit in bilateral cases and in patients with hernia recurrence after open surgery. National statistics show that the proportion of cases performed laparoscopically is slowly rising, but all agree that there is a slow learning curve associated with these technically demanding operations.

EMERGENCY INGUINAL HERNIA SURGERY

Of inguinal hernia patients 95% present at clinics and only 5% as an emergency with a painful irreducible hernia that may progress to strangulation and possible bowel infarction. The morbidity and mortality of emergency inguinal hernia surgery are high and surgery needs to be performed rapidly in a well-resuscitated patient with adequate postoperative high dependency or intensive care if necessary. The principles of surgery are the same as in an elective setting. Open surgery is preferred when a hernia is irreducible or if there is any risk of bowel resection. Infection may complicate these cases but most surgeons would still use a lightweight, synthetic mesh repair covered by appropriate antibiotics.

COMPLICATIONS OF INGUINAL HERNIA SURGERY

Despite this being a common procedure and technically straightforward, postoperative complications are common. Immediate complications include bleeding (which may be due to accidental damage to the inferior epigastric or iliac vessels) and urinary retention that may require catheterisation. Occasional over-enthusiastic infusion of local anaesthetic may lead to femoral nerve blockade, the patient being unable to move a leg. This usually resolves over 12 hours but is alarming.

Over the next week, seroma formation and wound infection may occur. Seroma is due to an excessive inflammatory response to sutures or mesh and cannot be prevented. In most cases the fluid resolves spontaneously but may require aspiration. After laparoscopic surgery, a seroma may be misdiagnosed as an early recurrence. Wound infection is not uncommon. Many surgeons use routine prophylactic antibiotics but recent studies suggest little benefit even when mesh is used.

In the longer term, hernia recurrence and chronic pain are the main concerns. No operation can be guaranteed to be recurrence free. Evidence shows that mesh repairs have lower recurrence rates than suture repairs, but there is no difference between the various mesh repairs and no difference between open and laparoscopic surgery. There is very strong evidence that specialist hernia surgeons will have lower recurrence rates whatever technique they use.

Chronic pain, defined as pain present 3 months after surgery, is common after all forms of surgery. It is less common and less severe after laparoscopic surgery. Different types of pain have been described but the most severe is neuralgic pain due to nerve irritation. This may be the result of nerve injury at the time of operation or chronic irritation of nerves by suture material or mesh. Careful identification and protection of all three nerves passing along the inguinal canal reduces the incidence of neuralgic pain. This type of pain is also very uncommon after laparoscopic surgery that is performed at a deeper level away from the nerves. Some contribution to chronic pain may be due to the mesh, which can become embedded in a dense collagenous reaction with shrinkage. This causes tissue tension and rigidity.

Rarely, damage to the testicular artery can lead to testicular infarction, perhaps the most serious complication of inguinal hernia surgery. There is no good evidence that hernia surgery has an effect on male fertility despite extensive study in this area.

Summary box 60.10

Complications

- Early pain, bleeding, urinary retention, anaesthetic related
- Medium seroma, wound infection
- Late chronic pain, testicular atrophy

Sportsman's hernia

This specific entity is well described and presents as severe pain in the groin area, extending into the scrotum and upper thigh. It is almost entirely restricted to young men who play contact sports such as football and rugby. The pain can be debilitating and prevent the patient from exercising. On examination there may be some tenderness in the region of the inguinal canal, over the pubic tubercle, and over the insertion of the thigh adductor muscles. Usually no hernia can be felt and only occasionally can a true inguinal hernia be found.

In most cases, the pain is due to an orthopaedic injury, such as adductor strain or pubic symphasis diastasis. However, some believe that it can be due to muscle tearing (Gilmore's groin) or stretching of the posterior wall of the inguinal canal. Other causes of pain should be excluded, such as hip, pelvic or lumbar spinal disease and bladder/prostate problems. MRI is most likely to detect an orthopaedic problem but ultrasonography, herniography or even laparoscopy may be used.

There are many anecdotal reports of successful treatment using all types of inguinal hernia surgery, suture and mesh, open and laparoscopic, but no randomised trials. Hernia surgery should be a last resort and the patient warned of a significant risk of failure to cure the pain.

Femoral hernia

Basic anatomy

The iliac artery and vein pass below the inguinal ligament to become the femoral vessels in the leg. The vein lies

medially and the artery just lateral to the artery with the femoral nerve lateral to the artery. They are enclosed in a fibrous sheath. Just medial to the vein is a small space containing fat and some lymphatic tissue (node of Cloquet). It is this space which is exploited by a femoral hernia. The walls of a femoral hernia are the femoral vein laterally, the inguinal ligament anteriorly, the pelvic bone covered by the iliopectineal ligament (Astley Cooper's) posteriorly and the lacunar ligament (Gimbernat's) medially. This is a strong curved ligament with a sharp unyielding edge which impedes reduction of a femoral hernia (**Figure 60.20**).

The female pelvis has a different shape to the male, increasing the size of the femoral canal and the risk of hernia. In old age, the femoral defect increases and femoral hernia is commonly seen in low-weight, elderly women. There is a substantial risk of developing a femoral hernia after a sutured inguinal hernia repair (Denmark Hernia Registry).

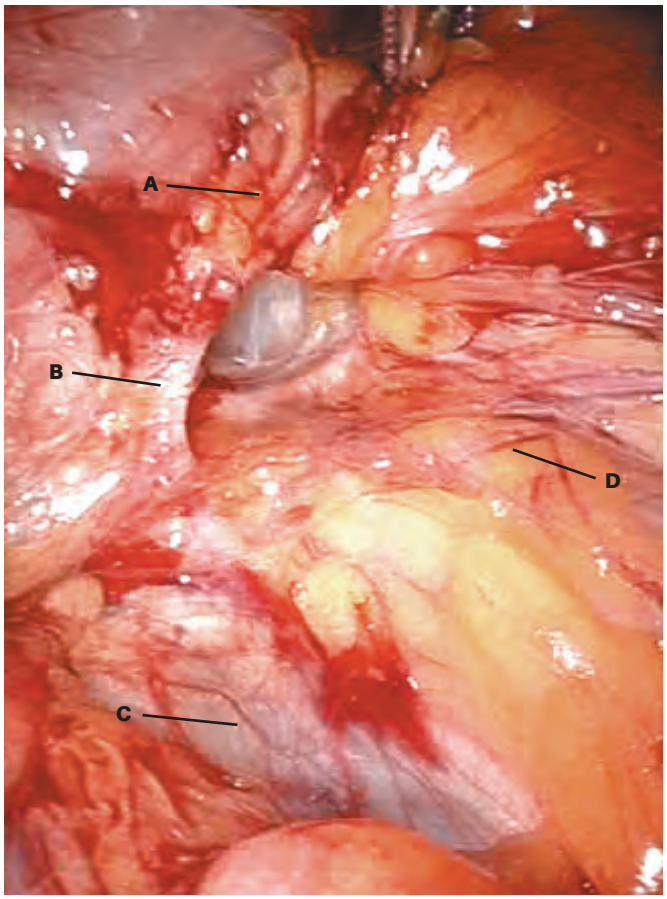

Figure 60.20 Right femoral hernia – laparoscopic view. The slightly oblique inguinal ligament can be seen superolaterally above the defect. The external iliac vein is not seen. A, Inguinal ligament; B, lacunar ligament; C, arch of pubic bone; D, fatty tissue overlying iliac vessels.

Summary box 60.11

Femoral hernia

- Less common than inguinal hernia
- It is more common in women than in men
- Easily missed on examination
- Of cases 50% present as an emergency with very high risk of strangulation

Diagnosis of femoral hernia

Diagnostic error is common and often leads to delay in diagnosis and treatment. The hernia appears below and lateral to the pubic tubercle and lies in the upper leg rather than in the lower abdomen. Inadequate exposure of this area during routine examination leads to failure to detect the hernia. The hernia often rapidly becomes irreducible and loses any cough impulse due to the tightness of the neck. It may only be 1–2 cm in size and can easily be mistaken for a lymph node. As it increases in size, it is reflected superiorly and becomes difficult to distinguish from a medial direct hernia, which arises only a few centimetres above the femoral canal. A direct inguinal hernia leaves the abdominal cavity just above the inguinal ligament and a femoral hernia just below (**Figure 60.21**).

Figure 60.21 The patient has a left femoral and a right inguinal hernia.

Summary box 60.12

Differential diagnosis

- Direct inguinal hernia
- Lymph node
- Saphena varix
- Femoral artery aneurysm
- Psoas abscess
- Rupture of adductor longus with haematoma

Jules Germain Cloquet, 1790–1883, Professor of Anatomy and Surgery, Paris, France.
Sir Astley Paston Cooper, 1768–1841, surgeon, Guy's Hospital, London, UK, received a baronetcy and 1000 guineas for successfully removing an infected wen from the head of King George IV at Brighton in 1821.
Manoel Louise Antonio don Gimbernat, 1734–1816, Professor of Anatomy, Barcelona, Spain and later Director of the Royal College of Surgeons in Spain.

Investigations

In routine cases, no specific investigations are required. However, if there is uncertainly then ultrasonography or CT should be requested. In the emergency patient, bowel obstruction usually occurs and a plain radiograph is likely to show small bowel obstruction. All patients with unexplained small bowel obstruction should undergo careful examination for a femoral hernia. It is now common to perform CT scanning in cases of bowel obstruction primarily to exclude malignancy, but it can identify an obstructing femoral hernia missed by clinicians.

Surgery for femoral hernia

There is no alternative to surgery for femoral hernia and it is wise to treat such cases with some urgency. There are three open approaches and appropriate cases can be managed laparoscopically.

LOW APPROACH (LOCKWOOD)

This is the simplest operation for a femoral hernia but suitable only when there is no risk of bowel resection. It can easily be performed under local anaesthesia. A transverse incision is made over the hernia. The sac of the hernia is opened and its contents reduced. The sac is also reduced and non-absorbable sutures are placed between the inguinal ligament above and the fascia overlying the bone below. A small incision can be made in the medial lacunar ligament to aid reduction but there may be an abnormal branch of the obturator artery just deep to it, which can bleed. The femoral vein, lateral to the hernia, needs to be protected. Some surgeons place a mesh plug into the hernia defect for further reinforcement.

THE INGUINAL APPROACH (LOTHEISSEN)

The initial incision is identical to that of Bassini's or Lichtenstein's operation into the inguinal canal. The spermatic cord (or round ligament) is mobilised and the transversalis fascia opened from deep inguinal ring to the pubic tubercle. A femoral hernia lies immediately below this incision and can be reduced by a combination of pulling from above and pushing from below. If necessary, the peritoneum can be opened to help with reduction. Once reduced, the neck of the hernia is closed with sutures or a mesh plug, protecting the iliac vein throughout. The layers are closed as for inguinal hernia and the surgeon may place a mesh into the inguinal canal to protect against development of an inguinal hernia.

Some surgeons believe that exploration of the femoral canal to exclude a hernia should be a routine part of inguinal hernia surgery but most surgeons do not do this.

HIGH APPROACH (McEVEDY)

This more complex operation is ideal in the emergency situation where the risk of bowel strangulation is high. It requires regional or general anaesthesia. A horizontal incision (classically vertical) is made in the lower abdomen centred at the lateral edge of the rectus muscle. The anterior rectus sheath is incised and the rectus muscle displaced medially. The surgeon proceeds deep to the muscle in the preperitoneal space. The femoral hernia is reduced and the sac opened to allow careful inspection of the bowel, and a decision made regarding the need for bowel resection. This is performed if necessary. In dubious cases, the bowel is replaced into the peritoneal cavity for 5 minutes and then re-examined. The femoral defect is then closed with sutures, mesh or plug. This approach allows a generous incision to be made in the peritoneum, which aids inspection of the bowel and facilitates bowel resection.

LAPAROSCOPIC APPROACH

Both the TEP and TAPP approaches can be used for a femoral hernia and a standard mesh inserted. This is ideal for reducible femoral hernias presenting electively, but not for emergency cases or irreducible hernia.

VENTRAL HERNIA

This term refers to hernias of the anterior abdominal wall. Inguinal and femoral hernias are not included even though they are ventral. Lumbar hernia is included despite being dorsolateral. The European Hernia Society classification (2009) distinguished primary ventral from incisional hernia but did not include parastomal hernia. We have included parastomal hernia and traumatic hernia.

Summary box 60.13

Ventral hernias

- Umbilical–paraumbilical
- Epigastric
- Incisional
- Parastomal
- Spigelian
- Lumbar
- Traumatic

Umbilical hernia

The umbilical defect is present at birth but closes as the stump of the umbilical cord heals, usually within a week of birth. This process may be delayed, leading to the development of herniation in the neonatal period. The umbilical ring may also stretch and reopen in adult life.

Charles Barrett Lockwood, 1856–1914, surgeon, St Bartholomew's Hospital, London, UK.
George Lotheissen, 1868–1941, surgeon, the Kaiser Franz Joseph Hospital, Vienna, Austria, described this operation in 1898.
Peter George McEvedy, 1890–1951, surgeon, Ancoats Hospital, Manchester, UK.

Umbilical hernia in children

This common condition occurs in up to 10% of infants, with a higher incidence in premature babies. The hernia appears within a few weeks of birth and is often symptomless, but increases in size on crying and assumes a classic conical shape. Sexes are equally affected but the incidence in black infants is up to eight times higher than in white. Obstruction and/or strangulation is extremely uncommon below the age of 3 years.

TREATMENT

Conservative treatment is indicated under the age of 2 years when the hernia is symptomless. Parental reassurance is all that is necessary. Of hernias 95% will resolve spontaneously. If the hernia persists beyond the age of 2 years it is unlikely to resolve and surgical repair is indicated.

SURGERY

A small curved incision is made immediately below the umbilicus. The neck of the sac is defined, opened and any contents are returned to the peritoneal cavity. The sac is closed and redundant sac excised. The defect in the linea alba is closed with interrupted sutures.

Summary box 60.14

Umbilical hernia in children

- Common in infants and most resolve spontaneously
- Rarely strangulate

Umbilical hernia in adults

Conditions that cause stretching and thinning of the midline raphe (linea alba), such as pregnancy, obesity and liver disease with cirrhosis, predispose to reopening of the umbilical defect. In adults, the defect in the median raphe is immediately adjacent to (most often above) the true umbilicus, although at operation this is indistinguishable. The term 'paraumbilical hernia' is commonly used. The defect is rounded with a well-defined fibrous margin. Small umbilical hernias often contain extraperitoneal fat or omentum. Larger hernias can contain small or large bowel but, even when very large, the neck of the sac is narrow compared with the volume of its contents. As a result, in adults, umbilical hernias that include bowel are prone to become irreducible, obstructed and strangulated.

CLINICAL FEATURES

Patients are commonly overweight with a thinned and attenuated midline raphe. The bulge is typically slightly to one side of the umbilical depression, creating a crescent-shaped appearance to the umbilicus (Figure 60.22). Women are affected more than men. Most patients complain of pain due to tissue tension or symptoms of intermittent bowel obstruction. In large hernias, the overlying skin may become thinned, stretched and develop dermatitis.

Figure 60.22 A small paraumbilical hernia.

TREATMENT

As a result of the high risk of strangulation, surgery should be advised in cases where the hernia contains bowel. Small hernias may be left alone if they are asymptomatic, but they may enlarge and require surgery at a later date. Surgery may be performed open or laparoscopically.

OPEN UMBILICAL HERNIA REPAIR

Very small defects less than 1 cm in size may be closed with a simple figure-of-eight suture, or repaired by a darn technique where a non-absorbable, monofilament suture is criss-crossed across the defect and anchored firmly to the fascia all around.

Defects up to 2 cm in diameter may be sutured primarily with minimal tension, although, the larger the defect, the more tension and the more likely it is that mesh reinforcement will be beneficial. The classic repair was described by Mayo. A transverse incision is made and the hernia sac dissected, opened and its content reduced. Any non-viable tissue is removed, sometimes involving bowel resection. The peritoneum is closed. The defect in the anterior rectus sheath is extended laterally on both sides and elevated to create an upper and lower flap. The lower flap is then inserted beneath the upper flap and sutured to it, with the upper flap being brought downwards over it so that the tissue is two layered (double breasted). Non-absorbable sutures are used. There is often a large subcutaneous space. A suction drain is placed to reduce the risk of seroma and haematoma. The skin is closed but stretched or redundant skin may need to be excised (apronectomy) to achieve a better cosmetic result. Today, with modern suture materials, surgeons simply close the anterior sheath in a single layer.

William James Mayo, 1861–1939, surgeon, the Mayo Clinic, Rochester, MN, USA, described this operation in 1901. He and his brother Charles Horace Mayo (1865–1939) joined their father's private practice in Rochester. This practice became the Mayo Clinic. Their father William Worrall Mayo was born in Manchester, UK in 1819.

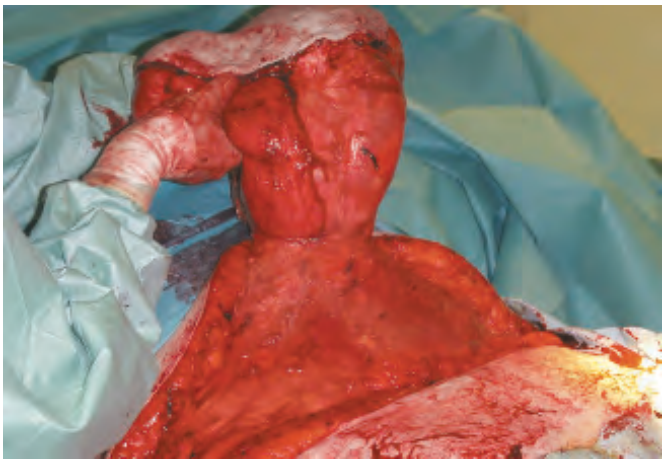

Figure 60.23 A massive paraumbilical hernia – operative view.

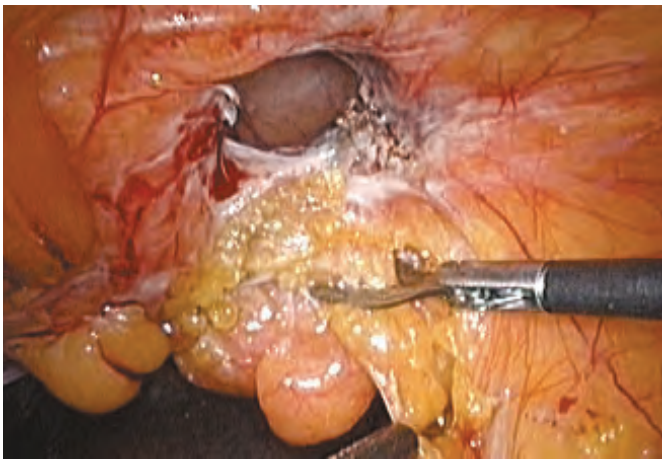

Figure 60.24 Paraumbilical defect – laparoscopic view.

For defects larger than 2 cm in diameter, mesh repair is recommended (Figure 60.23). The mesh may be placed in one of several anatomical planes:

- Within the peritoneal cavity – a tissue separating mesh is placed through the defect and spread out on the underside of the abdominal wall and fixed to it, ideally with an overlap of 5 cm in each direction. This is a quick repair but requires the use of expensive mesh.
- In the retromuscular space – the linea alba is opened vertically and both left and right posterior rectus sheaths are incised 1 cm to the side of the midline exposing the rectus muscle. The posterior sheaths are sutured together and the muscles elevated away from the sheath to develop the retromuscular space into which a sheet of mesh is placed and fixed by sutures. The mesh should overlap the midline by 5 cm laterally and the umbilicus vertically. It should therefore be a minimum diameter of 10 cm. A drain may be placed deep to the linea alba. This is a very secure repair but requires extensive dissection.
- In the extraperitoneal space – it is difficult, but possible, to develop the plane below the posterior rectus sheath, just outside the peritoneum. Care must be taken to avoid 'button-holing' the peritoneum because it is thin and fragile. Mesh can then be tucked into in this space, ensuring a good overlap as before. Ideally, the linea alba is closed over the mesh but, if this is not possible, a flap of peritoneal sac can be used to cover the mesh. This is a good repair, but, if the peritoneum is extensively damaged during the dissection, it will have to be abandoned in favour of an alternative technique.
- In the subcutaneous plane – this is the simplest technique, called an onlay mesh. The peritoneal sac and contents are dealt with as above. An attempt is made to close linea alba vertically with sutures and a disc of mesh is placed on the anterior rectus sheath and sutured to it. The mesh is lying in the subcutaneous space and is prone to infection.

LAPAROSCOPIC UMBILICAL HERNIA REPAIR

Three ports are placed laterally on the abdominal wall, usually on the left side unless adhesions from previous surgery are likely. The contents of the hernia are reduced by traction and external pressure. The falciform ligament above and the median umbilical fold below may need to be taken down if they interfere with mesh placement. A disc of non-adherent mesh, designed for intraperitoneal use, is introduced and positioned on the under surface of the abdominal wall, centred on the defect. It is then fixed to the peritoneum and posterior rectus sheaths using staples, tacks or sutures. This is a simple and secure repair, which achieves generous overlap without surgical damage to umbilicus and surrounding fascia (Figure 60.24). However, it requires specialised equipment and expensive tissue-separating mesh. Intraperitoneal meshes can cause severe pain lasting for 24–48 hours after surgery which can mimic peritonitis.

EMERGENCY REPAIR OF UMBILICAL HERNIA

Incarceration, bowel obstruction and strangulation are frequent because of the narrow neck and the fibrous edge of the defect in the midline raphe. Delay to surgery can lead to gangrene of the omentum or bowel. Large hernias are often multiloculated and there may be strangulated bowel in one component when other areas are clinically soft and a non-tender hernia.

SURGERY

In cases of simple incarceration without clinical evidence of strangulation, repair may be attempted laparoscopically but reduction of the contents can be very difficult if the hernia contains bowel. Most emergency repairs are performed by open surgery. In the presence of established strangulation it is unwise to place mesh at all because of the risk of infection, so an open sutured repair should be performed, accepting a high risk of later recurrence. Alternatively, a two-stage repair could be planned: the hernia contents being dealt with initially with little attempt made to close the defect and then subsequent definitive mesh repair once sepsis has been controlled.

Epigastric hernia

These hernias arise through the midline raphe (linea alba) any where between the xiphoid process and the umbilicus, usually midway. When close to the umbilicus they are called supraumbilical hernias. Epigastric hernias begin with a transverse split in the midline raphe so, in contrast to umbilical hernias, the defect is elliptical. It has been hypothesised that the defect occurs at the site where small blood vessels pierce the linea alba or, more likely, that it arises at weaknesses due to abnormal decussation of aponeurotic fibres related to heavy physical activity (**Figure 60.25**).

Epigastric hernia defects are usually less than 1 cm in maximum diameter and commonly contain only extraperitoneal fat, which gradually enlarges, spreading in the subcutaneous plane to resemble the shape of a mushroom. When very large they may contain a peritoneal sac but rarely any bowel. More than one hernia may be present. The most common cause of 'recurrence' is failure to identify a second defect at the time of original repair.

Clinical features

The patients are often fit, healthy men aged between 25 and 40 years. These hernias can be very painful even when the swelling is the size of a pea, due to the fatty contents becoming nipped sufficiently to produce partial strangulation. The pain may mimic that of a peptic ulcer but symptoms should not be ascribed to the hernia until gastrointestinal pathology has been excluded. A soft midline swelling can often be felt more easily than seen. It may be locally tender. It is unlikely to be reducible because of the narrow neck. It may resemble a lipoma. A cough impulse may or may not be felt.

Treatment

Very small epigastric hernias have been known to disappear spontaneously, probably due to infarction of the fat. Small-to-moderate-sized hernias without a peritoneal sac are not inherently dangerous and surgery should be offered only if the hernia is sufficiently symptomatic.

Figure 60.25 Epigastric hernia – external view.

Surgery

This may be done by open or laparoscopic surgery. At open surgery, a vertical or transverse incision is made over the swelling and down to the linea alba. Protruding extraperitoneal fat can simply be pushed back through the defect or excised. Often a small vessel is present in the hernia content that can cause troublesome bleeding. The defect in the linea alba is closed with non-absorbable sutures in adults and absorbable sutures in children. In larger hernias and when a peritoneal sac is present, the surgical approach is similar to an umbilical mesh repair.

Laparoscopic repair is very similar to that for umbilical hernia except that the defect is hidden behind the falciform ligament which must be taken down from the undersurface of the abdominal wall. The margins of the defect must be clearly exposed and the fatty contents reduced before the mesh is placed. Simply placing a mesh under the linea midline may not in fact remove the hernia when its contents are extraperitoneal fat.

Incisional hernia

These arise through a defect in the musculofascial layers of the abdominal wall in the region of a postoperative scar. Thus they may appear anywhere on the abdominal surface.

Incidence and aetiology

Incisional hernias have been reported in 10–50% of laparotomy incisions and 1–5% of laparoscopic port-site incisions. Factors predisposing to their development are patient factors (obesity, general poor healing due to malnutrition, immunosuppression or steroid therapy, chronic cough, cancer), wound factors (poor quality tissues, wound infection) and surgical factors (inappropriate suture material, incorrect suture placement).

An incisional hernia usually starts as disruption of the musculofascial layers of a wound in the early postoperative period. Often the event passes unnoticed if the overlying skin wound has healed securely. Many incisional hernias may be preventable with the use of good surgical technique. The classic sign of wound disruption is a serosanguineous discharge.

Clinical features

These hernias commonly appear as a localised swelling involving a small portion of the scar but may present as a diffuse bulging of the whole length of the incision (**Figure 60.26**). There may be several discrete hernias along the length of the incision and unsuspected defects are often found at surgery (**Figure 60.27**). Incisional hernias tend to increase steadily in size with time. The skin overlying large hernias may become thin and atrophic so that peristalsis may be seen in the underlying intestine. Vascular damage to skin may lead to dermatitis. Attacks of partial intestinal obstruction are common because there are usually coexisting internal adhesions. Strangulation is less frequent and most likely to occur when the fibrous defect is small and the sac is large. Most incisional hernias are broad-necked and carry a low risk of strangulation.

Figure 60.26 A large multilocular incisional hernia.

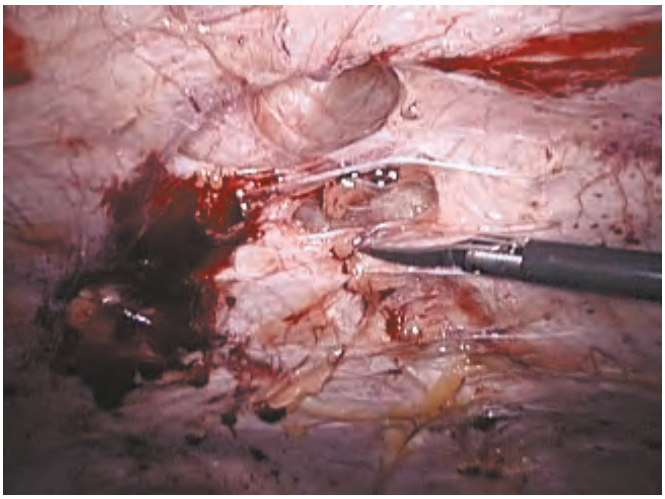

Figure 60.27 Multiple defects seen during laparoscopic operation.

Summary box 60.15

Incisional hernia

- Incidence 10–50% after surgery
- Causation due to patient, wound and surgeon factors
- Wide variation in size
- Often multiple defects within the same scar
- Obstruction is common but strangulation is rare
- Open and laparoscopic repairs possible

Treatment

Asymptomatic incisional hernias may not require treatment at all. The wearing of an abdominal binder or belt may prevent the hernia from increasing in size.

Principles of surgery

For most incisional hernias, surgery is relatively straightforward and both open and laparoscopic options are available. A number of principles apply, irrespective of the technique used.

The repair should cover the whole length of the previous incision. Approximation of the musculofascial layers should be done with minimal tension and prosthetic mesh should be used to reduce the risk of recurrence. Mesh may be contraindicated in a contaminated field, e.g. bowel injury during the dissection but, in a clean-contaminated field, such as after an elective bowel resection, mesh may be used if placed in a different anatomical plane to the contamination, such as in the extraperitoneal/retromuscular space. Appropriate systemic antibiotics should be used.

OPEN REPAIR

Simple suture techniques without the use of prosthetic mesh for reinforcement, even with layered closure such as in Mayo, 'keel' or da Silva repairs, are not recommended today because of the high risk of recurrence. However, they may be the only option in the presence of gross contamination such as peritonitis.

The previous incision is opened along its full length to reveal any clinically unsuspected defects. The hernial sac, its neck and the margins of the defect are fully exposed. The sac can be opened, contents reduced, local adhesions divided and any redundant sac excised to allow safe reclosure of the peritoneum.

Mesh can be placed in one of several planes as for umbilical hernia repair. The simplest approach is an onlay mesh but increasingly the retromuscular sublay repair is preferred by expert surgeons and is described below.

RETROMUSCULAR SUBLAY MESH REPAIR

Vertical incisions are made through the fascia surrounding the rectus abdominis muscles so that the muscle can be separated and elevated from the posterior rectus sheath below. If possible, the medial edges of the posterior rectus sheath edges are sutured together with a continuous suture. In very large defects this may not be possible and below the arcuate line where the posterior sheath is deficient, being peritoneum and transversalis fascia only. In the case of transverse incision, where the defect extends lateral to the rectus sheath, internal oblique and transversus abdominis muscles form the posterior layer. A sheet of lightweight, large-pore, prosthetic, elastic mesh is then laid between this posterior rectus sheath and belly/bellies of the rectus muscle. It is fixed to the sheath by interrupted sutures. The mesh must be large enough to ensure a 5-cm overlap of the underlying fascial defect in all directions. Careful haemostasis and meticulous asepsis are essential during this operation. The anterior rectus sheaths are then sutured together over the mesh so that, ideally, the mesh is completely covered by muscle and fascia and is not lying in the subcutaneous plane. Redundant skin may need to be excised. The risk of postoperative serous fluid collections is reduced by suction drainage.

LAPAROSCOPIC REPAIR

Incisional hernias are increasingly being repaired by laparoscopic mesh techniques. Laparoscopy and division of adhesions is initially performed. Hernia contents are reduced and the fibrous margins of the hernia defect(s) are exposed. Often the falciform ligament and median umbilical fold need to be

taken down. Some surgeons prefer to suture close the muscle defects first and then reinforce with mesh. Others simply fix the mesh under the defect with adequate overlap. The use of a tissue-separating mesh is essential. Various techniques have been described to size and then position the mesh accurately. The mesh is fixed to the abdominal wall by staples or transfascial sutures which pass through all muscle layers to hold the mesh.

In the presence of dense peritoneal adhesions, the laparoscopic surgeon needs to take great care because injury to the bowel is possible and may not be recognised. Diathermy is not used. If occult bowel injury does occur it can lead to postoperative peritonitis, which is an extremely dangerous complication.

Management of the very large incisional hernia

Very large incisional hernias often require careful thought before treatment begins. If the volume of the sac is more than 25% of the volume of the abdominal cavity (and this can be calculated from CT images), then there are likely to be issues of loss of abdominal domain when the hernia is repaired. The contents of the hernia, which have been outside the abdominal cavity for a long time, will not fit back inside or, if they do, it will result in high tension. High intra-abdominal pressure can lead to visceral compression and pulmonary complications due to impaired diaphragmatic movement. A tight abdomen can lead to wound breakdown and failure of the repair.

Techniques to overcome the potential loss of abdominal domain include preoperative abdominal expansion with progressive preoperative pneumoperitoneum over several weeks, resection of the omentum and/or colon at the time of repair, the use of prosthetic mesh to span the uncloseable gap in the musculofascial layer, or the use of musculofascial advancement or transpositional flaps to achieve closure.

Even if loss of domain is not a concern, large defects can still be very difficult to close and the same special techniques may need to be used to avoid producing excessive tension in the repair. Ramirez's component separation technique, which incorporates relaxing incisions in the external oblique aponeurosis and/or the posterior sheath, is very useful because this enables either the anterior or the posterior component of the rectus sheath to be drawn together. It may then be reinforced with a mesh.

Patients with poor quality or redundant skin may benefit from a wedge excision of skin and fat (lipectomy) to improve the abdominal contour postoperatively. Repair of these very large hernias is highly specialised surgery and is best done in specialist centres.

Reducing the risk of incisional hernia

The incidence of incisional hernia may be reduced by improving the patient's general condition preoperatively where possible, e.g. weight loss for obesity or improving nutritional state for malnutrition. Closing the fascial layers with non-absorbable, or very slowly absorbable, sutures of adequate gauge is important. Traditional teaching was that sutures should be 1 cm deep and 1 cm apart. Recent work has shown that lower incisional hernia rates and reduced infection rates are gained when smaller and closer bites are used with a 2/0 suture rather than traditional heavier materials.

There is no evidence that interrupted sutures are better or worse than continuous. However, if continuous suturing is used, the tissue bites must not be too near the fascial edge or pulled too tight because they may cut out. It has also been confirmed that the optimal ratio of suture length to wound length is 4:1 (Jenkins' rule). If less length than this is used, the suture bites are too far apart or too tight and the converse applies if more length than this is used.

Drains should be brought out through separate incisions and not through the wound itself because this leads to hernia formation.

Recent reports have suggested that placement of a prophylactic mesh in patients at high risk of hernia formation will substantially reduce that risk. This has been reported in obese patients undergoing bariatric surgery and also to prevent parastomal herniation, which occurs in up to 50% of patients.

Spigelian hernia

These hernias are uncommon although are probably underdiagnosed. They affect men and women equally and can occur at any age, but are most common in elderly people. They arise through a defect in the spigelian fascia, which is the aponeurosis of transversus abdominis. Often these hernias advance through the internal oblique as well and spread out deep to the external oblique aponeurosis. The spigelian fascia extends between the transversus muscle and the lateral border of the rectus sheath from the costal margin to the groin, where it blends into the conjoint tendon. Most spigelian hernias appear below the level of the umbilicus near the edge of the rectus sheath, but they can be found anywhere along the spigelian line (**Figure 60.28**). There is a common

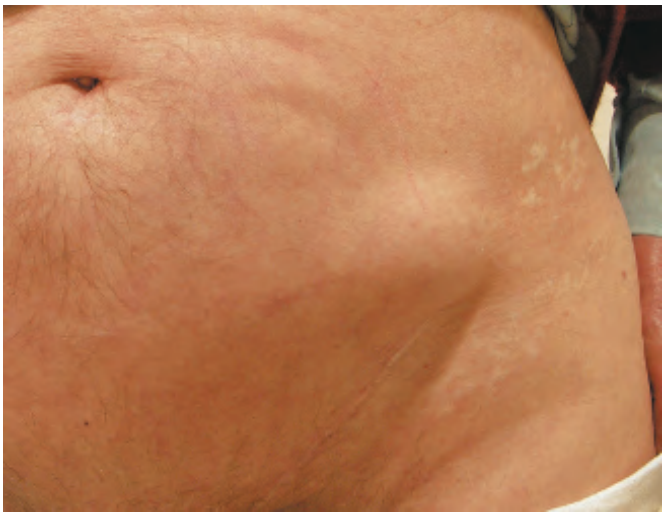

Figure 60.28 Spigelian hernia.

Adrian Van der Spieghel (Spigelius), 1578–1625, Professor of Anatomy, Padua, Italy.

misconception that they protrude below the arcuate line as a result of deficiency of the posterior rectus sheath at that level, but in fact the defect is almost always above the arcuate line. In young patients they usually contain extraperitoneal fat only but in older patients there is often a peritoneal sac and they can become very large indeed.

They have also been described in infants and may be congenital, reflecting incomplete differentiation of the mesenchymal layers within the abdominal wall.

Clinical features

Young patients usually present with intermittent pain, due to pinching of the fat, similar to an epigastric hernia. A lump may or may not be palpable because the fatty hernia is small and the overlying external oblique is intact. Older patients generally present with a reducible swelling at the edge of the rectus sheath and may have symptoms of intermittent obstruction. The diagnosis should be suspected because of the location of the symptoms and is confirmed by CT. Ultrasonography has the advantage that it can be performed in the upright patient because no defect may be visible with the patient lying down.

Treatment

Surgery is recommended because the narrow and fibrous neck predisposes to strangulation. Surgery can be open or laparoscopic. At open surgery a skin crease is made over the hernia, but no abnormality will be seen until the external oblique is opened. The sac and contents are dealt with and the small defect in the spigelian fascia is repaired by suture or mesh laid deep to the external oblique aponeurosis. The plane of the mesh can be extended medially into the posterior rectus sheath if required. The external oblique aponeurosis is closed over the mesh.

Laparoscopy is useful if no sac is palpable, but, in young patients with a hernia containing only extraperitoneal fat, no hernia will be seen from within the peritoneum. In such cases, the peritoneum can be incised and the extraperitoneal plane explored for the small defect, which can then be closed by either suture or mesh. When an intraperitoneal sac is present, laparoscopic repair can be performed using either the intraperitoneal onlay of mesh (IPOM) or TAPP technique.

Summary box 60.16

Spigelian hernia

- Rare
- Often misdiagnosed
- High risk of complications

Lumbar hernia

Most primary lumbar hernias occur through the inferior lumbar triangle of Petit bounded below by the crest of the ilium, laterally by the external oblique muscle and medially by latissimus dorsi (Figure 60.29). Less commonly, the sac comes through the superior lumbar triangle, which is bounded by the twelfth rib above, medially by sacrospinalis and laterally by the posterior border of the internal oblique muscle. Primary lumbar hernias are rare, but may be mimicked by incisional hernias arising through flank incisions for renal operations, or through incisions for bone grafts harvested from the iliac crest.

Figure 60.29 Inferior lumbar hernia, which contained caecum, appendix and small bowel. Note the filarial skin rash on the buttocks (courtesy of VJ Hartfield, formerly of south-east Nigeria).

Differential diagnosis

A lumbar hernia must be distinguished from:

- a lipoma;
- a cold (tuberculous) abscess pointing to this position;
- a pseudo-hernia due to local muscular paralysis. Lumbar pseudo-hernia can result from any interference with the nerve supply of the affected muscles, the most common cause being injury to the subcostal nerve during a kidney operation.

Treatment

The natural history is for these hernias to increase in size and surgery is recommended. Lumbar hernias can be approached by open or laparoscopic surgery. The defects can be difficult to close with sutures and mesh is recommended.

The TAPP laparoscopic approach is gaining popularity. With the patient in a semilateral position ports are inserted well away from the defect. The peritoneum is incised above the hernia and dissected back to expose the muscle defect. The content, often extraperitoneal fat, is reduced and a mesh fixed with ample overlap. The peritoneum can then be resutured or tacked back to cover the mesh.

Jean Louis Petit, 1674–1750, Director of the Academie de Chirurgie, Paris, France.

Lumbar incisional hernias can be approached in the same way but large ones, especially if there is a component of neuropathic muscle atrophy causing a diffuse bulge (pseudo-hernia), can be very difficult and muscle-flap double breasting with mesh reinforcement may be required.

Parastomal hernia

When surgeons create a stoma, such as a colostomy or ileostomy, they are effectively creating a hernia by bringing bowel out through the abdominal wall. The muscle defect created tends to increase in size over time and can ultimately lead to massive herniation around the stoma. The rate of parastomal hernia is over 50%. For patients, it is very difficult to manage a stoma that is lying adjacent to or atop a large hernia. Stoma appliance bags fit poorly leading to leakage.

The ideal surgical solution for the patient is to rejoin the bowel and remove the stoma altogether, but this is not always possible. The stoma may be re-sited but further recurrence is likely. Various open suture and mesh techniques have been described to repair parastomal hernia but failure rates are high. Meshes are best placed in the retromuscular space. Laparoscopic repair is also possible using a large mesh with a central hole. It can be positioned around the bowel onto the parietal peritoneum.

Recent reports (Millbourne *et al.*) have described the use of prophylactic mesh insertion at the time of formation of the stoma. A lightweight, polypropylene mesh is inserted in the retromuscular space so that the bowel passes through a hole in the mesh centre. Using this technique, parastomal hernia rates have been reduced significantly.

Traumatic hernia

These hernias arise through non-anatomical defects caused by injury. They can be classified into three types:

1. Hernias through abdominal stab wound sites. These are effectively incisional hernias.
2. Hernias protruding through splits or tears in the abdominal muscles after blunt trauma.
3. Abdominal bulging secondary to muscle atrophy that occurs as a result of nerve injury or other traumatic denervation. Akin to the lumbar pseudo-hernia seen after open nephrectomy, these can arise after a chest injury with damage to the intercostal nerves.

Clinical features

Traumatic hernias present as any other hernia. The key to the aetiology is in the history and the non-anatomical location of the hernia.

Treatment

Surgery may be justified if the hernia is sufficiently symptomatic, or if investigations suggest a narrow neck and hence a risk of obstruction or strangulation. Stab wound traumatic hernias are straightforward to repair using open or laparoscopic techniques as for other ventral hernias. Diffuse abdominal bulges are more difficult to correct and require some form of plication of the stretched musculofascial layer with mesh reinforcement to prevent further bulging in the future. Some bulging may persist, however.

Rare external hernias

Perineal hernia

This type of hernia is very rare and includes:

- postoperative hernia through a perineal scar, which may occur after excision of the rectum;
- median sliding perineal hernia, which is a complete prolapse of the rectum;
- anterolateral perineal hernia, which occurs in women and presents as a swelling of the labium majus;
- posterolateral perineal hernia, which passes through the levator ani to enter the ischiorectal fossa.

TREATMENT

A combined abdominoperineal operation is generally the most satisfactory for the last two types of hernia. The hernia is exposed by an incision directly over it. The sac is opened and its contents are reduced. The sac is cleared from surrounding structures and the wound closed. With the patient in semi-Trendelenburg position, either laparoscopically or at open surgery, the abdomen is opened and the mouth of the sac exposed. The sac is inverted, ligated and excised, and the pelvic floor repaired by muscle apposition and, if indicated, buttressing of the repair with prosthetic mesh.

Obturator hernia

Obturator hernia, which passes through the obturator canal, occurs six times more frequently in women than in men. Most patients are aged >60 years. The swelling is liable to be overlooked because it is covered by pectineus. It seldom causes a definite swelling in Scarpa's triangle, but, if the limb is flexed, abducted and rotated outwards, the hernia sometimes becomes apparent. The leg is usually kept in a semi-flexed position and movement increases the pain. In more than 50% of cases of strangulated obturator hernia, pain is referred along the obturator nerve by its geniculate branch to the knee. On vaginal or rectal examination the hernia can sometimes be felt as a tender swelling in the region of the obturator foramen.

These hernias have often undergone strangulation, frequently of the Richter type, by the time of presentation.

TREATMENT

Surgery is indicated. The diagnosis is rarely made preoperatively and so it is often approached through a laparotomy incision. The full Trendelenburg position is adopted. The constricting agent is the obturator fascia, which can be stretched by inserting the operator's index finger, or suitable forceps, through the gap in the fascia. Content is reduced. If incision

Antonio Scarpa, 1747–1832, Professor of Anatomy, Pavia, Italy.

of the fascia is required, it is made parallel to the obturator vessels and nerve. The contents of the sac are dealt with in a standard manner. The defect cannot simply be closed because one margin is bone and the obturator nerve and vessels run through it. It is best closed using a mesh plug. In the absence of mesh or in an infected field, the broad ligament can be used as a plug.

Laparoscopic TAPP repair may also be performed again using a mesh. To avoid nerve injury, glue can be used to fix a mesh over the defect.

Gluteal and sciatic hernias

Both of these hernias are very rare. A gluteal hernia passes through the greater sciatic foramen, either above or below piriformis. A sciatic hernia passes through the lesser sciatic foramen. Differential diagnosis must be made between these conditions and:

- a lipoma or other soft tissue tumour beneath gluteus maximus;
- a tuberculous abscess;
- a gluteal aneurysm.

All doubtful swellings in this situation can be characterised with CT scanning but, if in doubt, they should be explored by operation.

UMBILICAL CONDITIONS IN THE ADULT

Chronic infection

Chronic infection occurs in the umbilical area, particularly in patients with poor hygiene. It may also occur in obese people and when a paraumbilical hernia is present. It can be due to a plug of keratin causing chronic irritation. It is often encountered during elective surgery and may complicate the insertion of a laparoscope port at the umbilicus. A range of bacteria and fungi can be involved. Occasionally, a rapid-onset, superficial cellulitis occurs even after minor surgery in this region. It is normally a streptococcus and can be treated with penicillin or other appropriate antibiotic. Pre-existing infection should be treated before surgery where possible.

Chronic fistula

Patients may present with a persistent discharge from the umbilical area. This may be due to simple, superficial infection or possibly an infected epidermoid cyst within the umbilicus. However, it may also be due to a fistulous connection to deeper structures.

In normal patients, the umbilicus is connected to the liver, bladder and gynaecological organs by various ligaments. Diseases of these organs, such as infection or malignancy, can extend along these ligaments to appear at the umbilicus as a mass or fistulous discharge.

Chronic fistula may be a complication of umbilical hernia repair due to chronic infection of a mesh or around non-absorbable suture material. In most cases this problem arises soon after surgery but occasionally a chronic infection can occur months or even years after an operation. Antibiotics may help but most commonly the synthetic suture or mesh will need to be removed with a risk of recurrence of the hernia.

In fetal life the umbilicus was also connected to the gut by the vitellointestinal duct. In most patients this duct becomes totally obliterated and vanishes. The bowel end of the duct may persist as Meckel's diverticulum. More rarely, the umbilical end persists, leading to chronic discharge. If an abnormal connection between bowel and umbilicus persists, then this band can act as a cause of adhesional intestinal obstruction.

Patent urachus

A connection between the urinary bladder and umbilicus usually presents in later life. This is due to increased pressure in the bladder as a result of obstruction from conditions such as prostatic hypertrophy. The cause of obstruction should be dealt with initially, but if the problem persists then surgical excision of the patent urachus might be considered.

Malignancy at the umbilicus

Primary squamous carcinoma may occur. If tumour presents at the umbilicus it is most probably due to spread from the internal organs along internal ligaments, e.g. from the liver along the falciform ligament. A malignant mass at the umbilicus is called a Sister Joseph's nodule. It usually indicates very advanced malignant disease and surgery probably has little to offer (**Figure 60.30**).

GENERAL INFECTION OF THE ABDOMINAL WALL

The skin of the abdominal wall, similar to all skin, is prone to develop superficial infection that may be spontaneous, due to minor trauma or infection of skin lesions such as an epidermoid cyst. Although antibiotics will suffice in most

---

Johann Frederick Meckel (the Younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany, described his diverticulum in 1809.

Alexis Littre, 1658–1726, surgeon and lecturer in anatomy, Paris, France, described Meckel's diverticulum in a hernial sac in 1700, 81 years before Meckel was born.

The neoplastic nodule sited at the umbilicus is known as **Sister Joseph's nodule**. Sister Mary Joseph made the observation that her patients with terminal cancer sometimes developed a red papular lesion in the umbilicus. She and William Mayo published this observation in 1928. However, it was Hamilton Bailey who coined the term 'Sister Mary Joseph's nodule' in 1949.

Sister Mary Joseph (nee Julia Dempsey), Nursing Superintendent, St Mary's Hospital, which became the Mayo Clinic, Rochester, MN, USA.

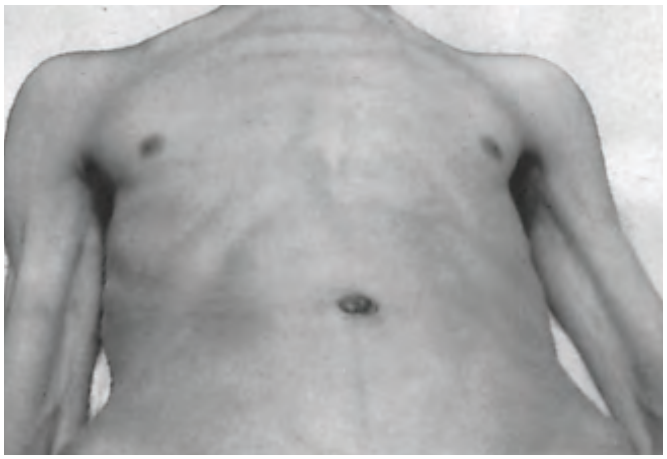

Figure 60.30 Secondary nodule at the umbilicus – Sister Joseph's nodule.

patients, if an abscess develops then surgical drainage may be required.

The close proximity of bowel and bowel organisms opens the abdominal wall to attack from a wide range of highly virulent bacteria. Most commonly, these are released during abdominal surgery such as appendicectomy and hence the need for appropriate antibiotic prophylactic cover.

Synergistic gangrene

This rare condition is due to the synergistic action of non-haemolytic streptococci and staphylococci causing rapid tissue necrosis and overwhelming systemic infection (**Figure 60.31**). It requires immediate administration of high-dose, broad-spectrum, powerful antibiotics in combination with early debridement of any non-viable tissue. Hyperbaric oxygen therapy has been advocated.

Other forms of severe abdominal wall infections occur, generally known as necrotising fasciitis (e.g. Fournier's gangrene). All of these conditions have a high associated morbidity and mortality. They occur in debilitated and immunocompromised patients but can occasionally occur in healthy patients. Rapid diagnosis and aggressive surgical debridement treatment are the key to success.

Figure 60.31 Bacterial synergistic gangrene of the chest and abdominal wall. The area has become gangrenous and looks like suede leather. Beware of amoebiasis cutis.

Cutaneous fistula

Due to the thickness of the abdominal wall, it is rare for abdominal inflammatory conditions to discharge spontaneously through the wall to the skin. Chronic intraperitoneal abscesses arising after occult bowel perforation, appendicitis, diverticulitis and cholecystitis are the most likely sources. CT will locate the internal abscess and suggest the likely origin. Treatment today is usually by CT- or ultrasound-guided drainage but the surgeon may be called on to remove the source organ, e.g. gall bladder.

Malignancy in its later stages can occasionally erode through the abdominal wall.

Crohn's disease also has a tendency to fistulate into adjacent organs and may develop an enterocutaneous fistula.

Abdominal compartment syndrome

Surgeons are increasingly aware of the harmful effect of high intra-abdominal pressures that can occur in severe intra-abdominal sepsis, such as pancreatitis and also aortic aneurysm rupture. High pressure leads to reduced blood flow and tissue ischaemia, which contributes to multiorgan failure. Although the abdominal wall has elasticity, if intra-abdominal volume increases due to fluid, gas, pus, tissue oedema, etc., then maximal capacity may be reached and pressure rises to a critical level. Tension-releasing incisions, equivalent to a fasciotomy, have been suggested, although this is not widely practised.

In some cases, after surgery for severe intraperitoneal sepsis, the surgeon cannot close the abdomen and may leave the incision wide open, covering abdominal contents with mesh or a saline-soaked dressing, planning to return at a future date to close the defect. This is called a laparostomy.

Neoplasms of the abdominal wall

As the abdominal wall is composed of muscle, fascia and bone, benign and malignant tumours can arise from each, although these are rare.

Desmoid tumour

This is usually considered by pathologists to be a hamartoma and is more common in women. Some, however, believe it to be a fibroma and possibly the result of repeated trauma. Desmoids have been reported in familial adenomatous polyposis (FAP). Histologically, they contain plasmoidal cell masses resembling giant cells. They undergo central myxomatous change. Surgical excision with a wide margin is required to prevent recurrence, which is a frequent problem.

Fibrosarcoma

These tumours can occur anywhere in the body. They are generally highly malignant and respond poorly to both radio- and chemotherapy. Wide excision will often require plastic surgical reconstruction.

Chapter 61

The peritoneum, omentum, mesentery and retroperitoneal space

Learning objectives

To recognise and understand:

- The causes and complications of localised and generalised peritonitis
- The clinical features of peritonitis and intraperitoneal abscess
- The principles of surgical management in patients with peritonitis and intraperitoneal abscess
- The causes and pathophysiology of ascites
- The pathophysiology and complications of adhesion formation
- The spectrum of mesenteric and retroperitoneal conditions

ANATOMY AND PHYSIOLOGY

Embryology

The peritoneal cavity, mesenteries and omentum have an anatomical complexity that can perhaps be truly understood only with surgical experience. Nevertheless, an understanding of the geometric alterations occurring during early gastrointestinal (GI) morphogenesis (regionalisation, elongation and coiling) of the derivatives of the endoderm (E = epithelium) and the visceral mesoderm (M = muscle and most of the rest) along with the later fusion of adjacent layers of peritoneum will give an appreciation of how the adult disposition is as it is.

Adult arrangement and functions

The peritoneal cavity is the largest cavity in the body, the surface area of its lining membrane (2 m^2 in an adult) being nearly equal to that of the skin. The peritoneal membrane is composed of flattened polyhedral cells (mesothelium), one layer thick, resting on a thin layer of fibroelastic tissue. This membrane is conveniently divided into two parts – the visceral peritoneum surrounding the viscera and the parietal peritoneum lining the other surfaces of the cavity. Beneath the peritoneum, supported by a small amount of areolar tissue, lies a network of lymphatic vessels and rich plexus of capillary blood vessels from which all absorption and exudation must occur. In health, only a few millilitres of peritoneal fluid are found in the peritoneal cavity. The fluid is pale yellow, somewhat viscid, and contains lymphocytes and other leukocytes; it lubricates the viscera, allowing easy movement and peristalsis. The parietal portion is richly supplied with nerves and, when irritated, causes severe pain that is accurately localised to the affected area. The visceral peritoneum, in contrast, is poorly supplied with nerves (these being situated around blood vessels) and its irritation causes pain that is usually poorly localised to the midline.

The peritoneum has a number of functions.

Summary box 61.1

Functions of the peritoneum

In health

- Visceral lubrication
- Fluid and particulate absorption

In disease

- Pain perception (mainly parietal)
- Inflammatory and immune responses
- Fibrinolytic activity

The peritoneum has the capacity to absorb large volumes of fluid: this ability is used during peritoneal dialysis in the treatment of renal failure. However, the peritoneum can also produce large volumes of fluid (ascites) and an inflammatory exudate when injured (peritonitis). During expiration, intra-abdominal pressure is reduced and peritoneal fluid, aided by capillary attraction, travels in an upward direction towards the diaphragm. Experimental evidence shows that particulate matter and bacteria are absorbed within a few minutes into the lymphatic network through a number of 'pores' within the diaphragmatic peritoneum. The circulation of peritoneal fluids may be responsible for the occurrence of

abscesses distant from primary disease. When parietal peritoneal defects are created, healing occurs not from the edges but by the development of new mesothelial cells throughout the surface of the defect. In this way, large defects heal as rapidly as small defects.

SCOPE OF DISEASE

The peritoneum, mesentery and omentum may be the site of a variety of conditions that reflect their relationship to other anatomical structures or, in some instances, their primary functions.

Summary box 61.2

Scope of disease

Intraperitoneal disease

- Peritonitis
  - Primary
  - Secondary
- Abscess

PERITONITIS

Peritonitis is simply defined as inflammation of the peritoneum and may be localised or generalised. Most cases of peritonitis are caused by an invasion of the peritoneal cavity by bacteria, so that, when the term 'peritonitis' is used without qualification, acute bacterial peritonitis is often implied. In this instance, free fluid spills into the peritoneal cavity and circulates, largely directed by the normal peritoneal attachments and gravity. For example, spillage from a perforated peptic ulcer may run down the right paracolic gutter, leading to presentation with pain in the right iliac fossa (Valentino's syndrome). Even in patients with non-bacterial peritonitis (e.g. acute pancreatitis, intraperitoneal rupture of the bladder or haemoperitoneum), the peritoneum often becomes infected by transmural spread of organisms from the bowel. Such translocation is a feature of the systemic inflammatory response on the bowel and it is not long (often a matter of hours) before a bacterial peritonitis develops. Most duodenal and gastric perforations are initially sterile for up to several hours before becoming secondarily infected.

Summary box 61.3

Causes of peritoneal inflammation

- Bacterial, gastrointestinal and non-gastrointestinal
- Chemical, e.g. bile, barium
- Allergic, e.g. starch peritonitis
- Traumatic, e.g. operative handling
- Ischaemia, e.g. strangulated bowel, vascular occlusion
- Miscellaneous, e.g. familial Mediterranean fever

Although acute bacterial peritonitis most commonly arises from a perforation of a viscus of the alimentary tract, other routes of infection can include the female genital tract and exogenous contamination. There are also less common forms in which the aetiology is a primary 'spontaneous' peritonitis, in which a pure infection with streptococcal, pneumococcal or haemophilus bacteria occurs.

Summary box 61.4

Paths to peritoneal infection

- Gastrointestinal perforation, e.g. perforated ulcer, appendix, diverticulum
- Transmural translocation (no perforation), e.g. pancreatitis, ischaemic bowel, **primary bacterial peritonitis**
- Exogenous contamination, e.g. drains, open surgery, trauma, **peritoneal dialysis**
- Female genital tract infection, e.g. pelvic inflammatory disease
- Haematogenous spread (rare), e.g. septicaemia

Microbiology

Bacteria from the gastrointestinal tract

The number of bacteria within the lumen of the gastrointestinal tract is normally low until the distal small bowel is reached. However, disease leading to stasis and overgrowth (e.g. obstruction, and chronic and acute motility disturbances) may increase proximal colonisation. The biliary

Rudolph Valentino, Italian actor, died during surgery for this in New York in 1926, aged 31 years.

and pancreatic tracts are also normally free from bacteria, although they may be infected in disease, e.g. gallstones. Peritoneal infection is usually caused by two or more bacterial strains. Gram-negative bacteria contain endotoxins (lipopolysaccharides) in their cell walls that have multiple toxic effects on the host, primarily by causing the release of tumour necrosis factor (TNF) from host leukocytes. Systemic absorption of endotoxin may produce endotoxic shock, with hypotension and impaired tissue perfusion. Other bacteria such as *Clostridium perfringens* produce harmful exotoxins. *Bacteroides* spp. are commonly found in peritonitis. These gram-negative, non-sporing organisms, although predominant in the lower intestine, often escape detection because they are strictly anaerobic and slow to grow on culture media unless there is an adequate carbon dioxide tension in the anaerobic apparatus (Gillespie). In many laboratories, the culture is discarded if there is no growth in 48 hours. These organisms are resistant to penicillin and streptomycin but sensitive to metronidazole, clindamycin, Augmentin (amoxicillin plus clavulanic acid) and cephalosporin compounds. Since the widespread use of metronidazole (Flagyl), bacteroides infections have greatly diminished.

Non-gastrointestinal causes of peritonitis

Pelvic infection via the fallopian tubes is responsible for a high proportion of 'non-gastrointestinal' infections. The most common offending organisms are *Chlamydia* spp. and gonococci. These organisms lead to a thinning of cervical mucus and allow bacteria from the vagina into the uterus and oviducts, causing infection and inflammation. A variant of transperitoneal spread of such organisms is perihepatitis which can cause scar tissue to form on Glisson's capsule, a thin layer of connective tissue surrounding the liver (Fitz-Hugh–Curtis syndrome). Other bacterial variants that are discussed separately include tuberculosis and other mycobacterial strains and those causing primary peritonitis (pneumococci, staphylococci and streptoccoci). Fungal peritonitis is uncommon but may complicate severely ill patients.

Summary box 61.5

Microorganisms in peritonitis

Gastrointestinal source

- *Escherichia coli*
- Streptococci
- Enterococci
- *Bacteroides* spp.
- *Clostridium* spp.
- *Klebsiella pneumoniae*

Other sources

- *Chlamydia trachomatis*
- *Neisseria gonorrhoeae*
- Haemolytic streptococci
- Staphylococci
- *Streptococcus pneumoniae*
- *Mycobacterium tuberculosis* and other species
- Fungal infections

Localised peritonitis

Anatomical and pathological factors may favour the localisation of peritonitis.

Anatomical

The greater sac of the peritoneum is divided into (1) the subphrenic spaces, (2) the pelvis and (3) the peritoneal cavity proper. The last is divided into a supracolic and an infracolic compartment by the transverse colon and transverse mesocolon, which deters the spread of infection from one to the other. When the supracolic compartment overflows, as is often the case when a peptic ulcer perforates, it does so over the colon into the infracolic compartment or by way of the right paracolic gutter to the right iliac fossa and hence to the pelvis.

Pathological

The clinical course is determined in part by the manner in which adhesions form around the affected organ. Inflamed peritoneum loses its glistening appearance and becomes reddened and velvety. Flakes of fibrin appear and cause loops of intestine to become adherent to each other and to the parietes. There is an outpouring of serous inflammatory exudate rich in leukocytes and plasma proteins that soon becomes turbid; if localisation occurs, the turbid fluid becomes frank pus. Peristalsis is retarded in affected bowel and this helps to prevent distribution of the infection. The greater omentum, by enveloping and becoming adherent to inflamed structures, often forms a substantial barrier to the spread of infection (see below).

Diffuse (generalised) peritonitis

A number of factors may favour the development of diffuse peritonitis:

- Speed of peritoneal contamination is a prime factor. If an inflamed appendix or other hollow viscus perforates before localisation has taken place, there will be an efflux of contents into the peritoneal cavity, which may spread over a large area almost instantaneously. Perforation proximal to an obstruction or from sudden anastomotic separation is associated with severe generalised peritonitis and a high mortality rate.
- Stimulation of peristalsis by the ingestion of food or even water hinders localisation. Violent peristalsis occasioned by the administration of a purgative or an enema may cause the widespread distribution of an infection that would otherwise have remained localised.
- The virulence of the infecting organism may be so great as to render the localisation of infection difficult or impossible.

William Alexander Gillespie, formerly Professor of Clinical Bacteriology, University of Bristol, Bristol, UK.
Named after the two physicians, **Thomas Fitz-Hugh, Jr** and **Arthur Hale Curtis** who first reported this condition in 1934 and 1930, respectively.

- Young children have a small omentum, which is less effective in localising infection.
- Disruption of localised collections may occur with injudicious handling, e.g. appendix mass or pericolic abscess.
- Deficient natural resistance ('immune deficiency') may result from use of drugs (e.g. steroids), disease [e.g. acquired immune deficiency syndrome (AIDS)] or old age.

With appropriate treatment, localised peritonitis usually resolves; in about 20% of cases, an abscess follows. Infrequently, localised peritonitis becomes diffuse. Conversely, in favourable circumstances, diffuse peritonitis can become localised, most frequently in the pelvis or at multiple sites within the abdominal cavity.

Clinical features

Localised peritonitis

The initial symptoms and signs of localised peritonitis are those of the underlying condition – usually visceral inflammation (hence abdominal pain, specific GI symptoms + malaise, anorexia and nausea). When the peritoneum becomes inflamed, abdominal pain will worsen and in general temperature and pulse rate will rise. The pathognomonic signs are localised guarding (involuntary abdominal wall contraction to protect the viscus from the examining hand), a positive 'release' sign (rebound tenderness) and sometimes rigidity (involuntary constant contraction of the abdominal wall over the inflamed parietes). If inflammation arises under the diaphragm, shoulder-tip ('phrenic') pain may be felt as the pain is referred to the C5 dermatome. In cases of pelvic peritonitis arising from an inflamed appendix in the pelvic position or from salpingitis, the abdominal signs are often slight; there may be deep tenderness of one or both lower quadrants alone, but a rectal or vaginal examination reveals marked tenderness of the pelvic peritoneum.

Diffuse (generalised) peritonitis

EARLY

Abdominal pain is severe and made worse by moving or breathing. It is first experienced at the site of the original lesion and spreads outwards from this point. The patient usually lies still. Tenderness and generalised guarding are found on palpation, when the peritonitis affects the anterior abdominal wall. Infrequent bowel sounds may still be heard for a few hours but they cease with the onset of paralytic ileus. Pulse and temperature rise in accord with degree of inflammation and infection.

LATE

If resolution or localisation of generalised peritonitis does not occur, the abdomen will become rigid (generalised rigidity). Distension is common and bowel sounds are absent. Circulatory failure ensues, with cold, clammy extremities, sunken eyes, dry tongue, thready (irregular) pulse, and drawn and anxious face (hippocratic facies – Figure 61.1). The patient finally lapses into unconsciousness. With early diagnosis and adequate treatment, this condition is rarely seen in modern surgical practice.

Figure 61.1 The hippocratic facies in terminal diffuse peritonitis.

Summary box 61.6

Clinical features of peritonitis

- Abdominal pain, worse on movement, coughing and deep respiration
- Constitutional upset: anorexia, malaise, fever, lassitude
- GI upset: nausea ± vomiting
- Pyrexia (may be absent)
- Raised pulse rate
- Tenderness ± guarding/rigidity/rebound of abdominal wall
- Pain/tenderness on rectal/vaginal examination (pelvic peritonitis)
- Absent or reduced bowel sounds
- 'Septic shock' (systemic inflammatory response syndrome [SIRS] and multi-organ dysfunction syndrome [MODS]) in later stages

Diagnostic aids

Investigations may elucidate a doubtful diagnosis, but the importance of a careful history and repeated examination must not be forgotten.

Bedside

- Urine dipstix for urinary tract infection.
- ECG if diagnostic doubt (as to cause of abdominal pain) or cardiac history.

Hippocrates of Kos, Greek physician and surgeon, and by common consent 'the father of medicine', was born on the island of Kos, off Turkey, about 460BC and probably died in 375BC.

Bloods

- Baseline urea and electrolytes (U&Es) for treatment.
- Full blood count for white cell count (WCC).
- Serum amylase estimation may establish the diagnosis of acute pancreatitis provided that it is remembered that moderately raised values are frequently found following other abdominal catastrophes and operations, e.g. perforated duodenal ulcer.
- Group and save may be taken as an adjunct to impending surgery.

Imaging

- Erect chest radiograph to demonstrate free subdiaphragmatic gas (**Figure 61.2a**).
- A supine radiograph of the abdomen may confirm the presence of dilated gas-filled loops of bowel (consistent with a paralytic ileus), and occasionally show other gas-filled structures that may aid diagnosis, e.g. biliary tree; the faecal pattern may act as a guide to colonic disease (absent in sites of significant inflammation, e.g. diverticulitis). In the patient who is too ill for an 'erect' film, a lateral decubitus film can show gas beneath the abdominal wall (if CT unavailable).
- Multiplanar computed tomography (CT) is increasingly used to identify the cause of peritonitis (**Figures 61.2b and 61.3**) and may also influence management decisions, e.g. surgical strategy. There is an abundance of recent published evidence to support its use in managing acute abdominal pain.
- Ultrasonography has undoubted value in certain situations such as pelvic peritonitis in women and localised right upper quadrant peritonism.

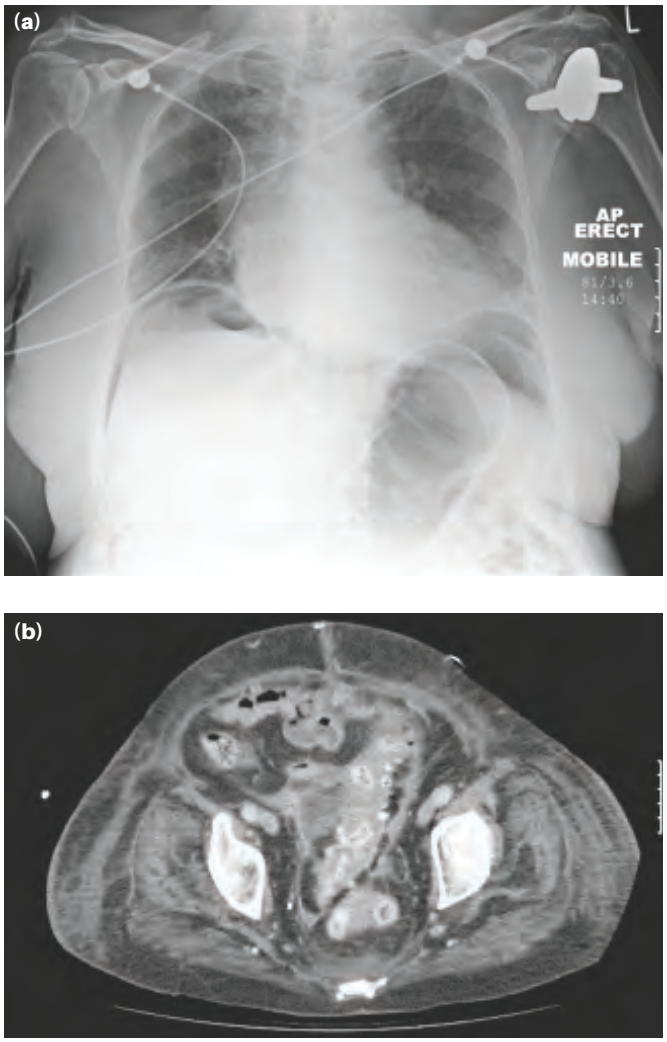

Figure 61.2 **(a)** Gas under the diaphragm in a patient with free perforation and peritonitis; **(b)** representative axial image through the pelvis of the same patient showing perforated sigmoid diverticular disease.

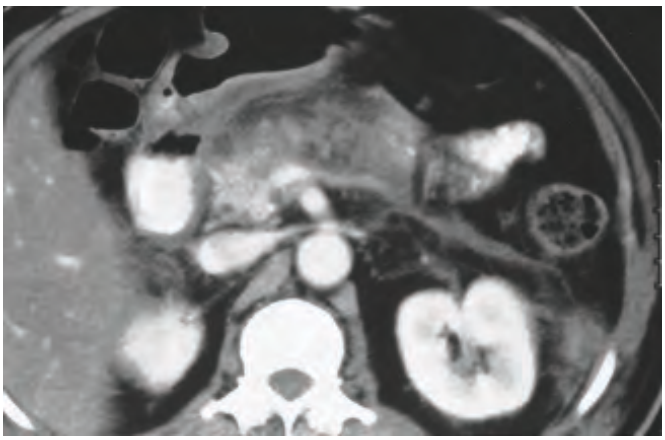

Figure 61.3 Acute pancreatitis seen on computed tomography scanning with swelling of the gland and surrounding inflammatory changes (courtesy of Dr J Healy, Chelsea and Westminster Hospital, London, UK).

Invasive

- In the era of access to high-quality CT scanning, peritoneal diagnostic aspiration has little residual value.

Management

General care of the patient

The care of critically ill surgical patients is described in detail in Chapters 2, 17 and 20. Nutritional support is covered in Chapter 19, and anaesthesia and pain relief in Chapter 18. Depending on degree (localised/generalised), duration and severity, patients will require some or all of the following.

CORRECTION OF FLUID LOSS AND CIRCULATING VOLUME

Patients are frequently hypovolaemic with electrolyte disturbances. The plasma volume must be restored and electrolyte concentrations corrected. Fluid balance should be monitored and pre-existent and ongoing losses corrected. Special measures may be needed for cardiac, pulmonary and renal support, especially if septic shock is present (see Chapter 2), including central venous pressure monitoring in patients with concurrent disease.

URINARY CATHETERISATION ± GASTROINTESTINAL DECOMPRESSION

A urinary catheter will give a guide to central perfusion and will be required if abdominal surgery is to proceed. A nasogastric tube is commonly passed to allow drainage ± aspiration until paralytic ileus has resolved.

ANTIBIOTIC THERAPY

Administration of parenteral broad-spectrum (aerobic and anaerobic) antibiotics prevents the multiplication of bacteria and the release of endotoxins.

ANALGESIA

The patient should be nursed in the sitting-up position and must be relieved of pain before and after the operation. If appropriate expertise is available, epidural infusion may provide excellent analgesia. Freedom from pain allows early mobilisation and adequate physiotherapy in the postoperative period, which helps to prevent basal pulmonary collapse, deep vein thrombosis and pulmonary embolism.

Specific treatment of the cause

Although difficult to generalise, in patients in whom specific treatment has not been guided by CT scanning, early surgical intervention is to be preferred to a 'wait and see' policy, assuming that the patient is fit for anaesthesia and that resuscitation has resulted in a satisfactory restitution of normal body physiology. This rule is particularly true for previously healthy patients and those with postoperative peritonitis. More caution is of course required in patients at high operative risk because of comorbidity or advanced age.

In those patients with a preoperative diagnosis, if the cause of peritonitis is amenable to surgery, an operation must be carried out as soon as the patient is fit. This is usually within a few hours. In peritonitis caused by pancreatitis or salpingitis, or in cases of primary peritonitis of streptococcal or pneumococcal origin, non-surgical treatment is preferred, provided that the diagnosis can be made with confidence. It is beyond the remit of this chapter to cover specific causes of peritonitis and their treatment, be it by an open or a laparoscopic approach. However, in general, surgery is directed to removing (or diverting) the cause and subsequent adequate peritoneal lavage ± drainage. In operations for generalised peritonitis it is essential that, after the cause has been dealt with, the whole peritoneal cavity be explored with the sucker and, if necessary, mopped dry until all seropurulent exudate has been removed. The use of a large volume of saline (typically 3 litres) containing dissolved antiseptic or antibiotic has been shown to be effective.

Summary box 61.7

Management of peritonitis

General care of patient

- Correction of fluid and electrolyte imbalance
- Insertion of nasogastric drainage tube and urinary catheter
- Broad-spectrum antibiotic therapy
- Analgesia
- Vital system support

Surgical treatment of cause when appropriate

- Remove or divert cause
- Peritoneal lavage ± drainage

Prognosis and complications

With modern treatment, diffuse peritonitis carries a mortality rate of about 10%, reflecting the degree and duration of peritoneal contamination, age and fitness of the patient, and the nature of the underlying cause. Paralytic ileus is covered in detail in Chapter 71, and abscess formation and adhesions are covered below.

Summary box 61.8

Systemic complications of peritonitis

- Septic shock
- Systemic inflammatory response syndrome
- Multi-organ dysfunction syndrome
- Death

Abdominal complications of peritonitis

- Paralytic ileus
- Residual or recurrent abscess/inflammatory mass
- Portal pyaemia/liver abscess
- Adhesional small bowel obstruction

SPECIAL FORMS OF PERITONITIS

Bile peritonitis

Unless there is reason to suspect that the biliary tract was damaged during surgery or the patient has proven acute cholecystitis, it is improbable that bile will be thought of as a cause of peritonitis until the abdomen has been opened.

Unless the bile has extravasated slowly and the collection becomes shut off from the general peritoneal cavity, there are symptoms (often severe pain) and signs of diffuse peritonitis. After a few hours a tinge of jaundice is not unusual. Laparotomy (or laparoscopy) should be undertaken with evacuation of the bile and peritoneal lavage. The source of bile leakage should be identified and treated accordingly. Infected bile is more lethal than sterile bile. A 'blown' duodenal stump should be drained because it is too oedematous to repair, but sometimes it can be covered by a jejunal patch. The patient is often jaundiced from absorption of peritoneal bile, but the surgeon must ensure that the abdomen is not closed until any obstruction to a major bile duct has been either excluded or relieved. Bile leaks after cholecystectomy or liver trauma may be dealt with by percutaneous (ultrasound-guided) drainage and endoscopic biliary stenting to reduce bile duct pressure. The drain is removed when dry and the stent at 4–6 weeks.

Summary box 61.9

Causes of bile peritonitis

- Perforated gall bladder secondary to inflammation or obstruction (especially empyema)
- Post-cholecystectomy:
  - Cystic duct stump leakage
  - Leakage from an accessory duct in the gall-bladder bed
  - Bile duct injury
  - T-tube drain dislodgement (or tract rupture on removal)
- Following other operations/procedures:
  - Duodenal injury
  - Leaking duodenal stump post gastrectomy
  - Leaking biliary–enteric anastomosis
  - Leakage around percutaneously placed biliary drains
- Blunt or penetrating hepatobiliary or duodenal trauma

Spontaneous bacterial peritonitis

Spontaneous bacterial peritonitis (SBP; sometimes called primary bacterial peritonitis) is an acute bacterial infection of ascitic fluid. It can occur in children and adults and can in theory occur as a complication of any disease state that produces the clinical syndrome of ascites. In practice, it is rare except in patients with cirrhosis and ascites, affecting 1.5–3.5% of outpatients and approximately 10% of inpatients.

Clinical features usually include local symptoms and/or signs of peritonitis, GI upset (secondary to ileus, e.g. nausea and vomiting), signs of systemic inflammation (hyper- or hypothermia, chills, tachycardia and tachypnoea ± signs of septic shock), worsening liver and renal function, hepatic encephalopathy and GI bleeding. It should, however, be noted that evolving infection may be asymptomatic, especially in outpatients.

The diagnosis is made by paracentesis, and this should be considered in patients with cirrhosis and ascites even when there is a low index of suspicion. Some guidelines recommend diagnostic paracentesis in all patients with cirrhosis and ascites on hospital admission. The diagnosis is made by an increased neutrophil of 250/mm^3 as determined by counting centrifuged ascitic fluid. Ascites culture is negative in as many as 60% of patients with clinical manifestations of SBP and increased ascitic neutrophil count. When culture is positive (40% of cases), the most common pathogens include gram-negative bacteria, usually *E. coli*, and gram-positive cocci (mainly streptococci and enterococci).

Empirical treatment of SBP must be initiated immediately after diagnosis before the results of culture have been received. Although the choice of antibiotic may vary internationally, a third-generation cephalosporin, e.g. cefotaxime, is the best investigated, and it avoids the renal toxicity of aminoglycosides. Alternatives are amoxicillin/clavulanic acid and quinolones such as ciprofloxacin. Complications of SBP, e.g. septic shock, GI bleeding and hypoalbuminaemia, should be managed accordingly.

When first described, the mortality rate of SBP exceeded 90%, but it has been reduced to approximately 20% with early diagnosis and treatment.

Primary pneumococcal peritonitis

This may complicate nephrotic syndrome or cirrhosis in children. Otherwise healthy children, particularly girls aged between 3 and 9 years, may also be affected, and it is likely that the route of infection is sometimes via the vagina and fallopian tubes. At other times, and always in boys, the infection is blood borne and secondary to respiratory tract or middle-ear disease. The prevalence of pneumococcal peritonitis has declined greatly and the condition is now rare. In brief, the clinical onset is sudden, with pain usually localised to the lower half of the abdomen. The temperature is raised to 39°C or more and there is usually frequent vomiting. After 24–48 hours, profuse diarrhoea is characteristic. There is usually increased frequency of micturition. The last two symptoms are caused by severe pelvic peritonitis. On examination, peritonism is usually diffuse but less prominent than in most cases of a perforated viscus, leading to peritonitis.

A leukocytosis of ≥30 000/μL, with approximately 90% polymorphs, suggests pneumococcal peritonitis rather than another cause, e.g. appendicitis. After starting antibiotic therapy and correcting dehydration and electrolyte imbalance, early surgery is required unless spontaneous infection of pre-existing ascites is strongly suspected, in which case a diagnostic peritoneal tap is useful. Laparotomy or laparoscopy may be used. Should the exudate be odourless and sticky, the diagnosis of pneumococcal peritonitis is practically certain, but it is essential to perform a careful exploration to exclude other pathology. Assuming that no other cause for the peritonitis is discovered, some of the exudate is aspirated and sent to the laboratory for microscopy, culture and sensitivity tests. Thorough peritoneal lavage is carried out and the incision closed. Antibiotics and fluid replacement therapy are continued and recovery is usual.

Other organisms are now known to cause some cases of primary peritonitis in children, including *Haemophilus* spp., group A streptococci and a few gram-negative bacteria. Underlying pathology (including an intravaginal foreign body in girls) must always be excluded before primary peritonitis can be diagnosed with certainty. Idiopathic streptococcal and staphylococcal peritonitis can also occur in adults.

Tuberculous peritonitis

Intra-abdominal tuberculosis (TB) is very common in resource-poor countries where all general surgeons are familiar with its presentation and management. The incidence is, however, also rising in resource-rich countries as a consequence of migration and immunosuppression where *Mycobacterium avium-intracellulare* is becoming increasingly prevalent with the widespread increase in human immunodeficiency virus (HIV) co-infection. The abdomen is involved in 11% of patients with extrapulmonary TB and includes intraperitoneal, GI tract and solid organ disease forms, with TB peritonitis being a common site-specific variant (ileocaecal is the most common site of involvement). Although still uncommon, TB peritonitis requires some specific mention because it is often diagnosed late in the course of the disease, resulting in undue patient morbidity and mortality.

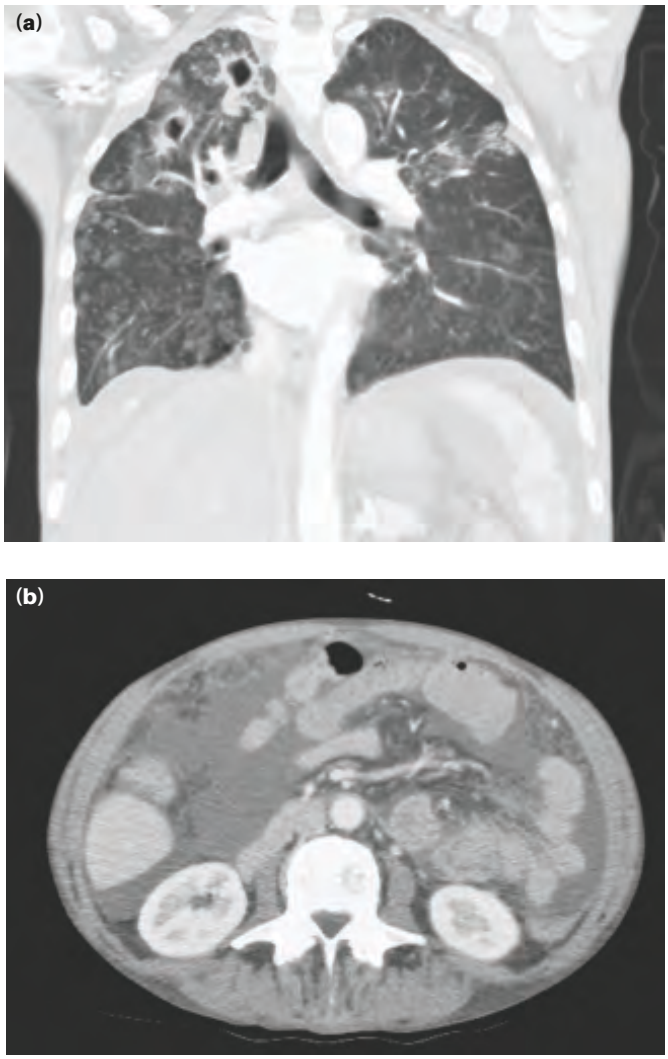

Figure 61.4 **(a)** Plain chest radiograph from a 55-year-old man showing miliary tuberculosis (TB); **(b, c)** representative computed tomography images from the same patient showing gross ascites, nodular stranding in the omentum and mesentery, as well as nodular enhancement of the peritoneum – TB peritonitis (courtesy of Dr S Burke, Homerton University Foundation Trust, London).

Tuberculosis can spread to the peritoneum through the GI tract (typically the ileocaecal region) via mesenteric lymph nodes or directly from the blood, usually from the 'miliary' (Figure 61.4a), but occasionally from the 'cavitating' form of pulmonary TB, lymph and the fallopian tubes; 50–83% of patients with abdominal TB can be expected to have peritoneal involvement. Clinical or subclinical ascites is reported in virtually all patients with TB peritonitis and is frequently a presenting feature. In the most common form of the disease, ascites may be localised or generalised throughout the peritoneal cavity. Multiple tubercle deposits appear on both layers of the peritoneum. Diagnosis is via abdominal ultrasonography or CT to detect ascites and lymphadenopathy ± diffuse thickening of the peritoneum, mesentery and/or omentum (Figure 61.4b, c). Ascitic fluid is typically a straw-coloured exudate (protein >25–30 g/L) with white cells >500 mm^3 and lymphocytes >40%. Unfortunately diagnostic smears for acid-fast bacilli are diagnostic in less than 3% of patients, and culture may take up to 4–8 weeks with no guarantee of a positive result. Laparoscopy and peritoneal biopsy may thus be helpful to couple typical appearances with histology. TB management is principally supportive (nutrition and hydration) and medical (systemic antituberculous therapy, noting that multiple-drug resistance may be higher for abdominal than for pulmonary TB), although surgery may be required for specific complications such as intestinal obstruction.

Summary box 61.10

Tuberculous peritonitis

- Acute (may be clinically indistinguishable from acute bacterial peritonitis) and chronic forms
- Abdominal pain, sweats, malaise and weight loss are frequent
- Ascites common, may be loculated
- Caseating peritoneal nodules are common – distinguish from metastatic carcinoma and fat necrosis of pancreatitis
- Intestinal obstruction may respond to anti-tuberculous treatment without surgery

Familial Mediterranean fever (periodic peritonitis)

Familial Mediterranean fever (periodic peritonitis) is characterised by abdominal pain and tenderness, mild pyrexia, polymorphonuclear leukocytosis and, occasionally, pain in the thorax and joints. The duration of an attack is 24–72 hours, when it is followed by complete remission, but exacerbations recur at regular intervals. Most of the patients have undergone appendicectomy in childhood. This disease, often familial, is limited principally to Arab, Armenian and Jewish populations; other races are occasionally affected. Mutations in the *MEFV* (Mediterranean fever) gene appear to cause the disease. This gene produces a protein called pyrin, which is expressed mostly in neutrophils; however, the exact function of pyrin is not known.

Usually, children are affected but it is not rare for the disease to make its first appearance in early adult life, with cases in women outnumbering those in men by two to one. Exceptionally, the disease becomes manifest in patients aged >40 years. At surgery, which may be necessary to exclude other causes (but should be avoided if possible), the peritoneum is inflamed, particularly in the vicinity of the spleen and the gall bladder. There is no evidence that the interior of these organs is abnormal. Colchicine therapy is used during attacks and to prevent recurrent attacks.

INTRAPERITONEAL ABSCESS

Following intraperitoneal sepsis (usually manifest first as local or diffuse peritonitis), the anatomy of the peritoneal cavity is such that with the influence of gravity (depending on patient position – sitting or supine), abscess development usually occupies one of a number of specific abdominal or pelvic sites.

In general, the symptoms and signs of a purulent collection may be vague and consist of nothing more than lassitude, anorexia and malaise, pyrexia (often low grade), mild tachycardia and localised tenderness. Certain sites have more specific clinical features. Larger abscesses will give rise to the picture of swinging pyrexia and pulse and a palpable mass. Blood tests will reveal elevated inflammatory markers.

Summary box 61.11

Clinical features of an abdominal/pelvic abscess

Symptoms

- Malaise, lethargy – failure to recover from surgery as expected
- Anorexia and weight loss
- Sweats ± rigors
- Abdominal/pelvic pain
- Symptoms from local irritation, e.g. shoulder tip/hiccoughs (subphrenic), diarrhoea and mucus (pelvic), nausea and vomiting (any upper abdominal)

Signs

- Increased temperature and pulse ± swinging pyrexia
- Localised abdominal tenderness ± mass (including on pelvic exam)

Pelvic abscess

The pelvis is the most common site of abscess formation because the vermiform appendix is often pelvic in position and the fallopian tubes are also frequent sites of infection. A pelvic abscess can also occur as a sequel to any case of diffuse peritonitis, and is common after anastomotic leakage following colorectal surgery.

Clinical features

The most characteristic symptoms are of pelvic pain, diarrhoea and the passage of mucus in the stools. Rectal examination reveals a bulging of the anterior rectal wall, which, when the abscess is ripe, becomes softly cystic.

Investigation and management

Left to nature, a proportion of these abscesses burst into the rectum, after which the patient almost always recovers rapidly. If this does not occur, the abscess should be drained deliberately. In women, vaginal drainage through the posterior fornix is often chosen. In other cases, when the abscess is definitely pointing into the rectum, rectal drainage (**Figure 61.5**) is employed. If any uncertainty exists, the presence of pus should be confirmed by ultrasonography or CT scanning (**Figure 61.6**). Laparotomy is almost never necessary and rectal drainage of a pelvic abscess is far preferable to suprapubic drainage, which risks exposing the general peritoneal cavity to infection. It is, however, increasingly common to insert drainage tubes percutaneously, e.g. via the buttock or via the vagina or rectum under CT guidance.

Abdominal abscess

Anatomy

The complicated arrangement of the peritoneum results in the formation of four intraperitoneal spaces in which pus may commonly collect (**Figure 61.7**).

LEFT SUBPHRENIC SPACE

This is bounded above by the diaphragm and behind by the left triangular ligament and the left lobe of the liver, the gastrohepatic omentum and the anterior surface of the stomach.

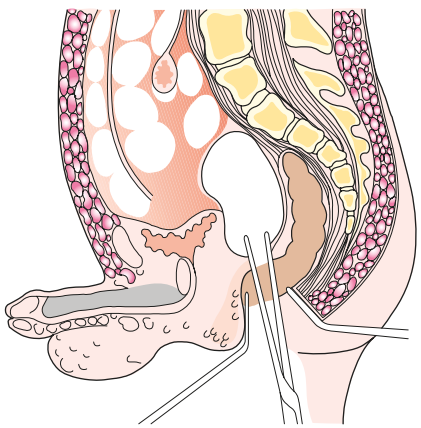

Figure 61.5 Opening a pelvic abscess into the rectum.

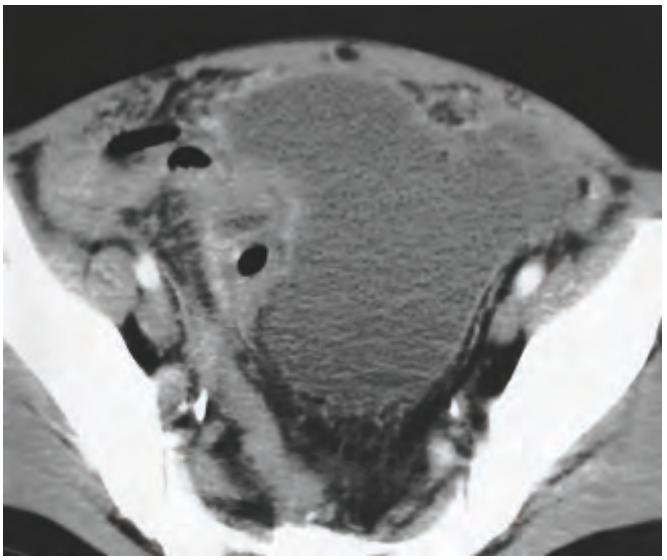

Figure 61.6 A pelvic abscess seen on CT scanning (courtesy of Dr J Healy, Chelsea and Westminster Hospital, London, UK).

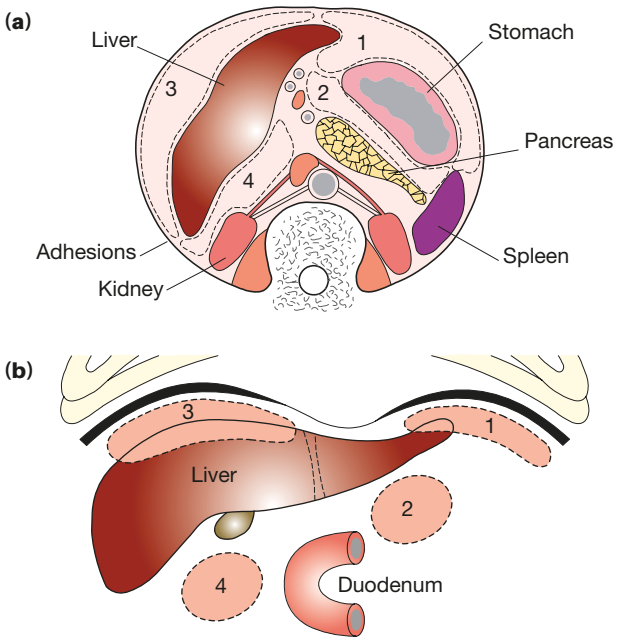

Figure 61.7 **(a)** Intraperitoneal abscesses on transverse section: 1, the left subphrenic space; 2, left subhepatic space/lesser sac; 3, right subphrenic space; 4, right subhepatic space. **(b)** Intraperitoneal abscesses on sagittal section: 1, left subphrenic; 2, left subhepatic/lesser sac; 3, right subphrenic; 4, right subhepatic.

To the right is the falciform ligament and to the left the spleen, gastrosplenic omentum and diaphragm. The common cause of an abscess here is an operation on the stomach, the tail of the pancreas, the spleen or the splenic flexure of the colon.

LEFT SUBHEPATIC SPACE/LESSER SAC

The most common cause of infection here is complicated acute pancreatitis. In practice, a perforated gastric ulcer rarely causes a collection here because the potential space is obliterated by adhesions.

RIGHT SUBPHRENIC SPACE

This space lies between the right lobe of the liver and the diaphragm. It is limited posteriorly by the anterior layer of the coronary and the right triangular ligaments, and to the left by the falciform ligament. Common causes of abscess here are perforating cholecystitis, a perforated duodenal ulcer and a duodenal cap 'blow-out' following gastrectomy and appendicitis.

RIGHT SUBHEPATIC SPACE

This lies transversely beneath the right lobe of the liver in Rutherford Morison's pouch. It is bounded on the right by the right lobe of the liver and the diaphragm. To the left is situated the foramen of Winslow and below this lies the duodenum. In front are the liver and the gall bladder, and behind are the upper part of the right kidney and the diaphragm. The space is bounded above by the liver and below by the transverse colon and hepatic flexure. It is the deepest space of the four and the most common site of a subphrenic abscess, which usually arises from appendicitis, cholecystitis, a perforated duodenal ulcer or following upper abdominal surgery.

Clinical features

The symptoms and signs of subphrenic infection are frequently non-specific and it is well to remember the following aphorism: 'pus somewhere, pus nowhere, pus under the diaphragm'. A common history is that, when some infective focus in the abdominal cavity has been dealt with, the condition of the patient improves temporarily but, after an interval of a few days or weeks, symptoms of toxaemia reappear. The condition of the patient steadily, and often rapidly, deteriorates. Sweating, wasting and anorexia are present. There is sometimes epigastric fullness and pain, or pain in the shoulder on the affected side, because of irritation of sensory fibres in the phrenic nerve, referred along the descending branches of the cervical plexus. Persistent hiccoughs may be a presenting symptom. A swinging pyrexia is usually present. If the abscess is anterior, abdominal examination will reveal some tenderness, rigidity or even a palpable swelling. Sometimes the liver is displaced downwards but more often it is fixed by adhesions.

Investigation and management

Examination of the chest and plain radiograph are important because, in most cases, collapse of the lung or evidence of basal effusion or even an empyema is evident. The modern management of an abscess is by radiological diagnosis using ultrasound or CT guidance (**Figures 61.8**), followed by drainage. The same tube can be used to instil antibiotic solutions or irrigate the abscess cavity if necessary. In some instances, monitoring may be appropriate by either clinically marking out limits on the abdominal wall (if palpable) with daily examination. However, more commonly, repeat ultrasonography or CT scanning will be required. Radiolabelled white cell

James Rutherford Morison, 1853–1939, Professor of Surgery, the University of Durham, Durham, UK.
Jacob Benignus Winslow, 1669–1760, Professor of Anatomy, Physic and Surgery, Paris, France.

scanning may occasionally prove helpful when other imaging techniques have failed. In most cases, with the aid of percutaneous drainage and antibiotic treatment, the abscess or mass gradually reduces in size until, finally, it is undetectable. Open drainage of an intraperitoneal collection is thus now uncommon but may be necessary. If a swelling can be detected in the subcostal region or in the loin, an incision is made over the site of maximum tenderness or over any area where oedema or redness is discovered. Cautious blunt finger exploration can then be used to avoid dissemination of pus into the peritoneal or pleural cavities and minimise the risk of an intestinal fistula. When the cavity is reached, all of the fibrinous loculi must be broken down with the finger and one or two drainage tubes fully inserted. These drains are withdrawn gradually over the next 10 days, and the closure of the cavity can be checked by sinograms or scanning. Appropriate antibiotics are also given.

ASCITES

Ascites is defined as an accumulation of excess serous fluid within the peritoneal cavity.

Pathophysiology

The balanced effects of plasma and peritoneal colloid osmotic and hydrostatic pressures determine the exchange of fluid between the capillaries and the peritoneal fluid. Protein-rich fluid enters the peritoneal cavity when capillary permeability is increased, as in peritonitis and carcinomatosis peritonei. Capillary pressure may be increased because of generalised water retention, cardiac failure, constrictive pericarditis or vena cava obstruction. Capillary pressure is raised selectively in the portal venous system in the Budd–Chiari syndrome, cirrhosis of the liver or extrahepatic portal venous obstruction. Plasma colloid osmotic pressure may be lowered in patients with reduced nutritional intake, diminished intestinal absorption, abnormal protein losses or defective protein synthesis, such as occurs in cirrhosis. Peritoneal lymphatic drainage may be impaired, resulting in the accumulation of protein-rich fluid.

George Budd, 1808–1882, Professor of Medicine, King's College Hospital, London, UK, described this syndrome in 1845.
Hans Chiari, 1851–1916, Professor of Pathological Anatomy, Strasbourg, Germany (Strasbourg was returned to France in 1918 at the end of the First World War). He gave his account of this condition in 1898.

Summary box 61.12

Causes of ascites

Transudates (protein <25 g/L)

- Low plasma protein concentrations:
  - Malnutrition
  - Nephrotic syndrome
  - Protein-losing enteropathy
- High central venous pressure:
  - Congestive cardiac failure
- Portal hypertension
  - Portal vein thrombosis
  - Cirrhosis

Exudates (protein >25 g/L)

- Peritoneal malignancy
- Tuberculous peritonitis
- Budd–Chiari syndrome (hepatic vein occlusion or thrombosis)
- Pancreatic ascites
- Chylous ascites
- Meigs' syndrome

Clinical features

Ascites can usually be recognised clinically only when the amount of fluid present exceeds 1.5 L depending on body habitus: in obese individuals a greater quantity than this is necessary before there is clear evidence. The abdomen is distended evenly with fullness of the flanks, which are dull to percussion. Usually, shifting dullness is present but, when there is a very large accumulation of fluid, this sign is absent. In such cases, on flicking the abdominal wall, a characteristic fluid thrill is transmitted from one side to the other. In women, ascites must be differentiated from an enormous ovarian cyst.

Congestive heart failure results in increased venous pressure in the vena cava and consequent obstruction to the venous outflow from the liver. The ascitic fluid is light yellow and of low specific gravity, about 1.010, with a low protein concentration (<25 g/L). Patients with constrictive pericarditis (Pick's disease) have both peritoneal and pleural effusions because of engorgement of the venae cavae, consequent upon the diminished capacity of the right side of the heart. Ascites occurs with low plasma albumin concentrations, e.g. in patients with albuminuria or starvation. The ascites in this instance is caused by alterations in the osmotic pressure of the capillary blood and has a low specific gravity.

In cirrhosis, now the most common cause of ascites internationally, there is obstruction to the portal venous system, which is caused by obliterative fibrosis of the intrahepatic venous bed. In the Budd–Chiari syndrome (see Chapter 65), thrombosis or obstruction of the hepatic veins is responsible for obstruction to venous outflow from the liver. The ascites seen in patients with peritoneal metastases is caused by excessive exudation of fluid and lymphatic blockage. The fluid is dark yellow and frequently blood stained. The specific gravity, ≥1.020, and the protein content (>25 g/L) are high. Microscopic examination often reveals cancer cells, especially if large quantities of fluid are 'spun down' to produce a concentrated deposit for sampling. Rarely, ascites and pleural effusion are associated with solid fibromas of the ovary (Meigs' syndrome). The effusions disappear when the tumour is excised.

Investigation

In addition to relevant investigations to determine the underlying cause, e.g. liver function tests (LFTs), cardiac function, ultrasonography and/or CT scanning (**Figure 61.9**) will determine much smaller quantities of ascites than possible clinically. These will often also diagnose aetiology, e.g. carcinomatosis or liver disease. Ascitic aspiration or tap (below) is now most commonly performed under imaging guidance to minimise the risk of visceral injury. After the bladder has been emptied, puncture of the peritoneum is carried out under local anaesthetic using a moderately sized trocar and cannula. Alternatively, a peritoneal drain may be inserted. In cases where the effusion is caused by cardiac failure, the fluid must be evacuated slowly. Fluid is sent for microscopy/cytology, culture, including mycobacteria, and analysis of protein content and amylase. Unless other measures are taken the fluid soon reaccumulates, and repeated tappings remove valuable protein.

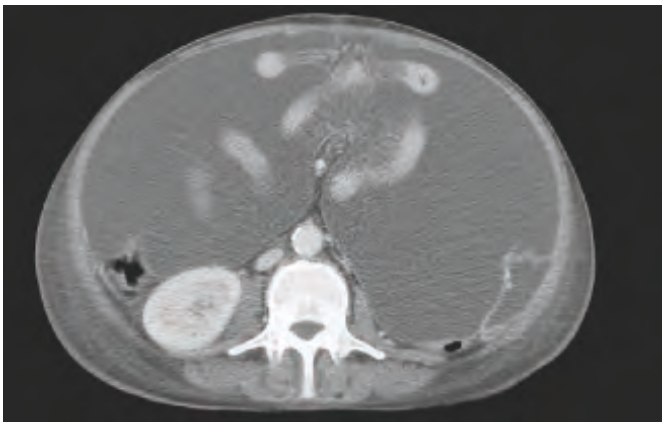

Figure 61.9 Computed tomography scan showing gross ascites.

Treatment

Treatment of the specific cause is undertaken whenever possible, e.g. if portal venous pressure is raised, it may be possible to lower it by treatment of the primary condition or by transjugular intrahepatic portosystemic shunt or transjugular intrahepatic portosystemic stent shunting (commonly abbreviated as TIPS or TIPSS). These procedures have become increasingly popular since the 1980s and are performed by interventional radiologists under fluoroscopic guidance. Access to the liver is gained via the internal jugular vein and

Joe Vincent Meigs, 1892–1963, Professor of Gynecology, Harvard University Medical School, Boston, MA, USA.
Friedel Pick, 1867–1926, physician, Prague, the former Czechoslovakia, described this disease in 1896.

a guidewire and introducer sheath facilitate cannulation of the hepatic vein. Once the catheter is in the hepatic vein, a wedge pressure is obtained to calculate the pressure gradient in the liver, and a special needle is advanced through the liver parenchyma to connect the hepatic to the portal vein. The channel for the shunt is created using an angioplasty balloon to dilate the needle tract and thence a stent placed through this track. Complications can occur, e.g. bleeding, liver injury and encephalopathy; however, in experienced hands the mortality rate is <1%. This procedure is thus, when possible, preferable to older surgical methods.

Dietary sodium restriction to 200 mg/day may be helpful, but diuretics are usually required (combination of spironolactone and furosemide). For patients failing to respond to such measures, therapeutic needle paracentesis can be performed. This is usually performed in the left of the right lower abdominal quadrant after diagnostic needle aspiration, and using a 'Z' track approach to ensure that peritoneal and skin puncture do not overlie the same point. Serial large volume paracentesis (4–6 L/day and up to 8 L in one session) can be performed safely with colloid replacement, and it can be performed in patients with cirrhosis and deranged clotting. Guidelines recommend albumin replacement after paracentesis to reduce complications. It is now also possible to leave an indwelling external drain for smaller-volume home paracentesis. In cases in which ascites accumulates rapidly after paracentesis and the patient is fit, drainage of the ascitic fluid by surgical peritoneovenous shunting (e.g. LeVeen, Denver) was previously employed; however, these procedures have been essentially abandoned due to their high rate of complications.

Special cases

Chylous ascites

In some patients the ascitic fluid appears milky because of an excess of chylomicrons (triglycerides). Most cases are associated with malignancy, usually lymphomas; other causes are cirrhosis, TB, filariasis, nephrotic syndrome, abdominal trauma (including surgery), constrictive pericarditis, sarcoidosis and congenital lymphatic abnormality. The prognosis is poor unless the underlying condition can be cured. In addition to other measures used to treat ascites, patients should be placed on a fat-free diet with medium-chain triglyceride supplements.

TUMOURS OF THE PERITONEUM

Primary tumours

Primary tumours of the peritoneum are rare and in most cases take their origin not from the serous layer but from some adjacent structure, e.g. lipoma from appendices epiploicae, fibroma from connective tissue. Mesothelioma of the peritoneum is less frequent than in the pleural cavity but equally lethal. Asbestos is a recognised cause. It has a predilection for the pelvic peritoneum. Chemocytotoxic agents are the mainstay of treatment. Desmoid tumours which have a relationship to the peritoneum are considered under familial adenomatous polyposis (see Chapter 70).

Secondary tumours

Carcinomatosis peritonei

This is a common terminal event in many cases of carcinoma of the stomach, colon, ovary or other abdominal organs, and also of the breast and bronchus. The peritoneum, both parietal and visceral, is studded with secondary growths and the peritoneal cavity becomes filled with clear, straw-coloured or blood-stained ascitic fluid.

The main forms of peritoneal metastases are:

- discrete nodules – by far the most common variety;
- plaques varying in size and colour;
- diffuse adhesions – this form occurs at a late stage of the disease and gives rise, sometimes, to a 'frozen pelvis'.

Gravity probably determines the distribution of free malignant cells within the peritoneal cavity. Cells not caught in peritoneal folds gravitate into the pelvic pouches or into a hernial sac, the enlargement of which is occasionally the first indication of the condition. Implantation occurs also on the greater omentum, the appendices epiploicae and the inferior surface of the diaphragm. The main differential diagnosis is from tuberculous peritonitis (tubercles are greyish and translucent and closely resemble the discrete nodules of peritoneal carcinomatosis). Investigation and treatment are as for underlying malignancy; however, newer treatment options such as cytoreductive surgery, intraperitoneal chemotherapy and hyperthermic intraperitoneal chemotherapy (HIPEC) are now offered in specialist centres. The last, a highly concentrated, heated (41–42°C) chemotherapy treatment is delivered directly into the abdomen for 90 minutes after cytoreductive surgery, and is progressing to a standard of care in some countries for patients without disease outside the abdomen.

Pseudomyxoma peritonei

This rare condition occurs more frequently in women. The abdomen is filled with a yellow jelly, large quantities of which are often encysted. The condition is associated with mucinous cystic tumours of the ovary and appendix. Recent studies suggest that most cases arise from a primary appendiceal tumour with secondary implantation on to one or both ovaries. It is often painless and there is frequently no impairment of general health. Pseudomyxoma peritonei does not give rise to extraperitoneal metastases but causes symptoms and complications due to tumour bulk. Although an abdomen distended with what seems to be fluid that cannot be made to shift should raise the possibility, the diagnosis is more often suggested by ultrasonography and CT scanning, or made at operation. At laparotomy, masses of jelly are scooped out. The appendix, if present, should be excised together with any ovarian tumour. More definitive treatment can be achieved by 'complete cytoreduction' (Sugarbaker technique) in which

Harry LeVeen, Professor of Surgery, the University of South Carolina, SC, USA.
Paul Sugarbaker, Director of Surgical Oncology at the Cancer Institute at Washington Hospital Center, Washington DC, USA.

the right hemicolon, spleen, gall bladder, and greater and lesser omentum are excised, along with stripping of the peritoneum from the pelvis and diaphragm, and stripping of the tumour from the surface of the liver (the uterus and ovaries are also removed in women). Intraoperative heated chemotherapy (using mitomycin C) follows and the whole procedure takes about 10 hours. There is international controversy about the effectiveness of this procedure although some large series report good 5-year survival.

Peritoneal inclusion cysts

These are usually caused by accumulation of ovarian fluid that is contained by peritoneal adhesions. The development of a peritoneal inclusion cyst thus depends on the presence of an active ovary and peritoneal adhesions. The normal peritoneum absorbs fluid easily. However, the absorptive capacity of the peritoneum is greatly diminished in the presence of mechanical injury, inflammation and peritoneal adhesions.

Peritoneal inclusion cysts occur only in premenopausal women with a history of pelvic or abdominal surgery. They range in size from several millimetres in diameter to bulky masses that may fill the entire pelvis and abdomen. Pathologically, the cyst results from non-neoplastic, reactive mesothelial proliferation.

Investigation includes the exclusion of ovarian tumour by blood tests and appropriate imaging (usually ultrasonography and magnetic resonance imaging [MRI]). Cysts may be managed expectantly or by hormonal modulation, e.g. oral contraceptives. Radiological drainage will give transient relief and may help diagnosis using cytology. Surgery can be performed to remove adhesions but the risk of recurrence is 30–50%.

Peritoneal loose bodies (peritoneal mice)

Peritoneal loose bodies (peritoneal mice) may be confused with a small tumour but almost never cause symptoms. One or more may be found in a hernial sac or in the pouch of Douglas. The loose body may come from an appendix epiploica that has undergone axial rotation followed by necrosis of its pedicle and detachment, but they are also found in those who have subacute attacks of pancreatitis. These hyaline bodies attain the size of a pea or bean and contain saponified fat surrounded by fibrin.

ADHESIONS

Pathophysiology

Adhesions are strands of fibrous tissue that form, usually as a result of surgery, between surgically injured tissues. After injury, there is bleeding and an increase in vascular permeability with extravasation of fibrinogen-rich fluid from the injured surfaces forming a temporary fibrin matrix. An inflammatory response ensues with cell migration, release of cytokines and activation of the coagulation cascade. The activation of the coagulation system results in thrombin formation, which is necessary for the conversion of fibrinogen to fibrin. In the absence of fibrinolysis, adhesions will form within 5–7 days as the matrix gradually becomes more organised with collagen secretion by fibroblasts. Fibrinolysis is therefore the key factor in determining whether an adhesion persists. This is governed by several cascades and activators that may account for inter-individual differences (see Chapter 3). Of great importance to the surgeon, however, is the fact that ischaemic tissue loses its ability to break down fibrin and inhibits fibrinolysis in adjacent tissues.

Complications

The most common adhesion-related problem is small bowel obstruction (SBO). Adhesions are the most frequent cause of SBO in resource-rich countries and are responsible for 60–70% of SBOs (see Chapter 71). Adhesions are also implicated as a major cause of secondary infertility (beyond the remit of this text). The relationship of adhesions to chronic abdominal and pelvic pain is contentious. Unguided division of adhesions has not been shown to reduce chronic abdominal pain in definitive RCTs although conscious pain mapping (laparoscopy under local anaesthesia) to direct lysis may improve success rates.

Prevention

As a result of the scale of the problem there has been significant research into ways of preventing postoperative adhesion formation. Minimising the production of ischaemic tissue by careful surgical technique, including meticulous control of bleeding, remain, however, the most critical concepts. The evolution of laparoscopic bowel surgery has been shown by collective review data to result in reduced adhesion-related readmissions for a number of abdominal and pelvic procedures, e.g. cholecystectomy, hysterectomy and colectomy. It should be noted, however, that only one randomised controlled trial (after Crohn's resection) has ever shown a definitive effect, and this was not confirmed by evidence synthesis at Cochrane review.

The effect of a number of drugs including anti-inflammatory drugs such as aspirin and steroids, some hormones, anticlotting agents, antibiotics, vitamin E and even methylene blue have been investigated in adhesion prevention but have not achieved widespread use, because of either side effects or lack of consistent evidence of effectiveness. Many barrier methods of reducing adhesions have also been trialled. Adept® (4% icodextrin solution) is a solution applied inside the abdomen at the time of surgery; it has been shown to reduce the extent and severity of adhesion formation in animal models. It has also been used widely as a peritoneal dialysis solution for many years. Interceed TC7® is a mesh-like product (oxidised regenerated cellulose) which quickly forms a soft gelatinous mass around healing tissues and is absorbed within 2 weeks. It has been shown to significantly reduce the number of adhesions at the site where it is used. However, it is worth noting that a reduction in the number of adhesions in such studies does not necessarily equate to a reduction in adhesion-related problems in the future. In a review of seven randomised trials looking at a similar

barrier-type product (hyaluronic acid/carboxymethyl membrane), there was a significant reduction in the incidence, extent and severity of adhesions but no reduction in the incidence of intestinal obstruction or surgical intervention. Such barriers, when placed around bowel anastomosis, also led to a significant increase in the anastomotic leaks. For these reasons barrier approaches have not gained popularity.

Special forms of intraperitoneal fibrosis

Sclerosing encapsulating peritonitis

Also known as abdominal cocoon syndrome, sclerosing encapsulating peritonitis (SEP) is described in patients as a complication of long-term peritoneal dialysis or portovenous shunting. The peritoneal cavity becomes obliterated as a result of gross subserosal thickening by fibrosis, leading to bowel obstruction and other sequelae. Surgery should be undertaken with trepidation and avoided if possible.

Diffuse fibromatosis

This is a variant of intra-abdominal fibromatosis (IAF) and is actually a rare tumour characterised by an abnormal proliferation of myofibroblasts. Although non-metastasising, and said to be benign, it can nevertheless prove widely invasive, compressing and infiltrating surrounding tissues such as the bowel and mesentery with complications thereof. IAF is very rare within the general population but has a recognised association with familial adenomatous polyposis (FAP).

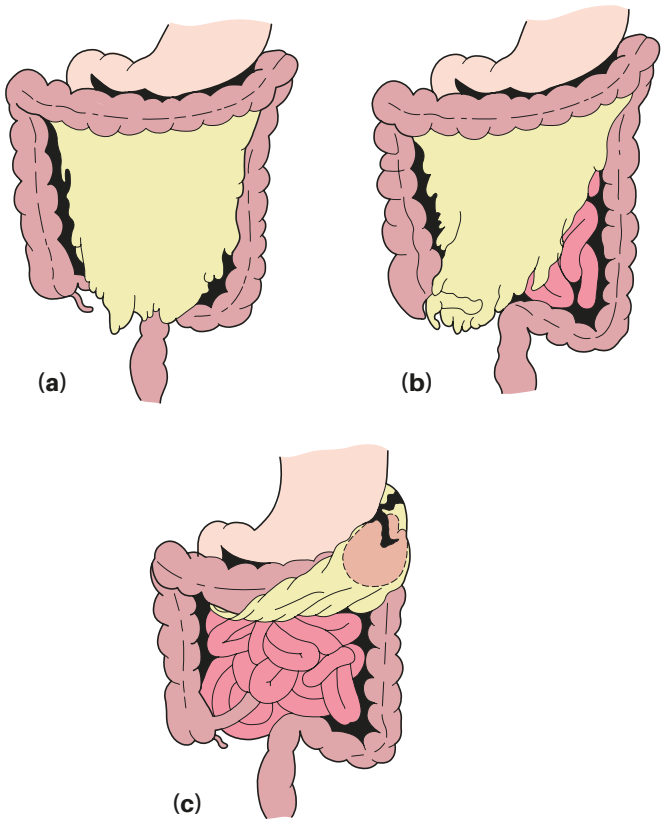

Figure 61.10 The greater omentum: **(a)** normal; **(b)** in appendicitis; **(c)** in a (comparatively small) laceration of the spleen.

THE OMENTUM

Rutherford Morison called the greater omentum 'the abdominal policeman'. The greater omentum attempts, often successfully, to limit intraperitoneal infective and other noxious processes (**Figure 61.10**). For instance, an acutely inflamed appendix is often found wrapped in omentum, and this saves many patients from developing diffuse peritonitis. Some sufferers of herniae are also greatly indebted to this structure, because it often plugs the neck of a hernial sac and prevents a coil of intestine from entering and becoming strangulated. It can of course also be a cause of obstruction (acting as a large adhesion). The omentum is usually involved in tuberculous peritonitis and carcinomatosis of the peritoneum.

Torsion of the omentum

Torsion of the omentum is a rare emergency and consequently is seldom diagnosed correctly. It is usually mistaken for appendicitis with somewhat abnormal signs. It may be primary or secondary to adhesion of the omentum to an old focus of infection or hernia. The patient is most frequently a middle-aged, obese man. A tender lump may be present in the abdomen. The blood supply having been jeopardised, the twisted mass sometimes becomes gangrenous, in which case bacterial peritonitis may follow. Treatment is surgical; the pedicle above the twist is ligated securely and the mass removed.

THE MESENTERY

Mesenteric injury

A wound of the mesentery can follow severe abdominal contusion and is a cause of haemoperitoneum. More commonly, it is injured by a torsional force, so-called seatbelt syndrome. This occurs during a vehicular collision when a seatbelt is being worn with sudden deceleration resulting in a torn mesentery. This possibility should be borne in mind, particularly as multiple injuries may distract attention from this injury (the management of abdominal trauma is covered in Chapter 27). Aside from control of any ongoing haemorrhage, associated ischaemic or ruptured gut will require resection.

Ischaemia

Torsion of the mesentery is covered under midgut volvulus and volvulus of the small intestine (see Chapter 69). Embolism and thrombosis of mesenteric vessels leading to intestinal ischaemia are also covered in Chapter 69.

Inflammation

A number of somewhat miscellaneous conditions are best described under this umbrella term.

Acute, non-specific, ileocaecal, mesenteric adenitis

Non-specific mesenteric adenitis was so named to distinguish it from specific (tuberculous) mesenteric adenitis. It is now much more common than the tuberculous variety. The aetiology often remains unknown, although some cases are associated with yersinia infection of the ileum. In other cases, an unidentified virus is blamed. In about 25% of cases, a respiratory infection precedes an attack of non-specific mesenteric adenitis. This self-limiting disease is never fatal but may be recurrent. Its significance thus mainly lies in its differential diagnosis with appendicitis in children.

DIAGNOSIS

During childhood, acute, non-specific mesenteric adenitis is a common condition. The typical history is one of short attacks of central abdominal pain lasting from 10 min to 30 min, commonly associated with vomiting. The patient seldom looks ill. In more than half the cases the temperature is elevated. Abdominal tenderness is poorly localised and, when present, shifting tenderness is a valuable sign for differentiating the condition from appendicitis. The neck, axillae and groins should be palpated for enlarged lymph nodes. There is often a leukocytosis of 10 000–12 000/μL (10–12 × 10^9/L) or more on the first day of the attack, but this falls on the second day.

TREATMENT

When the diagnosis can be made with assurance, bed rest and simple analgesia are the only treatment necessary. If, at a second examination a few hours later, acute appendicitis cannot be excluded, it is safer to perform either appendicectomy or diagnostic laparoscopy. If surgery is mistakenly undertaken, there is a small increase in the amount of peritoneal fluid. The ileocaecal mesenteric lymph nodes are enlarged, and can be seen and felt between the leaves of the mesentery. In very acute cases they are distinctly red, and many of them are the size of a walnut. The nodes nearest the attachment of the mesentery are the largest. They are not adherent to their peritoneal coats and, if a small incision is made through the overlying peritoneum, a node is extruded easily.

Tuberculosis of the mesenteric lymph nodes

Tuberculous mesenteric lymphadenitis is considerably less common than acute non-specific lymphadenitis. Tubercle bacilli, usually, but not necessarily, bovine, are ingested and enter the mesenteric lymph nodes by way of Peyer's patches. Sometimes only one lymph node is infected; usually there are several and occasionally massive involvement occurs. The presentation may be with abdominal pain (a rare differential for appendicitis) or with general constitutional symptoms (pyrexia, weight loss, etc.). Calcified lymph nodes may be demonstrated on a plain radiograph of the abdomen where they must be distinguished from other calcified lesions, e.g. renal or ureteric stones.

Misty mesentery

The term 'misty mesentery' indicates a pathological increase in mesenteric fat attenuation at CT (**Figure 61.11**). It is frequently observed on multidetector CT (MDCT) scans performed during daily clinical practice, and may be caused by various pathological conditions, including oedema, inflammation (especially in association with pancreatitis), haemorrhage, neoplastic infiltration (especially otherwise occult lymphoma) or sclerosing mesenteritis. In patients with acute abdominal disease, misty mesentery may be considered a feature of the underlying disease. Otherwise, it may represent an incidental finding on MDCT performed for other reasons. Follow-up scans may be required to dictate whether further investigation is required depending on progression or resolution. It should be noted that the term 'mesenteric panniculitis' is frequently used synonymously with 'misty mesentery'. Correctly this term should be reserved for the mesenteric manifestation of Weber–Christian disease; isolated lipodystrophy and mesenteric lipogranuloma. It is a very rare (200–300 cases reported worldwide) benign inflammatory or fibrotic change in the mesentery of the bowel.

Figure 61.11 Computed tomography scan showing 'misty mesentery' in a patient with probable peritoneal inflammation secondary to acute pancreatitis (courtesy of Dr K Patel, Homerton University Foundation Trust, London).

Mesenteric cysts

Cysts may occur in the mesentery of either the small intestine (60%) or the colon (40%) and can be classified as the following:

- Chylolymphatic
- Enterogenous
- Urogenital remnant (actually retroperitoneal but project into peritoneum)
- Dermoid.

Johann Conrad Peyer, 1653–1712, Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland, described the lymph follicles in the intestine in 1677.

Pathology

CHYLOLYMPHATIC CYST

Although all mesenteric cysts are rare, this is the most common variety, probably arising in congenitally misplaced lymphatic tissue that has no efferent communication with the lymphatic system (most frequently in the mesentery of the ileum). The thin wall of the cyst, which is composed of connective tissue lined by flat endothelium, is filled with clear lymph or, less frequently, with chyle, varying in consistency from watered milk to cream. Occasionally, the cyst attains a great size. More often unilocular than multilocular, a chylolymphatic cyst is almost invariably solitary, although there is an extremely rare variety in which myriads of cysts are found in the various mesenteries of the abdomen. A chylolymphatic cyst has a blood supply that is independent from that of the adjacent intestine and, thus, enucleation is possible without the need for resection of gut.

ENTEROGENOUS CYSTS

These are believed to be derived either from a diverticulum of the mesenteric border of the intestine that has become sequestrated from the intestinal canal during embryonic life, or from a duplication of the intestine (see Chapter 9). An enterogenous cyst has a thicker wall than a chylolymphatic cyst and it is lined by mucous membrane, which is sometimes ciliated. The content is mucinous and either colourless or yellowish brown as a result of past haemorrhage. The muscle in the wall of an enteric duplication cyst and the bowel with which it is in contact have a common blood supply; consequently, removal of the cyst always entails resection of the related portion of intestine.

UROGENITAL REMNANT

A cyst developing in the retroperitoneal space (see below) often attains very large dimensions and has first to be distinguished from a large hydronephrosis. Even after the latter condition has been eliminated by scanning or urography, a retroperitoneal cyst can seldom be distinguished with certainty from a retroperitoneal tumour until displayed at operation. The cyst may be unilocular or multilocular. Many of these cysts are believed to be derived from a remnant of the wolffian duct, in which case they are filled with clear fluid.

Clinical features

These are shown for mesenteric cysts in general in *Summary box 61.13*.

Investigation and treatment

Ultrasonography and CT scanning will demonstrate the lesion and may allow diagnosis of cyst type (**Figure 61.13a** and **b**). There are no suitable medical therapies. The goal of surgical therapy is complete excision of the mass. The preferred treatment of mesenteric cysts is enucleation, although bowel resection is frequently required to ensure that the remaining bowel is viable. Bowel resection may be required in 50–60% of children with mesenteric cysts, whereas resection is necessary in about a third of adults (**Figure 61.13c**). If enucleation or resection is not possible because of either the size of the cyst or its location deep within the root of the mesentery, the third option is partial excision with marsupialisation of

Summary box 61.13

Mesenteric cysts: clinical features

- Cysts occur most commonly in adults with a mean age of 45 years
- Twice as common in women as in me
- Rare: incidence around 1 per 140 000
- Approximately a third of cases occur in children younger than 15 years
- The mean age of children affected is 4.9 years
- The most common presentation is of a painless abdominal swelling with characteristic physical signs
  - there is a fluctuant swelling near the umbilicus
  - the swelling moves freely in a plane at right angles to the attachment of the mesentery (Tillaux's sign) (**Figure 61.12**)
  - there is a zone of resonance around the cyst
- Other presentations are with recurrent attacks of abdominal pain with or without vomiting (pain resulting from recurring temporary impaction of a food bolus in a segment of bowel narrowed by the cyst or possibly from torsion of the mesentery) and acute abdominal catastrophe, due to:
  - torsion of that portion of the mesentery containing the cyst
  - rupture of the cyst, often as a result of a comparatively trivial accident
  - haemorrhage into the cyst
  - infection

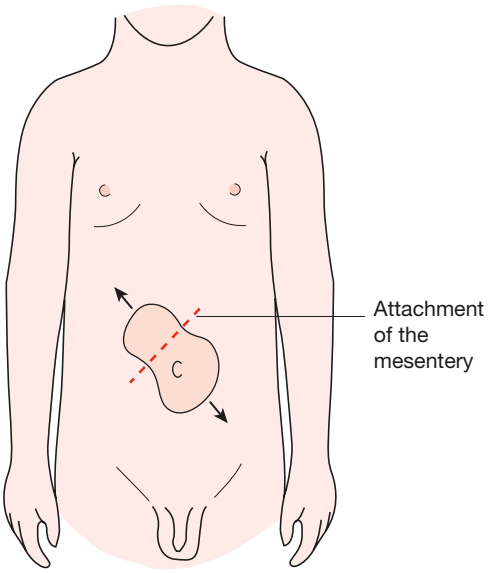

Figure 61.12 A mesenteric cyst moves freely in the direction of the arrows, i.e. at right angles to the attachment of the mesentery (Tillaux's sign).

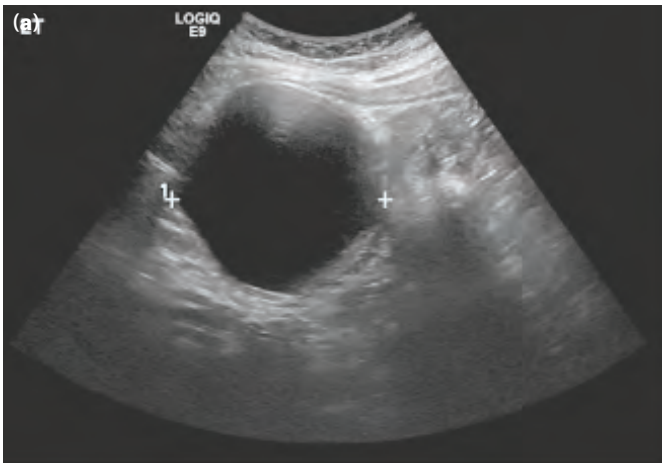
Kaspar Friedrich Wolff, 1733–1794, Professor of Anatomy and Physiology, St Petersburg, Russia, described the mesonephric duct and body in 1759.
Paul Jules Tillaux, 1834–1904, surgeon, Paris, France.



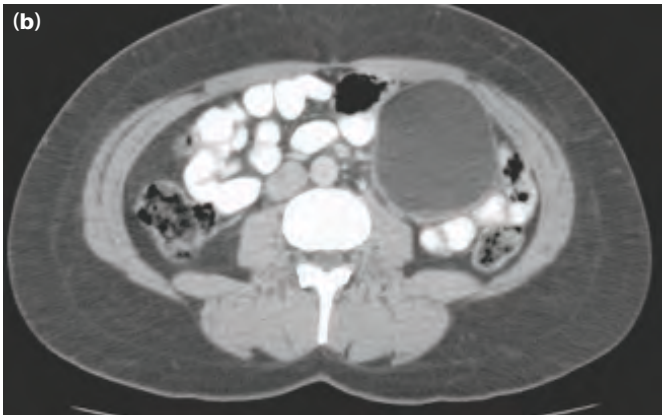


Figure 61.13 A mesenteric enterogenous cyst in a 37-year-old woman presenting with an asymptomatic palpable abdominal mass: **(a)** ultrasound findings; **(b)** computed tomography findings; and **(c)** intraoperative findings requiring en masse small bowel resection (courtesy of Mr F Olagbaiye, Homerton University Foundation Trust, London).

the remaining cyst into the abdominal cavity. Approximately 10% of patients require this form of therapy. If marsupialisation is performed, the cyst lining should be sclerosed with 10% glucose solution, diathermy or tincture of iodine to minimise recurrence. Recurrence rates vary from 0% to 13%.

DIFFERENTIAL DIAGNOSIS

The following, although not being mesenteric cysts in the true meaning of the term, give rise to the same physical signs:

- peritoneal inclusion cyst (see above);
- serosanguineous cyst, probably traumatic in origin although a history of an accident is seldom obtained;
- tuberculous abscess of the mesentery;
- hydatid cyst of the mesentery.

Neoplasms of the mesentery

The mesentery is necessarily affected by local lymphatic spread of carcinoma arising from the peritoneal viscera. Other benign and malignant tumours are less common.

Summary box 61.14

Mesenteric tumours

Benign

- Lipoma
- Fibroma
- Fibromyxoma

Malignant

- Lymphoma
- Secondary carcinoma

Tumours situated in the mesentery give rise to physical signs that are similar to those of a mesenteric cyst, the sole exception being that they sometimes feel solid. If indicated, a benign tumour of the mesentery is excised in the same way as an enterogenous mesenteric cyst, i.e. with resection of the adjacent intestine. A malignant tumour of the mesentery requires biopsy confirmation and specific, usually non-surgical, treatment, e.g. chemotherapy for lymphoma.

THE RETROPERITONEAL SPACE

Retroperitoneal fibrosis

This is a relatively rare diagnosis characterised by the development of a flat grey/white plaque of tissue, which is found first in the low lumbar region but then spreads laterally and upwards to encase the common iliac vessels, ureters and aorta. Histological appearances vary from active inflammation with a high cellular content interspersed with bundles of collagen through to one of acellularity and mature fibrosis/calcification. Its aetiology is obscure in most cases (idiopathic) being allied

Summary box 61.15

Causes of retroperitoneal fibrosis

Benign

- Idiopathic (Ormond's disease)
- Chronic inflammation
- Extravasation of urine
- Retroperitoneal irritation by leakage of blood or intestinal content
- Aortic aneurysm (inflammatory type)
- Trauma
- Drugs (chemotherapeutic agents and previously methysergide)

Malignant

- Lymphoma
- Carcinoid tumours
- Secondary deposits (especially from carcinoma of stomach, colon, breast and prostate)

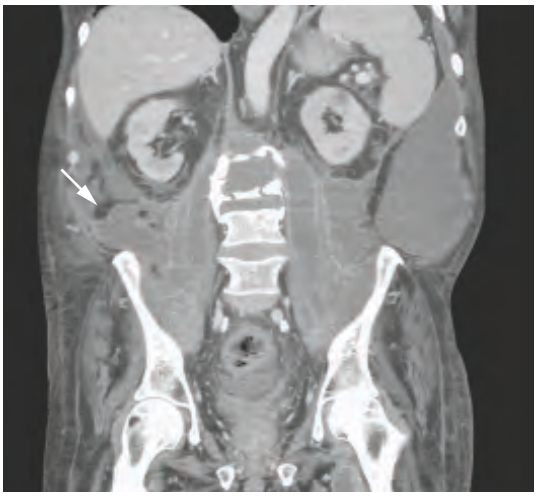

Figure 61.14 Representative sagittal computed tomography reconstruction of a right-sided psoas abscess (courtesy of Dr K Patel, Homerton University Foundation Trust, London).

to other fibromatoses (others being Dupuytren's contracture and Peyronie's disease). In other patients the cause is known.

The clinical presentation may be one of ill-defined chronic backache or occur as a result of compromise to involved structures, e.g. lower limb or scrotal oedema secondary to venous occlusion, or chronic renal failure secondary to ureteric obstruction. Treatment will be directed to the cause, the modification of disease activity when appropriate, e.g. immunomodulation with steroids, tamoxifen and restoration of flow in affected structures, e.g. ureteric stenting.

Retroperitoneal (psoas) abscess

The retroperitoneal space can also be a site for abscess formation, which for practical purposes is almost synonymous with psoas abscess. Psoas abscess is a relatively uncommon diagnosis, the true incidence of which is not well described. At the start of the twentieth century, psoas abscess was mainly caused by TB of the spine (Pott's disease). With the decline of *M. tuberculosis* as a major pathogen in resource-rich countries, a psoas abscess was mostly found secondary to direct spread of infection from the inflamed ± perforated digestive or urinary tract. In recent years a primary psoas abscess due to haematogenous spread from an occult source is more common, especially in immunocompromised and older patients, as well as in association with intravenous drug misuse.

Clinical presentation is with back pain, lassitude and fever. A swelling may point to the groin as it tracks along iliopsoas. Pain may be elicited by passive extension of the hip or a fixed flexion of the hip evident on inspection.

Radiological investigation is via CT scanning (**Figure 61.14**) and treatment usually by percutaneous CT-guided drainage and appropriate antibiotic therapy.

Retroperitoneal tumours

Although swellings in the retroperitoneum may include abscess, haematoma, cysts (see above) and spread of malignancy from retroperitoneal organs (kidney, ureter, adrenal), the term retroperitoneal tumour is usually confined to primary tumours arising in other tissues in this region e.g. muscles, fat, lymph nodes and nerves. The management of such tumours is now frequently by referral to a specialist centre and this should be done before biopsy which may compromise subsequent surgical cure. The two commonest are briefly described.

Retroperitoneal lipoma

The patient may seek advice on account of a swelling or because of indefinite abdominal pain. Women are more often affected. These swellings sometimes reach an immense size. Diagnosis is usually by ultrasonography and CT scanning. A retroperitoneal lipoma sometimes undergoes myxomatous degeneration, a complication that does not occur in a lipoma in any other part of the body. Moreover, a retroperitoneal lipoma is often malignant (liposarcoma) (see below) and may increase rapidly in size.

Retroperitoneal sarcoma

Retroperitoneal sarcomas are rare tumours accounting for only 1–2% of all solid malignancies (10–20% of all sarcomas are retroperitoneal). The peak incidence is in the fifth decade of life, although they can occur at almost any age. The most common types of retroperitoneal soft-tissue sarcomas in adults vary from study to study. However, in most studies, the most frequently encountered cell types are:

- liposarcoma;
- leiomyosarcoma;
- malignant fibrous histiocytoma (MFH).

JK Ormond, American urologist.
Baron Guillaume Dupuytren, 1777–1835, Surgeon in Chief, Hôtel Dieu, Paris, France, described this condition in 1831.
François de la Peyronie, 1678–1747, Surgeon to King Louis XIV of France, and Founder of the Royal Academy of Surgery, Paris, France.

CLINICAL FEATURES

Patients with sarcomas present late, because these tumours arise in the large potential spaces of the retroperitoneum and can grow very large without producing symptoms. Moreover, when symptoms do occur, they are non-specific, such as abdominal pain and fullness, and are easily dismissed as being caused by other less serious processes. Retroperitoneal sarcomas are, therefore, usually very large at the time of presentation.

INVESTIGATION

Detailed multiplanar imaging (CT + MRI) with reconstructions is required not only for tumour detection, staging and surgical planning, but also for guiding percutaneous or surgical biopsy of these tumours. Such biopsies have a greater role than for other sarcomas.

TREATMENT

The definitive treatment of primary retroperitoneal sarcomas is surgical resection. Chemotherapy and radiotherapy without surgical debulking have rarely been beneficial, when used alone or in combination A multidisciplinary treatment approach with imaging review will be required when assessing operability (based on adjacency or involvement of vital structures) and approach. Up to 75% of retroperitoneal sarcoma resections involve resection of at least one adjoining intra-abdominal visceral organ (commonly large or small bowel or kidney). The most common types of vascular involvement precluding resection are involvement of the proximal superior mesenteric vessels or involvement of bilateral renal vessels.

PROGNOSIS

In the vast majority of sarcomas, cell type has no impact on treatment and long-term survival. Survival rates are in general poor, even after complete resection, being in the order of 35–50% (excluding low-grade liposarcomas, which may frequently be cured by resection).

Chapter 62

The oesophagus

Learning objectives

To understand:

- The anatomy and physiology of the oesophagus and their relationship to disease
- The clinical features, investigations and treatment of benign and malignant disease with particular reference to the common adult disorders

BACKGROUND

Surgical anatomy

The oesophagus is a muscular tube, approximately 25 cm long, mainly occupying the posterior mediastinum and extending from the upper oesophageal sphincter (the cricopharyngeus muscle) in the neck to the junction with the cardia of the stomach. The musculature of the upper oesophagus, including the upper sphincter, is striated. This is followed by a transitional zone of both striated and smooth muscle with the proportion of the latter progressively increasing so that, in the lower half of the oesophagus, there is only smooth muscle. It is lined throughout with squamous epithelium. The parasympathetic nerve supply is mediated by branches of the vagus nerve that has synaptic connections to the myenteric (Auerbach's) plexus. Meissner's submucosal plexus is sparse in the oesophagus.

The upper sphincter consists of powerful striated muscle. The lower sphincter is more subtle and created by the asymmetrical arrangement of muscle fibres in the distal oesophageal wall just above the oesophagogastric junction. It is helpful to remember the distances 15, 25 and 40 cm for anatomical location during endoscopy (**Figure 62.1**).

Physiology

The main function of the oesophagus is to transfer food from the mouth to the stomach in a coordinated fashion. The initial movement from the mouth is voluntary. The pharyngeal phase of swallowing involves sequential contraction of the oropharyngeal musculature, closure of the nasal and respiratory passages, cessation of breathing and opening of the upper oesophageal sphincter. Beyond this level, swallowing is involuntary. The body of the oesophagus propels the bolus through a relaxed lower oesophageal sphincter (LOS) into the stomach, taking air with it (**Figure 62.2**). This coordinated oesophageal wave which follows a conscious swallow is called primary peristalsis. It is under vagal control, although there are specific neurotransmitters that control the LOS.

The upper oesophageal sphincter is normally closed at rest and serves as a protective mechanism against regurgitation of oesophageal contents into the respiratory passages. It also serves to stop air entering the oesophagus other than the small amount that enters during swallowing.

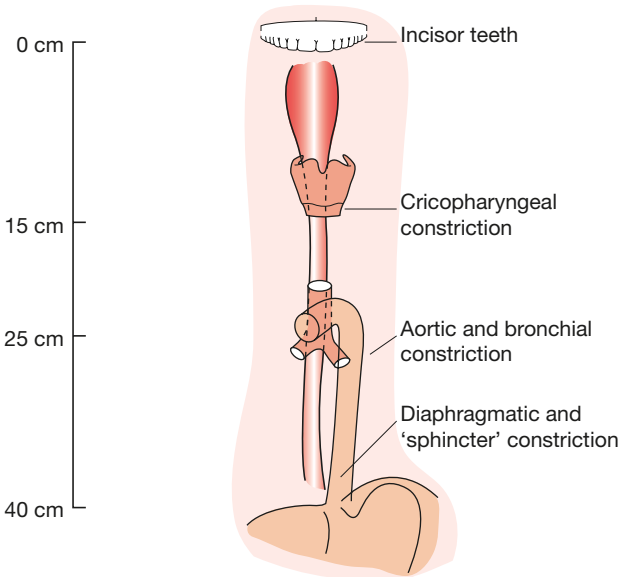

Figure 62.1 Endoscopic landmarks. Distances are given from the incisor teeth. They vary slightly with the build of the individual.

Leopold Auerbach, 1828–1897, Professor of Neuropathology, Breslau, Germany, (now Wroclaw, Poland), described the myenteric plexus in 1862.
Georg Meissner, 1829–1905, Professor of Physiology, Göttingen, Germany, described the submucosal plexus in 1852.

Figure 62.2 A bolus of barium or food usually takes air with it into the stomach.

The LOS is a zone of relatively high pressure that prevents gastric contents from refluxing into the lower oesophagus (**Figure 62.3**). In addition to opening in response to a primary peristaltic wave, the sphincter also relaxes to allow air to escape from the stomach and at the time of vomiting. A variety of factors influences sphincter tone, notably food, gastric distension, gastrointestinal (GI) hormones, drugs and smoking. The arrangement of muscle fibres, their differential responses to specific neurotransmitters and the relationship to diaphragmatic contraction all contribute to the action of the LOS. The presence of the physiological sphincter was first demonstrated by Code using manometry with small balloons. Until recently LOS pressure was measured by water-perfused tubes, but the introduction of catheters containing multiple microtransducers has meant that this approach has been superseded by high-resolution manometry. The normal LOS is 3–4 cm in length and has a pressure of 10–25 mmHg.

Manometry is also used to assess the speed and amplitude of oesophageal body contractions and ensure that peristalsis is propagated down the entire length of the oesophagus (**Figure 62.4**). Secondary peristalsis is the normal reflex preceded by a conscious swallow. It is worth remembering that most clearance swallows to neutralise refluxed gastric acid are, however, achieved by primary peristalsis, which carries saliva with its high bicarbonate content down to the lower oesophagus. Tertiary contractions are non-peristaltic waves that are infrequent (<10%) during laboratory-based manometry, although readily detected if manometry is undertaken while the patient eats a meal.

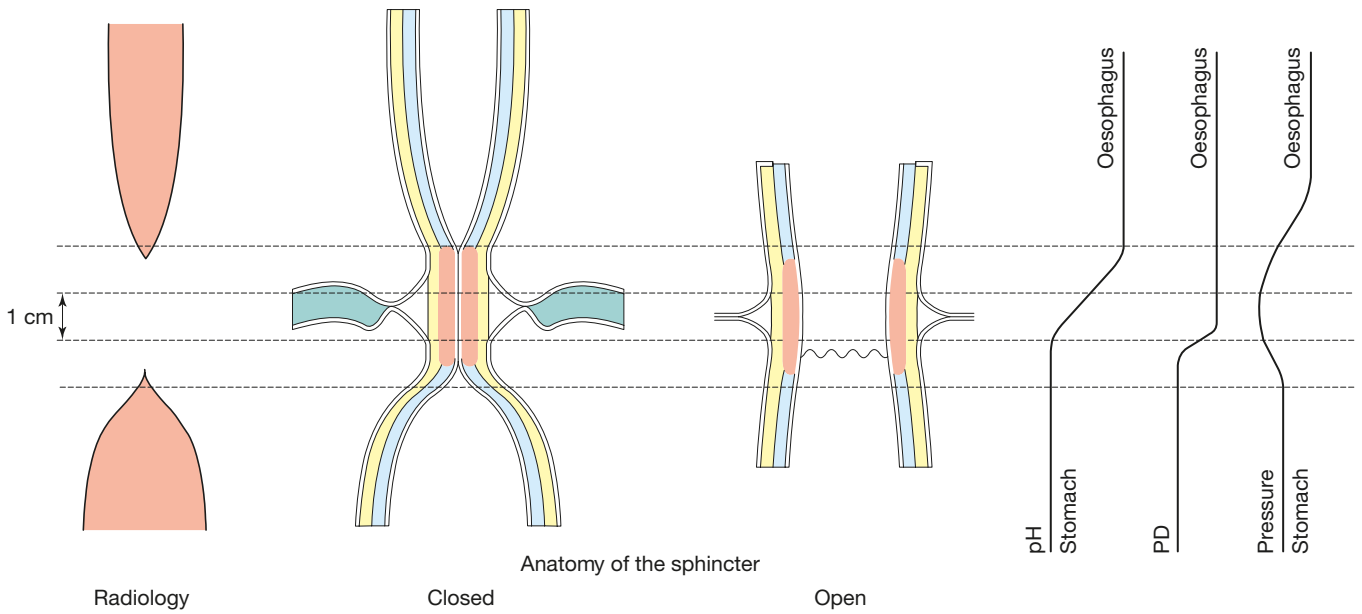

Figure 62.3 Correlation between the radiological appearances of a barium column and the lower oesophageal sphincter open and closed. The three curves on the right, set up vertically, show the pH gradient, the mucosal potential difference (PD), marking the junction of squamous and columnar epithelium, and the high-pressure zone of the sphincter.

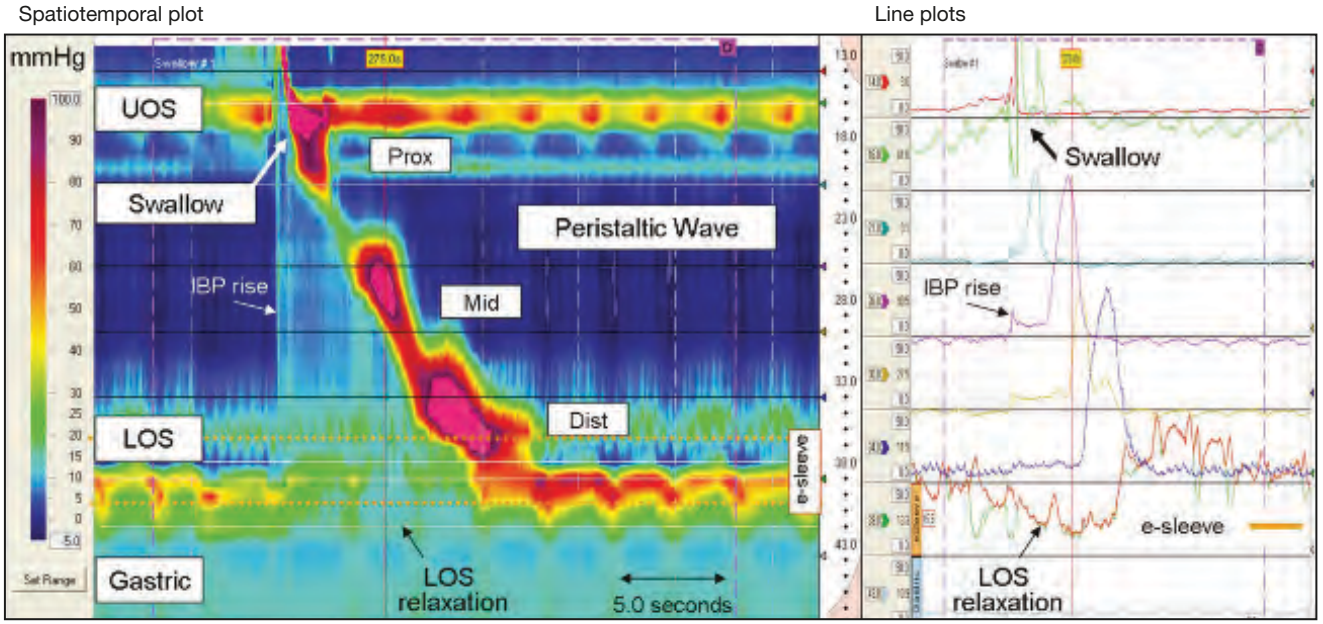

Figure 62.4 High-resolution manometry depicts oesophageal function from the pharynx to the stomach. The spatiotemporal plot presents the same information as presented in the 'conventional' line plots. Time is on the *x*-axis and distance from the nares is on the *y*-axis. Pressure is assigned a colour (legend right). The segmental anatomy of oesophagus is easy to appreciate (not seen on conventional manometry). The coordinated relaxation of the upper (UOS) and lower oesophageal sphincter (LOS) is obvious, as is the increasing pressure and duration of the peristaltic wave as it passes distally. The intrabolus pressure (IBP) between the peristaltic wave and oesophagogastric junction, and the pressure gradient across the gastro-oesophageal junction are visualized. These represent the force that drives bolus through the oesophagus and into the stomach.

Symptoms

Summary box 62.1

Symptoms of oesophageal disease

- Difficulty in swallowing described as food or fluid sticking (oesophageal dysphagia): must rule out malignancy
- Pain on swallowing (odynophagia): suggests inflammation and ulceration
- Regurgitation or reflux (heartburn): common in gastro-oesophageal reflux disease
- Chest pain: difficult to distinguish from cardiac pain

Dysphagia

Dysphagia is used to describe difficulty with swallowing. When there is a problem with swallowing in the voluntary (oral or pharyngeal) phases, patients will usually say that they cannot swallow properly, but they do not characteristically describe 'food sticking'. Instead, when they try to initiate a conscious swallow, food fails to enter the oesophagus, stays in the mouth or enters the airway, causing coughing or spluttering. Virtually all causes of this type of dysphagia are chronic neurological or muscular diseases. Oesophageal dysphagia occurs in the involuntary phase and is characterised by a sensation of food sticking. The nature of this type of dysphagia is often informative with regard to a likely diagnosis. Dysphagia may occur acutely or in a chronic fashion, can affect solids and/or fluids, and be intermittent or progressive. Although many patients point to a site of impaction, this is unreliable.

Odynophagia

Odynophagia refers to pain on swallowing. Patients with reflux oesophagitis often feel retrosternal discomfort within a few seconds of swallowing hot beverages, citrus drinks or alcohol. Odynophagia is also a feature of infective oesophagitis and may be particularly severe in chemical injury.

Regurgitation and reflux

Regurgitation and reflux are often used synonymously. It is helpful to differentiate between them, although it is not always possible. Regurgitation should strictly refer to the return of oesophageal contents from above a functional or mechanical obstruction. Reflux is the passive return of gastroduodenal contents to the mouth as part of the symptomatology of gastro-oesophageal reflux disease (GORD). Loss of weight, anaemia, cachexia, change of voice due to refluxed material irritating the vocal folds, and cough or dyspnoea due to tracheal aspiration may all accompany regurgitation and/or reflux.

Chest pain

Chest pain similar in character to angina pectoris may arise from an oesophageal cause, especially gastro-oesophageal reflux and motility disorders. Exercise-induced chest pain can be due to reflux.

Investigations

Radiography

Contrast radiography has been somewhat overshadowed by endoscopy but remains a useful investigation to demonstrate changes in oesophageal diameter, anatomical distortion or abnormal motility. An adequate barium swallow should be tailored to the problem under investigation. It may be helpful to give a solid bolus (bread or marshmallow) if a motility disorder is suspected. Video recording is useful to allow subsequent replay and detailed analysis. Barium radiology is, however, inaccurate in the diagnosis of gastro-oesophageal reflux, unless reflux is gross, and should not be used for this purpose. Plain radiographs will show some foreign bodies.

Cross-sectional imaging by computed tomography (CT) is now an essential investigation in the assessment of neoplasms of the oesophagus and can be used in place of a contrast swallow to demonstrate perforation. The role of CT and other cancer-specific tests is described later.

Endoscopy

Endoscopy is necessary for the investigation of most oesophageal conditions. It is required to view the inside of the oesophagus and the oesophagogastric junction, to obtain a biopsy or cytology specimen, for the removal of foreign bodies and to dilate strictures. Traditionally, there are two types of instrument available, the rigid oesophagoscope and the flexible video endoscope, but the rigid instrument is now virtually obsolete.

For flexible video gastroduodenoscopy, general anaesthesia is not required; most examinations can be done on an outpatient basis, and the quality of the magnified image is superb. The technology associated with video endoscopy continues to improve. Magnification is a standard feature of the modern endoscope and widely used in conjunction with agents that can be sprayed on to the mucosa, such as acetic acid to enhance mucosal detail. Novel techniques that rely on fluorescence and narrow band imaging to enhance visual contrast are becoming increasingly used for the identification of mucosal abnormalities that are not easily seen with white light, e.g. in patients with Barrett's oesophagus undergoing endoscopic surveillance.

As a matter of routine, the stomach and duodenum are examined as well as the oesophagus. If a stricture is encountered, it may be helpful to dilate it to allow a complete inspection of the upper GI tract, but this decision should be dictated by clinical circumstances and an appreciation of the perforation risk, especially if the visual appearances are thought to indicate neoplasia.

Endosonography

Endoscopic ultrasonography relies on a high-frequency (5–30 MHz) transducer located at the tip of the endoscope to provide highly detailed images of the layers of the oesophageal wall and mediastinal structures close to the oesophagus. Radial echoendoscopes have a rotating transducer that creates a circular image with the endoscope in the centre, and this type of scanner is widely used to create diagnostic transverse sectional images at right angles to the long axis of the oesophagus (**Figure 62.5**). Linear echoendoscopes produce a sectoral image in the line of the endoscope and are used to biopsy submucosal oesophageal lesions, mediastinal masses such as lymph nodes (**Figure 62.6**) or suspicious lesions that might lie outside a proposed surgical field. Radial scanners without optical components are available for passage through narrow strictures over a guidewire, and catheter probes are available that can be passed down the endoscope biopsy channel.

Oesophageal manometry

Manometry is now widely used to diagnose oesophageal motility disorders. Electronic microtransducers that are not influenced by changes in patient position during the test have gradually supplanted perfusion systems. High-resolution

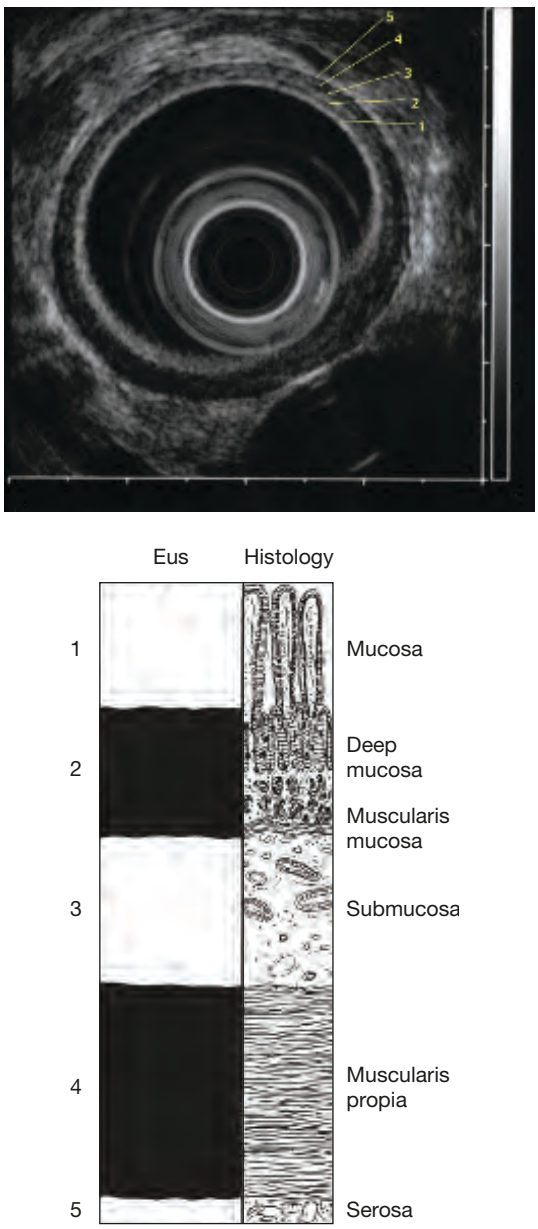

Figure 62.5 Radial endosonography indicating wall layers as alternating hyper- and hypoechoic bands.

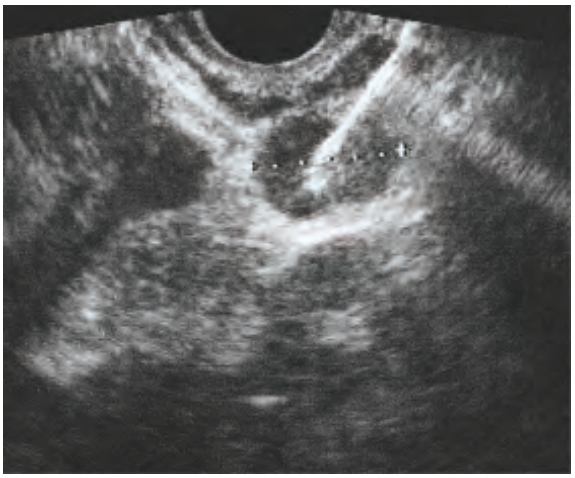

Figure 62.6 Linear endosonography with the needle traversing an ultrasound plane for guided biopsy.

manometry uses a multiple (up to 36) microtransducer catheter with the results displayed as spatiotemporal plots, and this has now largely supplanted earlier manometry systems. This system provides comprehensive information about oesophageal body function and associated behaviour of the LOS.

Twenty-four-hour pH and combined pH-impedance recording

Prolonged measurement of pH is now accepted as the most accurate method for the diagnosis of gastro-oesophageal reflux. It is particularly useful in patients with atypical reflux symptoms, those without endoscopic oesophagitis and when patients respond poorly to intensive medical therapy. A small pH probe is passed into the distal oesophagus and positioned 5 cm above the upper margin of the LOS, as defined by manometry. The probe is connected to a miniature digital recorder that is worn on a belt and allows most normal activities. Patients mark symptomatic events such as heartburn. A 24-hour recording period is usual, and the pH record is analysed by an automated computer program. An oesophageal pH <4 at the level of the pH electrode is conventionally considered the cut-off value and, in most oesophageal laboratories, the total time when pH is <4 in a 24-hour period does not exceed 4% in a healthy adult. Patterns of reflux and the correlation between symptoms and oesophageal pH <4 can be calculated. Most laboratories use a scoring system (Johnson–DeMeester) to create a numerical value, above which reflux is considered pathological. Radiotelemetry pH probes are also available that can be fixed to the oesophageal wall endoscopically without the need for a transnasal catheter. The introduction of catheter assemblies that incorporate multiple electrodes along the length of the catheter, as well as a pH probe, has resulted in combined measurement of pH and electrical impedance. Impedance measurement differentiates anterograde from retrograde bolus transit and gas from liquid, and provides a reliable measure of non-acidic or weakly acidic events that cause symptoms. This may be important in the identification of patients with non-erosive reflux disease on endoscopy.

Therapeutic procedures

Dilatation of strictures

Stricture dilatation is essentially undertaken for benign conditions and should be used with caution in the context of malignant disease. The risks associated with dilatation for malignant disease are discussed later. The advent of guidewire-directed dilatation of the oesophagus in the 1970s was a major advance over earlier blind dilatation systems. Their use is now considered standard practice. There are many different designs, but essentially they are solid dilators of increasing diameter or inflatable balloons with rigid walls. To restore normal swallowing, a stricture should be dilated to at least 16 mm in diameter, although this may need to be achieved over a series of procedures, depending on the perceived nature of the stricture. A guidewire is passed down the biopsy channel of an endoscope and through the stricture under vision. If the stricture is long or tortuous, this should be undertaken under radiological guidance to ensure that the guidewire passes easily into the stomach. The endoscope is withdrawn, leaving the guidewire in place, and graduated dilators or a balloon dilator are passed over the guidewire, sometimes with radiographic screening for safety purposes. The dilatation of reflux-induced strictures is usually straightforward. These strictures are nearly always short and at the oesophagogastric junction, so that the stomach is visible through the narrowed segment. Radiological control is rarely needed. Conversely, distal oesophageal adenocarcinomas extending into the stomach are often soft, friable and tortuous to negotiate. Caustic strictures often occur high in the thorax and may be very long.

Balloons for oesophageal use tend to have inflation diameters of 25–40 mm and may also be used for dilatation. Pneumatic dilatation is widely used to disrupt the non-relaxing LOS in achalasia.

Thermal recanalisation

Various types of laser (mainly Nd–YAG), bipolar diathermy, injection of absolute alcohol or argon-beam plasma coagulation have all been used successfully to ablate tissue in order to recanalise the oesophagus.

CONGENITAL ABNORMALITIES

See Chapter 9.

FOREIGN BODIES IN THE OESOPHAGUS

All manner of foreign bodies have become arrested in the oesophagus (**Figure 62.7**). Button batteries may be a troublesome problem in children. The most common impacted

Lawrence F Johnson, gastroenterologist, Birmingham, AL, USA.
Tom R DeMeester, Professor of Surgery, Los Angeles, CA, USA.

Figure 62.7 False teeth impacted in the oesophagus. (Note: modern dentures are usually radiolucent.)

material is food, and this usually occurs above a significant pathological lesion (**Figure 62.8**). Plain radiographs are often useful for foreign bodies, but modern denture materials are not always radiopaque. A contrast examination is not usually required and only makes endoscopy more difficult.

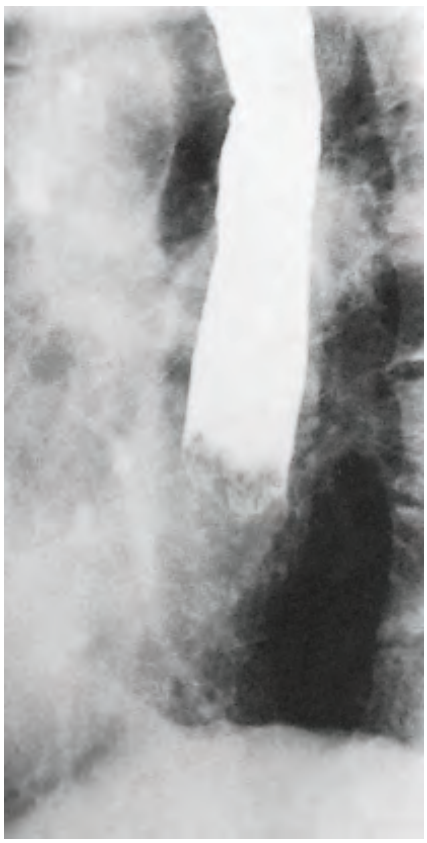

Figure 62.8 An impacted meat bolus at the lower end of the oesophagus. This may be the first presentation of a benign stricture or a malignant tumour.

Summary box 62.2

Foreign bodies

- The most common is a food bolus, which usually signifies underlying disease
- It is usually possible to remove foreign bodies by flexible endoscopy
- Beware of button batteries in the oesophagus

Foreign bodies that have become stuck in the oesophagus should be removed by flexible endoscopy using suitable grasping forceps, a snare or a basket. If the object may injure the oesophagus on withdrawal, an overtube can be used, and the endoscope and object can be withdrawn into the overtube before removal. Button batteries can be a particular worry because they are difficult to grasp, and it is tempting to push them on into the stomach. However, an exhausted battery may rapidly corrode in the GI tract and is best extracted. A multiwire basket of the type used for gallstone retrieval nearly always works. An impacted food bolus will often break up and pass on if the patient is given fizzy drinks and confined to fluids for a short time. The cause of the impaction must then be investigated. If symptoms are severe or the bolus does not pass, it can be extracted or broken up at endoscopy.

PERFORATION

Perforation of the oesophagus is usually iatrogenic (at therapeutic endoscopy) or due to 'barotrauma' (spontaneous perforation). Many instrumental perforations can be managed conservatively, but spontaneous perforation is often a life-threatening condition that regularly requires surgical intervention.

Summary box 62.3

Perforation of the oesophagus

- Potentially lethal complication due to mediastinitis and septic shock
- Numerous causes, but may be iatrogenic
- Surgical emphysema is virtually pathognomonic
- Treatment is urgent; it may be conservative or surgical, but requires specialised care

Barotrauma (spontaneous perforation, Boerhaave's syndrome)

This occurs classically when a person vomits against a closed glottis. The pressure in the oesophagus increases rapidly, and the oesophagus bursts at its weakest point in the lower third, sending a stream of material into the mediastinum and often the pleural cavity as well. The condition was first identified by Boerhaave, who reported the case of a grand admiral of

Hermann Boerhaave, 1668–1738, Professor of Medicine and Botany, the University of Leiden, the Netherlands, creator of the modern method of clinical teaching.

the Dutch fleet who was a glutton and practised autoemesis. Boerhaave's syndrome is the most serious type of perforation because of the large volume of material that is released under pressure. This causes rapid chemical irritation in the mediastinum and pleura followed by infection if untreated. Barotrauma has also been described in relation to other pressure events when the patient strains against a closed glottis (e.g. defecation, labour, weight-lifting).

Diagnosis of spontaneous perforation

The clinical history is usually of severe pain in the chest or upper abdomen after a meal or a bout of drinking. Associated shortness of breath is common. Many cases are misdiagnosed as myocardial infarction, perforated peptic ulcer or pancreatitis if the pain is confined to the upper abdomen. There may be a surprising amount of rigidity on examination of the upper abdomen, even in the absence of any peritoneal contamination.

The diagnosis can usually be suspected from the history and associated clinical features. A chest radiograph is often confirmatory with air in the mediastinum, pleura or peritoneum. Pleural effusion occurs rapidly either as a result of free communication with the pleural space or as a reaction to adjacent inflammation in the mediastinum. A contrast swallow or CT is nearly always required to guide management (**Figure 62.9**).

Pathological perforation

Free perforation of ulcers or tumours of the oesophagus into the pleural space is rare. Erosion into an adjacent structure with fistula formation is more common. Aerodigestive fistula is most common and usually encountered in primary malignant disease of the oesophagus or bronchus. Coughing on eating and signs of aspiration pneumonitis may allow the problem to be recognised at a time when intervention may be appropriate and feasible. Covering the communication with a self-expanding metal stent is the usual solution. Erosion into a major vascular structure is invariably fatal.

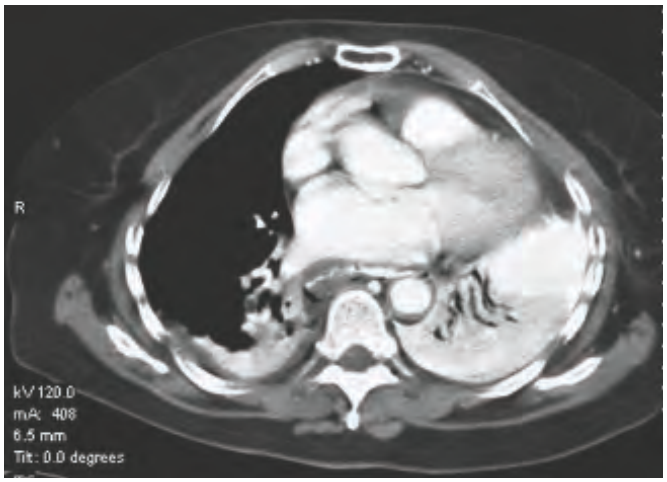

Figure 62.9 Computed tomography scan showing the site of perforation in the lower oesophagus.

Penetrating injury

Perforation by knives and bullets is uncommon, even in war, because the oesophagus is a relatively small target surrounded by other vital organs.

Foreign bodies

The oesophagus may be perforated during removal of a foreign body but, occasionally, an object that has been left in the oesophagus for several days will erode through the wall.

Instrumental perforation

Instrumentation is by far the most common cause of perforation. Modern instrumentation is remarkably safe, but perforation remains a risk that should never be forgotten.

Summary box 62.4

Instrumental perforation

- Prevention of perforation is better than cure

Perforation related to diagnostic upper GI endoscopy is unusual with an estimated frequency of about 1:4000 examinations. Perforation can occur in the pharynx or oesophagus, usually at sites of pathology or when the endoscope is passed blindly. A number of patient-related factors are associated with increased risk, including large anterior cervical osteophytes, the presence of a pharyngeal pouch and mechanical causes of obstruction. Perforation may follow biopsy of a malignant tumour.

Patients undergoing therapeutic endoscopy have a perforation risk that is at least 10 times greater than those undergoing diagnostic endoscopy. The oesophagus may be perforated by guidewires, graduated dilators or balloons, or during the placement of self-expanding stents. The risk is considerably higher in patients with malignancy.

Diagnosis of instrumental perforation

In most cases, a combination of technical difficulties and an interventional procedure should lead to a high index of suspicion. History and physical signs may be useful pointers to the site of perforation.

Cervical perforation may result in pain localised to the neck, hoarseness, painful neck movements and subcutaneous emphysema. Intrathoracic and intra-abdominal perforations, which are more common, can give rise to immediate symptoms and signs either during or at the end of the procedure, including chest pain, haemodynamic instability, oxygen desaturation or visual evidence of perforation. Within the first 24 hours, patients may additionally complain of abdominal pain or respiratory difficulties. There may be evidence of subcutaneous emphysema, pneumothorax or hydropneumothorax. In some patients, the diagnosis may be missed and recognised only at a late stage beyond 24 hours, as unexplained pyrexia, systemic sepsis or the development of a clinical fistula.

Prompt and thorough investigation is the key to management. Careful endoscopic assessment at the end of any procedure combined with a chest radiograph will identify many cases of perforation immediately. If not recognised immediately, then early and late suspected perforations should be assessed by CT. A pre-contrast scan easily demonstrates air outside the GI tract, while oral contrast localises the site of the oesophageal defect and accurately delineates specific fluid collections. Where CT is not available, a water-soluble contrast swallow should be performed although this is not always reliable in disclosing a small contained leak. If a water-soluble study is negative and clinical suspicion is high, a dilute barium swallow should be considered.

Treatment of oesophageal perforations

Perforation of the oesophagus usually leads to mediastinitis. The loose areolar tissues of the posterior mediastinum allow a rapid spread of GI contents. The aim of treatment is to limit mediastinal contamination and prevent or deal with infection. Operative repair deals with the injury directly, but imposes risks of its own; non-operative treatment aims to limit the effects of mediastinitis and provide an environment in which healing can take place.

The decision between surgical and non-surgical management rests on four factors. These are:

1. the site of the perforation (cervical vs thoracoabdominal oesophagus);
2. the event causing the perforation (spontaneous vs instrumental);
3. underlying pathology (benign or malignant);
4. the status of the oesophagus before the perforation (fasted and empty vs obstructed with a stagnant residue).

It follows that most perforations that can be managed non-surgically occur in the context of small instrumental perforations of a clean oesophagus without obstruction, where leakage is likely to be confined to the nearby mediastinum at worst (*Table 62.1*).

Instrumental perforations in the cervical oesophagus are usually small and can nearly always be managed conservatively. The development of a local abscess is an indication for cervical drainage, preventing the extension of sepsis into the mediastinum.

TABLE 62.1 Management options in perforation of the oesophagus.

Factors that favour non-surgical management	Factors that favour surgical repair
Small septic load	Large septic load
Minimal cardiovascular upset	Septic shock
Perforation confined to mediastinum	Pleura breached
Perforation by flexible endoscope	Boerhaave's syndrome
Perforation of cervical oesophagus	Perforation of abdominal oesophagus

The conservative management of an instrumental perforation in the thoracoabdominal parts of the oesophagus can be undertaken when the perforation is detected early and before oral alimentation. General guidelines for non-surgical management include:

- pain that is readily controlled with opiates;
- absence of crepitus, diffuse mediastinal gas, hydropneumothorax or pneumoperitoneum;
- mediastinal containment of the perforation with no evidence of widespread extravasation of contrast material;
- no evidence of on-going luminal obstruction or a retained foreign body.

In addition, conservative management might be appropriate in patients who have remained clinically stable despite diagnostic delay. The principles of non-interventional management involve hyperalimentation, preferably by an enteral route, nasogastric suction and broad-spectrum intravenous antibiotics.

Surgical management is required whenever patients:

- are unstable with sepsis or shock;
- have evidence of a heavily contaminated mediastinum, pleural space or peritoneum;
- have widespread intrapleural or intraperitoneal extravasation of contrast material.

Ongoing luminal obstruction (often related to malignancy) in a frail patient considered unfit for major surgery can be dealt with by placement of a covered self-expanding stent. Expanding metal stents should be used with caution in patients with benign disease because they cause significant tissue reaction and some designs are impossible to remove at a later date. Biodegradable and removable stents may be used alone or as a bridge to later definitive treatment where perforation accompanies obstruction.

For patients requiring surgery, the choice is from direct repair, the deliberate creation of an external fistula or, rarely, oesophageal resection with a view to delayed reconstruction. Direct repair is preferred by many surgeons if the perforation is recognised early (within the first 4–6 hours), and the extent of mediastinal and pleural contamination is small. After 12 hours, the tissues become swollen and friable and less suitable for direct suture. The hole in the mucosa is always bigger than the hole in the muscle, and the muscle should be incised to see the mucosal edges clearly. It is essential that there should be no obstruction distal to the repair. A variety of local tissues (gastric fundus, pericardium, intercostal muscle) have been used to buttress such repairs.

Primary repair is inadvisable with late presentation and in the presence of widespread mediastinal and pleural contamination. These patients tend to be more ill as a result of the delay, and the aim of treatment should be to achieve wide drainage with the creation of a controlled fistula and distal enteral feeding. This can usually be achieved by placing a T-tube into the oesophagus along with appropriately located drains and a feeding jejunostomy. In unusual circumstances, e.g. with extensive necrosis after corrosive ingestion, emergency oesophagectomy may be necessary. Oesophagostomy and gastrostomy should be performed with a view to delayed reconstruction.

MALLORY–WEISS SYNDROME

Forceful vomiting may produce a mucosal tear at the cardia rather than a full perforation. The mechanism of injury is different. In Boerhaave's syndrome, vomiting occurs against a closed glottis and pressure builds up in the oesophagus. In Mallory–Weiss syndrome, vigorous vomiting produces a vertical split in the gastric mucosa, immediately below the squamocolumnar junction at the cardia in 90% of cases. In only 10% is the tear in the oesophagus (**Figure 62.10**). The condition presents with haematemesis. Usually, the bleeding is not severe, but endoscopic injection therapy may be required for the occasional, severe case. Surgery is rarely required. There are two other injuries to the oesophagus that lie within the spectrum of the mucosal tear of Mallory–Weiss and the full-thickness tear of Boerhaave. Intramural rupture produces a dissection within the oesophageal wall that causes severe chest pain, often with odynophagia. It is best diagnosed by contrast radiology. Intramural haematoma is seen most often in elderly patients on anticoagulants or patients with coagulation disorders, and usually follows an episode of vomiting. Large haematomas causing dysphagia can occur, extending from the cardia up to the carina. The diagnosis is readily made on endoscopy. Both intramural rupture and intramural haematoma can be managed conservatively. Symptoms usually resolve in 7–14 days, and oral intake can be reinstituted as soon as symptoms allow.

CORROSIVE INJURY

Corrosives such as sodium hydroxide (lye, caustic soda) or sulphuric acid may be taken in an attempted suicide. Accidental ingestion occurs in children and when corrosives are stored in bottles labelled as beverages. All can cause severe damage to the mouth, pharynx, larynx, oesophagus and stomach. The type of agent, its concentration and the volume ingested largely determine the extent of damage. In general, alkalis are relatively odourless and tasteless, making them more likely to be ingested in large volume. Alkalis cause liquefaction, saponification of fats, dehydration and thrombosis of blood vessels which usually leads to fibrous scarring. Acids cause coagulative necrosis with eschar formation, and this coagulant may limit penetration to deeper layers of the oesophageal wall. Acids also cause more gastric damage than alkalis because of the induction of intense pylorospasm with pooling in the antrum.

Symptoms and signs are notoriously unreliable in predicting the severity of injury. The key to management is early endoscopy by an experienced endoscopist to inspect the whole of the oesophagus and stomach (**Figure 62.11**). Deep ulcers and the recognition of a grey or black eschar signify the most severe lesions with the greatest risk of perforation. Minor injuries with only oedema of the mucosa resolve rapidly with no late sequelae. These patients can safely be fed. With more severe injuries, a feeding jejunostomy may be appropriate until the patient can swallow saliva satisfactorily. The widespread use of broad-spectrum antibiotics and steroids is not supported by evidence.

Regular endoscopic examinations are the best way to assess stricture development (**Figure 62.12**). Significant stricture formation occurs in about 50% of patients with extensive mucosal damage (**Figure 62.13**). The role and timing of repeat endoscopies with or without dilatation in such patients

remain controversial. Other than the need for emergency surgery for bleeding or perforation, elective oesophageal resection should be deferred for at least 3 months until the fibrotic phase has been established. Oesophageal replacement is usually required for very long or multiple strictures. Resection can be difficult because of perioesophageal inflammation in these patients. Because of associated gastric damage, colon may have to be used as the replacement conduit.

There is also controversy with regard to the risk of developing carcinoma in the damaged oesophagus and stomach and how this might influence management. The lifetime risk is certainly less than 5%. Some surgeons advocate resection and replacement, whereas others believe that oesophageal bypass and endoscopic surveillance are preferable, because removal of the badly damaged oesophagus from a scarred mediastinum can be hazardous.

Summary box 62.5

Corrosive injury

- Skilled early endoscopy is mandatory

DRUG-INDUCED INJURY

Many medications, such as antibiotics and potassium preparations, are potentially damaging to the oesophagus, because tablets may remain for a long time, especially if taken without an adequate drink. Acute injury presents with dysphagia and odynophagia, which may be severe. The inflammation usually resolves within 2–3 weeks, and no specific treatment is required apart from appropriate nutritional support. A stricture may follow.

GASTRO-OESOPHAGEAL REFLUX DISEASE

Aetiology

Normal competence of the gastro-oesophageal junction is maintained by the LOS. This is influenced by both its physiological function and its anatomical location relative to the diaphragm and the oesophageal hiatus. In normal circumstances, the LOS transiently relaxes as a coordinated part of swallowing, as a means of allowing vomiting to occur and in response to stretching of the gastric fundus, particularly after a meal to allow swallowed air to be vented. Most episodes of physiological reflux occur during postprandial transient LOS relaxations (TLOSRs). In the early stages of GORD, most pathological reflux occurs as a result of an increased number of TLOSRs rather than a persistent fall in overall sphincter pressure. In more severe GORD, LOS pressure tends to be generally low, and this loss of sphincter function seems to be made worse if there is loss of an adequate length of intra-abdominal oesophagus.

The absence of an intra-abdominal length of oesophagus results in a sliding hiatus hernia. The normal condensation of peritoneal fascia over the lower oesophagus (the phreno-oesophageal ligament) is weak, and the crural opening widens, allowing the upper stomach to slide up through the hiatus. The loss of the normal anatomical configuration exacerbates reflux, although sliding hiatus hernia alone should not be viewed as the cause of reflux. Sliding hiatus hernia is associated with GORD and may make it worse but, as long as the LOS remains competent, pathological GORD does not occur. Many GORD sufferers do not have a hernia, and many of those with a hernia do not have GORD. It should be noted that rolling or paraoesophageal hiatus hernia is a quite different and potentially dangerous condition (see below). A proportion of patients have a rolling hernia and symptomatic GORD or a mixed hernia with both sliding and rolling components. Reflux oesophagitis that is visible endoscopically is a complication of GORD and occurs in a minority of sufferers overall, but in around 40% of patients referred to hospital.

In western societies, GORD is the most common condition affecting the upper GI tract. This is partly due to the declining incidence of peptic ulcer as the incidence of infection with *Helicobacter pylori* has reduced as a result of improved socioeconomic conditions, along with a rising incidence of GORD in the last 30 years. The cause of the increase is unclear, but may be due in part to increasing obesity. The strong association between GORD, obesity and the parallel rise in the incidence of adenocarcinoma of the oesophagus represents a major health challenge for most western countries.

Clinical features

The classic triad of symptoms is retrosternal burning pain (heartburn), epigastric pain (sometimes radiating through to the back) and regurgitation. Most patients do not experience all three. Symptoms are often provoked by food, particularly those that delay gastric emptying (e.g. fats, spicy foods). As the condition becomes more severe, gastric juice may reflux to the mouth and produce an unpleasant taste, often described as 'acid' or 'bitter'. Heartburn and regurgitation can be brought on by stooping or exercise. A proportion of patients have odynophagia with hot beverages, citrus drinks or alcohol. Patients with nocturnal reflux and those who reflux food to the mouth nearly always have severe GORD. Some patients present with less typical symptoms such as angina-like chest pain, pulmonary or laryngeal symptoms. Dysphagia is usually a sign that a stricture has occurred, but may be caused by an associated motility disorder.

As GORD is such a common disorder, it should always be the first thought when a patient presents with oesophageal symptoms that are unusual or that defy diagnosis after a series of investigations.

Diagnosis

In most cases, the diagnosis is assumed rather than proven, and treatment is empirical. Investigation is required only when the diagnosis is in doubt, when the patient does not respond to a proton pump inhibitor (PPI) or if dysphagia is present. The most appropriate examination is endoscopy with biopsy. If the typical appearance of reflux oesophagitis, peptic stricture or Barrett's oesophagus is seen, the diagnosis is clinched, but visible oesophagitis is not always present, even in patients selected as above. This is compounded in clinical practice by the widespread use of PPIs, which cause rapid healing of early mucosal lesions. Many patients will have received such treatment before referral. The endoscopic appearances of the normal oesophagus, hiatus hernia, oesophagitis and stricture are shown in **Figures 62.14–62.20**. It is worth remembering that the correlation between symptoms and endoscopic appearances is poor. On the other hand, there is a strong correlation between worsening endoscopic appearances and the duration of oesophageal acidification on pH testing.

In patients with atypical or persistent symptoms despite therapy, oesophageal manometry and 24-hour oesophageal pH recording (ideally with impedance measurement) may be justified to establish the diagnosis and guide management.

Summary box 62.6

Diagnostic measurement in GORD

- 24-hour pH recording is the 'gold standard' for diagnosis of GORD
- Length and pressure of the LOS are important

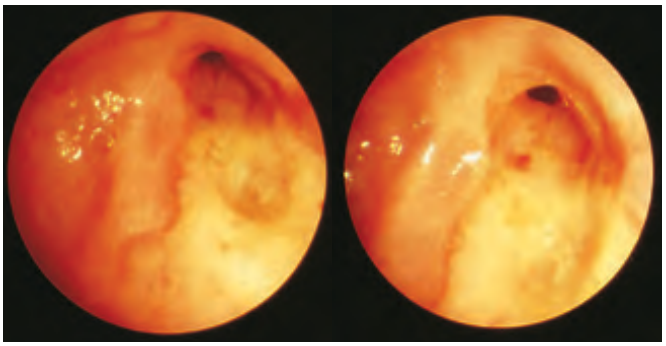

Figure 62.20 Ulceration associated with a benign peptic stricture.

As a matter of routine, proton pump inhibitors (PPIs) are stopped 1 week before oesophageal pH recording, but acid secretion is sometimes reduced for 2 weeks or more, and this can necessitate repeat examination after a prolonged interval without a PPI. Manometry and pH recording are essential in patients being considered for antireflux surgery. Although the main purpose of the test is objectively to quantify the extent of reflux disease, it is also used to rule out a diagnosis of achalasia. In the early stages of achalasia, chest pain can dominate the clinical picture and, when associated with intermittent swallowing problems and non-specific symptoms, it is easy to see how a clinical diagnosis of GORD might be made. Patients with achalasia can also have an abnormal pH study as a result of fermentation of food residue in a dilated oesophagus. Usually, the form of the pH trace is different from that of GORD, with slow undulations of pH rather than rapid bursts of reflux, but the complete absence of peristalsis on manometry is pathognomonic of achalasia.

A CT scan gives the best appreciation of gastro-oesophageal anatomy. This may be important in the context of surgery for rolling or mixed hiatus hernias, but it is unimportant in most patients with GORD.

Management of uncomplicated GORD

Medical management

Most sufferers from GORD do not consult a doctor and do not need to do so. They self-medicate with over-the-counter medicines such as simple antacids, antacid–alginate preparations, H_2-receptor antagonists or PPIs. Consultation is more likely when symptoms are severe, prolonged and unresponsive to the above treatments. Simple measures that are often neglected include advice about weight loss, smoking, excessive consumption of alcohol, tea or coffee, the avoidance of large meals late at night and a modest degree of head-up tilt of the bed. Tilting the bed has been shown to have an effect that is similar to taking an H_2-receptor antagonist. The common practice of using additional pillows has no significant effect.

PPIs are the most effective drug treatment for GORD. Indeed, they are so effective that, once started, patients are

very reluctant to stop taking them. Given an adequate dose for 8 weeks, most patients have a rapid improvement in symptoms (within a few days), and more than 90% can expect full mucosal healing at the end of this time. For this reason, a policy of 'step-down' medical treatment is advocated based on the general advice outlined above and a standard dose of a PPI given for 8 weeks. At the end of that time, the dose of PPI is reduced to that which keeps the patient free of symptoms, and this might even mean the cessation of PPI treatment. As most patients do not make major lifestyle changes and as PPIs are so effective, many remain on long-term treatment. For the minority who do not respond adequately to a standard dose, a trial at an increased dose or the addition of an H_2-receptor antagonist is recommended. If unsuccessful, these patients should be formally investigated.

PPI therapy is also important in patients with reflux-induced strictures, resulting in significant prolongation of the intervals between endoscopic dilatation. As yet, fears that chronic acid suppression might have serious long-term side effects including the risk of gastric cancer seem unwarranted.

Surgery

Strictly speaking, the need for surgery should have been reduced as medication has improved so much. Paradoxically, the number of antireflux operations has remained relatively constant and may even be increasing. This is probably due partly to increased patient expectations and partly to the advent of minimal access surgery, which has improved the acceptability of procedures.

Endoscopic treatments

A number of endoscopic treatments have been tried in the last 10 years that attempt to augment a failing LOS. These involve endoscopic suturing devices that plicate gastric mucosa just below the cardia to accentuate the angle of His, radiofrequency ablation (RFA) to the level of the sphincter and the injection of submucosal polymers into the lower oesophagus. The procedures have generally been applied to patients with only small hiatus hernias or none at all, so only a small proportion of patients who present to hospitals are suitable. Although most methods produce some temporary improvement in symptoms and objective assessments of reflux, failure rates at 1 year are high and can be over 50%. There are few large series that have reported long-term outcomes. Only RFA has been shown to be effective for as long as 10 years when around two-thirds patients remain off PPI medication.

Surgical treatments

The indication for surgery in uncomplicated GORD is essentially patient choice. The risks and possible benefits need to be discussed in detail. Risks include a small mortality rate (0.1–0.5%, depending on patient selection), failed operation (5–10%) and side effects such as dysphagia, gas bloat or abdominal discomfort (10%). With current surgical techniques, 85–90% of patients should be satisfied with the result of an antireflux operation. Patients who are asymptomatic on a PPI need a careful discussion of the risk side of the equation. Those who are symptomatic on a PPI need a careful clinical review to make sure that they will benefit from an operation. Reasons for failure on a PPI include 'volume' reflux (a good indication for surgery), a 'hermit' lifestyle in which the least deviation from lifestyle rules leads to symptoms (a good indication), psychological distress with intolerance of minor symptoms (a poor indication; these patients are likely to be dissatisfied with surgery), poor compliance (a good indication if the reason for poor compliance is the side effects of treatment, otherwise a bad indication) and misdiagnosis of GORD.

WHICH SURGERY?

There are many operations for GORD, but they are virtually all based on the creation of an intra-abdominal segment of oesophagus, crural repair and some form of wrap of the upper stomach (fundoplication) around the intra-abdominal oesophagus. The contribution of each component to operative success is widely debated, but it is clear that operations that fail to address all three components have inferior success rates. The major types of anti-reflux operation were all developed in the 1950s (**Figure 62.21**). When performed correctly, nearly all are effective. Most randomised trials do not show a clear advantage for any one operation over the

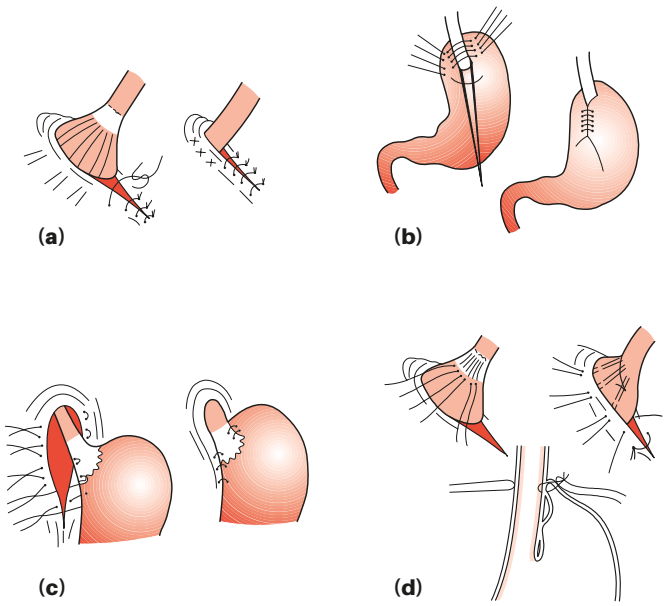

Figure 62.21 Various operations for the surgical correction of gastro-oesophageal reflux disease. **(a)** The original Allison repair of hiatus hernia (this is ineffective and is no longer done); **(b)** Nissen fundoplication; **(c)** Hill procedure; **(d)** Belsey mark IV operation.

Ronald Herbert Robert Belsey, d.2007, thoracic surgeon, Frenchay Hospital, Bristol, UK.

others, although one meta-analysis has come down in favour of posterior partial fundoplication over total fundoplication when performed laparoscopically.

Total fundoplication (Nissen) tends to be associated with slightly more short-term dysphagia but is the most durable repair in terms of long-term reflux control. Partial fundoplication, whether performed posteriorly (Toupet) or anteriorly (Dor, Watson), has fewer short-term side effects, although this is sometimes at the expense of a slightly higher long-term failure rate. One disadvantage of total fundoplication is the creation of an overcompetent cardia, resulting in the 'gas bloat' syndrome in which belching is impossible. The stomach fills with air, the patient feels very full after small meals and passes excessive flatus. This does not seem to occur with partial fundoplication. The problem has been largely overcome by the 'floppy' Nissen technique in which the fundoplication is loose around the oesophagus and is kept short in length. Although the other short-term side effects of fundoplication usually resolve within 3 months of surgery, this is rarely the case for gas bloat. The problem is best remedied by conversion to a partial fundoplication.

As with primary surgery, various revisional procedures have been described, usually for recurrent reflux or persistent dysphagia. For most patients, recurrent reflux relates to anatomical failure, so the solution is a revisional fundoplication. The results of surgery for recurrent reflux tend to be better than those for dysphagia, because the latter problem has many causes (too tight a wrap, slipping of the wrap, hiatal fibrosis) A very small proportion of patients may undergo more than two operations to correct recurrent reflux or unacceptable side effects. Revisional surgery carries a lower chance of success and, in some patients, local revision becomes technically impossible. The final resort is antrectomy with a Roux-en-Y reconstruction. This reduces gastric acid secretion and diverts bile and pancreatic secretions away from the stomach. Thus, the volume of potential refluxate in the stomach is reduced and, because of its changed composition, it is less damaging to the oesophagus.

For many years, the relative merits of thoracic and abdominal approaches were hotly debated. The introduction of minimal access surgery has made this debate obsolete. Most antireflux operations are now done with a laparoscopic approach.

LAPAROSCOPIC FUNDOPLICATION

Five cannulae are inserted in the upper abdomen (**Figure 62.22**). The cardia and lower oesophagus are separated from the diaphragmatic hiatus. An appropriate length of oesophagus is mobilised in the mediastinum. The fundus may be mobilised by dividing the short gastric vessels that tether the fundus to the spleen, although some surgeons feel that this is unnecessary. The hiatus is narrowed by sutures placed behind the oesophagus. In total (Nissen) fundoplication, the fundus is drawn behind the oesophagus and then sutured to itself in front of the oesophagus (**Figure 62.23a**). In partial fundoplication, the fundus is drawn either behind or in front of the oesophagus and sutured to it on each side, leaving a strip of exposed oesophagus either at the front (**Figure 62.23b**) or at the back. Robotic fundoplication has been described but comparisons with laparoscopic surgery do not indicate any clear clinical benefits.

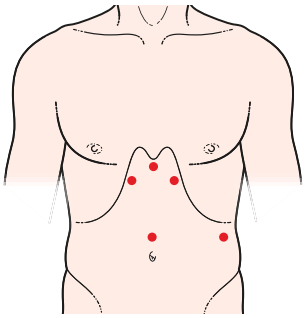

Figure 62.22 Laparoscope cannula sites for laparoscopic fundoplication.

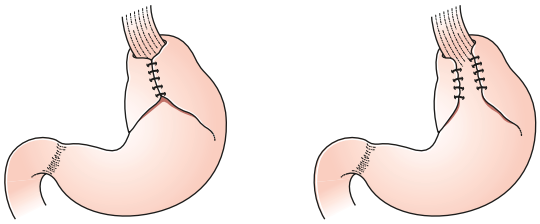

Figure 62.23 **(a)** Total (Nissen) fundoplication; **(b)** partial fundoplication (Toupet).

Complications of GORD

Stricture

Reflux-induced strictures (see **Figure 62.20**) occur mainly in late middle-aged and elderly people, but they may present in children. It is important to distinguish a benign reflux-induced stricture from a carcinoma. This is not usually difficult on the basis of location (immediately above the oesophagogastric junction), length (only about 1–2 cm) and smooth mucosa, but sometimes a cancer spreads under the oesophageal mucosa at its upper margin, producing a benign-looking stricture.

Peptic strictures generally respond well to dilatation and long-term treatment with a PPI. As most patients are elderly, antireflux surgery is not usually considered. However, it is an alternative to long-term PPI treatment, just as in uncomplicated GORD in younger and fitter patients. Most patients do not require anything other than a standard operation.

Summary box 62.7

Peptic stricture

- Day-case dilatation and PPI for peptic stricture

AM Toupet, French surgeon.
Cesar Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland, described this method of forming a jejunal conduit in 1908.

Oesophageal shortening

The issue of oesophageal shortening continues to provoke debate. There can be no doubt that, in the presence of a large sliding hiatus hernia, the oesophagus is short, but this does not necessarily mean that, with mobilisation from the mediastinum, it cannot easily be restored to its normal length. The extent to which severe inflammation in the wall of the oesophagus causes fibrosis and real shortening is less clear. If a good segment of intra-abdominal oesophagus cannot be restored without tension, a Collis gastroplasty should be performed (**Figure 62.24**). This produces a neo-oesophagus around which a fundoplication can be done (Collis–Nissen operation).

Summary box 62.8

GORD

- Is due to loss of competence of the LOS and is extremely common
- May be associated with a hiatus hernia, which may be sliding or, less commonly, rolling (paraoesophageal)
- The most common symptoms are heartburn, epigastric discomfort and regurgitation, often made worse by stooping and lying
- Achalasia and GORD are diagnostically easily confused
  - Dysphagia may occur, but a neoplasm must be excluded
  - Diagnosis and treatment can be instituted on clinical grounds
- Endoscopy may be required and 24-hour pH is the 'gold standard'
  - Management is primarily medical (PPIs being the most effective), but surgery may be required; laparoscopic fundoplication is the most popular technique
  - Stricture may develop in time

Barrett's oesophagus (columnar-lined lower oesophagus)

Barrett's oesophagus is a metaplastic change in the lining mucosa of the oesophagus in response to chronic gastro-oesophageal reflux (**Figure 62.25**). Many of these patients do not have particularly severe symptoms, although they do have the most abnormal pH profiles. This adaptive response involves a mosaic of cell types, probably beginning as a simple columnar epithelium which becomes 'specialised' with time. The hallmark of 'specialised' Barrett's epithelium is the presence of mucus-secreting goblet cells (intestinal metaplasia). One of the great mysteries of GORD is why some people develop oesophagitis and others develop Barrett's oesophagus, often without significant oesophagitis. In Barrett's oesophagus, the junction between squamous oesophageal mucosa and gastric mucosa moves proximally. It may be difficult to distinguish a Barrett's oesophagus from a tubular, sliding hiatus hernia during endoscopy, as the two often coexist (**Figure 62.26**) or where the visible Barrett's segment is very short. The key

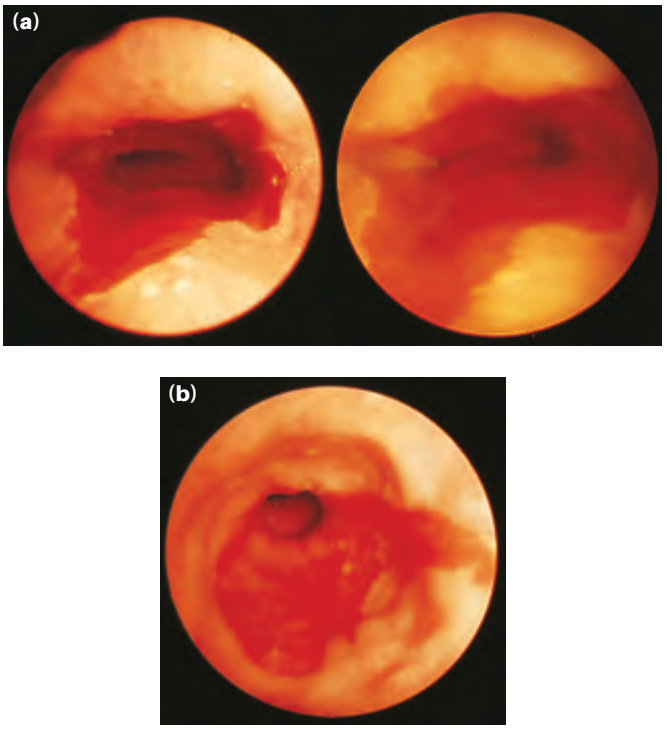

Figure 62.25 Barrett's oesophagus with **(a)** proximal migration of the squamocolumnar junction and **(b)** a view of the distal oesophagus.

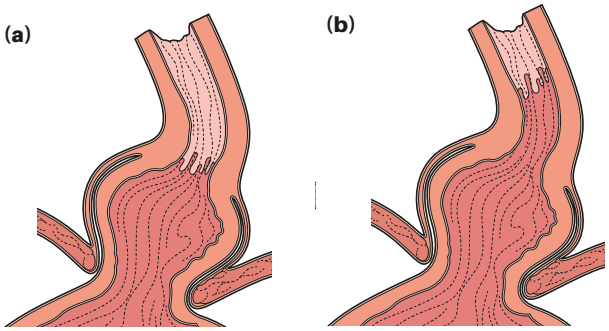

Figure 62.26 **(a)** The interrelationship of the lower oesophageal sphincter, the squamocolumnar junction and the diaphragm in sliding hiatus hernia. **(b)** Barrett's oesophagus and sliding hernia.

John Leigh Collis, 1911–2003, Professor of Thoracic Surgery, the University of Birmingham, Birmingham, UK.

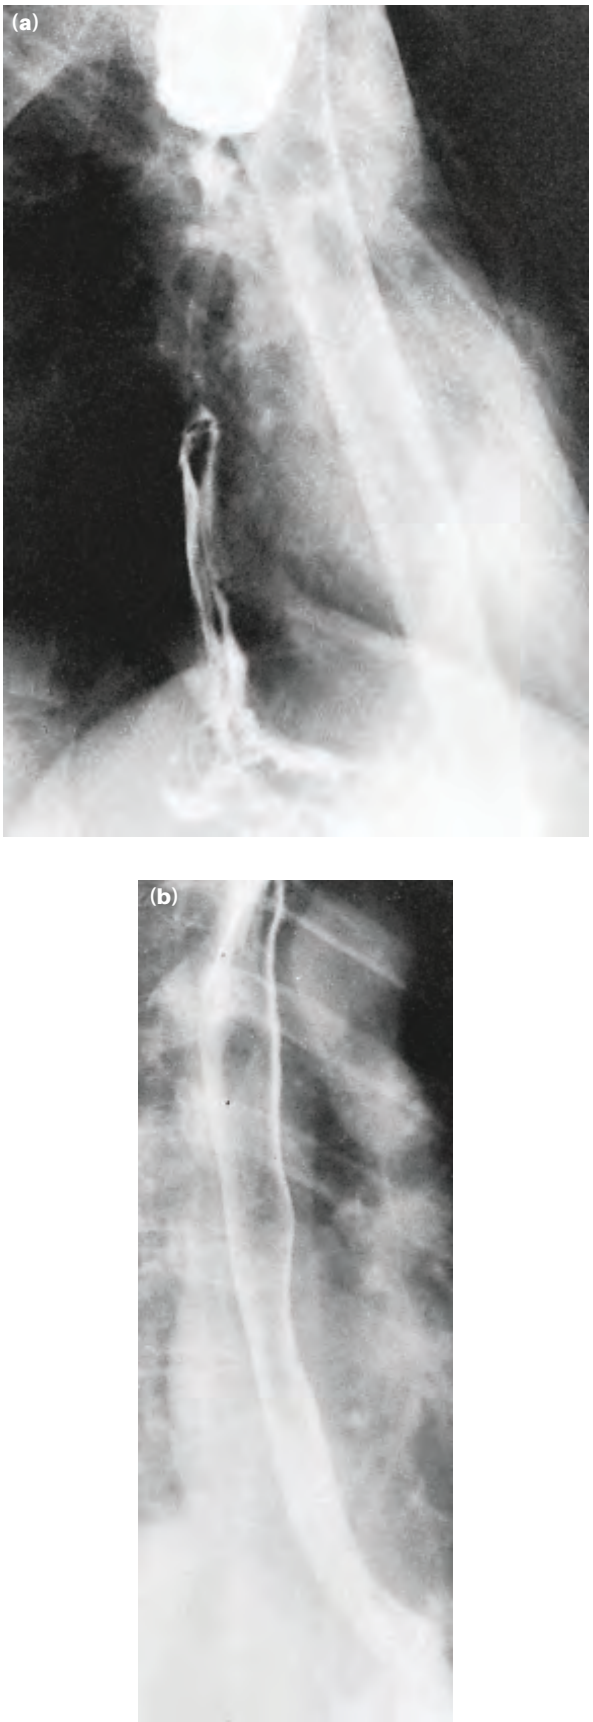

Figure 62.27 The radiological appearance of a midoesophageal stricture in **(a)**, a patient with Barrett's oesophagus and in **(b)** a normal lumen after dilatation.

is where the gastric mucosal folds end along with recognition of the mucosal vascular pattern. The mucosa in the body of the stomach has longitudinal folds; the columnar lining of Barrett's oesophagus is smooth. The lower oesophagus is characterised by palisade vessels that run longitudinally and are easily seen through the lower oesophageal mucosa. Strictures can occur in Barrett's oesophagus and nearly always appear at the new squamocolumnar junction (**Figure 62.27**). Rarely, a stricture may occur in the columnar segment after healing of a Barrett's ulcer (**Figure 62.28**). Although intestinal metaplasia and length of the Barrett's segment are important risk factors for the development of carcinoma, neither represents an essential feature for cancer development. The risk of transformation to cancer is probably no more than 0.5% per patient per year, which is about 25 times that of the general population (**Figures 62.29 and 62.30**).

Summary box 62.9

Barrett's oesophagus

- Intestinal metaplasia is a risk factor for the development of adenocarcinoma
- Do not confuse Barrett's ulcer with oesophagitis

Patients who are found to have Barrett's oesophagus may be submitted to regular surveillance endoscopy with multiple biopsies in the hope of finding dysplasia or in situ cancer, rather than allowing invasive cancer to develop and cause symptoms. There is no general agreement about the benefits of surveillance endoscopy, or its ideal frequency. Endoscopy at 2-year intervals is probably adequate, provided that no dysplasia has been detected. A significant problem is that the incidence of Barrett's oesophagus in the community is

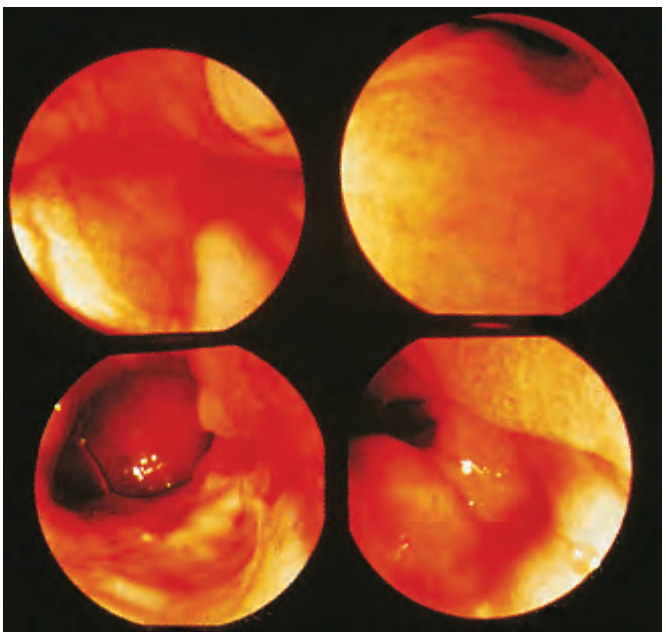

Figure 62.28 Barrett's ulcer in the columnar cell-lined oesophagus.

Figure 62.29 The macroscopic appearances of an adenocarcinoma in Barrett's oesophagus.

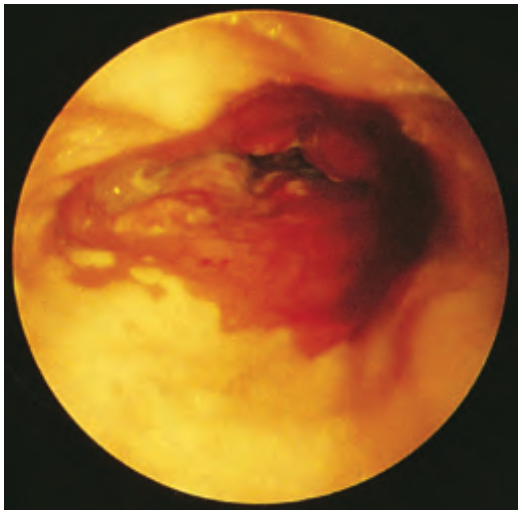

Figure 62.30 Endoscopic view of carcinoma in Barrett's oesophagus.

estimated to be at least 10 times the incidence discovered in dyspeptic patients referred for endoscopy. Thus, adenocarcinoma in Barrett's oesophagus often presents with invasive cancer without any preceding reflux symptoms.

Until recently, Barrett's oesophagus was not diagnosed until there was at least 3 cm of columnar epithelium in the distal oesophagus. With the better appreciation of the importance of intestinal metaplasia, Barrett's oesophagus may be diagnosed if there is any intestinal metaplasia in the oesophagus. The relative risk of cancer rises with increasing length of abnormal mucosa. The following terms are widely used:

- classic Barrett's (≥3 cm columnar epithelium);
- short-segment Barrett's (<3 cm of columnar epithelium);
- cardia metaplasia (intestinal metaplasia at the oesophagogastric junction without any macroscopic change at endoscopy).

When Barrett's oesophagus is discovered, the treatment is that of the underlying GORD. There has been considerable interest in recent years in endoscopic methods of treating Barrett's mucosa in the hope of eliminating the risk of cancer development. Laser, photodynamic therapy, argon-beam plasma coagulation, RFA and endoscopic mucosal resection (EMR) have all been used. Until recently, it was felt that intervention should only be offered in patients with high-grade dysplasia, but recent evidence suggests that patients with low-grade dysplasia also have a substantial risk of progressing to high-grade dysplasia of around 9% per year. For this reason endoscopic treatment is considered appropriate for patients with low-grade dysplasia when confirmed by a second independent histopathologist. EMR of dysplastic areas followed by RFA seems to be the most popular approach and, together with PPI treatment, these endoscopic methods can result in a neosquamous lining. Fears of buried glands that might give rise to cancer seem unfounded.

PARAOESOPHAGEAL ('ROLLING') HIATUS HERNIA

True paraoesophageal hernias in which the cardia remains in its normal anatomical position are rare. The vast majority of rolling hernias are mixed hernias in which the cardia is displaced into the chest and the greater curve of the stomach rolls into the mediastinum (**Figure 62.31**). Sometimes, the whole of the stomach lies in the chest (**Figure 62.32**). Colon or small intestine may sometimes lie in the hernia sac. The hernia is most common in elderly people, but may occur in young fit people. As the stomach rolls up into the chest, there is always an element of rotation (volvulus).

Figure 62.31 A paraoesophageal hernia showing the gastro-oesophageal junction just above the diaphragm and the fundus alongside the oesophagus, compressing the lumen.

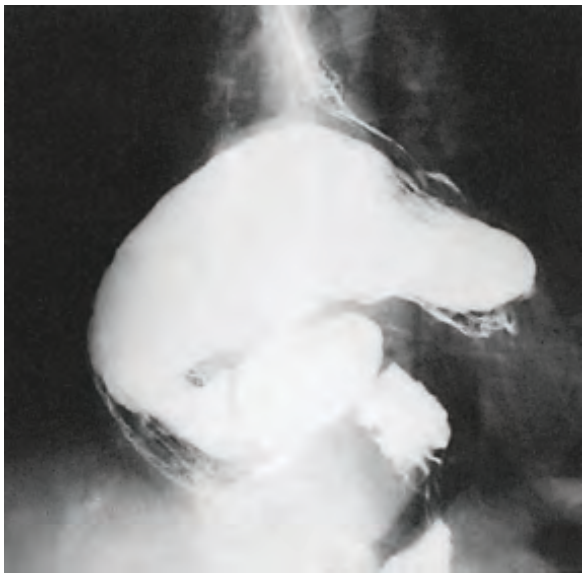

Figure 62.32 A huge paraoesophageal hernia with an upside-down stomach and the pylorus just below the hiatus.

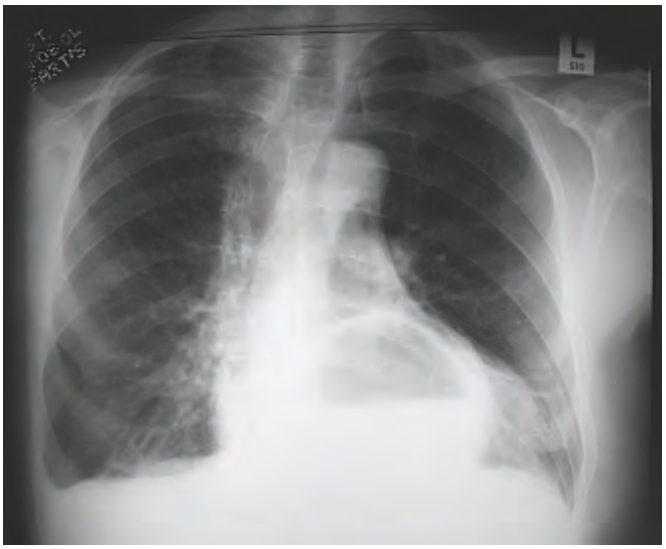

Figure 62.33 A gas bubble seen on a plain chest radiograph, showing the fundus of the stomach in the chest (courtesy of Dr Stephen Ellis, Bart's and the London NHS Trust).

Summary box 62.10

'Rolling' hiatus hernia

- Potentially dangerous, because of volvulus

The symptoms of rolling hernia are mostly due to twisting and distortion of the oesophagus and stomach. Dysphagia is common. Chest pain may occur from distension of an obstructed stomach. Classically, the pain is relieved by a loud belch. Symptoms of GORD are variable. Strangulation, gastric perforation and gangrene can occur. Emergency presentation with any of these complications carries high mortality on account of a combination of late diagnosis, generally elderly patients with comorbid diseases and the complexity of surgery involved.

The hernia may be visible on a plain radiograph of the chest as a gas bubble, often with a fluid level behind the heart (Figure 62.33). A CT scan with oral contrast is the best method of diagnosis, highlighting the gastric anatomy but also identifying other structures involved in the hernia. The endoscopic appearances may be confusing, especially in large hernias when it is easy to become disoriented.

Symptomatic rolling hernias nearly always require surgical repair because they are potentially dangerous. The risk of an asymptomatic patient developing a significant problem when a rolling hiatus hernia is discovered incidentally has probably been underestimated in the past. The annual risk is probably greater than the historical estimate of 1%. Patients who present as an emergency with acute chest pain may be treated initially by nasogastric tube, to relieve the distension that causes the pain, followed by surgical repair. Endoscopy is useful if nasogastric intubation is unsuccessful. If the pain is not relieved or perforation is suspected, immediate operation is mandatory.

Emergency surgery needs to be tailored to the problem encountered and the fitness of the patient. Elective surgery involves reduction of the hernia, excision of the sac, reduction of the crural defect and some form of retention of the stomach in the abdomen. Some surgeons perform a fundoplication, arguing that this is a very effective means of maintaining reduction and that it deals with the associated GORD. Others argue that fundoplication should be done only if reflux can be conclusively demonstrated beforehand. Surprisingly, both philosophies achieve good results. Laparoscopic repair has recently become popular. Full anatomical repair of a large rolling hernia can be difficult using this approach and requires considerable expertise. Secure closure of the hiatal defect can be a problem, and some surgeons advocate mesh to reinforce the repair.

NEOPLASMS OF THE OESOPHAGUS

Benign tumours

Benign tumours of the oesophagus are relatively rare. True papillomas, adenomas and hyperplastic polyps do occur, but most 'benign' tumours are not epithelial in origin and arise from other layers of the oesophageal wall (GI stromal tumour [GIST], lipoma, granular cell tumour). Most benign oesophageal tumours are small and asymptomatic, and even a large benign tumour may cause only mild symptoms (Figure 62.34). The most important point in their management is usually to carry out an adequate number of biopsies to prove beyond reasonable doubt that the lesion is not malignant (Figure 62.35).

Malignant tumours

Non-epithelial primary malignancies are also rare, as is malignant melanoma. Secondary malignancies rarely involve the oesophagus, with the exception of bronchogenic carcinoma

Figure 62.34 Classic appearance of a large oesophageal gastrointestinal stromal tumour on barium swallow.

by direct invasion of either the primary and/or contiguous lymph nodes.

Carcinoma of the oesophagus

Cancer of the oesophagus is the sixth most common cancer in the world. In general, it is a disease of mid to late adulthood, with a poor survival rate. Only 5–10% of those diagnosed will survive for 5 years.

Summary box 62.11

Carcinoma of the oesophagus

- Squamous cell usually affects the upper two-thirds; adenocarcinoma usually affects the lower third
- Common aetiological factors are tobacco and alcohol (squamous cell), GORD and obesity (adenocarcinoma)
- The incidence of adenocarcinoma is increasing
- Lymph node involvement is a bad prognostic factor
- Dysphagia is the most common presenting symptom, but is a late feature
- Accurate pretreatment staging is essential in patients thought to be fit to undergo 'curative' treatment

Pathology and aetiology

Squamous cell cancer (**Figures 62.36 and 62.37**) and adenocarcinoma (**Figures 62.38 and 62.39**) are the most common types. Squamous cell carcinoma generally affects the upper

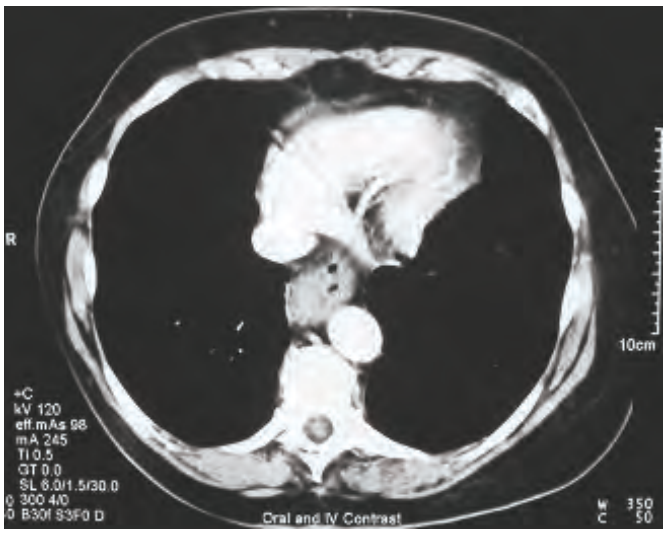

Figure 62.39 Computed tomography scan showing a primary tumour of the lower oesophagus.

two-thirds of the oesophagus and adenocarcinoma the lower third. Worldwide, squamous cell cancer is most common, but adenocarcinoma predominates in the west and is increasing in incidence.

Geographical variation in oesophageal cancer

The incidence of oesophageal cancer varies more than that of any other cancer. Squamous cell cancer is endemic in the Transkei region of South Africa and in the Asian 'cancer belt', which extends across the middle of Asia from the shores of the Caspian Sea (in northern Iran) to China. The highest incidence in the world is in Linxian in Henan province in China, where it is the most common single cause of death, with more than 100 cases per 100 000 population per annum. The cause of the disease in the endemic areas is not known. Although there is evidence of genetic susceptibility across much of central Asia, a variety of environmental factors along with nutritional deficiencies are probably involved. In Linxian, supplementation of the diet with β-carotene, vitamin E and selenium has been shown to reduce the incidence.

Away from the endemic areas, tobacco and alcohol are major factors in the occurrence of squamous cancer. Incidence rates vary from less than 5:100 000 in white people in the USA to 26.5:100 000 in some regions of France.

In many western countries, the incidence of squamous cell cancer has fallen or remained static, but the incidence of adenocarcinoma of the oesophagus has increased dramatically since the mid-1970s at a rate of 5–10% per annum.

The change is greater than that of any other neoplasm in this time. Adenocarcinoma now accounts for 60–75% of all oesophageal cancers in several countries. The reason for this change is not understood. A similar rate of increase in GORD over the same period, which mirrors an increase in obesity in the west, is likely to be an important factor, particularly through the link to Barrett's oesophagus. Obese, white men in their 60s represent the highest-risk group. There has also been an increase in the incidence of carcinoma of the cardia of the stomach, which suggests that cancer of the cardia and adenocarcinoma of the oesophagus may share common aetiological factors. With a falling incidence of cancer in the rest of the stomach, more than 60% of all upper GI cancers in the west involve the cardia or distal oesophagus.

Both adenocarcinomas and squamous cell carcinomas tend to disseminate early. Sadly, the classic presenting symptoms of dysphagia, regurgitation and weight loss are often absent until the primary tumour has become advanced, and so the tumour is often well established before the diagnosis is made. Tumours can spread in three ways: invasion directly through the oesophageal wall, via the lymphatics or in the bloodstream. Direct spread occurs both laterally, through the component layers of the oesophageal wall, and longitudinally within the oesophageal wall. Longitudinal spread is mainly via the submucosal lymphatic channels of the oesophagus. The pattern of lymphatic drainage is therefore not segmental, as in other parts of the GI tract. Consequently, the length of oesophagus involved by tumour is frequently much longer than the macroscopic length of the malignancy at the epithelial surface. Lymph node spread occurs commonly. Although the direction of spread to regional lymphatics is predominantly caudal, the involvement of lymph nodes is potentially widespread and can also occur in a cranial direction. Any regional lymph node from the superior mediastinum to the coeliac axis and lesser curve of the stomach may be involved, regardless of the location of the primary lesion within the oesophagus. Haematogenous spread may involve a variety of different organs including the liver, lungs, brain and bones. Tumours arising from the intra-abdominal portion of the oesophagus may also disseminate transperitoneally.

Clinical features

Most oesophageal neoplasms present with mechanical symptoms, principally dysphagia, but sometimes also regurgitation, vomiting, odynophagia and weight loss. Clinical findings suggestive of advanced malignancy include recurrent laryngeal nerve palsy, Horner's syndrome, chronic spinal pain and diaphragmatic paralysis. Other factors making surgical cure unlikely include weight loss of more than 20% and loss of appetite. Cutaneous tumour metastases or enlarged supraclavicular lymph nodes may be seen on clinical examination and indicate disseminated disease. Hoarseness due to recurrent laryngeal nerve palsy is a sign of advanced and incurable disease. Palpable lymphadenopathy in the neck is likewise a sign of advanced disease.

Patients with early disease may have non-specific dyspeptic symptoms or a vague feeling of 'something that is not quite right' during swallowing. Some are diagnosed during endoscopic surveillance of patients with Barrett's oesophagus and, although this does identify patients with the earliest stages of disease, such programmes have little overall impact, because most patients with Barrett's oesophagus are unknown to the medical profession and make their first presentation with a symptomatic, and therefore usually locally advanced, oesophageal cancer. The widespread use of endoscopy as a diagnostic tool does, nevertheless, provide an opportunity for early diagnosis (**Figure 62.40**). Biopsies should be taken of all lesions in the oesophagus (**Figures 62.41 and 62.42**), no matter how trivial they appear and irrespective of the indication for the examination.

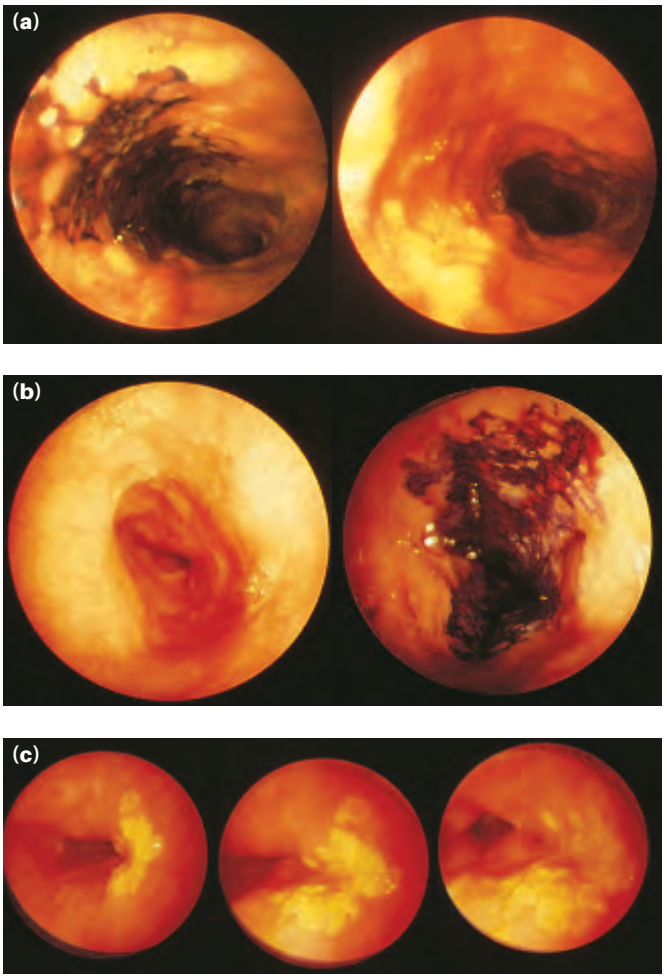

Figure 62.40 Carcinoma *in situ* showing the varied presentations: **(a)** occult form; **(b)** erythroplakia; **(c)** leukoplakia. The right-hand pictures in **(a)** and **(b)** demonstrate the use of vital staining with methylene blue.

Johann Friedrich Horner, 1831–1886, Professor of Ophthalmology, Zurich, Switzerland, described this syndrome in 1869.

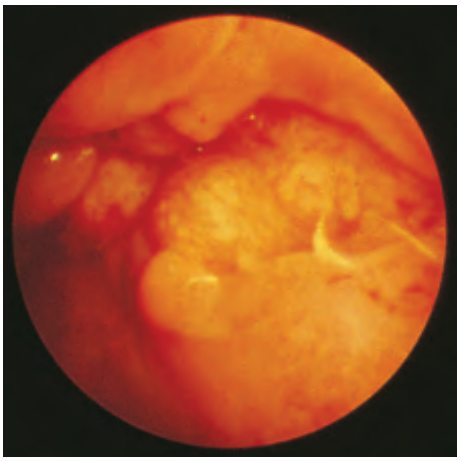

Figure 62.41 Endoscopic appearances of a midoesophageal squamous cell carcinoma.

Figure 62.42 Beware the differential diagnosis of infection, for what appears to be a tumour. This midoesophageal mass was actually tuberculosis.

Investigation

Endoscopy is the first-line investigation for most patients. It provides an unrivalled direct view of the oesophageal mucosa and any lesion allowing its site and size to be documented. Cytology and/or histology specimens taken via the endoscope are crucial for accurate diagnosis. The combination of histology and cytology increases the diagnostic accuracy to more than 95%. The chief limitation of conventional endoscopy is that only the mucosal surface can be studied and biopsied. Other investigations are therefore usually required to define the extent of local or distant spread. The improved image resolution of modern endoscopes and novel techniques involving magnification and the use of dyes to enhance surface detail may lead to more early lesions being recognised.

GENERAL ASSESSMENT AND STAGING

Once the initial diagnosis of a malignant oesophageal neoplasm has been made, patients should be assessed first in terms of their general health and fitness for potential therapies. Their preferences should also be considered. Most potentially curative therapies include radical surgery, although definitive chemoradiotherapy is an alternative in squamous cell carcinoma. Patients who are unfit for, or who do not wish to contemplate, radical treatments should not be investigated further, but should be diverted to appropriate palliative therapies, depending on the symptoms and current quality of life. Only those patients suitable for potentially curative therapies should proceed to staging investigations to rule out haematogenous spread (CT scan) and then to assess locoregional stage (endoscopic ultrasonography [EUS] ± laparoscopy). This will distinguish between early (T1/T2, N0) and advanced lesions (T3/T4, N1) and indicate whether surgery alone or multimodal therapy is most appropriate. Where attempted cure is deemed possible, the aim should be to provide the best chance of cure while minimising procedural risks. In general, surgery alone should be reserved for patients with early disease, and multimodal therapy should be used in patients with locally advanced disease, in whom the chance of cure by surgery alone is small (generally <20%).

The most widely used pathological staging system is that of the World Health Organization (tumour–nodes–metastasis TNM).

Table 62.2 shows the TNM system for oesophageal cancer. Similar to all pathological systems, it relies on the nature and extent of the surgery performed, e.g. performing more

TABLE 62.2 TNM staging scheme for oesophageal cancer.

Tis	High-grade dysplasia
T1	Tumour invading lamina propria or submucosa
T2	Tumour invading muscularis propria
T3	Tumour invading beyond muscularis propria
T4a	Tumour invading adjacent structures (pleura, pericardium, diaphragm)
T4b	Tumour invading adjacent structures (trachea, bone, aorta)
N0	No lymph node metastases
N1	Lymph node metastases in 1–2 nodes
N2	Lymph nodes metastases in 3–6 nodes
N3	Lymph node metastases in 7 or more lymph nodes
M0	No distant metastases
M1	All other distant metastases
Stage	1A: T1N0M0; 1B: T2N0M0; 2A: T3N0M0; 2B: T1/2N0M0; 3A: T4aN0M0, T3N1M0, T1/2N2M0
Stage	3B: T3N2M0; 3C: T4aN1/2M0, T4bN0–3M0, T1–4N3M0; 4T:1–4N1–3M1

extensive radical surgical lymphadenectomy provides a more accurate assessment of the 'N' stage. There is evidence that many patients described as N0 in the past were probably N1, a phenomenon described as stage migration.

Staging information may be gathered before the commencement of therapy, during therapy (e.g. at open operation) or following treatment (histology or postmortem examination). The techniques commonly used to provide preoperative staging data are described in **Figure 62.43**, along with a suggested algorithm.

BLOOD TESTS

These are of limited value. Blood tests reveal nothing about local invasion or regional lymph node spread and, to date, no reliable tumour marker for oesophageal cancer has been isolated from peripheral blood. The presence of abnormal liver function tests (LFTs) may suggest the presence of liver metastases, but this is generally too insensitive to be diagnostic. Many patients with known liver metastases have normal LFTs. At best, abnormal LFTs only reinforce the clinical suspicion of spread to the liver, and further imaging is usually required to confirm the diagnosis.

TRANSCUTANEOUS ULTRASONOGRAPHY

It is difficult to visualise mediastinal structures with transcutaneous ultrasonography. With the relatively low-frequency sound waves used, good depth of tissue penetration is achieved at the expense of poor image resolution. In addition, the mediastinal organs are surrounded by bone and air, which renders them largely inaccessible to external ultrasound. The technique is therefore used mainly to assess spread to the liver, the whole of which can be clearly visualised by standard transcutaneous ultrasonography. Haematogenous spread can be more fully assessed by combining ultrasonography with chest radiography, although this combination is less accurate than CT scanning.

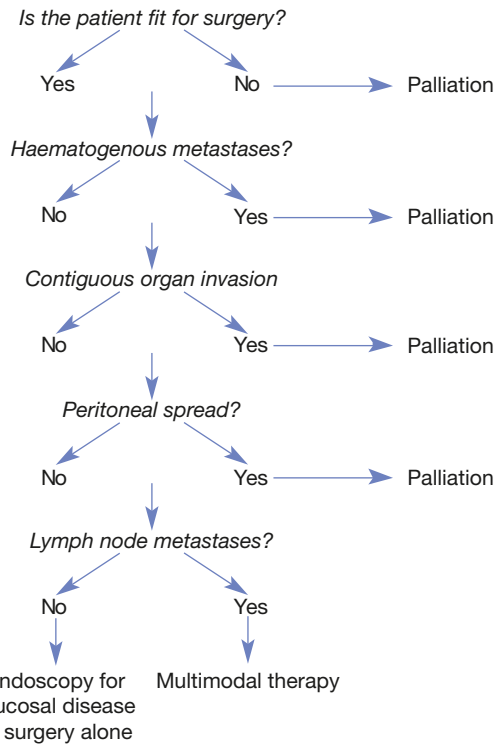

Figure 62.43 Algorithm for the management of oesophageal cancer.

BRONCHOSCOPY

Many middle- and upper-third oesophageal carcinomas (and therefore usually squamous carcinomas) are sufficiently advanced at the time of diagnosis that the trachea or bronchi are already involved (**Figure 62.44**). Bronchoscopy may reveal either impingement or invasion of the main airways in over 30% of new patients with cancers in the upper third of the oesophagus. In some cases, therefore, bronchoscopy alone can confirm that the tumour is locally unresectable.

LAPAROSCOPY

This is a useful technique for the diagnosis of intra-abdominal and hepatic metastases. It has the advantage of enabling tissue samples or peritoneal cytology to be obtained and is the only modality reliably able to detect peritoneal tumour seedlings (**Figure 62.45**). This is particularly important for tumours arising from the intra-abdominal portion of the oesophagus,

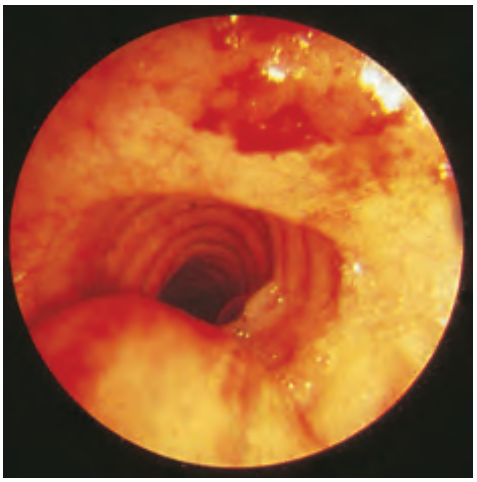

Figure 62.44 Invasion into the posterior wall of the trachea from an oesophageal carcinoma.

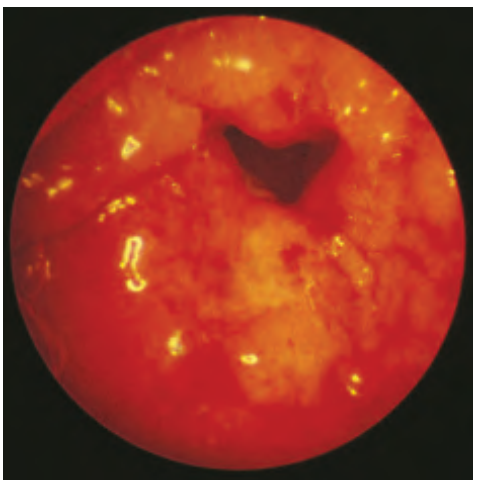

Figure 62.45 Adenocarcinoma of the cardia. Transcoelomic spread may occur with this type of lesion.

cardia and where there is a potential communication between a full-thickness tumour and the peritoneal cavity, for instance where there is a hiatus hernia.

COMPUTED TOMOGRAPHY

Computed tomography (CT) from the neck to the pelvis with intravenous contrast is the modality most used to identify haematogenous metastases (**Figure 62.46**). Distant organs are easily seen and metastases within them visualised with high accuracy (94–100%). The normal thoracic oesophagus is easily demonstrated by CT scanning. The mediastinal fat planes are usually clearly imaged in healthy individuals, and any blurring or distortion of these images is a fairly reliable indicator of abnormality. In cachectic patients with dysphagia and malnutrition, the mediastinal fat plane may be virtually absent, making local invasion difficult to assess. Thin-slice CT permits structures such as lymph nodes to be adequately imaged, down to a minimum diameter of about 5 mm. Smaller nodes cannot be reliably visualised, and it is not possible to distinguish between enlarged lymph nodes that have reactive changes only and metastatic nodes. Similarly, micrometastases within normal-sized nodes cannot be detected.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) does not expose the patient to ionising radiation and needs no intravascular contrast medium, although intraoesophageal air or contrast media may help to assess wall thickness. Distant metastases to organs such as the liver are usually reliably identified by MRI but, at the moment, there do not seem to be additional benefits over CT.

ENDOSCOPIC ULTRASONOGRAPHY

After haematogenous spread, the two principal prognostic factors for oesophageal cancer are the depth of tumour penetration through the oesophageal wall and regional lymph node spread. Although CT will detect distant metastasis, its limited axial resolution precludes a reliable assessment of both the depth of wall penetration and lymph node involvement. Endoscopic ultrasonography (EUS) can determine the depth of spread of a malignant tumour through the oesophageal wall (T1–3), the invasion of adjacent organs (T4) and metastasis to lymph nodes (N0 or N1) (**Figures 62.47–62.49**). It can also detect contiguous spread downward into the cardia and more distant metastases to the left lobe of the liver.

EUS visualises the oesophageal wall as a multilayered structure. The layers represent ultrasound interfaces rather than true anatomical layers, but there is close enough correlation to allow accurate assessment of the depth of invasion through the oesophageal wall. Structures smaller than 5 mm can be clearly seen, enabling very small nodes to be imaged. The EUS image morphology of such structures provides an additional means of distinguishing malignant from reactive or benign lymph nodes. For submucosal lesions, EUS can demonstrate the wall layer of origin of a lesion, suggesting the likely histological type.

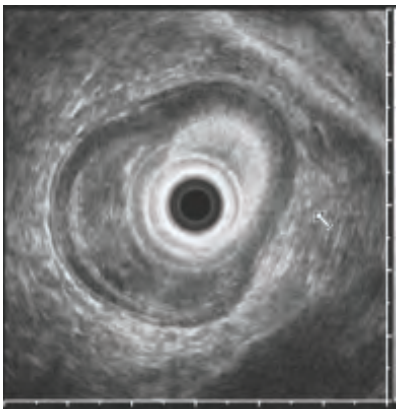

Figure 62.47 Endosonography demonstrating an 'early' tumour. Note the preservation of the outer dark wall layer that represents the muscle coat.

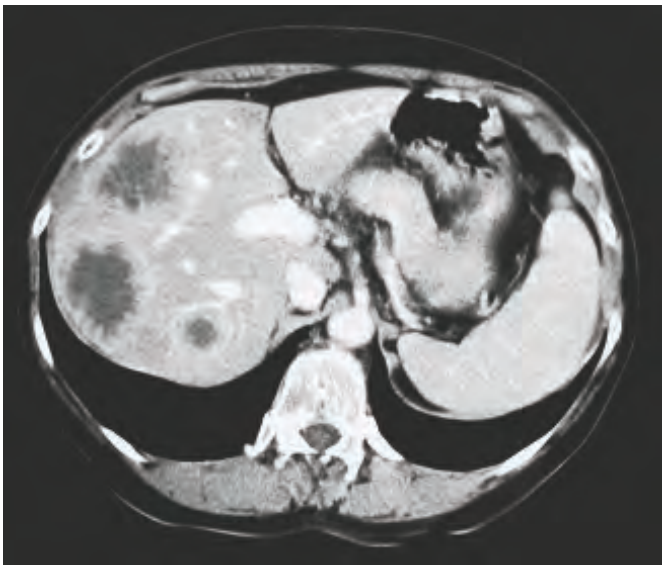

Figure 62.46 Computed tomography scan demonstrating liver metastases.

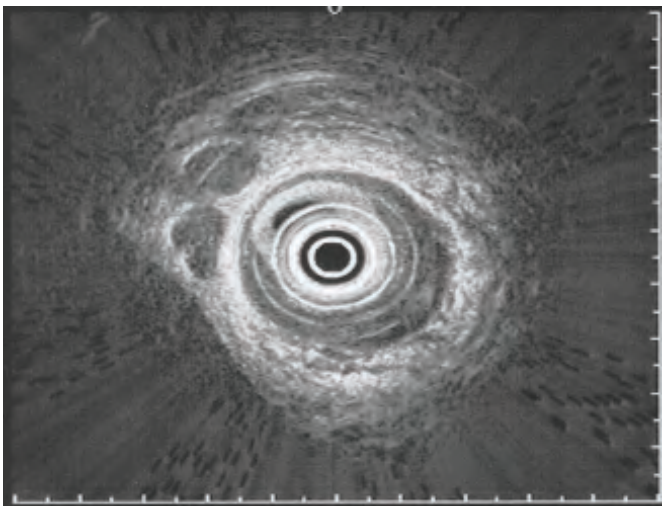

Figure 62.48 Endosonography demonstrating an 'advanced' local tumour. Note the breach of the outer white line that represents the interface between the oesophageal wall and the mediastinum.

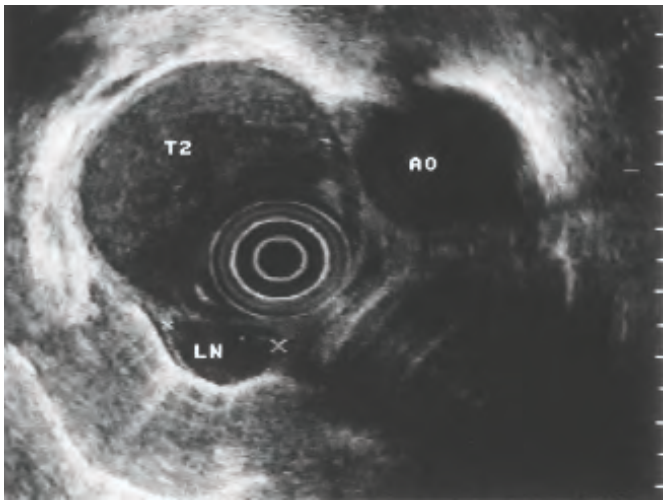

Figure 62.49 Endosonography demonstrating malignant nodes. These are usually large, hypoechoic and round compared with normal nodes.

Narrow EUS instruments are available for insertion over a guidewire to minimise the risk of technical failure, and linear array echoendoscopes can be used to biopsy lesions that might signify incurability outside the wall of the GI tract which might be considered to lie outside the proposed field of resection (usually lymph nodes outside a standard field).

Positron emission tomography with CT

Positron emission tomography (PET) with CT (PET-CT) in the context of cancer staging relies on the generally high metabolic activity (particularly in the glycolytic pathway) of tumours compared with normal tissues. The patient is given a small dose of the radiopharmaceutical agent [^{18}F]fluorodeoxyglucose (FDG). This enters cells and is phosphorylated. FDG 6-phosphate cannot be metabolised further and, as it is a highly polar molecule, it cannot easily diffuse back out of the cell. After intravenous injection of FDG, it continuously accumulates in metabolically active cells. Primary oesophageal cancers are usually sufficiently active to be easily visible, and spatial resolution of positive PET areas occurs down to about 5–8 mm. When used in isolation, there are problems with the anatomical location of these areas. This has been significantly improved by combining PET with CT (**Figure 62.50**), which covers the whole body. The main value of PET-CT is the identification of distant metastatic disease not seen on CT alone. Although there are wide variations between centres, a change in stage is frequently reported in around 15% of patients, but the timing of the scan in relation to the last date of treatment is important and probably accounts for differences in perceived effect. It has also been suggested that a reduction in PET activity after chemotherapy might be a way of predicting 'responders' to this approach, although the persistence of PET activity after a neoadjuvant treatment seems to be a poor prognostic sign.

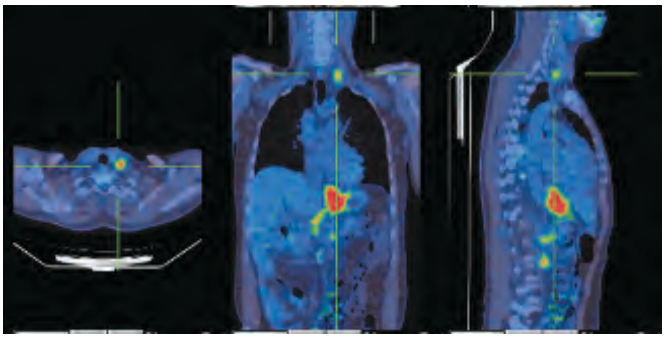

Figure 62.50 Positron emission tomography/computed tomography demonstrating a primary tumour and a distant metastatic node.

Treatment of malignant tumours

PRINCIPLES

At the time of diagnosis, around two-thirds of all patients with oesophageal cancer will already have incurable disease. The aim of palliative treatment is to overcome debilitating or distressing symptoms while maintaining the best quality of life possible for the patient. Some patients do not require specific therapeutic interventions, but do need supportive care and appropriate liaison with community nursing and hospice care services.

As dysphagia is the predominant symptom in advanced oesophageal cancer, the principal aim of palliation is to restore adequate swallowing. A variety of methods is available and, given the short life expectancy of most patients, it is important that the choice of treatment should be tailored to each individual. Tumour location and endoscopic appearance are important in this regard, as is the general condition of the patient.

Once oesophageal neoplasms reach the submucosal layer of the oesophagus, the tumour has access to the lymphatic system, meaning that, even at this early local stage, there is an incidence of nodal positivity for both squamous cell carcinoma and adenocarcinomas of about 20%. The principle of oesophagectomy is to deal adequately with the local tumour in order to minimise the risk of local recurrence and achieve an adequate lymphadenectomy to reduce the risk of staging error. Although studies in Japan would indicate that more extensive lymphadenectomy is associated with better survival, this may simply reflect more accurate staging. A number of studies support the view that the proximal extent of resection should ideally be 10 cm above the macroscopic tumour and 5 cm distal. When such a margin cannot be achieved proximally, particularly with squamous cell carcinoma, there is evidence that postoperative radiotherapy can minimise local recurrence, although this does not improve survival.

Adenocarcinoma commonly involves the gastric cardia and may therefore extend into the fundus or down the lesser curve. Some degree of gastric excision is essential in order to achieve adequate local clearance and accomplish an appropriate lymphadenectomy. Excision of contiguous structures, such as the crura, diaphragm and mediastinal pleura, needs to be considered as a method of creating negative resection margins.

The rarity of intramucosal cancer in symptomatic patients means that there are no randomised studies to compare different approaches to this type of very early disease. EMR for these apparently early (T1a) lesions has become increasingly popular, providing either a cure or at least sufficient histological information on which to base a further management strategy.

Surgery alone is best suited to patients with disease confined to the oesophagus (T1b, T2) without nodal metastasis (N0). The problem here is ensuring that patients are truly node negative. Despite careful preoperative investigation, these patients are not easily identified and so there is an argument for neoadjuvant therapy followed by surgery. A cure rate for the patient who is truly node negative having surgery alone of between 50% and 80% needs to be balanced against adverse events related to neoadjuvant therapy, the likelihood of response and the potential impact on survival. Patients with more advanced stages of disease require either multimodal approaches or entry into appropriate trials.

It is essential that oesophagectomy should be performed with a low hospital mortality and complication rate. Patient selection, volume and experience of the surgical team are all important. Preoperative risk analysis has shown that this can play a major part in reducing hospital mortality. There are really no circumstances in the western world in which surgery should be undertaken if it is not part of an overall treatment plan aimed at cure.

Summary box 62.12

Treatment of carcinoma of the oesophagus

- Radical oesophagectomy is the most important aspect of curative treatment
- Neoadjuvant treatments before surgery may improve survival in a proportion of patients
- Chemoradiotherapy alone may cure selected patients, particularly those with squamous cell cancers
- Useful palliation may be achieved by chemo-/radiotherapy or endoscopic treatments

Treatments with curative intent

SURGERY

Histological tumour type, location and the extent of the proposed lymphadenectomy all influence the surgical approach. This is largely an issue of surgical preference, although it should be recognised that a left thoracoabdominal approach is limited proximally by the aortic arch and should be avoided when the primary tumour is at or above this level. Similarly, transhiatal oesophagectomy is unsuitable for most patients with squamous cell carcinoma because a complete mediastinal lymphadenectomy is not easily achieved by this approach. The most widely practised approach in the west is the two-phase Ivor Lewis (sometimes called Lewis–Tanner) operation (Figure 62.51), with an initial laparotomy and construction of a gastric tube, followed by a right thoracotomy to excise the tumour and create an oesophagogastric anastomosis. The closer this is placed to the apex of the thoracic cavity, the fewer problems there are with reflux disease. Three-phase oesophagectomy (McKeown) may be more appropriate for more proximal tumours in order to achieve better longitudinal clearance, although the additional distance gained is less than many surgeons believe. A third cervical incision also permits lymphadenectomy in this region.

The extent of lymphadenectomy is highly controversial. For squamous cell carcinoma, because a higher proportion of patients will have middle- and upper-third tumours in the thoracic oesophagus, the rationale behind a three-phase operation with three-field lymphadenectomy is more understandable, even though this approach has not been widely adopted in the west. For adenocarcinoma, the incidence of metastases in the neck is relatively low in the context of patients who would otherwise be curable. For this reason, two-phase operations with two-field lymphadenectomy seem the most logical operations. Although two-field lymphadenectomy does not substantially increase surgical morbidity or mortality, the same cannot be said for more extended operations.

Minimal access techniques, pioneered in Australia by Gotley and Smithers and in North America by Luketich, have enjoyed increasing popularity, often combined with enhanced recovery programmes after surgery (ERAS). Hybrid (where at least one phase is performed as open surgery), total minimally invasive and robotic oesophagectomy all have their advocates, although there are no high-quality comparative studies and little evidence to indicate clear superiority of one approach

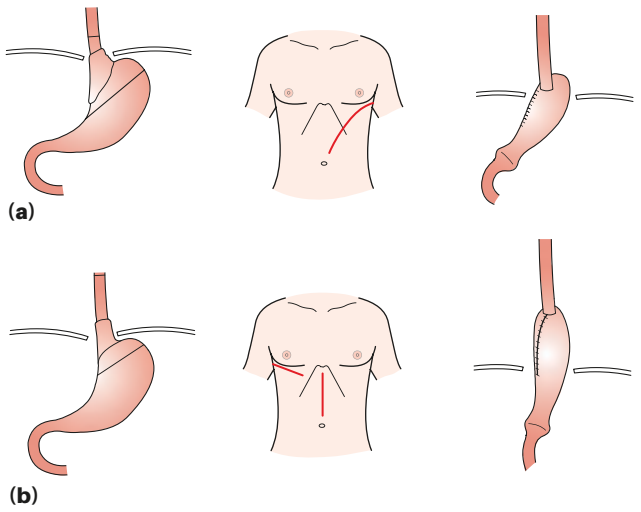

Figure 62.51 The two usual approaches for surgery of the oesophagus are **(a)** the thoracoabdominal, which opens the abdominal and thoracic cavities together, and **(b)** the two-stage Ivor Lewis approach, in which the abdomen is opened first, closed and then the thoracotomy is performed. In the McKeown operation, a third incision in the neck is made to complete the cervical anastomosis.

Ivor Lewis, 1895–1982, surgeon, the North Middlesex Hospital, London, UK, and later at Rhyl, North Wales, UK.
Norman Cecil Tanner, 1906–1982, surgeon, Charing Cross Hospital, London, UK.
Kenneth Charles McKeown, 1912–1995, surgeon, Darlington Memorial Hospital, Darlington, County Durham, UK.

over the others. In experienced hands, the open operation can be reproduced by less invasive approaches, without significant compromise. Many groups have reported similar lymph node yields and rates of resection margin positivity with open and minimal access approaches. As yet, benefits seem to be confined to reduced wound pain and the absence of specific complications associated with long incisions.

Although many centres have reduced hospital mortality to low single figures after oesophagectomy, the complication rate remains high. At least a third of all patients will develop some significant complication after surgery. The most common of these is respiratory, followed by anastomotic leakage, chylothorax and injury to the recurrent laryngeal nerves. The most common late problem is benign anastomotic stricture, which seems to be higher with cervical rather than with intrathoracic anastomoses, although the problem is usually easily dealt with by endoscopic dilatation.

Lesions of the cardia that do not involve the oesophagus to any significant extent may be dealt with by extended total gastrectomy to include the distal oesophagus, or by proximal gastrectomy and distal oesophagectomy.

Summary box 62.13

Oesophagogastric surgery

- Beware of satellite nodules proximal to the primary lesion
- Carefully preserve the blood supply of the stomach, both venous and arterial
- Right thoracic approach gives easy access to the oesophagus

TWO-PHASE OESOPHAGECTOMY (ABDOMEN AND RIGHT CHEST, IVOR LEWIS)

Mobilisation of the stomach must be done with care because it is essential to have a tension-free, well-vascularised stomach for transposition. The left gastric, short gastric and left gastroepiploic arteries are all divided. The viability of the transposed stomach mainly depends on the right gastroepiploic and, to a lesser extent, the right gastric vessels. It should be noted that venous drainage is as important as arterial supply, and it is essential to perform an accurate anatomical dissection that preserves the right gastroepiploic vein as well as the artery. The stomach is divided to remove the cardia and the upper part of the lesser curve, including the whole of the left gastric artery and its associated lymph nodes.

The approach to the oesophagus through the right chest is straightforward, providing excellent access to the mediastinum, the thoracic inlet and the hiatus. The azygos vein is divided, and the whole of the intrathoracic oesophagus can be mobilised along with the thoracic duct (which is ligated by most surgeons) and the mediastinal lymph nodes. The oesophagus is divided just below the thoracic inlet. As most lesions are in the lower or middle third, this usually gives adequate proximal clearance of at least 5 cm. Carcinomas of the upper thoracic oesophagus are almost always incurable at the time of diagnosis, and invasion of the trachea is common. If one of these lesions is resectable, it is essential to use an incision in the neck (McKeown or three-phase operation) and to resect more of the oesophagus than is customary in the operation of subtotal oesophagectomy.

Oesophagogastric anastomosis may be performed equally well by hand or stapler. Both methods require attention to detail. In experienced hands, clinical anastomotic leakage should be less than 10%. Most surgeons still prefer to keep patients nil by mouth for 5–7 days. Most centres have abandoned the use of routine contrast swallows in patients who are clinically well. Conversely, aggressive investigation of a suspected leak is mandatory for any unexplained fever or clinical event. This should involve early endoscopy, which has been shown to be safe and is the most reliable method for identifying necrosis in any part of the replacement conduit and/or CT scan to resolve the situation adequately.

Postoperative nutritional support remains controversial. There is general agreement that parenteral feeding is associated with more nosocomial infection, including pneumonia, than enteral feeding. It is also expensive. The simplicity of placing a modern feeding jejunostomy device at the time of resection means that this is in routine use in many centres.

TRANSHIATAL OESOPHAGECTOMY (WITHOUT THORACOTOMY)

This approach was popularised for cancer by Orringer, adapting a technique developed in Brazil by Pinotti for the removal of chagasic megaoesophagus (see the section on achalasia, p. 1095). The stomach is mobilised through a midline abdominal incision or by laparoscopy, and the cervical oesophagus is mobilised through an incision in the neck. The diaphragm is then opened from the abdomen, and the posterior mediastinum is entered. The lower oesophagus and the tumour are mobilised under direct vision, and the upper oesophagus is mobilised by blunt dissection. This approach can provide an adequate removal of the tumour and lymph nodes in the lower mediastinum, but it is not possible to remove the nodes in the middle or upper mediastinum. It may be a useful procedure for lesions of the lower oesophagus, but is hazardous for a middle third lesion that may be adherent to the bronchus or to the azygos vein.

NEOADJUVANT TREATMENTS WITH SURGERY

Apart from the earliest stages of disease, surgery alone produces relatively few cures in either squamous cell carcinoma or adenocarcinoma patients. This led to a number of trials throughout the 1980s and 1990s to investigate the value of chemotherapy and surgery or chemoradiotherapy and surgery compared with surgery alone. Some studies relate only to squamous cell cancer, and many are open to criticism on the grounds of trial design or patient numbers. Nevertheless,

Mark Burton Orringer, surgeon, Ann Arbor, MI, USA.
Walter Pinotti, Professor of Surgery, Sao Paulo, Brazil.
Carlos Justiniano Ribeiro Chagas, 1879–1934, Director of the Oswaldo Cruz Institute and Professor of Tropical Medicine, the University of Rio de Janeiro, Brazil.

positive results in favour of neoadjuvant therapy for adenocarcinoma in two large studies as well as a limited meta-analysis indicated that it was no longer appropriate to consider surgery alone as the 'gold standard' treatment for most patients who are surgical candidates with adenocarcinoma. The Dutch trial (CROSS) that compared chemoradiotherapy and surgery versus surgery alone has provided the most convincing evidence so far of survival benefit for squamous cell carcinoma. The same study was initially unable to show a survival benefit for adenocarcinomas, although subsequent analyses again suggested survival benefit of similar magnitude to that seen with chemotherapy and surgery.

GASTRO-OESOPHAGEAL REFLUX FOLLOWING OESOPHAGOGASTRIC RESECTION

Gastro-oesophageal reflux may be a major problem after any operation that involves resecting the cardia. Reflux may present with the typical symptoms of GORD or with a peptic stricture at the site of the anastomosis. However, the presentation may be different with a miserable patient who fails to thrive after the operation and who is then suspected of having recurrent cancer. This atypical presentation is particularly common after total gastrectomy with an inadequate reconstruction that allows bile reflux.

Summary box 62.14

Postoesophagectomy

- Reflux may be a problem after resection
- Symptoms may be atypical
- Reflux may be limited or avoided by subtotal oesophagectomy and gastric transposition high in the chest

Non-surgical treatments

Radiotherapy alone was widely used as a single-modality treatment for squamous cell carcinoma of the oesophagus until the late 1970s. The 5-year survival overall rate was 6%. As a result, multimodal approaches were adopted throughout the 1980s, initial trials indicating that similar long-term survival rates could be obtained with surgery. Subsequent randomised studies, essentially confined to patients with squamous cell carcinoma, have indicated significant survival advantages with chemoradiotherapy over radiotherapy alone. Although it is clear that chemoradiotherapy does offer a prospect of cure for patients who may not be fit for surgery, particularly in squamous cell carcinoma, the high rate of locoregional failure has meant that surgery remains the mainstay of attempted curative treatments for both adenocarcinoma and squamous cell carcinoma in patients who have potentially resectable disease and are fit for oesophagectomy. In most western series, this represents about a third of patients with adenocarcinoma and a slightly lower percentage of patients with squamous cell carcinoma. There has been no high-quality randomised comparison of the results of definitive radiotherapy versus chemoradiotherapy and surgical resection, and it is therefore impossible to make dogmatic statements about the relative merits of each form of treatment.

Summary box 62.15

Alternative therapeutic approaches

- Chemoradiotherapy may be a useful alternative to surgery, especially in unfit patients

Palliative treatment

Surgical resection and external beam radiotherapy may be used for palliation, but are not suitable when the expected survival is short, because most of the remainder of life will be spent recovering from the 'treatment'. Surgical bypass is likewise too major a procedure for use in a patient with limited life expectancy. A variety of relatively simple methods of palliation is now available that will produce worthwhile relief of dysphagia with minimal disturbance to the patient.

Summary box 62.16

Palliation

- Palliation should be simple and effective

Intubation has been used for many years after the invention of the Souttar tube, which was made of coiled silver wire. A variety of rigid plastic or rubber tubes had been developed for placement under endoscopic and/or radiological control. The technology of intubation has now moved on with the development of various types of expanding metal stent (**Figure 62.52**). These are also inserted under radiographic or endoscopic control. The stent is collapsed during insertion and released when it is in the correct position. Expanding stents produce a wider lumen for swallowing than rigid tubes. More importantly, it is not necessary to dilate the oesophagus to beyond 8 mm to insert the unexpanded stent through the tumour, so there is a lower risk of injury to the oesophagus.

Endoscopic laser treatment may be used to core a channel through the tumour. It is based on thermal tumour destruction. It produces a worthwhile improvement in swallowing, but has the disadvantage that it has to be repeated every few weeks. Lasers may also be used to unblock a stent that has become occluded by tumour overgrowth. Other endoscopic

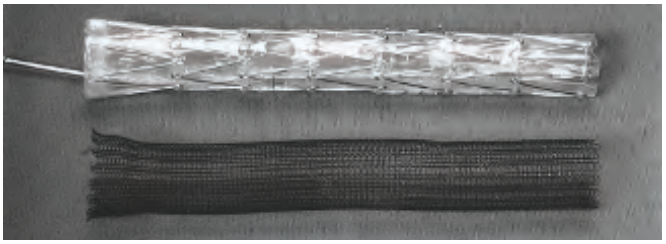

Figure 62.52 Expanding metal stents, covered and uncovered.

Sir Henry Sessions Souttar, 1875–1964, surgeon, the London Hospital, London, UK.

methods include bipolar diathermy, argon-beam plasma coagulation and alcohol injection.

Brachytherapy is a method of delivering intraluminal radiation with a short penetration distance (hence the prefix 'brachy') to a tumour. An introduction system is inserted through the tumour, and the treatment is then delivered in a single session lasting approximately 20 minutes. The equipment is expensive to purchase, but running costs are low.

Although the above methods are suitable for patients with very advanced disease, elderly people and those with significant comorbidities that would make more aggressive strategies inappropriate, an increasing proportion of patients (particularly with adenocarcinoma) are being treated with platinum-based chemotherapy. In general, this leads to only a modest prolongation of survival but a better quality of life than in those receiving an endoscopic treatment alone.

Malignant tracheo-oesophageal fistula

Malignant tracheo-oesophageal fistula is a sign of incurable disease. Some have advocated surgical bypass and oesophageal exclusion, but this is a major procedure. An expanding metal stent is probably the best treatment.

Post-cricoid carcinoma

Post-cricoid carcinoma is considered in Chapter 47.

MOTILITY DISORDERS AND DIVERTICULA

Oesophageal motility disorders

A motility disorder can be readily understood when a patient has dysphagia in the absence of a stricture, and a barium-impregnated food bolus is seen to stick in the oesophagus. If this can be correlated with a specific abnormality on oesophageal manometry, accepting that this is the cause of the patient's symptoms may be straightforward. Unfortunately, this is often not the case. Pain, with or without a swallowing problem, is frequently the dominant symptom, and patients often undergo extensive hospital investigation before the oesophagus is considered as a source of symptoms. Symptoms are often intermittent, and the correlation between symptoms and test 'abnormalities' is poor. Confirmation of a specific motility disturbance is made by high-resolution manometry. Much harm may be done by inappropriate enthusiastic surgery for ill-defined conditions. It should also be remembered that oesophageal dysmotility may be only a feature of a general disturbance in GI function.

Summary box 62.17

Oesophageal motility disorders

- May be part of a more diffuse GI motility problem
- May be associated with GORD

Oesophageal motility disorders are currently best classified by incorporation of the Chicago classification developed for use with high-resolution manometry as shown in *Tables 62.3 and 62.4*.

Functional pain and the oesophagus

Pain that is assumed to arise from dysfunction of the GI tract may reflect abnormal motor activity, abnormal perception or a combination of the two. There is evidence that all three exist. Very high-pressure uncoordinated contractions ('spasm') have been shown to correlate with pain. Distension of a balloon in the oesophagus indicates that some patients have a low threshold for the sensation of pain (visceral hypersensitivity), and this itself may reflect local or central neuronal dysfunction. In practice, the difficulty is in understanding the relative contributions of these elements, so that a logical treatment might follow.

Achalasia

Pathology and aetiology

Achalasia (Greek 'failure to relax') is uncommon, but merits prominence because it is reasonably understood and responds to treatment. It is due to loss of the ganglion cells in the myenteric (Auerbach's) plexus, the cause of which is unknown. In South America, chronic infection with the parasite *Trypanosoma cruzi* causes Chagas' disease, which has marked clinical similarities to achalasia. Achalasia differs

TABLE 62.3 General classification of oesophageal motility disorders.

Disorders of the pharyngo-oesophageal junction
Neurological – stroke, motor neuron disease, multiple sclerosis, Parkinson's disease
Myogenic – myasthenia, muscular dystrophy
Pharyngo-oesophageal (Zenker's) diverticulum
Disorders of the body of the oesophagus
Diffuse oesophageal spasm
Nutcracker oesophagus
Autoimmune disorders – especially systemic sclerosis (CREST)
Reflux associated
Idiopathic
Allergic
Eosinophilic oesophagitis
Non-specific oesophageal dysmotility
Disorders of the lower oesophageal sphincter
Achalasia
Incompetent lower sphincter (i.e. GORD)

CREST, calcinosis, Raynaud's syndrome, (o)esophageal motility disorders, sclerodactyly and telangiectasia.
GORD, gastro-oesophageal reflux disease.

TABLE 62.4 The Chicago Classification of oesophageal motility v3.0.

Achalasia and EGJ outflow obstruction	Criteria
Type I achalasia (classic achalasia)	Elevated median IRP (>15 mmHg), 100% failed peristalsis (DCI <100 mmHg·s·cm) *Premature contractions with DCI values* <450 mmHg·s·cm *satisfy criteria for failed peristalsis*
Type II achalasia (with oesophageal compression)	Elevated median IRP (>15 mmHg), 100% failed peristalsis, panoesophageal pressurisation with ≥20% of swallows *Contractions may be masked by oesophageal pressurisation and DCI should not be calculated*
Type III achalasia (spastic achalasia)	Elevated median IRP (>15 mmHg), no normal peristalsis, premature (spastic) contractions with DCI >450 mmHg·s·cm with ≥20% of swallows *May be mixed with panoesophageal pressurisation*
EGJ outflow obstruction	Elevated median IRP (>15 mmHg), sufficient evidence of peristalsis such that criteria for types I–III achalasia are not met
Major disorders of peristalsis	(Not encountered in normal individuals)
Absent contractility	Normal median IRP, 100% failed peristalsis *Achalasia should be considered when IRP values are borderline and when there is evidence of oesophageal pressurisation* *Premature contractions with DCI values* <450 mmHg·s·cm *meet criteria for failed peristalsis*
Distal oesophageal spasm	Normal median IRP, ≥20% premature contractions with DCI >450 mmHg·s·cm. Some normal peristalsis may be present
Hypercontractile oesophagus (jackhammer)	At least two swallows with DCI >8000 mmHg·s·cm *Hypercontractility may involve, or even be localised to, the LES*
Minor disorders of peristalsis	(Characterised by contractile vigour and contraction pattern)
Ineffective oesophageal motility (IEM)	≥50% ineffective swallows *Ineffective swallows can be failed or weak (DCI <450 mmHg·s·cm)* *Multiple repetitive swallow assessment may be helpful in determining peristaltic reserve*
Fragmented peristalsis	≥50% fragmented contractions with DCI >450 mmHg·s·cm
Normal oesophageal motility	Not fulfilling any of the above classifications

DCI, distal contractile integral (mmHg·s·cm); EGJ, o(e)sophaogastric junction; IRP, integrated relaxation pressure (mmHg); LES, lower o(e)sophageal sphincter. (From Kahrilas PJ *et al*. The Chicago Classification of esophageal motility disorders v3.0. *Neurogastroenterology and Motility* 2015; **27**(2): 160–74, with kind permission, John Wiley & Sons.)

from Hirschsprung's disease of the colon because the dilated oesophagus usually contains few ganglion cells, whereas the dilated colon contains normal ganglion cells proximal to a constricted, aganglionic segment. Histology of muscle specimens generally shows a reduction in the number of ganglion cells (and mainly inhibitory neurons) with a variable degree of chronic inflammation. When powerful non-peristaltic contractions are still present, perhaps representing an early stage of the disease, inflammation and neural fibrosis may be seen with normal numbers of ganglion cells.

Summary box 62.18

Achalasia

- Is uncommon
- Is due to selective loss of inhibitory neurons in the lower oesophagus
- The causes dysphagia and carcinoma must be excluded
- Treatment is by either endoscopic dilatation, or endoscopic or surgical myotomy

The classic physiological abnormalities are a non-relaxing LOS and absent peristalsis in the body of the oesophagus. The Chicago classification identifies three variants. Although most patients have almost no recognisable contractions (type I), some patients continue to exhibit pressurisation throughout the oesophagus (type 2), whereas in others the oesophagus is of normal calibre and exhibits high-pressure contractile (although non-peristaltic) activity (spastic oesophagus, vigorous achalasia). In some patients, these uncoordinated contractions result in pain as much as a sense of food sticking. High-resolution manometry recognises these contraction patterns, which may be important in predicting the outcome of treatment. With time, the oesophagus dilates and contractions disappear, so that the oesophagus empties mainly by the hydrostatic pressure of its contents. This is nearly always incomplete, leaving residual food and fluid. The gas bubble in the stomach is frequently absent, as no bolus with its accompanying normal gas passes through the sphincter. The 'megaoesophagus' becomes tortuous with a persistent retention oesophagitis due to fermentation of food residues (**Figure 62.53**), and this may account for the increased incidence of carcinoma of the oesophagus

Harald Hirschsprung, 1831–1916, physician, the Queen Louise Hospital for Children, and Professor of Paediatrics, Copenhagen, Denmark, described congenital megacolon in 1888.

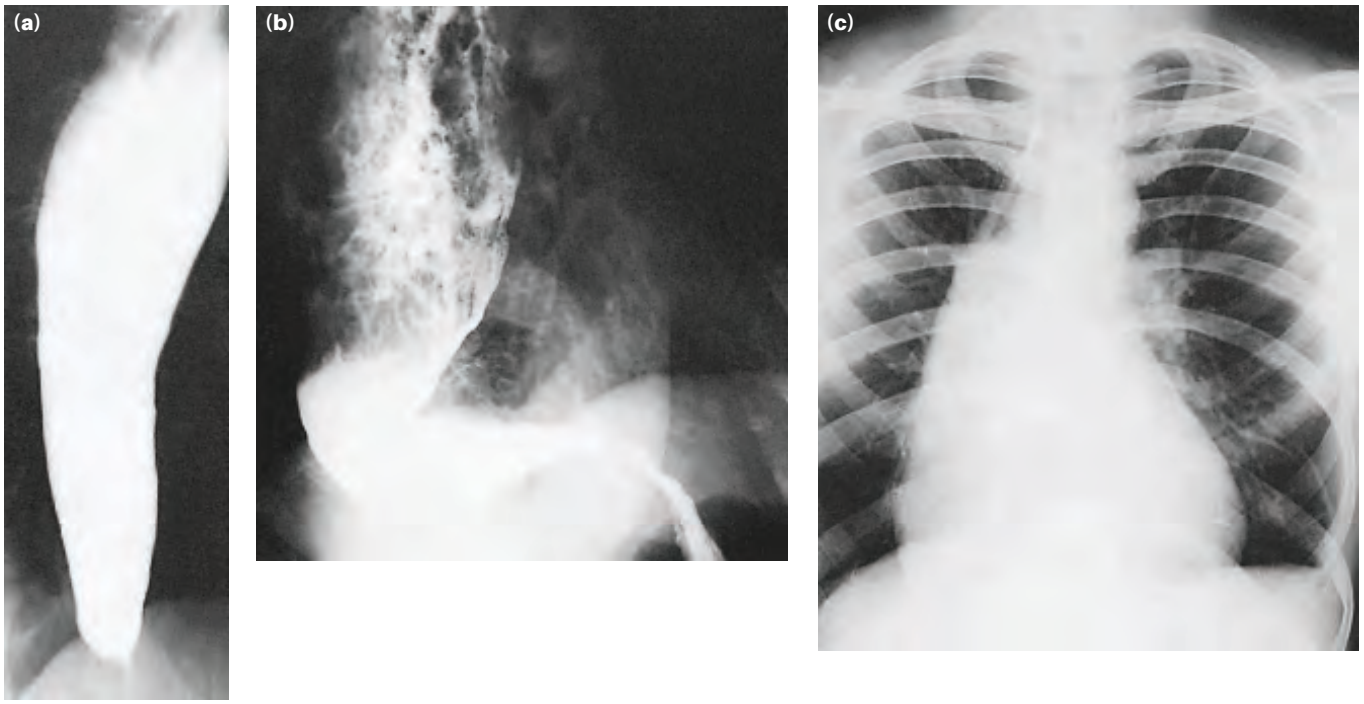

Figure 62.53 Achalasia of the oesophagus. **(a)** Barium swallow showing the smooth outline of the stricture, which narrows to a point at its lower end. **(b)** Tortuosity and sigmoid appearance of the lower oesophagus. **(c)** Mediastinal shadow due to a large, fluid-filled oesophagus.

Summary box 62.19

Lower oesophageal stricture

- Beware pseudoachalasia; look for tumour

Pseudoachalasia is an achalasia-like disorder that is usually produced by adenocarcinoma of the cardia (**Figure 62.54**), but has also been described in relation to benign tumours at this level. It has been presumed that the inability of the sphincter to relax is linked to the loss of body peristalsis, although other cancers outside the oesophagus (bronchus, pancreas) have also been associated with pseudoachalasia.

Clinical features

The disease is most common in middle life, but can occur at any age. It typically presents with dysphagia, although pain (often mistaken for reflux) is common in the early stages. Patients often present late and, having had relatively mild symptoms, remain untreated for many years. Regurgitation is frequent, and there may be overspill into the trachea, especially at night.

Diagnosis

Achalasia may be suspected at endoscopy by finding a tight cardia and food residue in the oesophagus. Barium radiology may show hold-up in the distal oesophagus, abnormal contractions in the oesophageal body and a tapering stricture in the distal oesophagus, often described as a 'bird's beak' (see

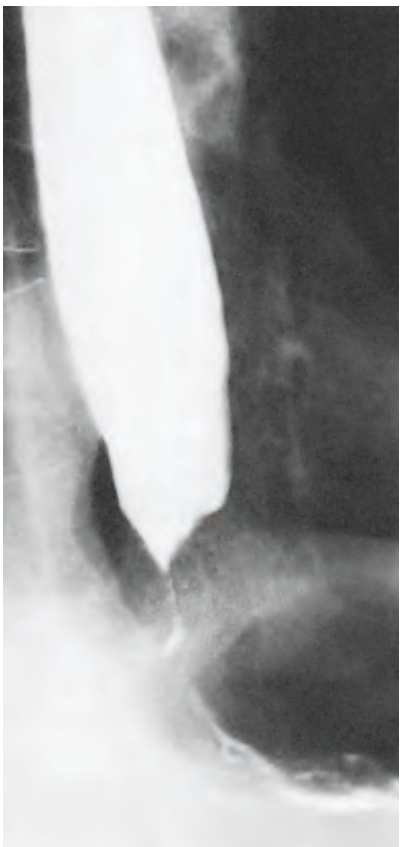

Figure 62.54 Almost achalasia, but note the irregularity of the taper, which indicates carcinoma of the cardia.

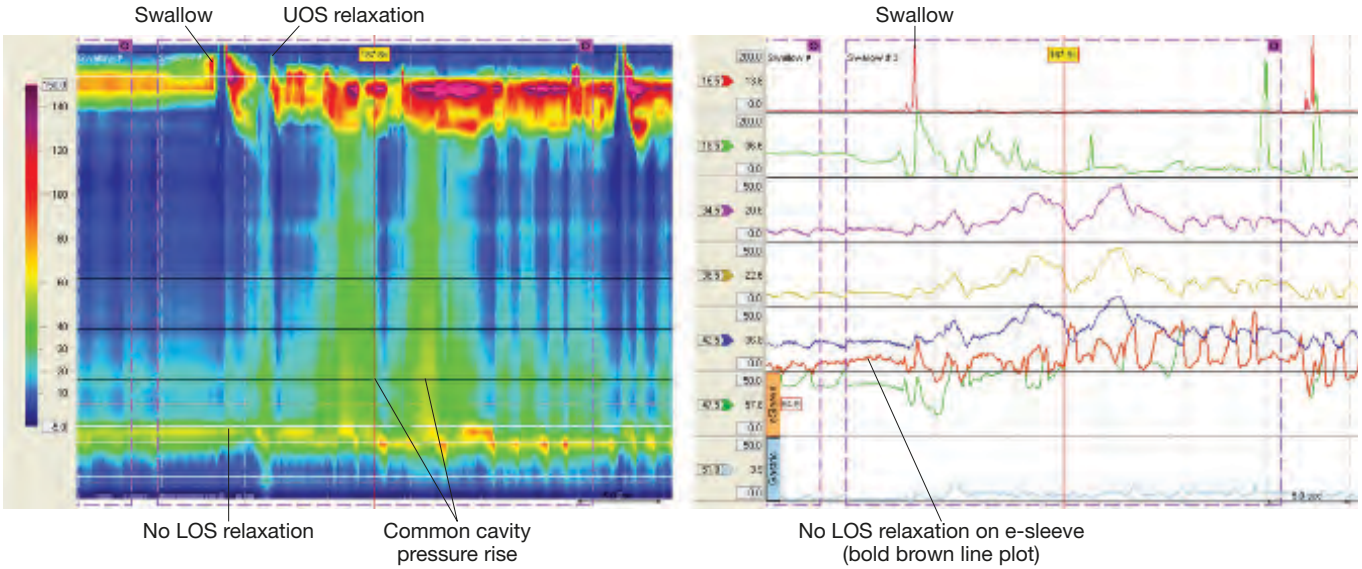

Figure 62.55 High-resolution oesophageal manometry from a patient presenting with dysphagia and regurgitation. The swallow is followed by a common cavity rise in oesophageal pressure indicating filling. Lower oesophageal sphincter (LOS) relaxation is absent and there is a positive oesophagogastric pressure gradient. Upper oesophageal sphincter (UOS) relaxation shortly after the swallow was related to regurgitation of oesophageal contents.

Figure 62.53). The gastric gas bubble is usually absent. These typical features of well-developed achalasia are often absent, and endoscopy and radiology can be normal. A firm diagnosis is established by high-resolution oesophageal manometry. Classically, the LOS does not relax completely on swallowing, there is no peristalsis and there is a raised resting pressure in the oesophagus (Figure 62.55). The LOS pressure may be elevated, but is often normal.

Treatment

Alone among motility disorders, achalasia responds well to treatment. The two main methods are forceful dilatation of the cardia and laparoscopic cardiomyotomy (conventionally performed together with a partial fundoplication), although in recent years there has been growing interest in the use of peroral endoscopic myotomy (POEM). Comparative studies between pneumatic dilatation and surgical myotomy suggest equivalence in terms of safety, effectiveness and cost when considered over a number of years.

PNEUMATIC DILATATION

This involves stretching the cardia with a balloon to disrupt the muscle and render it less competent. The treatment was first described by Plummer. Many varieties of balloon have been used but, nowadays, plastic balloons with a precisely controlled external diameter are used. If the pressure in the balloon is too high, the balloon is designed to split along its length rather than expanding further. Balloons of 30–40 mm in diameter are available and are inserted over a guidewire (Figure 62.56). Perforation is the major complication. With a 30-mm balloon, the incidence of perforation should be less than 0.5%. The risk of perforation increases with bigger balloons, and they should be used cautiously for progressive dilatation over a period of weeks. Forceful dilatation is curative in 75–85% of cases. The results are best in patients aged over 45 years.

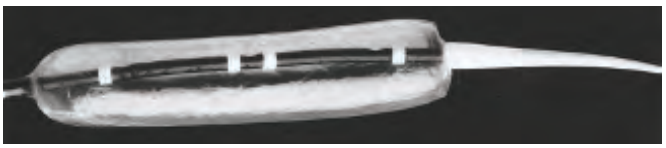

Figure 62.56 Balloon dilator for the treatment of achalasia by forceful dilatation.

Summary box 62.20

Achalasia

- Beware perforation due to dilatation of achalasia
- Beware postoperative reflux

HELLER'S MYOTOMY

This involves cutting the muscle of the lower oesophagus and cardia (Figure 62.57). The major complication is

Henry Stanley Plummer, 1874–1937, physician, the Mayo Clinic, Rochester, MN, USA.
Ernst Heller, 1877–1964, surgeon, St George's Krankenhaus, Leipzig, Germany.

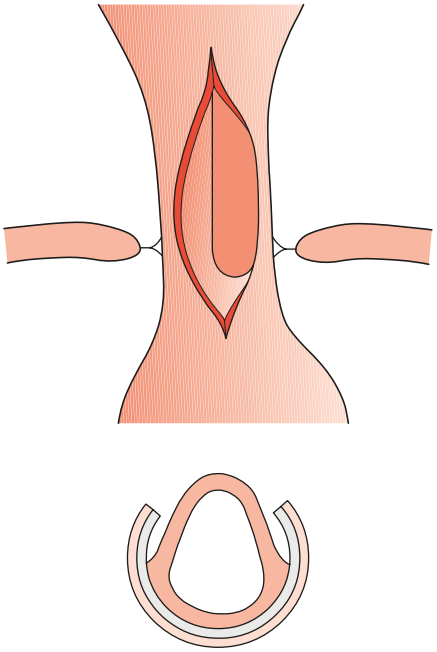

Figure 62.57 Heller's myotomy: the incision should not go too far on to the stomach. The lateral extent must enable the mucosa to pout out, to prevent the edges healing together.

gastro-oesophageal reflux, and most surgeons therefore add a partial anterior fundoplication (Heller–Dor operation). The procedure is ideally suited to a minimal access laparoscopic approach, and most surgeons use intraoperative endoscopy to judge the extent of the myotomy and to ensure that the narrow segment is abolished.

It is successful in more than 90% of cases and may be used after failed dilatation.

ENDOSCOPIC MYOTOMY

This was introduced in Japan in 2009. It involves the creation of a submucosal tunnel in the midoesophagus that can be developed distally, allowing a long myotomy to be performed. The oesophageal mucosal defect is clipped shut at the end. Many cohort studies indicate that the procedure can be performed safely and early clinical results imply equivalence to other approaches.

BOTULINUM TOXIN

This is done by endoscopic injection into the LOS. It acts by interfering with cholinergic excitatory neural activity at the LOS. The effect is not permanent, and the injection usually has to be repeated after a few months. For this reason, its use is restricted to elderly patients with other comorbidities.

DRUGS

Drugs such as calcium channel antagonists have been used but are ineffective for long-term use. However, sublingual nifedipine may be useful for transient relief of symptoms if definitive treatment is postponed.

Other oesophageal motility disorders

Disorders of the pharyngo-oesophageal junction

With the exception of Zenker's diverticulum (see below), most patients with oropharyngeal dysphagia have generalised neurological or muscular disorders with pharyngeal involvement. A small number of patients who have sustained a cerebrovascular accident benefit from myotomy of cricopharyngeus to alleviate pooling of saliva and nocturnal aspiration, but they should have good deglutition and phonation before this is performed. The operation is also effective in patients with oculopharyngeal muscular dystrophy.

Disorders of the body of the oesophagus

The older terms, 'diffuse oesophageal spasm' and 'jackhammer (nutcracker) oesophagus', have been replaced in the Chicago classification. There are, nevertheless, patients with incoordinate contractions of the oesophagus who experience dysphagia and/or chest pain. The condition may be dramatic, with spastic pressures on manometry of 400–500 mmHg, marked hypertrophy of the circular muscle and a corkscrew oesophagus on barium swallow (**Figure 62.58**). These abnormal contractions are more common in the distal two-thirds of the oesophageal body (**Figure 62.59**) and this may have some relevance to treatment. Making the diagnosis when chest pain is the only symptom may be difficult. Prolonged oesophageal manometry that correlates episodes of chest pain with manometric abnormalities may establish the diagnosis.

There is no proven pharmacological or endoscopic treatment. Calcium channel antagonists, vasodilators and endoscopic dilatation have only transient effects. Although the severity and frequency of symptoms may be tolerated by most

Figure 62.58 Corkscrew oesophagus in diffuse oesophageal spasm.

Friedrich Albert Zenker, 1825–1898, Professor of Pathology, Dresden, Germany.

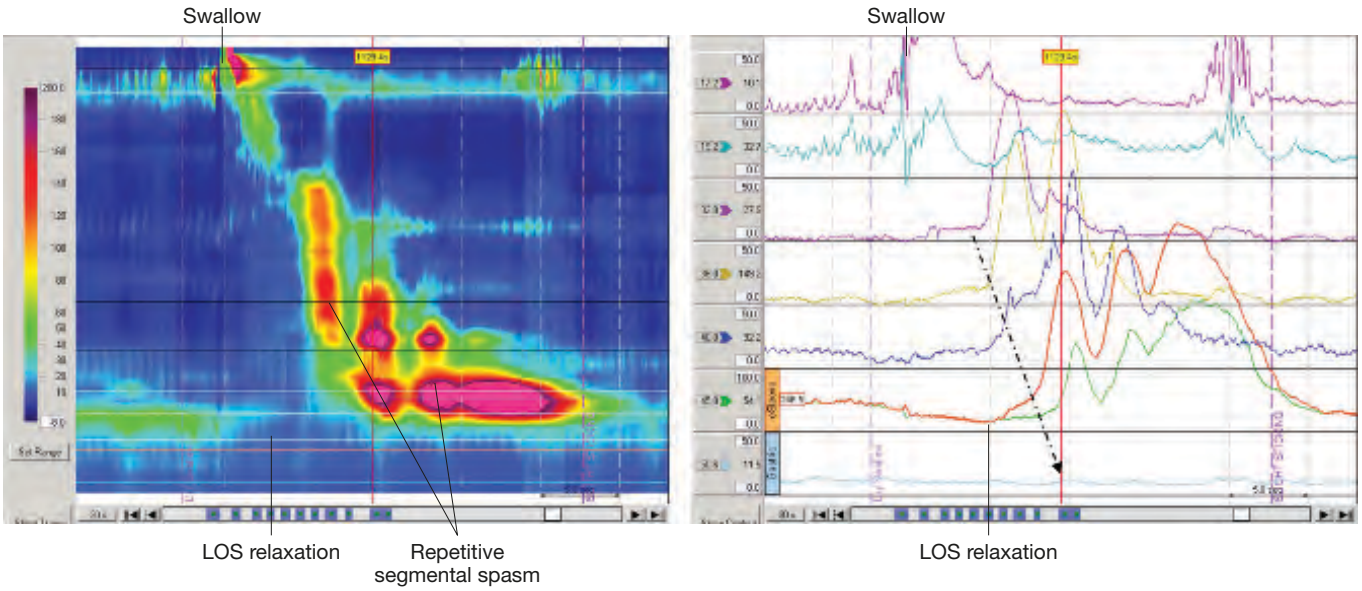

Figure 62.59 High-resolution oesophageal manometry from a patient presenting with dysphagia and chest pain. The swallow is followed by simultaneous, repetitive contractions in the mid-distal smooth muscle oesophagus. Lower oesophageal sphincter (LOS) relaxation is preserved. Note the sequential simultaneous contractions first in the mid- and distal segments of the oesophagus and then in the LOS make it appear as if there is progressive peristalsis on the conventional line plots (dotted arrow). Repetitive contractions are seen clearly on both.

patients, sometimes the combination of chest pain and dysphagia is sufficiently severe that malnutrition begins. In these patients, extended oesophageal myotomy up to the aortic arch may be required. Surgical treatment is more successful in improving dysphagia than chest pain, and caution should be exercised in patients in whom chest pain is the only symptom.

Jackhammer or nutcracker oesophagus is a condition with characteristic high-pressure manometric features (see *Table 62.4*). The correlation of manometric abnormalities with symptoms remains poor.

OESOPHAGEAL INVOLVEMENT IN AUTOIMMUNE DISEASE

Oesophageal involvement is mainly seen in systemic sclerosis, but may be a feature of polymyositis, dermatomyositis, systemic lupus erythematosus, polyarteritis nodosa and rheumatoid disease. Although most involve weak peristalsis, swallowing difficulties may be compounded by pharyngeal problems in the disorders that primarily affect skeletal muscle (e.g. polymyositis) or extraoesophageal problems such as involvement of the cricoarytenoid joint in rheumatoid disease or dry mouth in Sjögren's syndrome. In systemic sclerosis, smooth muscle atrophy causes hypoperistalsis (**Figure 62.60**). The LOS is involved, leading to a loss of the antireflux barrier. A wide range of symptoms can follow from mild to severe dysphagia accompanied by regurgitation and aspiration. Reflux can be severe and is exacerbated by weak acid clearance so that strictures can occur. There are no drugs that specifically correct the motor disorder, and medical treatment is mainly directed at minimising reflux-induced damage with PPIs. A small number of patients may require anti-reflux surgery.

Figure 62.60 Advanced scleroderma of the oesophagus. The oesophagus dilates, and the lower oesophageal sphincter is widely incompetent.

Eosinophilic oesophagitis is a disorder that occurs in children and adults either alone or as a manifestation of

Henrik Samuel Conrad Sjögren, 1899–1986, Professor of Ophthalmology, Gothenburg, Sweden.

eosinophilic gastroenteritis. It is characterised by eosinophilic infiltration of the oesophageal wall, presumably of allergic or idiopathic origin. The most common presenting symptom is dysphagia, and more than half have some history of atopy. The oesophagus often seems narrow and friable on endoscopy and may include mucosal rings. The most important feature is the development of deep ulcers, leading to stricture development, especially in the proximal oesophagus. The diagnosis is established by endoscopic biopsy.

Elimination diets, and topical and systemic steroids all seem to be helpful in the short term, but there is scant information on the long-term impact of any particular approach. Immunotherapy directed against interleukin (IL)-5, which has a major role in eosinophil recruitment, seems to be a promising innovative approach. Although endoscopic dilatation has been recommended, this can create deep ulcers and further scarring, so should be used with caution and only when the above therapies fail.

Pharyngeal and oesophageal diverticula

Most oesophageal diverticula are **pulsion** diverticula that develop at a site of weakness as a result of chronic pressure against an obstruction. Symptoms are mostly caused by the underlying disorder unless the diverticulum is particularly large. Traction diverticula (**Figure 62.61**) are much less common. They are mostly a consequence of chronic granulomatous disease affecting the tracheobronchial lymph nodes due to tuberculosis, atypical mycobacteria or histoplasmosis. Fibrotic healing of the lymph nodes exerts traction on the oesophageal wall and produces a focal outpouching which is usually small and has a conical shape. There may be associated broncholithiasis, and additional complications may occur, such as aerodigestive fistulation (**Figure 62.62**) and bleeding.

Zenker's diverticulum (pharyngeal pouch) is not really an oesophageal diverticulum as it protrudes posteriorly above the cricopharyngeal sphincter through the natural weak point (the dehiscence of Killian) between the oblique and horizontal (cricopharyngeus) fibres of the inferior pharyngeal constrictor (**Figures 62.63 and 62.64**). The exact mechanism that leads to its formation is unknown, but it involves loss of the coordination between pharyngeal contraction and opening of the upper sphincter. When the diverticulum is small, symptoms largely reflect this incoordination with predominantly pharyngeal dysphagia. As the pouch enlarges, it tends to fill with food on eating, and the fundus descends into the mediastinum. This leads to halitosis and oesophageal dysphagia. Treatment can be undertaken endoscopically with a linear cutting stapler to divide the septum between the diverticulum and the upper oesophagus, producing a

Figure 62.61 Midoesophageal traction diverticulum with the mouth facing downwards.

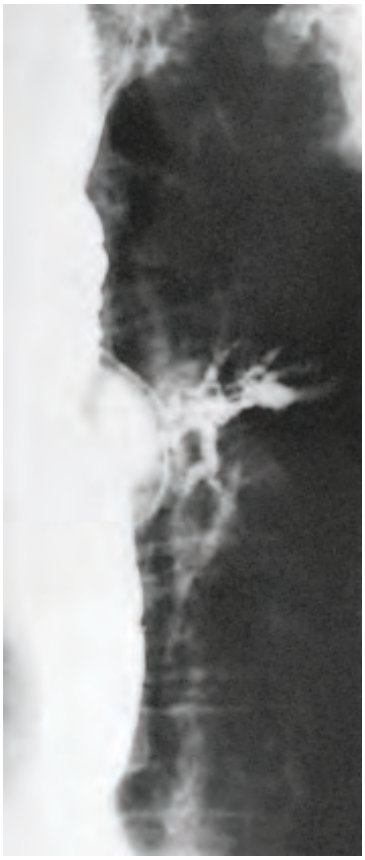

Figure 62.62 Midoesophageal diverticulum with a trachea-oesophageal fistula.

Gustav Killian, 1860–1921, Professor of Laryngology at Freiburg, and later at Berlin, Germany.

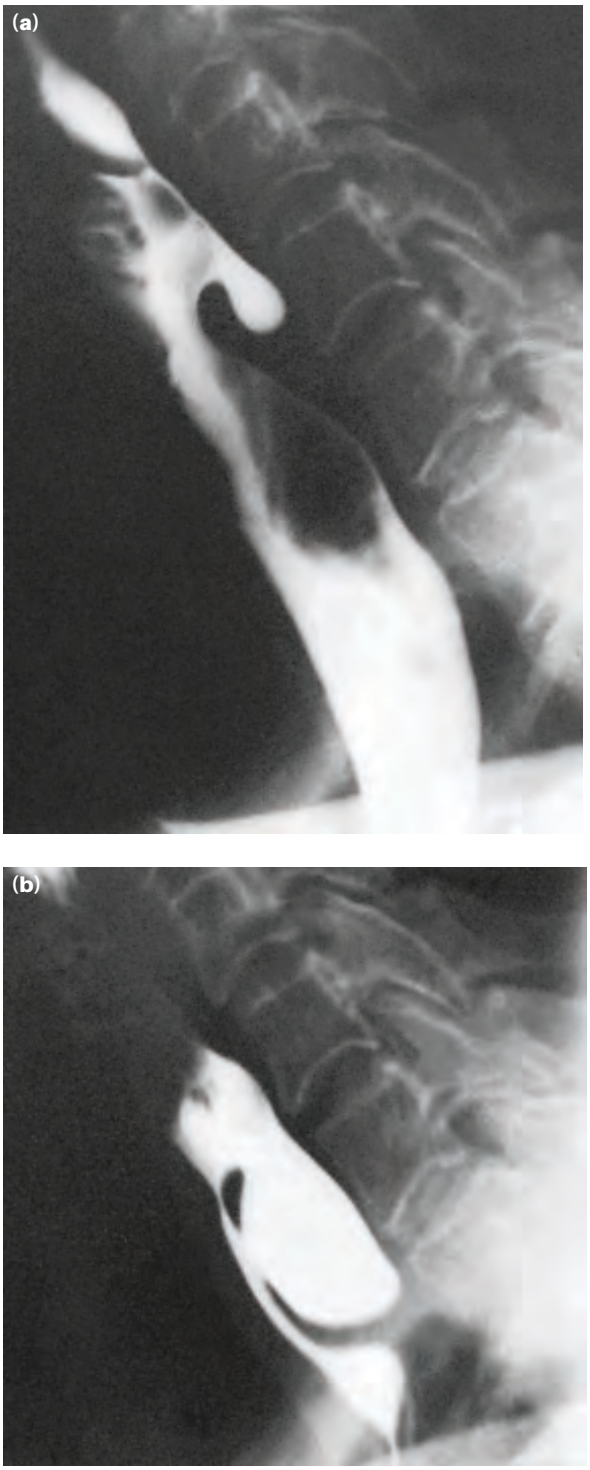

Figure 62.63 The typical appearances of: **(a)** a small pharyngeal pouch with a prominent cricopharyngeal impression and 'streaming' of barium, indicating partial obstruction; and **(b)** a large pouch extending behind the oesophagus towards the thoracic inlet.

diverticulo-oesophagostomy, or can be done by open surgery involving pouch excision, pouch suspension (diverticulopexy) and/or myotomy of cricopharyngeus. All techniques have good results.

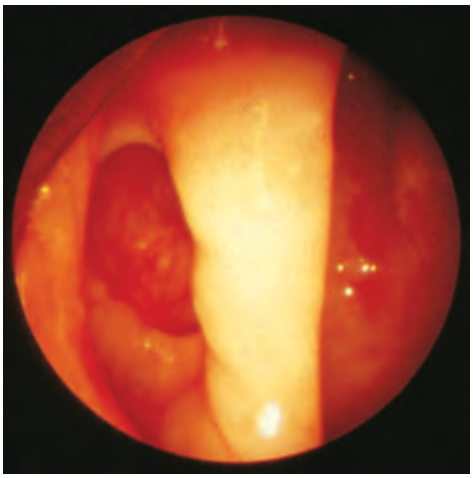

Figure 62.64 The endoscopic appearance of the mouth of a pharyngeal pouch posterior to the normal opening (left) of the oesophagus.

Midoesophageal diverticula are usually small pulsion diverticula of no particular consequence. The underlying motility disorder does not usually require treatment. Some pulsion diverticula may fistulate into the trachea (see **Figure 62.62**), but this is more common with traction diverticula in granulomatous disease.

Epiphrenic diverticula are pulsion diverticula situated in the lower oesophagus above the diaphragm (**Figure 62.65**). They may be quite large, but cause surprisingly few symptoms. They again probably reflect some loss of coordination between an incoming pressure wave and appropriate relaxation of the LOS. This needs to be acknowledged in the surgical management of the patient. The diverticulum, in isolation, should not be assumed to account for a patient's illness just because it looks dramatic on a radiograph. Large diverticula may be excised, and this should be combined with a myotomy from the site of the diverticulum down to the cardia to relieve functional obstruction.

Summary box 62.21

Oesophageal diverticula

- Diverticula are indicators of a motor disorder and not necessarily the cause of symptoms

Diffuse intramural pseudodiverticulosis is a rare condition in which there are multiple tiny outpouchings from the lumen of the oesophagus. The pseudodiverticula are dilated excretory ducts of oesophageal sebaceous glands. It is questionable whether the condition produces any symptoms in its own right.

OTHER NON-NEOPLASTIC CONDITIONS

Schatzki's ring

Schatzki's ring is a circular ring in the distal oesophagus (**Figure 62.66**), usually at the squamocolumnar junction. The

Richard Schatzki, 1901–1992, American radiologist.

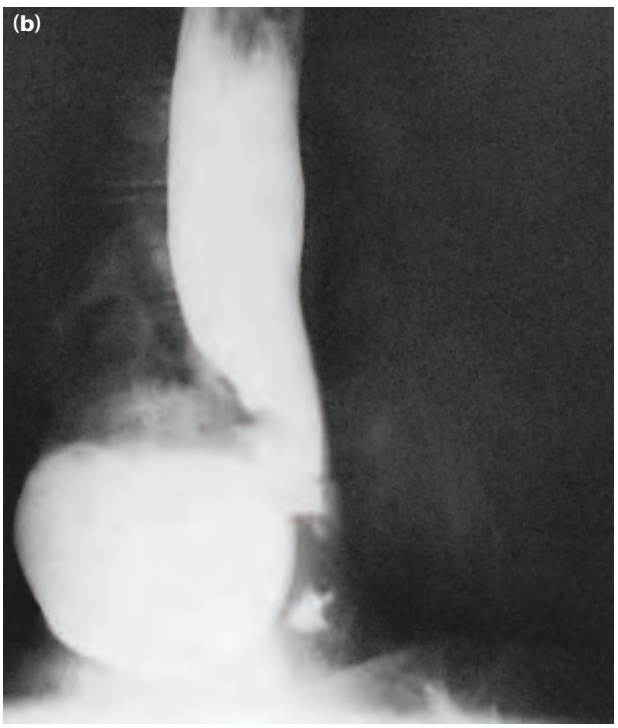

Figure 62.65 Epiphrenic diverticulum proximal to the gastro-oesophageal sphincter. **(a)** Small and asymptomatic; **(b)** large, symptomatic and appearing as a gas-filled bubble on the chest radiograph.

Figure 62.66 Schatzki's ring, a thin submucosal web completely encircling the whole of the lumen, usually situated at the squamo-columnar junction.

cause is obscure, but there is a strong association with reflux disease. The core of the ring consists of variable amounts of fibrous tissue and cellular infiltrate. Most rings are incidental findings. Some are associated with dysphagia and respond to dilatation in conjunction with medical antireflux therapy.

Oesophageal infections

Bacterial infection of the oesophagus is rare, but fungal and viral infections do occur. They are particularly important in immunocompromised patients.

Oesophagitis due to *Candida albicans* is relatively common in patients taking steroids (especially transplant recipients) or those undergoing cancer chemotherapy. It may present with dysphagia or odynophagia. There may be visible thrush in the throat. Endoscopy shows numerous white plaques that cannot be moved, unlike food residues (**Figure 62.67**). Biopsies are diagnostic. In severe cases, a barium swallow may show dramatic mucosal ulceration and irregularity that is surprisingly similar to the appearance of oesophageal varices (**Figures 62.68 and 62.69**). Treatment is with a topical antifungal agent.

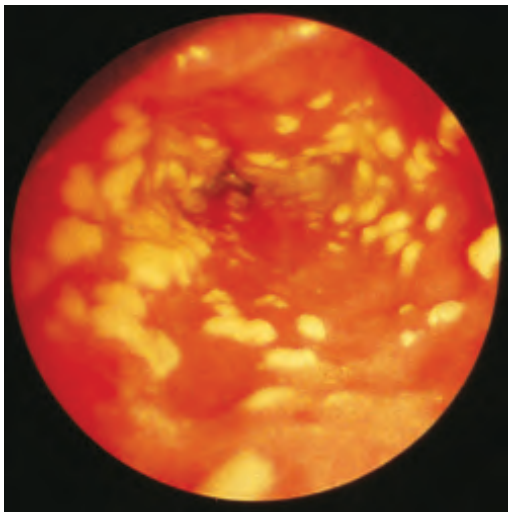

Figure 62.67 Endoscopic appearance of oesophageal candidiasis.

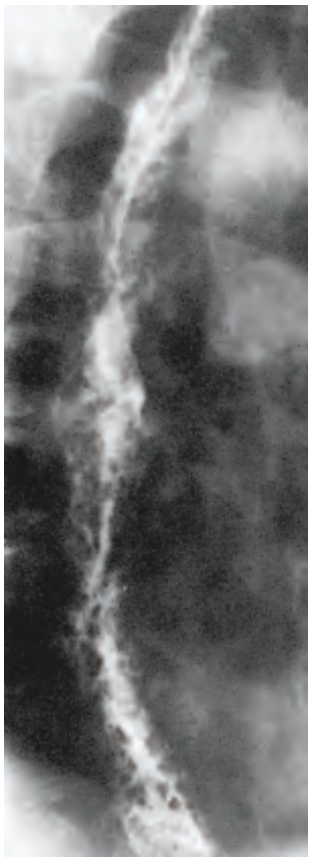

Figure 62.68 Oesophageal candidiasis with shaggy appearance of mucosal defects.

Dysphagia and odynophagia can also be caused by herpes simplex virus and cytomegalovirus (CMV). With the former, there may be a history of a herpetic lesion on the lip some days earlier, and endoscopy may reveal vesicles or small ulcers with raised margins, usually in the upper half of the oesophagus. CMV infection may be apparent in graft-versus-host disease following bone marrow transplantation. It has a characteristic endoscopic appearance with a geographical, serpiginous border. In both cases, endoscopic biopsy is diagnostic.

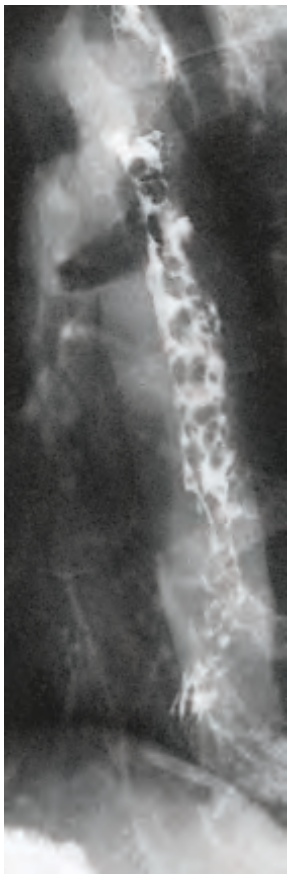

Figure 62.69 Oesophageal varices with smooth outline of the filling defects.

Chagas' disease

This condition is confined to South American countries, but is of interest because oesophageal symptoms occur that are similar to severe achalasia. It is caused by a protozoan, Trypanosoma cruzi, transmitted by an insect vector. Parasites reach the bloodstream and, after a long latent period, there is damage particularly to cardiac and smooth muscle. Destruction of both Auerbach's and Meissner's plexus leads to acquired megaoesophagus.

Crohn's disease

The oesophagus is not commonly affected by symptomatic Crohn's disease. However, pathological studies indicate that it may be present in 20% of patients without symptoms. Symptoms are often severe, and a diagnosis of reflux oesophagitis is usually made on the basis of retrosternal pain and dysphagia.

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

Endoscopy shows extensive oesophagitis that extends much further proximally than reflux oesophagitis. Biopsies may be diagnostic, but may show only non-specific inflammation. In severe cases, deep sinuses occur, and fistulation has been described. Crohn's oesophagitis is said to respond poorly to medical treatment and, although balloon dilatation of strictures and surgical resection for multiple internal fistulae have both been described, these interventions should be used with great caution.

Plummer–Vinson syndrome

This is also called the Paterson–Kelly (or Paterson–Brown Kelly) syndrome or sideropenic dysphagia. The original descriptions are vague and poorly supported by evidence of a coherent syndrome. Dysphagia is said to occur because of the presence of a postcricoid web that is associated with iron deficiency anaemia, glossitis and koilonychia. The classic syndrome is rarely complete. Some patients may have oropharyngeal leukoplakia, and this may account for an alleged increased risk of developing hypopharyngeal cancer.

Webs certainly occur in the upper and middle oesophagus, usually without any kind of associated syndrome. They are nearly always thin diaphanous membranes identified coincidentally by contrast radiology. Even symptomatic webs that cause a degree of obstruction may be inadvertently ruptured at endoscopy. Few require formal endoscopic dilatation.

Vascular abnormalities affecting the oesophagus

Several congenital vascular anomalies may produce dysphagia by compression of the oesophagus. Classically, this results from an aberrant right subclavian artery (arteria lusoria). However, the oesophagus is more commonly compressed by vascular rings, such as a double aortic arch. Dysphagia occurs in only a minority of cases and usually presents early in childhood, although it can occur in the late teens. Treatment is usually by division of the non-dominant component of the ring.

In adults, acquired causes include aneurysm of the aorta, diffuse cardiac enlargement and pressure from the left common carotid or vertebral arteries. It is rare that symptom severity justifies surgical intervention.

Mediastinal fibrosis

This rare condition can occur alone or together with retroperitoneal fibrosis. The cause is unknown and, although the major consequences are usually cardiovascular as a result of caval compression, dysphagia can occur. The existence of irreparable cardiovascular problems usually precludes surgical intervention on the oesophagus.

Chapter 63

Stomach and duodenum

Learning objectives

- To understand the gross and microscopic anatomy and pathophysiology of the stomach in relation to disease
- To be able to decide on the most appropriate techniques to use in the investigation of patients with complaints relating to the stomach and duodenum
- To understand the critical importance of gastritis and *Helicobacter pylori* in upper gastrointestinal disease
- To be able to investigate and treat peptic ulcer disease and its complications
- To be able to recognise the presentation of gastric cancer and understand the principles involved in its treatment
- To know about the causes of duodenal obstruction and the presentation of duodenal tumours

INTRODUCTION

The function of the stomach is to act as a reservoir for ingested food. It also serves to break down foodstuffs mechanically and commence the processes of digestion before these products are passed on into the duodenum.

GROSS ANATOMY OF THE STOMACH AND DUODENUM

Blood supply

Arteries

The stomach has an arterial supply on both lesser and greater curves (**Figure 63.1**). On the lesser curve, the left gastric artery, a branch of the coeliac axis, forms an anastomotic arcade with the right gastric artery, which arises from the common hepatic artery. Branches of the left gastric artery pass up towards the cardia. The gastroduodenal artery, which is also a branch of the hepatic artery, passes behind the first part of the duodenum, highly relevant with respect to the bleeding duodenal ulcer. Here it divides into the superior pancreaticoduodenal artery and the right gastroepiploic artery. The superior pancreaticoduodenal artery supplies the duodenum and pancreatic head, and forms an anastomosis with the inferior pancreaticoduodenal artery, a branch of the superior mesenteric artery. The right gastroepiploic artery runs along the greater curvature of the stomach, eventually forming an anastomosis with the left gastroepiploic artery, a branch of the splenic artery. This vascular arcade, important for the construction of the gastric conduit in oesophageal resection, is often variably incomplete. The fundus of the stomach is supplied by the vasa brevia (or short gastric arteries), which arise from near the termination of the splenic artery.

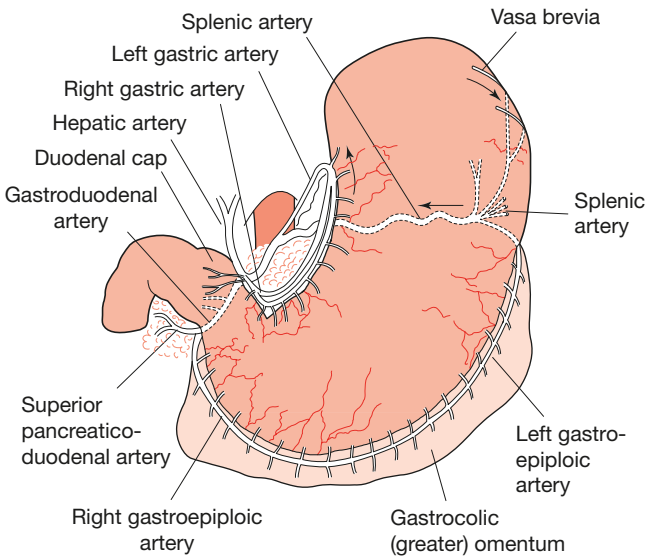

Figure 63.1 The arterial blood supply of the stomach.

Veins

In general, the veins are equivalent to the arteries, those along the lesser curve ending in the portal vein and those on the greater curve joining via the splenic vein. On the lesser curve, the coronary vein is particularly important. It runs up the lesser curve towards the oesophagus and then passes left to right to join the portal vein. This vein becomes markedly dilated in portal hypertension.

Lymphatics

The lymphatics of the stomach are of considerable importance in the surgery of gastric cancer and are therefore described in detail in that section.

Nerves

As with the entire gastrointestinal tract, the stomach and duodenum possess both intrinsic and extrinsic nerve supplies. The intrinsic nerves exist principally in two plexuses, the myenteric plexus of Auerbach and the submucosal plexus of Meissner. Compared with the rest of the gut, the submucosal plexus of the stomach contains relatively few ganglionic cells, as does the myenteric plexus in the fundus. However, in the antrum the ganglia of the myenteric plexus are well developed. The extrinsic supply is derived mainly from the vagus nerves (CN XI), fibres of which originate in the brainstem. The vagal plexus around the oesophagus condenses into bundles that pass through the oesophageal hiatus (**Figure 63.2**), the posterior bundle being usually identifiable as a large nerve trunk. Vagal fibres are both afferent (sensory) and efferent. The efferent fibres are involved in the receptive relaxation of the stomach and the stimulation of gastric motility, as well as having the well-known secretory function. The sympathetic supply is derived mainly from the coeliac ganglia.

MICROSCOPIC ANATOMY OF THE STOMACH AND DUODENUM

The gastric epithelial cells are mucus producing and are turned over rapidly. In the pyloric part of the stomach, and also the duodenum, mucus-secreting glands are found. Most of the specialised cells of the stomach (parietal and chief cells) are found in the gastric crypts (**Figure 63.3**). The stomach also has numerous endocrine cells.

Parietal cells

These are in the body (acid-secreting portion) of the stomach and line the gastric crypts, being more abundant distally. They are responsible for the production of hydrogen ions to form hydrochloric acid. The hydrogen ions are actively secreted by the proton pump, a hydrogen–potassium-ATPase (Sachs), which exchanges intraluminal potassium for hydrogen ions. The potassium ions enter the lumen of the crypts passively, but the hydrogen ions are pumped against an immense concentration gradient (1 000 000:1).

Chief cells

These lie principally proximally in the gastric crypts and produce pepsinogen. Two forms of pepsinogen are described: pepsinogen I and pepsinogen II. Both are produced by the chief cell, but pepsinogen I is produced only in the stomach. The ratio between pepsinogens I and II in the serum decreases with gastric atrophy. Pepsinogen is activated in the stomach to produce the digestive protease, pepsin.

Endocrine cells

The stomach has numerous endocrine cells, which are critical to its function. In the gastric antrum, the mucosa contains G cells, which produce gastrin. Throughout the body of the stomach, enterochromaffin-like (ECL) cells are abundant and produce histamine, a key factor in driving gastric acid secretion. In addition, there are large numbers of somatostatin-

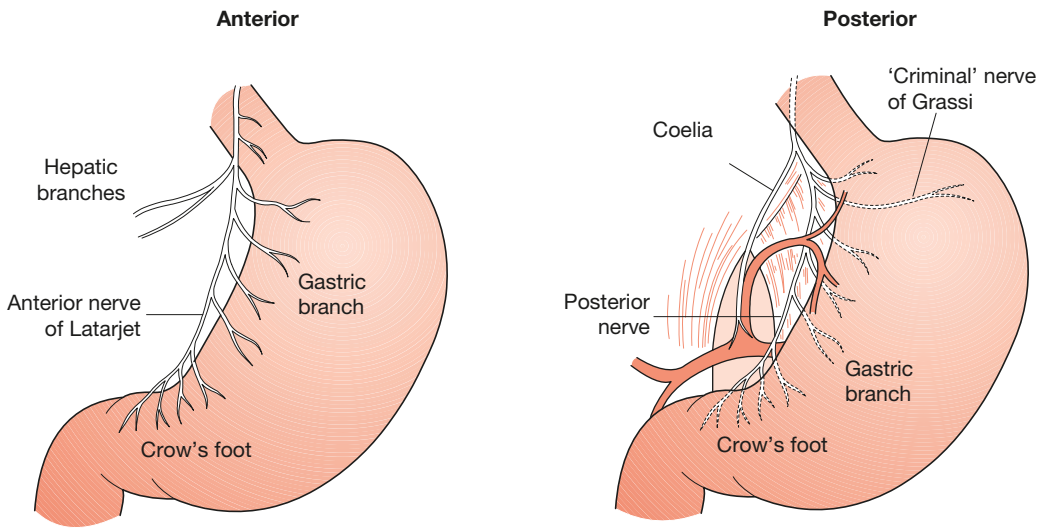

Figure 63.2 The anatomy of the anterior and posterior vagus nerves in relation to the stomach.

Leopold Auerbach, 1828–1897, Professor of Neuropathology, Breslau, Germany (now Wroclaw, Poland), described the myenteric plexus in 1862.
George Meissner, 1829–1905, Professor of Physiology, Gottingen, Germany.

producing D cells throughout the stomach, and somatostatin has a negative regulatory role. The peptides and neuropeptides produced in the stomach are discussed later.

Duodenum

The duodenum is lined by a mucus-secreting columnar epithelium. In addition, Brunner's glands lie beneath the mucosa and are similar to the pyloric glands in the pyloric part of the stomach. Endocrine cells in the duodenum produce cholecystokinin and secretin.

PHYSIOLOGY OF THE STOMACH AND DUODENUM

The stomach mechanically breaks up ingested food and, together with the actions of acid and pepsin, forms chyme that passes into the duodenum. In contrast with the acidic environment of the stomach, the environment of the duodenum is alkaline, due to the secretion of bicarbonate ions from both the pancreas and the duodenum. This neutralises the acid chyme and adjusts the luminal osmolarity to approximately that of plasma. Endocrine cells in the duodenum produce cholecystokinin, which stimulates the pancreas to produce trypsin and the gall bladder to contract. Secretin is also produced by the endocrine cells of the duodenum. This hormone inhibits gastric acid secretion and promotes production of bicarbonate by the pancreas.

Summary box 63.1

The anatomy and physiology of the stomach

- The stomach acts as a reservoir for food and commences the process of digestion
- Gastric acid is produced by a proton pump in the parietal cells, which in turn is controlled by histamine acting on the H_2-receptors
- The histamine is produced by the endocrine gastric ECL cells in response to a number of factors, particularly gastrin and the vagus
- Proton pump inhibitors abolish gastric acid production, whereas H_2-receptor antagonists only markedly reduce it
- The gastric mucous layer is essential to the integrity of the gastric mucosa

Gastric acid secretion

The secretion of gastric acid and pepsin tends to run in parallel, although the understanding of the mechanisms of gastric acid secretion is considerably greater than that of pepsin. Numerous factors are involved to some degree in the production of gastric acid. These include neurotransmitters, neuropeptides and peptide hormones. This complexity need not detract from the fact that there are basic principles that are relatively easily understood (**Figure 63.4**). Hydrogen ions are produced by the parietal cell by the proton pump. Although numerous factors can act on the parietal cell, the most important of these is histamine, which acts via the H_2-receptor. Histamine is produced, in turn, by the ECL cells of the stomach and acts in a paracrine (local) fashion on the parietal cells. These relationships explain why proton pump inhibitors can abolish gastric acid secretion, as they act on the final common pathway – hydrogen ion secretion. H_2-receptor antagonists have profound effects on gastric acid secretion, but this is not insurmountable (**Figure 63.4**). The ECL cell produces histamine in response to a number of stimuli that include the vagus nerve and gastrin. Gastrin is released by the G cells in response to the presence of the food in the stomach. The production of gastrin is inhibited by acid, creating a negative feedback loop. Various other peptides, including secretin, inhibit gastric acid secretion.

Classically, three phases of gastric secretion are described. The cephalic phase is mediated by vagal activity, secondary to sensory arousal as first demonstrated by Pavlov. The gastric phase is a response to food within the stomach, which is mediated principally, but not exclusively, by gastrin. In the intestinal phase, the presence of chyme in the duodenum and small bowel inhibits gastric emptying, and the acidification

of the duodenum leads to the production of secretin, which inhibits gastric acid secretion, along with numerous other peptides originating from the gut. The stomach also possesses somatostatin-containing D cells. Somatostatin is released in response to a number of factors including acidification. This peptide acts probably on the G cell, the ECL cell and the parietal cell itself to inhibit the production of acid.

Gastric mucus and the gastric mucosal barrier

The gastric mucous layer is essential to the integrity of the gastric mucosa. It is a viscid layer of mucopolysaccharides produced by the mucus-producing cells of the stomach and the pyloric glands. Gastric mucus is an important physiological barrier to protect the gastric mucosa from mechanical damage, and also the effects of acid and pepsin. Its considerable buffering capacity is enhanced by the presence of bicarbonate ions within the mucus. Many factors can lead to the breakdown of this gastric mucous barrier. These include bile, non-steroidal anti-inflammatory drugs (NSAIDs), alcohol, trauma and shock. Tonometry studies have shown that, of the entire gastrointestinal tract, the stomach is the most sensitive to ischaemia following a hypovolaemic insult and also the slowest to recover. This may explain the high incidence of stress ulceration in the stomach.

Peptides and neuropeptides in the stomach and duodenum

As with most of the gastrointestinal tract, the endocrine cells of the stomach produce peptide hormones and neurotransmitters. Previously, nerves and endocrine cells were considered distinct in terms of their products. However, it is increasingly realised that there is enormous overlap within these systems. Many peptides recognised as hormones may also be produced by neurones, hence the term neuropeptides. The term 'messenger' can be used to describe all such products. There are three conventional modes of action that overlap.

1. **Endocrine**. The messenger is secreted into the circulation, where it affects tissues that may be remote from the site of origin (Bayliss and Starling).
2. **Paracrine**. Messengers are produced locally and have local effects on tissues. Neurones and endocrine cells both act in this way.
3. **Neurocrine** (classical neurotransmitter). Messengers are produced by the neurone via the synaptic knob and pass across the synaptic cleft to the target.

Many peptide hormones act on the intrinsic nerve plexus of the gut (see later) and influence motility. Similarly, neuropeptides may influence the structure and function of the mucosa. Some of these peptides, neuropeptides and neurotransmitters are shown in *Table 63.1*. The stomach is vital in the regulation of appetite and weight control via a combination of mechanical and hormonal mechanisms; these are discussed further in following chapters.

Gastroduodenal motor activity

The motility of the entire gastrointestinal tract is modulated to a large degree by its intrinsic nervous system. Critical in this process is the migrating motor complex (MMC). In the fasted state, and after food has cleared, in the small bowel there is a period of quiescence lasting in the region of 40 minutes (phase I). There follows a series of waves of electrical and motor activity, also lasting for about 40 minutes, propagated from the fundus of the stomach in a caudal direction at a rate of about three per minute (phase II). These pass as far the pylorus, but not beyond. Duodenal slow waves are generated in the duodenum at a rate of about 10 per minute, which carry down the small bowel. The amplitude of these contractions increases to a maximum in phase III, which lasts for about 10 minutes. This 90-minute cycle of activity is then repeated. From the duodenum, the MMC moves distally at 5–10 cm/min, reaching the terminal ileum after 1.5 hours.

Following a meal, the stomach exhibits receptive relaxation, which lasts for a few seconds. Following this, adaptive relaxation occurs, which allows the proximal stomach to act as a reservoir. Most of the peristaltic activity is found in the distal stomach (the antral mill) and the proximal stomach demonstrates only tonic activity. The pylorus, which is most commonly open, contracts with the peristaltic wave and allows only a few millilitres of chyme through at a time. The antral contraction against the closed sphincter is important in the milling activity of the stomach. Although the duodenum is capable of generating 10 waves per minute, after a meal it only contracts after an antral wave reaches the pylorus. The coordination of the motility of the antrum, pylorus and duodenum

TABLE 63.1 Function and source of peptides and neuropeptides in the stomach.

Function	Source
Stimulate secretion	
Gastrin	G cells
Histamine	ECL cells
Acetylcholine	Neurones
Gastrin-releasing peptide	Neurones and mucosa
Cholecystokinin (CCK)	Duodenal endocrine cells
Inhibit secretion	
Somatostatin	D cells and neurones
Secretin	Duodenal endocrine cells
Enteroglucagon	Small intestinal endocrine cells
Prostaglandins	Mucosa
Neurotensin	Neurones
GIP	Duodenal and jejunal endocrine cells
PYY	Small intestinal endocrine cells
Stimulate motility	
Acetylcholine	Neurones
5-HT	Neurones
Histamine	ECL cell
Substance P	Neurones
Substance K	Neurones
Motilin	Neurones
Gastrin	G cells
Angiotensin	
Inhibit motility	
Somatostatin	D cells and neurones
VIP	Neurones
Nitric oxide	Neurones and smooth muscle
Noradrenaline	Neurones
Encephalin	Neurones
Dopamine	Neurones

ECL, enterochromaffin-like cells; GIP, gastric inhibitory polypeptide; PYY, peptide YY; VIP, vasoactive intestinal peptide.

means that only small quantities of food reach the small bowel at a time. It is important to consider that this control of gastric emptying can be abolished after gastric surgery leading to significant symptoms (discussed in later sections). Motility is influenced by numerous factors, including mechanical stimulation and neuronal and endocrine influences (*Table 63.1*).

INVESTIGATION OF THE STOMACH AND DUODENUM

Flexible endoscopy

Flexible endoscopy is the 'gold standard' investigation of the upper gastrointestinal tract. The original flexible endoscopes were fibreoptic (Hirschowitz), but now most use a solid-state camera mounted at the instrument's tip (**Figures 63.5** and **63.6**). Other members of the endoscopy team see the image and this is useful when taking biopsies or performing interventional techniques, and it also facilitates teaching and training.

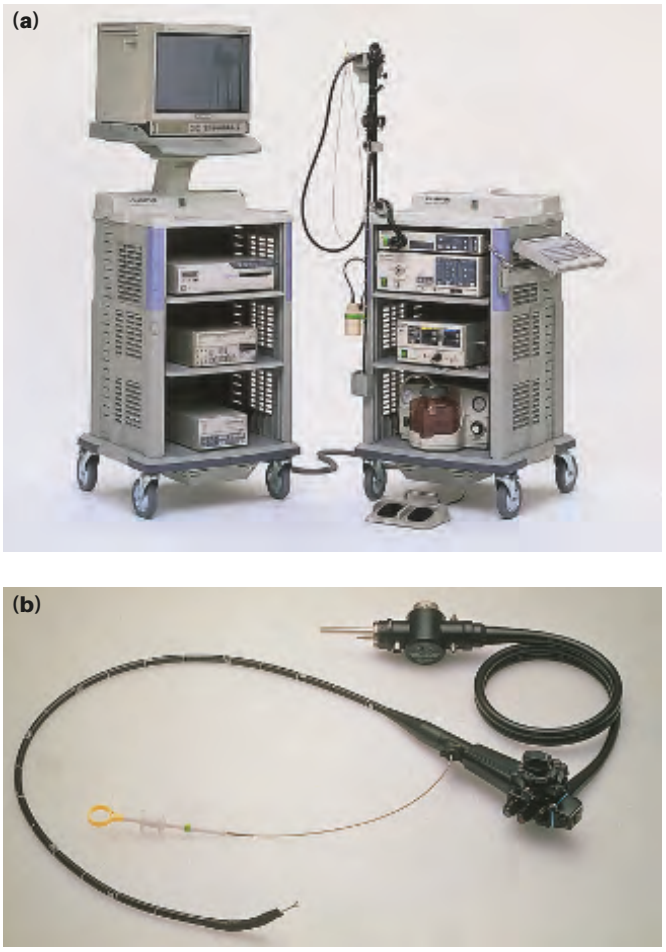

Figure 63.5 A video-gastroscope (courtesy of Keymed (Medical and Industrial Equipment Ltd)). **(a)** The camera stack; **(b)** the gastroscope and biopsy forceps in the working channel.

Summary box 63.2

The investigation of gastric disorders

- Flexible endoscopy is the most commonly used and sensitive technique for investigating the stomach and duodenum
- Great care needs to be exercised in performing endoscopy to avoid complications and missing important pathology
- Axial imaging, particularly multislice CT, is useful in the staging of gastric cancer, although it may be less sensitive in the detection of liver metastases than other modalities
- Endoscopic ultrasound is the most sensitive technique in the evaluation of the 'T' stage of gastric cancer and in the assessment of duodenal tumours
- Laparoscopy is very sensitive in detecting peritoneal metastases, and laparoscopic ultrasound provides an accurate evaluation of lymph node and liver metastases

Basil I Hirschowitz, Professor of Medicine, Birmingham, AL, USA.

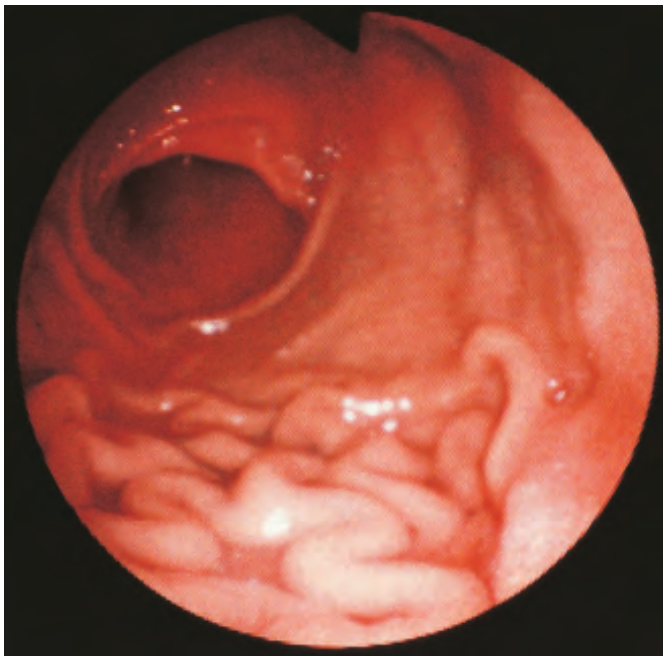

Figure 63.6 A view of the normal stomach during endoscopy (courtesy of GNJ Tytgat, Amsterdam, The Netherlands).

Flexible endoscopy is more sensitive than conventional radiology in the assessment of the majority of gastroduodenal conditions. This is particularly the case for peptic ulceration, gastritis and duodenitis. In upper gastrointestinal bleeding, endoscopy is far superior to any other investigation and offers the possibility of endoscopic therapy. In most circumstances it is the only investigation required.

Fibreoptic endoscopy is generally a safe investigation, but it is important that all personnel undertaking these procedures are adequately trained. Careless and rough handling of the endoscope during intubation of a patient may result in perforations of the pharynx and oesophagus. Any other part of the upper gastrointestinal tract may also be perforated. An inadequately performed endoscopy is also dangerous as a serious condition may be overlooked. This is particularly the case in respect of early and curable gastric cancer, the appearances of which may often be extremely subtle and may be missed by inexperienced endoscopists. A more experienced endoscopist will have a higher index of suspicion for any mucosal abnormalities and will take more biopsies. Spraying the mucosa with dye endoscopically may allow better discrimination between normal and abnormal mucosa, so allowing a small cancer to be more easily seen. In the future, advances in technology may allow 'optical biopsy' to determine the nature of mucosal abnormalities in real time.

Upper gastrointestinal endoscopy can be performed without sedation, but when sedation is required incremental doses of a benzodiazepine are usually administered. Sedation is of particular concern in the case of gastrointestinal bleeding as it may have a more profound effect on the patient's cardiovascular stability. It has now become the standard to use pulse oximetry to monitor patients during upper gastrointestinal endoscopy, and nasal oxygen is often also administered. Buscopan is useful to abolish duodenal motility for examinations of the second and third parts of the duodenum. Examinations of this type are best carried out using a side-viewing endoscope such as is used for endoscopic retrograde cholangiopancreatography (ERCP).

Some patients are relatively resistant to sedation with benzodiazepines, particularly those who are accustomed to drinking alcohol. Increasing the dose of benzodiazepines in these patients may not result in any useful sedation, but merely make the patient more restless and confused. Such patients are sometimes better endoscoped fully awake using a local anaesthetic throat spray and a narrow-gauge endoscope. Whatever the circumstances, it is important that resuscitation facilities are available including agents that reverse the effects of benzodiazepines, such as flumazenil.

The technology associated with upper gastrointestinal endoscopy is continuing to advance. Instruments which allow both endoscopy and endoluminal ultrasound to be performed simultaneously (see later) are used routinely. Bleeding from the stomach and duodenum can be treated with a number of haemostatic measures. These include injection with various substances, diathermy, heater probes, lasers and clips. These approaches appear to be useful in the treatment of bleeding ulcers, although there are few good controlled trials in this area. There is no good evidence that such interventional procedures at the moment work in patients who are bleeding from very large vessels, such as the gastroduodenal artery or splenic artery, although technology may overcome this problem in the future.

Contrast radiology

Upper gastrointestinal radiology is not used as much as in previous years, as endoscopy is a more sensitive investigation for most gastric problems. Computed tomography (CT) imaging with oral contrast has also replaced contrast radiology in many of the areas where anatomical information is sought, eg large hiatus hernias of the rolling type and chronic gastric volvulus. In these conditions it may be difficult for the endoscopist to determine exactly the anatomy or, indeed, negotiate the deformity to see the distal stomach.

Ultrasonography

Standard ultrasound imaging can be used to investigate the stomach, but used conventionally it is less sensitive than other modalities. In contrast, endoluminal ultrasound and laparoscopic ultrasound are probably the most sensitive techniques available in the preoperative local staging of gastric cancer. In endoluminal ultrasound, the transducer is usually attached to the distal tip of the instrument. However, devices have been developed which may be passed down the biopsy channel, albeit with poorer image quality. Five layers (**Figure 63.7**) of the gastric wall may be identified on endoluminal ultrasound and the depth of invasion of a tumour can be assessed with exquisite accuracy (90% accuracy for the 'T' component of the staging). Enlarged lymph nodes can also be identified and the technique's accuracy in this situation is about 80%.

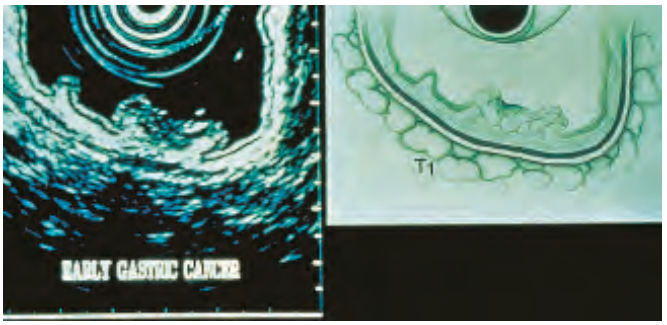

Figure 63.7 Endoscopic ultrasound of the stomach. Five layers can be identified in the normal stomach. A gastric cancer is shown invading the muscle of the gastric wall (courtesy of KeyMed (Medical and Industrial Equipment Ltd)).

Finally, it may be possible to identify liver metastases not seen on axial imaging. Laparoscopic ultrasound is also a very sensitive imaging modality to a large measure because of the laparoscopy itself (see below). It is one of the most sensitive methods of detecting liver metastases from gastric cancer.

An additional use of ultrasound is in the assessment of gastric emptying. Swallowed contrast is utilised, which is designed to be easily seen using an ultrasound transducer. The emptying of this contrast is then followed directly. The accuracy of the technique is similar to that of radioisotope gastric emptying studies (see below).

CT scanning and magnetic resonance imaging

The resolution of CT scanners is continuing to improve, and multislice CT is of increasing value in the investigation of the stomach, especially gastric malignancies (**Figure 63.8**). The presence of gastric wall thickening associated with a carcinoma of any reasonable size can be easily detected by CT, but the investigation lacks sensitivity in detecting smaller lesions. It is much less accurate in 'T' staging than endoluminal ultrasound. Lymph node enlargement can be detected and, based on the size and shape of the nodes, it is possible to be reasonably accurate in detecting nodal involvement with tumour. However, as with all imaging techniques, it is limited. Microscopic tumour deposits in lymph nodes cannot be detected when the node is not enlarged and, in contrast, lymph nodes may undergo reactive enlargement but not contain tumour. These problems apply to all imaging techniques.

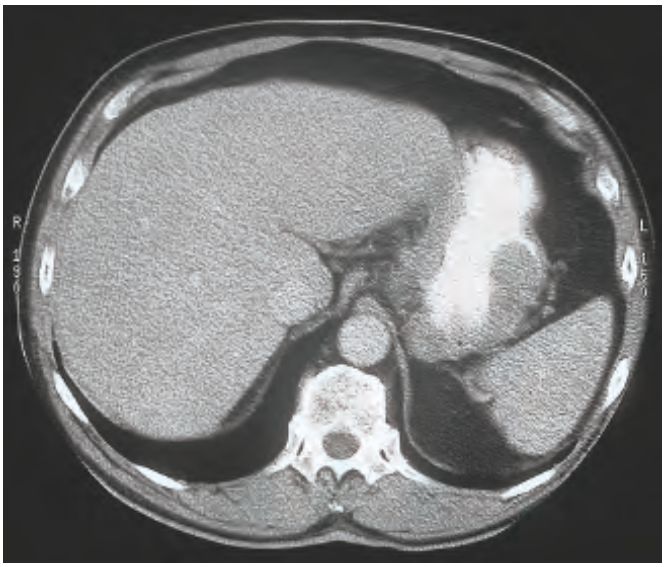

Figure 63.8 A computed tomography scan of the abdomen, showing a gastric cancer arising in the body of the stomach.

The detection of small liver metastases is improving, although in general terms metastases from gastric cancer are less easy to detect using CT than those, for instance, from colorectal cancer. This is because metastases from gastric cancer may be of the same density as liver and may not handle the intravenous contrast any differently. At present, magnetic resonance imaging (MRI) scanning does not offer any specific advantage in assessing the stomach, although it has a higher sensitivity for the detection of gastric cancer liver metastases than conventional CT imaging.

CT/positron emission tomography

Positron emission tomography (PET) is a functional imaging technique which relies on the uptake of a tracer in most cases by metabolically active tumour tissue. Fluorodeoxyglucose (FDG) is the most commonly used tracer. This tracer has a short half-life hence manufacture and use have to be carefully coordinated. To be of value, anatomical and functional information need to be linked, hence PET/CT is now used universally. It is increasingly being used in the preoperative staging of gastro-oesophageal cancer as it will demonstrate occult spread which renders the patient surgically incurable in up to 10% of patients who would otherwise have undergone major resections (**Figure 63.9**). PET/CT may also be used to determine the response to neoadjuvant chemotherapy in oesophagogastric malignancies although this is the subject of ongoing studies.

Laparoscopy

This technique is routine in the assessment of patients with gastric cancer. Its particular value is in the detection of peritoneal disease, which is difficult by any other technique, unless the patient has ascites or bulky intraperitoneal deposits. Its main limitation is in the evaluation of posterior extension but other techniques are available to evaluate posterior invasion, especially CT and endoluminal ultrasound. Usually laparoscopy is combined with peritoneal cytology unless laparotomy follows immediately.

Gastric emptying studies

These are useful in the study of gastric dysmotility problems, particularly those that follow gastric surgery. The principle of the examination is that radioisotope-labelled liquid and solid meals are ingested by the patient and the emptying of the stomach is followed on a gamma camera. This allows the

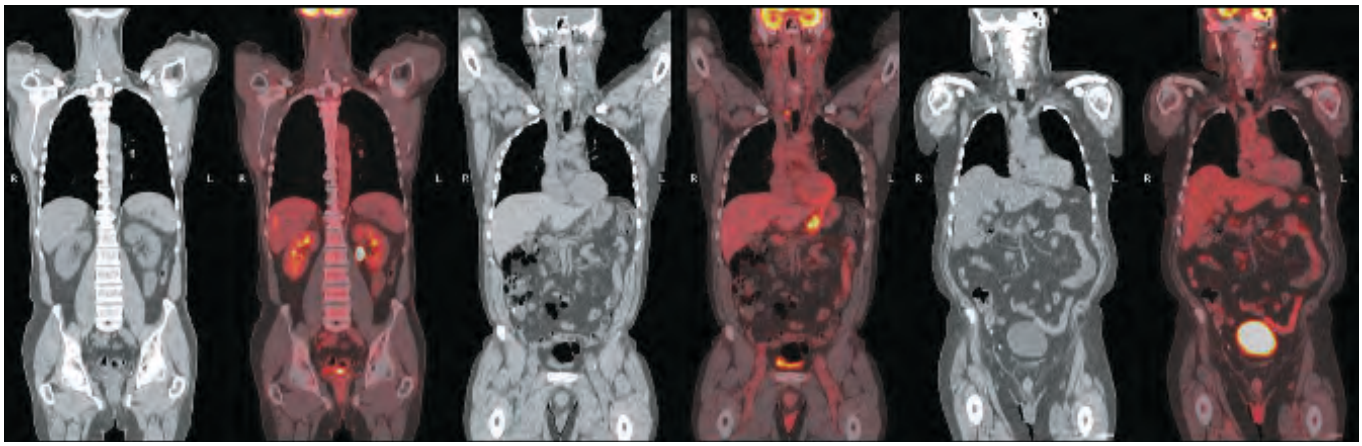

Figure 63.9 Computed tomography/positron emission tomography of a patient with gastric cancer. The middle pair of images shows the primary tumour. The two images on the left show unsuspected liver metastases, whereas the two on the right show a left cervical node positive for metastases.

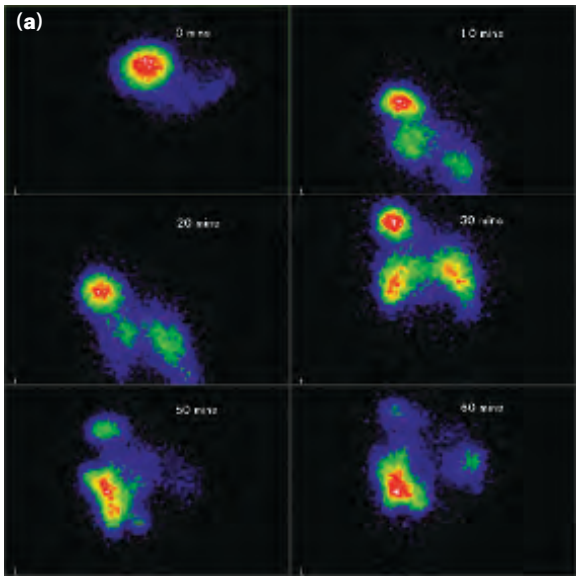
proportion of activity in the remaining stomach to be assessed numerically, and it is possible to follow liquid and solid gastric emptying independently (**Figure 63.10**).

Angiography

Angiography is used most commonly in the investigation of upper gastrointestinal bleeding that is not identified using endoscopy. Therapeutic embolisation may also be of value in the treatment of bleeding in patients in whom surgery is difficult or inadvisable. In expert centres embolisation now replaces surgery in the majority of cases.

HELICOBACTER PYLORI

Over the last 30 years, this organism has proved to be of overwhelming importance in the aetiology of a number of common gastroduodenal diseases such as chronic gastritis, peptic ulceration and gastric cancer. The organism had unquestionably been observed by a number of workers since Bircher's first description in 1874, but it was not until 1980 that Warren and Marshall, with enthusiasm but perhaps a lack of caution, ingested the organism to confirm that Koch's postulates could be fulfilled with respect to the gastritis that they succeeded in causing in themselves. Eradication therapy was then employed with mixed success, but both received the Nobel



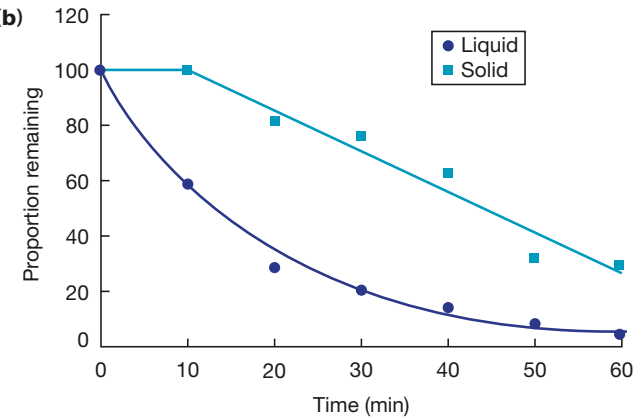


Figure 63.10 Dual-phase solid and liquid gastric emptying. The use of two isotopic labels allows the liquid and solid phases of the emptying to be followed separately. **(a)** Image acquisition. **(b)** Gastric emptying curves in a normal individual showing typical lag period in the solid phase before linear emptying (courtesy of Dr V Lewington, Southampton, UK).

C.S. Warren, Perth, Australia, now Chicago, IL, USA, credited with awakening the current interest in *Helicobacter*.
Barry Marshall, Perth, Australia, now Charlottesville, VA, USA, credited with awakening the current interest in *Helicobacter*.
Robert Koch, 1843–1910, Professor of Hygiene and Bacteriology, Berlin, Germany. Stated his 'postulates' in 1882. The postulates define the conditions that must be met before an organism can be shown to be the causal agent for a particular disease.

Prize for Medicine and Physiology in 2005. The organism is spiral shaped and is fastidious in its requirements, being difficult to culture outside the mucous layer of the stomach.

One of the characteristics of the organism is its ability to hydrolyse urea, resulting in the production of ammonia, a strong alkali. The effect of ammonia on the antral G cells is to cause the release of gastrin via the previously described negative-feedback loop. This is probably responsible for the modest, but inappropriate, hypergastrinaemia in patients with peptic ulcer disease, which, in turn, may result in gastric acid hypersecretion. The organism's obligate urease activity is utilised by various tests used to detect the presence of the organism, including the ^{13}C and ^{14}C breath tests and the CLO test (a commercially available urease test kit), which is performed on gastric biopsies. The organism can also be detected histologically (**Figure 63.11**), using the Giemsa or the Warthin–Starry stains, and cultured using appropriate media. Previous or current infection with the organism may also be detected serologically. Breath tests or faecal antigen tests are recommended for the pre-treatment diagnosis of *H. pylori* infection in the community. Less accurate, hospital-based serology tests have a place within the non-invasive test-and-treat strategy.

Infection with *H. pylori* leads to the disruption of the gastric mucous barrier by the enzymes produced by the organism, and the inflammation induced in the gastric epithelium is the basis of many of the associated disease processes. The association of the organism with chronic (type B) gastritis is not in doubt. Some strains of *H. pylori* produce cytotoxins, notably the *Cag A* and *Vac A* products, and the production of cytotoxins seems to be associated with the ability of the organism to cause gastritis, peptic ulceration and cancer. The effect of the organism on the gastric epithelium is to incite a classical inflammatory response that involves the migration and degranulation of acute inflammatory cells, such as neutrophils, and also the accumulation of chronic inflammatory cells, such as macrophages and lymphocytes.

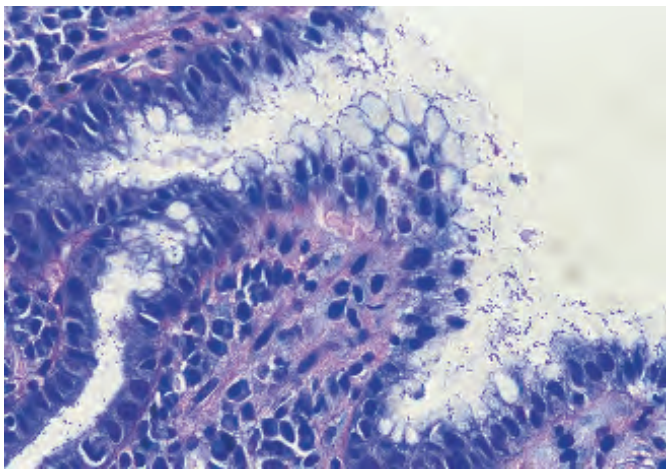

Figure 63.11 Antral mucosa showing colonisation with *Helicobacter pylori* (modified Giemsa stain).

It is evident how *H. pylori* infection results in chronic gastritis and also how this may progress to gastric ulceration, but for a while it remained an enigma as to how the organism could be involved in duodenal ulceration, as the normal duodenum is not colonised. As mentioned above, the production of ammonia does increase the level of circulating gastrin and it has been shown subsequently that eradication of the organism in patients with duodenal ulcer disease will reduce the acid levels to normal. However, the overlap in gastric acid secretion between normal subjects and those with duodenal ulcers is considerable and the modestly increased acid levels in patients with *Helicobacter*-associated antral gastritis are insufficient to explain the aetiology of duodenal ulceration.

The explanation can probably be found in the phenomenon of duodenal gastric metaplasia. Gastric metaplasia is the normal response of the duodenal mucosa to excess acidity. It can be thought of in the same way as any other metaplasia in the gastrointestinal tract: an attempt by the mucosa to resist an injurious stimulus. Although normal duodenal mucosa cannot be infected with *H. pylori*, gastric metaplasia in the duodenum is commonly infected and this infection results in the same inflammatory process that is observed in the gastric mucosa. The result is duodenitis, which is almost certainly the precursor of duodenal ulceration.

Infection with *H. pylori* may be the most common human infection. The incidence of infection within a population increases with age, and in many populations infection rates of 80–90% are not unusual. Up to 50% of the world's population may be infected with *Helicobacter*. It appears that most infection is acquired in childhood and the possibility of infection is inversely related to socioeconomic group. The means of spread has not been identified, but the organism can occur in the faeces and faecal–oral spread seems most likely. The organism is not normally found in saliva or dental plaque. There is evidence in different environments and in different population groups that the manifestations of the infection may be different. Predominantly antral gastritis, which is commonly seen in resource-rich countries, results initially in increased levels of acid production and peptic ulcer disease, whereas gastritis affecting the body, common in resource-poor countries, may lead to hypochlorhydria and gastric neoplasia.

It has been known since 1984 that *Helicobacter* infection is amenable to treatment with antibiotics. The profound hypochlorhydria produced by proton pump inhibitors combined with antibiotics is also effective in eradicating the organism. Commonly used eradication regimes include a proton pump inhibitor and two antibiotics, such as metronidazole and amoxycillin. Very high eradication rates, in the region of 90%, can be achieved with combinations that include the antibiotic clarithromycin, although it may be that in the future antibiotic resistance will become a problem. Reinfection following successful eradication appears rare (<0.5%) but incomplete eradication is a more important clinical problem.

Gustav Giemsa, 1867–1948, bacteriologist who became Privatdozent in Chemotherapy at the University of Hamburg, Hamburg, Germany.
Aldred Scott Warthin, 1866–1931, pathologist, the University of Michigan, USA.
Allen Chronister Starry, 1890–1973, pathologist, the University of Michigan, USA.

At present, eradication therapy is recommended for patients with duodenal ulcer disease, but not for patients with non-ulcer dyspepsia or in asymptomatic patients who are infected. However, recent data show that a proportion of patients with non-ulcer dyspepsia do respond to treatment. *H. pylori* is now classed by the World Health Organisation as a class 1 carcinogen and it may be that further epidemiological studies on the risk of gastric cancer change the current advice on treatment.

GASTRITIS

The great variety of names and classification systems used in gastritis is confusing. Thankfully, the understanding of gastritis has increased markedly following elucidation of the role of *H. pylori* in chronic gastritis and there is broad agreement that gastritis should be classified according to the underlying aetiology. Gastritis describes any histologically confirmed inflammation of the gastric mucosa. In most modern classification systems the amount of inflammatory infiltrate and the degree of gastric atrophy will be included.

Summary box 63.3

Gastritis

- The spiral bacterium *Helicobacter pylori* is critical in the development of gastritis, peptic ulceration and gastric cancer
- Infection appears to be acquired mainly in childhood and the infection rate is inversely associated with socioeconomic status
- Eradication, recommended specifically in patients with peptic ulcer disease, can be achieved in up to 90% of patients with a combination of a proton pump inhibitor and antibiotics, and reinfection is uncommon (<0.5%)
- Erosive gastritis is usually related to the use of NSAIDs
- Autoimmune gastritis is associated with the development of pernicious anaemia and gastric cancer

Autoimmune gastritis

This is an autoimmune condition in which there are circulating antibodies to the parietal cell. This results in the atrophy of the parietal cell mass, hence hypochlorhydria and ultimately achlorhydria. As intrinsic factor is also produced by the parietal cell there is malabsorption of vitamin B12, which, if untreated, may result in pernicious anaemia. The antrum is not affected and the hypochlorhydria leads to the production of high levels of gastrin from the antral G cells. This results in chronic hypergastrinaemia. This, in turn, results in hypertrophy of the ECL cells in the body of the stomach, which are not affected by the autoimmune damage. Over time it is apparent that microadenomas develop in the ECL cells of the stomach, sometimes becoming identifiable tumour nodules. Very rarely, these tumours can become malignant. Patients with autoimmune gastritis are predisposed to the development of gastric cancer, and screening such patients endoscopically may be appropriate.

H. pylori gastritis

Previously described as type B gastritis, this affects the antrum, and it is these patients who are prone to peptic ulcer disease. *Helicobacter*-associated pangastritis is also a very common manifestation of infection, but gastritis affecting the corpus alone does not seem to be associated. However, there are some data to suggest that *Helicobacter* may be involved in the initiation of the process. Patients with pangastritis seem to be most prone to the development of gastric cancer.

Intestinal metaplasia is associated with chronic pangastritis with atrophy. Although intestinal metaplasia per se is common, intestinal metaplasia associated with dysplasia has significant malignant potential and, if this condition is identified, endoscopic screening may be appropriate.

Reflux gastritis

This is caused by enterogastric reflux and is particularly common after gastric surgery. Its histological features are distinct from other types of gastritis. Although commonly seen after gastric surgery, it is occasionally found in patients with no previous surgical intervention or who have had a cholecystectomy. Bile chelating or prokinetic agents may be useful in treatment and as a temporising measure to avoid consideration of revisional surgery. Operation for the condition should be reserved for the most severe cases.

Erosive gastritis

This is caused by agents that disturb the gastric mucosal barrier; NSAIDs and alcohol are common causes. The NSAID-induced gastric lesion is associated with inhibition of the cyclo-oxygenase type 1 (COX-1) receptor enzyme, hence reducing the production of cytoprotective prostaglandins in the stomach. Many of the beneficial anti-inflammatory activities of NSAIDs are mediated by COX-2, and the use of specific COX-2 inhibitors reduces the incidence of these side effects. However, taken in the long term COX-2 inhibitors are associated with cardiovascular complications in common with many NSAIDs.

Stress gastritis

This is a common sequel of serious illness or injury and is characterised by a reduction in the blood supply to superficial mucosa of the stomach. Although common, this is not usually recognised unless stress ulceration and bleeding supervene, in which case treatment can be extremely difficult. The condition also sometimes follows cardiopulmonary bypass. Prevention of the stress bleeding from the stomach is much easier than treating it, and hence the routine use of H_2 antagonists with or without barrier agents, such as sucralfate, in patients who are on intensive care. These measures have been shown to reduce the incidence of bleeding from stress ulceration.

Ménétrier's disease

This is an unusual condition characterised by gross hypertrophy of the gastric mucosal folds, mucus production and hypochlorhydria. The condition is premalignant and may present with hypoproteinaemia and anaemia. There is no treatment other than a gastrectomy. The disease seems to be caused by overexpression of transforming growth factor alpha (TGF-α). Like epidermal growth factor (EGF), this peptide also binds to the EGF receptor. The histological features of Ménétrier's disease may be reproduced in transgenic mice overexpressing TGF-α.

Lymphocytic gastritis

This type of gastritis is seen rarely. It is characterised by the infiltration of the gastric mucosa by T cells and is probably associated with *H. pylori* infection. The pattern of inflammation resembles that seen in coeliac disease or lymphocytic colitis.

Summary box 63.4

Peptic ulceration

- Most peptic ulcers are caused by *H. pylori* or NSAIDs and changes in epidemiology mirror changes in these principal aetiological factors
- Duodenal ulcers are more common than gastric ulcers, but the symptoms are indistinguishable
- Gastric ulcers may become malignant and an ulcerated gastric cancer may mimic a benign ulcer
- Gastric antisecretory agents and *H. pylori* eradication therapy are the mainstay of treatment, and elective surgery is very rarely performed
- The long-term complications of peptic ulcer surgery may be difficult to treat
- The common complications of peptic ulcers are perforation, bleeding and stenosis
- The treatment of the perforated peptic ulcer is primarily surgical, although some patients may be managed conservatively

Other forms of gastritis

Eosinophilic gastritis appears to have an allergic basis, and is treated with steroids and cromoglycate. Granulomatous gastritis is seen rarely in Crohn's disease and also may be associated with tuberculosis. Acquired immunodeficiency syndrome (AIDS) gastritis is secondary to infection with cryptospiridiosis. Phlegmonous gastritis is a rare bacterial infection of the stomach found in patients with severe intercurrent illness. It is usually an agonal event.

PEPTIC ULCER

Although the name 'peptic' ulcer suggests an association with pepsin, this is essentially unimportant as in the absence of acid, peptic ulcers do not occur. Nearly all peptic ulcers can be healed by using proton pump inhibitors, which can render a patient virtually achlorhydric.

Common sites for peptic ulcers are the first part of the duodenum and the lesser curve of the stomach, but they also occur on the stoma following gastric surgery, the oesophagus and even in a Meckel's diverticulum, which contains ectopic gastric epithelium. In general, the ulcer occurs at a junction between different types of epithelia, the ulcer occurring in the epithelium least resistant to acid damage.

In the past, much distinction has been made between acute and chronic peptic ulcers, but this difference can sometimes be difficult to determine clinically. It is probably best to consider that there is a spectrum of disease from the superficial gastric and duodenal ulceration, frequently seen at endoscopy, to deep chronic penetrating ulcers. This does not minimise the importance of acute stress ulceration. These ulcers can both perforate and bleed.

For many years, the cause of peptic ulceration remained an enigma. When comparing groups of patients with duodenal and pre-pyloric peptic ulcers with normal subjects, gastric acid levels are higher, but the overlap is very considerable. Patients with gastric ulceration have relatively normal levels of gastric acid secretion. As peptic ulceration will occur in the presence of very high acid levels, such as those found in patients with a gastrinoma (Zollinger–Ellison syndrome), and as all ulcers can be healed in the absence of acid, it is clear that acid is important. In patients with a gastrinoma it may be the only aetiological factor, but this is not the case in the majority of patients. As with many diseases, genetic factors may be involved to a limited degree and social stress has also been falsely implicated (Asher).

It is now widely accepted that infection with *H. pylori* and the consumption of NSAIDs are the most important factors in the development of peptic ulceration. In combination *H. pylori* and NSAIDs act synergistically to promote ulcer development and ulcer bleeding. Cigarette smoking predisposes to peptic ulceration and increases the relapse rate after treatment, with either gastric antisecretory agents or, in the past, elective surgery. Multiple other factors may be involved in transition between the superficial and the deep penetrating chronic ulcer, but they are of lesser importance.

Edwin Homer Ellison, 1918–1970, Professor of Surgery, Marquette University, Milwaukee, WI, USA. Zollinger and Ellison described this condition in a joint paper in 1955 when they were both working at the Ohio State University.
Richard Asher, 1912–1969, physician, the Central Middlesex Hospital, London, UK. Ridiculed the concept that the stress of modern living caused peptic ulceration by pointing out that the same claim was made for syphilis! It is an interesting coincidence that both diseases have strong aetiological associations with spiral organisms.

Duodenal ulceration

Incidence

There have been marked changes in the last two decades in the demography of patients presenting with duodenal ulceration in resource-rich countries. First, even before the introduction of H_2-receptor antagonists, the incidence of duodenal ulceration and the frequency of elective surgery for the condition were falling. This trend has continued and now, dyspeptic patients presenting with a duodenal ulcer at gastroscopy are uncommon. In part, this may relate to the widespread use of gastric antisecretory agents and *H. pylori* eradication therapy for patients with dyspepsia. Second, the peak incidence is now in a much older age group than previously and, although it is still more common in men, the difference is less marked. These changes mirror the changes, at least in part, in the epidemiology of *H. pylori* infection. In Eastern Europe, the disease remains common and, from having been uncommon in some resource-poor nations, it is now observed more frequently. Again, the relationship with *H. pylori* appears convincing.

Pathology

Most occur in the first part of the duodenum (**Figures 63.12 and 63.13**). A chronic ulcer penetrates the mucosa and into the muscle coat, leading to fibrosis. The fibrosis causes deformities such as pyloric stenosis. When an ulcer heals, a scar can be observed in the mucosa. Sometimes there may be more than one duodenal ulcer. The situation in which there is both a posterior and an anterior duodenal ulcer is referred to as 'kissing ulcers'. Anteriorly placed ulcers tend to perforate and, in contrast, posterior duodenal ulcers tend to bleed, sometimes by eroding into the gastroduodenal artery. Occasionally, the ulceration may be so extensive that the entire duodenal cap is ulcerated and devoid of mucosa. With respect to the giant duodenal ulcer, malignancy in this region is so uncommon that under normal circumstances surgeons can be confident that they are dealing with benign disease, even though from external palpation it may not appear so. In the stomach the situation is different.

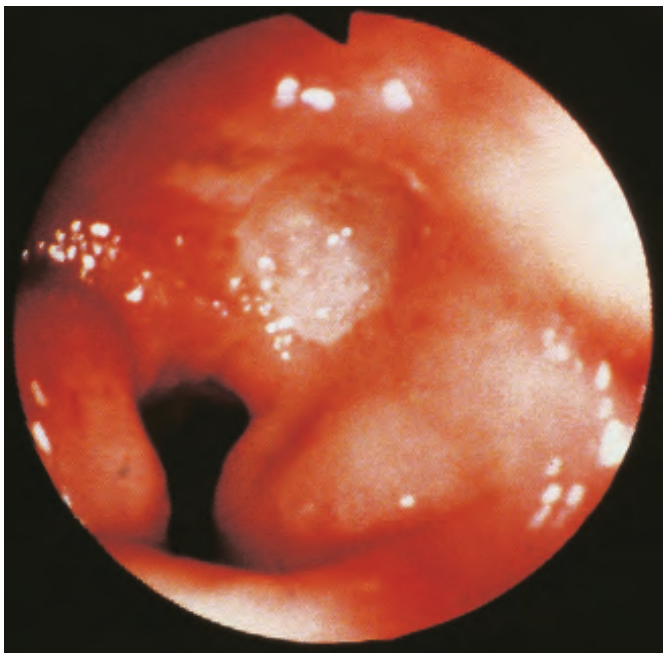

Figure 63.12 Duodenal ulcer at gastroduodenoscopy (courtesy of Dr GNJ Tytgat, Amsterdam, The Netherlands).

Figure 63.13 Duodenal ulcer shown by barium meal.

Histopathology

Microscopically, destruction of the muscular coat is observed and the base of the ulcer is covered with granulation tissue, the arteries in this region showing the typical changes of endarteritis obliterans. Sometimes the terminations of nerves can be seen among the fibrosis. The pathological appearances of the healing ulcer must be carefully interpreted as some of the epithelial downgrowths can be misinterpreted as invasion. This is unlikely to be important in duodenal ulcers when malignancy rarely, if ever, occurs, but it is much more important with gastric ulcers.

Gastric ulcers

Incidence

As with duodenal ulceration, *H. pylori* and NSAIDs are the important aetiological factors. Gastric ulceration is also associated with smoking; other factors are of lesser importance.

There are marked differences between the populations afflicted by chronic gastric ulceration compared with duodenal ulceration. First, gastric ulceration is substantially less common than duodenal ulceration. The sex incidence is equal and the population with gastric ulcers tends to be older. It is more prevalent in low socioeconomic groups and is considerably more common in resource-poor countries than in richer ones.

Pathology

This is essentially similar to that of a duodenal ulcer, except that gastric ulcers tend to be larger. Fibrosis, when it occurs,

may result in the now rarely seen hourglass contraction of the stomach. Large chronic ulcers may erode posteriorly into the pancreas and, on other occasions, into major vessels such as the splenic artery. Less commonly, they may erode into other organs such as the transverse colon. Chronic gastric ulcers are much more common on the lesser curve (especially at the incisura angularis; **Figures 63.14 and 63.15**) than on the greater curve and, even when high on the lesser curve, they tend to be at the boundary between the acid-secreting and the non-acid-secreting epithelia. With atrophy of parietal cell mass, non-acid-secreting epithelium migrates up the lesser curvature.

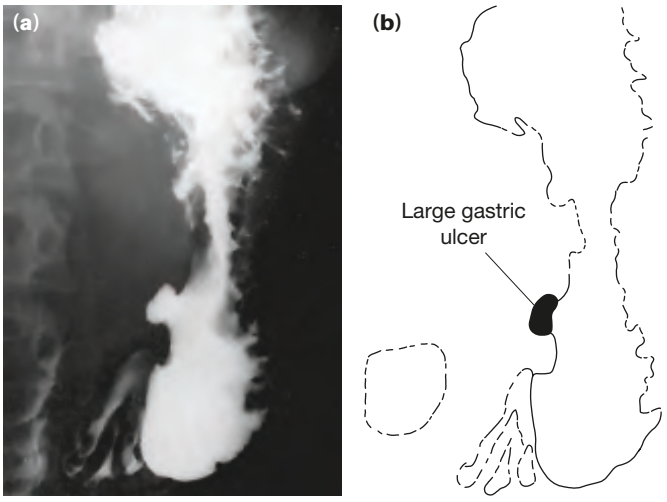

Figure 63.15 Benign gastric ulcer shown on barium meal. **(a)** Radiograph; **(b)** diagrammatic outline.

Malignancy in gastric ulcers

Chronic duodenal ulcers are not associated with malignancy and, in contrast, gastric ulcers are. Widely varying estimates are made of the incidence of gastric malignancy in gastric ulcers. The reason for this is that the authors reporting such diverse incidences are describing different clinical situations. Two clinical extremes must be distinguished to understand this problem properly. First, there is the situation in which a benign chronic gastric ulcer undergoes malignant transformation. This is known to happen, albeit rarely. The contrasting clinical extreme is the patient identified as having an ulcer in the stomach, either endoscopically or on contrast radiology, which is assessed as benign but biopsies reveal malignancy. In this situation the patient does not have, and probably never has had, chronic peptic ulceration in the stomach but has presented with an ulcerated cancer. This situation is common, although whether a lesion found in the stomach is described as being benign or malignant on clinical grounds depends very much on the skill and experience of the endoscopist or radiologist.

It is fundamental that any gastric ulcer should be regarded as being malignant, no matter how classical the features of a benign gastric ulcer. Multiple biopsies should always be taken, perhaps as many as 10 well-targeted biopsies, before an ulcer can be tentatively accepted as being benign. Even then it is important that further biopsies are taken while the ulcer is healing and when healed. Modern antisecretory agents can frequently heal the ulceration associated with gastric cancer but, clearly, are ineffective in treating the malignancy itself. At operation, even experienced surgeons may have difficulty distinguishing between the gastric cancer and a benign ulcer. Operative strategies differ so radically that it is essential, if at all possible, that a confident diagnosis is made before operation. If, at operation for perforation, it is determined that the ulcer is probably benign it should, nonetheless, be excised, in totality if possible, and submitted for histological examination. It is not known whether a patient's survival is compromised by this approach if the ulcer turns out to be malignant on biopsy, as convincing data are not available.

Other peptic ulcers

The pre-pyloric gastric ulcer was in the past difficult to treat, a problem overcome with the introduction of proton pump inhibitors. Pyloric channel ulcers are similar to duodenal ulcers. Both pre-pyloric and pyloric ulcers may be malignant, and biopsy is essential. Stomal ulcers occur after a gastroenterostomy (now most commonly after bariatric surgery; see later) or a gastrectomy of the Billroth II type. The ulcer is usually found on the jejunal side of the stoma.

Clinical features of peptic ulcers

Although many textbooks try to create differences in the clinical feature of gastric and duodenal ulceration, detailed analysis has shown that they cannot be differentiated on the

Christian Albert Theodor Billroth, 1829–1894, Professor of Surgery, Vienna, Austria.

basis of symptoms. The demographic characteristics of groups of patients with gastric and duodenal ulceration do differ but this does not allow discrimination.

Pain

The pain is epigastric, often described as gnawing and may radiate to the back. Eating may sometimes relieve the discomfort. The pain is normally intermittent rather than intractable.

Periodicity

One of the classical features of untreated peptic ulceration is periodicity. Symptoms may disappear for weeks or months to return again. This periodicity may be related to the spontaneous healing of the ulcer.

Vomiting

While this occurs, it is not a notable feature unless stenosis has occurred.

Alteration in weight

Weight loss or, sometimes, weight gain may occur. Patients with gastric ulceration are often underweight but this may precede the occurrence of the ulcer.

Bleeding

All peptic ulcers may bleed. The bleeding may be chronic and presentation with microcytic anaemia is not uncommon. All such patients should be investigated with endoscopy. Acute presentation with haematemesis and melaena is discussed later.

Clinical examination

Examination of the patient may reveal epigastric tenderness but, except in extreme cases (for instance, gastric outlet obstruction), there is unlikely to be much else to find.

Investigation of the patient with suspected peptic ulcer

Gastroduodenoscopy

This is the investigation of choice in the management of suspected peptic ulceration and in the hands of a well-trained operator is highly sensitive and specific.

In the stomach, any abnormal lesion should be multiply biopsied, and in the case of a suspected benign gastric ulcer numerous biopsies must be taken in order to exclude, as far as possible, the presence of a malignancy. Commonly, biopsies of the antrum will be taken to see whether there is histological evidence of gastritis and a CLO test performed to determine the presence of *H. pylori*. A 'U' manoeuvre should be performed to exclude ulcers around the gastro-oesophageal junction. This is important as the increasing incidence of cancer at the gastro-oesophageal junction requires that all mucosal abnormalities in this region should undergo multiple biopsy. Similarly, if a stoma is present, for instance after gastroenterostomy or Billroth II gastrectomy, it is important to enter both afferent and efferent loops. Almost all stomal ulcers will be very close to the junction between the jejunal and gastric mucosa. Attention should be given to the pylorus to note whether there is any pre-pyloric or pyloric channel ulceration, and also whether it is deformed, which is often the case with chronic duodenal ulceration. In the duodenum, care must be taken to view all of the first part. It is not infrequent for an ulcer to be just beyond the pylorus and easily overlooked.

Treatment of peptic ulceration

The vast majority of uncomplicated peptic ulcers are treated medically. Surgical treatment of uncomplicated peptic ulceration has decreased markedly since the 1960s and is now seldom performed in resource-rich countries. Surgical treatment was aimed principally at reducing gastric acid secretion and, in the case of gastric ulceration, removing the diseased mucosa. When originally devised, medical treatment also aimed to reduce gastric acid secretion, initially using the highly successful H_2-receptor antagonist and, subsequently, proton pump inhibitors. This has now largely given way to eradication therapy.

Medical treatment

It is reasonable that a doctor managing a patient with an uncomplicated peptic ulcer should suggest modifications to the patient's lifestyle, particularly the cessation of cigarette smoking. This advice is rarely followed and pharmacological measures form the mainstay of treatment.

H_2-receptor antagonists and proton pump inhibitors

H_2-antagonists (Black) revolutionised the management of peptic ulceration. Most duodenal ulcers and gastric ulcers can be healed by a few weeks of treatment with these drugs provided that they are taken and absorbed. There remained, however, a group of patients who were relatively refractory to conventional doses of H_2-receptor antagonists. This is largely now irrelevant as proton pump inhibitors can effectively render a patient achlorhydric and all benign ulcers will heal using these drugs, the majority within 2 weeks. Symptom relief is impressively rapid, most patients being asymptomatic within a few days. Like H_2-antagonists, proton pump inhibitors are safe and relatively devoid of serious side effects. The problem with all gastric antisecretory agents is that following cessation of therapy relapse is almost universal.

Eradication therapy

Eradication therapy is now routinely given to patients with peptic ulceration, and this is described earlier in this chapter. Evidence suggests that if a patient has a peptic ulcer and *H. pylori* is the principal aetiological factor (essentially the patient not taking NSAIDs) then complete eradication of the organism will cure the disease and reinfection as an adult is

Sir James Black, 1924–2002, Professor of Pharmacology, King's College Hospital Medical School, London, UK, introduced beta-blockers and H_2-receptor antagonists. He received the Nobel Prize for Physiology or Medicine in 1988.

uncommon. Eradication therapy is therefore the mainstay of treatment for peptic ulceration. It is extremely economical by comparison with prolonged courses of antisecretory agents or surgery. It is also considerably safer than surgical treatment.

There are some patients with peptic ulcers in whom eradication therapy may not be appropriate and this includes patients with NSAID-associated ulcers. Such patients should avoid these drugs if possible and, if not, they should be co-prescribed with a potent antisecretory agent. Similarly, patients with stomal ulceration are not effectively treated with eradication therapy and require prolonged prescription of antisecretory agents. Patients with Zollinger–Ellison syndrome should be treated in the long term with proton pump inhibitors unless the tumour can be adequately managed by surgery.

Ulcers that fail to heal

The introduction of antisecretory agents and effective treatments for *H. pylori* have revolutionised the management of peptic ulcers. Despite these advances peptic ulceration fails to heal in a small minority of patients. Endoscopic re-evaluation should be regarded as mandatory to confirm healing of all gastric ulcers. Furthermore, endoscopy permits the differentiation between a refractory ulcer and persistent symptoms despite ulcer healing. The most common cause of failed healing is persistent *H. pylori* infection. Biopsies should be repeated at the time of endoscopy as false-negative results with breath tests may be expected soon after eradication therapy and serum antibody titres may not fall for 6 months after successful eradication. Failure of eradication is usually due to poor compliance or bacterial resistance and bacteriological culture will guide further attempts at *H. pylori* eradication. The ingestion of NSAIDs should once again be addressed. A diagnosis of Zollinger-Ellison syndrome (described in detail later) should be suspected in *H. pylori* negative, non-NSAID-related peptic ulceration and serum gastrin levels should be measured. Very rarely, a recently described autoimmune IgG4-related phenomenon is the cause of resistant and recurrent gastric ulceration.

Surgical treatment of uncomplicated peptic ulceration

From its peak in the 1960s, the incidence of surgery for uncomplicated peptic ulceration has fallen markedly, to the extent that peptic ulcer surgery is now of little more than historical interest. A description of operations used in the treatment of peptic ulcers is still necessary because surgery is occasionally employed for the complicated ulcer and, in addition, many patients are left suffering from the consequences of the more destructive operations.

Operations for duodenal ulceration

Duodenal ulcer surgery (rationale)

Procedures devised for the treatment of duodenal ulcers have the common aim of excluding the damaging effects of acid from the duodenum. This has been achieved by diversion of the acid away from the duodenum, reducing the secretory potential of the stomach, or both. All of the operations devised achieved their aim to some extent, but with varying degrees of morbidity, mortality and postoperative side effects. There is now no role for acid-reducing operations in the routine management of peptic ulcer disease but occasionally operations which involve gastrectomy have to be performed in the emergency situation. In addition many patients have had such operations performed and suffer from the sequelae. Hence it is important for the clinician to understand the anatomical and physiological consequences of surgery. The operations are described in historical sequence.

Billroth II gastrectomy

The first successful gastrectomy was performed by Billroth in January 1881, and Wolfler performed the first gastroenterostomy in the same year. The original Billroth operations consisted of a gastric resection with gastroduodenal anastomosis (Billroth I technique) (**Figure 63.16**). The Billroth II operation was devised more by accident than design (**Figure 63.17**). A gastroenterostomy (**Figure 63.18**) was performed on a gravely ill patient with a pyloric cancer, who was not expected to survive. Contrary to expectations, the patient improved and the stomach distal to the anastomosis was resected. It soon became evident that the use of gastrojejunal anastomosis after gastric resection could be safer and easier than the Billroth I procedure, and it became popular and effective in the surgical treatment of duodenal ulcer. Because of its disadvantages, such as higher operative mortality and morbidity, it has not been used for many years in the patient with an uncomplicated ulcer, but it is still used occasionally

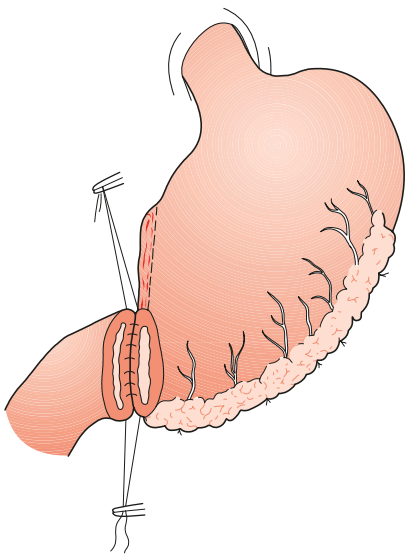

Figure 63.16 Billroth I gastrectomy. The lower half of the stomach is removed and the cut stomach anastomosed to the first part of the duodenum.

Anton Wolfler, 1850–1917, Professor of Surgery, Prague, Czechoslovakia.

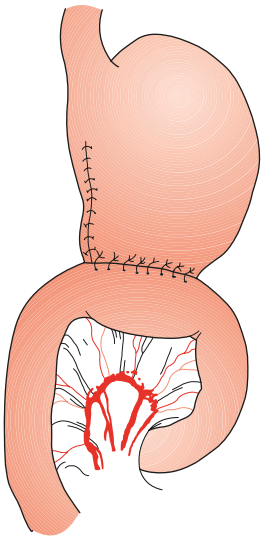

Figure 63.17 Billroth II. Two-thirds of the stomach is removed, the duodenal stump is closed and the stomach anastomosed to the jejunum.

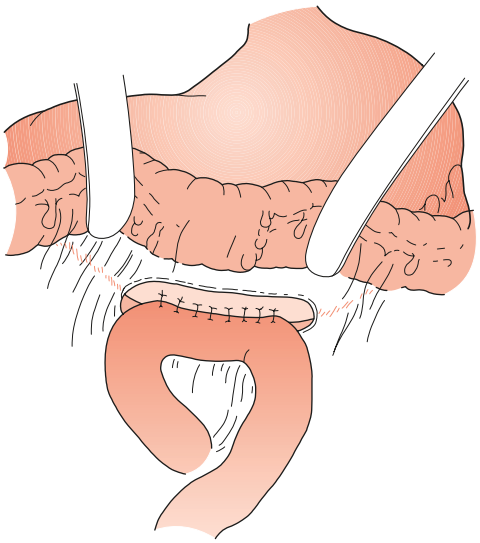

Figure 63.18 Gastroenterostomy. The jejunum is anastomosed to the posterior, dependent, wall of the stomach.

in the treatment of a complicated ulcer with a 'difficult' duodenum. In Billroth II gastrectomy, or its close relation Pólya gastrectomy, the antrum and distal body of the stomach are mobilised by opening the greater and lesser omentum and dividing the gastroepiploic arteries, right gastric artery and the left gastric artery arcade at the limit of the resection. The duodenum is closed off either by suture or using staples, sometimes with difficulty in patients with a very deformed duodenum. Various techniques are available to close the difficult duodenum and, in extremis, a catheter may be placed in the duodenal stump, the duodenum closed around it and a catheter brought out through the abdominal wall. Following resection, the distal end of the stomach is narrowed by the closure of the lesser curve aspect of the remnant. The greater curve aspect is then anastomosed, usually in a retrocolic fashion, to the jejunum, leaving as short an afferent loop as feasible (**Figure 63.17**). Even when well performed, this procedure has an operative mortality rate of a few per cent and morbidity is not unusual. A common cause of morbidity is leakage from the duodenal stump, which is particularly associated with kinking of the afferent loop. Leakage from the gastrojejunal anastomosis is unusual unless it is under tension or the stomach has been devascularised during the mobilisation. The incidence of side effects following gastrectomy is considerable, as shown in *Table 63.2*. Recurrence of the ulcer at the stoma is uncommon but can occur, especially as this procedure is traditionally not combined with the vagotomy. In the majority of expert centres a Roux-en-Y reconstruction rather than the Billroth II procedure is performed because postoperative function is better.

TABLE 63.2 Operative mortality, side effects and incidence of recurrence following duodenal ulcer operations.

Operation	Operative mortality (%)	Significant side effects (%)	Recurrent ulceration (%)
Gastrectomy	<1–2	<20–40	1–4
Gastroenterostomy alone	<1	<10–20	50
Truncal vagotomy and drainage	<1	<10–20	2–7
Selective vagotomy and drainage	<1	<10–20	5–10
Highly selective vagotomy	<0.2	<5	2–10
Truncal vagotomy and antrectomy	<1	<10–20	1

Gastrojejunostomy

Because of the potential for mortality after gastrectomy, the use of gastrojejunostomy alone in the treatment of duodenal ulceration was developed (**Figure 63.18**). Reflux of alkali from the small bowel into the stomach reduced duodenal acid exposure and was often successful in healing the ulcer. However, because the jejunal loop was exposed directly to gastric acid, stomal ulceration was extremely common, hence the procedure in isolation was ineffective.

Truncal vagotomy and drainage

Truncal vagotomy was first introduced in 1943 by Dragstedt and, for many years, combined with drainage, was the mainstay of treatment of duodenal ulceration (**Figure 63.19**). The principle of the operation is that section of the vagus nerves, which are critically involved in the secretion of gastric acid,

Eugen (Jeno) Alexander Pólya, 1876–1944, surgeon, St Stephen's Hospital, Budapest, Hungary.
César Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland. Described this method of forming a jejunal conduit in 1908.
Lester Reynold Dragstedt, 1893–1975, Professor of Surgery, Chicago, IL, USA.

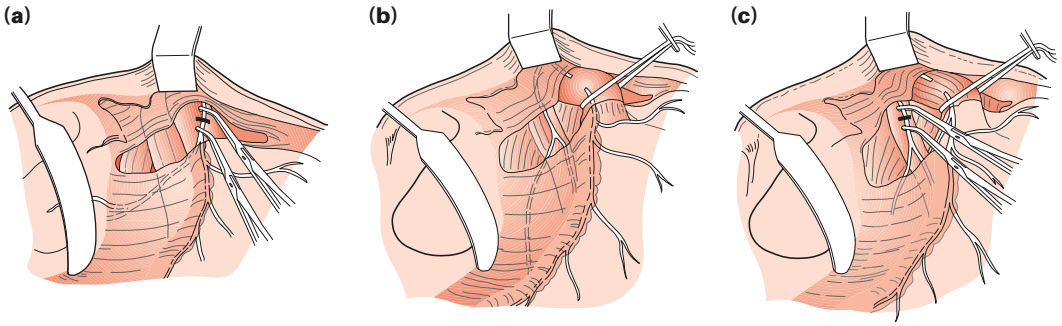

Figure 63.19 Truncal vagotomy: **(a)** division of the anterior vagus; **(b)** mobilisation of the oesophagus; **(c)** division of the posterior vagus.

reduces the maximal acid output by approximately 50%. Because the vagal nerves are motor to the stomach, denervation of the antropyloroduodenal segment results in gastric stasis in a substantial proportion of patients on whom truncal vagotomy alone is performed. This was first noted by Dragstedt, who did not perform a drainage procedure when he first introduced the operation. The most popular drainage procedure is the Heineke–Mikulicz pyloroplasty (**Figure 63.20**). It is simple to perform and involves the longitudinal section of the pyloric ring. The incision is closed transversely. Gastrojejunostomy (**Figure 63.18**) was the alternative drainage procedure to pyloroplasty. This is performed through opening the lesser sac and performing an anastomosis between the most dependent part of the antrum and the first jejunal loop. An isoperistaltic anastomosis was most commonly performed. The operation of truncal vagotomy and drainage is substantially safer than gastrectomy (*Table 63.2*). However, the side effects of surgery are, in fact, little different from those that follow gastrectomy.

Highly selective vagotomy

In 1968 Johnston and Amdrup independently devised the operation of highly selective vagotomy in which only the parietal cell mass of the stomach was denervated (**Figure 63.21**).

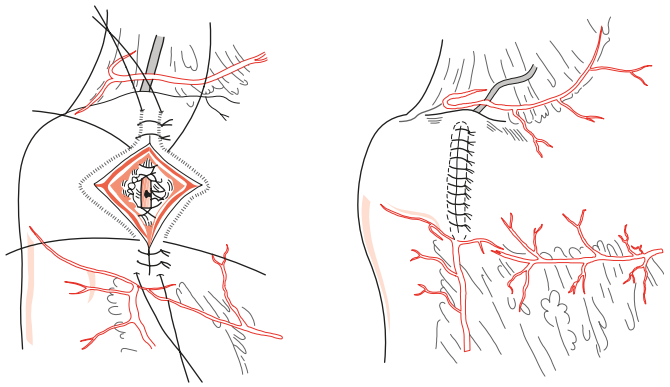

Figure 63.20 Pyroplasty.

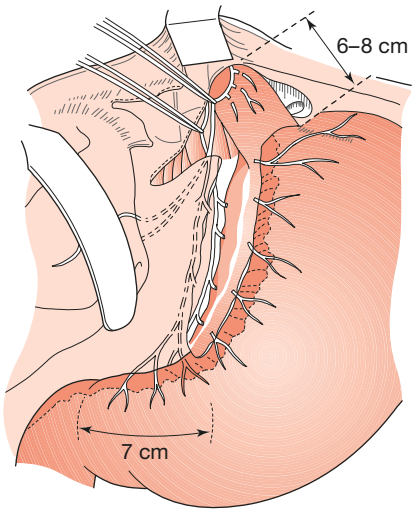

Figure 63.21 Highly selective vagotomy. The anterior and posterior vagus nerves are preserved but all branches to the fundus and body of the stomach are divided.

This proved to be the most satisfactory operation for duodenal ulceration, with a low incidence of side effects and acceptable recurrence rates when performed to a high technical standard. This operation became the gold standard for operations on duodenal ulceration in the 1970s. The operative mortality was lower than any other definitive operation for duodenal ulceration, in all probability because the gastrointestinal tract was not opened during this procedure. The unpleasant effects of peptic ulcer surgery were largely avoided, although loss of receptive relaxation of the stomach did occur, leading to epigastric fullness and sometimes mild dumping. However, the severe symptoms that occur after other more destructive gastric operations did not occur. It is often said that recurrent ulceration is the Achilles' heel of this operation although, when performed well, recurrence was no more common than after truncal vagotomy. The operation disappeared from routine use with the advent of antisecretory agents and eradication therapy.

Walther Hermann Heineke, 1834–1901, surgeon, Erlangen, Germany.
Johann von Mikulicz-Radecki, 1850–1905, Professor of Surgery, Breslau, Germany (now Wroclaw, Poland).
David Johnston, contemporary, Professor of Surgery, University of Leeds, Leeds, UK.
Eric Amdrup, 1923–1998, Professor of Surgery, Aarhus, Denmark.

Truncal vagotomy and antrectomy

For completeness, this operation should be mentioned as at one stage it was popular in the USA. In addition to a truncal vagotomy, the antrum of the stomach is removed, thus removing the source of gastrin, and the gastric remnant is joined to the duodenum. The recurrence rates after this procedure are exceedingly low. However, the operative mortality is higher than after vagotomy and drainage (*Table 63.2*) and the incidence of unpleasant side effects is similar.

Operations for gastric ulcer

In contrast with duodenal ulcer surgery, when the principal objective was to reduce duodenal acid exposure, in gastric ulceration the diseased tissue is usually removed as well. This has the advantage that malignancy can then be confidently excluded. As with duodenal ulceration such surgery is not now performed except for complications of gastric ulcer.

Billroth I gastrectomy

This was the standard operation (**Figure 63.16**) for gastric ulceration until medical treatments became prevalent. The distal stomach is mobilised and resected in the same way as in the Billroth II gastrectomy. This resection should include the ulcer that is usually situated on the lesser curve. The cut edge of the remnant is then partially closed from the lesser curve aspect, leaving a stoma at the greater curve aspect, which should be similar in size to the duodenum. Reconstruction may be facilitated by mobilising the duodenum using Kocher's manoeuvre. The incidence of recurrent ulceration after this operation is low, but it carries with it the morbidity and mortality associated with any gastric resection. This operation is virtually never performed now.

Sequelae of peptic ulcer surgery

There are a number of sequelae of peptic ulcer surgery, which include recurrent ulceration, small stomach syndrome, bilious vomiting, early and late dumping, diarrhoea and malignant transformation. These sequelae principally follow from the more destructive operations that are now seldom performed. However, a substantial number of patients suffer from side effects from operations undertaken in the past. Approximately 30% of patients can expect to suffer a degree of dysfunction following peptic ulcer surgery (*Table 63.2*) and, in about 5% of such patients, the symptoms will be intractable.

Recurrent ulceration

Although mentioned first, this is by far the easiest problem to treat. Just as all peptic ulcers will heal with potent antisecretory agents, so will ulcers that are recurrent after ulcer surgery.

As with other peptic ulcers, recurrent ulcers may present with complications, particularly bleeding and perforation. In this respect, the complication of gastrojejunal colic fistula requires a particular mention. In this rare condition, the anastomotic ulcer penetrates into the transverse colon. Patients suffer from diarrhoea that is severe and follows every meal. They have foul breath and may vomit formed faeces. Severe weight loss and dehydration are rapid in onset, and for this reason the condition may be mistaken for malignancy. The major factor producing the nutritional disturbance is the severe contamination of the jejunum with colonic bacteria. A number of imaging techniques can be used to detect the fistula, most commonly CT with oral contrast or indeed a barium enema. Endoscopy may not convincingly demonstrate the fistula and, in about one-half of such cases, the barium meal will not reveal the problem. The treatment of gastrocolic fistula consists of first correcting the dehydration and malnutrition and then performing revisional surgery.

Small stomach syndrome

Early satiety follows most ulcer operations to some degree, including highly selective vagotomy. In this latter circumstance, although there is no anatomical disturbance of the stomach there is loss of receptive relaxation. Fortunately, this problem does tend to get better with time and revisional surgery is not necessary.

Bile vomiting

Bile vomiting can occur after any form of vagotomy with drainage or gastrectomy. Commonly, the patient presents with vomiting a mixture of food and bile or sometimes some bile alone after a meal. Often eating will precipitate abdominal pain and reflux symptoms are common. Bile chelating agents can be tried but are usually ineffective. In intractable cases, revisional surgery may be indicated. The nature of that revisional surgery depends very much on the original operation. Following gastrectomy, Roux-en-Y diversion is probably the best treatment. In patients with a gastroenterostomy, this can be taken down and, in most circumstances a small pyloroplasty can be performed. In patients with a pyloroplasty, reconstruction of the pylorus has been attempted but, in general terms, the results of this operation have been rather poor. Antrectomy and Roux-en-Y reconstruction may be the better option.

Early and late dumping

Although considered together because the symptoms are similar, early and late dumping have different aetiologies. A common feature, however, is early rapid gastric emptying. Many patients have both early and late dumping.

EARLY DUMPING

Early dumping consists of abdominal and vasomotor symptoms that are found in about 10% of patients following gastrectomy or vagotomy and drainage. It also affects a small percentage of patients following highly selective vagotomy due to the loss of receptive relaxation of the stomach. The small bowel is filled with foodstuffs from the stomach, which have a high osmotic load, and this leads to the sequestration of fluid from the circulation into the gastrointestinal tract. This can be observed by the rise in the packed cell volume

Emil Theodor Kocher, 1841–1917, Professor of Surgery, Berne, Switzerland.

while the symptoms are present. All of the symptoms shown in *Table 63.3* can be related to this effect on the gut and the circulation.

The principal treatment is dietary manipulation. Small, regular meals based on fat and protein are best, and avoiding fluids with a high carbohydrate content also helps. Fortunately, following operation, the syndrome tends to improve with time. For some reason, however, there is a group of patients who suffer intractable dumping regardless of any of these measures. The somatostatin analogue octreotide given before meals has been shown to be useful in some individuals and the long-acting preparation may also be useful. However, this treatment can lead to the development of gallstones and it does not help the diarrhoea from which many patients with dumping also suffer.

Revisional surgery may be occasionally required. In patients with a gastroenterostomy, the drainage may be taken down or, in the case of a pyloroplasty, repaired. Alternatively, antrectomy with Roux-en-Y reconstruction is often effective, although the procedure is of greater magnitude; following gastrectomy, it is the revisional procedure of choice.

TABLE 63.3 Features of early and late dumping.

	Early	Late
Incidence	5–10%	5%
Relation to meals	Almost immediate	Second hour after meal
Durations of attack	30–40 minutes	30–40 minutes
Relief	Lying down	Food
Aggravated by	More food	Exercise
Precipitating factor	Food, especially carbohydrate-rich and wet	As early dumping
Major symptoms	Epigastric fullness, sweating, light-headedness, tachycardia, colic, sometimes diarrhoea	Tremor, faintness, prostration

LATE DUMPING

This is reactive hypoglycaemia. The carbohydrate load in the small bowel causes a rise in the plasma glucose, which, in turn, causes insulin levels to rise, causing a secondary hypoglycaemia. This can be easily demonstrated by serial measurements of blood glucose in a patient following a test meal. The treatment is essentially the same as for early dumping. Octreotide is very effective in dealing with this problem.

Post-vagotomy diarrhoea

This can be the most devastating symptom to afflict patients having peptic ulcer surgery. Most patients will suffer some looseness of bowel action to some degree (with the exception of highly selective vagotomy) but, in about 5%, it may be intractable. Despite much investigation, the precise aetiology of the problem is uncertain. It is related, to some degree, to rapid gastric emptying. In all probability, the denervation of the upper gastrointestinal tract as a result of the vagotomy is also important. Exaggerated gastrointestinal peptide responses may also aggravate the condition.

The diarrhoea in post-vagotomy patients may take several forms. It may be severe and explosive, the patient experiencing a considerable degree of urgency. The patients sometimes describe the diarrhoea as feeling like passing boiling water. At the other extreme, some patients only have minor episodes of diarrhoea, which are not as directly related to food.

Many authors regard diarrhoea and dumping as being essentially the same problem. However, many patients with severe diarrhoea do not have any of the other symptoms of dumping and likewise some patients with dumping do not experience any significant diarrhoea.

The condition is difficult to treat. The patient should be managed as for early dumping and antidiarrhoeal preparations may be of some value. Octreotide is not effective in this condition and the results of revisional surgery are too unpredictable to make this an attractive treatment option.

Malignant transformation

Many large studies now confirm that operations such as gastrectomy or vagotomy and drainage are independent risk factors for the development of gastric cancer. The increased risk appears to be approximately four times that of the control population.

It is not difficult to understand the increased incidence of gastric cancer, as bile reflux gastritis, intestinal metaplasia and gastric cancer are linked. The lag phase between operation and the development of malignancy is at least 10 years. Highly selective vagotomy does not seem to be associated with an increased incidence of gastric cancer in the long term.

Nutritional consequences

Nutritional disorders are more common after gastrectomy than after vagotomy and drainage. Weight loss is common after gastrectomy and the patient may, in fact, never return to their original weight. Nutritional advice advising the taking of small meals is often more useful. Anaemia may be due to either iron or vitamin B12 deficiency.

Iron-deficiency anaemia occurs after both gastrectomy and vagotomy and drainage and is probably multifactorial in origin. Reduced iron absorption is probably the most important factor, although the loss of blood from the gastric mucosa may also be important. Vitamin B12 deficiency is prone to occur after total gastrectomy. However, because of the very large vitamin B12 stores that most patients have, this may be very late in occurring. Vitamin B12 supplementation after total gastrectomy is essential. Rarely, vitamin B12 deficiency may occur after lesser forms of gastrectomy. In such patients the cause is probably a combination of reduced intrinsic factor production and also the fact that some patients have bacterial colonisation, which results in the destruction of the vitamin B12 in the gut.

Bone disease is seen principally after gastrectomy and mainly in women. The condition is essentially indistinguishable from the osteoporosis commonly seen in post-menopausal women. It is only the frequency and magnitude of the disorder that distinguish it. Treatment is with dietary supplementation, calcium and vitamin D, and exercise.

Gallstones

The development of gallstones is strongly associated with truncal vagotomy. Following truncal vagotomy, the biliary tree, as well as the stomach, is denervated, leading to stasis and hence stone formation. Patients developing symptomatic gallstones will require cholecystectomy. However, this may induce or worsen other postpeptic ulcer surgery syndromes such as bilious vomiting and postvagotomy diarrhoea.

The complications of peptic ulceration

The common complications of peptic ulcer are perforation, bleeding and stenosis. Bleeding and stenosis are considered below in the relevant sections.

Perforated peptic ulcer

EPIDEMIOLOGY

Despite the widespread use of gastric antisecretory agents and eradication therapy, the incidence of perforated peptic ulcer has changed little. However, there has been a considerable change in the epidemiology of perforated peptic ulcer in resource-rich countries over the last two decades. Previously, most patients were middle aged, with a ratio of 2:1 of male:female. With time there has been a steady increase in the age of the patients suffering this complication and an increase in the numbers of females, such that perforations now occur most commonly in elderly female patients. NSAIDs appear to be responsible for most of these perforations.

CLINICAL FEATURES

The classical presentation of perforated duodenal ulcer is instantly recognisable (**Figure 63.22**). The patient, who may have a history of peptic ulceration, develops sudden-onset severe generalised abdominal pain due to the irritant effect of gastric acid on the peritoneum. Although the contents of an acid-producing stomach are relatively low in bacterial load, bacterial peritonitis supervenes over a few hours, usually accompanied by a deterioration in the patient's condition. Initially, the patient may be shocked with a tachycardia but a pyrexia is not usually observed until some hours after the event. The abdomen exhibits a board-like rigidity and the patient is disinclined to move because of the pain. The abdomen does not move with respiration. Patients with this form of presentation need an operation, without which the patient will deteriorate with a septic peritonitis.

This classical presentation of the perforated peptic ulcer is observed less commonly than in the past. Very frequently the elderly patient who is taking NSAIDs will have a less dramatic presentation, perhaps because of the use of potent anti-inflammatory drugs (steroids). The board-like rigidity seen in the abdomen of younger patients may also not be observed and a higher index of suspicion is necessary to make the correct diagnosis. In other patients, the leak from the ulcer may not be massive. They may present only with pain in the epigastrium and right iliac fossa as the fluid may track down the right paracolic gutter. Sometimes perforations will seal owing to the inflammatory response and adhesion within the abdominal cavity, and so the perforation may be self-limiting. All of these factors may combine to make the diagnosis of perforated peptic ulcer difficult.

By far the most common site of perforation is the anterior aspect of the duodenum. However, the anterior or incisural gastric ulcer may perforate and, in addition, gastric ulcers may perforate into the lesser sac, which can be particularly difficult to diagnose. These patients may not have obvious peritonitis.

INVESTIGATIONS

An erect plain chest radiograph will reveal free gas under the diaphragm in excess of 50% of cases with perforated peptic ulcer (**Figure 63.23**) but CT imaging is more accurate (see below). All patients should have serum amylase performed, as distinguishing between peptic ulcer, perforation and pancreatitis can be difficult. Measuring the serum amylase, however, may not remove the diagnostic difficulty. It can be elevated following perforation of a peptic ulcer although, fortunately, the levels are not usually as high as the levels commonly seen

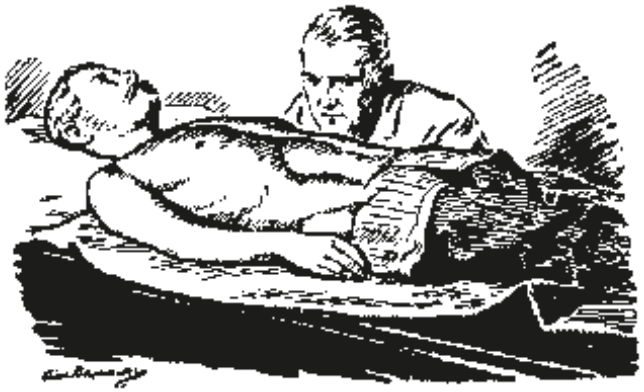

Figure 63.22 A sketch of Mr Hamilton Bailey watching for abdominal movement on respiration. In the case of a classically presenting perforated ulcer, the abdominal movement is restricted or absent.

Henry Hamilton Bailey, 1894–1961, surgeon, The Royal Northern Hospital, London, UK.

in acute pancreatitis. Several other investigations are useful if doubt remains. A CT scan will normally be diagnostic in both conditions.

TREATMENT

The initial priorities are resuscitation and analgesia. Analgesia should not be withheld for fear of removing the signs of an intra-abdominal catastrophe. In fact, adequate analgesia makes the clinical signs more obvious. It is important, however, to titrate the analgesic dose. Following resuscitation, the treatment is principally surgical. Laparotomy is performed, usually through an upper midline incision if the diagnosis of perforated peptic ulcer can be made with confidence. This is not always possible and hence it may be better to place a small incision around the umbilicus to localise the perforation with more certainty. Alternatively, laparoscopy may be used. The most important component of the operation is a thorough peritoneal toilet to remove all of the fluid and food debris. If the perforation is in the duodenum it can usually be closed by several well-placed sutures, closing the ulcer in a transverse direction as with a pyloroplasty. It is important that sufficient tissue is taken in the suture to allow the edges to be approximated, and the sutures should not be tied so tight that they tear out. It is common to place an omental patch over the perforation in the hope of enhancing the chances of the leak sealing. If the perforation is difficult to close primarily it is frequently possible to seal the leak with an omental patch alone, and many surgeons now employ this strategy for all perforations. When securing the omental patch it is important not to tie the sutures too tight so as to obliterate the omental blood supply. Gastric ulcers should, if possible, be excised and closed, so that malignancy can be excluded. Occasionally a patient is seen who has a massive duodenal or gastric perforation such that simple closure is impossible; in these patients a distal gastrectomy with Roux-en-Y reconstruction is the procedure of choice.

All patients should be treated with systemic antibiotics in addition to a thorough peritoneal lavage. In the past, many surgeons performed definitive procedures such as either truncal vagotomy and pyloroplasty or, more recently and probably more successfully, highly selective vagotomy during the course of an operation for a perforation. Studies show that in well-selected patients and in expert hands this is a very safe strategy. However, nowadays, surgery is confined to first-aid measures most commonly, and the peptic ulcer is treated medically as described earlier in this chapter. Following operation, gastric antisecretory agents should be started immediately. *H. pylori* eradication is mandatory.

Perforated peptic ulcers can often be managed by minimally invasive techniques if the expertise is available. The principles of operation are, however, the same; thorough peritoneal toilet is performed and the perforation is closed by intracorporeal suturing. Whatever technique is used, it is important that the stomach is kept empty postoperatively by nasogastric suction, and that gastric antisecretory agents are commenced to promote healing in the residual ulcer.

A great deal has been written about the conservative management of perforated ulcer. Some writers say that virtually all patients can be managed conservatively, whereas most surgeons have difficulty in understanding how a patient who is ill with widespread peritonitis and who has food debris widely distributed through the abdominal cavity will improve without an operation. However, undoubtedly, there are patients who have small leaks from a perforated peptic ulcer and relatively mild peritoneal contamination, who may be managed with intravenous fluids, nasogastric suction and antibiotics. These patients are in the minority. A number of factors have been associated with poor outcome after perforated peptic ulcer, including:

- delay in diagnosis (>24 hours);
- medical comorbidities;
- shock;
- increasing age (>75).

There is little evidence to advocate the conservative management of patients who exhibit any of these characteristics.

Patients who have suffered one perforation may suffer another one. Therefore, they should be managed aggressively to ensure that this does not happen. Lifelong treatment with proton pump inhibitors is a reasonable option especially in those who have to continue with NSAID treatment.

HAEMATEMESIS AND MELAENA

Upper gastrointestinal haemorrhage remains a major medical problem with an incidence over 100/100 000 per year in western practice that increases with increasing age. Haemorrhage is strongly associated with NSAID use. Despite improvements in diagnosis and the proliferation in treatment modalities over the last few decades, an in-hospital mortality of 5–10% can be expected. This rises to 33% when bleeding is first observed in patients who are hospitalised for other reasons. In patients in whom the cause of bleeding can be found, the most common causes are peptic ulcer, erosions, Mallory–Weiss tear and bleeding oesophageal varices (*Table 63.4*).

Whatever the cause, the principles of management are identical. First, the patient should be adequately resuscitated and, following this, the patient should be investigated urgently to determine the cause of the bleeding. Only then should treatment of a definitive nature be instituted. For any significant gastrointestinal bleed, intravenous access should be established and, for those with severe bleeding, central venous pressure monitoring should be set up and bladder catheterisation performed. Blood should be cross-matched and the patient transfused as clinically indicated, usually when >30% of blood volume has been lost. There is no evidence for the use of intravenous proton pump inhibitors prior to endoscopy. As a general rule, most gastrointestinal bleeding will stop, albeit temporarily, but there are sometimes instances when this is not the case. In these circumstances, resuscitation, diagnosis and treatment should be carried out simultaneously. There are occasions when life-saving manoeuvres have to

be undertaken without the benefit of an absolute diagnosis. For instance, in patients with known oesophageal varices and uncontrollable bleeding, a Sengstaken–Blakemore tube may be inserted before an endoscopy has been carried out. This practice is not to be encouraged, except in extremis. In some patients, bleeding is secondary to a coagulopathy. The most important current causes of this are liver disease and inadequately controlled warfarin therapy. In these circumstances the coagulopathy should be corrected, if possible, with fresh-frozen plasma or concentrated clotting factors.

Upper gastrointestinal endoscopy should be carried out by an experienced operator as soon as practicable after the patient has been stabilised. In patients in whom the bleeding is relatively mild, endoscopy may be carried out on the morning after admission; this is usually guided by local policy. In all cases of severe bleeding it should be carried out immediately. A number of scoring systems have been advocated for the assessment of rebleeding and death after upper gastrointestinal haemorrhage. Perhaps the most useful of these is the Rockall score. This can be used in a pre-endoscopy format to stratify patients to safe early discharge and postendoscopy it can relatively accurately predict rebleeding and death.

Bleeding peptic ulcers

The epidemiology of bleeding peptic ulcers exactly mirrors that of perforated ulcers. In recent years, the population affected has become much older and the bleeding is commonly associated with the ingestion of NSAIDs. Diagnosis can normally be made endoscopically, although occasionally the nature of the blood loss precludes accurately identifying the lesion. However, the more experienced the endoscopist, the less likely this is to be a problem.

Medical and minimally interventional treatments

Medical treatment has limited efficacy. All patients are commonly started on either an H_2-antagonist or a proton pump antagonist, and recent evidence confirms the benefit of proton pump inhibitor administration to prevent rebleeding after endoscopy. Furthermore, meta-analysis of studies suggests that tranexamic acid, an inhibitor of fibrinolysis, may reduce overall mortality.

Therapeutic endoscopy can achieve haemostasis in approximately 70% of cases, with the best evidence supporting a combination of adrenaline injection with heater probe and/or clips. Therapeutic endoscopy will probably never be effective in patients who are bleeding from large vessels and with which the majority of the mortality is associated.

In patients where the source of bleeding cannot be identified or in those who rebleed after endoscopy, angiography with transcatheter embolisation may offer a valuable alternative to surgery in expert centres. The risk of significant ischaemia following embolisation is low because of the rich collateral blood supply of the stomach and duodenum. The surgeon should be mindful that rescue surgery after failed embolisation is associated with poor outcome and it may be advantageous to proceed directly to surgery.

Surgical treatment

Criteria for surgery are well worked out. A patient who continues to bleed requires surgical treatment. The same applies to a significant rebleed. The only exception applies in expert centres with 24-hour interventional radiology and experience of angiographic embolisation where attempts may be made to arrest bleeding and avoid surgery. The surgical team should care for these patients and an operation should not be delayed if any concerns remain. Patients with a visible vessel in the ulcer base, a spurting vessel or an ulcer with a clot in the base are statistically likely to require surgical treatment to stop the bleeding. Elderly and unfit patients are more likely to die as a result of bleeding than younger patients. Ironically, they should have early surgery. A patient who has required more than six units of blood in general needs surgical treatment.

The aim of the operation is to stop the bleeding. The advent of endoscopy has greatly helped in the management of upper gastrointestinal bleeding as a surgeon can usually be confident about the site of bleeding prior to operation. The most common site of bleeding from a peptic ulcer is the duodenum. In tackling this, it is essential that the duodenum is fully mobilised. This should be done before the duodenum is opened as it makes the ulcer much more accessible and also allows the surgeon's hand to be placed behind the gastroduodenal artery, which is commonly the source of major bleeding. Following mobilisation, the duodenum, and usually the pylorus, is opened longitudinally as in a

Robert William Sengstaken, b.1923, surgeon, Garden City, NY, USA.
Arthur Hendley Blakemore, 1897–1970, Associate Professor of Surgery, the Columbia College of Physicians and Surgeons, New York, NY, USA. Sengstaken and Blakemore originally described the tube in 1950.
Timothy A Rockall, contemporary, Professor of Surgery, University of Surrey, UK.

pyloroplasty. This allows good access to the ulcer, which is usually found posteriorly or superiorly. Accurate haemostasis is important and can be achieved initially by direct pressure. It is the vessel within the ulcer that is bleeding and this should be controlled using well-placed sutures on a small round-bodied needle that under-run the vessel. The placing of more and more inaccurately positioned sutures is counter-productive. Following under-running, it is often possible to close the mucosa over the ulcer. The pyloroplasty is then closed with interrupted sutures in a transverse direction as in the usual fashion. In a giant ulcer the first part of the duodenum may be destroyed making primary closure impossible. In this circumstance one should proceed to distal gastrectomy with Roux-en-Y reconstruction. The duodenal stump may then be closed using the Nissen technique with T-tube drainage.

The principles of management of bleeding gastric ulcers are essentially the same. The stomach is opened at an appropriate position anteriorly and the vessel in the ulcer under-run. If the ulcer is not excised then a biopsy of the edge needs to be taken to exclude malignant transformation. Sometimes the bleeding is from the splenic artery and if there is a lot of fibrosis present then the operation may be challenging. However, most patients can be managed by conservative surgery. Gastrectomy for bleeding has been widely practised in the past, but is associated with a high perioperative mortality even if the incidence of recurrent bleeding is less.

Bearing in mind that most patients nowadays are elderly and unfit, the minimum surgery that stops the bleeding is probably optimal (damage control surgery). Acid can be inhibited by pharmacological means and appropriate eradication therapy will prevent ulcer recurrence. Definitive acid-lowering surgery is not now required. Patients on long-term NSAIDs can be managed as outlined earlier.

Stress ulceration

This commonly occurs in patients with major injury or illness, who have undergone major surgery or who have major comorbidity. Many such patients are found in intensive care units. There seems little doubt that the incidence of this problem has reduced in recent years due to the widespread use of prophylaxis. Acid inhibition and the nasogastric or oral administration of sucralfate has been shown to reduce the incidence of stress ulceration. There is no doubt that it is far better to prevent this condition than to try to treat it once it occurs. Endoscopic means of treating stress ulceration may be ineffective and operation may be required. The principles of management are the same as for the chronic ulcer.

Gastric erosions

Erosive gastritis has a variety of causes, especially NSAIDs. Fortunately, most such bleeding settles spontaneously, but when it does not it can be a major problem to treat. In general terms, although there is a diffuse erosive gastritis, there is one (or more) specific lesion that has a significant-sized vessel within it. This should be dealt with appropriately, preferably endoscopically, but sometimes surgery is necessary.

Mallory–Weiss tear

This is a longitudinal tear at the gastro-oesophageal junction, which is induced by repetitive and strenuous vomiting. Doubtless, many such lesions occur and do not cause bleeding. When it is a cause of haematemesis, the lesion may often be missed as it can be difficult to see as it is just below the gastro-oesophageal junction, a position that can be difficult for the inexperienced endoscopist. Occasionally these lesions continue to bleed and require surgical treatment. Often the situation arises in which the surgeon does not have guidance from the endoscopists as regards the site of bleeding, and a high index of suspicion in such circumstances is important. The experienced surgeon will perform on-table endoscopy prior to embarking on surgery. The stomach is opened by longitudinal gastrotomy and the upper section is carefully inspected. It is normally possible to palpate the longitudinal mucosal tear with a little induration at the edges, which gives a clue to the lesion's location. Under-running is all that is required.

Dieulafoy's disease

This is essentially a gastric arterial venous malformation that has a characteristic histological appearance. Bleeding due to this malformation is one of the most difficult causes of upper gastrointestinal bleeding to treat. The lesion itself is covered by normal mucosa and, when not bleeding, it may be invisible. If it can be seen while bleeding, all that may be visible is profuse bleeding coming from an area of apparently normal mucosa. If this occurs, the cause is instantly recognisable. If the lesion can be identified endoscopically there are various means of dealing with it, including injection of sclerosant and endoscopic clips. If it is identified at operation then only a local excision is necessary. Occasionally, a lesion is only recognised after gastrectomy and sometimes not even then. The pathologist, as well as the endoscopist, may have difficulty in finding it.

Tumours

All of the gastric tumours described below may present with chronic or acute upper gastrointestinal bleeding. Bleeding is not normally torrential but can be unremitting. Gastric stromal tumours commonly present with bleeding and have a characteristic appearance, as the mucosa breaks down over the tumour in the gastric wall (**Figure 63.24**). Whatever the nature, the tumours should be dealt with as appropriate.

Georges Dieulafoy, 1839–1911, physician, Paris, France.

Figure 63.24 Smooth muscle tumour of the stomach, with ulceration.

Portal hypertension and portal gastropathy

The management of bleeding gastric varices is very challenging. Fortunately, most bleeding from varices is oesophageal and this is much more amenable to sclerotherapy, banding and balloon tamponade. Gastric varices may also be injected, although this is technically more difficult. Banding can also be used, again with difficulty. The gastric balloon of the Sengstaken–Blakemore tube can be used to arrest the haemorrhage if it is occurring from the fundus of the stomach or gastro-oesophageal junction. Octreotide is a somatostatin analogue that reduces portal pressure in patients with varices, and trials suggest that it is of value in arresting haemorrhage in these patients, although its overall effect on mortality remains in doubt. Glypressin is also said to be of use.

Most surgeons prefer to avoid acute surgery on bleeding varices as, in contrast with elective operations for portal hypertension, acute shunts are attended by considerable operative mortality. For this reason the acute TIPSS procedure (transjugular intrahepatic portosystemic shunt), which is described in Chapter 65, can be an extremely useful, although technically demanding, procedure.

Portal gastropathy

Portal gastropathy is essentially the same disease process as described above. The mucosa is affected by the increased portal pressure and may exude blood, even in the absence of well-developed visible varices. The treatment is as above.

Aortic enteric fistula

This diagnosis should be considered in any patient with haematemesis and melaena that cannot be otherwise explained. Contrary to expectation, the bleeding from such patients is not always massive, although it can be. Very often there is nothing much to distinguish between the bleeding from the aortic enteric fistula and any other recurrent upper gastrointestinal bleeding. The vast majority of patients will have had an aortic graft and, in the absence of this, the diagnosis is unlikely. However, it is occasionally seen in patients with an untreated aortic aneurysm. A well-performed CT scan will commonly allow the diagnosis to be made with certainty. The condition should be managed by an expert vascular surgeon as, whether secondary or primary, the morbidity and mortality are high.

GASTRIC OUTLET OBSTRUCTION

The two common causes of gastric outlet obstruction are gastric cancer (see below) and pyloric stenosis secondary to peptic ulceration. Previously, the latter was more common. Now, with the decrease in the incidence of peptic ulceration and the advent of potent medical treatments, gastric outlet obstruction should be considered malignant until proven otherwise, at least in resource-rich countries.

The term 'pyloric stenosis' is normally a misnomer. The stenosis is seldom at the pylorus. Commonly, when the condition is due to underlying peptic ulcer disease, the stenosis is found in the first part of the duodenum, the most common site for a peptic ulcer. True pyloric stenosis can occur due to fibrosis around a pyloric channel ulcer. However, in recent years the most common cause of gastric outlet obstruction has been gastric cancer. In this circumstance the metabolic consequences may be somewhat different from those of benign pyloric stenosis because of the relative hypochlorhydria found in patients with gastric cancer.

Summary box 63.5

Gastric outlet obstruction

- Gastric outlet obstruction is most commonly associated with longstanding peptic ulcer disease and gastric cancer
- The metabolic abnormality of hypochloraemic alkalosis is usually only seen with peptic ulcer disease and should be treated with isotonic saline with potassium
- Endoscopic biopsy is essential to determine whether the cause of the problem is malignancy
- Aggressive medical therapy for peptic ulcer disease often leads to resolution
- Endoscopic dilatation of the gastric outlet may be effective in less severe cases of benign stenosis
- Operation is frequently required, with a drainage procedure being performed for benign disease and appropriate resectional surgery if malignant

Clinical features

In benign gastric outlet obstruction there is usually a long history of peptic ulcer disease. Nowadays, as most patients with peptic ulcer symptoms are treated medically, it is easy to understand why the condition is becoming much less

common. In some patients the pain may become unremitting and in other cases it may largely disappear. The vomitus is characteristically unpleasant in nature and is totally lacking in bile. Very often it is possible to recognise foodstuff taken several days previously. The patient commonly complains of losing weight, and appears unwell and dehydrated. When examining the patient, it may be possible to see the distended stomach and a succussion splash may be audible on shaking the patient's abdomen.

Metabolic effects

These are most interesting, as the metabolic consequences of benign pyloric stenosis are unique. The vomiting of hydrochloric acid results in hypochloraemic alkalosis. Initially the sodium and potassium may be relatively normal. However, as dehydration progresses, more profound metabolic abnormalities arise, partly related to renal dysfunction. Initially, the urine has a low chloride and high bicarbonate content, reflecting the primary metabolic abnormality. This bicarbonate is excreted along with sodium, and so with time the patient becomes progressively hyponatraemic and more profoundly dehydrated. Because of the dehydration, a phase of sodium retention follows and potassium and hydrogen are excreted in preference. This results in the urine becoming paradoxically acidic and hypokalaemia ensues. Alkalosis leads to a lowering in the circulating ionised calcium, and tetany can occur.

Management

Treating the patient involves correcting the metabolic abnormality and dealing with the mechanical problem. The patient should be rehydrated with intravenous isotonic saline with potassium supplementation. Replacing the sodium chloride and water allows the kidney to correct the acid–base abnormality. Following rehydration, it may become obvious that the patient is also anaemic, the haemoglobin being spuriously high on presentation.

It is notable that the metabolic abnormalities may be less if the obstruction is due to malignancy, as the acid–base disturbance is less pronounced.

The stomach should be emptied using a wide-bore gastric tube. A large nasogastric tube may not be sufficiently large to deal with the contents of the stomach, and it may be necessary to pass an orogastric tube and lavage the stomach until it is completely emptied. This then allows investigation of the patient with endoscopy and contrast radiology. Biopsy of the area around the pylorus is essential to exclude malignancy. The patient should also have a gastric antisecretory agent, initially given intravenously to ensure absorption.

Early cases may settle with conservative treatment, presumably as the oedema around the ulcer diminishes as the ulcer is healed. Traditionally, severe cases are treated surgically, usually with a gastroenterostomy rather than a pyloroplasty. Endoscopic treatment with balloon dilatation has been practised and may be most useful in early cases. However, this treatment is not devoid of problems. Dilating the duodenal stenosis may result in perforation. The dilatation may have to be performed several times and may not be successful in the long term. Occasionally duodenal stent insertion will be considered in specialist centres.

Other causes of gastric outlet obstruction

Adult pyloric stenosis

This is a rare condition and its relationship to the childhood condition is unclear, although some patients have a long history of problems with gastric emptying. It is commonly treated by pyloroplasty rather than pyloromyotomy.

Pyloric mucosal diaphragm

The origin of this rare condition is unknown. It usually does not become apparent until middle life. When found, simple excision of the mucosal diaphragm is all that is required.

GASTRIC POLYPS

A number of conditions manifest as gastric polyps. Their main importance is that they may actually represent early gastric cancer. Biopsy is essential.

The most common type of gastric polyp is metaplastic. These are associated with *H. pylori* infection and regress following eradication therapy. Inflammatory polyps are also common. Fundic gland polyps deserve particular attention. They seem to be associated with the use of proton pump inhibitors and are also found in patients with familial polyposis. None of the above polypoid lesions has proven malignant potential. True adenomas have malignant potential and should be removed, but they account for only 10% of polypoid lesions. Gastric carcinoids arising from the ECL cells are seen in patients with pernicious anaemia and usually appear as small polyps.

GASTRIC CANCER

Carcinoma of the stomach is a major cause of cancer mortality worldwide. Its prognosis tends to be poor, with cure rates little better than 5–10%, although better results are obtained in Japan, where the disease is common. Gastric cancer is actually an eminently curable disease provided that it is detected at an appropriate stage and treated adequately. It rarely disseminates widely before it has involved the lymph nodes and, therefore, there is an opportunity to cure the disease prior to dissemination. Early diagnosis is therefore the key to success with this disease. Unfortunately, the late presentation of many cases is the cause of the poor overall survival figures. The only treatment modality able to cure the disease is resectional surgery.

Incidence

There are marked variations in the incidence of gastric cancer worldwide. In the UK it is approximately 15 per 100 000 per year, in the USA 10 per 100 000 per year and in Eastern Europe 40 per 100 000 per year. In Japan, the disease is much more common, with an incidence of approximately 70 per

Summary box 63.6

Gastric cancer

- Gastric cancer is one of the most common causes of cancer death in the world
- The outlook is generally poor, owing to the advanced stage of the tumour at presentation
- Better results are obtained in Japan, which has a high population incidence, screening programmes and a high-quality surgical treatment
- The aetiology of gastric cancer is multifactorial, but *H. pylori* is an important factor for distal but not proximal gastric cancer
- Early gastric cancer is associated with very high cure rates
- Gastric cancer can be classified into intestinal and diffuse types, the latter having a worse prognosis
- In western resource-rich countries, proximal gastric cancer is now more common than distal cancer and is usually of the diffuse type
- Spread may be by lymphatics, blood, transcoelomic or direct, but distant metastases are uncommon in the absence of lymph node involvement
- The treatment of curable cases is by radical surgery and removal of the second tier of nodes (around the principal arterial trunks) may be advantageous
- Gastric cancer is chemosensitive and chemotherapy improves survival in patients having surgery for the condition and in advanced disease

100 000 per year, and there are small geographical areas in China where the incidence is double that in Japan. These underlying epidemiological data make it clear that this is an environmental disease. In general, men are more affected by the disease than women and, as with most solid organ malignancies, the incidence increases with age.

At present, marked changes are being observed in resource-rich countries in terms of the incidence and site of gastric cancer and the population affected, changes that to date have not been observed in Japan. First, the incidence of gastric cancer is continuing to fall at about 1% per year. This reduction exclusively affects carcinoma arising in the body and distal stomach. In contrast, there appears to be an increase in the incidence of carcinoma in the proximal stomach, particularly the oesophagogastric junction. Carcinoma of the distal stomach and body of the stomach is most common in low socioeconomic groups, whereas the increase in proximal gastric cancer seems to affect principally higher socioeconomic groups. Proximal gastric cancer does not seem to be associated with *H. pylori* infection, in contrast with carcinoma of the body and distal stomach.

Aetiology

Gastric cancer is a multifactorial disease (Correa). Epidemiological studies point to a role for *H. pylori*, although there is argument about how important this factor is. Studies reveal a correlation between the incidence of gastric cancer in various populations and the prevalence of *H. pylori* infection, but other factors are also important. There is insufficient evidence at the moment to support eradication programmes in asymptomatic patients who are infected with *Helicobacter*, with a view to reducing the population incidence of gastric cancer. However, clinical trials may subsequently change this view. As mentioned above, *Helicobacter* seems to be principally associated with carcinoma of the body, stomach and distal stomach rather than the proximal stomach. As *Helicobacter* is associated with gastritis, gastric atrophy and intestinal metaplasia, the association with malignancy is perhaps not surprising.

Several other risk factors have been identified as being important in the aetiology of gastric cancer. Patients with pernicious anaemia and gastric atrophy are at increased risk, as are those with gastric polyps. Patients who have had peptic ulcer surgery, particularly those who have had drainage procedures such as Billroth II or Polya gastrectomy, gastroenterostomy or pyloroplasty, are at approximately four times the average risk. Presumably duodenogastric reflux and reflux gastritis are related to the increased risk of malignancy in these patients. Intestinal metaplasia is a risk factor. Carcinoma is associated with cigarette smoking and dust ingestion from a variety of industrial processes. Diet appears to be important, as illustrated by the often quoted example of the change in the incidence of gastric cancer in Japanese families living in the USA. The high incidence of gastric cancer in some pockets in China is probably environmental and probably diet related. The ingestion of substances such as spirits may induce gastritis and, in the long term, cancer. Excessive salt intake, deficiency of antioxidants and exposure to *N*-nitroso compounds are also related. The aetiology of proximal gastric cancer remains an enigma. It is not associated with *Helicobacter* but is associated with obesity and higher socioeconomic status. Genetic factors are also important but imperfectly elucidated (see below).

Clinical features

The features of advanced gastric cancer are usually obvious. However, curable gastric cancer has no specific features to distinguish it symptomatically from benign dyspepsia. The key to improving the outcome of gastric cancer is early diagnosis and, although in Japan there is a screening programme, most curable cases are picked up by the liberal use of gastroscopy in patients with dyspepsia. In western resource-rich countries it is much more difficult as the population incidence is much lower. Hence the cost effectiveness of performing gastroscopy for mild dyspeptic symptoms is low. However a high index of suspicion is necessary as only endoscoping patients with symptoms of advanced cancer is unlikely to be beneficial as such patients are not surgically curable. It is important to note that gastric antisecretory agents will improve the symptoms of gastric cancer so the disease should be excluded, preferably before therapy is started.

P. Correa, contemporary, pathologist, New Orleans, LA, USA. Produced a cogent hypothesis to explain the development of the intestinal type of gastric cancer.

In advanced cancer, early satiety, bloating, distension and vomiting may occur. The tumour frequently bleeds, resulting in iron deficiency anaemia. Obstruction leads to dysphagia, epigastric fullness or vomiting. Weight loss can be profound. With pyloric involvement the presentation may be of gastric outlet obstruction, although the alkalosis is usually less pronounced or absent compared with when duodenal ulceration leads to obstruction. In recent years, gastric outlet obstruction is more commonly associated with malignancy than benign disease. Non-metastatic effects of malignancy are seen, particularly thrombophlebitis (Trousseau's sign) and deep venous thrombosis. These features result from the effects of the tumour on thrombotic and haemostatic mechanisms.

Site

The proximal stomach is now the most common site for gastric cancer in resource-rich western countries. Because so many malignancies occur at the oesophageal–gastric junction, and because the lower oesophagus is also a very common site of adenocarcinoma, it is artificial to separate the stomach from the oesophagus. Therefore, it is best to consider the whole of the upper gastrointestinal tract from the cricopharyngeus to the pylorus. The incidence of cancer at these various sites is shown in **Figure 63.25**. It can be seen that just under 60% of all of the malignancies occurring in the oesophagus and stomach occur in proximity to the oesophagogastric junction. Adenocarcinoma at this site has doubled in incidence in the UK over the last 30 years. This high prevalence of proximal gastric cancer is not seen in Japan, where distal cancer still predominates, as it does in most of the rest of the world.

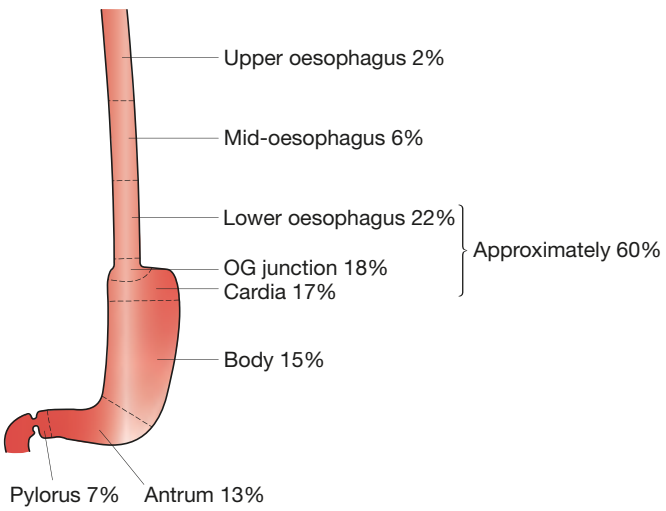

Figure 63.25 The incidence of cancer in the various parts of the upper gastrointestinal tract in the UK. OG, oesophagogastric.

Pathology

The most useful clinicopathological classification of gastric cancer is the Lauren classification. In this system there are principally two forms of gastric cancer: intestinal gastric cancer and diffuse gastric cancer (often with signet ring cells). In intestinal gastric cancer, the tumour resembles a carcinoma elsewhere in the tubular gastrointestinal tract and forms polypoid tumours or ulcers. It probably arises in areas of intestinal metaplasia. In contrast, diffuse gastric cancer infiltrates deeply into the stomach without forming obvious mass lesions, but spreads widely in the gastric wall. Not surprisingly, this has a much worse prognosis. A small proportion of gastric cancers are of mixed morphology.

Gastric cancer can be divided into early gastric cancer and advanced gastric cancer. Early gastric cancer is defined as cancer limited to the mucosa and submucosa with or without lymph node involvement (T1, any N). The classification is shown in **Figures 63.26 and 63.27**. This can be either protruding, superficial or excavated in the Japanese classification. This type of cancer is eminently curable, and even early gastric cancers associated with lymph node involvement have 5-year survival rates in the region of 90%. In Japan, approximately one-third of gastric cancers diagnosed are in this stage. However, in the UK it is uncommon to detect gastric cancers at this stage. A number of reasons probably still account for this. First, because gastric cancer is less common in the UK, dyspeptic patients are not always referred for endoscopy at an appropriate stage. Second, endoscopists are unfamiliar with the appearances of early gastric cancer and in all probability many such cases are missed.

Advanced gastric cancer involves the muscularis. Its macroscopic appearances have been classified by Bormann into four types (**Figures 63.28 and 63.29**). Types III and IV are commonly incurable.

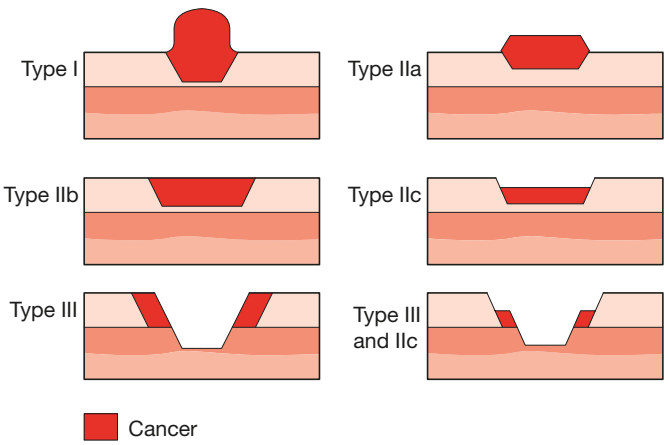

Figure 63.26 Early gastric cancer, Japanese classification.

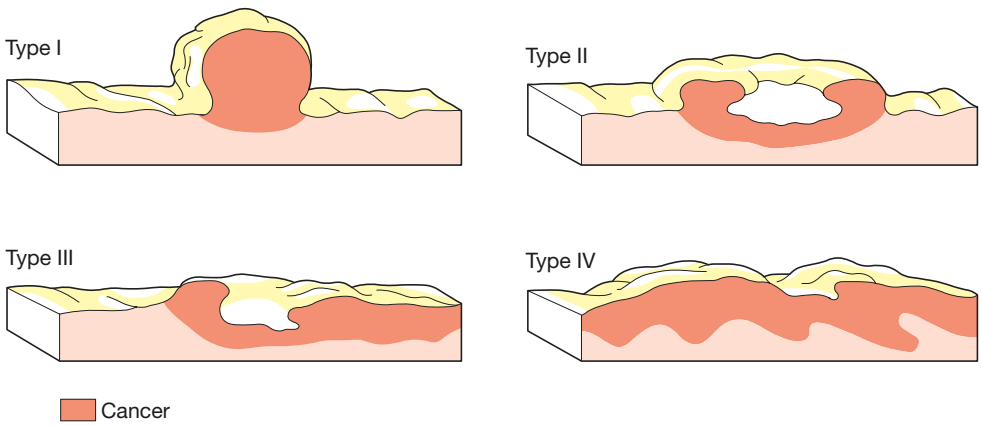

Figure 63.28 Bormann classification of advanced gastric cancer.

The molecular pathology of gastric cancer

Our understanding of the molecular pathology of gastric cancer has been revolutionised by the application of next-generation sequencing platforms to the disease. In a recent landmark paper The Cancer Genome Atlas (TCGA) group described four molecular subtypes of gastric cancer: Epstein–Barr virus positive, microsatellite instable, genomically stable and chromosomal instability. Recognition of these sub-groups and their underlying common gene mutations and driver events is leading to the development of targeted therapies including immunotherapies. Similar genetic classifications are now available for other tumours of the gastrointestinal tract meaning that novel treatments can be applied across tumour types. A range of mutations in genes related to genome integrity (e.g. *BRCA2*, *TP53*, *ARID1A*), chromatin remodelling (e.g. *SMARCA1*, *CHD3&4*) and cell–cell adhesion and

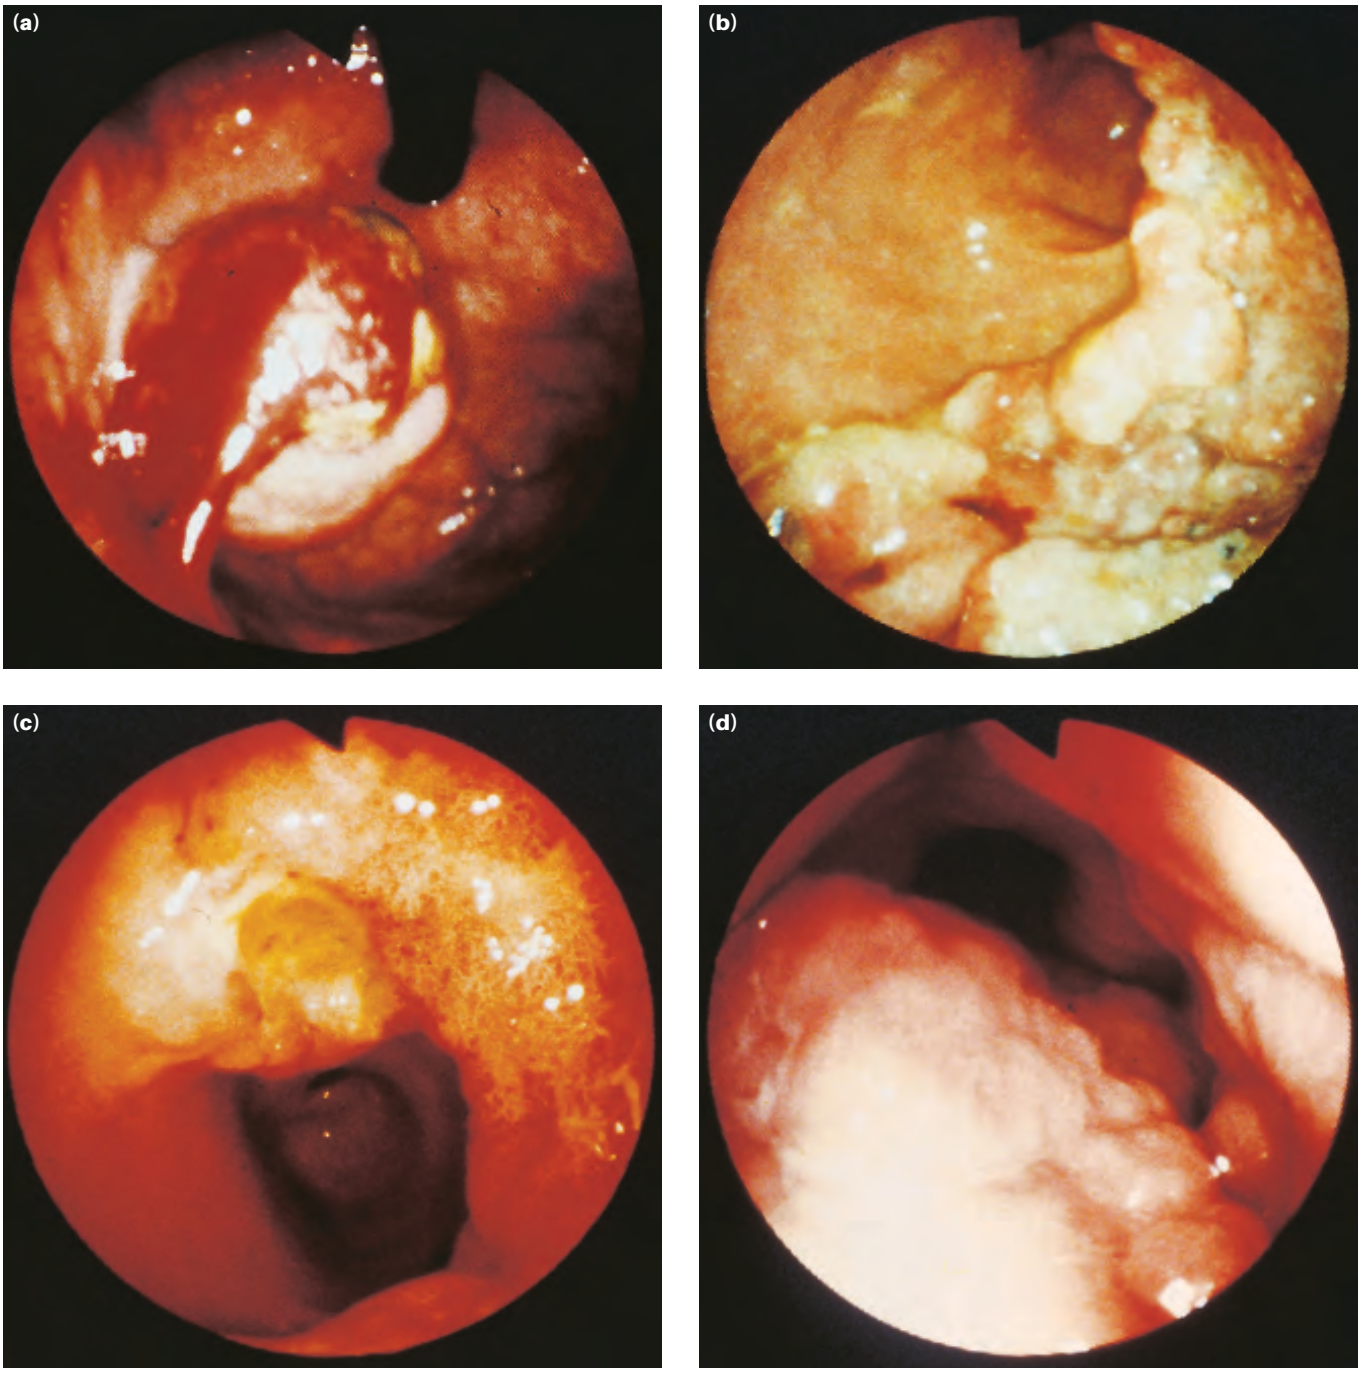

Figure 63.29 Advanced gastric cancer: **(a)** type I; **(b)** type II; **(c)** type III; **(d)** type IV (linitus plastica) (courtesy of Dr GNJ Tytgat, Amsterdam, The Netherlands).

motility (e.g. *RHOA*, *CDH1*) have been described in gastric cancer. In addition, cell signalling pathways commonly mutated in other solid organ tumours are commonly found perturbed in gastric cancer. For example, the Wnt pathway may be amenable to specific small molecule inhibitors. Unsurprisingly, gastric cancer exhibits a range of mutations in receptor tyrosine kinases and PI3K/MAPK signalling.

The rapid development of sequencing technologies, including single-cell platforms and the development of real-time sequencing, offers the promise of precision therapy for gastric cancer in the future, but currently treatment is still based on surgery with or without conventional chemo/radiotherapy.

Staging

The International Union Against Cancer (UICC) staging system is shown in *Table 63.5*. Important changes have been made in the seventh edition of the TNM staging system that are worthy of discussion. In an attempt to reflect the current

TABLE 63.5 UICC staging of gastric cancer.

T1	Tumour involves lamina propria, submucosa		
	T1a lamina propria		
	T1b submucosa

evidence base and to improve outcome prediction for individual patients, all gastric tumours whose epicentre is within 5 cm of the gastro-oesophageal junction and which extend into the oesophagus are now classified according to the oesophageal system. Tumours whose epicentre is within 5 cm of the gastro-oesophageal junction but which do not extend into the oesophagus, and all other gastric cancers, are staged using the revised gastric staging system. In addition, any tumour that perforates the serosa is now classified as T4 disease.

Spread of carcinoma of the stomach

No better example of the various modes by which carcinoma spreads can be given than the case of stomach cancer. It is important to note that this distant spread is unusual before the disease spreads locally, and distant metastases are uncommon in the absence of lymph node metastases. The intestinal and diffuse types of gastric cancer spread differently. The diffuse type spreads via the submucosal and subserosal lymphatic plexus and it penetrates the gastric wall at an early stage.

Direct spread

The tumour penetrates the muscularis, serosa and ultimately adjacent organs such as the pancreas, colon and liver.

Lymphatic spread

This is by both permeation and emboli to the affected tiers (see below) of nodes. This may be extensive, the tumour even appearing in the supraclavicular nodes (Troisier's sign). Unlike malignancies such as breast cancer, nodal involvement does not imply systemic dissemination.

Blood-borne metastases

These occur first to the liver and subsequently to other organs, including lung and bone. This is uncommon in the absence of nodal disease.

Transperitoneal spread

This is a common mode of spread once the tumour has reached the serosa of the stomach and indicates incurability. Tumours can manifest anywhere in the peritoneal cavity and commonly give rise to ascites. Advanced peritoneal disease may be palpated either abdominally or rectally as a tumour 'shelf'. The ovaries may sometimes be the sole site of transcoelomic spread (Krukenberg's tumours). Tumour may spread via the abdominal cavity to the umbilicus (Sister Joseph's nodule). Transperitoneal spread of gastric cancer can be detected most effectively by laparoscopy and cytology.

Lymphatic drainage of the stomach

Understanding the lymphatic drainage of the stomach is the key to comprehending the radical surgery of gastric cancer. The lymphatics of the antrum drain into the right gastric lymph node superiorly, and right gastroepiploic and subpyloric lymph nodes inferiorly. The lymphatics of the pylorus drain into the right gastric suprapyloric nodes superiorly and the subpyloric lymph nodes situated around the gastroduodenal artery inferiorly. The efferent lymphatics from suprapyloric lymph nodes converge on the para-aortic nodes around the coeliac axis, whereas the efferent lymphatics from the subpyloric lymph nodes pass up to the main superior mesenteric lymph nodes situated around the origin of the superior mesenteric artery. The lymphatic vessels related to the cardiac

Charles Emile Troisier, 1844–1919, Professor of Pathology, Paris, France.
Friedrich Ernst Krukenberg, 1870–1946, ophthalmologist, Halle, Germany, wrote a classic paper on malignant tumours of the ovary in 1896.
Sister Mary Joseph (Julia Dempsey), 1856–1939, Nursing Superintendent, St Mary's Hospital, Rochester, MN, USA, noted the presence of an umbilical nodule in many patients who proved to have advanced gastric cancer and pointed this out to William Mayo while she was working as theatre sister at the Mayo Clinic.

orifice of the stomach communicate freely with those of the oesophagus.

The prognosis of operable cases of carcinoma of the stomach depends on whether or not there is histological evidence of regional lymph node involvement. Retrograde (downwards) spread may occur if the upper lymphatics are blocked. In Japan, the lymph node dissection is highly advanced and the Japanese Research Society for Gastric Cancer has assigned a number to each lymph node station to aid the pathological staging (Figure 63.30). Many centres in resource-rich countries now perform surgery that involves a radical lymphadenectomy but, in other centres, both the staging and surgery are less developed.

Operability

It is important that patients with incurable disease are not subjected to radical surgery that cannot help them, hence the value of CT/PET and preoperative laparoscopy. Unequivocal evidence of incurability is haematogenous metastases, involvement of the distant peritoneum, N4 nodal disease and disease beyond the N4 nodes, and fixation to structures that cannot be removed. It is important to note that involvement of another organ per se does not imply incurability, provided that it can be removed. Controversies with respect to operability include N3 nodal involvement and involvement of the adjacent peritoneum, performed in Japan but seldom elsewhere. Curative resection should be considered on the remaining patients.

Most operable patients should have neoadjuvant chemotherapy as described below as this improves survival.

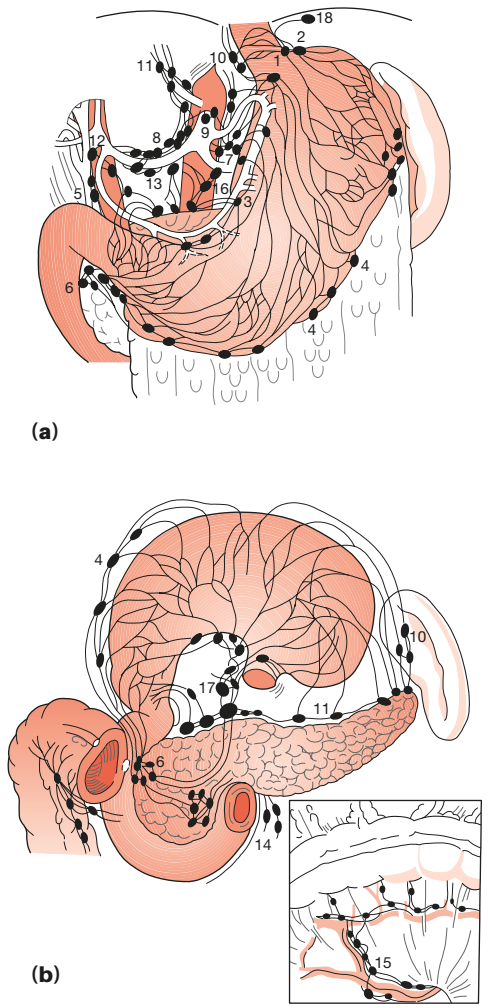

Figure 63.30 Lymphatic drainage of the stomach and nodal stations by the Japanese classification: **(a)** the anterior view of the stomach; **(b)** the posterior view.

Total gastrectomy

This is best performed through a long upper midline incision. The stomach is removed en bloc, including the tissues of the entire greater omentum and lesser omentum (Figure 63.31). In commencing the operation, the transverse colon is completely separated from the greater omentum. The dissection may then be commenced proximally or, more usually, distally. The subpyloric nodes are dissected and the first part of the duodenum is divided, usually with a surgical stapler. The hepatic nodes are dissected down to clear the hepatic artery; this dissection also includes the suprapyloric nodes. The right gastric artery is taken on the hepatic artery. The lymph node dissection is continued to the origin of the left gastric artery, which is divided flush with its origin. The dissection is continued along the splenic artery, taking all of the nodes at the superior aspect of the pancreas and accessible nodes in the splenic hilum. Separation of the stomach from the spleen, if this organ is not going to be removed, is carried out and this then allows access to the nodal tissues around the upper stomach and oesophagogastric junction. The oesophagus can then be divided at an appropriate point using a combination of stay sutures and a soft non-crushing clamp, usually of the right-angled variety. It is important that the resection margins are well clear of the tumour (>5 cm). Involvement of either proximal or distal resection margin carries an appalling prognosis and, if in doubt, frozen section should be performed. There is some controversy regarding the management of the spleen and distal pancreas in this procedure and this is discussed below.

Gastrointestinal continuity is reconstituted by means of a Roux loop. Other methods of reconstruction should be discouraged because of poor functional results. The alimentary limb of the Roux loop should be at least 50 cm long to avoid bile reflux oesophagitis. The simplest means of effecting the oesophagojejunostomy is to place a purse string in the cut end of the oesophagus and, using a circular stapler introduced through the blind end of the Roux loop, staple the end of the oesophagus onto the side of the Roux loop. The blind open end of the Roux loop may then be closed either with sutures or, alternatively, with a linear stapler. The anastomosis can also be fashioned end to end. The Roux loop may be placed in either an anticolic or retrocolic position. The jejunojejunostomy is undertaken at a convenient point in the usual fashion (end to side, Figure 63.32).

There remains some controversy about the extent of the lymphadenectomy required for the optimal treatment of curable gastric cancer. In Japan, at least a D2 gastrectomy (removal of the second tier of nodes) is performed on all

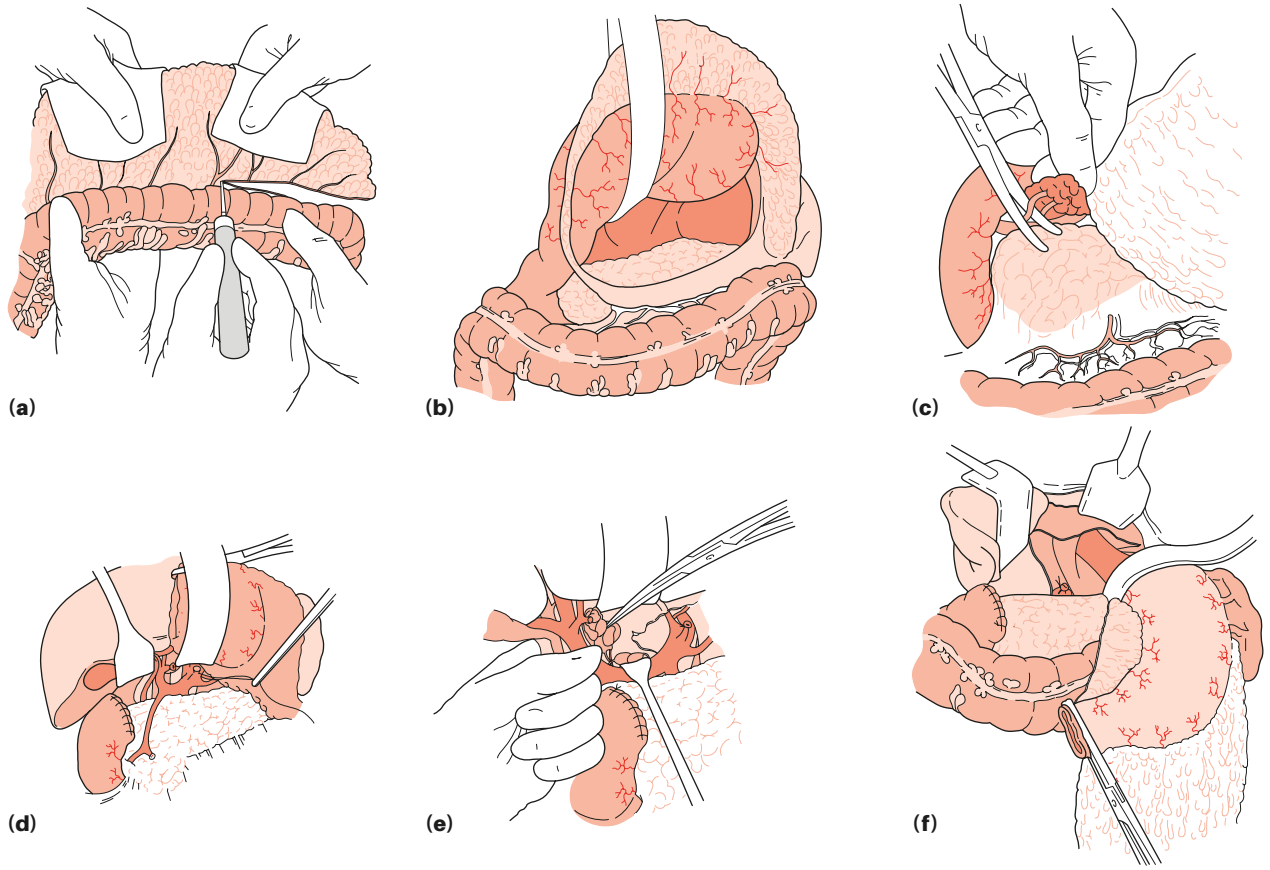

Figure 63.31 Radical total gastrectomy: **(a)** dissection of omentum off the transverse colon; **(b)** exposure of the lesser sac; **(c)** splenectomy; **(d)** division and oversewing of the duodenum; **(e)** dissection of the left gastric artery nodes (group 17); **(f)** mobilisation of the oesophagus.

operable gastric cancer and some centres are practicing more radical surgery (D3 and even D4 resections). Certainly, the results of surgical treatment stage for stage in Japan are much better than commonly reported in western resource-rich countries, and the Japanese contention is that the difference is principally related to the staging and the quality of the surgery. It is observed that the physical proportions of the average Japanese patient favour the performance of more radical procedures compared with the average patient in western countries. However, radical lymphadenectomies above D2 have not been subjected to any randomised controlled trials. In the UK and Europe, randomised trials have been set up to compare D1 and D2 gastrectomy, but the results are difficult to interpret. One of the problems relates to standardisation of the operation. Overall, it seems that the oncological outcome may be better following a D2 gastrectomy, but this operation is associated with higher levels of morbidity and perioperative mortality. It is clear that most of this morbidity and mortality relates to the removal of the spleen with or without the distal pancreas. The traditional radical gastrectomy removes the spleen and distal pancreas en bloc with the stomach and, although this is indeed an adequate means of performing clearance of the lymph nodes around the splenic artery, there now seems little doubt that adding this substantially increases the complication rate. The Japanese D2 gastrectomy will commonly preserve spleen and pancreas and this practice has been widely adopted by specialist centres in western countries.

The differentiation between a D1 and a D2 operation depends upon the tiers of nodes removed. Different tiers need to be removed depending on the positions of primary tumour and this is outlined in *Table 63.6*. In general, a D1 resection involves the removal of the perigastric nodes and a D2

TABLE 63.6 The lymph node stations (see Figure 63.30) that need to be removed in a D1 (N1 nodes removed) or a D2 (N2 nodes removed) resection.

LN number		Site of cancer			
		Antrum	Middle	Cardia	Cardia and oesophagus
1	Right cardia	N2	N1	N1	N1
2	Left cardial		N1	N1	N1
3	Lesser curve	N1	N1	N1	N1

110	Lower oesophagus				N2
111	Supradiaphragmatic				N2

The nodes in stations 12–18 are not routinely removed in a D1 or D2 gastrectomy.

resection involves the clearance of the major arterial trunks. In practice the majority of specialist centres will perform a radical total gastrectomy, conserving the spleen and pancreas, with D2 lymphadenectomy sparing station 10 lymph nodes.

Subtotal gastrectomy

For tumours distally placed in the stomach, it appears unnecessary to remove the whole stomach. However, the operation is very similar to that of a total gastrectomy except that the proximal stomach is preserved, the blood supply being derived from the short gastric arteries. Following the resection, the simplest form of reconstruction is to close the stomach from the lesser curve, near the oesophagogastric junction, with either sutures or staples and then perform an anastomosis of the greater curve to the jejunum. Although this can be performed as in a Billroth II/Polya-type gastrectomy, this reconstruction may result in quite marked enterogastric reflux and bile reflux oesophagitis, and the preferred method is to perform the reconstruction using a Roux loop.

Palliative surgery

In patients suffering from significant symptoms of either obstruction or bleeding, palliative resection is appropriate. A palliative gastrectomy need not be radical and it is sufficient to remove the tumour and reconstruct the gastrointestinal tract. Sometimes it is impossible to resect an obstructing tumour in the distal stomach and other palliative procedures need to be considered, although the prognosis in such patients, even in the short term, is poor. A high gastroenterostomy is a poor operation that very frequently does not allow the stomach to empty adequately, but may produce the additional problem of bile reflux. A Roux loop with a wide anastomosis between the stomach and jejunum may be a better option, although even this may not allow the stomach to empty particularly well. Gastric exclusion and oesophagojejunostomy is practised by some surgeons. For inoperable tumours situated in the cardia, either palliative intubation, stenting or another form of recanalisation can be used (Chapter 62). Recanalisation appears to offer better functional results.

Postoperative complications of gastrectomy

Radical gastrectomy is complex major surgery and predictably there are a large number of potential complications of the operation. Leakage of the oesophagojejunostomy should be uncommon in experienced hands. When it occurs it can often be managed conservatively as the Roux-en-Y reconstruction means that it is mainly saliva and ingested food that leaks. Some patients may establish a fistula from the wound or drain site and others may need radiological or surgically placed drains. It is unclear whether a nasoenteric tube should be used routinely. Many surgeons use such tubes routinely, but this is not supported by any evidence base. It is unusual to detect a major anastomotic leak in the absence of clinical signs and the use of postoperative water-soluble contrast swallows is not now routine in expert centres. Physiological scoring systems

to predict those patients likely to experience significant complications offer potential in this area.

As with any gastrectomy, leakage from the duodenal stump can occur. This is usually due to a degree of distal obstruction and care must be taken when performing the Roux-en-Y anastomosis that there is no kinking. Paraduodenal collections can be drained radiologically, which will often convert the collection into an external fistula. Biliary peritonitis requires a laparotomy and peritoneal toilet, and in this circumstance it is best to leave a Foley catheter in the duodenum to establish a controlled duodenal fistula. If it is established that there is no distal obstruction, or if any such obstruction is managed, then with time the fistula will close.

The presence of septic collections along with a very radical vascular dissection may lead to catastrophic secondary haemorrhage from the exposed or divided blood vessels. This situation may be very difficult to manage, whether or not reoperation or interventional radiology is employed.

Long-term complications of surgery

It is surprising that, considering the radical nature of the total gastrectomy, many patients, particularly the younger ones, have good functional results. However, most patients will have a reduced capacity, particularly in the short term. They need to be given detailed nutritional advice, the substance of which is to eat small meals and often, while the jejunum or small gastric remnant adapts. In fact, there is very little functional difference between patients who have a total gastrectomy and those who have a subtotal gastrectomy. Various attempts have been made to try to improve the short-term functional results by a forming a jejunal pouch and attaching this to the oesophagus. Most surgeons do not perform this as in the long term there seems little functional advantage. It is surprising that these patients only infrequently suffer from the complications of gastric surgery, such as dumping and diarrhoea. Nutritional deficiencies may occur and the patient should be monitored with this in view. The loss of the parietal mass leads to vitamin B12 deficiency and replacement should be given routinely.

Outlook after surgical treatment

The outlook after surgical treatment varies considerably between western countries and Japan. In Japan, approximately 75% of patients will have a curative resection and, of these, the overall 5-year survival rate will be in the region of 50–70%. In contrast, in western countries most series show that only 25–50% of patients undergoing surgery will have a curative operation and the 5-year survival rate in such patients is only about 25–30%, although in some series it approaches Japanese levels. A combination of differences in staging and a higher standard of surgery in Japan probably accounts for the differences. Staging is clearly crucial when survival figures are being compared. The more thorough the staging, the higher the stage is likely to be and, therefore, stage for stage the outcome seems better in patients who are adequately staged pathologically. This phenomenon is termed 'stage migration'.

Other treatment modalities

Because of the failure of radical surgery to cure advanced gastric cancer, there has been an interest in the use of radiotherapy and chemotherapy.

Radiotherapy

The routine use of radiotherapy is controversial as the results of clinical trials are inconclusive. There are a number of radiosensitive tissues in the region of the gastric bed, which limits the dose that can be given. Radiotherapy has a role in the palliative treatment of painful bony metastases.

Chemotherapy

Gastric cancer may respond well to combination cytotoxic chemotherapy and neoadjuvant chemotherapy improves the outcome following surgery. Most patients therefore should have prior chemotherapy. There are a number of well-investigated regimes, but the best results are currently obtained using a combination of epirubacin, *cis*-platinum and infusional 5-FU or an oral analogue such as capecitabine. The same regimen is used as first line for patients with inoperable disease although oxaliplatin is being substituted for *cis*-platinum as it has fewer side effects. Second-line treatment using combinations which include taxotere are increasingly being used. Chemotherapy for advanced disease is palliative. Newer biological agents such as trastuzumab (Herceptin) offer potential advantages to survival in the minority of patients (<20%) with *HER2*-positive gastric cancer. However the absolute survival advantages are small (~4 months) and the cost of treatment is high. Nevertheless, trastuzumab has been approved for use in metastatic *HER2*-positive gastric cancer in the UK and the European Union.

Pattern of relapse following surgical treatment

As might be expected, the most common site of relapse following radical gastrectomy is the gastric bed, representing inadequate extirpation of the primary tumour. Widespread nodal intraperitoneal metastases, distant nodal metastases and liver metastases are all common. Dissemination to the lung and bones usually only occurs after liver metastases are already established.

GASTROINTESTINAL STROMAL TUMOURS

Gastrointestinal stromal tumours (GISTs) may arise in any part of the gastrointestinal tract but 50% will be found in the stomach. Previously named leiomyoma and leiomyosarcoma, the term GIST is now used, recognising their particular

Frederic Eugene Basil Foley, 1891–1966, urologist, Ankher Hospital, St Paul, MN, USA.

distinct phenotype. They are tumours of mesenchymal origin and are observed equally commonly in males and females. The tumours are universally associated with a mutation in the tyrosine kinase *c-kit* oncogene. These tumours are sensitive to the tyrosine kinase antagonist imatinib, and an 80% objective response rate can be observed. Tumours with mutations in exon 11 of *c-kit* are particularly sensitive to this drug. The biological behaviour of these tumours is unpredictable but size and mitotic index are the best predictors of metastasis. Peritoneal and liver metastases are most common but spread to lymph nodes is extremely rare.

The incidence of the condition is unclear as small stromal tumours of the stomach are probably quite common and remain unnoticed. Clinically obvious tumours are considerably less common than gastric cancer. GISTs comprise 1–3% of all gastrointestinal neoplasia.

The only ways that many stromal tumours are recognised are either that the mucosa overlying the tumour ulcerates (see **Figure 63.24**), leading to bleeding, or that they are noticed incidentally at endoscopy. Because the mucosa overlying the tumour is normal, endoscopic biopsy can be uninformative unless the tumour has ulcerated. Targeted biopsy by endoscopic ultrasound is more helpful. Larger tumours present with non-specific gastric symptoms and, in many instances, they may be thought to be gastric cancer initially (**Figure 63.33**).

As the biological behaviour is difficult to predict, the best guide is to consider the size of the tumour. Tumours over 5 cm in diameter should be considered to have metastatic potential. If easily resectable, surgery is the primary mode of treatment. Smaller tumours can be treated by wedge excision although the appropriate management of asymptomatic diminutive tumours found incidentally at endoscopy is unclear. Larger tumours may require a gastrectomy or duodenectomy (see Chapter 68) but lymphadenectomy is not required. Larger tumours which require multivisceral resection may be better treated with 3–6 months of imatinib prior to operation as this will usually radically reduce the size and vascularity of the tumours. Adjuvant imatinib for large resected tumours of high malignant potential should probably be continued indefinitely.

The prognosis of advanced metastatic GISTs has been dramatically improved with imatinib chemotherapy but resection of metastases, especially from the liver, still has an important role.

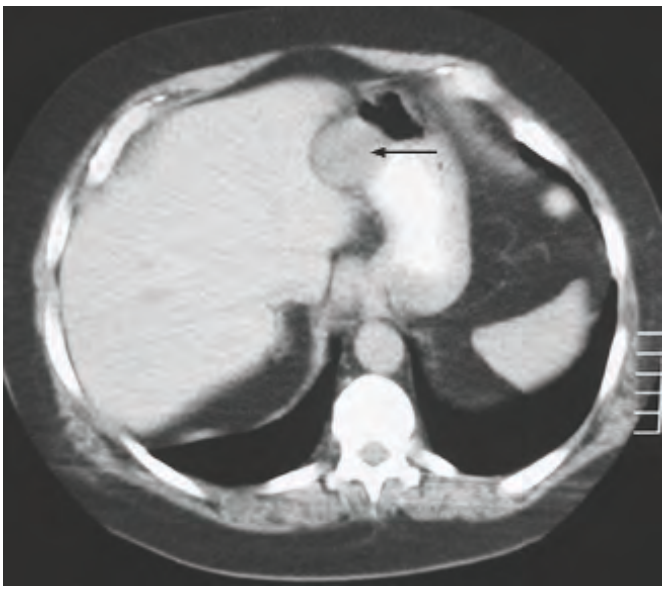

Figure 63.33 Computed tomography scan of the upper abdomen showing a 3.5 cm gastrointestinal stromal tumour arising from the gastric wall.

GASTRIC LYMPHOMA

Gastric lymphoma is an interesting disease and some aspects of its management are controversial. It is first important to distinguish primary gastric lymphoma from involvement of the stomach in a generalised lymphomatous process. This latter situation is more common than the former. Unlike gastric carcinoma, the incidence of lymphoma seems to be increasing. Primary gastric lymphoma accounts for approximately 5% of all gastric neoplasms.

Gastric lymphoma is most common in the sixth decade and the presentation is no different from gastric cancer, the common symptoms being pain, weight loss and bleeding. Acute presentations of gastric lymphoma such as haematemesis, perforation or obstruction are not common. Primary gastric lymphomas are B-cell derived, the tumour arising from the mucosa-associated lymphoid tissue (MALT). Primary gastric lymphoma remains in the stomach for a prolonged period before involving the lymph nodes. At an early stage, the disease takes the form of a diffuse mucosal thickening, which may ulcerate. Diagnosis is made as a result of the endoscopic biopsy and seldom on the basis of the endoscopic features alone, which are not specific.

Following diagnosis, adequate staging is necessary, primarily to establish whether the lesion is a primary gastric lymphoma or part of a more generalised process. CT scans of the chest and abdomen and bone marrow aspirate are required, as well as a full blood count.

Although the treatment of primary gastric lymphoma is somewhat controversial, it seems most appropriate to use surgery alone for the localised disease process. No benefit has been shown from adjuvant chemotherapy, although some oncologists contend that primary gastric lymphoma can be treated by chemotherapy alone. Chemotherapy alone is appropriate for patients with systemic disease.

Some of the more controversial aspects of gastric lymphoma concern the role of *H. pylori*. Lymphocytes are not found to any degree in normal gastric mucosa, but are found in association with *Helicobacter* infection. It has also been shown that early gastric lymphomas may regress and disappear when the *Helicobacter* infection is treated (Isaacson).

Peter Gersohn Isaacson, contemporary, Professor of Morbid Anatomy, University College, London, UK.

Gastric involvement with diffuse lymphoma

These patients are treated with chemotherapy, sometimes with dramatic and rapid responses. Surgeons are frequently asked to deal with the complications of gastric involvement. The two common complications are bleeding and perforation. Both may occur at presentation, but more usually may follow the chemotherapy when there is rapid regression and necrosis of the tumour. These operations can be technically very challenging and normally require gastrectomy.

DUODENAL TUMOURS

Benign duodenal tumours

Duodenal villous adenomas occur principally in the periampullary region. Although generally uncommon, they are often found in patients with familial adenomatous polyposis. The appearances are similar to those adenomas arising in the colon and, as they have malignant potential, they should be locally excised with histologically clear margins.

Summary box 63.7

Duodenal tumours

- Duodenal villous adenomas are commonly found around the ampulla of Vater and are premalignant
- Duodenal carcinoma is uncommon, but the commonest site for adenocarcinoma is in the small intestine
- Both adenoma and carcinoma occur commonly in patients with familial polyposis and screening these patients is advised
- Pancreatic cancer is the most common cause of duodenal obstruction

Duodenal adenocarcinoma

Although uncommon, this is the most common site for adenocarcinoma arising in the small bowel. Most tumours originate in the periampullary region and commonly arise in pre-existing villous adenomas. Patients present with anaemia due to ulceration of the tumour or obstruction as the polypoid neoplasm begins to obstruct the duodenum. Direct involvement in the ampulla leads to obstructive jaundice. Histologically, the lesion is a typical adenocarcinoma and the metastases are commonly to regional lymph nodes and the liver. At presentation, about 70% of the patients have resectable disease and for those who survive operation the 5-year survival rate is in the region of 20%, this approximately equating to cure. Poor prognostic features in the resected specimen include regional lymph node metastases, transmural involvement and perineural invasion. Curative surgical treatment will normally involve a pancreaticoduodenectomy (Whipple's procedure).

Patients with familial polyposis, which is due to a mutation in the *APC* gene on chromosome 5, are predisposed to periampullary cancer, which is one of the most common causes of death in patients who have had their colon removed. Other duodenal malignancies include GISTs (see above) and neuroendocrine tumours.

Neuroendocrine tumours

A number of neuroendocrine neoplasms occur in the duodenum. It is a common site for primary gastrinoma (Zollinger–Ellison syndrome). Non-functioning neuroendocrine tumours (usually called carcinoid tumours) also occur but uncommonly in comparison to the ileum.

Zollinger–Ellison syndrome

This syndrome is mentioned here because the gastrin-producing endocrine tumour is often found in the duodenal loop, although it also occurs in the pancreas, especially the head. It is a cause of persistent peptic ulceration. Before the development of potent gastric antisecretory agents, the condition was recognised by the sometimes fulminant peptic ulceration which did not respond to gastric surgery short of total gastrectomy. It was also recognisable from gastric secretory studies in which the patient had a very high basal acid output but no marked response to pentagastrin, as the parietal cell mass was already nearly maximally stimulated by pathological levels of gastrin. The advent of proton pump inhibitors such as omeprazole has rendered this extreme endocrine condition fully controllable, but also less easily recognised.

Gastrinomas may be either sporadic or associated with the autosomal dominantly inherited multiple endocrine neoplasia (MEN) type I (in which a parathyroid adenoma is almost invariable). The tumours are most commonly found in the 'gastrinoma triangle' (Passaro) defined by the junction of the cystic duct and common bile duct superiorly, the junction of the second and third parts of the duodenum inferiorly, and the junction of the neck and body of the pancreas medially (essentially the superior mesenteric artery). Many are found in the duodenal loop, presumably arising in the G cells found in Brunner's glands. It is extremely important that the duodenal wall is very carefully inspected endoscopically and also at operation. Very often all that can be detected is a small nodule that projects into the medial wall of the duodenum.

Even malignant sporadic gastrinomas may have a very indolent course. The palliative resection of liver metastases may be beneficial and liver transplantation is practised in some centres, as for other gut endocrine tumours, with reasonable long-term results. However, the minority of tumours found to the left of the superior mesenteric artery (outside the 'triangle') seem to have a worse prognosis, more having liver metastases at presentation. In MEN type I, the tumours may be multiple and the condition is incurable. Even in this situation,

Abraham Vater, 1684–1751, Professor of Anatomy and Biology, Wittenburg, Germany.
Allen Oldfather Whipple, 1881–1963, Valentine Mott Professor of Surgery, The College of Physicians and Surgeons, Columbia University, New York, NY, USA.
Edward Passaro, Emeritus Professor of Surgery 1974–1997, Los Angeles, CA, USA.

as with sporadic gastrinoma, surgical treatment should be employed to remove any obvious tumours and associated lymphatic metastases, as the palliation achieved may be good.

DUODENAL OBSTRUCTION

Duodenal obstruction in the adult is usually due to malignancy, and cancer of the pancreas is the most common cause. About one-fifth of patients with pancreatic cancer treated with endoscopic stenting will develop obstruction. Treatment is usually by gastroenterostomy but duodenal stenting is increasingly being used. In patients having a surgical biliary bypass for pancreatic cancer, gastric drainage may be necessary.

A variety of other malignancies can cause duodenal obstruction, including metastases from colorectal and gastric cancer. Primary duodenal cancer is much less common as a cause of obstruction than these other malignancies.

Annular pancreas may rarely cause duodenal obstruction. Obstruction usually follows an attack of pancreatitis and, on occasions, the obstruction may be mistaken for malignancy.

Arteriomesenteric compression is an ill-defined condition in which it is proposed that the fourth part of the duodenum is compressed between the superior mesenteric artery and the vertebral column; when it is convincingly demonstrated and causing weight loss, duodenojejunostomy may be performed.

Figure 63.34 Trichobezoar of the stomach in a girl aged 15 years.

OTHER GASTRIC CONDITIONS

Acute gastric dilatation

This condition usually occurs in association with pyloroduodenal disorders or postsurgery without nasogastric suction. The stomach, which may also be atonic, dilates enormously. Often the patient is also dehydrated and has electrolyte disturbances. Failure to treat this condition can result in a sudden massive vomit with aspiration into the lungs. The treatment is nasogastric suction, with a large-bore tube, fluid replacement and treatment of the underlying condition.

Trichobezoar and phytobezoar

Trichobezoar (hair balls) (**Figure 63.34**) are unusual and are virtually exclusively found in female psychiatric patients, often young. It is caused by the pathological ingestion of hair, which remains undigested in the stomach. The hair ball can lead to ulceration and gastrointestinal bleeding, perforation or obstruction. The diagnosis is made easily at endoscopy or, indeed, from a plain radiograph. Treatment consists of removal of the bezoar, which may require open surgical treatment. Phytobezoars are made of vegetable matter and found principally in patients who have gastric stasis. Often this follows gastric surgery.

Foreign bodies in the stomach

A variety of ingested foreign bodies reach the stomach, and very often these can be seen on a plain radiograph. If possible, they should be removed endoscopically but, if not, most can be left to pass normally. Even objects such as needles, with which there is understandable anxiety, will seldom cause harm. In general, an object which leaves the stomach will pass spontaneously. In contrast, attempted removal at laparotomy can be very difficult as the object may be much more difficult to find than might be expected. Most adults who swallow foreign bodies have ill-defined psychiatric problems and may appear to relish the attention associated with serial laparotomies. The treatment should therefore be expectant and intervention reserved for patients with symptoms in whom the foreign body is failing to progress.

Volvulus of the stomach

Rotation of the stomach usually occurs around the axis and between its two fixed points, i.e. the cardia and the pylorus. In theory, rotation can occur in the horizontal (organoaxial) or vertical (mesenteroaxial) direction but, commonly, it is the former which occurs. This condition is usually associated with a large diaphragmatic defect around the oesophagus (paraoesophageal herniation) (**Figure 63.35**). What commonly happens is that the transverse colon moves upwards to lie under the left diaphragm, thus taking the stomach with it, and the stomach and colon may both enter the chest through the eventration of the diaphragm. The condition is commonly chronic, the patient presenting with difficulty in eating. An acute presentation with ischaemia may occur. Endoscopically, it can be extremely difficult to sort out the anatomy, and this is one situation in which the contrast radiograph is superior.

Treatment

If the problem is causing symptoms then surgical treatment is the only satisfactory approach. Traditionally, open surgery

Figure 63.35 Barium meal showing organoaxial volvulus of the stomach associated with eventration of the diaphragm.

has been employed but this problem is suitable for laparoscopic treatment if appropriate skill is available. If there is a hernia, the sac and its contents (usually the stomach) should be reduced. The defect in the diaphragm should be closed, if necessary, with a mesh. It is advisable to separate the stomach from the transverse colon and then perform an anterior gastropexy to fix the stomach to the anterior abdominal wall. The results from this treatment are good.

Chapter 64

Bariatric and metabolic surgery

Learning objectives

To know and understand:

- What severe and complex obesity is
- Rationale for surgery and the concept of metabolic surgery
- Eligibility and NICE guidelines
- Multidisciplinary assessment
- The common operations and how they work
- How to assess and treat perioperative complications
- Follow-up, nutritional supplements and biochemical monitoring

INTRODUCTION

Obesity is becoming the plague of the 21st century. With overweight becoming the norm in most western countries and newly resource-rich countries, two-thirds of adults are overweight or obese (*Table 64.1*). Every clinician faces the condition and its associated diseases, such as type 2 diabetes, as part of their practice. Obesity and lack of physical activity have the second largest public health impact after smoking. Severe obesity increases the risk of cancer, is associated with multiple other diseases, affects quality of life and reduces life expectancy by 5–20 years. Obese people will more often be of lower social class, unemployed and/or on state benefits. Obesity runs in families and social networks and very few obese people have an identifiable genetic, hormonal basis such as Prader–Willi syndrome. Surgeons encounter the problem of obesity on a daily basis as it affects the treatment of nearly every abdominal pathology in terms of approach and outcomes.

Dieting, increasing energy expenditure through exercise, and intensive lifestyle intervention, are successful for most obese people in helping them lose 6–8% body weight in the short term, up to 1–3 years. Reaching a plateau and cyclical rebound weight regain is, however, expected with all diets. Currently there is no available pharmacotherapy that is safe and clinically or cost-effective in the long term, and there is none on the horizon remotely as effective as bariatric surgery.

Bariatric surgery is the branch of surgery involving manipulation of the stomach and/or small bowel to aid weight loss. Severe and complex obesity is a phrase commonly used for patients with body mass index (BMI) ≥35 and obesity-related disease, or BMI ≥40 by itself (*Table 64.2*).

TABLE 64.1 Definitions of overweight and obesity*.

Adult weight status	BMI (kg/m^2)
Normal	18.5–24.9
Overweight	25–29.9
Class 1 obesity	30–34.9
Class 2 obesity	35–39.9
Class 3 obesity	≥40
Body mass index (BMI) = weight (kg)/height (m)^2.	

* Obesity for children is defined as BMI at or above the 95th centile.

TABLE 64.2 Conditions that are associated with severe and complex obesity.

Type 2 diabetes
Hypertension
Dyslipidaemia
Obstructive sleep apnoea (OSA)
Arthritis and functional impairment
Gastro-oesophageal reflux disease
Non-alcoholic fatty liver disease/non-alcoholic steatohepatosis
Polycystic ovary syndrome
Clinical depression
Functional impairment

Bariatric surgery comes from the Greek *baros*: weight/pressure, and -iatric: the medicine or surgery thereof.
Andrea Prader, 1919–2001, paediatric endocrinologist, Zurich, Switzerland.
Heinrich Willi, 1900–1971, paediatrician, Zurich, Switzerland.

RATIONALE

Bariatric surgery leads to weight loss of 25–35% of body weight (usually at least 15 kg) after 1 year, and this is sustained at 15–25% after 20 years. Additional benefits are that most or all of the obesity-related diseases improve as weight is lost. Quality of life improves. A number of randomised controlled trials (RCTs) have reported on the outcomes of bariatric surgery versus intensive lifestyle interventions, and all favour surgery. The longest follow-up in an RCT is 5 years. However, the non-randomised Swedish Obese Subjects (SOS) study has now shown sustained weight loss and improvement in obesity-related disease up to 20 years after surgery. In this study 2010 patients who chose to have surgery were compared to 2037 controls who did not. All had best medical care throughout and follow-up was better than 99%.

The SOS study was among the first to demonstrate that bariatric surgery also leads to survival benefit. The primary end point was overall mortality and a significant difference was found at mean follow-up of 10 years. Several other studies have found similarly, including one of nearly 8000 operated patients from Utah, USA.

The SOS study also reported a lower incidence of both microvascular and macrovascular complications at 15 years' follow-up in the surgical group. Although there are no RCT data available for this potential outcome, the Swedish registry (SOREG) data indicate lower mortality within only 3–4 years after surgery in diabetic patients. Both the SOS and Utah studies have shown that bariatric surgery also effectively reduces cancer risk in large series of patients.

Summary box 64.1

Rationale for surgery

Due to the tendency for basal metabolic rate to decrease with dieting, most people will regain all their weight, returning to the previous homeostatic set point

Bariatric surgery appears to alter this mechanism and 'reset' this point, with 15–25% weight loss maintenance up to 20 years

Bariatric surgery leads to long-term survival benefit and improves obesity-related disease and quality of life

METABOLIC SURGERY

'Metabolic' or 'diabetes' surgery is increasingly being used in conjunction with, or instead of, 'bariatric surgery' due to the highly effective way surgery improves the metabolic syndrome, with weight loss being a welcomed additional effect. Type 2 diabetes is part of the 'metabolic syndrome' that includes high blood pressure, dyslipidaemia and polycystic ovary syndrome.

It has been known for more than 20 years that control of type 2 diabetes improves with weight loss. Remarkably, after several types of bariatric surgery diabetes control appears to improve **before** significant weight loss occurs. Some of the effects on glucose metabolism can be attributed to the caloric restriction, but changes in gut hormone levels, particularly glucagon-like-peptide 1 (GLP-1), have provoked much interest. GLP-1 is an incretin, which stimulates the beta cells in the pancreas to restore the normal first phase insulin response after eating. Bile acids are also involved.

Although type 2 diabetes is a chronic disease, surgeons initially claimed to 'cure' it. The emphasis has now changed to improving glycaemic control by lowering HbA1c and improving insulin resistance. Patients with the shortest duration of type 2 diabetes have a higher rate of remission or improvement. Even so, patients with depleted pancreatic beta cell reserve, associated with longer disease duration and being on insulin, still benefit from the improved glycaemic control. As they are usually able to reduce or stop their diabetes medications as well, including insulin, it adds to the cost effectiveness. Diabetes 'remission' is defined as patients being off all medication with normal glucose homeostasis. In the SOS study, diabetic patients not only went into remission after surgery, but there was a decreased incidence of patients becoming diabetic.

Many surgical societies have added the word 'metabolic' to their titles, e.g. American Society for Metabolic and Bariatric Surgery (ASMBS), and British Obesity and Metabolic Surgery Society (BOMSS), to emphasise the goal of surgery as an accepted treatment option for metabolic syndrome, rather than just for weight loss. It is hoped that this approach will improve the acceptability in public funded healthcare systems of bariatric/metabolic surgery.

Summary box 64.2

Metabolic surgery

The term refers to the marked effects of some operations on diabetes and the metabolic syndrome, which may have an impact more important than weight loss itself

The improvement in type 2 diabetes may be additional to the weight loss

Surgery is very cost effective since medications reduce or stop as glycaemic control improves

COST EFFECTIVENESS

The cost effectiveness of bariatric surgery has been shown in studies from several different countries. A 2009 Health Technology Assessment report in the UK showed bariatric surgery to be cost effective compared to non-surgical options. The

In the wrong place at the wrong time. The Utah paper was the first large study to show improved survival after gastric bypass surgery compared to matched population controls. One of the operated patients was staying in a hotel and killed by a stray bullet fired from the next room by a complete stranger. The mortality still had to be included as a death after surgery (source Dr Ted Adams, author of the Utah study).

When the SOS study was conceived in 1987, all surgery was done by laparotomy and it was considered unethical to attempt to randomise patients between best medical therapy and bariatric surgery as the latter was considered too risky.

incremental cost-effectiveness ratio (ICER) compared to no surgery was between £2000 and £4000 per Quality Adjusted Life Year (QALY) gained for patients with BMI ≥40 kg/m^2 over 20 years. For patients with BMI 30–40 kg/m^2 the ICER was £1367 per QALY gained. Regarding maximum willingness to pay, compared with non-surgical interventions, if a decision-maker is willing to pay £20 000 for an additional QALY, then the probability of surgery being cost effective over a 20-year time horizon was reported as 100%. The ICERs are similar to the cost effectiveness of stopping smoking and routine statin therapy for the primary prevention of cardiovascular disease. In practice it means that the cost of the operation is recouped within 1–2 years after surgery from reduced medication costs. All the cost-effectiveness studies assess direct or indirect healthcare costs, but not additional benefits of surgery. Thus, return to paid work, coming off state benefits, improved functional capacity and quality of life are 'add-ons' that incur no cost.

ELIGIBILITY

Eligibility criteria were first proposed by the United States' National Institutes of Health in 1991, when the obesity epidemic was just starting. All bariatric surgery was done by laparotomy, and the safety profile was very different. The National Institute of Health and Care Excellence (NICE) in the UK recommends consideration of bariatric surgery for people with severe obesity in whom all non-surgical measures have been tried with no adequate weight loss achieved or maintained. Commitment to long-term follow-up and behaviour change are also advised. After a review of recent RCTs NICE updated its guidance and lowered the BMI threshold to 30 kg/m^2 for recent-onset type 2 diabetes (*Table 64.3*).

NICE estimated that about 80% of people fulfilling the eligibility criteria would have no medical or psychological reason why they would not be fit for surgery. An estimate is that perhaps 10% of these might want it.

TABLE 64.3 Summary of 2014 updated NICE guidance on bariatric surgery (CG 189).

Bariatric surgery is a treatment option for anyone with a BMI ≥40
Offer an expedited assessment for people with a BMI ≥35 with onset of type 2 diabetes in the past 10 years
Consider an assessment for people with a BMI of 30–34.9 with onset of type 2 diabetes within 10 years
Consider an assessment for people of Asian origin with onset of type 2 diabetes at a lower BMI than other populations
Bariatric surgery is the option of choice for adults with BMI >50 when other interventions have not been effective
People fitting the above criteria are also required to be receiving, or to receive, assessment in a specialist weight-management service before referral to a surgical team

There is far more accumulated evidence now that surgery is an effective treatment option for severe and complex obesity than there was historically for the first effective therapies for human immunodeficiency virus infection, which were universally taken up in western countries. The uptake of bariatric surgery worldwide is much less than 1% of those who could benefit.

PRINCIPLES OF SETTING UP A BARIATRIC/METABOLIC SURGERY SERVICE

As for gastrointestinal cancer surgery where oncologists and surgeons routinely work together, it is now agreed that 'bariatric physicians/internists' should be part of the team assessing and managing long-term care after bariatric surgery (*Table 64.4*). Very obese sick patients with, for instance, sleep apnoea with complications need careful multidisciplinary team (MDT) work-up. Using risk scores such as the Edmonton Obesity Staging System (EOSS) and Obesity Surgery-Mortality Risk Score (OS-MRS) can help the team discuss with patients the likely prognosis without surgery, and the risk of complications. The OS-MRS scores one point for each of: age ≥45, BMI ≥50, male gender (due to central obesity), hypertension (due to central obesity), increased deep vein thrombosis (DVT)/pulmonary embolus (PE) risk. The more points that are present the greater is the risk. Swedish registry data indicate that obstructive sleep apnoea (OSA) is a risk factor for anastomotic leak. Therefore, OSA should be actively investigated, as treatment with continuous positive airway pressure might reduce risk. Uncontrolled diabetes must also be considered a risk factor, as it is for all other operations.

Better surgical results are likely in high-volume surgical units. The International Federation for Surgery of Obesity (IFSO) and the ASMBS recommended 100–125 cases per year, and there should be at least two surgeons each performing 50 or more cases. Surgeons early in the learning curve (about 100 for gastric bypass) need to be mentored before independent practice. Irrespective of the technical expertise of each surgeon, higher volumes usually mean that there are sufficient MDT members available to provide support and follow-up. Each unit should have expertise in a variety of surgical procedures including revisions.

It is routine to put patients on a 'liver shrinkage diet' for at least 2 weeks before surgery, especially when there is central obesity, as this is associated with large livers that can make surgery impossible. If a patient cannot lose weight or comply with the liver diet it implies there may be important psychological blocks that need addressing. Male patients especially, with

TABLE 64.4 NICE-accredited guidance on the make-up of the medical and surgical bariatric multidisciplinary team.

Bariatric physician in primary (can be the general practitioner) or secondary care (usually a diabetologist)
Dietitian
Specialist nurse
Appropriately trained mental health professional
Bariatric surgeon
Anaesthetist
Radiologist
± Exercise therapists
Other secondary care specialities, e.g. respiratory/sleep medicine, cardiology

central obesity, a very dense/hard abdomen, OSA/diabetes and a BMI >50 may need more, supervised, mandatory weight loss to make surgery safe.

Although not stipulated in any national guidance, every successful bariatric unit depends on active patient support groups and preoperative education sessions, best run by bariatric nurses and dietitians. These are invaluable in preparing patients for surgery and it is difficult to conceive how a programme can run without them. Also, the ward and outpatient environment must be suitably equipped for severely obese patients, to include scales that can measure up to 250 kg.

Summary box 64.3

Multidisciplinary assessment

Every patient should be assessed and managed by a coherent and well-functioning team of healthcare professionals with a varied background and expertise

Improved outcomes are usually achieved in high-volume, specialised units

Data collection and submission to national registries are recommended to provide quality assurance and long-term outcome data

Laparoscopic surgery and enhanced recovery

Bariatric surgery has been transformed by its amenability to laparoscopic techniques, including intracorporeal suturing and modern laparoscopic stapling devices. Probably equally important is enhanced recovery with the avoidance of catheters, central venous and arterial lines. Free access to fluids is routine immediately after surgery, and due to the relative lack of pain patients can mobilise straightaway. It is usual for gastric bypass and sleeve gastrectomy patients to go home on postoperative day 2 or 3. Gastric banding patients go home as day cases or within 24 hours. The main cause of death after surgery is now DVT/PE, rather than anastomotic leakage or bleeding, and appropriate prophylaxis is usually used for at least 1 week.

Randomised controlled trial evidence for the different types of surgery

Bariatric surgery needs more RCTs comparing different procedures, with long-term follow-up. One of the challenges is keeping the research question relevant, given the rapidity with which surgeons adopt different techniques. Long-term, large scale, pragmatic RCTs with good follow-up are needed to inform practice. The By-Band-Sleeve study is an ongoing pragmatic, multicentre, 3-arm RCT in the UK assessing weight loss and quality of life at 3 years between gastric banding, gastric bypass and sleeve gastrectomy in 1341 patients.

In the 1970s a hospital in the USA designed lavatories to be wall-mounted to make cleaning the floor easier. A bariatric patient broke the lavatory, resulting in a 20-storey waterfall (source Dr Neil Hutcher, past-president ASBS).

Summary box 64.4

Evidence for the different operations

Usually the operation choice is guided by patient, surgeon and unit preference

Well-conducted RCTs comparing the the different operations, with comprehensive follow-up, are needed

The common operations

An international survey by IFSO in 2013 indicated that there were nearly 500 000 procedures done annually. Gastric bypass comprised 45%, sleeve gastrectomy 37%, gastric banding 10% and biliopancreatic diversion/duodenal switch (BPD/DS) 1.5%. The variety of procedures usually reflects surgeon expertise and surgeon and patient preferences, as there are no RCTs beyond 5 years comparing different operations. Sleeve gastrectomy is rapidly gaining popularity at the expense of gastric banding and to a lesser extent gastric bypass. Some clinical outcomes are shown in *Table 64.5*). The mechanism of action of most weight-loss procedures remains incompletely understood. Reduced appetite and early satiety are common features that are potentially explained by changes in levels of gut hormones, such as PYY and GLP-1, and how these interact with the brain.

TABLE 64.5 Malabsorption, percent excess weight loss (EWL)* and diabetes remission after bariatric surgery.

	Protein/calorie malabsorption	3-year % EWL	3-year % diabetes remission
Gastric band	No	40–50%	20%
Gastric bypass	No	50–60%	50%
Sleeve gastrectomy	No	50–60%	50%
BPD/DS	Yes	70–80%	80%

BPD, biliopancreatic diversion; DS, duodenal switch.
* % EWL refers to the excess weight lost above a notional upper normal BMI of 25. Percent weight loss is another way of measuring weight change, preferred by physicians.

Gastric banding

Although adjustable gastric banding is declining in the UK and elsewhere, it did boost the popularity of bariatric surgery due to the perioperative safety, the lack of nutritional complications and its relative ease and availability. The pars flaccida technique (through the window of the lesser omentum) is now standard practice with a band placed just below the oesophagogastric junction, making a small 'virtual' gastric pouch (**Figure 64.1**). The band is sutured into place anteriorly with gastrogastric tunneling sutures to reduce slippage.

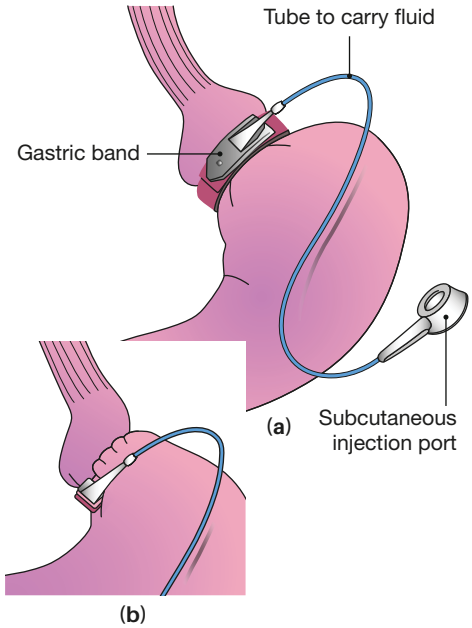

Figure 64.1 Adjustable gastric band. Gastric band surgery showing **(a)** a small 'virtual' pouch of stomach below the gastro-oesophageal junction and **(b)** gastrogastric tunnelling sutures. (Reproduced from Griffin SM, Raimes SA, Shenfine J. *Oesophagogastric surgery*, 5th edn. Saunders Elsevier, 2013.)

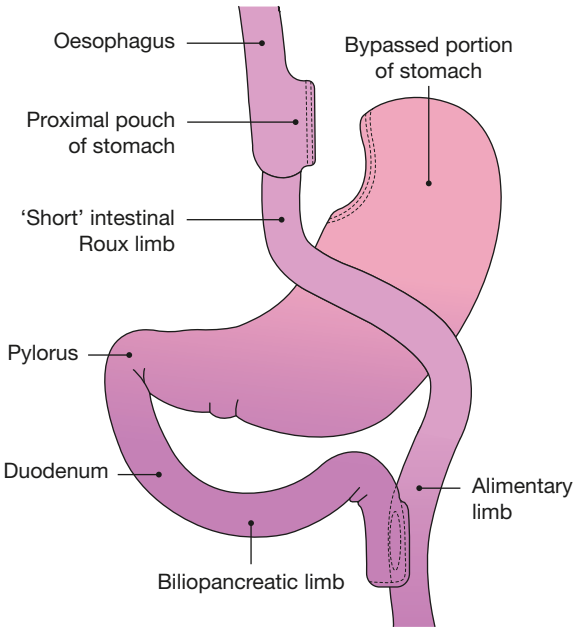

Figure 64.2 Gastric bypass showing a short vertical lesser curve-based gastric pouch with Roux-en-Y jejunojejunostomy reconstruction. (Reproduced from Griffin SM, Raimes SA, Shenfine J. *Oesophagogastric surgery*, 5th edn. Saunders Elsevier, 2013.)

The access port is routinely sutured to the rectus sheath in the upper abdomen for ease of access by a non-coring, Huber needle for band adjustments.

The operation appears to work by reducing hunger, probably vagally mediated. The initial surgical placement is only the beginning of the treatment. Specialist nurses, physicians and surgeons do 'band consultations' to assess eating habits and then perform an adjustment with injection or aspiration of saline if indicated. The objective is to reach the so-called 'sweet spot' of optimal appetite control. Follow-up should be monthly to begin with as needed during the first year, with full MDT support to help patients get the best use out of their bands. Lack of appropriate follow-up accounts for why some of the results in the literature vary so much, with a consequent high band removal rate.

Roux-en-Y gastric bypass

Despite the variety in laparoscopic techniques described and the lack of standardisation, most agree that Roux-en-Y gastric bypass includes a short vertical lesser curvature-based gastric pouch. The available techniques of pouch-jejunostomy are linear stapler with suture closure of the defect, circular stapler and entirely hand sewn. It is routine to perform a leak test. The Roux limb can be retro- or antecolic. Again, there is no standard length of the biliary and Roux limbs; however, the biliary limb is usually kept short with the objective to reduce vitamin and mineral deficiencies and the Roux limb length is varied between 100 and 150 cm (**Figure 64.2**). There are no consistent data regarding the effect of different limb lengths on weight loss. Bowel continuity is restored by a 'Y' jejuno-jejunostomy, which is either stapled with suture closure of the defect, or stapled in its entirety.

Despite the widespread belief that the mechanism of action is a combination of restriction and malabsorption of calories, there is no evidence to suggest this. Patients lose weight, at least in part, because they eat less, due to a change in appetite, facilitated by a change in satiety gut hormones. Other mechanisms such as changes in energy expenditure and change in food preferences, may also play a role.

Sleeve gastrectomy

This operation is less challenging to perform than gastric bypass. It evolved from the Magenstrasse and Mill operation, where the divided fundus (the 'mill') was left in continuity with the lesser curve-based tube (the 'main street'). At the same time, it was acting as the first step of the DS operation and proving to be effective on its own.

The lesser curve-based gastric tube is constructed over a size 32–36 Fr bougie, although some advocate that even larger sizes reduce the risk of staple line leakage (**Figure 64.3**). Linear stapling devices are used and again there is variation in the different techniques between how wide the staplers should be and whether reinforcement strips should be used. The 'Achilles heel' of the sleeve is the risk of staple line leaks at the angle of His, which can take months to heal due to the high-pressure system in the stomach with an intact pylorus. There is no consensus on how these should be treated and many patients become severely catabolic, having multiple procedures with long hospital stays. However, the sleeve is considered to be associated with lower perioperative risk and similar weight-loss outcomes to gastric bypass up to 3 or more years. Long-terms results are still awaited. A proportion of patients will need revisional surgery in future for weight regain.

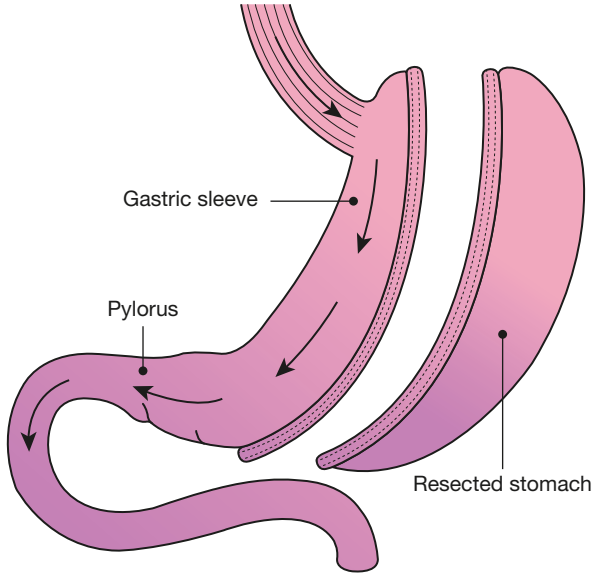

Figure 64.3 Sleeve gastrectomy. (Reproduced from Griffin SM, Raimes SA, Shenfine J. *Oesophagogastric surgery*, 5th edn. Saunders Elsevier, 2013.)

The mechanism of action is still being investigated. The initial thought that this is a restrictive procedure has been challenged with studies suggesting that gastric emptying is accelerated rather than delayed after sleeve gastrectomy. A change in satiety gut hormones and bile salt metabolism, similar to those described after gastric bypass, may explain some of the phenomena observed.

Biliopancreatic diversion/duodenal switch

BPD, described by Scopinaro in Naples, produces greater weight loss than other procedures, but is associated with a higher nutritional complication rate. The mechanism of action appears to be mainly malabsorption of calories. The DS is a variant of the BPD (**Figure 64.4**). A sleeve gastrectomy is followed by division of the duodenum just distally to the pylorus. The ileum is divided with a linear stapler, followed by a duodenoileostomy and ileoileostomy with the objective to create a common channel of 75–125 cm and an alimentary channel of 100–250 cm. The long remaining biliary limb is not measured.

DS is increasingly seen as a definitive procedure, particularly after significant weight regain following sleeve gastrectomy. A high protein diet and regular vitamin and mineral supplements with life-long monitoring and patient commitment, to avoid malnutrition, are essential postoperatively. Only a few centres offer these procedures.

Banded Roux-en-Y gastric bypass

Less common procedures include the banded bypass of Fobi and Capella, where a silicone ring is placed around the gastric pouch above the gastrojejunostomy with the objective to reduce weight regain. The design is not supported by our current understanding of the mechanism of action of gastric bypass and no benefit has been demonstrated by RCT.

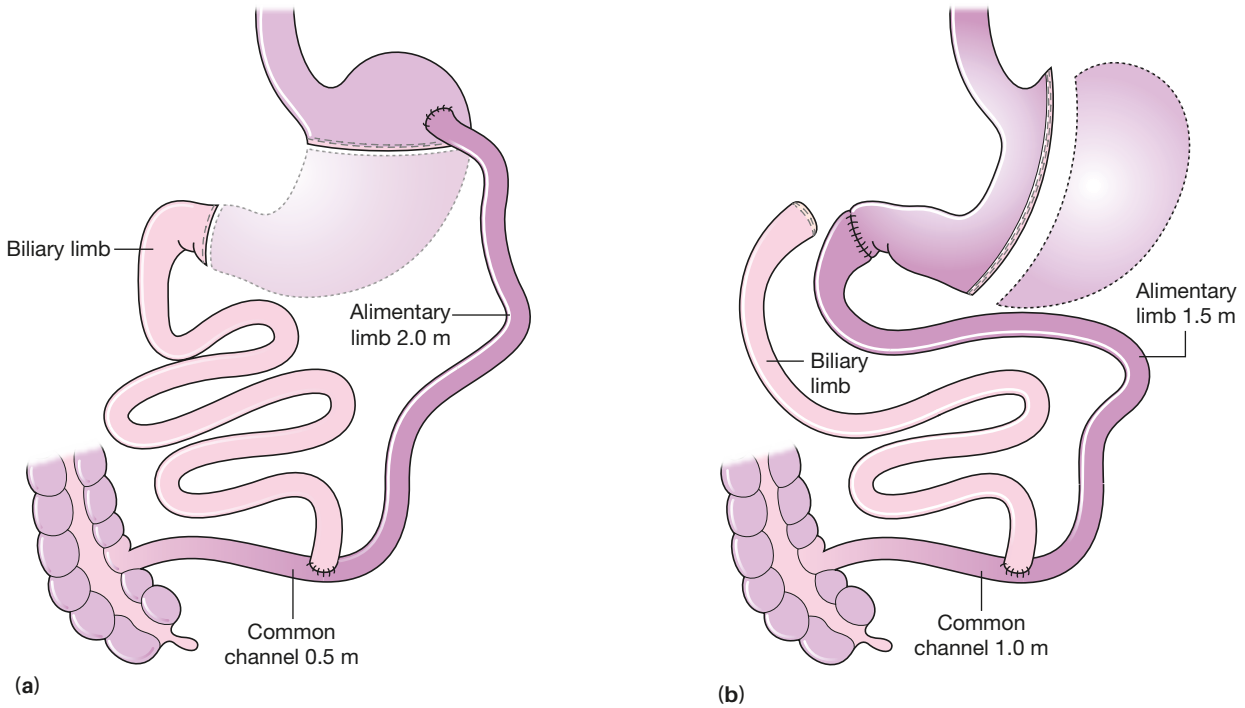

Figure 64.4 **(a)** Biliopancreatic diversion (BPD); **(b)** BPD with duodenal switch variant (BPD/DS).

Rafael Capella, contemporary, Assistant Professor of Surgery, New Jersey Medical School of Newark, NJ, USA.

One anastomosis gastric bypass

One anastomosis gastric bypass, also known as mini-gastric bypass, was first described by Rutledge. The objective was to develop a technique that is technically less demanding, with only one anastomosis (antecolic loop gastrojejunostomy without a Roux-en-Y configuration) and a longer gastric pouch than for standard gastric bypass. Similar weight-loss outcomes have been reported, but there is concern regarding symptomatic biliary reflux causing gastritis or oesophagitis, marginal ulcers and the management of anastomotic leaks due to a potentially high volume of biliary and pancreatic secretions. With the Roux-en-Y historically the standard in surgery of the stomach for ulcer disease and cancer, there is further concern due to possibly increased risk of Barrett's oesophagus and gastric or oesophageal cancer associated with biliary reflux. These outcomes will need long-term investigation.

Single anastomosis duodenoileal bypass with sleeve gastrectomy

Single anastomosis duodenoileal bypass with sleeve gastrectomy (SADI-S) is a novel procedure based on the BPD-DS. A sleeve gastrectomy is followed by an end-to-side duodenoileal anastomosis. The length of the common channel–alimentary limb is 200 cm. Potential advantages include the preservation of the pylorus, elimination of one anastomosis compared to the DS, reduced operating time and reduced risk of perioperative complications.

Sleeve gastrectomy and ileal transposition

Addition to the sleeve gastrectomy of an ileal transposition has also been suggested as an alternative option. In this operation, a large part of the ileum is transposed to the jejunum, in continuity. The lack of a bypass component with the potential benefits on glucose homeostasis should be balanced against the addition of three anastomoses and the creation of mesenteric defects at risk of internal herniation. This technique remains experimental and comparative studies are needed to establish the role of this procedure.

Complications

The common complications are shown in *Table 64.6*. Very few gastric banding patients develop early intra-abdominal complications. Unfortunately, a large number of patients have their bands removed later on if there is inadequate follow-up or a late complication.

Anastomotic leakage, bleeding and closed loop obstruction after gastric bypass can be life-threatening. If a bypass patient is not well after 24 hours, urgent consideration should be given to oral contrast x-ray swallow or computed tomography (CT) scanning and/or relaparoscopy. Other than a feeling of 'impending doom' patients may have few overt features of sepsis and abdominal examination can be very misleading. Deterioration after an anastomotic leak can be very rapid and there is no time for delay.

In sleeve gastrectomy, a staple line leak at the angle of His usually presents any time **after** discharge up to 30 days, and patients can also deteriorate rapidly with sepsis. Urgent CT scanning and relaparoscopy are indicated, with source control by drainage the major goal. Patients are typically in hospital for months and need multiple reinterventions, including any of stenting, making a controlled fistula, conversion to gastric bypass and fistula enterostomy. Long-term nutritional support is needed as patients are severely catabolic after complications from both bypass and sleeve surgery.

A 7-month pregnant patient presented with 48 hours of colicky abdominal pain and vomiting 5 years after a gastric bypass. At laparoscopy/laparotomy there was an internal hernia at the jejunojejunostomy. The patient lost two-thirds of her small bowel and the pregnancy. A Swedish RCT has now shown that closure of hernia defects at the time of surgery reduces the incidence of symptomatic internal hernias.

TABLE 64.6 Estimated early surgical complication rates, operative mortality after gastric banding, gastric bypass and sleeve gastrectomy and late complications.

	Early	Mortality	Late
Gastric band	Access port infection (1%) DVT/PE (<0.1%)	0.05–0.1%	Band infection Tubing leak Slippage Erosion into stomach Band intolerance Failure to lose weight/weight regain
Gastric bypass	Anastomotic leak (<1%) Intra-abdominal bleed (2–3%) Unspecified obstruction (1–2%) DVT/PE (<1%)	0.1–0.2%	Internal hernia Chronic abdominal pain Malnutrition if long limb bypass Anastomotic ulcer/stricture Weight regain
Sleeve gastrectomy	Leak at angle of His (2–3%) Intra-abdominal bleed (2–3%) DVT/PE (<1%)	0.1–0.2%	Gastro-oesophageal reflux Weight regain

DVT, deep vein thrombosis; PE, pulmonary embolus.

Robert Rutledge, contemporary, surgeon, Las Vegas USA.

Summary box 64.5

Acute complications

Anastomotic leak and staple line dehiscence can be rapidly fatal and require emergency laparoscopy

Internal hernias developing after surgery, e.g. gastric bypass, are very difficult to diagnose other than by prompt laparoscopy, and require a high index of suspicion

The incidence of late complications is difficult to estimate, as so many patients are lost to follow-up. Internal hernias develop as weight is lost and hernia spaces open up after gastric bypass. CT scanning has a high rate of false negatives for internal hernia, so anyone presenting with severe, cramping abdominal pain 2–3 years after surgery needs to be high priority for investigation by laparoscopy.

Outcomes reported

There is wide variation in how surgeons report the results of surgery, which means that it is often difficult to compare studies. There is a need to standardise clinician reported outcomes and patient reported outcome measures (PROMs) into an agreed core outcome set that includes risk stratification. Obvious PROMs include quality of life.

Follow-up and a shared-care model of chronic disease

Shared-care arrangements with surgeons/physicians and primary care need to be in place so that diabetes and hypertension medications and dosage can be appropriately reduced as weight is lost. Every diabetic needs at least an annual review. Although gastric banding, gastric bypass and sleeve gastrectomy do not cause protein–calorie malabsorption, bariatric surgery can cause severe vitamin and mineral deficiencies, amplifying pre-existing deficiencies caused by being obese.

TABLE 64.7 Summary of British Obesity and Metabolic Surgery Society (BOMSS) biochemical guidance after bariatric surgery.

Blood tests all patients should have at baseline:
Full blood count, urea and electrolytes, liver function tests, thyroid function tests, ferritin, folate, vitamin D, Ca^{++}, parathyroid hormone plus HbA1c, fasting glucose, lipid profile if diabetic
After gastric banding:
Annual full blood count, urea and electrolytes, HbA1c, fasting glucose, lipids as appropriate
After gastric bypass, sleeve gastrectomy, BPD/DS:
As for bands + liver function tests, ferritin, folate, vitamin D, Ca^{++}, parathyroid hormone at 3, 6, 12 months then annually; vitamin B12 at 6, 12 months then annually; zinc, copper annual; vitamin A, E, K, selenium if concern (e.g. steatorrhoea, night blindness, unexplained fatigue, anaemia, metabolic bone disease, chronic diarrhoea, heart failure)

BPD, biliopancreatic diversion; DS, duodenal switch.

TABLE 64.8 Summary of British Obesity and Metabolic Surgery Society (BOMSS) nutritional and micronutrient guidance after bariatric surgery.

After gastric banding:
Multivitamin and mineral supplement, thiamine if vomiting, vitamin D, iron
After gastric bypass, sleeve gastrectomy, BPD/DS:
As for banding + selenium, copper, zinc, folic acid, vitamins B12, A, E, K (BPD/DS may require higher doses)

BPD, biliopancreatic diversion; DS, duodenal switch.

All patients should have routine metabolic and nutritional monitoring lifelong (*Table 64.7*). Patients need regular multivitamins/trace element supplements (*Table 64.8*). The minimum frequency of assessment is 3–6 monthly in the first postoperative year, 6–12 monthly in the second year and at least annually thereafter. Folic acid supplementation should be considered in all sexually active women of child-bearing age, due to the risk of neural tube defects. This is especially important as fertility often improves after surgery. The MDT also needs to support the small number of patients who develop severe mental health issues after surgery, as there is a slightly increased risk of suicide after gastric bypass.

A female patient travelled abroad to have a self-funded laparoscopic Roux-en-Y gastric bypass. Three months after returning she came to the clinic in a wheelchair, unable to stand, with polyneuropathy and severe paraesthesia up to her chest ('bariatric beriberi'). She had not received multidisciplinary care or been advised to take multivitamins and have nutritional monitoring. After prompt thiamine injections and multivitamin support, she made a partial recovery.

Summary box 64.6

Shared-care model of chronic disease

Close collaboration between surgeons, physicians and primary care clinicians is needed to enable seamless follow-up before and after surgery, with a focus on long-term care of patients

Patients should be committed to lifelong vitamin and micronutrient monitoring and replacement

FUTURE CHALLENGES

Patients with obesity suffer from widespread prejudice. Understanding that the obesity epidemic currently experienced in different parts of the world is driven by a change in the environment towards becoming 'obesogenic', and not lack of willpower, would be the first step in removing the barriers to more surgery.

All surgeons should contribute their results to national registries so that safety can be monitored and operation trends established. Ideally, registries should also link to other national healthcare records, e.g. diabetes databases, so that long-term outcomes data can be collected outside of funded RCTs.

Chapter 65

The liver

Learning objectives

To understand:

- The anatomy of the liver
- The signs of acute and chronic liver disease
- The investigation of liver disease
- The management of liver trauma
- The management of liver infections
- The management of colorectal liver metastases
- The management of hepatocellular carcinoma

INTRODUCTION

The liver is the largest organ in the body, weighing 1.7 kg in the average 80-kg man. It sits in the right upper quadrant beneath the diaphragm, and is protected by the rib cage. The liver parenchyma is entirely covered by a thin capsule (Glisson's capsule) and by visceral peritoneum on all but the posterior surface of the liver, termed the 'bare area'. The liver is divided into a large right lobe, which constitutes three-quarters of the liver volume, and a smaller left lobe.

ANATOMY OF THE LIVER

Ligaments and peritoneal reflections

The liver is fixed in the right upper quadrant by peritoneal reflections that form ligaments. On the superior surface of the left lobe is the left triangular ligament. Dividing the anterior and posterior folds of this ligament allows the left lobe to be mobilised from the diaphragm and the left lateral wall of the inferior vena cava (IVC) to be exposed. The right triangular ligament fixes the entire right lobe of the liver to the undersurface of the right hemidiaphragm. Division of this ligament allows the liver to be mobilised from under the diaphragm and rotated to the left. Another major supporting structure is the falciform ligament (remnant of the umbilical vein), which runs from the umbilicus to the liver between the right and left lobes, passing into the interlobar fissure. From the fissure, it passes anteriorly on the surface of the liver, attaching it to the posterior aspect of the anterior abdominal wall. Division of the superior leaves of the falciform ligament allows exposure of the suprahepatic IVC, lying within a thin sheath of fibrous tissue. The final peritoneal reflection is between the stomach and the liver. This lesser omentum is often thin and fragile, but contains the hilar structures in its free edge.

Liver blood supply

The blood supply to the liver is unique, 80% being derived from the portal vein and 20% from the hepatic artery. The arterial blood supply in most individuals is derived from the coeliac trunk of the aorta, where the hepatic artery arises along with the splenic and left gastric artery. After supplying the gastroduodenal artery, the hepatic artery branches at a very variable level to produce the right and left hepatic arteries. The right artery supplies the majority of the liver parenchyma and is, therefore, the larger of the two arteries. There are many anatomical variations, knowledge of which is essential for safe surgery on the liver. The blood supply to the right lobe of the liver may be partly or completely supplied by a right hepatic artery arising directly from the superior mesenteric artery, rather than the coeliac trunk. This vessel passes posterior to the uncinate process and head of the pancreas, and runs to the liver on the posterior wall of the bile duct. Similarly, the arterial blood supply to the left lobe of the liver may be derived from a branch of the left gastric artery. This vessel runs between the lesser curve of the stomach and the left lobe of the liver in the lesser omentum.

Structures in the hilum of the liver

The porta hepatis, a transverse fissure on the visceral surface of the liver, is the hilum of the liver. The hepatic artery, portal vein and bile duct are present within the free edge of the lesser omentum (the hepatoduodenal ligament) and together with nerves and lymphatics enter the liver at the porta hepatis.

Francis Glisson, 1597–1677, Regius Professor of Physic, Cambridge, UK, described the capsule of the liver and its blood supply in his book *Anatomia hepatis* (1654).

The usual anatomical relationship of these structures is for the bile duct to be within the free edge, the hepatic artery to be above and medial, and the portal vein to lie posteriorly. Within this ligament, the common hepatic duct is joined by the cystic duct (draining the gallbladder) at a varying level to form the common bile duct (CBD). The common hepatic artery branches at a variable level within the ligament, with the right hepatic artery crossing the bile duct either anteriorly or posteriorly before giving rise to the cystic artery. Multiple small hepatic arterial branches provide blood to the bile duct, predominantly from the right hepatic artery. The portal vein arises from the confluence of the splenic vein and the superior mesenteric vein behind the neck of the pancreas. It has some important tributaries, including the left gastric vein, which joins just above the pancreas.

Division of structures at the hilum

At the hilum, the major structures divide into right and left branches. The right and left hepatic ducts arise from the hepatic parenchyma and join to form the common hepatic duct. The left duct has a longer extrahepatic course of approximately 2 cm. Once within the liver parenchyma, the duct accompanies the branches of the hepatic artery and portal vein within a fibrous sheath. The portal vein often gives off two large branches to the right lobe, which are usually outside the liver for a short length, before giving a left portal vein branch that runs behind the left hepatic duct.

Venous drainage of the liver

The venous drainage of the liver is via the hepatic veins into the IVC. The vena cava lies within a groove in the posterior wall of the liver. Above the liver, it immediately penetrates the diaphragm to join the right atrium, whereas below the liver parenchyma, there is a short length of vessel before the insertion of the renal veins. The inferior hepatic veins are short vessels that pass directly between the liver parenchyma and the anterior wall of the IVC. The major venous drainage is through three large veins that join the IVC immediately below the diaphragm. Outside the liver, these vessels are surrounded by a thin fibrous layer. The right hepatic vein can be exposed fully outside the liver, but the middle and left veins usually join within the liver parenchyma. The right kidney and adrenal gland lie immediately adjacent to the retrohepatic IVC. The right adrenal vein drains into the IVC at this level, usually via one main branch. The IVC can be mobilised fully from the retroperitoneal tissues and, in the healthy state, there are no large vessels in this tissue plane.

Segmental anatomy of the liver

Understanding the internal anatomy of the liver has greatly facilitated safe liver surgery. Couinaud, a French surgeon, described the liver as being divided into eight segments (Figure 65.1). Each of these segments can be considered as a functional unit, with a branch of the hepatic artery, portal vein and bile duct, and drained by a branch of the hepatic vein. It is the concept of these segments as distinct functional units that guides 'anatomical' liver resection. The overall anatomy of the liver is divided into a functional right and left 'unit'

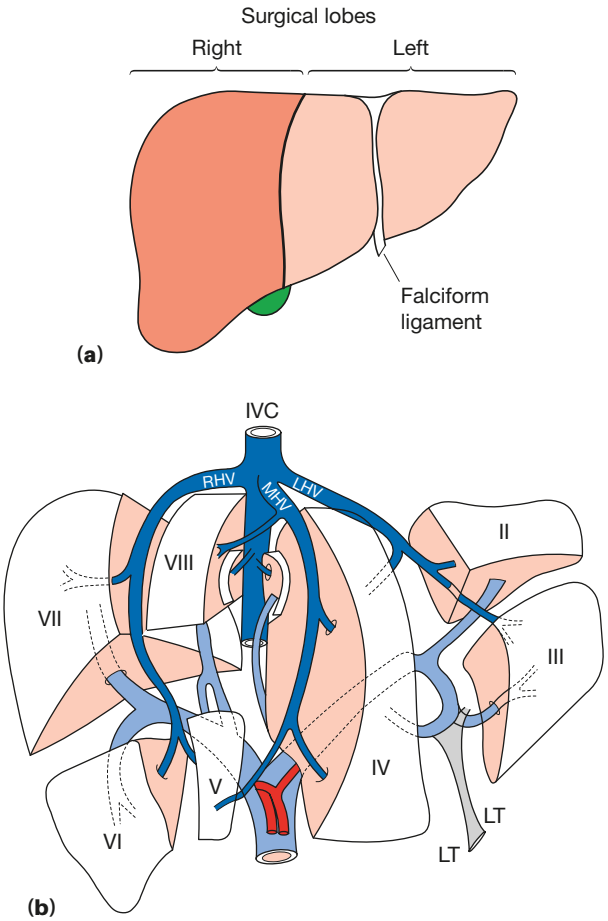

Figure 65.1 **(a)** The 'surgical' labels of the liver compared with the usual anatomical division into right and left lobes by the falciform ligament. **(b)** Segments of the liver (after Couinaud). IVC, inferior vena cava; LHV, left hepatic vein; LT, ligamentum teres; MHV, middle hepatic vein; RHV, right hepatic vein.

Summary box 65.1

Liver anatomy

- There are two anatomical lobes with separate blood supply, bile duct and venous drainage
- Dual blood supply (20% hepatic artery and 80% portal vein)
- The liver regenerates fully after partial resection
- Resection is based on anatomical lines to preserve maximal functioning liver

Claude Couinaud, 1922–2008, French surgeon and anatomist, described the segmental anatomy of the liver in his seminal book *Le Foie: Études anatomiques et chirurgicales*.

Sir James Cantlie, 1851–1926, Scottish born physician who cofounded the Hong Kong College of Medicine for Chinese (now Hong Kong University School of Medicine).

along the line between the gallbladder fossa and the middle hepatic vein (Cantlie's line). Liver segments (V–VIII) to the right of this line are supplied by the right hepatic artery and the right branch of the portal vein, and drain bile via the right hepatic duct. To the left of this line (segments I–IV), functionally, is the left liver, which is supplied by the left branch of the hepatic artery and the left portal vein branch, and drains bile via the left hepatic duct. Resections can be performed of individual segments or of the whole of the left or right hemiliver.

The hepatic lobules

The functional units within the liver segments are the liver lobules. These comprise plates of liver cells separated by the hepatic sinusoids, large, thin-walled venous channels that carry blood to the central vein, a tributary of the hepatic vein, from the portal tracts, which contain branches of the hepatic artery and portal vein. During passage through the sinusoids, the many functions of the liver take place, including bile formation, which is channelled in an opposite direction to the blood flow to drain via the bile duct tributaries within the portal tracts.

Embryology

The liver is a foregut structure and forms as a small endodermal bud early in gestation. The cell population is bipotential, and cells may develop into hepatocytes or intrahepatic ductal cells. The liver endothelium is derived from the vitelline and umbilical veins, which merge with the endodermal bud to form the liver sinusoids. The supporting connective tissue, haemopoietic cells, and Kupffer cells are derived from the mesoderm of the septum transversum, which is a mass of mesenchymal connective tissue.

ACUTE AND CHRONIC LIVER DISEASE

Liver function and tests

Adequate liver function is essential to survival; humans will survive for only 24–48 hours in the anhepatic state despite full supportive therapy. The liver is central to many key metabolic pathways.

Summary box 65.2

Main functions of the liver

- Maintaining core body temperature
- pH balance and correction of lactic acidosis
- Synthesis of clotting factors
- Glucose metabolism, glycolysis and gluconeogenesis
- Urea formation from protein catabolism
- Bilirubin formation from haemoglobin degradation
- Drug and hormone metabolism and excretion
- Removal of gut endotoxins and foreign antigens

TABLE 65.1 Routinely available tests of liver function.

Test	Normal range
Bilirubin	5–17 μmol/L
Alkaline phosphatase (ALP)	35–130 IU/L
Aspartate transaminase (AST)	5–40 IU/L
Alanine transaminase (ALT)	5–40 IU/L
Gamma-glutamyl transpeptidase (GGT)	10–48 IU/L
Albumin	35–50 g/L
Prothrombin time (PT)	12–16 s

An awareness of the currently available liver function tests and their significance is essential (*Table 65.1*).

Bilirubin is synthesised in the liver and excreted in bile. Increased levels may be associated with increased haemoglobin breakdown, hepatocellular dysfunction resulting in impaired bilirubin transport and excretion or biliary obstruction. In patients with known parenchymal liver disease, progressive elevation of bilirubin in the absence of a secondary complication suggests deterioration in liver function. The serum alkaline phosphatase (ALP) is particularly elevated with cholestatic liver disease or biliary obstruction. It is important to note that routine laboratory analysis of ALP is not isoform-specific and so alkaline phosphatase from a skeletal source may also lead to elevation. The transaminase levels (aspartate transaminase (AST) and alanine transaminase (ALT)) reflect acute hepatocellular damage, as does the gamma-glutamyl transpeptidase (GGT) level, which may be used to detect the liver injury associated with acute alcohol ingestion. However, marked liver injury can occur in the presence of normal liver function tests. The synthetic functions of the liver are reflected in the ability to synthesise proteins (albumin level) and clotting factors (prothrombin time). The standard method of monitoring liver function in patients with chronic liver disease is therefore serial measurement of bilirubin, albumin and prothrombin time.

Clinical signs of impaired liver function

These signs depend on the severity of dysfunction and whether it is acute or chronic.

Acute liver failure

Causes of acute liver failure

In the early stages, there may be no objective signs, but with severe dysfunction the onset of clinical jaundice may be associated with neurological signs of liver failure (hepatic encephalopathy), consisting of a liver flap, drowsiness, confusion and, eventually, coma.

Karl Wilhelm von Kupffer, 1829–1902, Professor of Anatomy at Kiel (1867), Königsberg (1875) and Munich, Germany (1880), described these 'stellate cells' in 1880.

Summary box 65.3

Causes of acute liver failure

- Viral hepatitis (hepatitis A, B, C, D, E)
- Drug reactions (halothane, isoniazid–rifampicin, antidepressants, non-steroidal anti-inflammatory drugs, valproic acid)
- Paracetamol overdose
- Mushroom poisoning
- Shock and multiorgan failure
- Acute Budd–Chiari syndrome
- Wilson's disease
- Fatty liver of pregnancy

Treatment of acute liver failure

The overall mortality from acute liver failure is approximately 50%, even with the best supportive therapy.

Summary box 65.4

Supportive therapy for acute liver failure

- Fluid balance and electrolytes
- Acid–base balance and blood glucose monitoring
- Nutrition
- Renal function (haemofiltration)
- Respiratory support (ventilation)
- Monitoring and treatment of cerebral oedema
- Treat bacterial and fungal infection

Liver transplantation is appropriate for some patients with acute liver failure, although the short-term results are poor in comparison with liver transplantation for chronic liver disease and suitable donor livers are frequently unavailable during the brief window of opportunity before death from liver failure.

Summary box 65.5

King's College selection criteria for liver transplantation in acute liver failure

Paracetamol induced

- pH <7.30 (irrespective of grade of encephalopathy) or prothrombin time (PT) >100 s + serum creatinine >300 μmol/L + grade 3 or 4 encephalopathy.

Non-paracetamol induced (irrespective of encephalopathy)

- PT >100 s

or any three of the following:

- Age <10 years or >40 years
- Aetiology non-A, non-B, halothane or idiosyncratic drug reaction
- More than 7 days' jaundice before encephalopathy
- PT >50 s
- Bilirubin >300 μmol/L

Chronic liver disease

Lethargy and weakness are common features irrespective of the underlying cause. These often precede clinical jaundice, which indicates impairment of the liver's ability to metabolise bilirubin. Progressive deterioration in liver function is associated with a hyperdynamic circulation involving a high cardiac output, large pulse volume, low blood pressure and flushed warm extremities. Fever is a common feature, which may be related to underlying inflammation and cytokine release from the diseased liver or may be due to bacterial infection, to which patients with chronic liver disease are predisposed. Skin changes may be evident, including spider naevi, cutaneous vascular abnormalities that blanch on pressure, palmar erythema and white nails (leuconychia). Endocrine abnormalities are responsible for hypogonadism and gynaecomastia. The mental derangement associated with chronic liver disease is termed hepatic encephalopathy. This is associated with memory impairment, confusion, personality changes, altered sleep patterns and slow, slurred speech. The most useful clinical sign is the flapping tremor, demonstrated by asking the patient to extend his or her arms and hyperextend the wrist joint. Abdominal distension due to ascites is a common late feature. This may be suggested clinically by the demonstration of a fluid thrill or shifting dullness. Protein catabolism produces loss of muscle bulk and wasting, and a coagulation defect is suggested by the presence of skin bruising.

Summary box 65.6

Features of chronic liver disease

- Lethargy
- Fever
- Jaundice
- Protein catabolism (wasting)
- Coagulopathy (bruising)
- Cardiac (hyperdynamic circulation)
- Neurological (hepatic encephalopathy)
- Portal hypertension
  - Ascites
  - Oesophageal varices
  - Splenomegaly
- Cutaneous
  - Spider naevi
  - Palmar erythema

Quantifying the severity of chronic liver disease

Two prognostic models commonly used to assess the severity of chronic liver disease and perioperative risk are the Child–Turcotte–Pugh (CTP) Classification and the Model for End-Stage Liver Disease (MELD) score. The original Child classification was developed to predict mortality following

George Budd, 1808–1882, Professor of Medicine, King's College Hospital, London, UK.
Hans Chiari, 1851–1916, Austrian pathologist, later Professor at University of Strasbourg, France.
SA Kinnier Wilson, 1878–1937, Professor of Neurology, King's College, London, UK.

shunt surgery in cirrhotic patients, with the modified CTP classification developed to predict mortality after any surgery. The CTP classification is detailed in *Table 65.2*. The MELD score was originally developed to predict short-term prognosis in patients undergoing transjugular intrahepatic portosystemic shunt insertion, but has now been adopted to prioritise patients awaiting liver transplantation. In the MELD model the survival probability of patients with end-stage liver disease is computed based on the patient's international normalised ratio (INR), serum bilirubin and serum creatinine.

Surgery in the presence of chronic liver disease

Patients with liver disease are at greater risk of surgical and anaesthetic complications, with the magnitude of risk dependent on size of procedure, degree of liver impairment and type of anaesthesia. Overall surgical mortality rates are generally considered to be increased by 10% in CTP A disease, 30% in CTP B and 75–80% in CTP C. MELD score also correlates with operative mortality, with a 1% increase for each MELD point up to 20, with a further 2% for each point above 20. These figures are considerably higher in patients who present as an emergency.

IMAGING THE LIVER

Major advances have taken place over recent years in surgical approaches to the liver, and the enormous improvement in the safety of liver surgery and surgical outcomes are in part due to improvements in preoperative imaging. The ideal choice of imaging modality is determined by the likely pathology as well as locally available equipment and radiological expertise (*Table 65.3*).

Ultrasound

Ultrasound is conventionally the first line modality in imaging the liver and biliary tract for detection of focal liver lesions (FLL) and assessment of biliary tract dilatation (**Figure 65.2**). Good quality ultrasound can characterise a definite benign lesion (e.g. cyst), from a definite malignant lesion (e.g. metastasis). However, due to considerable overlap in appearance of benign and malignant lesions, as well as interoperator variability, accurate characterisation is often not possible using unenhanced ultrasound alone. Obese patients and those with variant anatomy can be particularly difficult to evaluate. Fatty liver attenuates ultrasound, resulting in poor liver penetration, reducing confidence in accurate evaluation of the entire liver, and the technique should not be used when there is a high clinical suspicion of malignancy. Although ultrasound is frequently used to assess biliary dilatation, it is less useful in determining the aetiology. Dilatation of the ducts can suggest the presence of malignancy in a high-risk patient, but due to frequent overlying gastric and duodenal gas, the ducts are

TABLE 65.2 Child–Turcotte–Pugh (CTP) classification of hepatocellular function in cirrhosis.

Points	1 point each	2 points each	3 points each
Bilirubin (μmol/L)	<34	34–50	>50
Albumin (g/L)	>35	25–35	<25
Ascites	None	Easily controlled	Poorly controlled
Encephalopathy	None	GR I–II	Gr III–IV
INR	<1.7	1.7–2.2	>2.2

CTP A= 5–6 points, CTP B= 7–9 points, CTP C= 10–15 points

TABLE 65.3 Imaging the liver.

Imaging modality	Principal indication
Ultrasound	Standard first-line investigation
Spiral CT	Anatomical planning for liver surgery
MRI	Alternative to spiral CT
MRCP	First-line, non-invasive cholangiography
ERCP	Imaging the biliary tract when endoscopic intervention is anticipated (e.g. ductal stones)
PTC	Biliary tract imaging when ERCP impossible or failed
Angiography	To detect vascular involvement by tumour
PET scanning	To quantify tumour spread
Laparoscopy/ laparoscopic ultrasound	To detect peritoneal tumour spread and superficial liver metastases

CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; MRCP, magnetic resonance cholangiopancreatography; MRI, magnetic resonance imaging; PET, positron emission tomography; PTC, percutaneous transhepatic cholangiography.

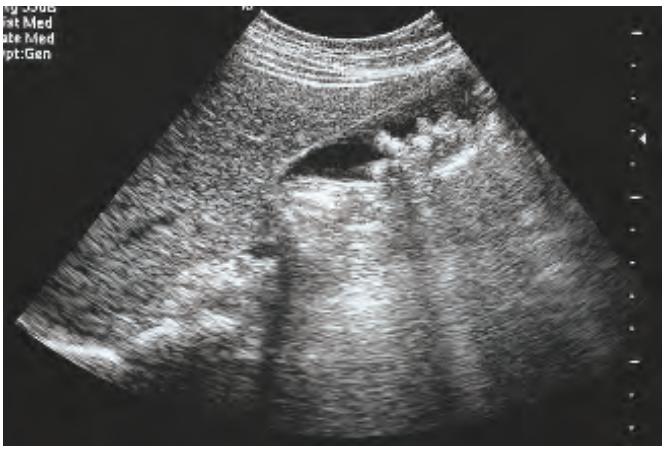

Figure 65.2 Ultrasound scan of the upper abdomen, showing the liver on the left and a gallbladder containing multiple gallstones centrally. The stones can be seen to cast an acoustic shadow.

Charles Gardner Child, 1908–1991, surgeon, Michigan, USA. Child and **JG Turcotte** first proposed the scoring system in 1964. In 1972, **RN Pugh** and colleagues from King's College Hospital, London modified the scoring system by replacing nutritional status with prothrombin time or international normalised ratio.

rarely seen throughout their entire course. The advent of contrast enhanced ultrasound scanning (CEUS), which employs transient intravascular bubbles to delineate normal liver parenchyma from solid tumours, has significantly increased the sensitivity and specificity of ultrasound scanning. CEUS assesses real-time lesion vascularity with a temporal resolution superior to that of other imaging modalities.

Computed tomography

Modern spiral computed tomography (CT) technology has increased the accuracy of diagnosis and staging of liver lesions, and contrast-enhanced CT is currently the most widely used and best validated modality for liver imaging. It provides fine detail of liver lesions down to less than 1 cm in diameter and gives information on their nature (**Figure 65.3**). Oral contrast enhancement allows visualisation of the stomach and duodenum in relation to the liver hilum. The early arterial phase of the intravenous contrast vascular enhancement is particularly useful for detecting small primary liver cancers, owing to their preferential arterial blood supply. The venous phase maps the branches of the portal vein within the liver and the drainage via the hepatic veins. Inflammatory liver lesions often exhibit rim enhancement with intravenous contrast, whereas commonly found haemangiomas characteristically show late venous enhancement. The density of any liver lesion can be measured, which is useful in establishing the presence of a cystic lesion. CT has high accuracy in determining the stage, and high sensitivity and specificity in determining resectability, of liver tumours. Local and distant metastases can also be detected, although peritoneal metastases are often missed on CT.

Magnetic resonance imaging

Magnetic resonance (MR) of the liver is superior to CT in characterising liver lesions and detecting small liver metastases (**Figure 65.4**). The advent of liver-specific contrast agents has significantly improved lesion characterisation and detection, particularly in differentiating small hepatocellular carcinoma (HCC) from regenerative nodules. These contrast agents are taken up by normally functioning hepatocytes. A lesion not containing hepatocytes will not take up contrast, and will appear dark against an enhancing background liver. These contrast agents are now being used more frequently due to the increased detection of lesions on liver-specific phase CT scans. This observation is particularly important for colorectal liver metastases prior to consideration of liver resection. In addition to standard MR scanning, magnetic resonance cholangiopancreatography (MRCP) provides excellent quality non-invasive imaging of the biliary tract, the accuracy of which is comparable to direct cholangiography by endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC).

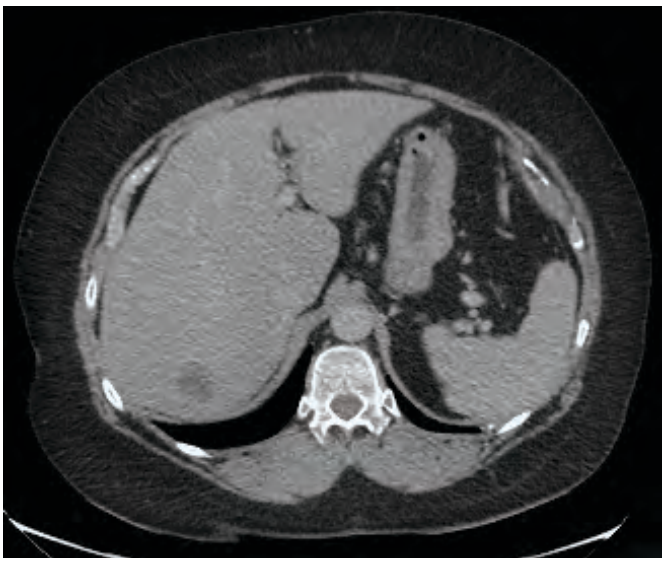

Figure 65.3 Computed tomography scan of a patient with a liver tumour in the right lobe of the liver, using intravenous contrast enhancement.

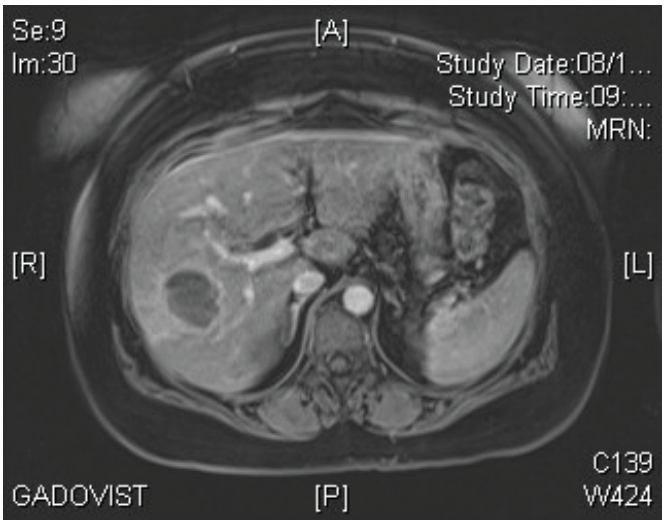

Figure 65.4 Magnetic resonance imaging (MRI) is increasingly used for the diagnosis and staging of liver cancers. This figure shows a colorectal liver metastasis as seen on contrast MRI.

Endoscopic retrograde cholangiopancreatography

ERCP (**Figure 65.5**) is performed in patients with obstructive jaundice when an endoscopic intervention is anticipated based on prior imaging (endoscopic removal of CBD stones, biliary drainage in septic patient or insertion of a biliary tract stent). Preoperative assessment of coagulation is essential, and if abnormal it is appropriately corrected, along with prophylactic antibiotics and an explanation of the main complications, which include pancreatitis, cholangitis and bleeding or perforation of the duodenum related to sphincterotomy.

Direct endoscopic cholangioscopy

Cholangioscopy enables direct visualisation of the bile ducts, either operatively or endoscopically. Originally, 'mother and baby' ERCP cholangioscopy only visualised the biliary mucosa of the common duct, and required two endoscopists to operate. This has changed with the development of the

Figure 65.5 Endoscopic retrograde cholangiopancreatography demonstrating the biliary tract with multiple stones in the distal common bile duct.

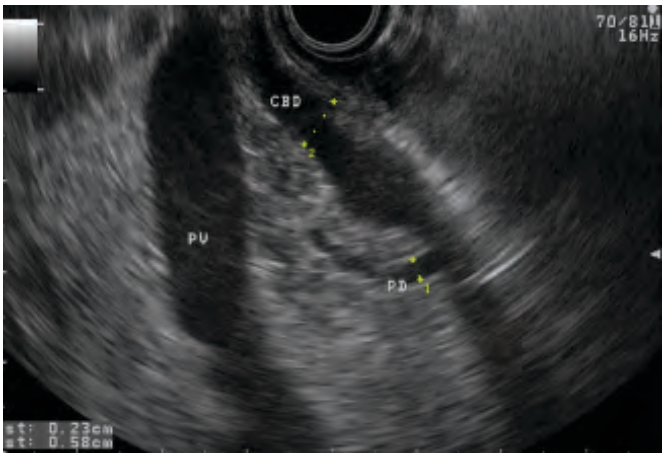

Figure 65.6 Endoscopic ultrasound gives excellent views of the head of pancreas and distal biliary tree, and is a sensitive method of detecting microcalculi not seen on standard transabdominal ultrasonography. This figure demonstrates the common bile duct (CBD) and confluence with the pancreatic duct (PD), with the portal vein lying deep to this (PV).

new SpyGlass™ (Boston Scientific) cholangioscope. SpyGlass™ cholangioscopy enables a single operator to visualise the biliary mucosa to at least second- and third-order ducts, with the benefit of a working channel to allow directly visualised biopsies and application of targeted therapy. Directly targeted biopsies improve the diagnostic yield to >80% in patients with indeterminate biliary strictures.

Endoscopic ultrasound

EUS evaluates the extrahepatic biliary tree, including indeterminate lymphadenopathy at the porta hepatis and para-aortic regions. EUS provides detailed views of the bile ducts, ampulla, pancreas and liver hilum, but does not carry the associated risks of ERCP. Radial EUS provides a 360° image, whereas linear EUS provides a view in the plane of the scope and allows for the sampling of tissue via biopsy or fine-needle aspiration (FNA). EUS is also the most sensitive tool for diagnosing small bile duct calculi (**Figure 65.6**).

Percutaneous transhepatic cholangiography

PTC is indicated where endoscopic cholangiography has failed or is impossible, e.g. in patients with previous pancreatoduodenectomy or gastrectomy. It is often required in patients with hilar bile duct tumours to guide external drainage of the obstructed bile ducts to relieve jaundice, evaluate resectability and to direct stent insertion (**Figure 65.7**).

Angiography

Angiography is generally employed only for direct therapeutic intervention. Therapeutic interventions include the occlusion of arteriovenous malformations, the embolisation of bleeding sites in the liver and the treatment of liver tumours (transarterial chemoembolisation, TACE).

Figure 65.7 Percutaneous transhepatic cholangiography. Some contrast has extravasated at the site of hepatic puncture of the percutaneously placed needle, but the biliary tract is clearly demonstrated and shows the multiple strictures typical of primary sclerosing cholangitis.

Positron emission tomography

18F-2-fluoro-2-deoxy-D-glucose positron emission tomography (FDG–PET) depends on the avid uptake of glucose by cancerous tissue in comparison with benign or inflammatory tissue. Deoxyglucose is labelled with the positron emitter fluorine-18 (18FDG), and this is administered to the patient

prior to imaging by PET. A three-dimensional image of the whole body is obtained, highlighting areas of increased glucose metabolism (Figure 65.8). PET or integrated PET-CT can be useful in the diagnosis of regional lymph node metastases and distant metastases.

Laparoscopy

Laparoscopy is useful for the staging of primary hepatopancreatobiliary cancers. Lesions overlooked by conventional imaging are mainly peritoneal metastases and superficial liver tumours. These lesions can be detected at laparoscopy thus avoiding an unnecessary laparotomy. A liver biopsy to confirm or exclude chronic liver disease can also be performed during laparoscopy, but routine biopsy of resectable lesions should be avoided because of the risk of tumour seeding. There is no role for routine laparoscopy in patients with colorectal liver metastases.

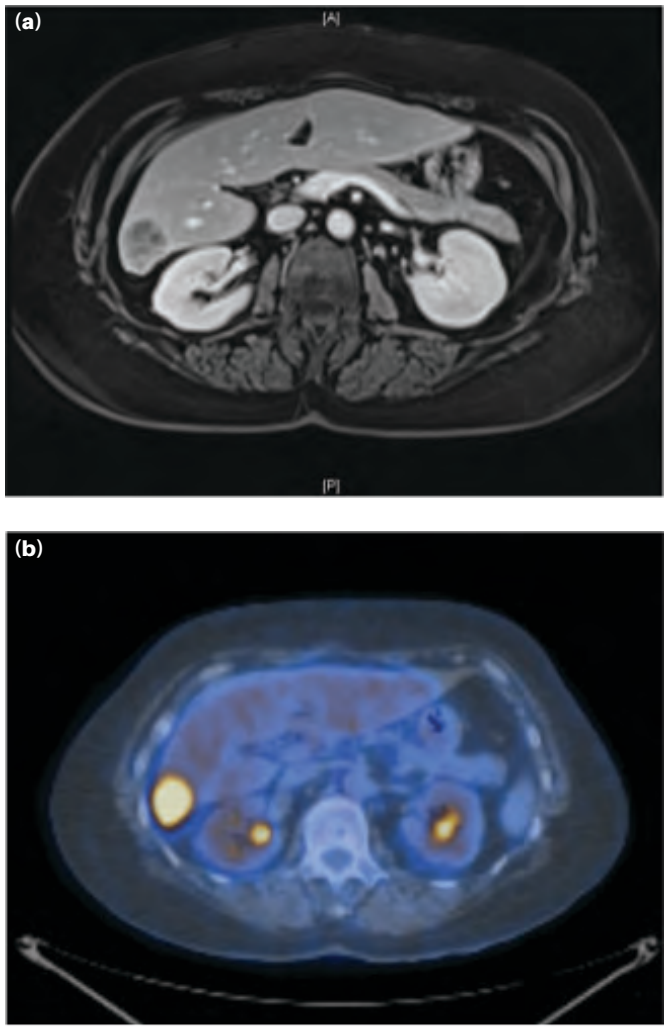

Figure 65.8 Patient with colorectal liver metastasis seen on **(a)** an MRI liver and **(b)** 18F-2-fluoro-2- deoxy-D-glucose uptake on a combined PET-CT scan. Similar uptake outside the liver usually precludes curative intent surgery as it indicates distant metastases. As seen in these images, some background renal activity is expected.

LIVER TRAUMA

General

The liver is the second most common organ injured in abdominal trauma after the spleen.

Liver trauma can be divided into blunt and penetrating injuries. Blunt injury produces contusion, laceration and avulsion injuries to the liver, often in association with splenic, mesenteric or renal injury. Penetrating injuries, such as stab and gunshot wounds, are often associated with chest or pericardial involvement. Blunt injuries are more common and have a higher mortality than penetrating injuries.

Summary box 65.7

Management of liver trauma

- Remember associated injuries
- At-risk groups
  - Stabbing/gunshot in lower chest or upper abdomen
  - Crush injury with multiple rib fractures
- Resuscitate
  - Airway
  - Breathing
  - Circulation
- Assessment of injury
  - CT chest and abdomen with contrast
  - Laparotomy if haemodynamically unstable
- Treatment
  - Correct coagulopathy
  - Suture lacerations
  - Resect if major vascular injury
  - Packing if diffuse parenchymal injury

Diagnosis of liver injury

The liver is an extremely well-vascularised organ, and blood loss is therefore the major early complication of liver injuries. Clinical suspicion of a possible liver injury is essential, as a laparotomy by an inexperienced surgeon with inadequate preoperative preparation is doomed to failure. All lower chest and upper abdominal stab wounds should be suspect, especially if considerable blood volume replacement has been required. Similarly, severe crushing injuries to the lower chest or upper abdomen often combine rib fractures, haemothorax and damage to the spleen and/or liver. Focused assessment sonography in trauma (FAST) performed in the emergency room by an experienced operator can reliably diagnose free intraperitoneal fluid. Patients with free intraperitoneal fluid on FAST and haemodynamic instability, and patients with a penetrating wound, will require a laparotomy and/or thoracotomy once active resuscitation is under way. Owing to the opportunity for massive ongoing blood loss and the rapid development of a coagulopathy, the patient should be directly transferred to the operating theatre while blood products are obtained and volume replacement is taking place. Patients who are haemodynamically stable should have a contrast-

enhanced CT scan of the chest and abdomen as the next step. This scan will demonstrate evidence of parenchymal damage to the liver or spleen, as well as associated traumatic injuries to their feeding vessels. Free fluid can also be clearly established. The chest scan will help to exclude injuries to the great vessels and demonstrate damage to the lung parenchyma.

Initial management of liver injuries

Penetrating

The initial management is maintenance of airway patency, breathing and circulation (ABC) following the principles of advanced trauma life support (ATLS). Peripheral venous access is gained with two large-bore cannulae and blood sent for cross-match of 10 units of blood, full blood count, urea and electrolytes, liver function tests, clotting screen, glucose and amylase. Initial volume replacement should be with blood. Arterial blood gases should be obtained and the patient intubated and ventilated if the gas exchange is inadequate. Intercostal chest drains should be inserted if associated pneumothorax or haemothorax is suspected. Once initial resuscitation has commenced, the patient should be transferred to the operating theatre, with further resuscitation performed on the operating table. The necessity for fresh frozen plasma and cryoprecipitate should be discussed with the blood transfusion service immediately the patient arrives in the hospital (often by activation of a major transfusion protocol), as these patients rapidly develop irreversible coagulopathies due to a lack of fibrinogen and clotting factors. Standard coagulation profiles are inadequate to evaluate this acute loss of clotting factors, and factors should be given empirically, aided by the results of thromboelastography (TEG), if available (**Figure 65.9**). A contrast CT prior to laparotomy should be considered if the patient is haemodynamically stable.

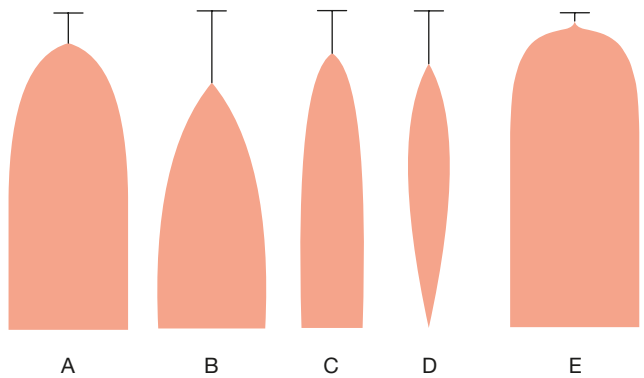

Figure 65.9 Thromboelastography (TEG). This dynamic form of assessing the coagulation status is being used increasingly for intraoperative monitoring. The shape of the TEG trace defines the nature of the underlying coagulation deficiency as shown. A, normal; B, delayed clot formation; C, reduced clot strength; D, clot lysis; E, hypercoagulable.

Blunt trauma

With blunt injuries, the initial plan for resuscitation and management is as outlined above for penetrating injuries. Patients who are haemodynamically unstable will require an immediate laparotomy. For the patient who is haemodynamically stable, imaging by CT should be performed to further evaluate the nature of the injury. Most patients with blunt liver injury who are haemodynamically stable can be managed conservatively. The indication for discontinuing conservative treatment is the development of haemodynamic instability, evidence of ongoing blood loss despite correction of any underlying coagulopathy and the development of signs of generalised peritonitis. Interventional radiology has an important role in management of liver trauma and embolisation to control hepatic artery bleeding is safe and effective in a stable patient with no evidence of hollow viscus perforation.

The surgical approach to liver trauma

Good access is vital. A 'rooftop' incision with midline extension to the xiphisternum and retraction of the costal margins gives excellent access to the liver and spleen. If the laparotomy has been started through a midline incision, a transverse lateral extension to the right can be added to improve access to the liver. Compression of the liver with packs and correction of coagulopathy, if present, will control most of the active bleeding. If bleeding persists, further control can be acheived by vascular inflow occlusion by placing an atraumatic clamp across the foramen of Winslow (the Pringle manoeuvre). A stab incision in the liver can be sutured with a fine absorbable monofilament suture. Lacerations to the hepatic artery should be identified and repaired with 6/0 Prolene suture. If unavoidable, the hepatic artery may be ligated, although parenchymal necrosis and abscess formation will result in some individuals. Portal vein injuries should be repaired with 5/0 Prolene. Inflow occlusion facilitates suturing of lacerations and vessels.

If bleeding persists despite inflow occlusion, consider major hepatic vein or IVC injuries, and also look for abberant arteries to the liver. Deceleration injuries often produce lacerations of the liver parenchyma adjacent to the anchoring ligaments of the liver. These may be amenable to suture with an absorbable monofilament suture. Again, inflow occlusion may facilitate this suturing and, if necessary, the sutures can be buttressed to prevent them cutting through the liver parenchyma. With more severe deceleration injuries, a portion of the liver may be avulsed. These injuries are more complex as they are associated with a devitalised portion of the liver and, often, major injuries to the hepatic veins and IVC. Diffuse parenchymal injuries should be treated by packing the liver to achieve haemostasis (**Figure 65.10**). This is effective for the majority of liver injuries if the liver is packed against the natural contour of the diaphragm by packing from below. Large

James Hogarth Pringle, 1863–1941, surgeon, The Royal Infirmary, Glasgow, UK. Born in Australia and trained in Edinburgh, he was a strong supporter of women in medicine; he performed the first successful autologous vein graft in the UK and the first excision and block dissection for malignant melanoma. He and his father, George Hogarth Pringle (1830 –1872, who practised in Australia), formed a famous team of surgical innovators.

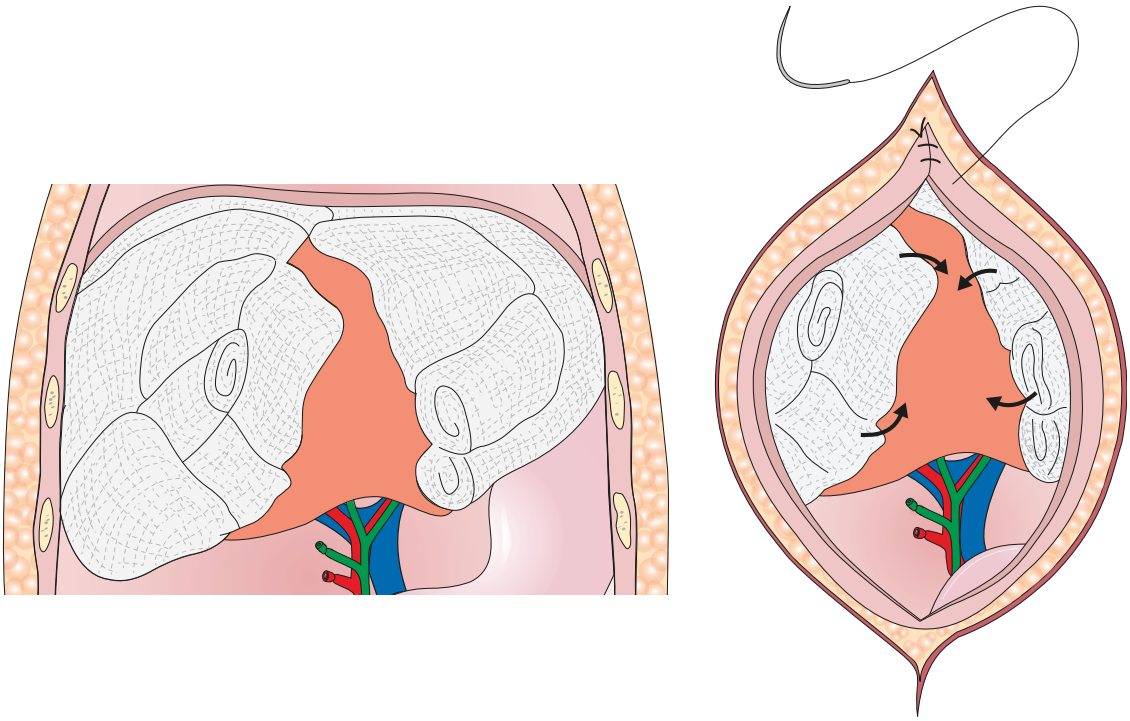

Figure 65.10 Packing the liver to achieve haemostasis. The abdomen can then be closed and the patient transferred to critical care for stabilisation prior to relook laparotomy 24–48 hours later. (Adapted from Poston, D'Angelica, Adam (eds). *Surgical management of hepatobiliary and pancreatic disorders*. Boca Raton: CRC Press, 2010.)

abdominal packs should be used to ease their removal, and the abdomen closed to facilitate compression of the parenchyma. Care should be taken to avoid overzealous packing, as this may produce pressure necrosis of the liver parenchyma or abdominal compartment syndrome.

Crush injuries to the liver often result in large parenchymal haematomas and diffuse capsular lacerations (**Figure 65.11**). Suturing is usually ineffective, and perihepatic packing, which involves placing packs above, behind and below the liver, is the most useful method of providing haemostasis. Necrotic tissue should be removed, but poorly perfused, though viable, liver left *in situ*. If packing is necessary, the patient should have the packs removed after 48 hours, and usually no further surgical intervention is required. Antibiotic cover is advisable, and full reversal of any coagulopathy is essential. If a major liver vascular injury (hepatic vein or vena cava, grade V or VI) is suspected at the time of the initial laparotomy, then packing and referral to a specialist centre should be considered. A common surgical approach in these circumstances would be to place the patient on venovenous bypass, using cannulae in the femoral vein via a long saphenous cut-down, with the blood returned using a roller pump to the superior vena cava (SVC) via an internal jugular line. Venovenous bypass allows the IVC to be safely clamped to facilitate caval or hepatic vein repair. A rapid infuser blood transfusion machine facilitates the delivery of large volumes of blood instantaneously. Once prepared, the patient is relaparotomised via the rooftop incision with a midline extension to the xiphisternum. The liver is mobilised by division of the supporting ligaments, and complete vascular isolation of the liver is achieved by occluding the hilar inflow and the IVC above the renal veins and at the level of the diaphragm with atraumatic vascular clamps. Venous return is provided by the venovenous bypass. Warm ischaemia of the liver is tolerated for up to 45 minutes, allowing sufficient time in a blood-free field for repair of injuries to the IVC or hepatic veins.

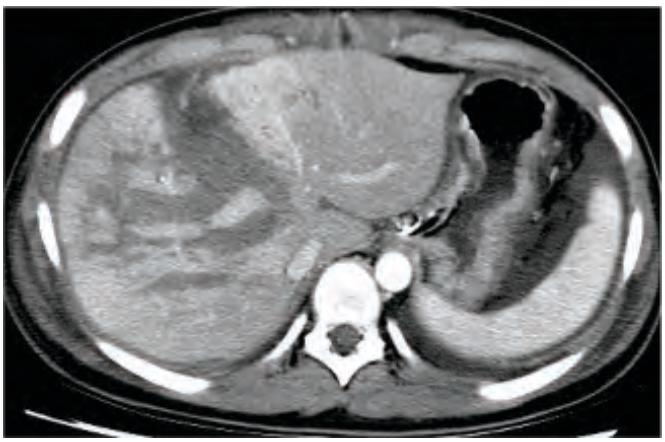

Figure 65.11 Computed tomography scan demonstrating grade IV liver injury.

Other complications of liver trauma

A subcapsular or intrahepatic haematoma requires no specific intervention and should be allowed to resolve spontaneously. Abscesses may form as a result of secondary infection of an area of parenchymal ischaemia, especially after penetrating trauma. Treatment is with systemic antibiotics and aspiration

under ultrasound guidance once the necrotic tissue has liquefied. Bile collections require aspiration under ultrasound guidance or percutaneous insertion of a pigtail drain. The site of origin of a biliary fistula should be determined by endoscopic or percutaneous cholangiography, and biliary decompression achieved by nasobiliary or percutaneous transhepatic drainage or stent insertion. If this fails to control the fistula, the affected portion of the liver may require resection. Late vascular complications include hepatic artery aneurysm and arteriovenous (precipitating acute heart failure if between the hepatic artery and hepatic vein and acute portal hypertension if arterioportal) or arteriobiliary fistulae (resulting in often painful haemobilia) (Figure 65.12). These are best treated non-surgically by a specialist hepatobiliary interventional radiologist. The feeding vessel can be embolised transarterially.

Hepatic failure may occur following extensive liver trauma. This will usually reverse with conservative supportive treatment if the blood supply and biliary drainage of the liver are intact.

Summary box 65.8

Complications of liver trauma

- Intrahepatic haematoma
- Liver abscess
- Bile collection
- Biliary fistula
- Hepatic artery aneurysm
- Arteriovenous fistula
- Arteriobiliary fistula
- Liver failure

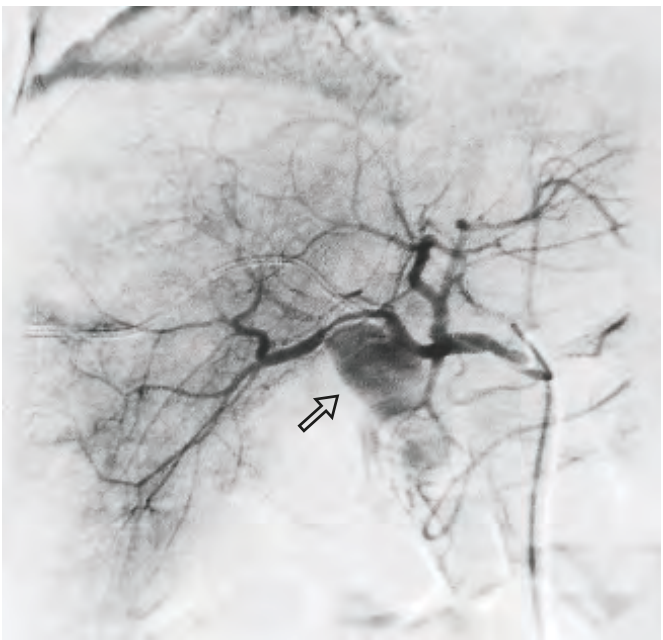

Figure 65.12 Hepatic aneurysm following liver trauma. An aneurysm arising from the right hepatic artery (arrow), which can be optimally treated by the interventional radiologist using transarterial embolisation.

Long-term outcome of liver trauma

The capacity of the liver to recover from extensive trauma is remarkable, and parenchymal regeneration occurs rapidly. Late complications are rare, but the development of biliary strictures many years after recovery from liver trauma has been reported. The treatment depends on the mode of presentation and the extent and site of stricturing. A segmental or lobar stricture, associated with atrophy of the corresponding area of liver parenchyma and compensatory hypertrophy of the other liver lobe, may be treated expectantly. A dominant extrahepatic bile duct stricture associated with obstructive jaundice may be treated initially with endobiliary balloon dilatation or stenting, but will usually require surgical correction using a Roux-en-Y hepatodochojejunostomy.

PORTAL HYPERTENSION

An elevation in portal pressure is most commonly found in the presence of liver cirrhosis, although it may be present in patients with extrahepatic portal vein occlusion, intrahepatic veno-occlusive disease or occlusion of the main hepatic veins (Budd–Chiari syndrome (BCS)). As portal hypertension *per se* produces no symptoms, it is usually diagnosed following presentation with decompensated chronic liver disease and encephalopathy, ascites or variceal bleeding.

Management of bleeding varices

General resuscitation

Varices usually present with the acute onset of a large-volume haematemesis, the lower oesophagus being the most common site for variceal bleeding. The diagnosis may be suspected if the patient is known to have liver cirrhosis, but it needs to be confirmed following initial resuscitation of the patient. Variceal haemorrhage is a medical emergency. Patients with massive hemorrhage should be admitted to the intensive care unit. Venous access should be obtained through two large-bore peripheral cannulae. Resuscitation should be commenced, ideally with blood. Liver function tests will reveal underlying liver disease, and a coagulation profile will reveal any underlying coagulopathy. Hypervolaemia should be avoided since this may increase portal pressure and exacerbate the bleeding. Vitamin K is administered (10 mg intravenously (i.v.)) as well as tranexamic acid (1 g i.v.), but correction of a coagulopathy will require the administration of fresh frozen plasma (FFP). A major transfusion protocol should be activated. An associated thrombocytopenia is usually secondary to hypersplenism due to cirrhosis and is treated if the platelet count falls below 50×10^9/L. Treatment with a splanchnic vasoconstrictor (such as terlipressin) should be started. Administration of a prophylactic antibiotic is recommended to prevent or treat associated bacterial infection. As soon as the patient is haemodynamically stabilised, an upper gastrointestinal endoscopy should be performed to establish the diagnosis because 50% of patients with portal hypertension will have a non-variceal source of bleeding. Variceal bleeding is often associated with hepatic encephalopathy and, in these circumstances and when bleeding is severe, endotracheal intubation

will be required to provide definitive airway protection prior to endoscopy. Bronchial aspiration is a frequent complication of variceal bleeding.

Summary box 65.9

Management of bleeding oesophageal varices

- Blood transfusion
- Correct coagulopathy
- Oesophageal balloon tamponade (Sengstaken–Blakemore tube)
- Drug therapy (terlipressin)
- Endoscopic sclerotherapy or banding
- Assess portal vein patency (Doppler ultrasound or CT)
- Transjugular intrahepatic portosystemic stent shunts (TIPSS)
- Surgery
  - Portosystemic shunts
  - Splenectomy and gastric devascularisation

If the rate of blood loss prohibits endoscopic evaluation, a Sengstaken–Blakemore tube may be inserted to provide temporary haemostasis (**Figure 65.13**). Once inserted, the gastric balloon is inflated with 300 mL of air and retracted to the gastric fundus, where the varices at the oesophagogastric junction are tamponaded by the subsequent inflation of the oesophageal balloon to a pressure of 40 mmHg. The two remaining channels allow gastric and oesophageal aspiration. The position of the tube is confirmed radiologically. The balloons should be temporarily deflated after 12 hours to prevent pressure necrosis of the oesophagus. Aspiration pneumonia and oesophageal ulceration are other complications. Balloon tamponade is very effective in stopping bleeding and once the patient is stabilised, a more definitive treatment can be carried out.

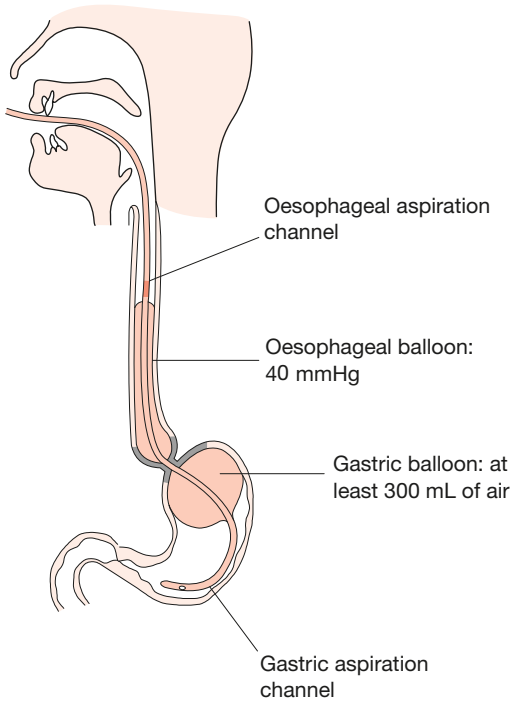

Figure 65.13 Oesophageal balloon tamponade with a Sengstaken–Blakemore tube. The tube should be decompressed every 12 hours to prevent necrosis.

Endoscopic treatment of varices

Treatment with a vasoconstrictor combined with endoscopic therapy is the standard medical treatment for acute variceal bleeding. The two most commonly used endoscopic techniques are endoscopic band ligation, which involves placing a constricting rubber band at the base of the varix, and endoscopic sclerotherapy, which involves injection of a sclerosant into or around the varix. Although both are effective in controlling the bleed, banding is signficantly better in preventing rebleeding and is the preferred option. The majority of variceal bleeds will respond to a single course of endoscopic treatment.

Transjugular intrahepatic portosystemic stent shunts

The emergency management of variceal haemorrhage has been revolutionised by the introduction of transjugular intrahepatic portosystemic stent shunts (TIPSS). Over a short period, this has become the main treatment of variceal haemorrhage that has not responded to drug treatment and endoscopic therapy. The shunts are inserted under local anaesthetic, analgesia and sedation, using fluoroscopic guidance and ultrasonography. Via the internal jugular vein and SVC, a guidewire is inserted into a hepatic vein and through the hepatic parenchyma into a branch of the portal vein. The track through the parenchyma is then dilated with a balloon catheter to allow insertion of a metallic stent, which is expanded once a satisfactory position is achieved (**Figure 65.14**) to form a channel between systemic and portal venous systems. A satisfactory drop in portal venous pressure is usually associated with good control of the variceal haemorrhage. The main early complication of this technique is perforation of the liver capsule, which can be associated with fatal intraperitoneal haemorrhage. TIPSS occlusion may result in further variceal haemorrhage and occurs more commonly in patients with well-compensated liver disease and good synthetic function. Post-shunt encephalopathy is a confusional state caused by the portal blood bypassing the detoxification of the liver. It occurs in about 40% of patients, a similar incidence to that found after surgical shunts. If severe, the lumen of the TIPSS can be reduced by insertion of a smaller stent. The main contraindication to TIPSS is portal vein occlusion. The main long-term complication of TIPSS is stenosis of the shunt, which is common (approximately 50% at 1 year) and may present as further variceal haemorrhage.

Robert William Sengstaken Sr., 1923–1978, neurosurgeon, Garden City, New York, NY, USA.
Arthur Blakemore, 1897–1970, surgeon, The Columbia College of Physicians and Surgeons, New York, NY, USA.

Figure 65.14 A check angiogram following insertion of a TIPSS (transjugular intrahepatic portosystemic stent shunt) (open arrow). Injection of contrast into the portal vein flows through the metallic stent and outlines the right hepatic vein. Pressure measurements are taken from within the portal vein before and after insertion. Solid arrows indicate coils placed at the site of previous embolisation.

Surgical shunts for variceal haemorrhage

The increasing availability of liver transplantation and TIPSS has greatly reduced the indications for surgical shunts. It is rarely considered for the acute management of variceal haemorrhage, as the morbidity and mortality in these circumstances are high. The main current indication for a surgical shunt is a patient with CTP grade A cirrhosis, in whom the initial bleed has been controlled by sclerotherapy. Long-term β-blocker therapy and chronic sclerotherapy or banding are the main alternatives. β-blockers lower portal pressure by a combination of vasodilation and decreasing cardiac output, reducing the risk of subsequent rebleeds.

Surgical shunts are an effective method of preventing rebleeding from oesophageal or gastric varices, as they reduce the pressure in the portal circulation by diverting the blood into the low-pressure systemic circulation. Shunts may be divided into selective (e.g. splenorenal) and non-selective (e.g. portocaval), the former attempting to preserve blood flow to the liver while decompressing the left side of the portal circulation responsible for giving rise to the oesophageal and gastric varices (**Figure 65.15**). Selective shunts are associated with a lower incidence of portal systemic encephalopathy (PSE), a confusional state commonly found in patients with chronic liver disease who have undergone radiological or surgical portosystemic shunts. There is no evidence that prophylactic shunting is beneficial in patients with varices that have not bled.

Management of recurrent variceal bleeds secondary to splenic or portal vein thrombosis

Treatment is by splenectomy and gastro-oesophageal devascularisation, in which the blood supply to the greater and lesser curve of the stomach and lower oesophagus is divided. Splenic vein thrombosis may be seen secondary to chronic

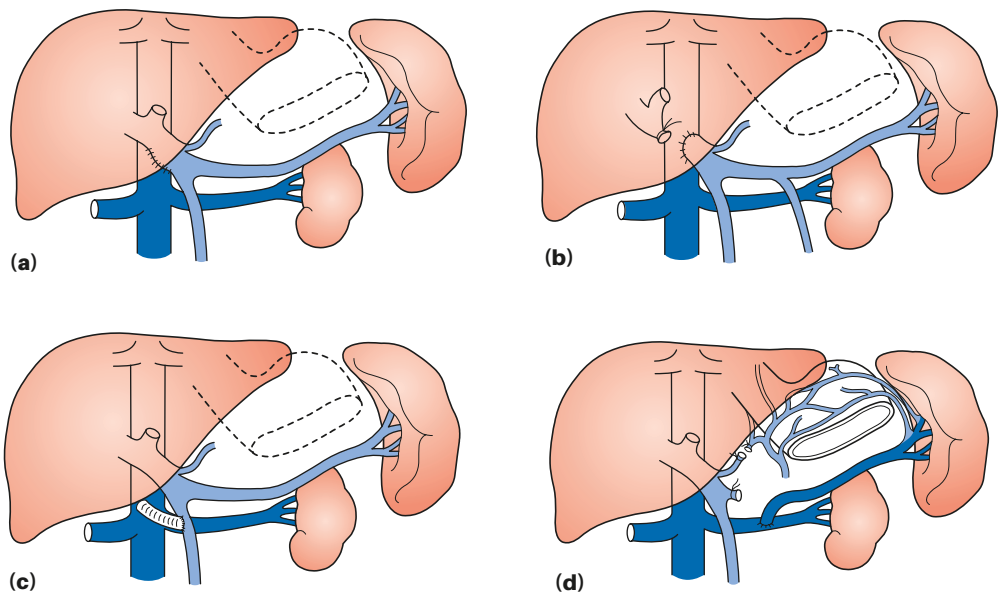

Figure 65.15 **(a-d)** Surgical shunts. Surgical shunts for portal hypertension involve shunting portal blood into the systemic veins. This commonly involves a side-to-side portocaval anastomosis **(a)** or end-to-side portocaval **(b)**, mesocaval **(c)** or splenorenal **(d)** anastomoses.

pancreatitis, and portal vein thrombosis is a common late complication of liver cirrhosis.

Variceal bleeding and orthotopic liver transplantation

Liver transplantation is the only therapy that will treat both portal hypertension and the underlying liver disease. The management of variceal bleeding should always take into account the possibility of liver transplantation when this is available. Previous surgical shunts greatly increase the morbidity associated with orthotopic liver transplantation. TIPSS would be the preferred management for bleeds resistant to sclerotherapy, as long as placement is optimal.

Ascites

The accumulation of ascites is a common feature of advanced liver disease independent of the aetiology. The fluid accumulation is usually associated with abdominal discomfort and a dragging sensation. Development is usually insidious. The aetiology of the ascites must be established.

Summary box 65.10

Determining the cause of ascites

- Imaging (ultrasound or CT)
  - Irregular cirrhotic liver
  - Portal vein patency
  - Splenomegaly of cirrhosis
- Aspiration
  - Culture and microscopy
  - Protein content
  - Cytology
  - Amylase level

Imaging by CT will confirm the ascites and demonstrate the irregular and shrunken nature of a cirrhotic liver and associated portal hypertension and splenomegaly. Intravenous contrast enhancement will allow abdominal varices to be demonstrated and assess patency of the portal vein, as portal vein thrombosis is a common predisposing factor to the development of ascites in chronic liver disease. In patients without evidence of liver disease, malignancy is a common cause, and the primary site may also be established on CT. Aspiration of the peritoneal fluid allows the measurement of protein content to determine whether the fluid is an exudate or transudate, and an amylase estimation to exclude pancreatic ascites. Cytology will determine the presence of malignant cells, and both microscopy and culture will exclude primary bacterial and tuberculous peritonitis.

Treatment of ascites in chronic liver disease

The initial treatment is to restrict additional salt intake and commence diuretics using either spironolactone or furosemide. This should be combined with advice on avoiding any precipitating factors for impaired liver function, such as alcohol intake in patients with alcoholic cirrhosis. Patients on diuretics should be monitored for the development of hyponatraemia and hypokalaemia.

Summary box 65.11

Treatment of ascites in chronic liver disease

- Salt restriction
- Diuretics
- Abdominal paracentesis
- TIPSS
- Liver transplantation

Abdominal paracentesis

Patients who fail to respond to diuretic treatment may require repeated percutaneous aspiration of large volumes of the ascites (abdominal paracentesis), combined with volume replacement using salt-poor or standard human albumin solution, dependent on the serum sodium level. Paracentesis provides only short-term symptomatic relief.

TIPSS for ascites

The use of TIPSS for ascites is for symptomatic relief. In patients with intractable ascites, TIPSS is a good alternative to repeated paracentesis but post-stent encephalopathy is common (about 40%), and the majority of stents will stenose or thrombose on follow-up (approximately 50% by 1 year).

Liver transplantation for ascites

Diuretic-resistant ascites is an indication for liver transplantation if associated with deterioration in liver function (rising bilirubin, dropping albumin, prolonged prothrombin time). The patient's age, underlying aetiology of liver disease and associated medical problems will be the major factors determining suitability for liver transplantation. In those considered inappropriate for liver transplantation, management is aimed at symptomatic control of ascites.

CHRONIC LIVER CONDITIONS

There are several chronic liver conditions, which, although rare, are important to recognise because they require a specific plan for investigation and treatment, and may present mimicking a more common clinical condition (*Table 65.4*).

Budd–Chiari syndrome

Budd–Chiari syndrome (BCS) is a condition principally affecting young females, in which the venous drainage of the liver is occluded by hepatic venous thrombosis or obstruction from a venous web. As a result of venous outflow obstruction, the liver becomes acutely congested, with the development of impaired liver function and, subsequently, portal hypertension, ascites and oesophageal varices. In an acute thrombosis, the patient may rapidly progress to fulminant liver failure but,

TABLE 65.4 Important chronic liver conditions.

Condition	Common presentations
Budd–Chiari syndrome	Ascites
Primary sclerosing cholangitis	Abnormal LFTs or jaundice
Primary biliary cirrhosis	Malaise, lethargy, itching, abnormal LFTs
Caroli's disease	Abdominal pain, sepsis
Simple liver cysts	Coincidental finding, pain
Polycystic liver disease	Hepatomegaly, pain

LFTs, liver function tests.

in the majority of cases, abdominal discomfort and ascites are the main presenting features. If chronic, the liver progresses to established cirrhosis. The cause of the venous thrombosis needs to be established, and an underlying myeloproliferative disorder or procoagulant state is commonly found, such as antithrombin 3, protein C or protein S deficiency. The diagnosis is commonly suspected in a patient presenting with ascites, in whom a CT scan shows a large congested liver or a small cirrhotic liver in which there is gross enlargement of segment I (the caudate lobe); this feature results from preservation and hypertrophy of the segment with direct venous drainage to the IVC in the face of atrophy of the rest of the liver due to venous obstruction. IVC compression or occlusion from the segment I hypertrophy is also a common feature, as is portal vein thrombosis.

Treatment of BCS must be tailored to the individual patient and, in particular, to the stage of disease at presentation. Patients presenting in fulminant liver failure should be considered for liver transplantation, as should those with established cirrhosis and the complications of portal hypertension. Those in whom cirrhosis is not established may be considered for portosystemic shunting by TIPSS. IVC compression may be relieved by the insertion of a retrohepatic expandable metallic stent. If the BCS is treated satisfactorily, the prognosis of this patient group is largely dependent on the underlying aetiology and whether this is amenable to treatment. Patients are usually left on lifelong anticoagulation.

Primary sclerosing cholangitis

This condition often presents in young adults with mild non-specific symptoms, and biliary disease is suggested by the finding of abnormal liver function tests. Rarely, the first presentation is with jaundice due to biliary obstruction. The disease process results in progressive fibrous stricturing and obliteration of both the intrahepatic and the extrahepatic bile ducts. Although the aetiology is unknown, a genetic predisposition is likely, owing to its association with ulcerative colitis (UC). In patients with primary sclerosing cholangitis (PSC) and UC, the condition usually progresses even if the diseased colon is removed. The diagnosis is principally based on the findings at cholangiography, in which irregular, narrowed bile ducts are demonstrated in both the intrahepatic and the extrahepatic biliary tree (**Figure 65.16**). If the radiological appearances are equivocal, a liver biopsy is required

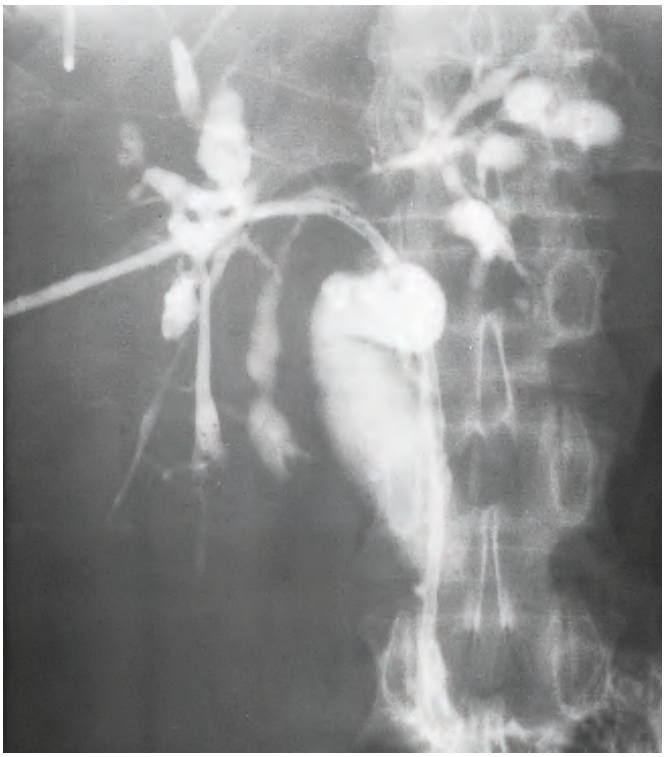

Figure 65.16 Primary sclerosing cholangitis (PSC). Percutaneous cholangiography showing the characteristic extensive bile duct strictures and dilatations associated with PSC.

to demonstrate the fibrous obliteration of the biliary tracts. There is no specific treatment that can reverse the ductal changes, and the patients usually slowly progress to progressive cholestasis and death from liver failure. There is a strong predisposition to cholangiocarcinoma (CCA) and gallbladder cancer, and this should be considered in any patient with PSC in whom a new or dominant stricture is demonstrated on cholangiography, or in whom gallbladder polyps are identified.

Diagnosis of CCA in PSC is greatly facilitated by biliary brush cytology and direct endoscopic inspection (Spyglass, see above), as imaging rarely shows evidence of a mass lesion even in patients with advanced CCA. Further, imaging cannot reliably differentiate between inflammatory and malignant biliary strictures. Serum CA 19-9 level may be increased but the sensitivity of CA 19-9 in detecting CCA in PSC is only 60%. Patients with good liver function, no dominant strictures and negative biliary cytology may simply be monitored for disease progression. The only useful treatment modality is liver transplantation, which is associated with excellent results if carried out before bile duct cancer has developed. Temporary relief of obstructive jaundice due to a dominant bile duct stricture can be achieved by biliary stenting, although there is considerable risk of cholangitis from the introduction of bacteria to the biliary tract.

Primary biliary cirrhosis

As with PSC, the presentation of patients with primary biliary cirrhosis (PBC) is often hidden, with general malaise, lethargy and pruritus prior to the development of clinical jaundice or

the finding of abnormal liver function tests. The condition is largely confined to females. Diagnosis is suggested by the finding of circulating antismooth muscle antibodies and, if necessary, is confirmed by liver biopsy. The condition is slowly progressive, with deterioration in liver function resulting in lethargy and malaise. It may be complicated by the development of portal hypertension and the secondary complications of ascites and variceal bleeding. The mainstay of treatment is liver transplantation, which should be considered when the patient's general condition starts to deteriorate with inability to lead a normal lifestyle.

Caroli's disease

This is congenital dilatation of the intrahepatic biliary tree, which is often complicated by the presence of intrahepatic stone formation. Presentation may be with abdominal pain or sepsis. Imaging is usually diagnostic, with the finding on ultrasound or CT of intrahepatic biliary lakes containing stones. Biliary stasis and stone formation combine to predispose to biliary sepsis, which may be life-threatening. No specific treatment is available. Acute infective episodes are treated with antibiotics. Obstructed and septic bile ducts may be drained either radiologically or surgically. Malignant change within the ductal system results in cholangiocarcinoma, which may be amenable to resection. Segmental involvement of the liver by Caroli's disease may be treated by resection of the affected part, although the ductal dilatation is usually diffuse. Liver transplantation is a radical but definitive treatment.

Simple cystic disease

Simple cysts are generally solitary, and occur more frequently in women. Most are incidental findings, and have a characteristic blue hue when seen at laparoscopy. Indications for surgical intervention include symptoms, rupture, haemorrhage, infection or indeterminate diagnosis. Surgical resection typically involves laparoscopic deroofing, with oversewing of the cyst wall. Polycystic liver disease is less common. It is an autosomal dominant condition, more commonly seen in women, and around half of patients will also have polycystic kidneys. Indications for surgical intervention are broadly similar to those for simple cysts, although the large number of lesions means that deroofing a single cyst is unlikely to relieve symptoms.

LIVER INFECTIONS

Ascending cholangitis

Ascending bacterial infection of the biliary tract is usually associated with obstruction and presents with clinical jaundice, rigors and a tender right upper quadrant (Charcot's triad). The diagnosis is confirmed by the finding of dilated bile ducts on ultrasound, an obstructive picture of liver function tests and the isolation of an organism from the blood on culture. The condition is a medical emergency, and delay in appropriate treatment results in multiorgan failure secondary to septicaemia. Once the diagnosis has been confirmed, the patient should be commenced on a first-line broad spectrum antibiotic and rehydrated, and arrangements should be made for urgent endoscopic or percutaneous transhepatic drainage of the biliary tree. Biliary stone disease is a common predisposing factor, and the causative ductal stones may be removed at the time of endoscopic cholangiography by endoscopic sphincterotomy.

Pyogenic liver abscess

The aetiology of a pyogenic liver abscess is unexplained in the majority of patients. Common causes include biliary stone disease and other causes of intra-abdominal sepsis, including appendicitis and diverticular disease. It has an increased incidence in the elderly, diabetics and the immunosuppressed, who usually present with anorexia, fevers and malaise, accompanied by right upper quadrant discomfort. The diagnosis is suggested by the finding of a multiloculated cystic mass on ultrasound or CT scan (**Figure 65.17**) and is confirmed by aspiration for culture and sensitivity. The most common organisms are *Streptococcus milleri* and *Escherichia coli*, but other enteric organisms such as *Streptococcus faecalis*, *Klebsiella* and *Proteus vulgaris* also occur, and mixed growths are common. Opportunistic pathogens include staphylococci. Treatment is with antibiotics and ultrasound-guided aspiration. First-line antibiotics to be used are a penicillin, aminoglycoside and metronidazole or a cephalosporin and metronidazole. Often repeated aspirations may be necessary. Percutaneous drainage without ultrasound guidance should be performed with caution as an empyema may follow drainage through the pleural space. A source for the liver abscess should be sought,

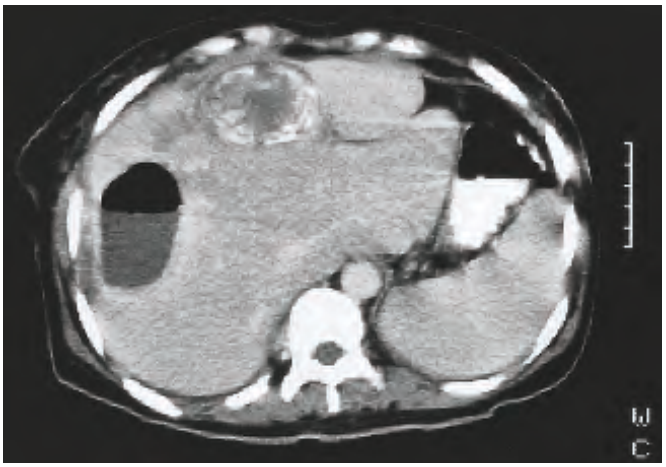

Figure 65.17 Liver abscess. Computed tomography scan showing an air–fluid level and rim enhancement with intravenous contrast typical of a liver abscess. In the adjacent liver is a calcified hydatid cyst.

Jacques Caroli, 1902–1979, Professor of Medicine, St Antoine Hospital, Paris, France, described the disease in 1958.
Jean-Martin Charcot, 1825–1893, French neurologist and Professor of Pathology at Pitié-Salpêtrière Hospital, Paris, France.

particularly from the colon. Atypical clinical or radiological findings should raise the possibility of a necrotic neoplasm.

Amoebic liver abscess

Entamoeba histolytica is endemic in many parts of the world. It exists in vegetative form outside the body and is spread by the faecal–oral route. The most common presentation is with dysentery, but it may also present with an amoebic abscess, the common sites being paracaecal and in the liver. The amoebic cyst is ingested and develops into the trophozoite form in the colon, and then passes through the bowel wall and to the liver via the portal blood. Diagnosis is by isolation of the parasite from the liver lesion or the stool and confirming its nature by microscopy. Often patients with clinical signs of an amoebic abscess will be treated empirically with metronidazole (400–800 mg t.d.s. for 7–10 days) and investigated further only if they do not respond. Resolution of the abscess can be monitored using ultrasound.

Hydatid liver disease

This is a very common condition in countries around the Mediterranean and Middle East. The causative tapeworm, *Echinococcus granulosus*, is present in the dog intestine, and ova are ingested by humans and pass in the portal blood to the liver. Liver abscesses are often large by the time of presentation with upper abdominal discomfort or may present after minor abdominal trauma as an acute abdomen due to rupture of the cyst into the peritoneal cavity. Diagnosis is suggested by the finding of a multiloculated cyst on ultrasound and is further supported by the finding of a floating membrane within the cysts on CT scan (**Figure 65.18**). Active cysts contain a large number of smaller daughter cysts (**Figure 65.19**), and rupture can result in these implanting and growing within the peritoneal cavity. Liver cysts can also rupture through the diaphragm producing an empyema, into the biliary tract producing obstructive jaundice, or into the stomach. Clinical and radiological diagnosis can be supported by serology

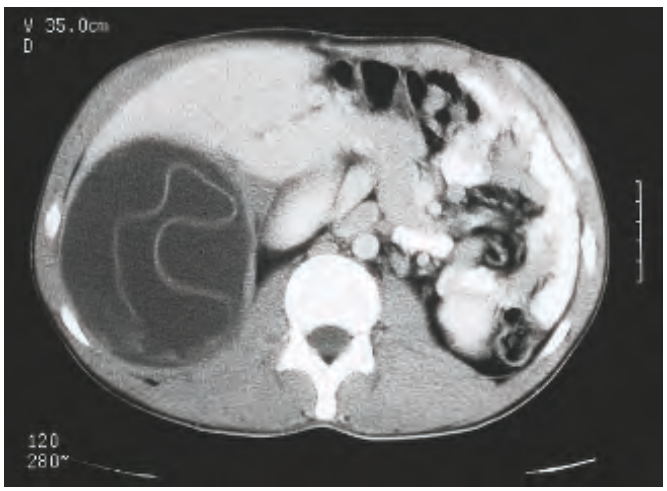

Figure 65.18 Hydatid liver cyst. Active hydatid disease usually produces a non-calcified liver cyst and, within the cyst, floating layers of the germinal membrane can be seen.

Figure 65.19 Hydatid 'daughter' cysts. These were removed from the bile duct of a patient presenting with obstructive jaundice due to a hydatid liver cyst communicating with the bile duct. Endoscopic removal should also be considered.

for antibodies to hydatid antigen, in the form of an enzyme-linked immunosorbent assay (ELISA). Treatment is indicated to prevent progressive enlargement and rupture of the cysts. In the first instance, a course of albendazole or mebendazole may be tried. There are many reports that percutaneous treatment of hydatid cysts is safe and effective. Percutaneous treatment (PAIR) constitutes of an intial course of albendazole followed by puncture of the cyst under image guidance, aspiration of the cyst's contents, instillation of hypertonic saline in the cyst cavity and reaspiration. PAIR should only be attempted if there is no communication with the biliary tree. Failure to respond to medical treatment or percutaneous treatment usually requires surgical intervention. The surgical options range from liver resection or local excision of the cysts to deroofing with evacuation of the contents. Contamination of the peritoneal cavity at the time of surgery with active hydatid daughters should be avoided by continuing drug therapy with albendazole and adding peroperative praziquantel. This should be combined with packing of the peritoneal cavity with 20% hypertonic saline-soaked packs and instilling 20% hypertonic saline into the cyst before it is opened. A biliary communication should be actively sought and sutured. The residual cavity may become infected, and this may be reduced, as may bile leakage, by packing the space with pedicled greater omentum (an omentoplasty). Calcified cysts may well be dead. If doubt exists as to whether a suspected cyst is active, it can be followed on ultrasound, as active cysts gradually become larger and more superficial in the liver. Rupture of daughter hydatids into the biliary tract may result in obstructive jaundice or acute cholangitis. This may be treated by endoscopic clearance of the daughter cysts prior to cyst removal from the liver.

LIVER TUMOURS

Surgical approaches to resection of liver tumours

Adequate exposure of the liver is an absolute prerequisite to safe liver surgery. A transverse abdominal incision in the right upper quadrant with a vertical midline extension to the xiphoid provides excellent access to the liver if adequate

retraction of the costal margin is employed, using a costal margin retractor. If necessary the incision can be extended across the midline transversely in the left upper quadrant. Thoracoabdominal incisions are very rarely required. The procedure for complete mobilisation of the liver is described, although this will not be necessary in all cases. There are many variations in surgical technique.

Mobilisation of the liver

The falciform ligament is first divided and followed along the anterosuperior surface of the liver towards the suprahepatic IVC. The left triangular ligament is divided, facilitated by placing a swab in front of the oesophagogastric junction. The right triangular ligament is then divided by retraction of the diaphragm away from the right lobe. On exposure of the bare area of the liver, the IVC can be seen as it passes behind the liver, and this can be slung above the renal veins below the liver and at the level of the main hepatic veins. Mobilisation of the liver is completed by division of the lesser omentum. Separating the liver from the IVC is achieved by lifting the liver anteriorly, to expose the multiple small veins (inferior hepatic veins) passing between the liver parenchyma and the IVC. These should be suture ligated to ensure haemostasis. This proceeds from above the renal veins until the main named hepatic veins are reached below the diaphragm.

Dissection of the hilum

The peritoneum overlying the hilum is divided. The CBD is then exposed on the free edge of the lesser omentum, mobilisation being facilitated by ligation and division of the cystic duct and artery followed by removal of the gallbladder. Slinging the CBD with an elastic sling allows exposure of the common hepatic artery and dissection of the main right and left branches. These again may be slung to allow the remaining lymphatic tissue surrounding the portal vein to be ligated and divided. The possibility of a replaced right hepatic artery should be sought arising from the superior mesenteric artery and lying posterior to the bile duct (25% of people), and an accessory left hepatic artery from the left gastric artery in the lesser omentum (25% of people). Dissection of the hilar bile ducts requires careful retraction on segment IV of the liver, and division of the small vessels and bile duct branches passing between segment IV and the confluence of the right and left hepatic ducts.

Division of the parenchyma: hemihepatectomy

Once the liver has been adequately mobilised and the hilar vessels have been exposed, the main inflow vessels and bile duct to the liver to be resected can be divided. The arterial branch, bile duct and portal vein branch are all suture ligated. For a hemihepatectomy, division of the inflow vessels in the portal pedicle produces a line of demarcation between the right and left liver, passing to the right of, and parallel with, the falciform ligament. The parenchyma is divided along this plane of demarcation, commencing by diathermy of the liver capsule. The ultrasound dissector (CUSA®, Cavitron ultrasonic surgical aspirator) is the most common method used for division of the parenchyma, but alternative methods including stapling, Kelly-clasia crushing and Aquaseal have all been used. Prospective evidence suggests there is no difference in speed of transection or blood loss between these methods. As the parenchyma is divided, vessels and bile duct branches are diathermised or ligated depending on their size. Dissection continues on until the hepatic vein branches are approached from within the liver parenchyma, when they are ligated or stapled then divided. Alternatively, the hepatic veins can be divided outside the liver at the time of mobilisation (**Figure 65.20**).

Segmental and local resections

Traditionally, surgical strategy has involved removal of the entire liver segment or hemiliver containing disease, with a view to providing the largest possible negative margin. Although anatomical resection remains the treatment of choice for patients with HCC (**Figure 65.21**), for those with colorectal liver metastasis a parenchymal-sparing non-anatomical approach involving multiple metastectomies is now considered the standard of care (**Figure 65.22**). This approach has no impact on long-term oncological outcome, and preserves liver remnants, so allowing the opportunity for further resection in the case of recurrent disease.

Laparoscopic liver resections

Laparoscopic liver surgery aims to provide curative resection while minimising postoperative time to recovery. There are

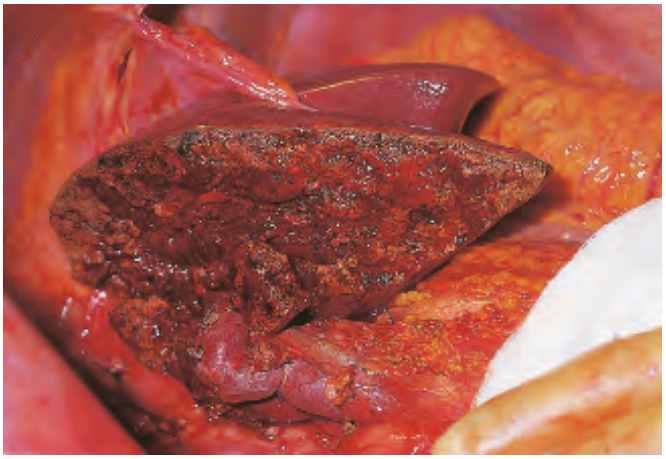

Figure 65.20 Hepatectomy post resection. Cut surface of the residual liver following a right hepatectomy in which segments V–VIII have been removed. On the lower edge, the portal vein and bile duct can be visualised.

Howard A Kelly, 1858–1943, American gynaecologist, who together with William Osler, William Halstead and William Welsh, was one of the founding professors of Johns Hopkins Hospital in Baltimore, MD, USA.

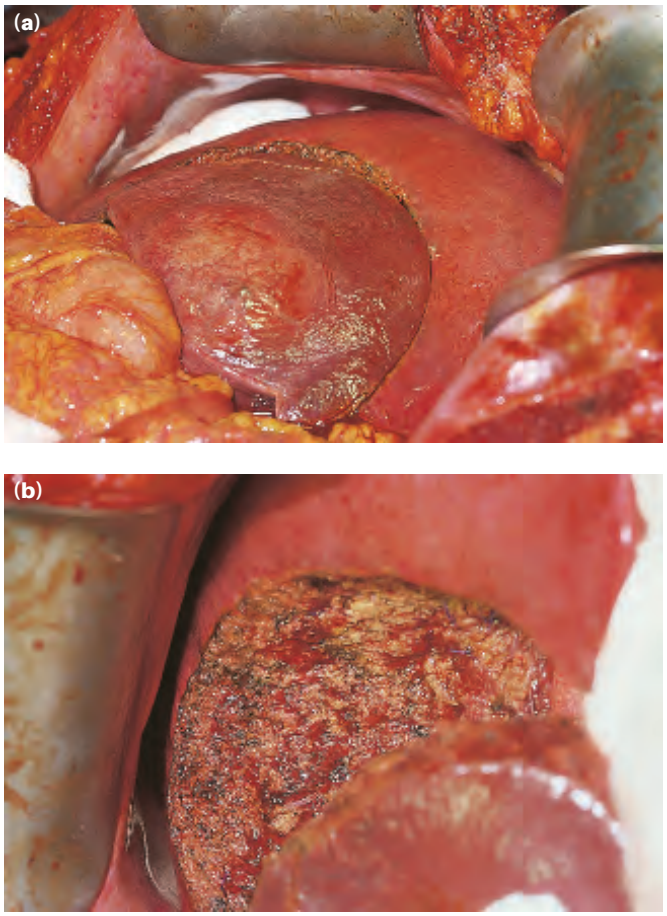

Figure 65.21 (a, b) Segmental resection. Removal of a primary liver tumour by resection of liver segment VI in a patient with well-compensated liver cirrhosis.

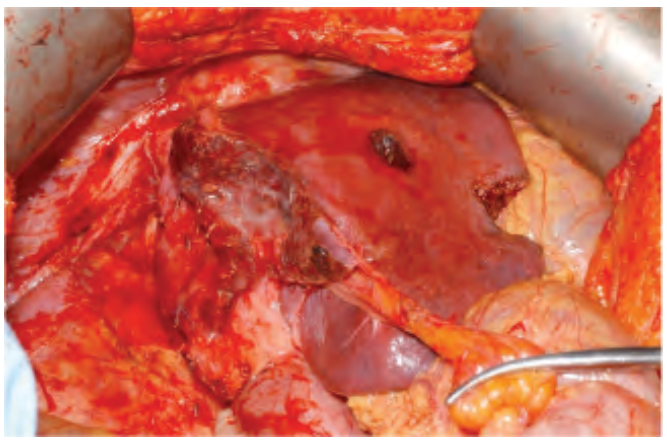

Figure 65.22 Combined anatomical and non-anatomical resection with formal right hemihepatectomy and multiple metastectomies. Sparing the maximal amount of parenchyma is critical for patients with colorectal liver metastases, as it maximises the chance of further resection in the event of disease recurrence.

no randomised controlled trials comparing laparoscopic and open surgery, and so the evidence is based on retrospective series. Meta-analysis suggests that blood loss and duration of hospital stay are significantly reduced after laparoscopic surgery, with no impact on oncological clearance. Prospective studies are underway to validate these findings.

Blood loss and transfusion

The reduction of blood loss during liver surgery has been one of the major achievements in the last 20 years, and resection is often possible without blood transfusion. Better understanding of the segmental anatomy of the liver, better patient selection for surgery and low central venous pressure anaesthesia (<10 mmHg) have all helped to reduce the need for blood transfusions. Better control of the coagulation cascade has been achieved using TEG, and the antifibrinolytic drug aprotinin has significantly reduced bleeding in patients with liver disease and an underlying coagulopathy. Oozing from the resected surface of the remnant liver can be reduced by the topical application of fibrin glue or fibrin-impregnated collagen fleece. The main alternative is use of an argon-beam coagulator. Intermittant temporary clamping of the portal vein and hepatic artery in the hepatoduodenal ligament (Pringle manoeuvre) can reduce blood loss during parenchymal transection. The optimal duration of the Pringle manoeuvre is unknown, but it can be applied intermittently, e.g. cycles of 15 minutes inflow occlusion followed by 5 minutes of reperfusion, until parenchymal transection is complete.

Ablation for liver tumours

Ablative therapies aim to destroy tumour by the direct application of energy to discrete lesions and can be perfomed percutaneously, laparoscopically or at open surgery. There is wide variation in overall survival and local recurrence rates after ablation, so surgery remains the gold standard treatment for resectable disease. Despite these concerns, ablation still has a role as an adjunct to resection. Patients with small volume resectable lesions who are not sufficiently fit to undergo liver resection should be considered for ablation, as should those with limited liver metastases who have insufficient liver volume to undergo resection. In addition, a combined resection/ablation approach has also been advocated.

Radiofrequency ablation (RFA) is the most widely used ablative technique and relies on direct current transmission through tissue to generate heat and ablation of the tumour. Increasing lesion size leads to exponential increases in resistance to current, limiting the size of the effective ablation zone and explaining the increased risk of local recurrence and diminished survival with lesions >3 cm. Microwave ablation has been designed to overcome some of the limitations of RFA and offers higher intratumoural temperatures, larger tumour ablation volumes and faster ablation times. Despite this, local recurrence after microwave ablation has been reported at between 5% and 13%.

Benign liver tumours

Haemangiomas

These are the most common liver lesions, and the reported incidence has increased with the widespread availability of

diagnostic ultrasound. They consist of an abnormal plexus of vessels, and their nature is usually apparent on ultrasound. If diagnostic uncertainty exists, CT scanning with delayed contrast enhancement shows the characteristic appearance of slow contrast enhancement due to small vessel uptake in the haemangioma. Often, haemangiomas are multiple. Lesions found incidentally require radiological confirmation of their nature and no further treatment. The management of 'giant' haemangiomas is more controversial. Occasional reports of rupture of haemangiomas have led some to consider resection for large lesions, especially if they appear to be symptomatic. Diagnosis is usually incidental, and surgical resection only recommended if patients are significantly symptomatic or significant diagnostic uncertainty remains after multimodal imaging.

Hepatic adenoma

Adenomas are benign liver tumours seen almost exclusively in women aged between 25 and 50 years. These well-defined and vascular lesions are classically associated with use of the oral contraceptive pill, and are generally solitary. The majority are found incidentally on imaging, although up to one-third may present with pain because of rupture or bleeding. Adenomas are recognised as having malignant potential, with up to 10% developing into hepatocellular carcinoma. The risk of rupture and malignancy means that surgical excision is generally recommended if >5 cm in size, although some lesions may regress after discontinuation of the oral contraceptive pill.

Focal nodular hyperplasia

Focal nodular hyperplasia (FNH) is an unusual but not uncommon benign condition of unknown aetiology, in which there is a focal overgrowth of functioning liver tissue supported by fibrous stroma. Patients are usually middle-aged females, and there is no association with underlying liver disease. Ultrasound shows a solid tumour mass. Contrast CT or MRI may show central scarring and a hypervascular lesion. FNH contains both hepatocytes and Kupffer cells. MRI using liver-specific contrast agents, such as gadoxetic acid, which is taken up by hepatocytes and excreted in bile, or superparamagnetic iron oxide, which is taken up by Kupffer cells, may be useful in determining the hepatocellular origin of FNH and allowing differentiation of FNH from metastatic cancer. FNH does not have any malignant potential and once the diagnosis is confirmed, does not require any treatment or follow-up.

Colorectal liver metastases

Twenty years ago, a diagnosis of stage IV (metastatic) colorectal cancer was associated with a survival of less than 3% at 5 years. A small minority of patients with liver-only metastatic disease were offered surgical resection and these patients had a 50% chance of being alive after 5 years. These excellent long-term outcomes highlighted the potential survival benefits of resection in appropriate cases, and lead to a revolution in the approach to metastatic colorectal disease. Instead of a terminal diagnosis, it was recognised that in certain situations resection could offer a cure.

Around 30% of patients with colorectal cancer will have metastatic disease at the time of presentation, and a further 20% will develop liver disease after the primary colorectal malignancy has been resected. In 2016, 20% of these patients will be candidates for upfront curative liver surgery and a further 20–30% of patients with initially unresectable liver disease may achieve a response to systemic therapy of sufficient magnitude to render the liver disease resectable (see below).

Defining resectability for colorectal liver metastases

Previously, patients with synchronous disease, rectal primary, multiple diffuse metastases, metastases larger than 5 cm, disease-free interval of less than 1 year from the diagnosis of primary disease or a high serum carcinoembryonic antigen (CEA) were considered irresectable and suitable only for palliative treatment. Modern surgical techniques and chemotherapeutic regimes mean none of these contraindications now hold true.

Resectability with curative intent is now loosely defined as the ability to successfully remove all residual disease from the liver with clear surgical margins, while leaving adequate disease-free viable liver tissue to sustain life. Technical contraindications to resection are related to the anatomical location of metastases, mainly due to close proximity to major vascular or biliary drainage structures. The boundaries of technical resectability have been extended by the development of techniques such as total vascular exclusion, which offer hope for certain patients with involvement of major vessels. Resection with a negative surgical margin of 1 cm (R0) has always been considered the gold standard, but in an era of effective modern chemotherapy, patients with R1 (microscopically negative) resection have similar survival to those with R0 resections. A future liver remnant (FLR) of 25% preoperative volume is considered sufficient to prevent postoperative hepatic failure, although patients with impaired hepatic function, including those with chemotherapy-induced liver damage, may require a larger FLR. The regenerative nature of liver parenchyma means that significant regrowth takes place after resection, and this unique feature means that two-stage procedures are feasible, with parenchymal regeneration between resections ensuring adequate FLR. This regenerative capacity can be further manipulated further using preoperative portal vein embolisation (PVE) to cause reactive hypertrophy in the proposed FLR.

The ALPPS procedure (associating liver partition and portal vein ligation for staged hepatectomy) combines both these procedures, maximising hypertrophy of the FLR, but is associated with significant operative mortality (10%) and morbidity (>50%). For some patients, a combination of resection and thermal ablation may also offer long-term benefits.

Oncological contraindications to hepatic resection include unresectable extrahepatic malignancy. Twenty years ago, any extrahepatic metastatic disease was considered a contraindication to liver resection. However, long-term survival is now possible in selected groups of patients with resected extrahepatic disease. Survival after lung resection for colorectal metastases is similar to that seen after liver resection, with

most series quoting a 5-year survival in the order of 40–50%, with low operative morbidity and mortality.

Staging and selection of patients for liver surgery

Patients with colorectal liver metastases must be fully staged prior to any treatment plan and this should be coordinated by a specialist multidisciplinary team. Routine staging commonly involves triple phase CT chest/abdomen/pelvis (**Figure 65.23**), contrast MRI scan of the liver and whole body PET-CT to identify metastatic disease.

Chemotherapy for colorectal liver metastases

The precise role of adjuvant and neoadjuvant chemotherapy in the management of resectable disease remains controversial. Current consensus is that the majority of patients with colorectal liver metastases should receive perioperative chemotherapy irrespective of their initial resectability, with the rationale that this will result in the destruction of occult disease, and allow a test of biology where progression despite chemotherapy signifies poorer prognosis, as well as reducing lesion size and so improving resectability.

A major development in the chemotherapeutic management of advanced disease over the last 20 years has been the recognition that there is a subgroup of patients who may not be resectable at presentation, but become resectable after systemic chemotherapy as lesions decrease in size and move away from critical vascular and biliary structures. Resectability rates after chemotherapy for initially irresectable disease vary widely from 6% to 60%. Attempting to convert irresectable disease into resectable is a worthwhile aim, with 5-year survival around 35–50% if liver resection becomes feasible, similar to those patients who are able undergo resection at the time of presentation. Chemotherapy with 5-fluorouracil (5FU) and folinic acid produces a response rate of approximately 30% but, when combined with oxaliplatin, the response rate increases to 50–60%, often with a dramatic size reduction of the lesions. The combination of chemotherapy with monoclonal antibodies (mAbs) that recognise vascular endothelial growth factor receptor (VEGFR) or the epidermal growth factor receptor (EGFR) may provide additional benefit.

Hepatocellular carcinoma

HCC comprises the overwhelming majority of primary liver cancers, with a steadily rising global burden. There is wide variation in the geographical incidence of HCC, with >80% of cases occurring in Asia and sub-Saharan Africa, with an incidence of 99 per 100 000. By contrast, the incidence in Europe is considerably lower (approximately 5 per 100 000). The wide variations in distribution reflect the varying incidence of aetiological factors known to be integral to the development of hepatocellular carcinogenesis (*Table 65.5*). Chronic hepatitis B virus (HBV) infection accounts for >50% of cases of HCC worldwide. HBV as a risk factor for HCC is supported by strong evidence that HBV vaccination programmes have led to falls in the incidence of HCC in high-risk areas such as Hong Kong. Hepatitis C virus (HCV) increases the risk of HCC by 17 times, primarily by promoting end-stage liver disease. There is clear evidence that lifetime alcohol exposure correlates with the incidence of HCC. Hepatic metabolism of alcohol is thought to lead to the production of free radicals, causing intracellular oxidative stress eventually leading to a chronic inflammatory state. Because of the critical role of the liver in glucose metabolism, it is not surprising that obesity and diabetes mellitus (both of which involve impaired glucose handling) are significant independent risk factors for the development of HCC, and the global rise in obesity and diabetes is likely to lead to a significant increase in HCC developing on a background of hepatic non-alcoholic fatty liver disease (NAFLD).

Figure 65.23 Colorectal liver metastases on a computed tomography scan.

TABLE 65.5 Liver infections and their treatment.

Condition	Causative agent	Treatment
Viral hepatitis	Hepatitis A, B, C	Supportive, antiviral agents (lamivudine, interferon, ribavirin)
		Liver transplant for cirrhosis
Ascending cholangitis	Enteric bacteria	Antibiotics (cephalosporin)
		Relieve obstruction
Pyogenic liver abscess	*Streptococcus milleri*	Antibiotics
	Escherichia coli	Aspiration
	Streptococcus faecalis	Drainage
Amoebic liver abscess	Entamoeba	Metronidazole
Hydatid liver disease	Echinococcus	Mebendazole, Resection/omentoplasty

Cohort studies have suggested that 60% of patients with HCC die of cancer-related causes, with the remaining 40% succumbing to underlying parenchymal liver disease. It is therefore critical that treatments for patients with HCC are considered in the context of both the cancer and the underlying parenchymal disease.

Staging of hepatocellular carcinoma

Clinical staging systems for HCC are often designed to guide choice of therapy, the most commonly used being the Barcelona Clinic Liver Group (BCLC) staging system, which was initially designed to define both prognosis and optimal treatment for patients with HCC (**Figure 65.24**). As patients with HCC usually have underlying liver disease as well as cancer (both of which have a marked impact on prognosis), the BCLC system was designed to reflect underlying liver function and patient performance status as well as characteristics of the tumour. Underlying liver function is assessed using the CTP system (see *Table 65.2*).

Surgical resection for HCC

Only 20–40% of patients with HCC are considered candidates for surgical resection. However, with the introduction of surveillance programmes for those patients identified to be at risk, improved imaging and better perioperative management, surgical resection is increasingly considered the mainstay of treatment for patients with preserved hepatic function.

Considerable controversy remains over which patients should be considered surgical candidates. Although tumour size, vascular invasion and multifocal disease are recognised as poor prognostic indicators, none is considered an absolute contraindication to surgical intervention. Multinodular lesions present a particular management challenge. These may represent multiple discrete lesions occurring independently against a background of procarcinogenic parenchymal damage, or may represent aggressive tumour biology with intrahepatic metastases.

In general, oncological contraindications to resection now include: (1) extrahepatic metastasis; (2) multiple and

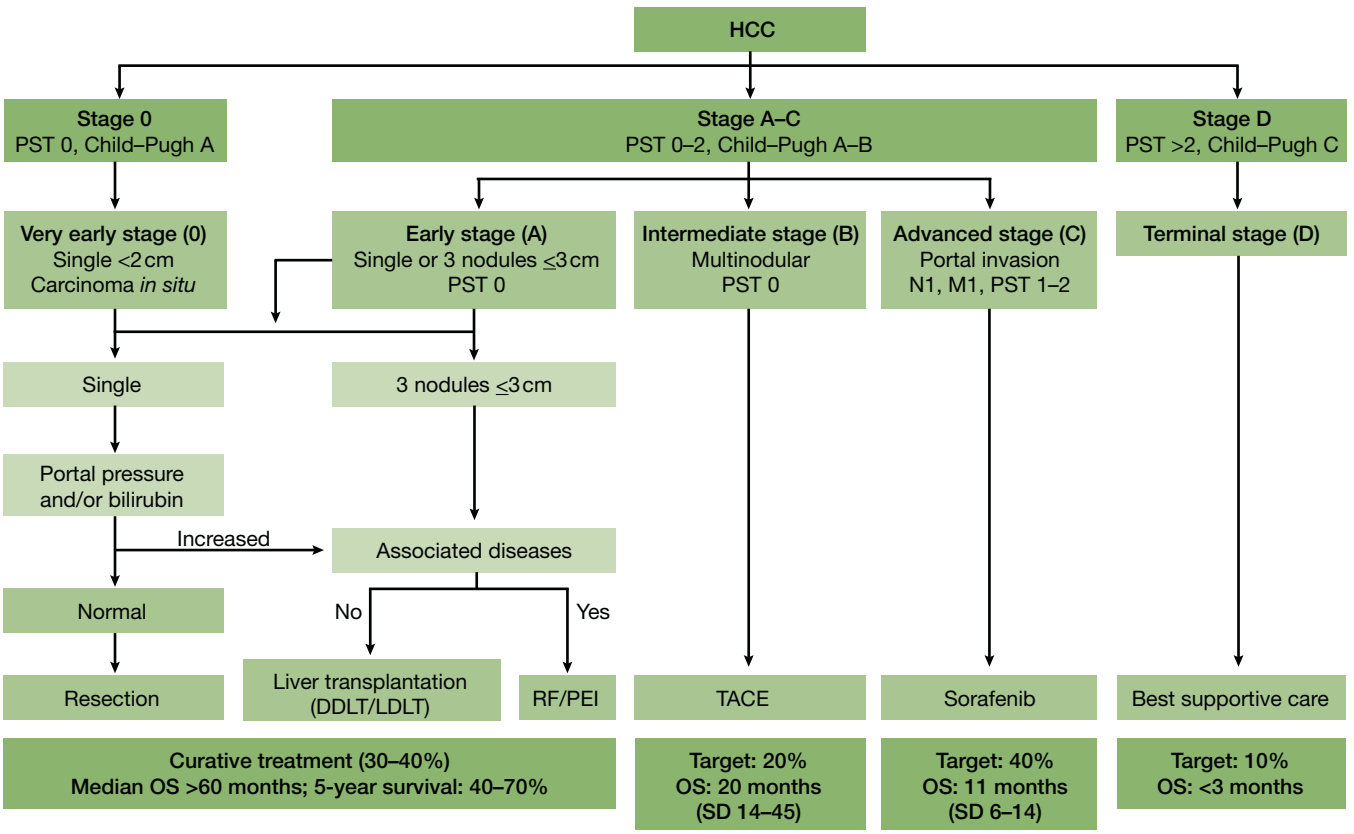

Figure 65.24 The Barcelona Clinic Liver Group staging system for the management of hepatocellular carcinoma (HCC). Patients with asymptomatic early tumours (stage 0–A) are candidates for curative therapies (resection, transplantation or local ablation). Asymptomatic patients with multinodular HCC (stage B) are suitable for chemoembolisation (TACE), whereas patients with advanced symptomatic tumours and/or an invasive tumoural pattern (stage C) are candidates for sorafenib. End-stage disease (stage D) includes patients with grim prognosis who should be treated by best supportive care. DDLT, deceased donor liver transplantation; LDLT, living donor liver transplantation; OS, overall survival; PEI, percutaneous ethanol injection; PST, ECOG performance status; RF, radiofrequency ablation; SD, standard deviation; TACE, transcatheter arterial chemoembolisation. (Reproduced with permission from Villanueva A. Medical therapies for hepatocellular carcinoma: a critical view of the evidence. *Nature Rev Gastroenterolol Hepatol* 2013; **10**: 34–42).

bilobar tumours; (3) involvement of the main bile duct; and (4) presence of tumour thrombus in the main portal vein/vena cava. However, reasonable long-term outcomes from highly selected patients outside these contraindications have also been reported.

Preoperative evaluation of patients with HCC

Ensuring good outcome for patients undergoing surgical resection for HCC relies on an accurate assessment of tumour stage, patient fitness and underlying liver function. This is particularly important when considering patients for larger resections, where the function of the FLR becomes critical. Postoperative morbidity and mortality are known to increase with a higher CTP score, and major liver resection is generally only considered feasible in patients with CTPA disease. Minor liver resection may be considered in CTP grade B, but remains a high-risk procedure. CTP grade C score patients are not candidates for liver resection. For some patients, inadequate FLR may the only contraindication to surgical resection. For this group, preoperative radiological portal vein embolisation can be performed to induce hypertrophy in the proposed remnant liver, increasing the FLR.

Preoperative imaging for HCC

Imaging is a critical part of the pretreatment assessment of HCC. Accurate tumour staging and anatomical assessment is essential, to determine both technical and oncological resectability, as well as to exclude distant metastatic spread. Triple phase CT chest/abdomen/pelvis and MRI of the liver is considered standard of care in most units. However, both MRI and CT have limited sensitivity and specificity for detection of lesions <1 cm, although this is improved with the use of liver-specific contrast agents. There is also growing interest in the assessment of background liver fibrosis and cirrhosis with functional imaging techniques that use hepatospecific contrast medium. The use of FDG-PET to exclude extrahepatic involvement has been investigated, but it remains unclear whether this offers any benefit over standard CT chest/abdomen/pelvis.

Surgical principles for HCC

The objectives of surgical resection for HCC can appear contradictory: (1) resection of all malignant and as much preneoplastic tissue as possible; and (2) preserving enough functional hepatic parenchyma to reduce the risk of postoperative liver failure. HCC spreads within the liver by direct invasion of both the portal and hepatic venous systems, and anatomical resection that includes removal of the entire venous drainage of a HCC is therefore considered the optimal approach to increase the removal of occult micrometastases. There is a clear long-term survival advantage to anatomical versus non-anatomical resection, and this approach is now considered standard of care where underlying liver function allows. Improvements in patient selection and surgical technique have led to a reduction in mortality, with 30-day postoperative death rates consistently quoted as <5%, including patients with underlying cirrhosis.

Disease recurrence after resection

Intrahepatic recurrence occurs in around 80% of cases within 5 years of resection. There are no effective neoadjuvant or adjuvant treatment options to reduce the risk of recurrence after resection. Intrahepatic recurrence after surgery is thought to consist of two discrete groups: patients who had missed micrometastases at initial staging, and those who developed lesions *de novo* in diseased background liver. The most effective approach to reducing intrahepatic recurrence of HCC is to remove both of these possibilities by performing liver transplantation.

Liver transplantation

Liver transplantation for HCC offers the advantage of not only definitively treating the tumour but also removing the diseased hepatic parenchyma, so reducing the potential for intrahepatic recurrence. The concept of organ transplantation for primary liver cancer was first described by Mazzaferro in 1996, who performed liver transplantation for patients with one hepatocellular carcinoma of ≤5 cm, or up to three nodules of ≤3 cm, and reported a 4-year overall survival of 75% and recurrence-free survival of 83%. Other groups have since replicated these results, and these inclusion criteria (Milan criteria) are now considered the benchmark indications for transplantation for HCC. Patients outside these criteria can also be successfully downstaged using locoregional therapies (such as ablation), and following a period of observation with adequate disease control may be considered suitable candidates for transplantation.

Chapter 66

The spleen

Learning objectives

To understand:

- The function of the spleen
- The common pathologies involving the spleen
- The principles and potential complications of splenectomy
- The potential advantages of laparoscopic splenectomy
- The benefits of splenic conservation
- The importance of prophylaxis against infection following splenectomy

EMBRYOLOGY, ANATOMY AND PHYSIOLOGY

Embryology

Fetal splenic tissue develops from condensations of mesoderm in the dorsal mesogastrium. This peritoneal fold attaches the dorsal body wall to the fusiform swelling in the foregut that develops into the stomach. This condensation divides the mesogastrium into two parts, one between the fetal splenic tissue and the stomach to form the gastrosplenic ligament and the other between it and the left kidney to form the lienorenal ligament.

Anatomy

The weight of the normal adult spleen is 75–250 g and it measures up to 10 × 7 × 3 cm. It lies in the left hypochondrium between the gastric fundus and the left hemidiaphragm, with its long axis lying along the 10th rib. The hilum sits in the angle between the stomach and the kidney and is in contact with the tail of the pancreas. The concave visceral surface lies in contact with these structures, and the lower pole extends no further than the mid-axillary line. There is a notch on the inferolateral border, and this may be palpated when the spleen is enlarged. The tortuous splenic artery arises from the coeliac axis, usually from a common stem with a hepatic artery, and runs along the upper border of the body and tail of the pancreas, to which it gives small branches. The short gastric and left gastroepiploic branches pass between the layers of the gastrosplenic ligament. The main splenic artery generally divides into superior and inferior branches, which, in turn, subdivide into several segmental branches (**Figure 66.1**).

The splenic vein is formed from several tributaries that drain the hilum. The vein runs behind the pancreas, receiving several small tributaries from the pancreas before joining the superior mesenteric vein at the neck of the pancreas to form the portal vein.

The splenic pulp is invested by an external serous and internal fibroelastic coat which is reflected inwards at the hilum onto the vessels to form vascular sheaths. The lymphatic drainage comprises efferent vessels in the white pulp that run with the arterioles and emerge from nodes at the hilum. These nodes and lymphatics drain via retropancreatic nodes to the coeliac nodes.

Sympathetic nerve fibres run from the coeliac plexus and innervate splenic arterial branches.

Physiology

The splenic parenchyma consists of white and red pulp that is surrounded by serosa and a collagenous capsule with smooth muscle fibres. These penetrate the parenchyma as trabeculae of dense connective tissue fibres rich in collagen and elastic tissue. These, with the reticular framework, support the cells of the spleen and surround the vessels in the splenic pulp. The white pulp comprises a central trabecular artery surrounded by nodules with germinal centres and periarterial lymphatic sheaths that provide a framework filled with lymphocytes and macrophages. Arteries from the central artery and the peripheral 'penicillar' arteries pass into the marginal zone that lies at the edge of the white pulp. Plasma-rich blood that has passed through the central lymphatic nodules is filtered as it passes through the sinuses within the marginal zone, and particles are phagocytosed.

Immunoglobulins produced in the lymphatic nodules enter the circulation through the sinuses in the marginal

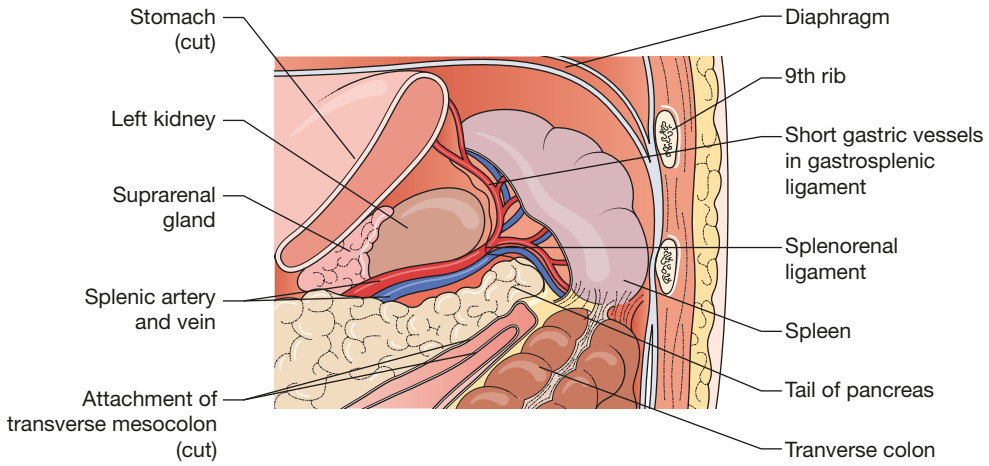

Figure 66.1 Anatomy of the spleen.

zone, beyond which lies the red pulp, which consists of cords and sinuses. Cell-concentrated blood passes in the trabecular artery through the centre of the white pulp to the red pulp cords. Red cells must elongate and become thinner to pass from the cords to the sinuses, a process that removes abnormally shaped cells from the circulation (**Figure 66.2**). As 90% of the blood passing through the spleen moves through an open circulation in which blood flows from arteries to cords, and thence sinuses, splenic pulp pressure reflects the pressure throughout the portal system. The remaining 10% of the blood flow through the spleen bypasses the cords and sinuses by direct arteriovenous communications. The overall flow rate of blood is about 300 mL/min.

FUNCTIONS OF THE SPLEEN

Although the spleen was previously thought to be dispensable, increasing knowledge of its function has led to a conservative approach in the management of conditions involving the spleen. It is now recognised that an incidental splenectomy during the course of another operative procedure increases the risk of complication and death. The surgeon should therefore normally endeavour to preserve the spleen to maintain the following functions:

- **Immune function**. The spleen contains 66.5% and 10–15% of the body's total T and B lymphocyte population, respectively. It processes foreign antigens and is the

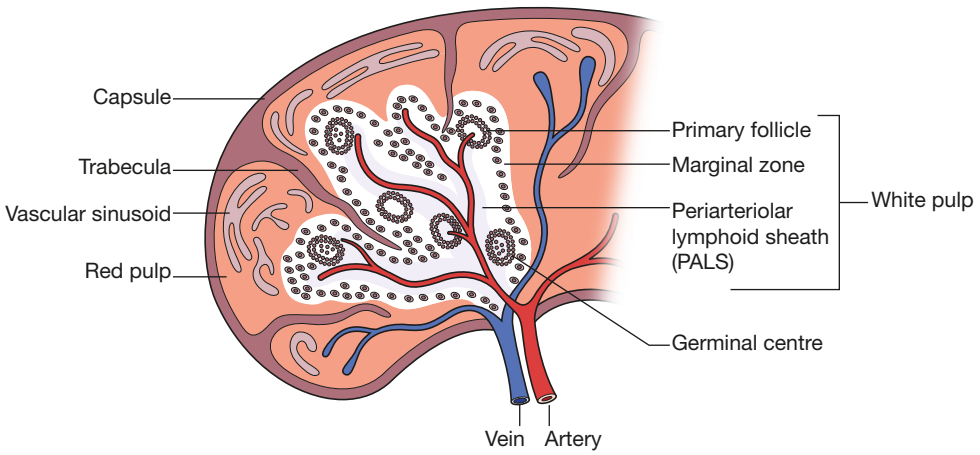

Figure 66.2 Functional anatomy of the spleen. Blood from a central trabecular artery passes through the white pulp into the surrounding red pulp and hence to the vascular cords and sinuses that drain into the trabecular vein.

major site of specific immunoglobulin M (IgM) production. The non-specific opsonins, properdin and tuftsin, are synthesised. These antibodies are of B- and T-cell origin and bind to the specific receptors on the surface of macrophages and leukocytes, stimulating their phagocytic, bactericidal and tumoricidal activity.

- **Filter function**. Macrophages in the reticulum capture cellular and non-cellular material from the blood and plasma. This will include the removal of effete platelets and red blood cells. This process takes place in the sinuses and the splenic cords by the action of the endothelial macrophages. Iron is removed from the degraded haemoglobin during red cell breakdown and is returned to plasma. Removed non-cellular material may include bacteria and, in particular, pneumococci.
- **Pitting**. Particulate inclusions from red cells are removed, and the repaired red cells are returned to the circulation. These include Howell–Jolly and Heinz bodies, which represent nuclear remnants and precipitated haemoglobin or globin subunits, respectively.
- **Reservoir function**. This function in humans is less marked than in other species, but the spleen does contain approximately 8% of the red cell mass. An enlarged spleen may contain a much larger proportion of the blood volume.
- **Cytopoiesis**. From the fourth month of intrauterine life, some degree of haemopoiesis occurs in the fetal spleen. Stimulation of the white pulp may occur following antigenic challenge, resulting in the proliferation of T and B cells and macrophages. This may also occur in myeloproliferative disorders, thalassaemias and chronic haemolytic anaemias.

Summary box 66.1

Functions of the spleen

- Immune
- Filter function
- Pitting
- Reservoir
- Cytopoiesis

INVESTIGATION OF THE SPLEEN

Conditions that result in splenomegaly can be diagnosed on the basis of the history and examination findings and from laboratory examination. In haemolytic anaemia, a full blood count, reticulocyte count and tests for haemolysis will determine the cause of the anaemia. Splenomegaly associated with portal hypertension caused by cirrhosis is diagnosed on the history, physical signs of liver dysfunction, abnormal tests of liver function, often anaemia, leukopenia and thrombocytopenia, as well as endoscopic evidence of oesophageal varices. Sinistral or segmental portal hypertension may result from isolated occlusion of the splenic vein by thrombosis, pancreatic inflammation or tumour infiltration. As many conditions that cause splenomegaly are associated with lymphadenopathy, investigation should be directed at those disease processes known to be associated with both physical signs. Lymph node biopsy may be required.

Radiological imaging

Plain radiology is rarely used in investigation, but the incidental finding of calcification of the splenic artery or spleen may raise the possible diagnosis of a splenic artery aneurysm, an old infarct, a benign cyst or hydatid disease. Multiple areas of calcification may suggest splenic tuberculosis. Ultrasonography can determine the size and consistency of the spleen, and whether a cyst is present. However, computed tomography (CT) with contrast enhancement is more commonly undertaken to better characterise the nature of the suspected splenic pathology and to exclude other intra-abdominal pathology. Magnetic resonance imaging (MRI) may be similarly useful. Radioisotope scanning is used occasionally to provide information about the spleen. The use of technetium-99m (^{99m}Tc)-labelled colloid is normally restricted to determining whether the spleen is a significant site of destruction of red blood cells.

CONGENITAL ABNORMALITIES OF THE SPLEEN

Splenic agenesis is rare but is present in 5% of children with congenital heart disease. Polysplenia is a rare condition resulting from failure of splenic fusion.

Splenunculi are single or multiple accessory spleens that are found in approximately 10–30% of the population. They are located near the hilum of the spleen in 50% of cases and are related to the splenic vessels, or behind the tail of the pancreas in 30%. The remainder are located in the mesocolon, greater omentum or the splenic ligaments. Their significance lies in the fact that failure to identify and remove these at the time of splenectomy may give rise to persistent disease.

Hamartomas are rarely found in life and vary in size from 1 cm in diameter to masses large enough to produce an abdominal swelling. One form is mainly lymphoid and resembles the white pulp, whereas the other resembles the red pulp.

Non-parasitic **splenic cysts** are rare. Splenic cysts are classified as primary cysts (true) or pseudocysts (secondary) on the basis of the presence or absence of lining epithelium. True cysts form from embryonal rests and include dermoid

William Henry Howell, 1860–1945, Professor of Physiology, Johns Hopkins University, Baltimore, MD, USA.

Robert Heinz, 1865–1962, Professor of Pharmacology and Toxicology, Erlangen, Germany.

and mesenchymal inclusion cysts (Figure 66.3). True cysts of the spleen are very rare, and are frequently classified as cystic haemangiomas, cystic lymphangiomas, and epidermoid and dermoid cysts. Epidermoid cysts are thought to be of congenital origin and represent 10% of splenic cysts. They are lined by flattened squamous epithelium and more frequent in children and young patients. Splenectomy or partial splenectomy is usually considered for cysts larger than 5 cm in diameter. These should be differentiated from false or secondary cysts that may result from trauma and contain serous or haemorrhagic fluid. The walls of such degenerative cysts may be calcified and therefore resemble the radiological appearances of a hydatid cyst. The spleen is also a common site for pseudocyst development following a severe attack of pancreatitis (Figure 66.4). Pseudocysts can easily be diagnosed on scanning, and intervention is normally required for symptomatic lesions that persist following a period of observation.

SPLENIC ARTERY ANEURYSM, INFARCT AND RUPTURE

Splenic artery aneurysm

Aneurysms involving the splenic artery are estimated to be identified at 0.04–1% of postmortem examinations. They are twice as common in women and are usually situated in the main arterial trunk. Although these are generally single, more than one aneurysm is found in one-quarter of cases. These may be a consequence of intra-abdominal sepsis and pancreatic necrosis, in particular. They are more likely to be associated with arteriosclerosis in elderly patients.

The aneurysm is symptomless unless it ruptures and is more likely to be detected on a plain abdominal radiograph or scan. It is unlikely to be palpable, although a bruit may be present. Rupture is unsuspected in the majority of cases and, as it will generally rupture into the peritoneal cavity, the symptoms mimic those of splenic rupture. Almost half the cases of rupture occur in patients younger than 45 years of age, and one-quarter are in pregnant women, usually in the third trimester of pregnancy or at labour. Aneurysmal rupture carries a high mortality rate and this increases disproportionately in pregnant women, with almost inevitable fetal death.

The treatment of choice previously consisted of splenectomy and removal of the diseased artery. Some surgeons advocate ligation of the proximal and distal ends of the sac to allow thrombosis of the aneurysm and partial or complete splenectomy, if necessary. The procedure has been performed laparoscopically with success. Embolisation or endovascular stenting following selective splenic artery angiography can be considered, and is now more commonly undertaken. In the younger patient with an asymptomatic splenic artery aneurysm, surgery or interventional radiology is indicated depending on local expertise after CT scan, MRI or selective coeliac angiography has confirmed the diagnosis (Figure 66.5). In the elderly patient with a calcified aneurysm, there is less risk of rupture, and observation may be preferred. In patients with pancreatic necrosis, the treatment will include drainage of the septic focus.

Splenic infarction

This condition commonly occurs in patients with a massively enlarged spleen from myeloproliferative syndrome, portal hypertension or vascular occlusion produced by previous surgical intervention (such as spleen-preserving distal pancreatectomy), pancreatic disease, splenic vein thrombosis or sickle cell disease. The infarct may be asymptomatic or give rise to left upper quadrant and left shoulder tip pain. Contrast-enhanced CT will show the characteristic perfusion defect in the enlarged spleen (Figure 66.6). Treatment is conservative, and splenectomy should be considered only when a septic infarct causes an abscess.

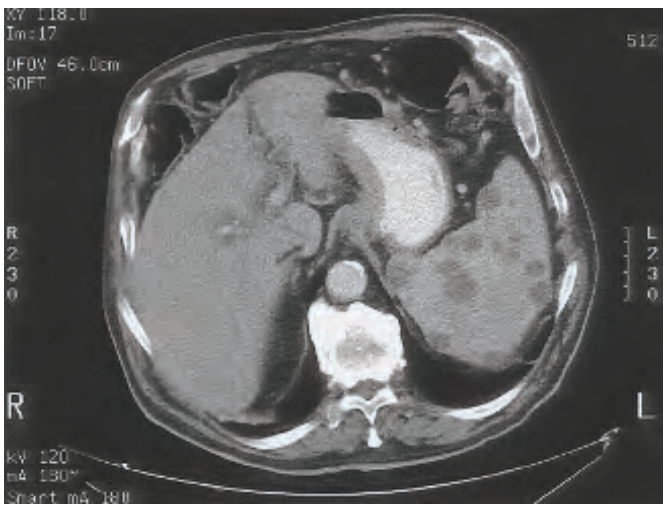

Figure 66.3 Computed tomography scan showing multiple low-density areas in the spleen consistent with multiple benign splenic cysts.

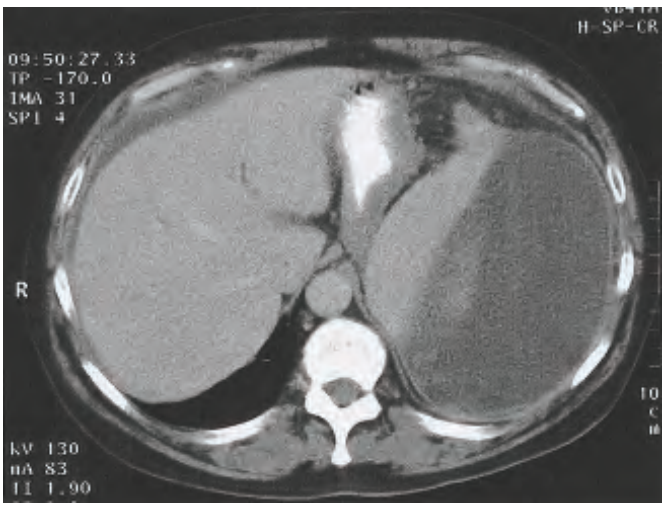

Figure 66.4 Computed tomography scan showing a large pseudocyst involving the spleen. There is displacement of the stomach medially, and a trace of ascitic fluid is present above the liver.

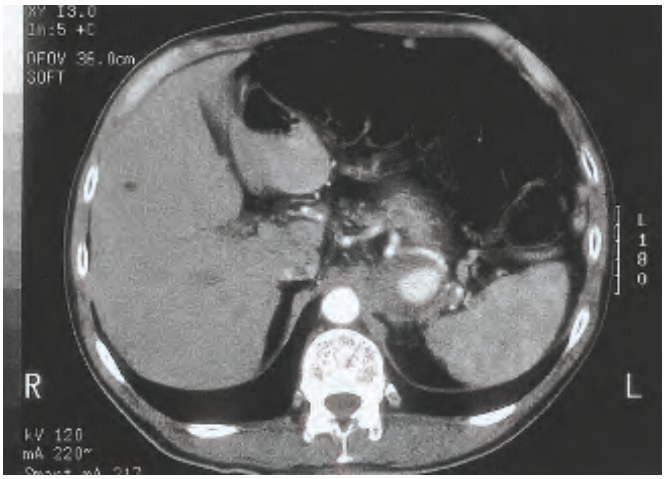

Figure 66.5 Computed tomography scan showing a pool of contrast in a pseudoaneurysm situated in the tail of the pancreas adjacent to the spleen.

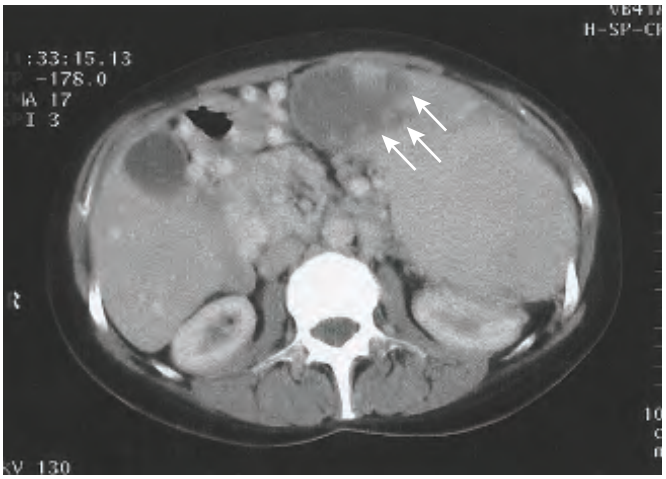

Figure 66.6 Computed tomography scan showing a splenic infarct (arrows) in a patient with splenomegaly and hypersplenism secondary to portal hypertension and portal vein thrombosis. The varices are evident at the hilus and at the greater curvature of the stomach.

Splenic rupture

Splenic rupture should be considered in any case of blunt abdominal trauma, particularly when the injury occurs to the left upper quadrant of the abdomen. Iatrogenic injury to the spleen remains a frequent complication of any surgical procedure, particularly those in the left upper quadrant when adhesions are present.

Rupture of a malarial spleen

In tropical countries, rupture of a spleen enlarged due to malaria is not uncommon (see Tropical spleen, below). Delayed presentation following a 'trivial' injury is not infrequent. In such patients, radiological embolisation may be performed if available, and splenectomy should be considered before a perisplenic haematoma ruptures, a complication that is associated with a worse prognosis.

Surgery in such patients is challenging, and early ligation of the splenic vessels along the superior border of the pancreatic body should be considered before disturbing the haematoma.

SPLENOMEGALY AND HYPERSPLENISM

Splenomegaly is a common feature of many disease processes, although the spleen has to enlarge three times before it is palpable (*Table 66.1*). It should be borne in mind that many conditions affecting the spleen, such as idiopathic thrombocytopenic purpura, may be associated with enlargement, but the gland is seldom palpable. Few conditions that cause splenomegaly will require splenectomy as part of treatment. **Hypersplenism** is an indefinite clinical syndrome that is characterised by splenic enlargement, any combination of anaemia, leucopenia or thrombocytopenia, compensatory bone marrow hyperplasia and improvement after splenectomy. Careful clinical judgement is required to balance the long- and short-term risks of splenectomy against continued conservative management.

Splenic abscess

Splenic abscess may arise from an infected splenic embolus or in association with typhoid and paratyphoid fever, osteomyelitis, otitis media and puerperal sepsis. In general surgical practice, it may be associated with pancreatic necrosis or other intra-abdominal infection (**Figure 66.7**). An abscess may rupture and form a left subphrenic abscess, or result in diffuse peritonitis. Treatment involves that of the underlying cause; percutaneous drainage of the splenic abscess under radiological guidance is normally required, with splenectomy being reserved when interventional radiology is not available.

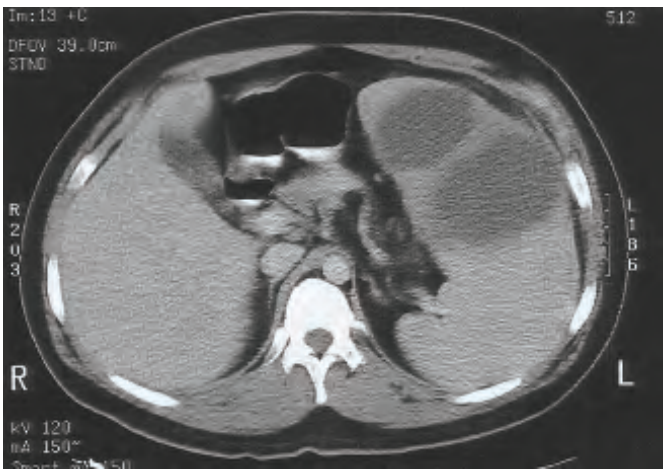

Figure 66.7 Computed tomography scan showing a multiloculated abscess in the enlarged spleen. This was managed successfully by percutaneous drainage under ultrasound guidance.

Sir George Frederic Still, 1868–1941, Professor of Diseases of Children, King's College Hospital, London, UK, described chronic articular rheumatism in children in 1896.
Augustus Roy Felty, 1895–1964, physician Hartford CT, USA, described the combination of arthritis, splenomegally and leukopenia in 1924, while still a medical student at Johns Hopkins School of Medicine, Baltimore, ML, USA.

Tuberculosis

The diagnosis of tuberculosis should be considered in young adults with splenomegaly presenting with asthenia, loss of weight and fever. Tuberculosis of the spleen may produce portal hypertension or, rarely, cold abscess. Treatment with antituberculous drugs will normally produce improvement. Splenectomy is not normally required and is made difficult by the inflammatory adhesions.

Tropical splenomegaly

Massive splenic enlargement frequently occurs in the tropics from malaria, kala-azar and schistosomiasis. Occasionally, splenomegaly cannot be fully attributed to these diseases. It may result from occult infection or be related to malnutrition. The massive splenomegaly observed in this condition may require removal in those patients disabled by anaemia or local symptoms. Lifelong antimalarial therapy is indicated in malaria endemic areas.

Schistosomiasis

This condition is prevalent in Africa, Asia and South America. It is caused by infection with *Schistosoma mansoni* in 75% of cases and by *S. haematobium* in the remainder. The splenic enlargement may result from portal hypertension associated with hepatic fibrosis, but can also result from hyperplasia induced by the phagocytosis of disintegrated worms, ova and toxin. Splenomegaly can occur at any age. The diagnosis is based on examination of the urine and faeces for ova, abnormal liver function tests and the presence of hypochromic anaemia.

Successful medical treatment of established cases does not result in regression of splenomegaly, and removal of the painful and bulky spleen is indicated where there is no evidence of hepatic or renal insufficiency. Splenectomy may be required as part of a devascularisation procedure in patients with portal hypertension associated with schistosomiasis.

Leukaemia

Leukaemia should be considered in the differential diagnosis of splenomegaly and the diagnosis is made by examining blood or marrow film. Splenectomy is reserved for hypersplenism that occurs during the chronic phase of chronic granulocytic leukaemia.

Idiopathic thrombocytopenic purpura

In most cases of idiopathic thrombocytopenic purpura (ITP), the low platelet count results from the development of antibodies to specific platelet membrane glycoproteins (antiplatelet IgG autoantibodies) that damage the patient's own platelets. It is also known as immune and autoimmune thrombocytopenic purpura. It is defined as isolated thrombocytopenia with normal bone marrow and the absence of other causes of thrombocytopenia. Two distinct clinical types are evident: the acute condition in children and a chronic condition in adults. Acute ITP often follows an acute infection and has a spontaneous resolution within 2 months. Chronic ITP persists longer than 6 months without a specific cause being identified. Approximately 50–75 cases per million arise each year in adults compared with 50 cases per million each year in children.

Clinical features

The adult form normally affects females between the ages of 15 and 50 years, although it can be associated with other conditions, including systemic lupus erythematosus, chronic lymphatic leukaemia and Hodgkin's disease. The childhood form is distributed equally between males and females and commonly presents before the age of 5 years. Purpuric patches (ecchymoses) occur on the skin and mucous membranes. Following trauma or pressure, examination often reveals numbers of petechial haemorrhages in the skin. There is a tendency to spontaneous bleeding from mucous membranes (e.g. epistaxis); in women, menorrhagia and the prolonged bleeding of minor wounds are common. Haemorrhage from the urinary and gastrointestinal tracts and haemarthrosis are rare. Although intracranial haemorrhage is also uncommon, it is the most frequent cause of death. The diagnosis is made based upon the presence of cutaneous ecchymoses and a positive tourniquet test. The spleen is palpable in fewer than 10% of patients, and the presence of gross splenic enlargement should raise the suspicion of an alternative diagnosis.

Investigations

Coagulation studies are normal, and a bleeding time is not helpful in diagnosis. Platelet count in the peripheral blood film is reduced (usually $<60 \times 10^9$/L). Bone marrow aspiration reveals a plentiful supply of platelet-producing megakaryocytes.

Treatment

The course of the disease differs in children and adults. The disease regresses spontaneously in 75% of paediatric cases following the initial attack. Short courses of corticosteroids in both adult and child are usually followed by recovery. Prolonged steroid therapy should not be continued if this does not produce remission. Splenectomy is usually recommended if a patient has two relapses on steroid therapy, or if the platelet count remains low. Generally, this is indicated where the ITP has persisted for more than 6–9 months.

Up to two-thirds of patients will be cured by surgical intervention, and 15% will be improved, but no benefit will be

Sir Patrick Manson, 1844–1922, practised in Formosa (now Taiwan) and Hong Kong before becoming physician to the Dreadnought Hospital, Greenwich, London, UK. He is regarded as 'the father of tropical medicine'.
Thomas Hodgkin, 1798–1866, lecturer in morbid anatomy and curator of the Museum, Guy's Hospital, London, UK, described lymphadenoma in 1836.

derived in the remainder. The response to steroids predicts a good response to splenectomy. In the acute setting, if severe bleeding has not been controlled by steroid therapy, fresh blood transfusion or transfusion with platelet concentrates before operation is necessary, although these are generally withheld until the splenic vessels have been controlled at operation.

Haemolytic anaemias

There are four causes of haemolytic anaemia that are generally amenable to splenectomy.

Hereditary spherocytosis

Hereditary spherocytosis is an autosomal dominant hereditary disorder characterised by the presence of spherocytic red cells, caused by various molecular defects in the genes that code for alpha- and beta-spectrin, ankyrin, band 3 protein, protein 4.2 and other erythrocyte membrane proteins. These proteins are necessary to maintain the normal biconcave shape of the erythrocyte. Spherocytosis arises essentially from an increase in permeability of the red cell membranes to sodium. As this ion leaks into the cell, the osmotic pressure rises, resulting in swelling and increased fragility of the spherocyte. As the sodium pump has to work harder to rid the cells of sodium, there is greater loss of membrane phospholipid, resulting in an increased fragility of the membrane, and the energy and oxygen requirements increase. A large number of red cells are destroyed in the spleen, where there is a relative deficiency of both glucose and oxygen.

The clinical presentation is generally in childhood, but may be delayed until later life. Mild intermittent jaundice is associated with mild anaemia, splenomegaly and gallstones. Circulating bilirubin is not conjugated with glucuronic acid, and is not therefore excreted in the urine as it is bound to albumin. Excretion of the resulting bilirubin complex by the liver favours the formation of pigment gallstones. Once the disease manifests itself, spontaneous remissions are uncommon; the patient is often pale and jaundiced at presentation and, in established cases, lassitude and undue fatigue are present.

In some families, the disease is characterised by a severe crisis of red blood cell destruction, during which the erythrocyte count may fall from 4.5×10^6/mL to 1.5×10^6/mL within 1 week. Such crises are characterised by the onset of pyrexia, abdominal pain, nausea, vomiting and extreme pallor, followed by increased jaundice. These episodes may be precipitated by acute infection. Any child with gallstone disease should be investigated for hereditary spherocytosis and a family history sought.

Examination reveals splenomegaly, and the liver may also be palpable. Chronic leg ulcers may arise in adults with the disease.

Haematological investigations include the fragility test. Erythrocytes begin to haemolyse in 0.47% saline solution but, in this condition, haemolysis may occur in 0.6% or even stronger solutions. Immature red blood cells (reticulocytes), which differ from adult cells by possessing a reticulum, are discharged into the circulation by the bone marrow to compensate for the loss of erythrocytes by haemolysis.

Faecal urobilinogen is increased as this route excretes most of the urinobilinogen.

Radioactive chromium (^{51}Cr) labelling of the patient's own red cells will demonstrate the severity of red cell destruction. Daily scanning over the spleen will show the degree of red cell sequestration by the spleen. The presence of high levels of splenic radioactivity generally predicts a good response to splenectomy, but this test is used less commonly.

All patients with hereditary spherocytosis should be treated by splenectomy but, in juvenile cases, this is generally delayed until 6 years of age to minimise the risk of postsplenectomy infection, but before gallstones have had time to form. Ultrasonography should be performed preoperatively to determine the presence or absence of gallstones.

Acquired autoimmune haemolytic anaemia

This condition is divided into immune- and non-immune-mediated forms. It may arise following exposure to agents such as chemicals, infection or drugs, e.g. alpha-methyldopa, or be associated with another disease (e.g. systemic lupus erythematosus). In most instances, the cause is unknown, and red cell survival is reduced because of an immune reaction triggered by immunoglobulin or complement on the red cell surface. This condition is more common in women after the age of 50 years. In half the patients, the spleen is enlarged and, in 20% of cases, pigment gallstones are present.

Anaemia is invariably present and may be associated with spherocytosis because of red cell membrane damage. In the immune type, antibody, which coats the red cells, can be detected by agglutination when antihuman globulin is added to a suspension of the patient's erythrocytes (Coombs' test positive). The disease runs an acute self-limiting course, and no treatment is necessary. Splenectomy should, however, be considered if corticosteroids are ineffective, when the patient is developing complications from long-term steroid treatment or if corticosteroids are contraindicated; 80% of patients respond to splenectomy.

Thalassaemia (synonyms: Cooley's anaemia, Mediterranean anaemia)

This condition results from a defect in haemoglobin peptide chain synthesis and is transmitted most commonly as a recessive trait. The disease is really a group of related diseases, alpha, beta and gamma, depending upon which haemoglobin peptide chain's rate of synthesis is reduced. Most patients suffer from beta-thalassaemia, in which a reduction in the rate of beta-chain synthesis results in a decrease in haemoglobin A. Intracellular precipitates (Heinz bodies) contribute to premature red cell destruction.

Robin Royston Amos Coombs, 1921–2006, Quick Professor of Biology, University of Cambridge, Cambridge, UK, described this test in 1945.
Thomas Benton Cooley, 1871–1945, Professor of Pediatrics, Wayne University, Detroit, MI, USA, described this type of anaemia in 1927.

Graduations of the disease range from heterozygous thalassaemia minor to homozygous thalassaemia major, which is associated with chronic anaemia, jaundice and splenomegaly. Patients with homozygous thalassaemia major frequently develop clinical signs in the first year of life, and these include retarded growth, enlarged head with slanting eyes and depressed nose, leg ulcers, jaundice and abdominal distension secondary to splenomegaly.

Red cells are small, thin and misshapen and have a characteristic resistance to osmotic lysis. In the more severe forms, nucleated red cells and other immature blood cells are seen. The final diagnosis is by haemoglobin electrophoresis.

Blood transfusion may be required to correct profound anaemia, but the patient may become transfusion dependent because of the development of hypersplenism. Splenectomy is therefore of benefit in patients who require frequent blood transfusion, and if haemolytic antibodies have developed as a result.

Sickle cell disease

Sickle cell disease is a hereditary, autosomal recessive haemolytic anaemia occurring mainly among those of African origin, in whom the normal haemoglobin A is replaced by haemoglobin S (HbS). The HbS molecule crystallises when the blood oxygen tension is reduced, thus distorting and elongating the red cell. The resulting increased blood viscosity may obstruct the flow of blood in the spleen. Splenic microinfarcts are therefore common.

The sickle cell trait can be detected in 9% of those of African origin, but most are asymptomatic; sickle cell disease occurs in about 1% of Africans. Depending upon the vessels affected by vascular occlusion, patients may complain of bone or joint pain, priapism, neurological abnormalities, skin ulcers or abdominal pain due to visceral blood stasis. The diagnosis is made by the finding of characteristic sickle-shaped cells on blood film, although this investigation has largely been replaced by haemoglobin electrophoresis.

Hypoxia that provokes a sickling crisis should be avoided and is particularly relevant in patients undergoing general anaesthesia. Adequate hydration and partial exchange transfusion may help in a crisis. Splenectomy is of benefit in a few patients in whom excessive splenic sequestration of red cells aggravates the anaemia. Chronic hypersplenism usually occurs in late childhood or adolescence, although *Streptococcus pneumoniae* infection may precipitate an acute form in the first 5 years of life.

Porphyria

Porphyria is a hereditary error of haemoglobin catabolism in which porphyrinuria occurs. Abdominal crises, characterised by severe intestinal colic and constipation, can be precipitated by the administration of barbiturates. The patient is anaemic and may suffer from photosensitivity; in advanced forms of the disease, neurological and mental symptoms are present. The splenomegaly associated with this condition may be overlooked. The urine may be orange and develops a port-wine colour after a few hours of exposure to the air. Splenectomy has little role to play in the management of this condition.

Gaucher's disease

This lipid storage disease is characterised by storage of glucocerebroside in the reticuloendothelial system and in the spleen. Enormous splenic enlargement may be associated with yellowish brown discolouration of the skin on the hands and face, anaemia and conjunctival thickening (pinguecula). Slavonic and Jewish races are more prone to the disease, and the detection of Gaucher cells in the bone marrow confirms the diagnosis. Splenectomy is indicated only for severe symptoms related to the splenomegaly.

Hypersplenism due to portal hypertension

Splenomegaly is an invariable feature of portal hypertension (**Figure 66.8**) and results in the thrombocytopenia and granulocytopenia observed in these patients. These may be improved if the portal hypertension is relieved by shunt surgery or liver transplantation. Splenectomy would normally be required only in those patients whose segmental portal hypertension has resulted in symptomatic oesophagogastric varices.

Felty's syndrome

Patients with rheumatoid arthritis may develop leukopenia. This is referred to as Felty's syndrome if it is extreme and associated with splenomegaly. There is no definite relationship between the severity of the arthritic changes and the leukopenia and splenomegaly. Splenectomy produces only a transient

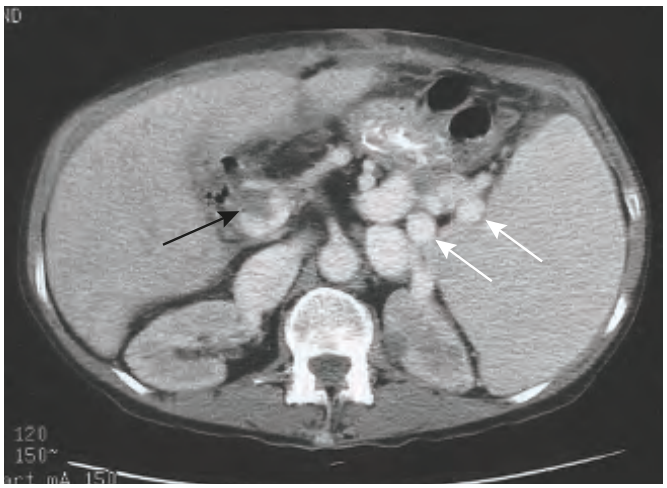

Figure 66.8 Computed tomography scan showing an enlarged spleen in a patient with portal hypertension secondary to portal vein thrombosis. Clot is evident within the lumen of the portal vein (black arrow), and large varices (white arrows) are present at the splenic hilus.

Philippe Charles Ernest Gaucher, 1854–1918, physician, Hôpital St Louis, Paris, France, described familial splenic anaemia in 1882.

improvement in the blood picture, but rheumatoid arthritis may respond to steroid therapy to which it had previously become resistant.

NEOPLASMS

Haemangioma is the most common benign tumour of the spleen and may rarely develop into a haemangiosarcoma that is managed by splenectomy. The spleen is rarely the site of metastatic disease. Lymphoma is the most common cause of neoplastic enlargement, and splenectomy may play a part in its management. Splenectomy may be required to achieve a diagnosis in the absence of palpable lymph nodes or to relieve the symptoms of gross splenomegaly. However, the need for staging laparoscopy has largely receded with the advent of CT. Its use has been restricted to those patients in whom a definite histological diagnosis of intra-abdominal disease will affect management. Thus, selected patients with stage IA or IIA Hodgkin's disease may be candidates for staging laparotomy or laparoscopy, although percutaneous biopsy under ultrasound or CT guidance is more commonly performed. In the absence of obvious liver or intra-abdominal nodal disease, splenectomy is an integral part of the staging procedure to exclude splenic involvement, which would alter the method of treatment.

Myelofibrosis results from an abnormal proliferation of mesenchymal elements in the bone marrow, spleen, liver and lymph nodes. Most patients present over the age of 50 years, and the spleen may produce pain, owing to its gross enlargement (**Figure 66.9**) or from splenic infarcts. Splenectomy reduces the need for transfusion and may relieve the discomfort resulting from the splenomegaly.

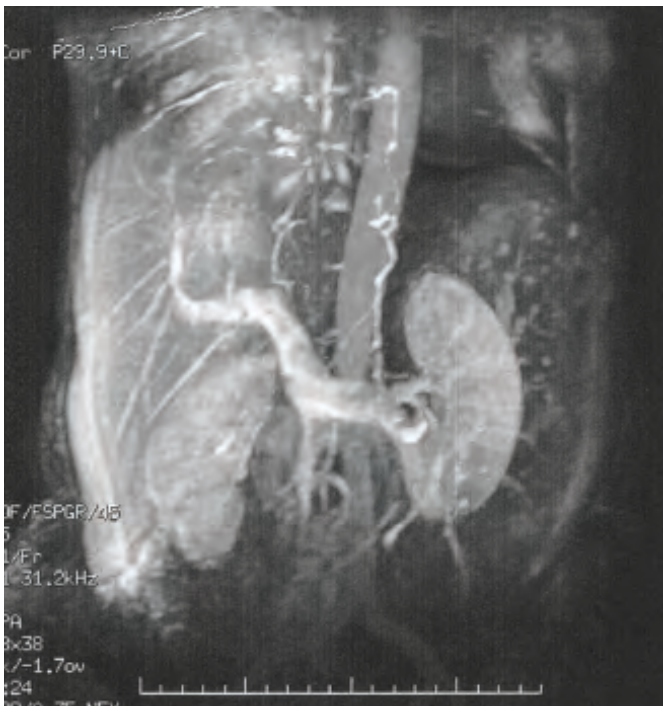

Figure 66.9 Magnetic resonance imaging scan showing massive hepatosplenomegaly secondary to myelofibrosis. Note the prominent portal system and the left kidney, which is superimposed over the grossly enlarged spleen.

SPLENECTOMY

The common indications for splenectomy are:

- trauma resulting from an accident or during a surgical procedure, as for example during mobilisation of the oesophagus, stomach, distal pancreas or splenic flexure of the colon;
- removal *en bloc* with the stomach as part of a radical gastrectomy, or with the pancreas as part of a distal or total pancreatectomy;
- to reduce anaemia or thrombocytopenia in spherocytosis, idiopathic thrombocytopenic purpura or hypersplenism;
- in association with shunt or variceal surgery for portal hypertension.

Summary box 66.2

Indications for splenectomy

Trauma
- Accidental
- Operative

Oncological
- Part of *en bloc* resection
- Diagnostic
- Therapeutic

Haematological
- Spherocytosis
- Purpura (ITP)
- Hypersplenism

Portal hypertension
- Variceal surgery

Preoperative preparation

In the presence of a bleeding tendency, transfusion of blood, fresh-frozen plasma, cryoprecipitate or platelets may be required. Coagulation profiles should be as near normal as possible at operation, and platelets should be available for patients with thrombocytopenia at operation and in the early postoperative period.

Antibiotic prophylaxis appropriate to the operative procedure should be given, and consideration should be given to the risk of postsplenectomy sepsis (see below).

Technique of open splenectomy

Most surgeons use a midline or transverse left subcostal incision for open splenectomy with the patient in the supine position. Rarely, a thoracoabdominal incision may be necessary for a massive spleen that is adherent to the diaphragm. Passage of a nasogastric tube following induction of the anaesthetic enables the stomach to be emptied.

In elective splenectomy, the gastrosplenic ligament is opened up, and the short gastric vessels are divided. The splenic vessels at the superior border of the pancreas are

suture-ligated. The posterior surface of the spleen is exposed, the posterior leaf of the lienorenal ligament divided with long curved scissors, and the spleen rotated medially along with the tail and body of the pancreas (**Figure 66.10**). The pancreas is separated from the hilar vessels, which are normally doubly ligated separately and divided. Accessory splenic tissue in the splenic hilum or omentum should be excluded by a careful search at operation. There is no need to drain the wound if haemostasis is adequate.

The segmental vasculature of the spleen does make it possible to undertake limited resection of the parenchyma. Haemostasis can be achieved by ligation of, or application of metal clips to, intrasplenic vessels, and by careful application of topical haemostatic agents such as fibrin pad (EVAREST®). Conservative splenic surgery is therefore possible in some cases of splenic trauma and other pathology such as splenic cysts.

Technique of laparoscopic splenectomy

The patient is placed on the right side with the space between the left ilium and costal margin exposed. Placement of access ports is often determined by the size of the patient and the spleen. Insufflation of the abdomen can be performed once access is obtained through an incision 1 cm from the costal margin at the left mid-clavicular line. A further trocar is inserted close to the costal margin below the xiphoid. A 12-mm trocar is inserted at a similar distance from the costal margin at the posterior axillary line. The splenocolic ligament is divided to give access to the lower splenic pole. The spleen is separated from the kidney and diaphragm before the gap between the splenic hilum and the tail of the pancreas is enlarged. The spleen is elevated to expose the splenic hilum, which is secured and divided with an endoscopic vascular stapler (**Figure 66.11**). Two or three applications of the instrument may be required to secure the hilum and the short gastric vessels. Any remaining attachments to the diaphragm are divided before a self-retaining opening bag is introduced through the incision of the open laparoscopy, after removal of the 12-mm port. The spleen is placed in the bag, the mouth of which is pulled out of the abdominal opening before the spleen is crushed and retrieved with an instrument. The operation may be undertaken as a hand-assisted procedure, particularly when the spleen is grossly enlarged.

Postoperative complications

Immediate complications specific to splenectomy include haemorrhage resulting from a slipped ligature. Haematemesis from gastric mucosal damage and gastric dilatation is uncommon. Left basal atelectasis is common, and a pleural effusion may be present. Adjacent structures at risk during the procedure include the stomach and pancreas. A fistula may result from damage to the greater curvature of the stomach during ligation of the short gastric vessels. Damage to the tail of the pancreas may result in pancreatitis, a localised abscess or a pancreatic fistula.

Postoperative thrombocytosis may arise and, if the blood platelet count exceeds 1×10^6/mL, prophylactic aspirin is recommended. Long-term surveillance programmes have emphasised an increased risk of deep vein thrombosis and pulmonary embolism. The relative risk and benefit of thromboprophylaxis in this setting has not been assessed adequately.

Postsplenectomy septicaemia may result from *Streptococcus pneumoniae*, *Neisseria meningitides*, *Haemophilus influenzae* and *Escherichia coli*. Long-term surveillance programmes have

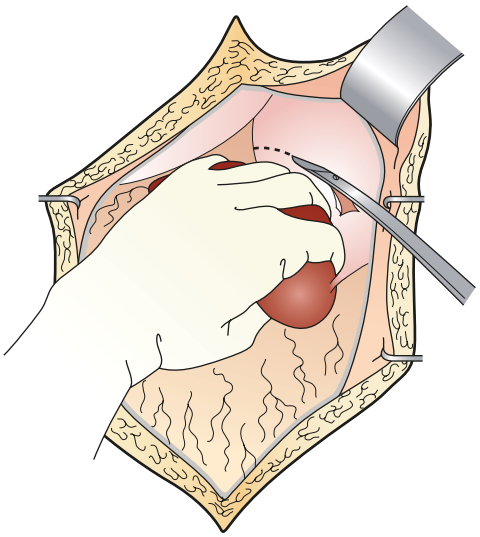

Figure 66.10 Diagrammatic view of the approach required to divide the short gastric vessels anteriorly and the lienorenal ligament posteriorly.

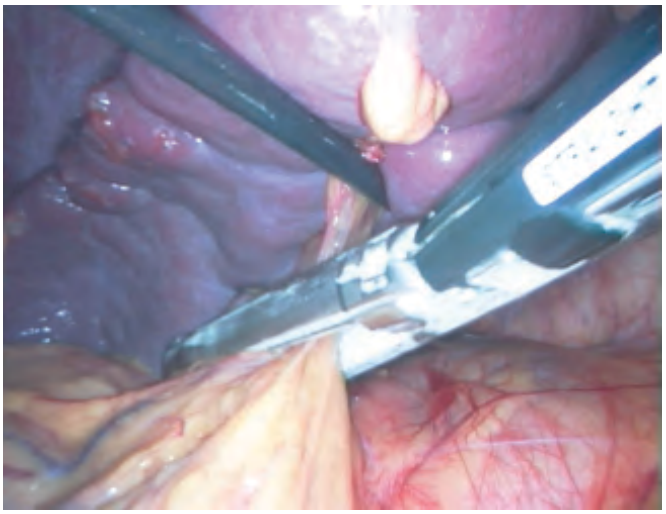

Figure 66.11 Photograph showing a stapling device across the splenic hilus for division of the splenic vessels during laparoscopic splenectomy.

Albert Ludwig Siegmund Neisser, 1855–1916, Director of the Dermatological Institute, Breslau, Germany (now Wroclaw, Poland).
Theodor Escherich, 1857–1911, Professor of Paediatrics, Vienna, Austria.

suggested that the risk of pneumonia, meningitis and major sepsis following splenectomy is increased three-fold. However, the risk is greater in the young patient, in splenectomised patients treated with chemoradiotherapy and in patients who have undergone splenectomy for thalassaemia, sickle cell disease and autoimmune anaemia or thrombocytopenia.

Opportunist postsplenectomy infection (OPSI) is a major concern. Published guidelines emphasise that most infections after splenectomy could be avoided through measures that include offering patients appropriate and timely immunisation, antibiotic prophylaxis, education and prompt treatment of infection. The benefit of prophylactic antibiotics in this setting remains controversial. It is thought that children who have undergone splenectomy before the age of 5 years should be treated with a daily dose of penicillin until the age of 10 years. Prophylaxis in older children should be continued at least until the age of 16 years, but its use is less well defined in adults. Furthermore, compliance is problematic in the long term but, as the risk of overwhelming sepsis is greatest within the first 2–3 years after splenectomy, it seems reasonable to give prophylaxis during this time. However, all patients with compromised immune function should receive prophylaxis. Satisfactory oral prophylaxis can be obtained with penicillin, erythromycin, amoxicillin or co-amoxiclav. Suspected infection can be treated intravenously with these same antibiotics and cefotaxime or ceftriaxone, or chloramphenicol in patients allergic to penicillin and cephalosporins.

If elective splenectomy is planned, consideration should be given to vaccinating against pneumococcus, meningococcus C (both repeated every 5 years) and *H. influenzae* type B (Hib) (repeated every 10 years). The latter two vaccines are commonly delivered as a combined preparation. Yearly influenza vaccination has been recommended, as there is some evidence that it may reduce the risk of secondary bacterial infection. Such vaccinations should be administered at least 2 weeks before elective surgery or as soon as possible after recovery from surgery but before discharge from hospital. Pneumococcal vaccination is recommended in those patients aged over 2 years. *Haemophilus influenzae* type b vaccination is recommended irrespective of age. Asplenic patients should carry a medical alert and an up-to-date vaccination card. They require specific advice regarding travel and animal handling. Patients who have undergone splenectomy and are travelling to countries where malaria is present are strongly advised to use all physical antimosquito barriers as well as antimalarial therapy since they are at increased risk of severe malaria. Overwhelming postsplectomy sepsis due to *Capnocytophaga canimorsus* may result from dog, cat or other animal bites.

In the trauma victim, vaccination can be given in the postoperative period, and the resulting antibody levels will be protective in the majority of cases. Antibody levels are, however, less than 50% of those achieved if vaccination is given in the presence of an intact spleen. Protection following vaccination is not always guaranteed.

Summary box 66.3

Splenectomy

- Remember preoperative immunisation
- Prophylactic antibiotics in the long term
- Opportunistic postsplenectomy infection is a real clinical danger
- Splenic conservation should be considered

Chapter 67

The gallbladder and bile ducts

Learning objectives

- To understand the anatomy and physiology of the gallbladder and bile ducts
- To be familiar with the pathophysiology and management of gallstones
- To be aware of unusual disorders of the biliary tree
- To be aware of malignant disease of the gallbladder and bile ducts

SURGICAL ANATOMY AND PHYSIOLOGY

The gallbladder lies on the underside of the liver in the main liver scissura at the junction of the right and left lobes of the liver. The relationship of the gallbladder to the liver varies between being embedded within the liver substance to being suspended by a mesentry. It is a pear-shaped structure, 7.5–12 cm long, with a normal capacity of about 25–30 mL. The anatomical divisions are a fundus, a body and a neck that terminates in a narrow infundibulum. The muscle fibres in the wall of the gallbladder are arranged in a criss-cross manner, being particularly well developed in its neck. The mucous membrane contains indentations of the mucosa that sink into the muscle coat; these are the crypts of Luschka.

The cystic duct is about 3 cm in length but the length is variable. The lumen is usually 1–3 mm in diameter. The mucosa of the cystic duct is arranged in spiral folds known as the valves of Heister and the wall is surrounded by a sphincteric structure called the sphincter of Lütkens. The cystic duct joins the supraduodenal segment of the common hepatic duct in 80% of cases, however the anatomy may vary and the junction may be much lower in the retroduodenal or even retropancreatic part of the bile duct. Occasionally, the cystic duct may join the right hepatic duct or even a right hepatic sectorial duct (see below).

The common hepatic duct is usually less than 2.5 cm long and is formed by the union of the right and left hepatic ducts. The common bile duct is about 7.5 cm long and formed by the junction of the cystic and common hepatic ducts. It is divided into four parts:

- the supraduodenal portion, about 2.5 cm long, runs in the free edge of the lesser omentum;
- the retroduodenal portion;
- the infraduodenal portion lies in a groove, but at times in a tunnel, on the posterior surface of the pancreas;
- the intraduodenal portion passes obliquely through the wall of the second part of the duodenum, where it is surrounded by the sphincter of Oddi, and terminates by opening on the summit of the ampulla of Vater.

The cystic artery, a branch of the right hepatic artery, usually arises behind the common hepatic duct (**Figure 67.1**). Occasionally, an accessory cystic artery arises from the gastroduodenal artery. In 15% of cases the right hepatic artery and/or the cystic artery crosses in front of the common hepatic duct and the cystic duct.

Calot's triangle, or the hepatobiliary triangle, was initially described by Calot as the space bordered by the cystic duct inferiorly, the common hepatic duct medially and the superior border of the cystic artery. This has been modified in contemporary literature to be the area bound superiorly by the inferior surface of the liver, laterally by the cystic duct and the medial border of the gallbladder and medially by the common hepatic duct. It is an important surgical landmark as the cystic artery usually can be found within its boundaries and should be identified by surgeons performing a cholecystectomy to avoid damage to the extrahepatic biliary system (**Figure 67.2a**).

The most dangerous anomalies are where the hepatic artery takes a tortuous course on the front of the origin of the cystic duct (**Figure 67.2b**), or the right hepatic artery

Hubert Luschka, 1820–1875, Professor of Anatomy, Tübingen, Germany.
Ulrich Lütkens, b.1894, surgeon at the University Clinic, Berlin, Germany, published a monograph on the structure and function of the extrahepatic biliary tract in 1926.
Lorenz Heister, 1683–1758, Professor of Surgery and Botany, Helmstädt, Germany.
Ruggero Oddi, 1845–1906, physiologist, Perugia, Italy.
Abraham Vater, 1684–1751, Professor of Anatomy and Botany, Wittenberg, Germany.

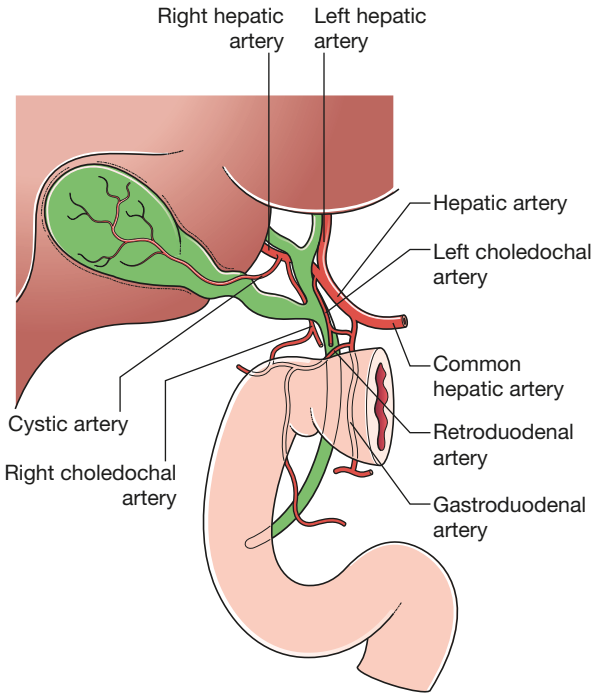

Figure 67.1 The anatomy of the gallbladder and bile ducts. Note the arrangement of the arterial tree.

is tortuous and the cystic artery short (Figure 67.2c). The tortuosity is known as the 'caterpillar turn' or 'Moynihan's hump'. This variation is the cause of many problems during a difficult cholecystectomy with inflammation in the region of the cystic duct.

Lymphatics

The lymphatic vessels of the gallbladder (subserosal and submucosal) drain into the cystic lymph node of Lund (the sentinel lymph node), which lies in the fork created by the junction of the cystic and common hepatic ducts. Efferent vessels from this lymph node go to the hilum of the liver, and to the coeliac lymph nodes. The subserosal lymphatic vessels of the gallbladder also connect with the subcapsular lymph channels of the liver, and this accounts for the frequent spread of carcinoma of the gallbladder to the liver.

Surgical physiology

Bile is produced by the liver and stored in the gallbladder, from which it is released into the duodenum. As it leaves the liver it is composed of 97% water, bile salts (cholic and chenodeoxycholic acids, deoxycholic and lithocholic acids), phospholipids, cholesterol and bilirubin. The liver excretes bile at a rate estimated to be approximately 40 mL/hour. About 95% of bile salts are reabsorbed in the terminal ileum (enterohepatic circulation).

Functions of the gallbladder

The gallbladder is a reservoir for bile. During fasting, resistance to flow through the sphincter of Oddi is high, and bile excreted by the liver is diverted to the gallbladder. After feeding, the resistance to flow through the sphincter is reduced, the gallbladder contracts and the bile enters the duodenum. These motor responses of the biliary tract are in part affected by the hormone cholecystokinin.

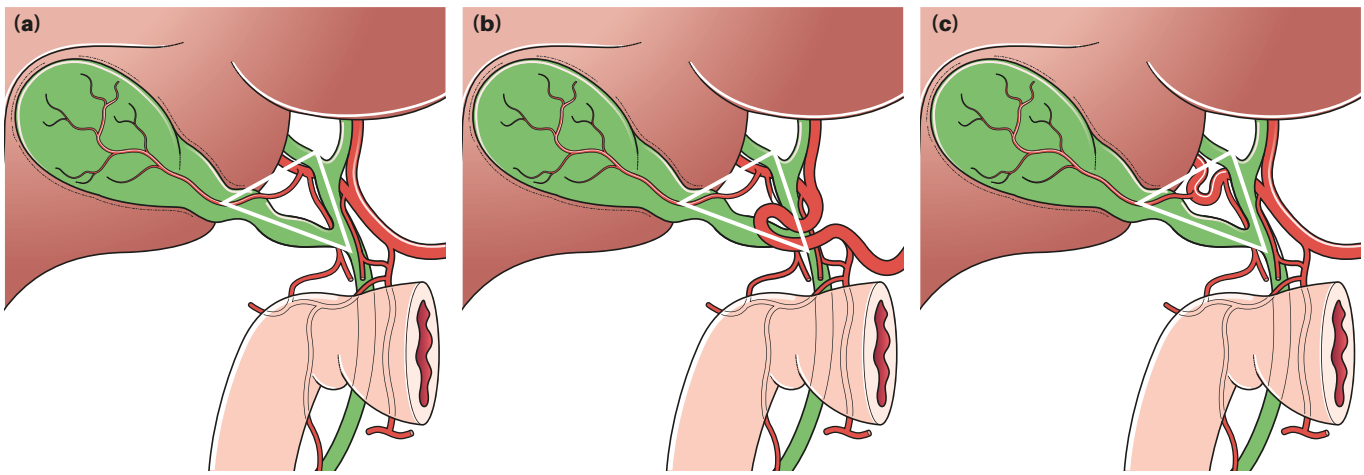

Figure 67.2 **(a)** Usual anatomy of Calot's triangle; **(b)** tortuous common hepatic artery; **(c)** tortuous right hepatic artery with short cystic artery; **(b)** and **(c)** are examples of so-called 'caterpillar turn' or 'Moynihan's hump', which if not recognised can lead to inadvertent arterial injury or bleeding during cholecystectomy.

Berkeley George Andrew Moynihan (Lord Moynihan), 1865–1936, Professor of Clinical Surgery, Leeds, UK.
Jean François Calot, 1861–1944, surgeon, Paris, France.
Fred Bates Lund, 1865–1950, surgeon, Boston City Hospital, Boston, MA, USA.

The second function of the gallbladder is concentration of bile by active absorption of water, sodium chloride and bicarbonate via the mucous membrane of the gallbladder. The hepatic bile which enters the gallbladder becomes concentrated 5–10 times, with a corresponding increase in the proportion of bile salts, bile pigments, cholesterol and calcium.

The third function of the gallbladder is the secretion of mucus – approximately 20 mL is produced per day. With complete obstruction of the cystic duct in an otherwise healthy gallbladder, a mucocoele may develop as a result of ongoing mucus secretion by the gallbladder mucosa.

RADIOLOGICAL INVESTIGATION OF THE BILIARY TRACT

Plain radiographs

The skillfully taken plain radiograph of the gallbladder will show radiopaque gallstones in 10% of patients (**Figure 67.3**). Rarely, the centre of a stone may contain radiolucent gas in a triradiate or biradiate fissure and this gives rise to characteristic dark shapes on a radiograph: the 'Mercedes–Benz' or 'seagull' sign.

A plain x-ray may also show the rare cases of calcification of the gallbladder, a so-called 'porcelain' gallbladder (**Figure 67.4**). This is more commonly seen on computed tomography (CT) (**Figure 67.5**). Traditionally, this has been considered an indication for cholecystectomy as it was associated with a high incidence of gallbladder carcinoma. However, contemporary data suggest that this may not be the case, with the true incidence of cancer being less than 5%. Therefore, decisions on whether or not a cholecystectomy should be performed should be individualised depending on the age of the patient, comorbidities and presence or absence of symptoms.

Figure 67.3 Plain radiograph showing radiopaque stones in the gallbladder. Radiopaque stones are rare (10%).

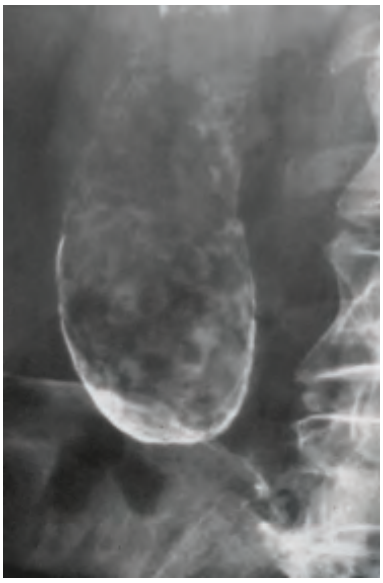

Figure 67.4 Porcelain gallbladder.

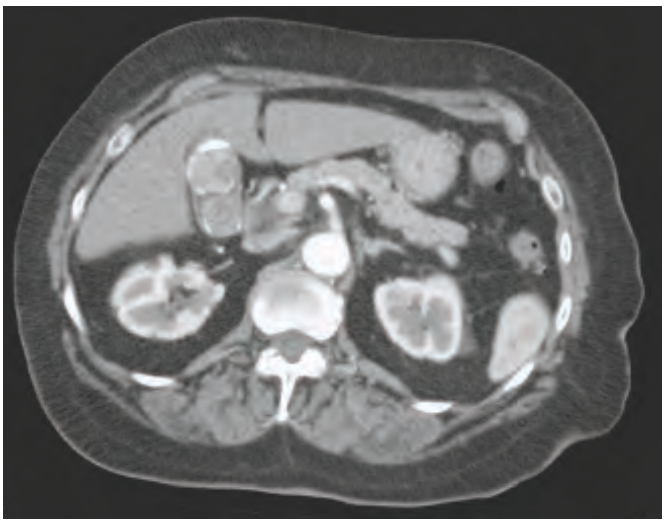

Figure 67.5 Computed tomography scan demonstrating calicification in the gallbladder wall ('porcelain gallbladder').

Gas may be seen in the wall of the gallbladder (emphysematous cholecystitis) (**Figure 67.6**). Gas in the biliary tree may also be seen normally after endoscopic sphincterotomy or following a surgical anastomosis

Oral cholecystography and intravenous cholangiography

Oral and intravenous cholecystography are of interest for historical purposes only as they have been replaced by more accurate imaging modalities.

The Mercedes–Benz sign takes its name from the insignia displayed on the bonnet of a Mercedes–Benz car.

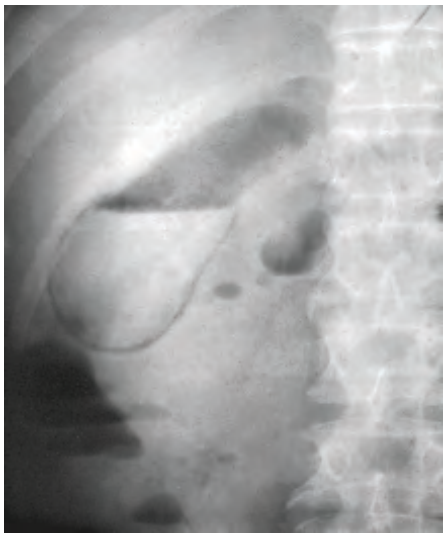

Figure 67.6 Gas in the gallbladder and gallbladder wall (*Clostridium perfringens*). Emergency surgery is indicated.

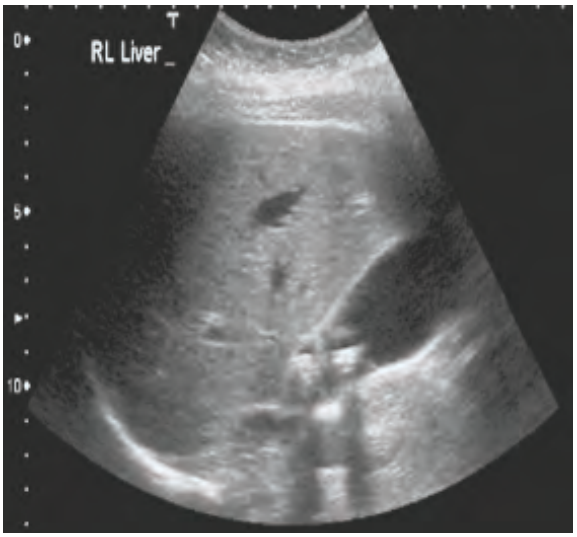

Figure 67.8 Ultrasound examination. Gallstones noted at the neck of the gallbladder with associated acoustic shadowing.

Ultrasonography

Transabdominal ultrasonography (US) (**Figures 67.7 and 67.8**) is the initial imaging modality of choice as it is accurate, readily available, inexpensive and quick to perform. However, it is operator dependent and may be compromised by excessive body fat and intraluminal bowel gas. The size of the gallbladder can be seen, the presence of stones or polyps determined and the thickness of the wall measured. Additionally, the presence of inflammation around the gallbladder, the size of the common bile duct and, occasionally, the presence of stones within the extrahepatic biliary tree can be determined.

For the patient who presents with obstructive jaundice, ultrasonography is particularly helpful because it can identify intra- and extrahepatic biliary dilatation and often the level of obstruction. In addition, the cause of the obstruction may also be determined, such as gallstones in the gallbladder, common hepatic or common bile duct stones, lesions within the wall of the common bile duct suggestive of a cholangiocarcinoma or enlargement of the pancreatic head indicative of a pancreatic carcinoma.

Endoscopic ultrasonography (EUS) utilises a specially designed endoscope with an ultrasound transducer at its tip which allows the gastroenterologist to visualise the liver and biliary tree from within the stomach and duodenum (**Figure 67.9**). It is accurate in imaging the bile duct and detecting the presence of choledocholithiasis. In addition, it has been shown to be useful in diagnosing and staging both pancreatic and periampullary cancers. Biopsies can be taken from suspicious areas for either cytological or histopathological analysis.

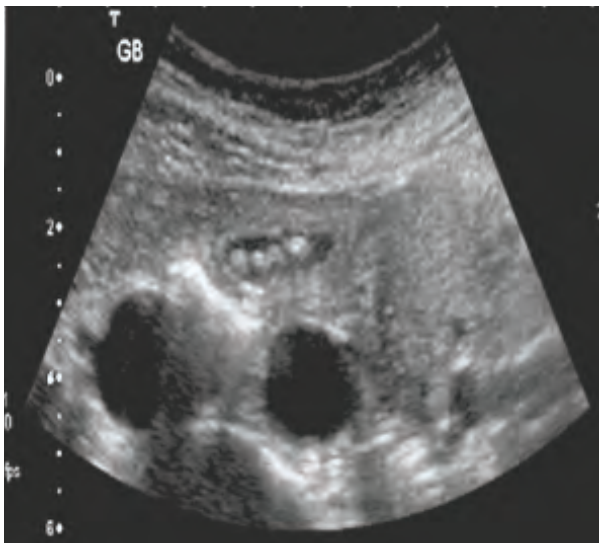

Figure 67.7 Ultrasound examination. Multiple gallstones noted within the gallbladder.

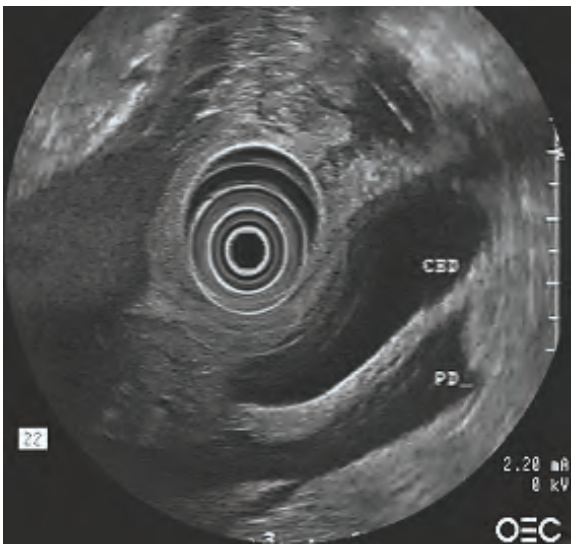

Figure 67.9 Endoscopic ultrasonography. CBD, common bile duct; PD, pancreatic duct.

Cholescintigraphy

Technetium-99m (^{99m}Tc)-labelled derivatives of iminodiacetic acid (HIDA, IODIDA) when injected intravenously are selectively taken up by the retroendothelial cells of the liver and excreted into the bile. This allows visualisation of the biliary tree and gallbladder. In 90% of normal individuals the gallbladder is visualised within 30 minutes following injection, with 100% being seen within 1 hour (**Figure 67.10**). The bowel is seen, usually within 1 hour, in the majority of patients.

Non-visualisation of the gallbladder is suggestive of acute cholecystitis. If the patient has a contracted gallbladder, as often seen in chronic cholecystitis, the gallbladder visualisation may be reduced or delayed.

An abnormally low gallbladder ejection fraction may be suggestive of gallbladder dyskinesia; however, the diagnosis and interpretation of cholescintigraphy in this context are controversial.

Biliary scintigraphy may also be helpful in diagnosing bile leaks and iatrogenic biliary obstruction.

Computed tomography (CT)

Unlike ultrasonography, CT is less affected by body habitus and is not operator dependent. It allows visualisation of the liver, bile ducts, gallbladder and pancreas (**Figure 67.11**). It is particularly useful in detecting hepatic and pancreatic lesions and is the modality of choice in the staging of cancers of the liver, gallbladder, bile ducts and pancreas. It can identify the extent of the primary tumour and define the relationship of the tumour to other organs and blood vessels (**Figure 67.12**). In addition, the presence of enlarged lymph nodes or metastatic disease may be seen. However, as only 75% of gallstones are identified by CT, it is not used as a screening modality for uncomplicated gallstones.

Magnetic resonance cholangiopancreatography (MRCP)

Magnetic resonance cholangiopancreatography is a non-invasive modality that provides excellent imaging of the gallbladder and biliary system (**Figures 67.13 and 67.14**). Images can be obtained of the biliary tree demonstrating ductal obstruction, strictures or other intraductal abnormalities. Images comparable to those obtained using ERCP or PTC (see below) can be achieved non-invasively without the potential complications of either technique.

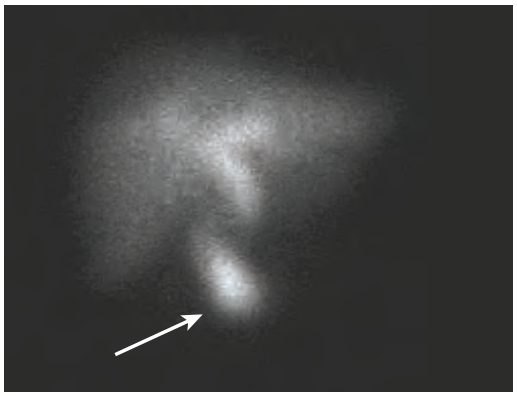

Figure 67.10 Dimethyl iminodiacetic acid (HIDA) scan (arrow indicates the gallbladder).

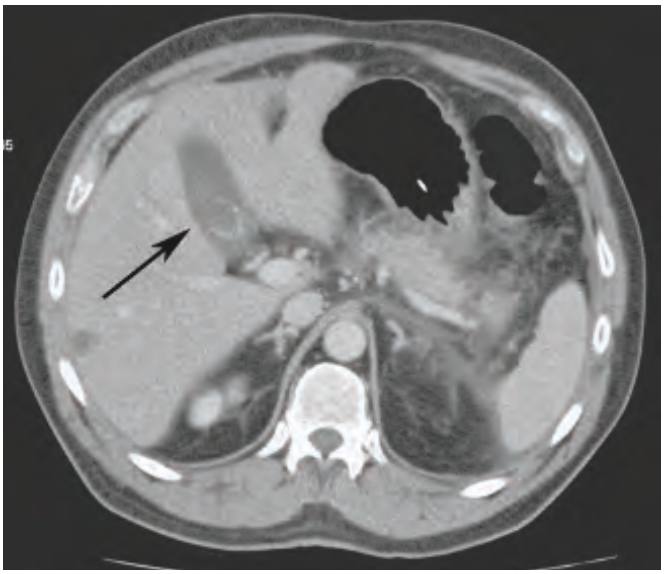

Figure 67.11 Computed tomography scan demonstrating a gallstone within the gallbladder (arrow).

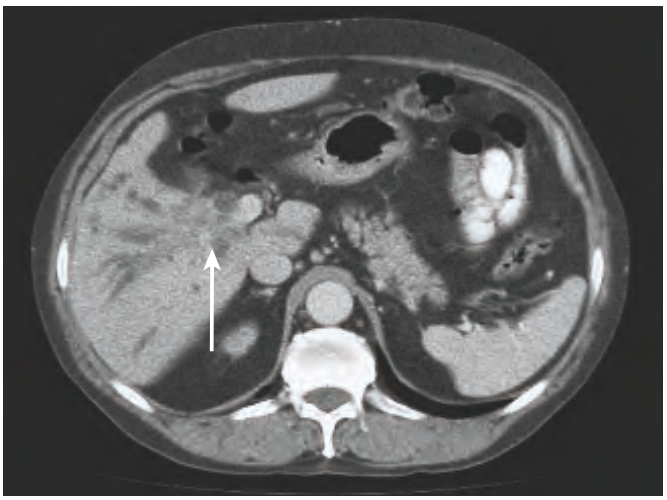

Figure 67.12 Computed tomography scan demonstrating a hilar mass (arrow).

Endoscopic retrograde cholangiopancreatography (ERCP)

This technique remains widely used as both a diagnostic and a therapeutic modality. Using a side-viewing endoscope the ampulla of Vater can be identified and cannulated. Injection of water-soluble contrast directly into the bile duct provides excellent images of the ductal anatomy (**Figure 67.15**) and can identify causes of obstruction such as calculi (**Figure 67.16**) or malignant strictures (**Figure 67.17**). While the widespread availability of ultrasound and MRCP has reduced

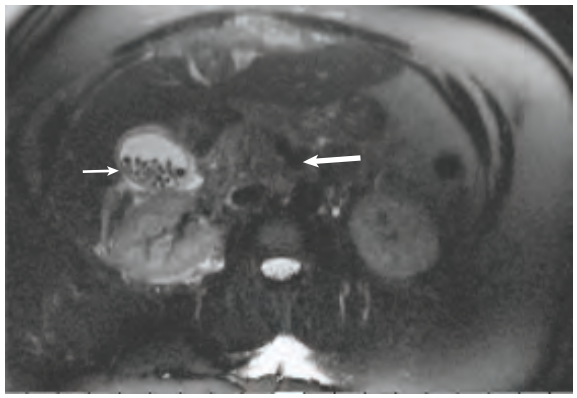

Figure 67.13 Magnetic resonance cholangiopancreatography: cross-sectional image demonstrating a hilar mass (thick arrow) and gallstones (thin arrow).

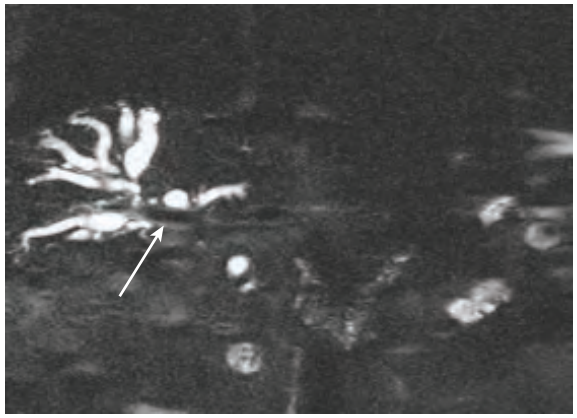

Figure 67.14 Magnetic resonance cholangiopancreatography: projectional images demonstrating stones and hilar obstruction (arrow).

Figure 67.15 Endoscopic retrograde cholangiopancreatography: normal cholangiogram.

its diagnostic use, ERCP still has an important role in the assessment of the patient with obstructive jaundice. In this group of patients it is especially useful in determining the cause and level of obstruction.

Figure 67.16 Endoscopic retrograde cholangiopancreatography: common duct obstruction (arrow).

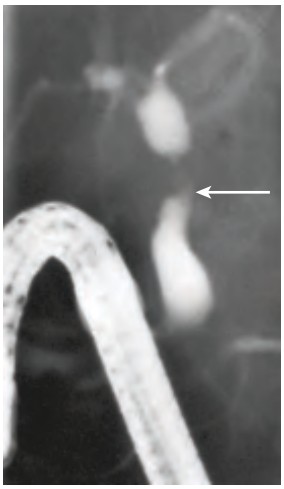

Figure 67.17 Endoscopic retrograde cholangiopancreatography: partial occlusion of the bile duct by a malignant stricture (arrow).

During ERCP, bile aspirates can be sent for cytological and microbiological examination, and endoluminal brushings can be taken from strictures for cytological studies. Therapeutic interventions such as stone removal or stent placement to relieve the obstruction can be performed. Thus, ERCP has evolved into a mainly therapeutic rather than a diagnostic technique.

Percutaneous transhepatic cholangiography (PTC)

This is an invasive technique in which the bile ducts are cannulated percutaneously. It is only undertaken once a bleeding tendency has been excluded and if the patient's prothrombin time is normal. Antibiotics should be given prior to the procedure. Usually, under fluoroscopic control, a needle (the Chiba or Okuda needle) is introduced percutaneously into the liver substance. Under radiological control (either ultrasound or CT) a bile duct is cannulated. Successful entry is confirmed

Evarts Ambrose Graham, 1883–1957, Bixby Professor of Surgery, Washington University, St Louis, MO, USA.
Warren Henry Cole, 1898–1990, Emeritus Professor of Surgery, University of Illinois, Chicago, IL, USA, introduced cholecystography in 1924.
Kunio Okuda, 1921–2003, Professor of Medicine, Chiba University, Japan.

by contrast injection or aspiration of bile. Water-soluble contrast medium is injected to visualise the biliary system. Multiple images can be taken demonstrating areas of strictures or obstruction (Figure 67.18). Bile can be sent for cytology. In addition, this technique enables placement of a catheter into the bile ducts to provide external biliary drainage or the insertion of indwelling stents. The scope of this procedure can be further extended by leaving the drainage catheter *in situ* for a number of days and then dilating the track sufficiently for a fine flexible choledochoscope to be passed into the intrahepatic biliary tree in order to diagnose strictures, take biopsies and remove stones.

In general, if a malignant stricture at the level of the confluence of the right and left hepatic ducts or higher is suspected in a jaundiced patient, a PTC is preferred to ERCP because successful drainage is more likely.

Summary box 67.1

Radiological investigation of the biliary tree

- Plain radiograph: calcification, air within biliary system
- Ultrasound: stones and biliary dilatation
- MRCP: anatomy and stones
- CT scan: anatomy, liver, gallbladder and pancreatic cancer
- Radioisotope scanning (HIDA scan): function
- ERCP: anatomy, stones and biliary strictures
- PTC: anatomy and biliary strictures
- EUS: anatomy, stones

Intraoperative imaging techniques

Peroperative cholangiography

During open or laparoscopic cholecystectomy a catheter can be placed in the cystic duct and contrast injected directly into the biliary tree. The technique defines the anatomy and is used mainly to exclude the presence of stones within the bile ducts (Figures 67.19–67.21). A single x-ray plate or image intensifier can be used to obtain and review the images intraoperatively. Irrespective of the technique used the operating table should be tilted head down by approximately 20° to facilitate filling of the intrahepatic ducts. In addition, care should be taken when injecting contrast not to introduce air bubbles into the system as these may give the appearance of stones and lead to a false-positive result.

Operative biliary endoscopy (choledochoscopy)

At operation, a flexible fibreoptic endoscope can be passed either via the cystic duct or directly via a choledochotomy into the common bile duct, enabling stone identification and removal under direct vision. After exploration of the bile duct, a tube can be left in the cystic duct remnant or in the common bile duct (a T-tube) and drainage of the biliary tree established. After 7–10 days, a track will be established. This track can be used subsequently for the passage of a choledochoscope to remove residual stones in the awake patient in an endoscopy suite.

A normal duct with no problems. **(b)** The duct is dilated and contains multiple stones. There is hold-up of contrast passing into the duodenum. A sphincterotomy was performed.

Laparoscopic ultrasonography

At laparoscopy, the use of a laparoscopic ultrasound probe can be used to image the extrahepatic biliary system. It is a useful technique in biliary and pancreatic tumour staging as it can identify the primary tumour and determine its relationship to major vessels such as the hepatic artery, superior mesenteric artery, portal vein and superior mesenteric vein.

CONGENITAL ABNORMALITIES OF THE GALLBLADDER AND BILE DUCTS

Embryology

The hepatic diverticulum arises from the ventral wall of the foregut and elongates into a stalk to form the choledochus. A lateral bud is given off, which is destined to become the gallbladder and cystic duct. The embryonic hepatic duct sends out many branches which join up the canaliculi between the liver cells. As is usual with embryonic tubular structures, hyperplasia obliterates the lumina of this ductal system; normally recanalisation subsequently occurs and bile begins to flow. During early fetal life the gallbladder is entirely intrahepatic.

Absence of the gallbladder

Occasionally, the gallbladder is absent. Failure to visualise the gallbladder does not necessarily indicate a pathological problem.

The Phrygian cap

The Phrygian cap (Figure 67.22) is present in 5% of cases and may be mistaken for a pathological deformity of the organ. 'Phrygian cap' refers to hats worn by the people of Phrygia, an ancient country of Asia Minor; it was rather like a liberté cap of the French Revolution.

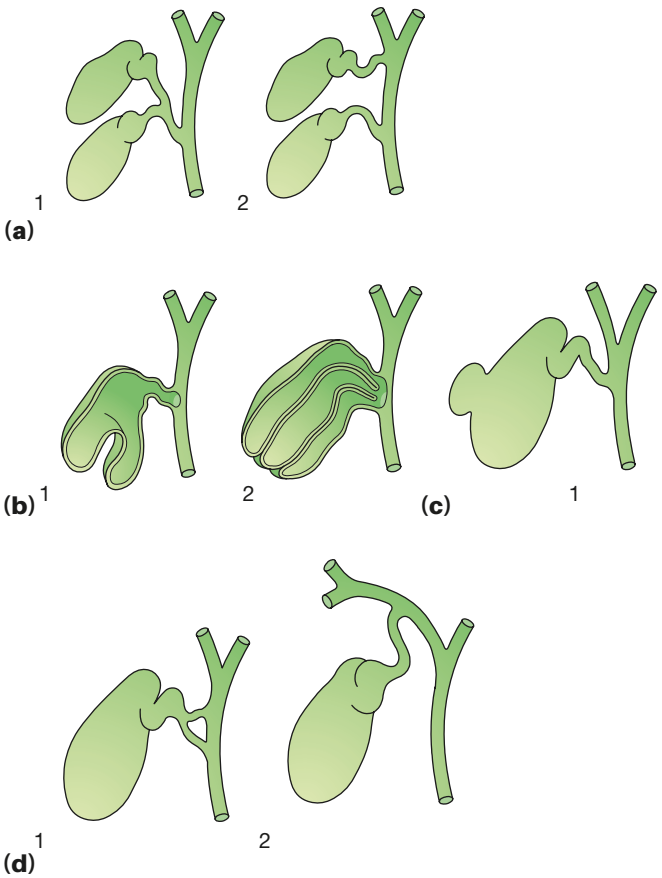

Figure 67.22 The main variations in gallbladder and cystic duct anatomy. **(a)** Double gallbladder. **(b)** Septum of the gallbladder: 1 is the most common, the so-called 'Phrygian cap'. **(c)** Diverticulum of the gallbladder. **(d)** Variations in cystic duct insertion.

Floating gallbladder

The gallbladder may hang on a mesentery, which makes it liable to undergo torsion.

Absence of the cystic duct

This is usually a pathological, as opposed to an anatomical, anomaly and indicates the recent passage of a stone or the presence of a stone at the lower end of the cystic duct, which is ulcerating into the common bile duct. The main danger at surgery is damage to the bile duct, and particular care to identify the correct anatomy is essential before division of any duct.

Low insertion of the cystic duct

The cystic duct opens into the common bile duct near the ampulla. Variations of this anomaly can occur (Figure 67.23). It is important that the operating surgeon correctly identifies the anatomy to avoid inadvertent damage to the common hepatic or common bile duct. Complete dissection of a cystic duct which is inserted low into the bile duct (Figure 67.24) should be avoided because there is a potential to devascularise the common bile duct, which could result in stricture formation.

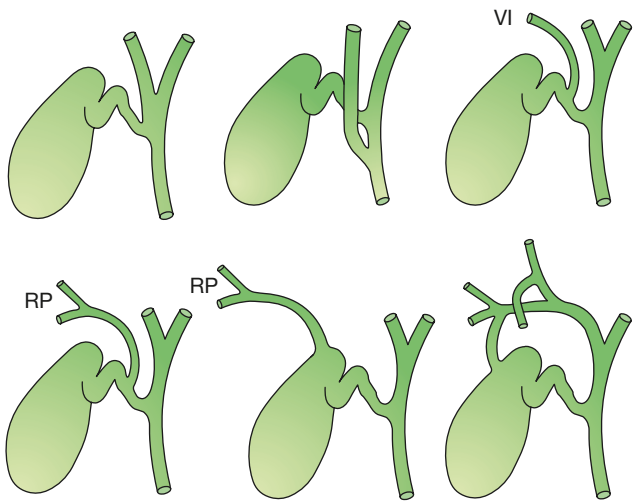

Figure 67.23 Patterns of cystic duct anatomy – note segment VI drainage into the cystic duct and the drainage of the right posterior sectorial duct (RP) into the neck of the gallbladder, or an accessory duct, the so-called duct of Luschka.

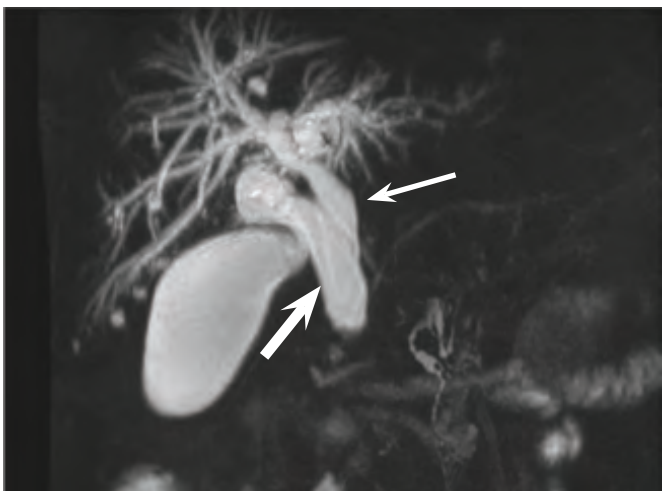

Figure 67.24 Magnetic resonance cholangiopancreatography demonstrating low insertion of the cystic duct (thick arrow) into the common bile duct (thin arrow).

An accessory cholecystohepatic duct

Ducts passing directly into the gallbladder from the liver are not uncommon. Larger ducts should be closed, but before doing so the precise anatomy should be carefully ascertained to ensure that a right hepatic duct is not being ligated (Figure 67.23).

EXTRAHEPATIC BILIARY ATRESIA

Aetiology and physiology

Atresia is present in approximately 1 per 12 000 live births, and affects males and females equally. The extrahepatic bile ducts are progressively destroyed by an inflammatory process which starts around the time of birth. The aetiology is unclear. Intrahepatic changes also occur and eventually result in biliary cirrhosis and portal hypertension. Untreated, death from the consequences of liver failure occurs before the age of 3 years.

The inflammatory destruction of the bile ducts has been classified into three main types (Figure 67.25):

- type I: atresia restricted to the common bile duct;
- type II: atresia of the common hepatic duct;
- type III: atresia of the right and left hepatic ducts.

Associated anomalies occur in about 20% of cases and include cardiac lesions, polysplenia, situs inversus, absent vena cava and a preduodenal portal vein.

Clinical features

About one-third of patients are jaundiced at birth. In all, however, jaundice is present by the end of the first week and deepens progressively. Liver function tests show an obstructive pattern with elevated bilirubin and alkaline phosphatase. The meconium may be a little bile stained, but later the stools are pale and the urine is dark. Prolonged steatorrhoea gives rise to osteomalacia (biliary rickets). Pruritus is severe. Clubbing and skin xanthomas, probably related to raised serum cholesterol, may be present.

Differential diagnosis

This includes any form of jaundice in a neonate giving a cholestatic picture. Examples are α_1-antitrypsin deficiency, cholestasis associated with intravenous feeding, choledochal cyst and inspissated bile syndrome. Neonatal hepatitis is the most difficult to differentiate. Both extrahepatic biliary atresia and neonatal hepatitis are associated with giant cell transformation of the hepatocytes. Liver biopsy and radionuclide excretion scans are essential.

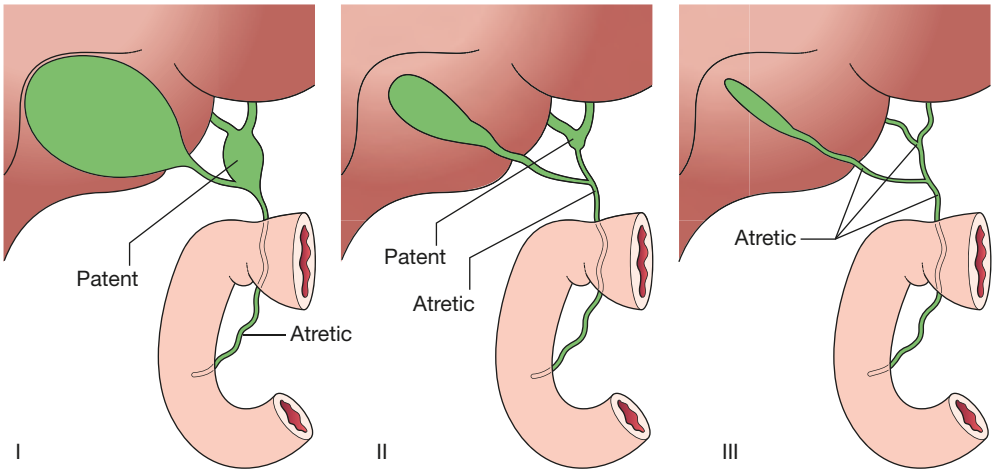

Figure 67.25 Classification of biliary atresia. Gallbladder filling provides a clue to the type of atresia.

Treatment

Patent segments of proximal bile duct are found in 10% of type I lesions. A direct Roux-en-Y hepaticojejunostomy will achieve bile flow in 75%, but progressive fibrosis results in disappointing long-term results. A simple biliary–enteric anastomosis is not possible in the majority of cases in which the proximal hepatic ducts are either very small (type II) or atretic (type III). These are treated by the Kasai procedure, in which radical excision of all bile duct tissue up to the liver capsule is performed. A Roux-en-Y loop of jejunum is anastomosed to the exposed area of liver capsule above the bifurcation of the portal vein, creating a portoenterostomy. The chances of achieving effective bile drainage after portoenterostomy are maximal when the operation is performed before the age of 8 weeks, and approximately 90% of children whose bilirubin falls to within the normal range can be expected to survive for 10 years or more. Early referral for surgery is critical.

Postoperative complications include bacterial cholangitis, which occurs in 40% of patients. Repeated attacks lead to hepatic fibrosis, and 50% of long-term survivors develop portal hypertension, with one-third having variceal bleeding.

Liver transplantation should be considered in children in whom a portoenterostomy is unsuccessful. Results are improving, with 70–80% alive 2–5 years following transplant.

CONGENITAL DILATATION OF THE INTRAHEPATIC DUCTS (CAROLI'S DISEASE)

This rare congenital condition is characterised by multiple irregular saccular dilatations of the intrahepatic ducts, separated by segments of normal or stenotic ducts, with a normal extrahepatic biliary system. In Caroli's syndrome, the biliary dilatation is associated with congenital hepatic fibrosis. The presentation is varied, with many patients presenting with abdominal pain, cholangitis or end-stage liver disease. The majority of patients present before the age of 30. Sex distribution is equal. Management is multidisciplinary: cholangitis or jaundice are treated with appropriate antibiotic therapy and endoscopic or interventional stenting. Malignancy is a complication of long-standing disease. Hepatic resection is indicated for patients with limited disease. Patients with diffuse disease and concomitant hepatic fibrosis are candidates for liver transplantation. Recurrence is common, particularly after resection, and long-term surveillance is required.

CHOLEDOCHAL CYST

Cystic disease of the biliary system is rare. Choledochal cysts are congenital dilations of the intra and/or extrahepatic biliary system. The pathogenesis is unclear. Anomalous junctions of the biliary pancreatic junction are frequently observed, but whether or not these play a role in the pathogenesis of the condition is unclear. Todani and colleagues proposed a classification of cystic disease of the biliary tract (**Figure 67.26**). Type I cysts are the most common and account for approximately 75% of patients.

Patients may present at any age with jaundice, fever, abdominal pain and a right upper quadrant mass on examination; however, 60% of cases are diagnosed before the age of 10 years. Pancreatitis is not an infrequent presentation in adults. Patients with choledochal cysts have an increased risk of developing cholangiocarcinoma with the risk varying directly with the age at diagnosis.

Ultrasonography will confirm the presence of an abnormal cyst and magnetic resonance imaging (MRI/MRCP) will reveal the anatomy, in particular the relationship between the lower end of the bile duct and the pancreatic duct. CT is also useful for delineating the extent of the intra- or extrahepatic dilatation.

César Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland. Described the Roux-en-Y loop in 1908.
Morio Kasai, 1922–2008, Professor of Surgery, Tokyo University, Japan.
Jacques Caroli, 1902–1979, gastrogenterologist, Hôpital St Antoine, Paris, described cavernous ectasia in the biliary tree in 1958.
Takuji Todani, b.1931, Department of Surgery, Okayama University Medical School, Japan, modified Alonso-Lej's classification of choledochal cysts in 1977.

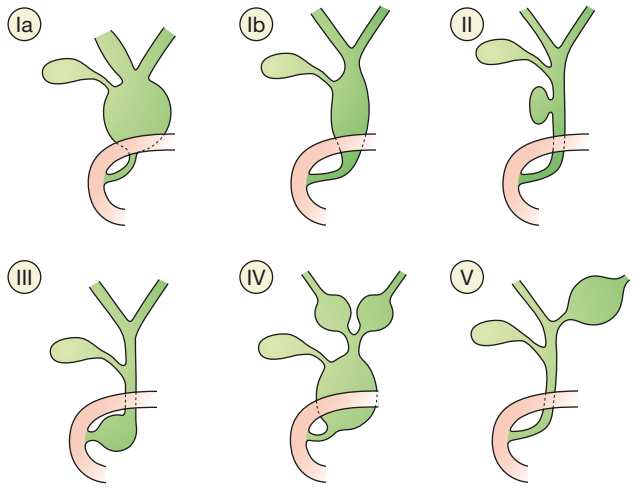

Figure 67.26 Classification of types of choledochal cyst. Type Ia and b: diffuse cystic. Note extension into pancreas of type Ib. Type II: diverticulum of common bile duct. Type III: diverticulum within pancreas. Type IV: extension into the liver. Type V: cystic dilatation only of the intrahepatic ducts.

Radical excision of the cyst is the treatment of choice, with reconstruction of the biliary tract using a Roux-en-Y loop of jejunum. Complete resection of the cyst is important because of the association with the development of cholangiocarcinoma. Resection and roux-en-Y reconstruction are also associated with a reduced incidence of stricture formation and recurrent cholangitis.

TRAUMA

Injuries to the gallbladder and extrahepatic biliary tree are rare. They occur as a result of blunt or penetrating abdominal trauma. Iatrogenic injury is perhaps more frequent than external trauma. The physical signs are those of an acute abdomen. Management depends on the location and extent of the biliary and associated injury. In the stable patient a transected bile duct is best repaired by a Roux-en-Y choledochojejunostomy. Injuries to the gallbladder can be dealt with by cholecystectomy.

TORSION OF THE GALLBLADDER

This is very rare and requires a long mesentery, and therefore often occurs in an older patient with a large mucocoele of the gallbladder. The patient presents with extreme pain and an acute abdomen. Immediate exploration is indicated, with cholecystectomy as the only treatment.

GALLSTONES (CHOLELITHIASIS)

Gallstones are the most common biliary pathology. It is estimated that gallstones affect 10–15% of the population in Western societies. They are asymptomatic in the majority of cases (>80%). In the UK, the prevalence of gallstones at the time of death is estimated to be 17% and may be increasing. Approximately 1–2% of asymptomatic patients will develop symptoms requiring surgery per year, making cholecystectomy one of the most common operations performed by general surgeons.

Causal factors in gallstone formation

Gallstones can be divided into three main types: cholesterol, pigment (brown/black) or mixed stones. In the USA and Europe 80% are cholesterol or mixed stones, whereas in Asia 80% are pigment stones. Cholesterol or mixed stones contain 51–99% pure cholesterol plus an admixture of calcium salts, bile acids, bile pigments and phospholipids.

Cholesterol, which is insoluble in water, is secreted from the canalicular membrane in phospholipid vesicles. Whether cholesterol remains in solution depends on the concentration of phospholipids and bile acids in the bile, and on the type of phospholipid and bile acid. Micelles formed by the phospholipid hold cholesterol in a stable thermodynamic state. When bile is supersaturated with cholesterol or bile acid concentrations are low, unstable unilamellar phospholipid vesicles form, from which cholesterol crystals may nucleate, and stones may form. The process of gallstone formation is complex (**Figure 67.27**), and many areas remain unclear. Obesity, high-caloric diets and certain medications (e.g. oral contraceptives) can increase secretion of cholesterol and supersaturate the bile, increasing the lithogenicity of bile. Resection of the terminal ileum, which diminishes the enterohepatic circulation, will deplete the bile acid pool and result in cholesterol supersaturation. Nucleation of cholesterol monohydrate crystals from multilamellar vesicles is a crucial step in gallstone formation. Abnormal emptying of the gallbladder may aid the aggregation of nucleated cholesterol crystals; hence, removing gallstones without removing the gallbladder inevitability leads to gallstone recurrence.

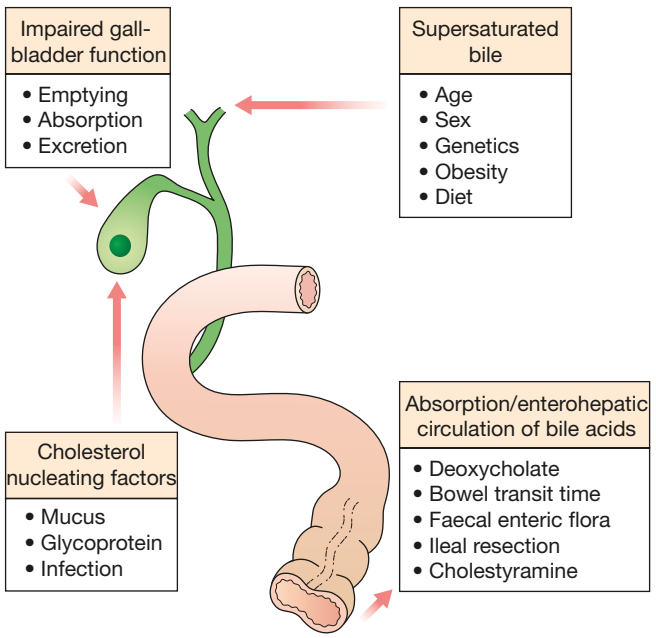

Figure 67.27 Factors associated with gallstone formation.

Pigment stone is the name used for stones containing <30% cholesterol. There are two types: black and brown. Black stones are largely composed of an insoluble bilirubin pigment polymer mixed with calcium phosphate and calcium bicarbonate. Overall, 20–30% of stones are black. The incidence rises with age. Black stones are associated with haemolysis, usually hereditary spherocytosis or sickle cell disease. For reasons that are unclear, patients with cirrhosis have a higher instance of pigmented stones.

Brown pigment stones contain calcium bilirubinate, calcium palmitate and calcium stearate, as well as cholesterol. Brown stones are rare in the gallbladder. They form in the bile duct and are related to bile stasis and infected bile. Stone formation is related to the deconjugation of bilirubin deglucuronide by bacterial β-glucuronidase. Insoluble unconjugated bilirubinate precipitates. Brown pigment stones are also associated with the presence of foreign bodies within the bile ducts such as endoprostheses (stents) or parasites such as *Clonorchis sinensis* and *Ascaris lumbricoides*.

Clinical presentation

Gallstones may remain asymptomatic, being detected incidentally as imaging is performed for other symptoms. If symptoms occur, patients typically complain of right upper quadrant or epigastric pain, which may radiate to the back. This may be described as colicky but more often is dull and constant. Other symptoms include dyspepsia, flatulence, food intolerance particularly to fats and some alteration in bowel frequency. Biliary colic is typically present in 10–25% of patients. This is described as a severe right upper quadrant pain which ebbs and flows, associated with nausea and vomiting. Pain may radiate to the chest. The pain is usually severe and may last for minutes or even several hours. Frequently, the pain starts during the night and wakes the patient. Minor episodes of the same discomfort may occur intermittently during the day. Dyspeptic symptoms may coexist and be worse after such an attack. As the pain resolves the patient improves and is able to eat and drink again, often only to suffer further episodes. It is of interest that a patient may have several episodes of this nature over a period of a few weeks and then no more trouble for some months. Jaundice may result if the stone migrates from the gallbladder and obstructs the common bile duct. Rarely, a gallstone can lead to bowel obstruction (gallstone ileus).

When the symptoms do not resolve but progress to continued pain with fever and leukocytosis, the diagnosis of acute cholecystitis should be considered. The differential diagnosis is given in *Summary box 67.3*.

Summary box 67.2

Effects and complications of gallstones

- Biliary colic
- Acute cholecystitis
- Chronic cholecystitis
- Empyema of the gallbladder
- Mucocoele
- Perforation
- Biliary obstruction
- Acute cholangitis
- Acute pancreatitis
- Intestinal obstruction (gallstone ileus)

Summary box 67.3

Differential diagnosis of acute cholecystitis

Common

- Appendicitis
- Perforated peptic ulcer
- Acute pancreatitis

Rare

- Acute pyelonephritis
- Myocardial infarction
- Pneumonia – right lower lobe

Diagnosis

A diagnosis of gallstone disease is based on the history and physical examination with confirmatory radiological studies such as transabdominal ultrasonography and radionuclide scans (see above). In the acute phase the patient may have right upper quadrant tenderness that is exacerbated during inspiration by the examiner's right subcostal palpation (Murphy's sign). A positive Murphy's sign suggests acute inflammation and may be associated with a leukocytosis and moderately elevated liver function tests. A mass may be palpable as the omentum walls off an inflamed gallbladder. While the presentation and examination may suggest acute cholecystitis, a definitive diagnosis can only be made following appropriate imaging studies (US or CT). Fortunately, in the majority of cases the process is limited by the stone slipping back into the body of the gallbladder and the contents of the gallbladder escaping by way of the cystic duct. This achieves adequate drainage of the gallbladder and enables the inflammation to resolve.

If resolution does not occur, an empyema of the gallbladder may result. The wall may become necrotic and perforate, with development of localised peritonitis. The abscess may then perforate into the peritoneal cavity with a septic peritonitis; however, this is uncommon, because the inflamed gallbladder is usually localised by omentum which contains the perforation.

A palpable, non-tender gallbladder (Courvoisier's sign) portends a more sinister diagnosis. This usually results from a distal common duct obstruction secondary to a peripancreatic

John Benjamin Murphy, 1857–1916, surgeon, Mercy Hospital Chicago, IL, USA.
Ludwig Courvoisier, 1843–1918, Professor of Surgery, Basle, Switzerland.

malignancy. Rarely, a non-tender, palpable gallbladder results from complete obstruction of the cystic duct with reabsorption of the intraluminal bile salts and secretion of uninfected mucus by the gallbladder epithelium, leading to a mucocoele of the gallbladder.

Treatment

Most consider that it is safe to observe patients with asymptomatic gallstones, with cholecystectomy reserved for patients who develop symptoms or complications. However, prophylactic cholecystectomy may be considered for diabetic patients, those with congenital haemolytic anaemia and those patients who are undergoing bariatric surgery for morbid obesity because it has been found in these groups that the risk of developing symptoms is increased. For patients with symptomatic gallstones, cholecystectomy is the treatment of choice if there are no medical contraindications.

Experience shows that, in more than 90% of cases, the symptoms of acute cholecystitis subside with conservative measures. Non-operative treatment is based on four principles:

- Nil per mouth (NPO) and intravenous fluid administration until the pain resolves.
- Administration of analgesics.
- Administration of antibiotics. As the cystic duct is blocked in most instances, the concentration of antibiotic in the serum is more important than its concentration in bile. A broad-spectrum antibiotic effective against gram-negative aerobes is most appropriate (e.g. cefazolin, cefuroxime or ciprofloxacillin).
- Subsequent management. When the temperature, pulse and other physical signs show that the inflammation is subsiding, oral fluids are reinstated, followed by a regular diet. Ultrasonography is performed to confirm the diagnosis. If jaundice is present MRCP is performed to exclude choledocholithiasis. If there is any concern regarding the diagnosis or presence of complications such as perforation CT should be performed. Cholecystectomy may be performed on the next available list, or the patient may be allowed home to return later when the inflammation has completely resolved.

The 2013 Toyko guidelines allow assessment of severity to be made (*Table 67.1*). In patients with grade III disease depending on the status of the patient either operative intervention and cholecystectomy should be performed or if the patient has comorbid conditions, a percutaneous cholecystostomy can be performed by a radiologist under ultrasound control. This will usually rapidly relieve symptoms, however an interval cholecystectomy will be required once the patient's condition has stablised.

The timing of surgery in acute cholecystitis remains controversial, with many units favouring an early intervention within the first week whereas others suggest that a delayed approach is preferable. Early cholecystectomy during acute cholecystitis appears to be safe and shortens the total hospital stay.

Provided that the operation is undertaken within 5–7 days of the onset of the attack, the surgeon is experienced and excellent operating facilities are available, good results are achieved. Nevertheless, the conversion rate in laparoscopic cholecystectomy is higher in acute than in elective surgery. If an early operation is not indicated one should wait approximately 6 weeks for the inflammation to subside before operating.

TABLE 67.1 Tokyo Consensus Guidelines for severity grading of acute cholecystitis. Reproduced with permission from Yokoe *et al*. *J Hepatobiliary Pancreat Sci* 2013; **30**: 35–46.

Grade III (severe) acute cholecystitis	
Associated with dysfunction of any one of the following organs/systems:	
1 Cardiovascular dysfunction	Hypertension requiring treatment with dopamine ≤5 μg/kg/min, or any dose of norepinephrine (noradrenaline)
2 Neurological dysfunction	Decreased level of consciousness
3 Respiratory dysfunction	P_aO_2/FiO_2 ratio <300
4 Renal dysfunction	Oliguria; creatinine >2.0 mg/dL
5 Hepatic dysfunction	Prothrombin time (PT-INR) >1.5
6 Haematological dysfunction	Platelet count <100 000/mm^3
Grade II (moderate) acute cholecystitis	
Associated with any one of the following conditions: 1 Elevated white cell count (>18 000/mm^3) 2 Palpable tender mass in the right upper abdominal quadrant 3 Duration of complaints >72 hours 4 Marked local inflammation (gangrenous cholecystitis, pericholecystic abscess, hepatic abscess, biliary peritonitis, emphysematous cholecystitis)	
Grade I (mild) acute cholecystitis	
Does not meet the criteria of grade II or grade III acute cholecystitis. Grade I can also be defined as acute cholecystitis in a healthy person with no organ dysfunction and mild inflammatory changes in the gallbladder, making cholecystectomy a safe and low-risk operative procedure	

EMPYEMA OF THE GALLBLADDER

Empyema may be a sequel to acute cholecystitis or the result of a mucocoele becoming infected. The gallbladder is distended with pus. The optimal treatment is drainage (cholecystostomy, see above) and, later, cholecystectomy.

Acalculous cholecystitis

Acute and chronic inflammation of the gallbladder can occur in the absence of stones and give rise to a clinical picture similar to that of calculous cholecystitis. Some patients have non-specific inflammation of the gallbladder, whereas others have one of the cholecystoses (see below). Acute acalculous cholecystitis is particularly seen in critically ill patients and those recovering from major surgery, trauma and burns. The diagnosis is often missed and the mortality rate is high.

THE CHOLECYSTOSES (CHOLESTEROSIS, POLYPOSIS, ADENOMYOMATOSIS AND CHOLECYSTITIS GLANDULARIS PROLIFERANS)

This is a relatively uncommon group of conditions affecting the gallbladder, in which there are chronic inflammatory changes with hyperplasia of all tissue elements.

Cholesterosis ('strawberry gallbladder')

In the fresh state, the interior of the gallbladder looks something like a strawberry in patients with this condition; the yellow specks (submucous aggregations of cholesterol crystals and cholesterol esters) correspond to the seeds (**Figure 67.28**). It may be associated with cholesterol stones.

Cholesterol polyposis of the gallbladder

Ultrasound may show a non-mobile defect in the gallbladder lumen which does not exhibit an associated acoustic shadow. The differential is an adenomatous polyp, and interval follow-up is indicated to ensure stability. Surgery is only advised if there is a diagnostic dilemma.

Cholecystitis glandularis proliferans (polyp, adenomyomatosis and intramural diverticulosis)

Figure 67.29 summarises the varieties of this condition. A polyp of the mucous membrane is fleshy and granulomatous.

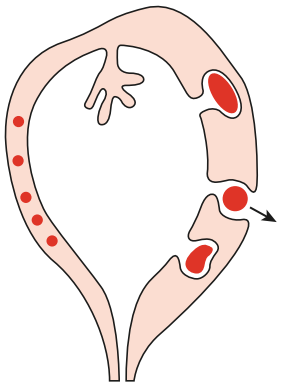

Figure 67.29 Types of cholecystitis glandularis proliferans (polypus, intramural or diverticular stones and fistula).

All layers of the gallbladder wall may be thickened, but sometimes an incomplete septum forms that separates the hyperplastic from the normal. Intraparietal 'mixed' calculi may be present. These can be complicated by an intramural, and later extramural, abscess and potentially fistula formation. If symptomatic, the patient is treated by cholecystectomy.

Diverticulosis of the gallbladder

Diverticulosis of the gallbladder is usually manifest as black pigment stones impacted in the outpouchings of the lacunae of Luschka. Diverticulosis of the gallbladder may be demonstrated by cholecystography, especially when the gallbladder contracts after a fatty meal. There are small dots of contrast medium just within and outside the gallbladder (**Figure 67.30**). A septum may also be present, to be distinguished from the Phrygian cap. The treatment is cholecystectomy.

Typhoid infection of the gallbladder

Salmonella typhi or *Salmonella typhimurium* can infect the gallbladder. Acute cholecystitis can occur. More frequently,

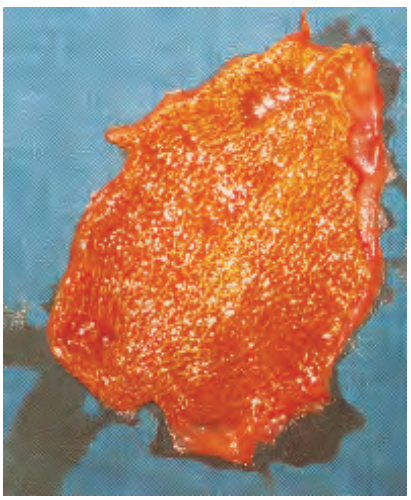

Figure 67.28 The interior of a strawberry gallbladder (cholesterosis) (courtesy of Dr Sanjay P Thakur, Patna, India).

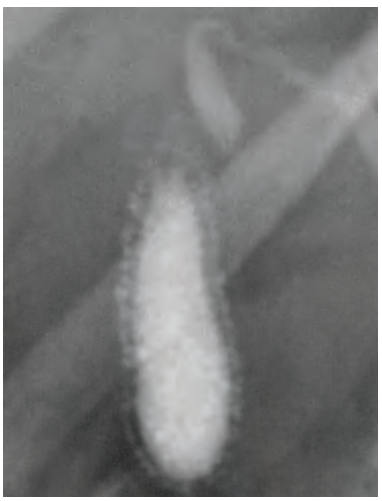

Figure 67.30 Cholecystogram showing diverticulosis with dots of contrast medium in the gallbladder wall.

Daniel Elmer Salmon, 1850–1914, veterinary pathologist, Chief of the Bureau of Animal Industry, Washington, DC, USA.

chronic cholecystitis occurs, the patient becoming a typhoid carrier excreting the bacteria in the bile. Gallstones may be present (surgeons should not give patients their stones after their operation if there is any suspicion of typhoid!). It is debatable whether the stones are secondary to the *Salmonella* cholecystitis or whether pre-existing stones predispose the gallbladder to chronic infection. Salmonellae can, however, frequently be cultured from these stones. Treatment with ampicillin and cholecystectomy are indicated. In cases of penicillin allergy a quinolone antibiotic can be used.

CHOLECYSTECTOMY

Preparation for operation

After appropriate history taking and assessment of the patient's fitness for the procedure, a full blood count and biochemical profile should be performed to exclude anaemia and to identify abnormal liver function. A blood coagulation screen should be checked if there is a history of jaundice or liver function is abnormal. Prophylactic antibiotics should be administered either with the premedication or at the time of induction of anaesthesia. A second-generation cephalosporin is appropriate. Subcutaneous heparin or antiembolic stockings should be prescribed. The patient must sign a consent form to indicate that he or she is fully aware of the procedure being undertaken, alternative options and the risks involved and complications that may occur.

Summary box 67.4

Preparation for cholecystectomy

- Full blood count
- Renal profile and liver function tests
- Prothrombin time
- Chest x-ray and electrocardiogram (if over 45 years or medically indicated)
- Antibiotic prophylaxis
- Deep vein thrombosis prophylaxis
- Informed consent

Laparoscopic cholecystectomy

The preparation and indications for cholecystectomy are the same whether it is performed by laparoscopy or by open techniques. Laparoscopic cholecystectomy is the procedure of choice for the majority of patients with gallbladder disease. The key, as in open surgery, is the identification and safe dissection of Calot's triangle (**Figure 67.31**).

The patient is placed supine on the operating table. Following induction and maintenance of general anaesthesia, the abdomen is prepared in a standard fashion. Pneumoperitoneum is established. A number of techniques are described. The author's preference is to use an open subumbilical cutdown with direct visualisation of the peritoneum, to place the initial port. This port will function as the camera port. An angled telescope (30°) is preferred. Many surgeons perfer a 'closed' technique using a Verres needle to establish pneumoperitoneum prior to placing the initial trocar. Recently, single-port laparoscopic cholecystectomy has been described. Proponents report decreased postoperative pain and improved cosmesis. However, recent systematic reviews have reported a higher failure rate, longer operative time and increased blood loss without any substantive benefits for the technique.

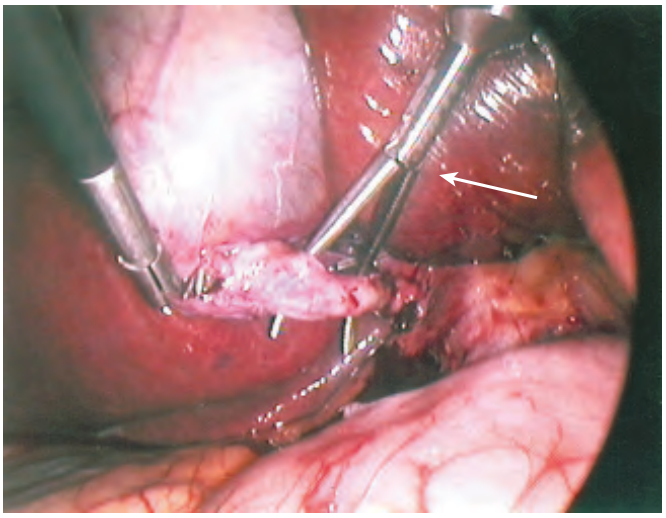

Figure 67.31 Operative image of a laparoscopic cholecystectomy. Laparoscopic forceps (arrow) are used to dissect Calot's triangle.

Additional operating ports are inserted in the subxiphoid area and in the right subcostal area. The patient is placed in a reverse Trendelberg position slightly rotated to the left. This exposes the fundus of the gallbladder which is retracted towards the diaphragm. The neck of the gallbladder is then retracted towards the right iliac fossa, exposing Calot's triangle. This area is laid wide open by dividing the peritoneum on the posterior and on the anterior aspect. The cystic duct is carefully defined, as is the cystic artery. The gallbladder is separated from the liver bed for about 2 cm to allow confirmation of the anatomy. Unless there are specific indications (see below) a routine cholangiogram is not performed. However, if doubt exists regarding the anatomy a cholangiogram is warranted. Once the anatomy is clearly defined and the triangle of Calot has been laid wide open, the cystic duct and artery are clipped and divided. The gallbladder is then removed from the gallbladder bed by sharp or cautery dissection and, once free, removed via the umbilicus.

Open cholecystectomy

For patients in whom a laparoscopic approach is not indicated or in whom conversion from a laparoscopic approach is required an open cholecystectomy is performed.

Either an upper midline or a short right upper transverse incision is made, centred over the lateral border of the rectus muscle. The gallbladder is appropriately exposed and packs are placed on the hepatic flexure of the colon, the duodenum and the lesser omentum to ensure a clear view of the anatomy of the porta hepatis. These packs may be retracted by the assistant's hand ('It is the left hand of the assistant that

does all the work' – Moynihan). Alternatively, a stabilised ring retractor is used to keep the packs in position.

An artery or Duval forceps is placed on the infundibulum of the gallbladder and the peritoneum overlying Calot's triangle is placed on a stretch. The peritoneum is then divided close to the wall of the gallbladder and the fat in the triangle of Calot carefully dissected away to expose the cystic artery and the cystic duct. The cystic duct is cleaned down to the common bile duct, whose position is clearly ascertained. The cystic artery is tied and divided. The whole of the triangle of Calot is displayed to ensure that the anatomy of the ducts is clear and the cystic duct is then divided between ligatures (**Figure 67.32**). The gallbladder is then dissected away from the gallbladder bed.

Some golden rules to observe in case of difficulty:

- When the anatomy of the triangle of Calot is unclear, blind dissection should stop.
- Bleeding adjacent to the triangle of Calot should be controlled by pressure and not by blind clipping or clamping.
- When there is doubt about the anatomy, a retrograde or 'fundus-first' cholecystectomy dissection on the gallbladder wall from the fundus to the cystic duct can be helpful.
- If the cystic duct is densely adherent to the common bile duct and there is the possibility of a Mirizzi syndrome (a stone ulcerating through the neck of the gallbladder into the common hepatic duct), the infundibulum of the gallbladder should be opened, the stone removed and the infundibulum oversewn. Attempts to dissect out the cystic duct completely will only lead to injury to the common hepatic or common bile duct.
- A cholecystostomy is rarely indicated but, if required, as many stones as possible should be extracted and a large Foley catheter (14 Fr) placed in the fundus of the gallbladder with a direct track externally. By so doing, stones retained in the gallbladder can be subsequently extracted with a choledochoscope.

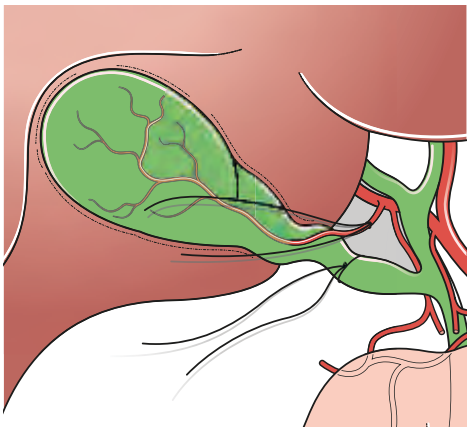

Figure 67.32 Ligatures are passed and tied around the cystic artery and cystic duct. The grey shaded area represents Calot's triangle.

Indications for choledochotomy

In an environment in which neither the modern diagnostic armamentarium described at the beginning of this chapter nor peroperative cholangiography is available, it is well to remember the traditional indications for choledochotomy, which are:

- palpable duct stones;
- jaundice or a history of jaundice or cholangitis;
- a dilated common bile duct;
- abnormal liver function tests, in particular a raised alkaline phosphatase.

Unless the expertise is available, it is probably inadvisable to perform a choledochotomy laparoscopically; rather, one should rely on endoscopic techniques or convert to an open operation. The incidence of symptomatic stones in the bile duct varies from 5% to 8%. These can, in the main, be dealt with endoscopically without resort to opening the duct. However, current trials suggest that in experienced hands the morbidity associated with the two techniques is identical.

Complications of cholecystectomy

Recovery after laparoscopic cholecystectomy is associated with less pain and faster return to normal activity than after open cholecystectomy. The majority of patients undergoing an elective laparoscopic cholecystectomy can have this performed as a day case, avoiding hospital admission. Any untoward symptoms in the postoperative period such as fevers, chills or abdominal pain require immediate investigation.

The operative mortality for cholecystectomy is less than 1%. Factors increasing the risk for postoperative mortality include advanced age, comorbid conditions and acute presentation. Complications can occur in 10–15% of cases. Serious complications of laparoscopic cholecystectomy fall into two major areas: access complications and bile duct injuries. The latter are rare, occurring in approximately 0.5% of cases. In the main, biliary injury results from poor dissection and failure to define the surgical anatomy adequately. Controversy exists as to whether or not the use of operative cholangiography reduces the incidence of bile duct injury. The majority of surgeons use cholangiography only in selected cases.

Patients who develop jaundice in the postoperative period require urgent investigation. This is especially true if the jaundice is associated with infection, a condition called cholangitis.

The first step in management following resuscitation and administration of appropriate antibiotics is to undertake an urgent ultrasound scan. This will demonstrate whether there is intra- or extrahepatic ductal dilatation. The anatomy needs to be defined by either an ERCP or a MRCP. The former will also allow therapeutic manoeuvres such as removal

Pierre Alfred Duval, 1874–1941, French surgeon.
Pablo Luis Mirizzi, 1893–1964, Argentinian surgeon, described this condition in 1932.
Frederic Eugene Basil Foley, 1891–1965, urologist, The Miller and Anker Hospitals, St Paul, MN, USA.

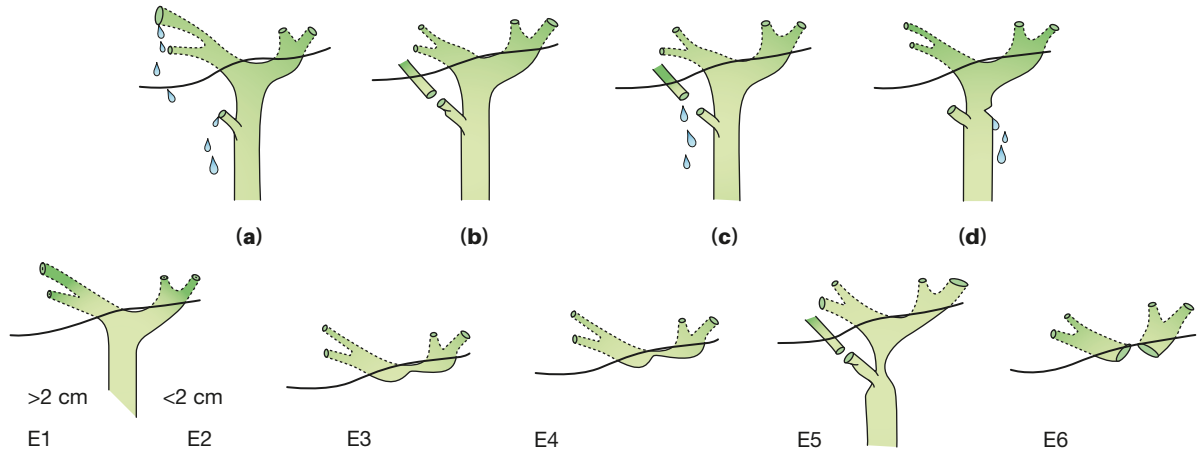

Figure 67.33 Schematic representation of the Strasberg classification of bile duct injuries. **(a)** Bile leak from cystic duct stump or a minor biliary radical in gallbladder fossa. **(b)** Occluded right posterior sectoral duct. **(c)** Bile leak from divided right posterior sectoral duct. **(d)** Bile leak from main bile duct without major tissue loss. E1: Transected main bile duct with a stricture more than 2 cm from the hilus. E2: Transected main bile duct with a stricture less than 2 cm from the hilus. E3: Stricture of the hilus with right and left ducts in communication. E4: Stricture of the hilus with separation of right and left hepatic ducts. E5: Stricture of the main bile duct and the right posterior sectoral duct. E6: Complete excision of the extrahepatic ducts involving the confluence (this injury is not described in Strasberg's classification). (After Connor S, Garden OJ, *Br J Surg* 2006; **93**: 158–168.)

of an obstructing stone or insertion of a stent across a biliary leak. If a fluid collection is present in the subhepatic space, drainage catheters may be required. These can be inserted under radiological control or, if this expertise is not available, at open operation. Small biliary leaks will usually resolve spontaneously, especially if there is no distal obstruction. Should the common bile duct be damaged, the patient should be referred to an appropriate expert for reconstruction of the duct.

About 15% of injuries to the bile ducts are recognised at the time of operation; in the remaining 85% of cases, the injury declares itself postoperatively by either a profuse and persistent leakage of bile, if drainage has been provided, bile peritonitis if such drainage has not been provided, or deepening obstructive jaundice. When the obstruction is incomplete, jaundice is delayed until subsequent fibrosis renders the lumen of the duct inadequate.

Any postoperative elevation in serum bilirubin or suggestion of duct damage requires investigation and the nature of the bile duct injury clarified.

HIDA scanning may be helpful as it can confirm the presence of a leak or biliary obstruction. It can be used to identify and quantitate the leak. If available, ERCP should be considered because this is both diagnostic and potentially therapeutic. The most common bile leak following cholecystectomy is from the cystic duct. This can be treated by a gastroenterologist placing a biliary endoprosthesis (stent) in the common bile duct across the origin of the cystic duct. MRCP is also helpful in determining the level and degree of injury.

The surgical repair and subsequent outcome are related to the level and degree of injury, in conjunction with the presence or absence of concomitant vascular injury. A number of classification systems have been proposed, with the Strasberg classification being commonly utilised (**Figure 67.33**).

In a debilitated patient, temporary external biliary drainage may be achieved by passing a catheter percutaneously into an intrahepatic duct. Also, stents may be passed through strictures at the time of ERCP and left to drain into the duodenum. When the general condition of the patient has improved, definitive surgery can be undertaken. The principles of surgical repair are maintenance of duct length and restoration of biliary drainage. For benign stricture or duct transection, the preferred treatment is Roux-en-Y choledochojejunostomy performed by an experienced hepatobiliary surgeon. For a stricture of recent onset through which a guidewire can be passed, balloon dilatation with insertion of a stent is an acceptable alternative, provided that the services of an experienced endoscopist are available. The outcome of such surgery is good, with 90% of patients having no further cholangitis or stricture formation.

Late symptoms after cholecystectomy

In up to 15% of patients, cholecystectomy fails to relieve the symptoms for which the operation was performed. Such patients may be considered to have a 'post-cholecystectomy' syndrome. However, such problems are usually related to the preoperative symptoms and are merely a continuation of those symptoms. Full investigation should be undertaken to confirm the diagnosis and exclude the presence of a stone in the bile duct, a stone in the cystic duct stump or operative damage to the biliary tree. This is best performed by MRCP or ERCP, the latter of which has the added advantage that if a stone is in the common bile duct it can be removed.

Post-cholecystectomy choledocholithiasis

Duct stones may occur many years after a cholecystectomy or be related to the development of new pathology, such as

infection of the biliary tree or infestation by *Ascaris lumbricoides* or *Clinorchis sinensis*. Any obstruction to the flow of bile can give rise to stasis with the formation of stones within the duct. The consequence of duct stones is either obstruction to bile flow or infection. Stones in the bile ducts are more often associated with infected bile (80%) than are stones in the gallbladder.

Symptoms

The patient may be asymptomatic but usually has bouts of pain, jaundice and fever. The patient is often ill and feels unwell. The term 'cholangitis' is given to the triad of pain, jaundice and fevers sometimes known as 'Charcot's triad'.

Signs

Tenderness may be elicited in the epigastrium and the right hypochondrium. In the jaundiced patient it is useful to remember Courvoisier's law: 'in obstruction of the common bile duct due to a stone, distension of the gallbladder seldom occurs; the organ usually is already shrivelled'. In obstruction from other causes, distension is common, by comparison. However, if there is no disease in the gallbladder and the obstruction is due to a cancer of the ampulla, pancreas or bile duct, then the gallbladder may well be distended.

Management

It is essential to determine whether the jaundice is due to liver disease, disease within the duct, such as sclerosing cholangitis, or obstruction. Ultrasound scanning, liver function tests, liver biopsy if the ducts are not dilated, and MRI or ERCP will identify the nature of the obstruction.

The patient may be ill. Pus may be present within the biliary tree and liver abscesses may develop. Full supportive measures are required with rehydration, attention to clotting, exclusion of diabetes and administration of appropriate broad-spectrum antibiotics. As soon as resuscitation has taken place, relief of the biliary obstruction is essential. Endoscopic papillotomy is the preferred first technique, by means of a sphincterotomy, removal of the stones using a Dormia basket or placement of a stent if stone removal is not possible (**Figures 67.34 and 67.35**). If this technique fails, percutaneous transhepatic cholangiography can be performed to provide drainage and subsequent percutaneous choledochoscopy. Surgery, in the form of choledochotomy, is now rarely used for this situation as most patients can be managed by minimally invasive techniques.

Choledochotomy

When faced with a sick patient whose investigations show that the cause of the cholangitis is stones in the common bile duct and minimally invasive techniques for stone extraction are not available, the surgeon has no alternative but to undertake a laparotomy. The aim of this surgery is to drain the common bile duct and remove the stones through a longitudinal incision in the duct. When the duct is clear of stones, a T-tube is inserted and the duct closed around it; the long limb is brought out on the right side and the bile allowed to drain externally. When the bile has become clear and the patient has recovered, a cholangiogram is performed. If residual stones are found, the tube is left in place for 6 weeks so that the track is 'mature'. The radiologist can then use the tract for percutaneous removal of the stones (**Figure 67.36**). Once the radiologist has removed the tube, the track will close and the patient will make a rapid recovery.

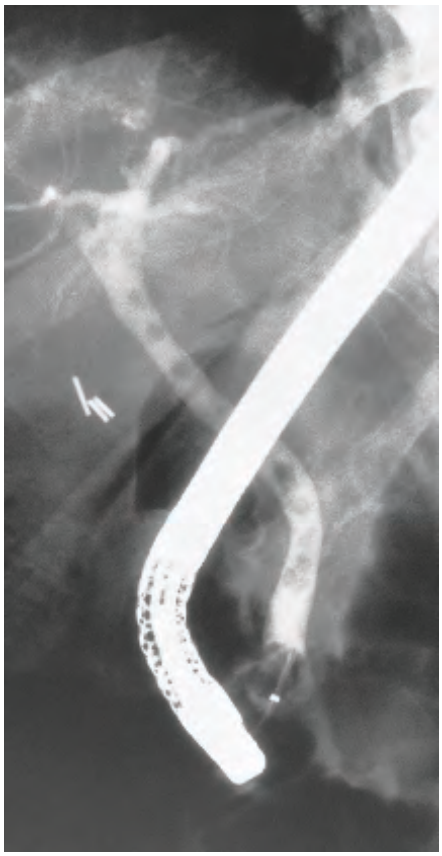

Figure 67.34 This patient presented with jaundice 4 days after a laparoscopic cholecystectomy. The duct contained multiple stones.

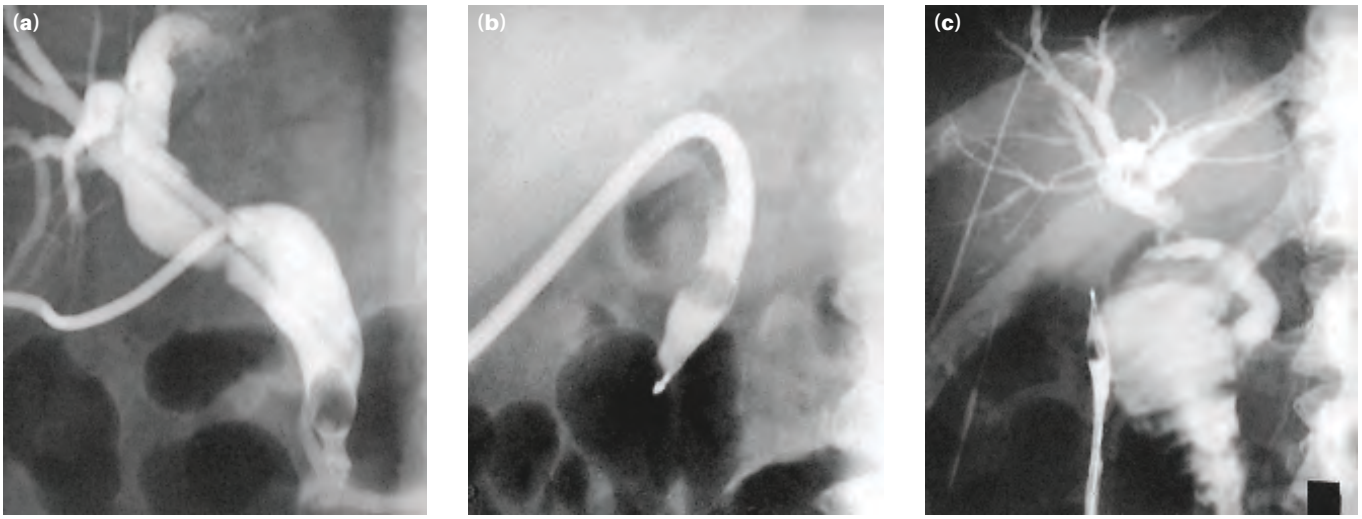

Figure 67.36 Extraction of a stone from the common bile duct by the Burhenne technique. **(a)** A T-tube in situ with a stone in the duct. **(b)** A steerable catheter has been manipulated into the duct and a basket placed around the stone. **(c)** The stone being extracted from the bile duct along the T-tube track.

Stricture of the bile duct

The causes of benign biliary stricture are given in *Summary box 67.5*. Bile duct strictures may be investigated radiologically as described in *Summary box 67.6*.

Summary box 67.5

Causes of benign biliary stricture

Congenital
- Biliary atresia

Bile duct injury at surgery
- Cholecystectomy
- Choledochotomy
- Gastrectomy
- Hepatic resection
- Transplantation

Inflammatory
- Stones
- Cholangitis
- Parasitic
- Pancreatitis
- Sclerosing cholangitis
- Radiotherapy

Trauma

Idiopathic

Summary box 67.6

Radiological investigation of biliary strictures
- Ultrasonography
- Cholangiography via T-tube, if present
- ERCP
- MRCP
- Percutaneous transhepatic cholangiography
- CT scan

PRIMARY SCLEROSING CHOLANGITIS

Primary sclerosing cholangitis is an idiopathic fibrosing inflammatory condition of the biliary tree that affects both intrahepatic and extrahepatic ducts. It is of unknown origin but the association of hypergammaglobulinaemia and elevated markers such as smooth muscle antibodies and antinuclear factor suggest an immunological basis. The majority of patients are between 30 and 60 years of age. There appears to be a male predominance and a strong association with inflammatory bowel disease, especially ulcerative colitis.

Common symptoms include right upper quadrant discomfort, jaundice, pruritus, fever, fatigue and weight loss. Investigation reveals a cholestatic pattern to the liver function tests with elevation of the serum alkaline phosphatase and γ-glutamyl transferase and smaller rises in the aminotransferases. Bilirubin values can be variable and may fluctuate. Imaging studies such as MRCP or ERCP may demonstrate stricturing and beading of the bile ducts (**Figure 67.37**). A liver biopsy is helpful to confirm the diagnosis and may help guide therapy by excluding cirrhosis. The important differential diagnoses are secondary sclerosing cholangitis and cholangiocarcinoma. The latter may be very difficult to diagnose and a high index of suspicion is required especially in the setting of unexplained clinical deterioration.

Medical management with antibiotics, vitamin K, cholestyramine, steroids and immunosuppressant drugs such as azathioprine is generally unsuccessful. Endoscopic stenting of dominant strictures and, in selected patients with predominantly extrahepatic disease, operative resection may be worthwhile. For patients with cirrhosis, liver transplantation is the best option. Five-year survival following transplantation in high-volume centres is in excess of 80%.

Joachim Burhenne, 1926–1996, radiologist, Vancouver, Canada. His technique transformed stone management in the 1970s.

Figure 67.37 Sclerosing cholangitis in a patient with ulcerative colitis, visualised by endoscopic retrograde cholangiopancreatography.

Immunoglobulin (Ig)G_4-related cholangitis

This recently recognised entity presents with diffuse or segmental narrowing of the intra- or extrahepatic bile ducts. Its features may make differentiation from primary sclerosing cholangitis (PSC), cholangiocarcinoma or pancreatic cancer difficult. However, patients often have elevated serum IgG_4 levels and concomitant autoimmune pancreatitis, IgG_4-related sialadenitis or retroperitoneal fibrosis. Biliary biopsies show lymphoplasmacytic sclerosing cholangitis. Treatment is with systemic steroids. Failure to respond to steroid therapy should make one reconsider the diagnosis and exclude an underlying malignancy.

PARASITIC INFESTATION OF THE BILIARY TRACT

Biliary ascariasis

The roundworm *Ascaris lumbricoides* commonly infests the intestines of inhabitants of Asia, Africa and Central America. It may enter the biliary tree through the ampulla of Vater and cause biliary pain. Complications include strictures, suppurative cholangitis, liver abscesses and empyema of the gallbladder. In the uncomplicated case, antispasmodics can be given to relax the sphincter of Oddi and the worms will return to the small intestine to be dealt with by anthelminthic drugs. Operation may be necessary to remove the worms or deal with complications. Worms can be extracted via the ampulla of Vater by ERCP.

Clonorchiasis (Asiatic cholangiohepatis)

This disease is endemic in the Far East. The fluke, up to 25 mm long and 5 mm wide, inhabits the bile ducts, including the intrahepatic ducts. Fibrous thickening of the duct walls occurs. Many cases are asymptomatic. Complications include biliary pain, stones, cholangitis, cirrhosis and bile duct carcinoma. Choledochotomy and T-tube drainage and, in some cases, choledochoduodenostomy are required. Because a process of recurrent stone formation is set up, a choledochojejunostomy with a Roux loop fixed to the adjacent abdominal wall is performed in some centres to allow easy subsequent access to the duct system.

Hydatid disease

A large hydatid cyst may obstruct the hepatic ducts. Sometimes, a cyst will rupture into the biliary tree and its contents cause obstructive jaundice or cholangitis, requiring appropriate surgery (see Chapter 6).

TUMOURS OF THE BILE DUCT

Benign tumours of the bile duct

These are uncommon and may be an incidental finding. For symptomatic patients, the duration of symptoms may vary from a few days to months and their clinical presentation may in fact mimic conditions such as cholecystitis, choledocholithiasis, cholangiocarcinoma or pancreatic cancer.

Benign neoplasms causing biliary obstruction may be classified as follows:

- papilloma and adenoma;
- multiple biliary papillomatosis;
- granular cell myoblastoma;
- neural tumours;
- leiomyoma;
- endocrine tumours.

Papilloma and adenoma

The most common benign neoplasms arise from the glandular epithelium lining the bile ducts. They can occur throughout the biliary system but are more frequent in the periampullary area. Lesions in this area may protrude through the ampulla of Vater and be visible at endoscopy. Jaundice is the most common symptom, occurring in >90% of cases. Coexisting gallstones are uncommon.

Treatment depends on the age, the general status of the patient and site of the disease but in general should consist of total resection of the lesion. In some cases a wide local resection can be performed.

Papillomatosis

This rare condition is characterised by the presence of multiple mucus-secreting tumours of the biliary epithelium. Patients present with obstructive jaundice, which may be intermittent, often complicated by cholangitis. These tumours have

malignant potential and should be resected. This may involve liver resection if the disease is confined to a hepatic lobe. If both lobes are affected then liver transplantation may be required.

Granular cell myoblastoma, neural tumours, leiomyoma and endocrine tumours are extremely uncommon. In general, if biliary obstruction occurs it should be relieved by biliary resection, bypass or endoscopic stenting.

Malignant tumours of the biliary tract

Malignant tumours of the gallbladder and extrahepatic biliary tree are uncommon. Gallbladder cancer is the predominant type, accounting for 60–70% of cases with the remainder distributed between the intra- and extrahepatic biliary trees.

Unfortunately, owing to advanced stage at presentation, surgical resection, which offers the best survival, is only possible for a minority of patients. Thus, for most patients treatment is generally palliative in nature and survival is limited.

Summary box 67.7

Bile duct cancer (cholangiocarcinoma)

- Rare, but incidence increasing
- Most patients present with abnormal liver function tests or frank jaundice
- Diagnosis by ultrasound, CT or MRCP scanning
- The majority of patients receive palliative care only
- Complete surgical excision possible in <10%
- Prognosis poor: 90% die within 1 year, from liver failure or biliary sepsis
- Adjuvant chemoradiation therapy has a limited role

Incidence

Cholangicarcinoma is a rare malignancy. The overall annual incidence is 1–1.5 per 100 000 with the peak incidence in the 8th decade. The male:female ratio is approximately 1.5:1.

Anatomically, tumours involving the biliary confluence (hilar cholangiocarcinoma or Klatskin tumours) account for 60% of cases, with the remainder involving the distal bile duct (20–30%) or intrahepatic ducts (10–20%).

Risk factors

A minority of patients presenting with cholangiocarcinoma have a known risk factor. The major risk factor in Western practice is primary sclerosing cholangitis (PSC). It is estimated that a long-standing history of PSC increases the risk of developing biliary tract cancer by 20-fold compared to the normal population. It appears that patients with PSC and concomitant inflammatory bowel disease are at significantly higher risk of developing cancer compared to those without the disease. Cholangiocarcinoma appears to occur at an earlier age in patients with PSC (30–50 years of age) compared to the general population. In addition, disease is usually multifocal and detected at advanced stage with resultant poor prognosis.

Congenital cystic disease (Caroli's disease, choledochal cysts), hepatolithiasis, oriental cholangiohepatitis, hepatitis C viral infection and infestation with liver flukes have also been associated with an increased risk of cholangiocarcinoma. Liver fluke infestations are particularly important in South-East Asia. *Opisthorchis viverrini* and *Clonorchis sinensis* infestations are important in Thailand, Laos and western Malaysia. While the pathophysiology is unclear, it is thought that these parasites cause chronic inflammation that leads to DNA mutations through production of carcinogens and free radicals, which stimulate cellular proliferation in the intrahepatic bile ducts and ultimately can lead to invasive cancer.

Other risk factors suggested include chemical carcinogens such as thorium dioxide, vinyl chloride, dioxin and asbestos.

Summary box 67.8

Risk factors for cholangiocarcinoma

Chronic inflammatory conditions

- Primary sclerosing cholangitis (PSC)
- Oriental cholangiohepatitis
- Hepatitis C infection

Parasitic infections

- *Opisthorchis viverrini*
- *Clonorchis sinensis*

Congenital

- Choledochal cysts
- Caroli's disease

Chemical agents

- Thorium dioxide (Thorotrast)
- Vinyl chloride
- Dioxin
- Asbestos

Post surgical

- Biliary–enteric anastomosis

Clinical features

Early symptoms of cholangiocarcinoma are often non-specific, with abdominal pain, early satiety, anorexia and weight loss commonly seen. Symptoms associated with biliary obstruction (puritus and jaundice) may be present in a minority of patients. In these patients, examination often demonstrates clinical signs of jaundice, cachexia is often noticeable and a palpable gallbladder present if the obstruction is in the distal common bile duct (Courvoisier's sign).

Investigations

Biochemical investigations will confirm the presence of obstructive jaundice (elevated bilirubin, alkaline phosphatase and γ-glutamyltransferase). The tumour-marker CA 19-9 may also be elevated. Imaging studies such as ultrasound, MDR-CT and MRI/MRCP are essential for diagnosis and staging. These studies allow the level of biliary obstruction to be defined and determine the locoregional extent of disease and the presence of metastases (**Figure 67.38**).

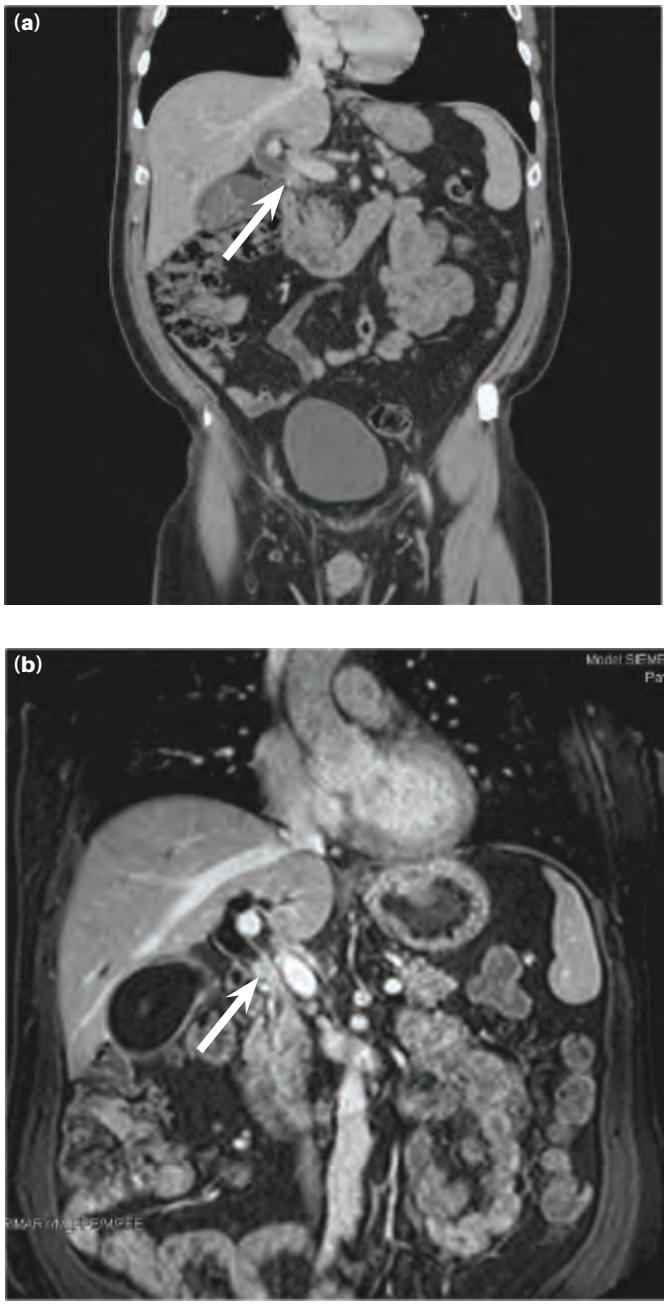

Figure 67.38 **(a)** A computed tomography scan demonstrating a cholangiocarcinoma obstructing the common hepatic duct (arrow). **(b)** Magnetic resonance cholangiopancreatography showing the level of obstruction (arrow).

Direct cholangiography using ERCP or PTC is also used following non-invasive studies. Both can define the level of obstruction and allow access to the biliary system for biopsy and placement of endobiliary stents for biliary drainage. The choice between the modalities depends on local availability and the anatomical site of the tumour, with PTC preferred for more proximal lesions and ERCP favoured for distal tumours. Cytology can be obtained from either procedure but it is often non-diagnostic.

Positron emission tomography (PET) is useful in detecting lymph node and distant metastases but has limited value in assessment of local resectability.

The anatomical extent of the disease is classified according to either the Bismuth–Corette or Memorial Sloan–Kettering Cancer Centre Classification (**Figure 67.39**).

Treatment

A multidisciplinary approach is required in all cases. The choice of treatment depends on the site and extent of the disease. Unfortunately, the majority of patients present with advanced disease. However, 10–15% are suitable for surgical resection, which offers the only hope for long-term survival. The aim of surgical resection is to achieve a complete resection with negative pathological margins (R0 resection) and safely restore biliary–enteric continuity.

Whether or not the disease is resectable depends on patient factors (comorbidities, presence or absence of chronic liver disease), and tumour factors (extent of disease within the biliary tree, vascular involvement, presence or absence of metastatic disease). Depending on the site of disease, surgery may involve either a standard or extended hepatic resection with *en bloc* lymphadenectomy and reconstruction of the biliary tree. Distal common duct tumours may require a pancreaticoduodenectomy (Whipple procedure). Local resection should be avoided.

In selected patients, liver transplantation has been recommended for those with locally unresectable disease without evidence of distant metastases. Transplantation is often combined with neoadjuvant chemoradiation therapy. While emerging data are encouraging, this aggressive approach remains controversial and is reserved for selected patients in specialised centres.

Following resection, disease-specific survival is related to the T-stage, nodal and margin status. Approximately 35% of patients will survive 5 years after surgery. Adjuvant chemotherapy and radiotherapy have a limited role to play and have not been demonstrated to add survival benefit following surgical resection. However, patients at high risk for recurrence (positive surgical margins or node positive) may benefit from adjuvant therapy and should be referred for a medical or radiation oncology opinion.

The majority of patients who present with unresectable disease are candidates for palliative therapy. The aim is to maintain or improve quality of life by relieving symptoms and preventing cholestatic liver failure. Biliary obstruction can be relieved by either endoscopic (ERCP) or percutaneous (PTC) methods. Surgical bypass rarely has a role apart from in patients who present with a distal bile duct lesion and are found to have unresectable disease at operation.

Cancer of the gallbladder

Incidence

Carcinoma of the gallbladder is a rare disease, but extremely variable by geographical region and racial–ethnic groups. The

Herni Bismuth, contemporary, hepatobiliary surgeon, Hôpital Paul Bruce, Villejif, France, with **Dr Marvin Corlette** described the classification of cholangiocarcinoma in 1975.

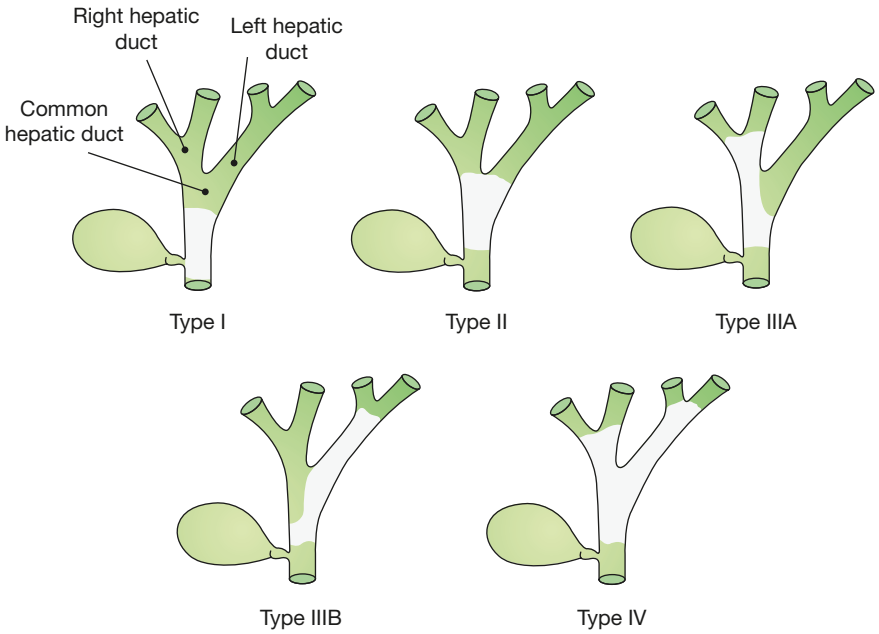

Figure 67.39 Bismuth-Corlette Classification for cholangiocarcinoma.

highest incidence is among Chileans, American Indians and residents in parts of northern India, where it accounts for as much as 9% of all biliary tract disease. Women appear to have a higher incidence across all geographical areas. In Western practice, gallbladder cancer accounts for less than 1% of new cancer diagnoses. The disease usually presents in the 7th or 8th decade. The aetiology is unclear but there appears to be an association with pre-existing gallstone disease, suggesting that chronic inflammation may play a role in a manner similar to tumours of the common bile duct. Calcification of the gallbladder wall, presumably due to chronic inflammation (porcelain gallbladder), is also associated with a small increased risk of cancer (see **Figure 67.4**). Chronic infection may also promote development of gallbladder cancer and the risk in typhoid carriers is significantly increased over the general population.

Gallbladder polyps may be found in approximately 5% of patients who undergo ultrasonography (**Figure 67.40**). The majority are either adenomyomatosis or cholesterol polyps and have no malignant potential. True adenomatous polyps occur in 0.3–0.5% of the population. The risk of malignant transformation increases with increasing size of the polyp.

Summary box 67.9

Gallbladder cancer

- Very rare
- Similar presentation to benign biliary disease i.e., gallstones
- Diagnosis by ultrasound, CT, MRI/MRCP
- Most patients present with advanced disease
- Surgical resection in less than 10% – remainder receive palliative treatment
- Prognosis is poor – median survival approximately 6 months

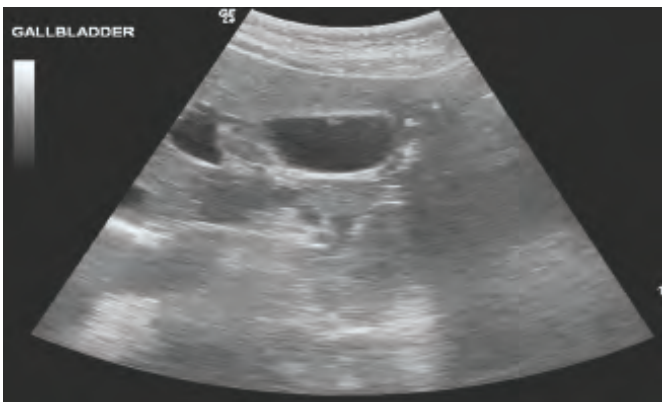

Figure 67.40 Ultrasound demonstrating a gallbladder polyp. Note the lack of the acoustic shadow.

Pathology

The majority (90%) of tumours are adenocarcinomas. Squamous carcinomas also occur and are believed to arise from areas of mucosal squamous metaplasia.

At operation, localised carcinomas are difficult to differentiate from chronic cholecystitis; the tumour most commonly is nodular and infiltrative, with thickening of the gallbladder wall, often extending to the whole gallbladder. The tumour spreads by direct extension into the liver, seeding of the peritoneal cavity and involvement of the perihilar lymphatics and neural plexuses. At the time of presentation the majority of tumours are advanced.

Clinical features

Patients may be asymptomatic at the time of diagnosis. Symptoms, if present, are usually indistinguishable from those of benign gallbladder disease such as biliary colic or cholecystitis, particularly in older patients. Jaundice and anorexia are late features. A palpable mass is a late sign.

Investigation

Laboratory findings are generally non-specific but may be consistent with biliary obstruction. Non-specific findings such as anaemia, leukocytosis, mild elevation in transaminases and increased inflammatory markers such as ESR or C-reactive protein may be present. Serum CA19-9 is elevated in approximately 80% of patients.

The preoperative diagnosis is often made on ultrasonography, and confirmed by a CT scan or MRI/MRCP. Preoperative staging should aim to determine the local extent of disease and exclude the presence of distant metastases. A percutaneous biopsy under radiological guidance is often done to obtain tissue for pathological examination. In selected cases, laparoscopic examination is useful in staging the disease. Laparoscopy can detect peritoneal or liver metastases which would preclude further surgical resection (**Figure 67.41**).

PET scanning also has a role in detecting metastatic disease.

Summary box 67.10

Aims of staging gallbladder cancer

- Assessment of local disease
- Detection of metastatic disease:
  - Liver
  - Peritoneal
  - Lymphatic
  - Extra-abdominal disease

Figure 67.41 Laparoscopic staging in a patient with gallbladder carcinoma demonstrating gross peritoneal metastases.

Treatment and prognosis

The majority of patients have advanced disease at presentation, and are not candidates for surgical therapy. Surgery is indicated in only very selected cases.

Cholecystectomy should be performed for all gallbladder polyps greater than 1 cm. Polyps less than 1 cm can be followed with serial ultrasonography to detect any change in size or character as the incidence of malignancy in polyps less than 1 cm is extremely low.

Radical *en bloc* resection that may include segmental or extended hepatectomy, bile duct resection and regional lymphadenectomy should be considered in selected patients. The aim is to remove the tumour entirely and achieve negative histopathological margins.

Patients can have the disease diagnosed following histopathological examination of the gallbladder removed for presumed benign disease. In these cases, the need for further surgery is determined by the stage of disease. For early-stage disease, confined to the mucosa or muscle of the gallbladder, no further treatment is indicated. However, for transmural disease, a radical *en bloc* resection of the gallbladder fossa and surrounding liver along with the regional lymph nodes should be performed. If the initial procedure was performed laparoscopically, the surgeon should examine the laparoscopic port sites. Routine resection of port sites is no longer recommended. However, it is recognised that the finding of disease at the port sites is a sign of generalised peritoneal disease and carries a very poor prognosis.

For the majority of patients a non-operative approach to palliation is best. Obstructive jaundice can be relieved by endoscopic and/or percutaneous methods. The value of adjuvant therapy is unproven.

Gallbladder cancer for most patients is a lethal disease with a grim prognosis. The median survival is less than 6 months and a 5-year survival figure of 5% has been reported.

Chapter 68

The pancreas

Learning objectives

To understand:

- The anatomy and physiology of the pancreas
- Investigations of the pancreas
- Congenital abnormalities of the pancreas
- Assessment and management of pancreatitis
- Diagnosis and treatment of pancreatic cancer

ANATOMY AND PHYSIOLOGY

Anatomy

The name 'pancreas' is derived from the Greek '*pan*' (all) and '*kreas*' (flesh). For a long time, its glandular function was not understood, and it was thought to act as a cushion for the stomach. The pancreas is situated in the retroperitoneum. It is divided into a head, which occupies 30% of the gland by mass, and a body and tail, which together constitute 70%. The head lies within the curve of the duodenum, overlying the body of the second lumbar vertebra and the vena cava. The aorta and the superior mesenteric vessels lie behind the neck of the gland. Coming off the side of the pancreatic head and passing to the left and behind the superior mesenteric vein is the uncinate process of the pancreas. Behind the neck of the pancreas, near its upper border, the superior mesenteric vein joins the splenic vein to form the portal vein (**Figures 68.1 and 68.2**). The tip of the pancreatic tail extends up to the splenic hilum.

The pancreas weighs approximately 80 g. Of this, 80–90% is composed of exocrine acinar tissue, which is organised into lobules. The main pancreatic duct branches into interlobular and intralobular ducts, ductules and, finally, acini. The main duct is lined by columnar epithelium, which becomes cuboidal in the ductules. Acinar cells are clumped around a central lumen, which communicates with the duct system. Clusters of endocrine cells, known as islets of Langerhans, are distributed throughout the pancreas. Islets consist of different cell types: 75% are B cells (producing insulin); 20% are A cells (producing glucagon); and the remainder are D cells (producing somatostatin) and a small number of pancreatic polypeptide cells. Within an islet, the B cells form an inner core surrounded by the other cells. Capillaries draining the islet cells drain into the portal vein, forming a pancreatic portal system.

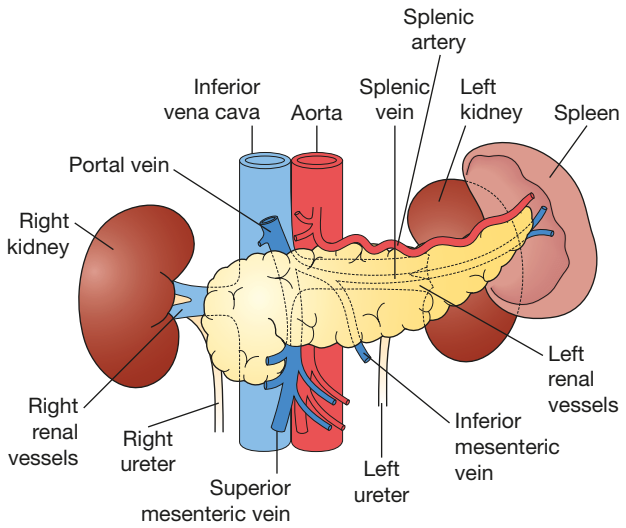

Figure 68.1 The posterior relations of the pancreas.

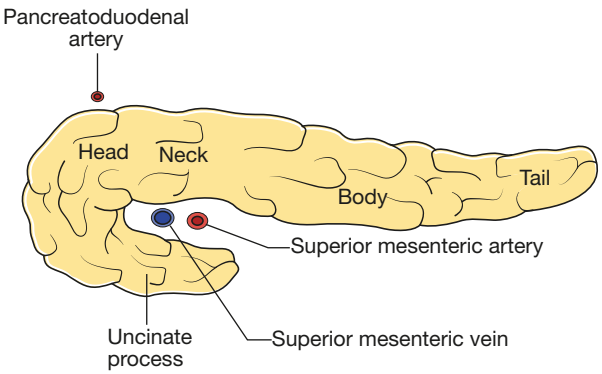

Figure 68.2 Transverse section of the pancreas. Note the position of the uncinate process behind the vessels.

Paul Langerhans, 1847–1888, Professor of Pathological Anatomy, Freiberg, Germany, described the islets in 1869, in his doctoral thesis. He later contracted tuberculosis, resigned and moved to warmer climes in Madeira, where he also studied marine worms.

There are nine key processes that occur during pancreatic embryogenesis (*Table 68.1*). Malrotation of the ventral bud in the fifth week results in an annular pancreas, while the mode of ductule fusion in the seventh week produces the various possible ductular patterns. Between the 12th and 40th weeks of fetal life, the pancreas differentiates into exocrine and endocrine elements. The primitive ducts and their ductules are responsible for the lobular arrangement of the pancreas. Congenital anomalies of the pancreas are varied and arise during the early phase of development. The anatomy of the pancreatic duct is variable as a result of the primordial bud development. The dorsal duct is expressed in a variable manner in the adult, as outlined in **Figure 68.3**. Approximately 10% of patients will have a significant flow from the main duct through the accessory papilla. The anatomy of the main duodenal papilla, also known as the ampulla of Vater, is also variable (**Figure 68.4**).

TABLE 68.1 Steps in the development of the pancreas.

1	Day 26	Dorsal pancreatic duct arises from the dorsal side of the duodenum
2	Day 32	Ventral bud arises from the base of the hepatic diverticulum
3	Day 37	Contact occurs between the two buds. Fusion by the end of week 6
4	Week 6	Ventral bud produces the head and uncinate process
5	Week 6	Ducts fuse
6	Week 6	Ventral duct and distal portion of the dorsal duct form the main duct (duct of Wirsung)
7	Week 6	Proximal dorsal duct forms the duct of Santorini
8	Month 3	Acini appear
9	Months 3–4	Islets of Langerhans appear and become biologically active

Giovanni Domenico Santorini, 1681–1737, Professor of Anatomy and Medicine, Venice, Italy. His drawings of the accessory pancreatic duct were published after his death.

Johann Georg Wirsung, 1589–1643, Professor of Anatomy, Padua, Italy, described the pancreatic duct in 1642, when dissecting the cadaver of a man hanged for murder. He died a year later from an assassin's bullet, on his doorstep.

Eugen von Hippel, 1866–1939, Professor of Ophthalmology, Göttingen, Germany.

Arvid Lindau, 1892–1958, pathologist, Lund, Sweden, established the link between the retinal angiomatosis described by von Hippel and the cerebellar and visceral components of the syndrome.

Abraham Vater, 1684–1751, Professor of Anatomy and Botany, and later of Pathology and Therapeutics, Wittenberg, Germany.

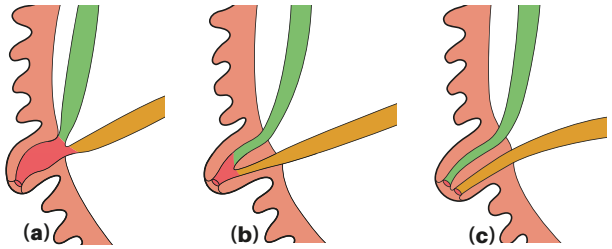

Figure 68.4 Variations in the relation of the common bile duct and main pancreatic duct at the main duodenal papilla. In **(a)**, there is a common channel with no sphincter mechanism protecting flow between the ducts. In **(b)**, there is a partial common channel, while in **(c)**, there is separation of the two channels. Gallstone pancreatitis is more likely with **(a)** and **(b)**.

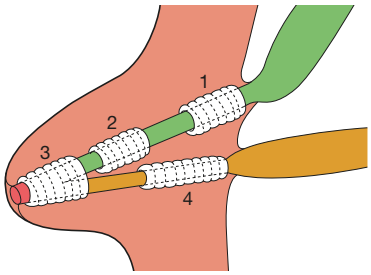

Figure 68.5 The complexity of the sphincter of Oddi. (1) Superior choledochal sphincter; (2) inferior choledochal sphincter; (3) ampullary sphincter; (4) pancreatic sphincter.

The outlet of each duct is protected by a complex sphincter mechanism (sphincter of Oddi) (Figure 68.5).

Physiology

In response to a meal, the pancreas secretes digestive enzymes in an alkaline (pH 8.4) bicarbonate-rich fluid. Spontaneous secretion is minimal; the hormone secretin, which is released from the duodenal mucosa, evokes a bicarbonate-rich fluid. Cholecystokinin (CCK) (synonym: pancreozymin) is released from the duodenal mucosa in response to food. CCK is responsible for enzyme release. Vagal stimulation increases the volume of secretion. Protein is synthesised at a greater rate (per gram of tissue) in the pancreas than in any other tissue, with the possible exception of the lactating mammary gland. About 90% of this protein is exported from the acinar cells as a variety of digestive enzymes. Approximately 6–20 g of digestive enzymes enters the duodenum each day. Nascent proteins are synthesised as preproteins and undergo modification in a sequence of steps. The proteins move from the rough endothelial endoplasmic reticulum to the Golgi complex, where lysosomes and mature zymogen storage granules containing proteases are stored, and then to the ductal surface of the cell, from which they are extruded by exocytosis. During this phase, the proteolytic enzymes are in an inactive form, the maintenance of which is important in preventing pancreatitis.

INVESTIGATIONS (*TABLE 68.2*)

Estimation of pancreatic enzymes in body fluids

When the pancreas is damaged, enzymes such as amylase, lipase, trypsin, elastase and chymotrypsin are released into the serum. Measurement of serum amylase is the most widely used test of pancreatic damage (serum lipase is more sensitive and specific, but is not widely available). The serum amylase rises within a few hours of pancreatic damage and declines over the next 4–8 days. A markedly elevated serum level is highly suspicious but not diagnostic of acute pancreatitis. Urinary amylase and amylase–creatinine clearance ratios add little to diagnostic accuracy. If confirmation of the diagnosis is required, computed tomography (CT) of the pancreas is of greater value.

TABLE 68.2 Investigation of the pancreas.

Serum enzyme levels

Summary box 68.2

Causes of raised serum amylase level other than acute pancreatitis

- Upper gastrointestinal tract perforation
- Mesenteric infarction
- Torsion of an intra-abdominal viscus
- Retroperitoneal haematoma
- Ectopic pregnancy
- Macroamylasaemia
- Renal failure
- Salivary gland inflammation

Pancreatic function tests

Pancreatic exocrine function can be assessed by directly measuring pancreatic secretion in response to a standardised stimulus. The stimulus to secretion can be physiological, e.g. ingestion of a test meal, as in the Lundh test, or pharmacological, e.g.

Ruggero Oddi, 1866–1913, anatomist and physiologist, Perugia, Italy, wrote about the structure and function of the ampullary sphincter in 1887, when still a student. He struggled in later life with drug addiction.

Camillo Golgi, 1844–1926, Professor of Anatomy and Histology at Pavia, and later at Siena, Italy, developed silver staining of neural tissue and received the Nobel Prize in 1906 (with Ramon y Cajal) for his studies in neuroanatomy.

Göran Lundh, 1926–1999, surgeon, Södersjukhuset, Stockholm, Sweden. Working with Bengt Borgstrom, a biochemist at Lund University, he described this test of pancreatic function in 1962. The test has largely been superseded by measurement of faecal elastase.

intravenous injection of a hormone such as secretin or CCK. Duodenal intubation has to be performed with a triple-lumen tube so that the gastric and duodenal juices can be aspirated, and a non-absorbable marker such as polyethylene glycol is used to assess the completeness of the aspiration. The nitroblue tetrazolium–*para*-aminobenzoic acid (NBT–PABA) test provides an indirect measure of pancreatic function. The substance is administered orally and degraded in the gut by a pancreatic enzyme, and the breakdown product (PABA) is absorbed by the intestine and excreted in the urine; its urinary level is measured. The pancreolauryl test works on a similar principle. These tests are cheap and easy to perform, but are non-specific, especially following gastrectomy and in conditions that may alter gastrointestinal transit and intestinal absorptive capacity. Measurement of the enzyme elastase in stool is simple, specific and now used widely. A low level of faecal elastase indicates exocrine insufficiency.

Imaging investigations

Ultrasonography

Ultrasonography is the initial investigation of choice in patients with jaundice to determine whether or not the bile duct is dilated, the coexistence of gallstones or gross disease within the liver such as metastases. It may also define the presence or absence of a mass in the pancreas (**Figure 68.6**). However, obesity and overlying bowel gas often make interpretation of the pancreas itself unsatisfactory.

Computed tomography

Most significant pathologies within the pancreas can be diagnosed on high-quality CT scans, with three-dimensional reconstruction if necessary. A specific pancreatic protocol should be followed. An initial unenhanced CT scan is essential to determine the presence of calcification within the pancreas and gall bladder (**Figure 68.7**). Then, following rapid injection of intravenous contrast, scanning is performed in the arterial and venous phases. The stomach and duodenum should be outlined with water and distended to define the duodenal loop. Pancreatic carcinomas of 1–2 cm in size can usually be demonstrated (**Figure 68.8**). Endocrine tumours are also well imaged on CT (**Figure 68.9**). In patients with pancreatitis, necrotic areas within the gland can be identified by the absence of contrast enhancement on CT. Inflammatory collections and pseudocysts can be seen (**Figure 68.10**). CT-guided drainage is helpful in the treatment of pancreatic collections, cysts and pseudocysts, and facilitates percutaneous fine-needle or Trucut biopsy.

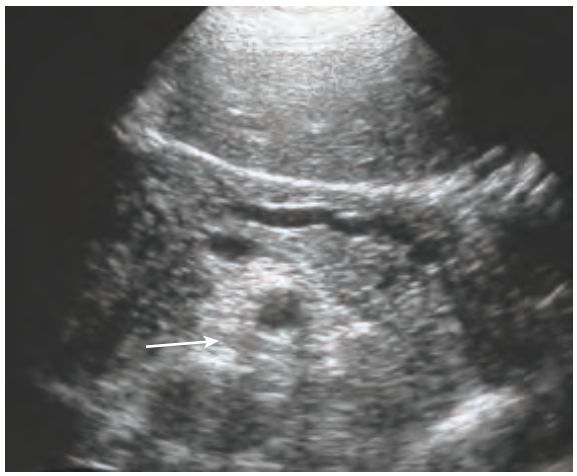

Figure 68.6 Ultrasound scan showing a mass in the head of the pancreas (marked by an arrow) and a dilated pancreatic duct in the body of the gland (courtesy of Dr Alison McLean).

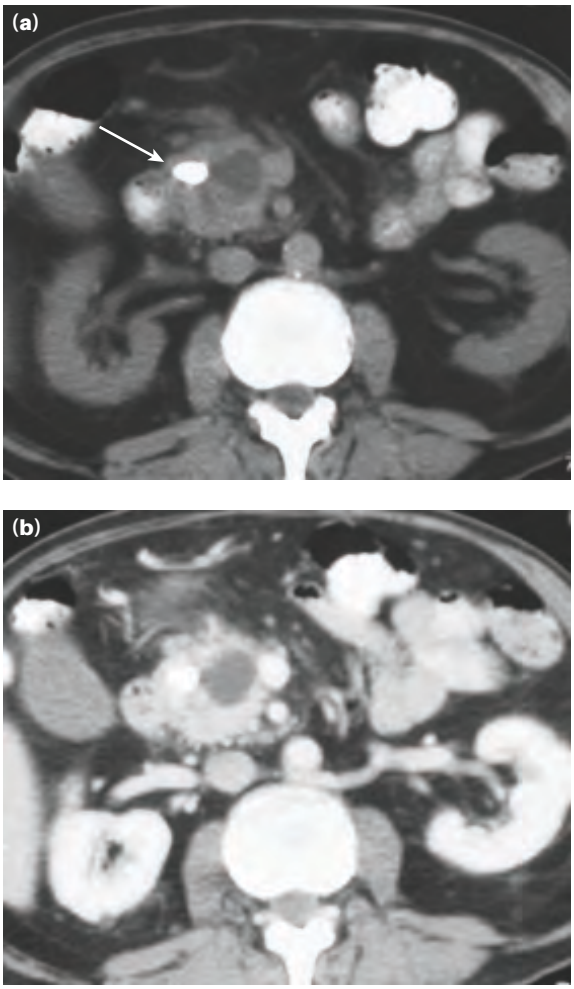

Figure 68.7 **(a)** Unenhanced computed tomography scan of a man with chronic pancreatitis, showing a focus of calcification (marked by an arrow) in the head of the pancreas and a cyst adjacent to that. Oral contrast has been administered. **(b)** The same area after injection of intravenous contrast.

Magnetic resonance imaging

With magnetic resonance imaging (MRI), the pancreas can be clearly identified, and the anatomy of the bile duct and the pancreatic duct, together with fluid collections, can be defined. Magnetic resonance cholangiography and pancreatography (MRCP) may well replace *diagnostic* endoscopic cholangiography and pancreatography (ERCP) as it is non-invasive and less expensive (**Figure 68.11**). Using the technique in conjunction with intravenous injection of secretin, emptying of the pancreatic duct can be demonstrated to show the absence or presence of obstruction.

Figure 68.8 Contrast-enhanced computed tomography scan of a patient with a carcinoma of the pancreatic head. The main bulk of the tumour lies inferior to the section shown here. The dilated bile duct (1) and main pancreatic duct (2) can be seen, with tumour infiltration around them. There is a thrombus in the superior mesenteric vein (3). The gall bladder is distended (4).

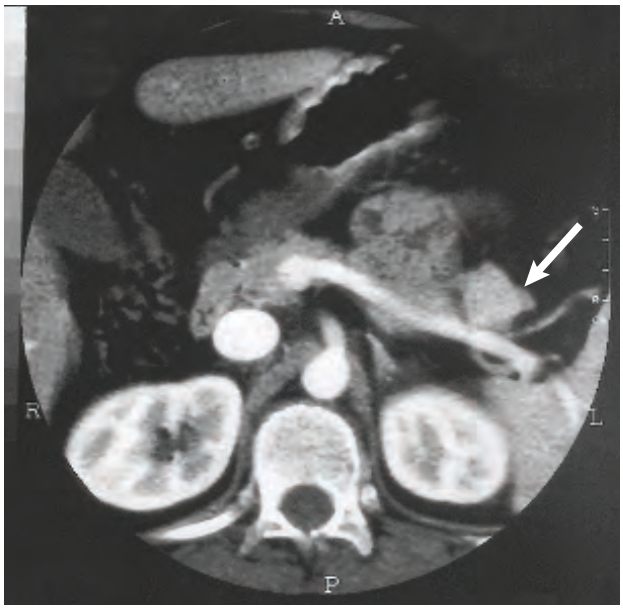

Figure 68.9 Computed tomography scan showing a hypervascular insulinoma (arrow) adjacent to the splenic vein. Local excision of the tumour resulted in normoglycaemia.

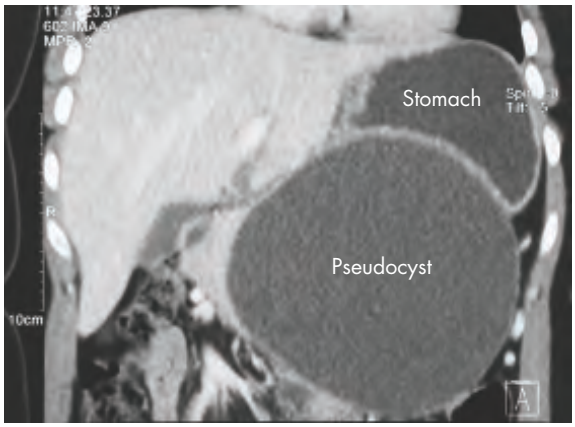

Figure 68.10 Computed tomography scan of a large pseudocyst in relation to the body and tail of the pancreas.

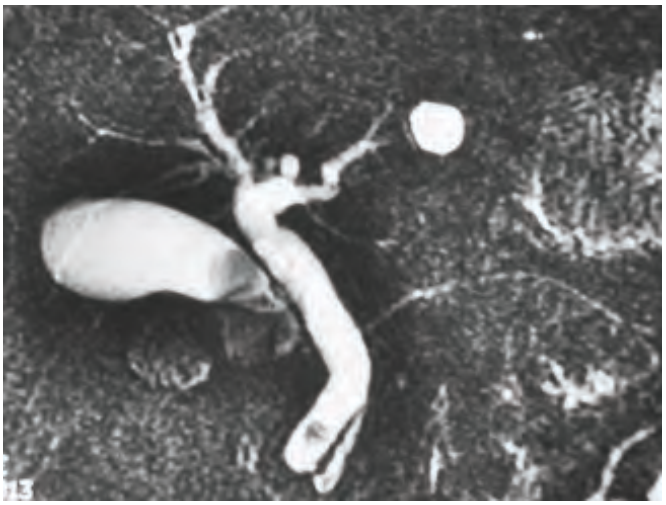

Figure 68.11 Magnetic resonance cholangiopancreatography in a patient with obstructive jaundice. A dilated common bile duct was seen on ultrasound, but no pancreatic mass lesion was visible on computed tomography. The bile duct and the main pancreatic duct are seen very well, with a stone visible in the lower part of the bile duct and another in the neck of the gall bladder.

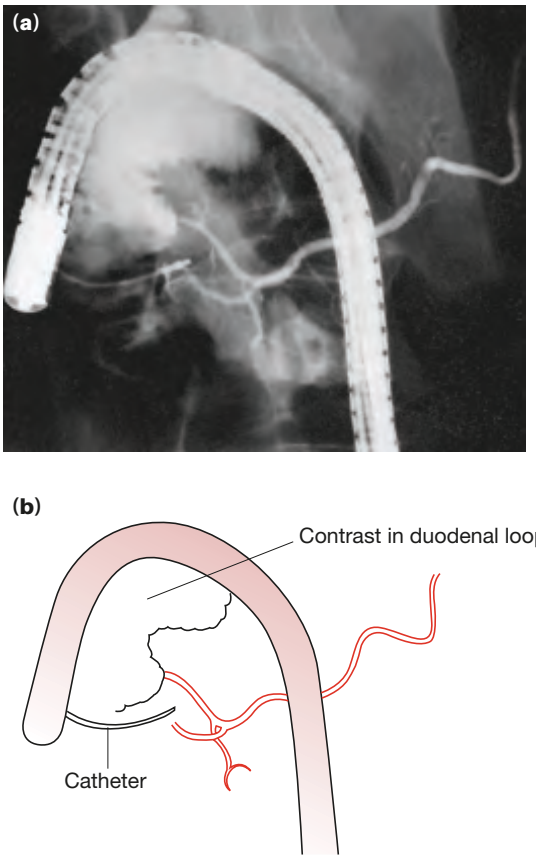

Figure 68.12 Endoscopic retrograde cholangiopancreatography. **(a)** Normal pancreatic duct with filling of the duct of Santorini from the duct of Wirsung. **(b)** Diagrammatic outline of **(a)**.

Endoscopic retrograde cholangiopancreatography

ERCP is performed using a side-viewing fibreoptic duodenoscope. The ampulla of Vater is intubated, and contrast is injected into the biliary and pancreatic ducts to display the anatomy radiologically (Figure 68.12). In pancreatic carcinoma, the main pancreatic duct may be narrowed or completely obstructed at the site of the tumour (Figure 68.13), or the distal bile duct may be narrowed. Concurrent narrowing of both ducts results in the so-called double duct sign (Figure 68.14). Changes seen in chronic pancreatitis include the presence of pancreatic duct strictures, dilatation of the main pancreatic duct with stones, abnormalities of pancreatic duct side branches, communication of the pancreatic duct with cysts, and bile duct strictures (Figures 68.15–68.17). A plain radiograph before contrast studies is essential to delineate calcification (Figure 68.18). In addition to imaging, bile or pancreatic fluid and brushings from duct strictures can yield cells that confirm the suspected diagnosis of carcinoma (Figure 68.19). Brush cytology taken from malignant strictures at the time of ERCP yields a positive diagnosis in 40–50% of patients. ERCP also allows the placement of biliary and pancreatic stents.

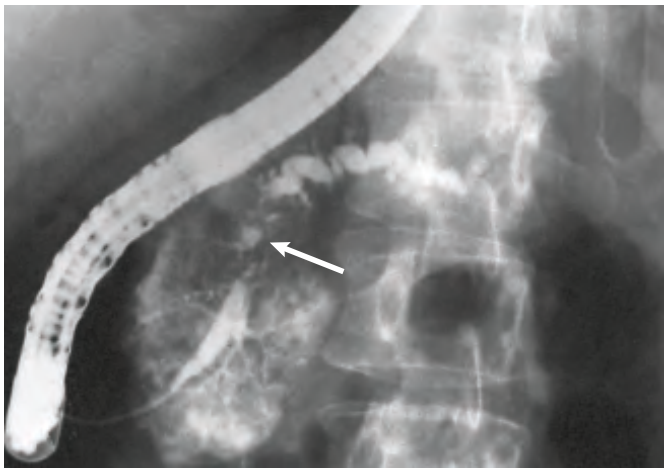

Figure 68.13 Endoscopic retrograde cholangiopancreatography: pancreatic carcinoma. Irregular stricture of the main pancreatic duct (arrow) with dilatation distal to the obstruction.

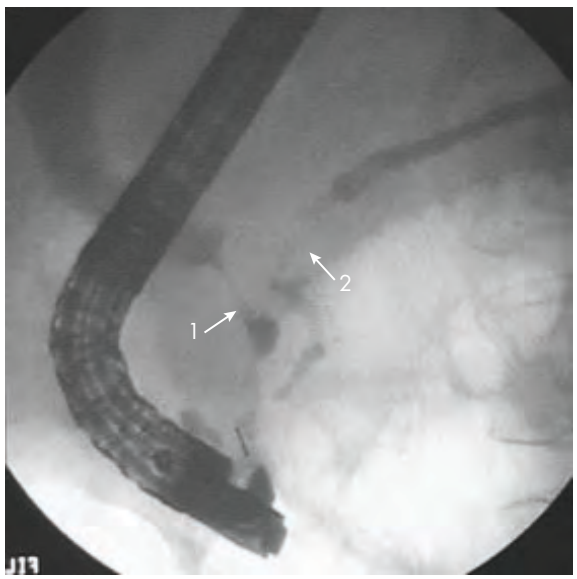

Figure 68.14 Endoscopic retrograde cholangiopancreatography depicting a malignant stricture in the lower part of the common bile duct (1) and in the main pancreatic duct (2), an appearance referred to as the double duct sign (courtesy of Dr George Webster).

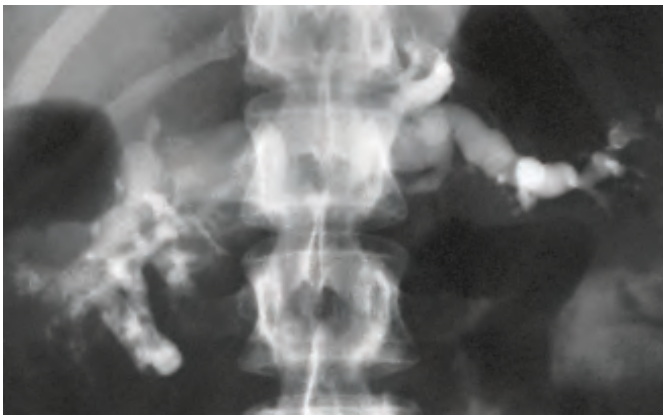

Figure 68.15 Endoscopic retrograde cholangiopancreatography: chronic pancreatitis. Most of the opacities lie within the duct system and are stones. Gross dilatation of ducts in the body and tail are due to obstruction by stones in the head of the pancreas.

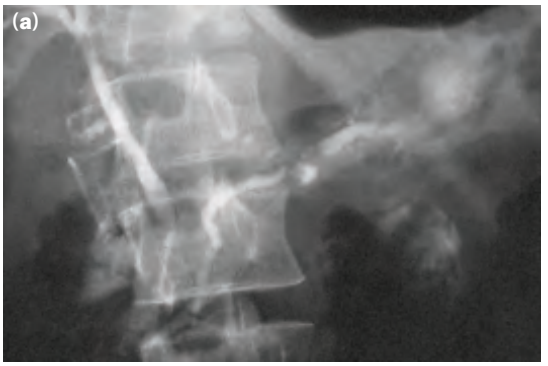

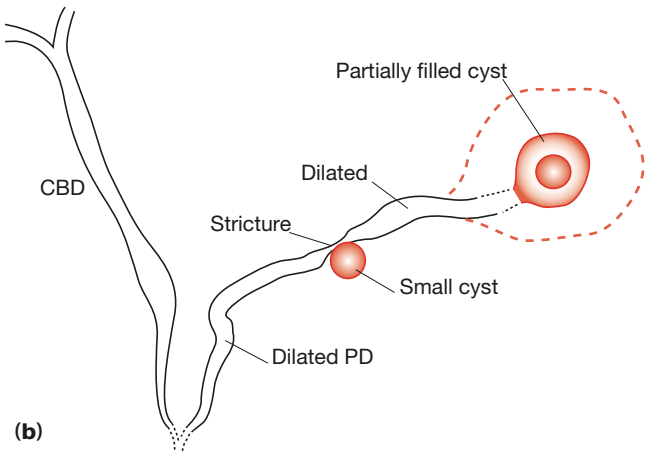

Figure 68.16 **(a)** Endoscopic retrograde cholangiopancreatography: relapsing acute pancreatitis. Normal biliary tree. Pancreatogram shows stricture of the main duct in the body with distal dilatation and cyst formation. **(b)** Diagrammatic outline of **(a)**. CBD, common bile duct; PD, pancreatic duct.

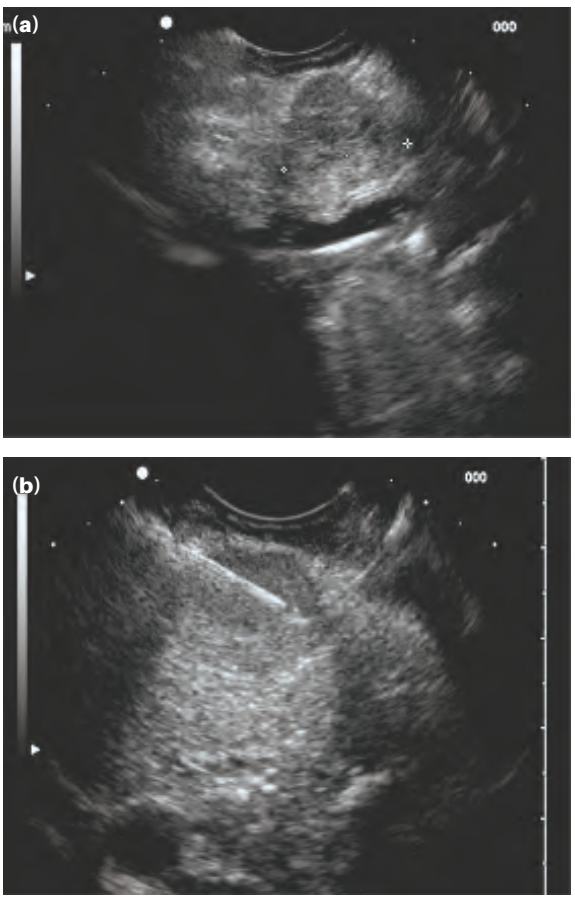

Figure 68.20 **(a)** Carcinoma of the pancreatic head as seen on endoscopic ultrasound (EUS). **(b)** Aspiration biopsy carried out under EUS guidance: needle seen entering the tumour (courtesy of Dr Peter Fairclough).

Endoscopic ultrasound

Endoscopic ultrasound (EUS) is performed using a special endoscope that has a high-frequency ultrasonic transducer at its tip. When the endoscope is in the lumen of the stomach or duodenum, the pancreas and its surrounding vasculature and lymph nodes can be assessed (**Figure 68.20**). This is particularly useful in identifying small tumours that may not show up well on CT or MRI, and in demonstrating the relationship of a pancreatic tumour to major vessels nearby. EUS can clarify the relationship of a neuroendocrine tumour to the main pancreatic duct (important if enucleation is being considered).

It helps to distinguish cystic tumours from pseudocysts. Transduodenal or transgastric fine needle aspiration (FNA) or Trucut biopsy performed under EUS guidance avoids spillage of tumour cells into the peritoneal cavity.

CONGENITAL ABNORMALITIES

Cystic fibrosis

This is inherited as an autosomal recessive condition. It occurs most frequently among Caucasians, in whom it is the most common inherited disorder (incidence of 1:2000 live births in the UK). Cystic fibrosis (CF) develops when there is a mutation in the *CFTR* (cystic fibrosis transmembrane conductance regulator) gene on chromosome 7. This gene creates a cell membrane protein that helps to control the movement of chloride across the cell membrane.

CF is a multisystem disorder of exocrine glands that affects the lungs, intestines, pancreas and liver, and is characterised by elevated sodium and chloride ion concentrations in sweat. The mother may notice that the child is salty when kissed.

Most of the organ damage is due to blockage of narrow passages by thickened secretions. Chronic pulmonary disease arises from plugging of bronchi and bronchioles. CF is the most common cause of chronic lung disease among children in resource-rich countries. Cor pulmonale may develop later. At birth, the meconium may set in a sticky mass and produce intestinal obstruction (meconium ileus) (see Chapter 9). Secretions precipitate in the lumen of the pancreatic duct causing blockage, which results in duct ectasia and fatty replacement of exocrine acinar tissue. Pancreatic exocrine insufficiency leads to fat malabsorption. Steatorrhoea is usually present from birth, resulting in stools that are bulky, oily and offensive. The islets of Langerhans usually appear normal, but diabetes mellitus can occur in older patients. The liver may become cirrhotic as a result of bile duct plugging, and signs of portal hypertension may appear. Infertility is common, due to the absence of the vas deferens in men and thick cervical mucus in women.

Outside the newborn period, the earliest clinical signs of CF are poor growth, poor appetite, rancid greasy stools, abdominal distension, chronic respiratory disease and finger clubbing. The appearance of secondary sexual characteristics may be delayed. The diagnosis can be made by genetic testing (which may be part of prenatal or newborn screening) and by the sweat test. Levels of sodium and chloride ions in the sweat above 90 mmol/L confirm the diagnosis.

Treatment is aimed at control of the secondary consequences of the disease. Pulmonary function is preserved with aggressive physiotherapy and antibiotics. Malabsorption is treated by administration of oral pancreatic enzyme preparations. The diet should be low in fat but contain added salt to replace the high losses in the sweat. With early diagnosis and optimal treatment, patients in resource-rich countries can now expect to survive to their mid-thirties. Those with end-stage lung disease may be considered for lung transplantation. Heterozygous carriers of the various gene mutations are asymptomatic but can be identified by DNA analysis. There is a suggestion that such patients may develop pancreatitis later in life.

Pancreas divisum

Pancreas divisum occurs when the embryological ventral and dorsal parts of the pancreas fail to fuse (**Figure 68.3**). The dorsal pancreatic duct becomes the main pancreatic duct and drains most of the pancreas through the minor or accessory papilla. The incidence of pancreas divisum ranges from 5% in autopsy series to 10% in some ERCP and MRCP series. Pancreas divisum found incidentally in an asymptomatic person does not warrant any intervention. But the incidence of pancreas divisum ranges from 25–50% in patients with recurrent acute pancreatitis, chronic pancreatitis and pancreatic pain. The minor papilla is substantially smaller than the major papilla (and many of these patients probably have papillary stenosis). A large volume of secretions flowing through a narrow papilla probably leads to incomplete drainage, which may then cause obstructive pain or pancreatitis. Certainly in patients with idiopathic recurrent pancreatitis, pancreas divisum should be excluded. The diagnosis can be arrived at by MRCP, EUS or ERCP, augmented by injection of secretin if necessary. There may be changes indicative of obstruction or chronic inflammation in the dorsal duct system. Endoscopic sphincterotomy and stenting of the minor papilla may relieve the symptoms. Surgical intervention can take the form of sphincteroplasty, pancreatojejunostomy or even resection of the pancreatic head.

Annular pancreas

This is the result of failure of complete rotation of the ventral pancreatic bud during development, so that a ring of pancreatic tissue surrounds the second or third part of the duodenum. It is most often seen in association with congenital duodenal stenosis or atresia and is therefore more prevalent in children with Down syndrome. Duodenal obstruction typically causes vomiting in the neonate (see Chapter 9). The usual treatment is bypass (duodenoduodenostomy). The disease may occur in later life as one of the causes of pancreatitis, in which case resection of the head of the pancreas is preferable to lesser procedures.

Ectopic pancreas

Islands of ectopic pancreatic tissue can be found in the submucosa in parts of the stomach, duodenum or small intestine (including Meckel's diverticulum), the gall bladder, adjoining the pancreas, in the hilum of the spleen and within the liver. Ectopic pancreas may also be found in the wall of an alimentary tract duplication cyst.

John Langdon Haydon Down, (sometimes given as Haydon-Down), 1828–1896, physician, The London Hospital, London, and Superintendent, Earlswood Asylum for Idiots, Surrey, UK, described this syndrome in 1866.

Johann Friedrich Meckel (The Younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany, described the embryological origin of the eponymous diverticulum in 1809.

Congenital cystic disease of the pancreas

This sometimes accompanies congenital disease of the kidneys and liver, and occurs as part of the von Hippel–Lindau syndrome.

INJURIES TO THE PANCREAS

External injury

Presentation and management

The pancreas, thanks to its somewhat protected location in the retroperitoneum, is not frequently damaged in blunt abdominal trauma. If there is damage to the pancreas, it is often concomitant with injuries to other viscera, especially the liver, the spleen and the duodenum. Occasionally, a forceful blow to the epigastrium (such as a kick from a human or a horse, or pressure from the steering wheel in a car accident) may crush the body of the pancreas against the vertebral column. Penetrating trauma to the upper abdomen or the back carries a higher chance of pancreatic injury. Pancreatic injuries may range from a contusion or laceration of the parenchyma *without* duct disruption to major parenchymal destruction *with* duct disruption (sometimes complete transection) and, rarely, massive destruction of the pancreatic head. The most important factor that determines treatment is whether the pancreatic duct has been disrupted.

Blunt pancreatic trauma usually presents with epigastric pain, which may be minor at first, with the progressive development of more severe pain due to the sequelae of leakage of pancreatic fluid into the surrounding tissues. The clinical presentation can be quite deceptive; careful serial assessments and a high index of suspicion are required. A rise in serum amylase occurs in most cases. A CT scan of the pancreas will delineate the damage that has occurred to the pancreas (**Figure 68.21**). If there is doubt about duct disruption, an urgent ERCP should be sought. MRCP may also provide the answer, but the images can be difficult to interpret. Support with intravenous fluids and a 'nil by mouth' regimen should be instituted while these investigations are performed. There is no need to rush to a laparotomy if the patient is haemodynamically stable, without peritonitis. It is preferable to manage conservatively at first, investigate and, once the extent of the damage has been ascertained, undertake appropriate action. Operation is indicated if there is disruption of the main pancreatic duct; in almost all other cases, the patient will recover with conservative management.

In penetrating injuries, especially if other organs are injured and the patient's condition is unstable, there is a greater need to perform an urgent surgical exploration. Assessment of pancreatic damage and duct disruption at the time of surgery can be difficult, because the bruising associated with the retroperitoneal damage prevents clear visualisation of the pancreas. A patient and thorough examination of the gland should be carried out. Haemostasis and closed drainage is adequate for minor parenchymal injuries. If the gland is transected in the body or tail, a distal pancreatectomy should be performed, with or without splenectomy. If damage is purely confined to the head of the pancreas, haemostasis and external drainage is normally effective. In the emergency setting, in an unstable patient with concomitant injuries, a surgeon unaccustomed to pancreatic surgery should refrain from trying to ascertain whether the duct in the pancreatic head is intact or embarking on a major resection. However, if there is severe injury to the pancreatic head and duodenum, then a pancreatoduodenectomy may be necessary.

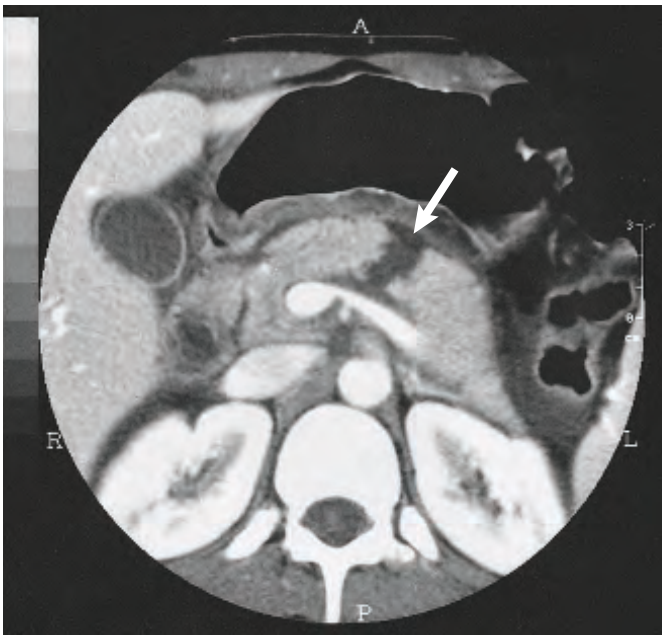

Figure 68.21 Computed tomography scan showing a pancreatic transection due to a bicycle handlebar injury. A distal pancreatectomy was performed.

Summary box 68.3

External injury to the pancreas

- Other organs are likely to be injured
- It is important to ascertain if the pancreatic duct has been disrupted
- CT and ERCP are the most useful tests
- Surgery is indicated if the main pancreatic duct is disrupted

Prognosis

The most common cause of death in the immediate period is bleeding, usually from associated injuries. Once the acute phase has passed, the mortality and morbidity related to the pancreatic injury itself are treatable, with a complete return to normal activity the usual outcome.

Persistent drain output occurs in up to a third of patients (see the section on pancreatic fistulae below). Sometimes, in the aftermath of trauma that has been treated conservatively, duct stricturing develops, leading to recurrent episodes of pancreatitis. The appropriate treatment in such cases is resection of the tail of the pancreas distal to the site of duct disruption.

Also, a pancreatic pseudocyst may develop. If the main duct is intact, the cyst can be aspirated percutaneously in the first instance; it may not be necessary to undertake a cystgastrostomy. If the cyst develops in the presence of complete disruption of the pancreas, there is no alternative but to undertake a distal resection or, occasionally, a pancreatojejunostomy with a Roux-en-Y loop. In a patient who presents with a peripancreatic cyst and a history of previous blunt abdominal trauma, do not assume that it is a post-traumatic pseudocyst. The possibility of a cystic neoplasm should be considered and excluded.

Iatrogenic injury

This can occur in several ways:

- Injury to the tail of the pancreas during splenectomy, resulting in a pancreatic fistula.
- Injury to the pancreatic head and the accessory pancreatic duct (Santorini), which is the main duct in 7% of patients, during Billroth II gastrectomy. A pancreatogram performed by cannulating the duct at the time of discovery of such an injury will demonstrate whether it is safe to ligate and divide the duct. If no alternative drainage duct can be demonstrated, then the duct should be reanastomosed to the duodenum or alternatively resection of the pancreatic head should be considered.
- Enucleation of islet cell tumours of the pancreas can result in fistulae.
- Duodenal or ampullary bleeding following sphincterotomy. This injury may require duodenotomy to control the bleeding.

Pancreatic fistula

Pancreatic fistula usually follows operative trauma to the gland or occurs as a complication of acute or chronic pancreatitis. It is important to define the site of the fistula and the epithelial structure with which it communicates (e.g. externally to skin, or internally to bowel). If there is uncertainty about whether the fluid issuing from a drain site or a wound is pancreatic juice, measurement of the amylase content will be diagnostic.

Management includes correction of metabolic and electrolyte disturbances and adequate drainage of the fistula into a stoma bag with protection of the skin. Investigation of the cause of the fistula is required as the underlying cause must be treated before the fistula will close. Frequently, the cause is related to obstruction within the pancreatic duct, which can be overcome by the insertion of a stent or catheter endoscopically into the pancreatic duct. While waiting for closure of the fistula, the patient should be given parenteral or nasojejunal nutritional support (as opposed to nasogastric or oral feeding; the rationale is that parenteral or nasojejunal feeding reduces the volume of pancreatic secretion). The use of octreotide will also suppress pancreatic secretion.

Summary box 68.4

Management of pancreatic fistulae

Tests

- Measure amylase level in fluid
- Determine the anatomy of the fistula
- Check if the main pancreatic duct is blocked or disrupted

Measures

- Correct fluid and electrolyte imbalances
- Protect the skin
- Drain adequately
- Parenteral or nasojejunal feeding
- Octreotide to suppress secretion
- Relieve pancreatic duct obstruction if possible (ERCP and stent)
- Treat underlying cause

PANCREATITIS

Pancreatitis is inflammation of the pancreatic parenchyma. For clinical purposes, it is useful to divide pancreatitis into acute, which presents as an emergency, and chronic, which is a prolonged and frequently lifelong disorder resulting from the development of fibrosis within the pancreas. It is possible that acute and chronic pancreatitis are different phases of the same process.

Acute pancreatitis is defined as an acute condition presenting with abdominal pain, a threefold or greater rise in the serum levels of the pancreatic enzymes amylase or lipase, and/or characteristic findings of pancreatic inflammation on contrast-enhanced CT. Acute pancreatitis may recur.

The underlying mechanism of injury in pancreatitis is thought to be premature activation of pancreatic enzymes within the pancreas, leading to a process of autodigestion. Anything that injures the acinar cell and impairs the secretion of zymogen granules, or damages the duct epithelium and thus delays enzymatic secretion, can trigger acute pancreatitis. Once cellular injury has been initiated, the inflammatory process can lead to pancreatic oedema, haemorrhage and, eventually, necrosis. As inflammatory mediators are released into the circulation, systemic complications can arise, such as haemodynamic instability, bacteraemia (due to translocation of gut flora), acute respiratory distress syndrome and pleural effusions, gastrointestinal haemorrhage, renal failure and disseminated intravascular coagulation (DIC).

Acute pancreatitis may be categorised as mild (*interstitial oedematous pancreatitis*) or severe (*necrotising pancreatitis*). The former is characterised by interstitial oedema of the gland and minimal organ dysfunction. The majority of patients will have a mild attack of pancreatitis, the mortality from which is around 1%. Severe acute pancreatitis is seen in 5–10% of patients, and is characterised by pancreatic necrosis, a severe systemic inflammatory response and often multi-organ failure.

Cesar Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland, described this method of forming a jejunal conduit in 1908.
Christian Albert Theodor Billroth, 1829–1894, Professor of Surgery, Vienna, Austria. A hugely influential surgical teacher and an early proponent of surgical audit, Billroth performed the first oesophagectomy, first laryngectomy and first successful gastrectomy.

In those who have a severe attack of pancreatitis, the mortality varies from 20 to 50%.

Acute pancreatitis has an *early phase* that usually lasts a week. It is characterised by a systemic inflammatory response syndrome (SIRS) which – if severe – can lead to transient or persistent organ failure (deemed persistent if it lasts for over 48 hours). About one-third of deaths occur in the early phase of the attack, from multiple organ failure. The *late* phase is seen typically in those who suffer a severe attack, and can run from weeks to months. It is characterised by persistent systemic signs of inflammation, and/or local complications, particularly fluid collections and peripancreatic sepsis. Deaths occurring after the first week of onset are often due to septic complications.

Chronic pancreatitis is defined as a continuing inflammatory disease of the pancreas characterised by irreversible morphological change typically causing pain and/or permanent loss of function. Many patients with chronic pancreatitis have painful exacerbations, but the condition may be completely painless.

Acute pancreatitis

Incidence

Acute pancreatitis accounts for 3% of all cases of abdominal pain among patients admitted to hospital in the UK. The hospital admission rate for acute pancreatitis is 9.8 per year per 100 000 population in the UK, although worldwide, the annual incidence may range from 5 to 50 per 100 000. The disease may occur at any age, with a peak in young men and older women.

Aetiology

The two major causes of acute pancreatitis are biliary calculi, which occur in 50–70% of patients, and alcohol abuse, which accounts for 25% of cases. Gallstone pancreatitis is thought to be triggered by the passage of gallstones down the common bile duct. If the biliary and pancreatic ducts join to share a common channel before ending at the ampulla, then obstruction of this passage may lead to reflux of bile or activated pancreatic enzymes into the pancreatic duct. Patients who have small gallstones and a wide cystic duct may be at a higher risk of passing stones. The proposed mechanisms for alcoholic pancreatitis include the effects of diet, malnutrition, direct toxicity of alcohol, concomitant tobacco smoking, hypersecretion, duct obstruction or reflux, and hyperlipidaemia. The remaining cases may be due to rare causes or be idiopathic.

Among patients who undergo ERCP, 1–3% develop pancreatitis, probably as a consequence of duct disruption and enzyme extravasation. Patients with sphincter of Oddi dysfunction or a history of recurrent pancreatitis, and those who undergo sphincterotomy or balloon dilatation of the sphincter, carry a higher risk of developing post-ERCP pancreatitis. Patients who have undergone upper abdominal or cardiothoracic surgery may develop acute pancreatitis in the postoperative phase, as may those who have suffered blunt abdominal trauma.

Hereditary pancreatitis is a rare familial condition associated with mutations of the cationic trypsinogen gene. Patients have a tendency to suffer acute pancreatitis while in their teens, progress to chronic pancreatitis in the next two decades and have a high risk (possibly up to 40%) of developing pancreatic cancer by the age of 70 years.

Occasionally, tumours at the ampulla of Vater may cause acute pancreatitis. It is important to check the serum calcium level, a fasting lipid profile, autoimmune markers and viral titres in patients with so called idiopathic acute pancreatitis. It is equally important to take a detailed drug history and remember the association of corticosteroids, azathioprine, asparaginase and valproic acid with acute pancreatitis. Statins (taken over a long time) and gliptins have been linked with pancreatitis, but the evidence is slim. It is essential to exclude tiny gallstones. A careful search for the aetiology must be made in all cases, and no more than 20% of cases should fall into the idiopathic category.

Summary box 68.5

Possible causes of acute pancreatitis

- Gallstones
- Alcoholism
- Post ERCP
- Abdominal trauma
- Following biliary, upper gastrointestinal or cardiothoracic surgery
- Ampullary tumour
- Drugs (corticosteroids, azathioprine, asparaginase, valproic acid, thiazides, oestrogens)
- Hyperparathyroidism
- Hypercalcaemia
- Pancreas divisum
- Autoimmune pancreatitis
- Hereditary pancreatitis
- Viral infections (mumps, coxsackie B)
- Malnutrition
- Scorpion bite
- Idiopathic

Summary box 68.6

Aetiology of acute pancreatitis

- It is essential to establish the aetiology
- Investigate thoroughly before labelling it as 'idiopathic'
- After the acute episode resolves, remember further management of the underlying aetiology
- If the aetiology is gallstones, cholecystectomy is desirable during the same admission

Clinical presentation

Pain is the cardinal symptom. It characteristically develops quickly, reaching maximum intensity within minutes rather than hours and persists for hours or even days. The pain is frequently severe, constant and refractory to the usual doses of analgesics. Pain is usually experienced first in the

epigastrium but may be localised to either upper quadrant or felt diffusely throughout the abdomen. There is radiation to the back in about 50% of patients, and some patients may gain relief by sitting or leaning forwards. The suddenness of onset may simulate a perforated peptic ulcer, while biliary colic or acute cholecystitis can be mimicked if the pain is maximal in the right upper quadrant. Radiation to the chest can simulate myocardial infarction, pneumonia or pleuritic pain. In fact, acute pancreatitis can mimic most causes of the acute abdomen and should seldom be discounted in differential diagnosis.

Nausea, repeated vomiting and retching are usually marked accompaniments. The retching may persist despite the stomach being kept empty by nasogastric aspiration. Hiccoughs can be troublesome and may be due to gastric distension or irritation of the diaphragm.

On examination, the appearance may be that of a patient who is well or, at the other extreme, one who is gravely ill with profound shock, toxicity and confusion. Tachypnoea is common, tachycardia is usual, and hypotension may be present. The body temperature is often normal or even subnormal, but frequently rises as inflammation develops. It is useful to reiterate here that SIRS is defined by the presence of two or more of the following criteria: heart rate >90/min, core temperature <36° C or >38° C, respirations >20/min or pCO_2 <32 mmHg, and white blood cell count <4000 or >12 000/mm^3. Mild icterus can be caused by biliary obstruction in gallstone pancreatitis, and an acute swinging pyrexia suggests cholangitis. Bleeding into the fascial planes can produce bluish discolouration of the flanks (Grey Turner's sign) or umbilicus (Cullen's sign). Neither sign is pathognomonic of acute pancreatitis; Cullen's sign was first described in association with rupture of an ectopic pregnancy. Subcutaneous fat necrosis may produce small, red, tender nodules on the skin of the legs.

Abdominal examination may reveal distension due to ileus or, more rarely, ascites with shifting dullness. A mass can develop in the epigastrium due to inflammation. There is usually muscle guarding in the upper abdomen, although marked rigidity is unusual. A pleural effusion is present in 10–20% of patients. Pulmonary oedema and pneumonitis are also described and may give rise to the differential diagnosis of pneumonia or myocardial infarction. The patient may be confused and exhibit the signs of metabolic derangement together with hypoxaemia.

Investigations

Typically, the diagnosis is made on the basis of the clinical presentation and an elevated serum amylase level. A serum amylase level three times above normal is indicative of the disease. A normal serum amylase level does not exclude acute pancreatitis, particularly if the patient has presented a few days later. If the serum lipase level can be checked, it provides a slightly more sensitive and specific test than amylase. If there is doubt, and other causes of acute abdomen have to be excluded, contrast-enhanced CT is probably the best single imaging investigation (see below).

Summary box 68.7

Investigations in acute pancreatitis should be aimed at answering three questions:

- Is a diagnosis of acute pancreatitis correct?
- How severe is the attack?
- What is the aetiology?

ASSESSMENT OF SEVERITY

It is important to define that group of patients who will develop severe pancreatitis, as they are the ones with poorer outcomes and therefore they require aggressive early management and possibly transfer to a specialist unit. A severe attack may be heralded by an initial clinical impression of a very ill patient and a worsening physiological state at 24–48 hours. Various prognostic scoring systems have been used, all aimed at predicting persistent organ failure, particularly respiratory, cardiac and renal. Severity stratification assessments should be performed in patients at 24 hours, 48 hours and 7 days after admission. The Ranson and Glasgow scoring systems are specific for acute pancreatitis, and a score of 3 or more at 48 hours indicates a severe attack (*Table 68.3*). Several other systems that are used in intensive care units can also be applied. These include the APACHE, SAPS, SOFA, MODS and modified Marshall scoring systems (the latter has the advantage of simplicity). Regardless of the system used, persisting organ failure indicates a severe attack. A serum C-reactive protein level >150 mg/L at 48 hours after the onset of symptoms is also an indicator of severity. Patients with a body mass index over 30 are at higher risk of developing complications. A revision in 2013 of the Atlanta classification of acute pancreatitis (1992) recommends that patients with acute pancreatitis be stratified into 3 groups:

- Mild acute pancreatitis:
  - no organ failure;
  - no local or systemic complications.
- Moderately severe acute pancreatitis:
  - organ failure that resolves within 48 hours (transient organ failure); and/or
  - local or systemic complications without persistent organ failure.

George Grey Turner, 1877–1951, Professor of Surgery, The University of Durham, Durham (1927–1934), and at the Postgraduate Medical School, Hammersmith, London, UK (1934–1945).

Thomas Stephen Cullen, 1868–1953, Professor of Gynecology, The Johns Hopkins University, Baltimore, MD, USA. Described bluish discoloration of the periumbilical skin as a sign of ruptured ectopic pregnancy.

John HC Ranson, 1938–95, Professor of Surgery, The New York University School of Medicine, New York, NY, USA. Published his scoring criteria for severe acute pancreatitis in 1974.

John C Marshall, contemporary, trauma surgeon and intensivist, St Michael's Hospital, Toronto, Canada.

TABLE 68.3 The Ranson and Glasgow scoring systems to predict the severity of acute pancreatitis: in both systems, disease is classified as severe when three or more factors are present.

Ranson score	Glasgow score
On admission	**Within 48 hours**
Age >55 years	Age >55 years
White blood cell count >16 × 10^9/L	White blood cell count >15 × 10^9/L
Blood glucose >1.1 mmol/L (>200 mg/dL)	Blood glucose >10 mmol/L (no history of diabetes)
LDH >350 units/L	LDH > 600 units/L
AST >250 units/L	Serum urea >16 mmol/L (no response to intravenous fluids)
Within 48 hours	Arterial oxygen saturation (PaO_2) <8 kPa (60 mmHg)
Haematocrit fall of 10% or greater	Serum calcium <2.0 mmol/L
Blood urea nitrogen rise >5 mg/dL (1.8 mmol/L) despite fluids	Serum albumin <32 g/L
Arterial oxygen saturation (PaO_2) <8 kPa (60 mmHg)	
Serum calcium <2.0 mmol/L	
Base deficit >4 mmol/L	
Fluid sequestration >6 litres	

AST, aspartate aminotransferase; LDH, lactate dehydrogenase; PaO_2, arterial oxygen tension.

- Severe acute pancreatitis:
  - persistent organ failure (>48 hours);
  - single organ failure;
  - multiple organ failure.

IMAGING

Plain erect chest and abdominal radiographs are not diagnostic of acute pancreatitis, but are useful in the differential diagnosis. Non-specific findings in pancreatitis include a generalised or local ileus (sentinel loop), a colon cut-off sign and a renal halo sign. Occasionally, calcified gallstones or pancreatic calcification may be seen. A chest radiograph may show a pleural effusion and, in severe cases, a diffuse alveolar interstitial shadowing may suggest acute respiratory distress syndrome.

Ultrasound does not establish a diagnosis of acute pancreatitis. The swollen pancreas may be seen, but ultrasonography should be performed within 24 hours in *all* patients to detect gallstones as a potential cause, rule out acute cholecystitis as a differential diagnosis and determine whether the common bile duct is dilated.

CT is not necessary for all patients, particularly those deemed to have a mild attack on prognostic criteria. But a contrast-enhanced CT is indicated in the following situations:

- If there is diagnostic uncertainty.
- In patients with severe acute pancreatitis, to distinguish interstitial from necrotising pancreatitis (**Figure 68.22**). In the first 72 hours, CT may underestimate the extent of necrosis. The severity of pancreatitis detected on CT may be staged according to the Balthazar criteria.
- In patients with organ failure, signs of sepsis or progressive clinical deterioration.
- When a localised complication is suspected, such as fluid collection, pseudocyst or a pseudoaneurysm.

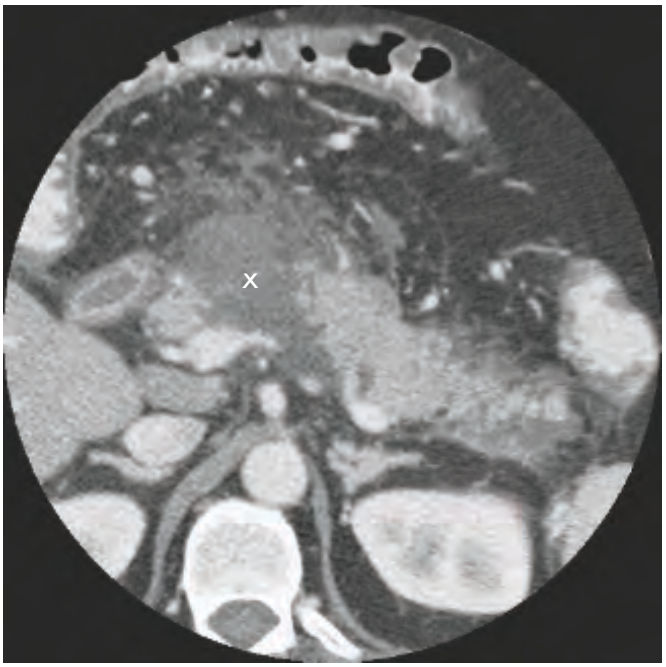

Figure 68.22 Contrast-enhanced computed tomography scan showing acute necrotising pancreatitis. Note the area of reduced enhancement in the pancreas (marked X), the peripancreatic oedema and stranding of the fatty tissues (courtesy of Dr Niall Power).

Cross-sectional MRI can yield similar information to that obtained by CT. EUS and MRCP can help in detecting stones in the common bile duct and directly assessing the pancreatic parenchyma, but are not widely available. ERCP allows the identification and removal of stones in the common bile duct in gallstone pancreatitis. In patients with severe acute gallstone pancreatitis and signs of ongoing biliary obstruction and cholangitis, an urgent ERCP should be sought (see below).

Emil J Balthazar, contemporary, Professor Emeritus, The Department of Radiology, The New York University, New York, NY, USA.

The presentation is so variable that sometimes even an experienced clinician can be mistaken. While this is not desirable, occasionally the diagnosis is only made at laparotomy. The appearances at laparotomy are characteristic (**Figure 68.23**).

Figure 68.23 Widespread fat necrosis of the omentum. A test tube has been filled with blood-stained peritoneal fluid. This specimen was rich in amylase. Fat necroses are dull, opaque, yellow-white areas suggestive of drops of wax. They are most abundant in the vicinity of the pancreas, but are widespread in the greater omentum and the mesentery. At necropsy, they can sometimes be demonstrated beneath the pleura and pericardium, and even in the subsynovial fat of the knee joint. Fat necroses consist of small islands of saponification caused by the liberation of lipase, which splits into glycerol and fatty acids. Free fatty acids combine with calcium to form soaps (fatty necrosis) (courtesy of Dr GD Adhia, Mumbai, India).

Management

If after initial assessment a patient is considered to have a mild attack of pancreatitis, a conservative approach is indicated with intravenous fluid administration and frequent, but non-invasive, observation. A brief period of fasting may be sensible in a patient who is nauseated and in pain, but there is little physiological justification for keeping patients on a prolonged 'nil by mouth' regimen. Antibiotics are not indicated. Apart from analgesics and anti-emetics, no drugs or interventions are warranted, and CT scanning is unnecessary unless there is evidence of deterioration. However, if a stable patient meets the prognostic criteria for a severe attack of pancreatitis, then a more aggressive approach is required, with the patient being admitted to a high-dependency or an intensive care unit and monitored invasively.

Patients with a severe attack should be admitted to an intensive care or high-dependency unit (*Table 68.4*). Adequate analgesia should be administered. Aggressive fluid resuscitation is important, guided by frequent measurement of vital signs, urine output and central venous pressure. Supplemental oxygen should be administered and serial arterial blood gas analysis performed. The haematocrit, clotting profile, blood glucose and serum levels of calcium and magnesium should be closely monitored.

TABLE 68.4 Early management of severe acute pancreatitis.

Admission to HDU/ICU
Analgesia
Aggressive fluid rehydration
Supplemental oxygen
Invasive monitoring of vital signs, central venous pressure, urine output, blood gases
Frequent monitoring of haematological and biochemical parameters (including liver and renal function, clotting, serum calcium, blood glucose)
Nasogastric drainage (only initially)
Antibiotics if cholangitis suspected; prophylactic antibiotics can be considered
CT scan essential if organ failure, clinical deterioration or signs of sepsis develop
ERCP within 72 hours for severe gallstone pancreatitis or signs of cholangitis
Supportive therapy for organ failure if it develops (inotropes, ventilatory support, haemofiltration, etc.)
If nutritional support is required, consider enteral (nasogastric) feeding

CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; HDU, high-dependency unit; ICU, intensive care unit.

A nasogastric tube is not essential but may be of value in patients with vomiting. Specific treatments such as aprotinin, somatostatin analogues, platelet-activating factor inhibitors and selective gut decontamination have failed to improve outcome in numerous clinical trials and should not be given. There are no data to support a practice of 'resting' the pancreas and feeding only by the parenteral or nasojejunal routes. If nutritional support is felt to be necessary, enteral nutrition (e.g. feeding via a nasogastric tube) should be used.

There is some evidence to support the use of prophylactic antibiotics in patients with severe acute pancreatitis but there is no consensus. The rationale is to prevent local and other septic complications. The regimens used include intravenous cefuroxime, or imipenem, or ciprofloxacin plus metronidazole. The duration of antibiotic prophylaxis should not exceed 14 days. Additional antibiotic use should be guided by microbiological cultures. If however there is evidence of cholangitis, or concomitant respiratory or urinary infection, then antibiotics should be given promptly.

If gallstones are the cause of an attack of predicted or proven severe pancreatitis, or if the patient has jaundice, cholangitis or a dilated common bile duct, urgent ERCP should be carried out within 72 hours of the onset of symptoms. There is evidence that sphincterotomy and clearance of the bile duct can reduce the incidence of infective complications in these patients. In patients with cholangitis, sphincterotomy should be carried out or a biliary stent placed to drain the duct. ERCP is an invasive procedure and carries a small risk of worsening the pancreatitis.

Systemic complications

Pancreatitis may involve all organ systems (*Table 68.5*) and place demands on the surgeon beyond his or her skills. Patients with systemic complications should be managed by a multidisciplinary team that includes intensive care specialists. When there is organ failure, appropriate supportive therapies may include inotropic support for haemodynamic instability, haemofiltration in the event of renal failure, ventilatory support for respiratory failure and correction of coagulopathies (including DIC). There is no role for surgery during the initial period of resuscitation and stabilisation; surgical intervention is contemplated only in the patient who deteriorates as a result of local complications following successful stabilisation.

Local complications and their management

Once the acute phase has been survived, usually by the end of the first week, and major organ failure is under control, then local complications become pre-eminent in the management of these patients. The course of the patient should be followed carefully. If pain persists or recurs, clinical resolution does not progress as expected, signs of sepsis develop, organ dysfunction worsens, or there is a further spike in the serum amylase level, a CT scan should be performed. Local complications in pancreatic disease are serious and carry a significant mortality. The management approach is conservative on the whole, with surgery restricted to situations in which conservative management has failed. It is important to be clear about the definitions. Certain terms are confusing, such as 'phlegmon', which may refer to an abscess or to an inflammatory mass in the pancreas, and are best avoided.

TABLE 68.5 Complications of acute pancreatitis.

Systemic	Local
(More common in the first week)	*(Usually develop after the first week)*
Cardiovascular	Acute fluid collection
Shock	Sterile pancreatic necrosis
Arrhythmias	Infected pancreatic necrosis
Pulmonary	Pancreatic abscess
ARDS	Pseudocyst
Renal failure	Pancreatic ascites
Haematological	Pleural effusion
DIC	Portal/splenic vein thrombosis
Metabolic	Pseudoaneurysm
Hypocalcaemia	
Hyperglycaemia	
Hyperlipidaemia	
Gastrointestinal	
Ileus	
Neurological	
Visual disturbances	
Confusion, irritability	
Encephalopathy	
Miscellaneous	
Subcutaneous fat necrosis	
Arthralgia	

ARDS, acute respiratory distress syndrome; DIC, disseminated intravascular coagulation.

ACUTE PERIPANCREATIC FLUID COLLECTION (APFC)

This occurs early in the course of mild pancreatitis without necrosis, and is located adjacent to the pancreas. It has no encapsulating wall and is confined within normal fascial planes. The fluid is sterile, and most such collections resolve. No intervention is necessary unless a large collection causes symptoms or pressure effects, in which case it can be percutaneously aspirated under ultrasound or CT guidance. Transgastric drainage under EUS guidance is another option.

STERILE AND INFECTED PANCREATIC NECROSIS

The term 'pancreatic necrosis' refers to a diffuse or focal area of non-viable parenchyma. This can be identified by an absence of parenchymal enhancement on CT with intravenous contrast. Pancreatic necrosis is typically associated with lysis of peripancreatic fat. This may lead to what is described as an *acute necrotic collection* (ANC). This is typically an intra- or extrapancreatic collection containing fluid and necrotic material, with no definable wall. Gradually, over a period of over 4 weeks, this may develop a well-defined inflammatory capsule, and evolve into what is termed *walled-off necrosis* (WON). Collections associated with necrotising pancreatitis are sterile to begin with but often become subsequently infected, probably due to translocation of gut bacteria. Infected necrosis is associated with a mortality rate of up to 50%. Sterile necrotic material should not be drained or interfered with. But if the patient shows signs of sepsis, then one should determine whether the collection is infected (**Figure 68.24**). A CT scan should be performed and a needle passed into the area under CT guidance, choosing a path that does

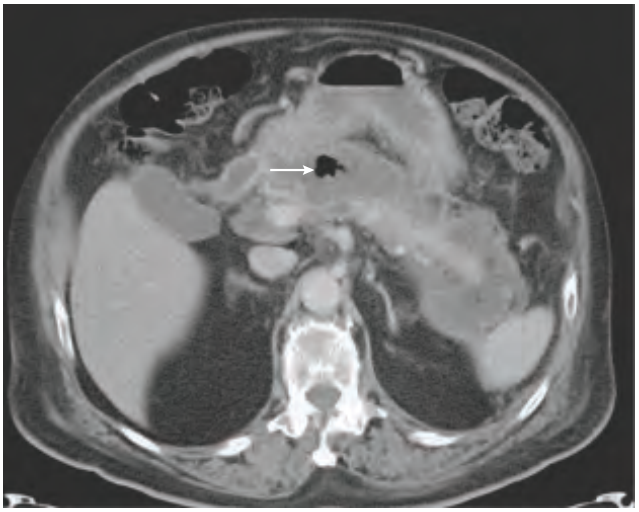

Figure 68.24 Infected pancreatic necrosis in an elderly patient. Note the areas of reduced enhancement in the pancreas and the peripancreatic fluid collection with pockets of gas within it (arrow). This resolved after percutaneous drainage and antibiotic therapy.

not traverse hollow viscera. This may be done under ultrasonographic guidance as well. If the aspirate is purulent, percutaneous drainage of the infected fluid should be carried out. The tube drain inserted should have the *widest* bore possible. The aspirate should be sent for microbiological assessment, and appropriate antibiotic therapy should be commenced as per the sensitivity report. The fluid can be quite viscous with particulate matter, and the drain may need regular flushing with full aseptic precautions. Often, repeated imaging and repeated insertion of progressively wider drains is necessary.

If the sepsis worsens despite this, then a pancreatic necrosectomy should be considered. This is a challenging operation that carries a high morbidity and mortality, and is best carried out in a specialist unit. The overwhelming majority of patients with peripancreatic sepsis can be successfully treated by conservative means, and necrosectomy should be necessary in a very small proportion of patients. The surgical approach may be through a mid-line laparotomy, especially if the area involved is around the head of the gland. The duodenocolic and gastrocolic ligaments should be divided and the lesser sac opened. Thorough debridement of the dead tissue around the pancreas should be carried out. If the body and tail of the gland are primarily involved (**Figure 68.25**), a retroperitoneal approach through a left flank incision may be more appropriate. The tissues are inevitably friable, and one should be careful not to precipitate excessive bleeding or inadvertently breach the bowel wall. Blunt dissection is preferable to sharp dissection. A feeding jejunostomy may be a useful adjunct to the procedure. If gallstones are the precipitating factor of the pancreatitis, a cholecystectomy should be included. Some prefer a minimally invasive approach to a formal laparotomy. A rigid laparoscope is inserted into the peripancreatic area through a retroperitoneal approach, and vigorous irrigation and suction is combined with a gradual nibbling away of the necrotic debris.

Once a necrosectomy has been completed, further necrotic tissue may form. There are several possible ways of dealing with this (listed below), none of which has been proved to be more effective than the others. The last two approaches make greater logistic demands as one is committed to a re-exploration every 48–72 hours.

- **Closed continuous lavage.** Tube drains are left in and the raw area flushed (Beger) (**Figure 68.26**).
- **Closed drainage.** The incision is closed, but the cavity is packed with gauze-filled Penrose drains and closed suction drains. The Penrose drains are brought out through the flank and slowly pulled out and removed after 7 days.
- **Open packing.** The incision is left open, and the cavity is packed with the intention of returning to the operating room at regular intervals and repacking until there is a clean granulating cavity.
- **Closure and relaparotomy.** The incision is closed with drains with the intention of performing a series of planned relaparotomies every 48–72 hours until the raw area granulates (Bradley).

Figure 68.25 Necrotic body and tail of the pancreas removed as an intact specimen rather than piecemeal. The patient had suffered severe necrotising gallstone pancreatitis complicated by persistent pancreatic sepsis. Necrosectomy was carried out through a left flank retroperitoneal approach.

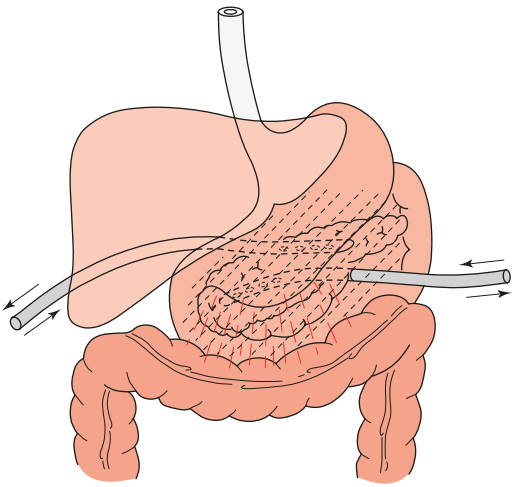

Figure 68.26 Continuous postoperative closed lavage of the lesser sac as advised by Beger. Lavage is carried out through several double-lumen and single-lumen catheters. Each time, 1 litre of saline is infused through and then drained over a period of hours, and the process is repeated.

There is a subgroup of patients who respond initially to percutaneous treatment but then develop recurrent sepsis that requires repeated insertion of drains, and fail to thrive. Necrosectomy should be considered in these patients, but it can be a difficult judgement call.

Patients with peripancreatic sepsis are ill for long periods of time, and may require management in an intensive care unit. Nutritional support is essential. The parenteral and nasojejunal approaches are more popular (on the assumption that they rest the pancreas), although there is little evidence to show that nasogastric feeding, if tolerated, is harmful in any way.

PANCREATIC ABSCESS

This is a circumscribed intra-abdominal collection of pus, usually in proximity to the pancreas. It may be an ANC or a WON that has become infected. The principles of diagnosis

Hans Beger, contemporary, Emeritus Professor of Surgery, Ulm, Germany.
Charles Bingham Penrose, 1862–1925, Professor of Gynecology, The University of Pennsylvania, Philadelphia, PA, USA.
Edward Bradley III, contemporary, Professor, The Department of Clinical Sciences, Florida State University College of Medicine, FL, USA.

and management are as outlined above for infected pancreatic necrosis. Percutaneous drainage with the widest possible drains placed under imaging guidance is the treatment, along with appropriate antibiotics and supportive care. Repeated scans may be required depending on the progress of the patient, and drains may need to be flushed, repositioned or re-inserted. Very occasionally, open drainage of the abscess may be necessary.

PANCREATIC ASCITES

This is a chronic, generalised, peritoneal, enzyme-rich effusion usually associated with pancreatic duct disruption. Paracentesis will reveal turbid fluid with a high amylase level. Adequate drainage with wide-bore drains placed under imaging guidance is essential. Measures that can be taken to suppress pancreatic secretion include parenteral or nasojejunal feeding and administration of octreotide. An ERCP may allow demonstration of the duct disruption and placement of a pancreatic stent.

PANCREATIC EFFUSION

This is an encapsulated collection of fluid in the pleural cavity, arising as a consequence of acute pancreatitis. Concomitant pancreatic ascites may be present, or there may be a communication with an intra-abdominal collection. Percutaneous drainage under imaging guidance is necessary.

HAEMORRHAGE

Bleeding may occur into the gut, into the retroperitoneum or into the peritoneal cavity. Possible causes include bleeding into a pseudocyst cavity, diffuse bleeding from a large raw surface, or a pseudoaneurysm. The last is a false aneurysm of a major peripancreatic vessel confined as a clot by the surrounding tissues and often associated with infection. Recurrent bleeding is common, often culminating in fatal haemorrhage. CT, angiography or MR angiography helps to make the diagnosis. Treatment involves embolisation or surgery.

PORTAL OR SPLENIC VEIN THROMBOSIS

This may often develop silently and is identified on a CT scan. A marked rise in the platelet count should raise suspicions. In the context of acute pancreatitis, treatment is usually conservative. The patient should be screened for pro-coagulant tendencies. If varices or other manifestations of portal hypertension develop, they will require treatment, such as endoscopic injection or banding, β-blockade, etc. Thrombocytosis may mandate the use of aspirin or other antiplatelet drugs for a period. Systemic anticoagulation, if instituted early in the process, may achieve recanalisation of the vein, but it is not routinely used as it carries considerable risks in a patient with ongoing pancreatitis.

PSEUDOCYST

A pseudocyst is a collection of amylase-rich fluid enclosed in a well-defined wall of fibrous or granulation tissue. Pseudocysts typically arise following an attack of mild acute pancreatitis, lie outside the pancreas, and represent an APFC that has not resolved and matured. Formation of a pseudocyst requires 4 weeks or more from the onset of acute pancreatitis. The term 'pseudocyst' is often used more loosely, to include sterile WON that has failed to resolve, or a collection that has developed in the context of chronic pancreatitis or after pancreatic trauma. (**Figure 68.27**; see also **Figure 68.10**). If carefully investigated, more than half of these will be found to have a communication with the main pancreatic duct. Pseudocysts are often single but, occasionally, patients will develop multiple pseudocysts.

A pseudocyst is usually identified on ultrasound or a CT scan. It is important to differentiate a pseudocyst from an APFC; the clinical scenario and the radiological appearances should allow that distinction to be made. Occasionally, a cystic neoplasm may be confused with a chronic pseudocyst. EUS and aspiration of the cyst fluid is very useful in such a situation. The fluid should be sent for measurement of carcinoembryonic antigen (CEA) levels, amylase levels and cytology. Fluid from a pseudocyst typically has a low CEA level, and levels above 400 ng/mL are suggestive of a mucinous neoplasm. Pseudocyst fluid usually has a high amylase level, but that is not diagnostic, as a tumour that communicates with the duct system may yield similar findings. Cytology typically reveals inflammatory cells in pseudocyst fluid. If there is no access to EUS, then percutaneous FNA is acceptable (just aspiration, *not* percutaneous insertion of a drain). ERCP and MRCP may demonstrate communication of the cyst with the pancreatic duct system, demonstrate ductal anomalies, or diagnose chronic pancreatitis and thus help in planning treatment.

Pseudocysts will resolve spontaneously in most instances, but complications can develop (*Table 68.6*). Pseudocysts that are thick-walled or large (over 6 cm in diameter), have lasted for a long time (over 12 weeks), or have arisen in the context of chronic pancreatitis are less likely to resolve spontaneously,

Figure 68.27 Barium meal. Pseudocyst displacing the stomach (courtesy of Professor VK Kapoor, Lucknow, India).

TABLE 68.6 Possible complications of a pancreatic pseudocyst.

Process	Outcomes
Infection	Abscess
	Systemic sepsis
Rupture	
Into the gut	Gastrointestinal bleeding
	Internal fistula
Into the peritoneum	Peritonitis
Enlargement	
Pressure effects	Obstructive jaundice from biliary compression
	Bowel obstruction
Pain	
Erosion into a vessel	Haemorrhage into the cyst
	Haemoperitoneum

but these factors are not specific indications for intervention. Therapeutic interventions are advised only if the pseudocyst causes symptoms, if complications develop, or if a distinction has to be made between a pseudocyst and a tumour.

There are three possible approaches to draining a pseudocyst: percutaneous, endoscopic and surgical. Percutaneous drainage to the exterior under radiological guidance should be avoided. It carries a very high likelihood of recurrence. Moreover, it is not advisable unless one is absolutely certain that the cyst is not neoplastic and that it has no communication with the pancreatic duct (or else a pancreaticocutaneous fistula will develop). A percutaneous transgastric cystgastrostomy can be done under imaging guidance, and a double-pigtail drain placed with one end in the cyst cavity and the other end in the gastric lumen. This requires specialist expertise but, in experienced hands, the recurrence rates are no more than 15%. Endoscopic drainage usually involves puncture of the cyst through the stomach or duodenal wall under EUS guidance, and placement of a tube drain with one end in the cyst cavity and the other end in the gastric lumen. The success rates depend on operator expertise. Occasionally, ERCP and placement of a pancreatic stent across the ampulla may help to drain a pseudocyst that is in communication with the duct. Surgical drainage involves internally draining the cyst into the gastric or jejunal lumen (**Figure 68.28**). Recurrence rates should be no more than 5%, and this still remains the standard against which the evolving radiological and endoscopic approaches are measured. The approach is conventionally through an open incision, but laparoscopic cystgastrostomy is also feasible. Pseudocysts that have developed complications are best managed surgically.

There is a small group of patients who, having suffered an attack of necrotising pancreatitis with duct disruption, go on to suffer repeated complications in the form of recurrent fluid collections, pseudocysts, pleural effusions or pancreatic ascites. Very often disruption of the main pancreatic duct in the neck, body or tail is compounded by a stricture or a stone in the head that cannot be treated endoscopically. In such patients, some form of surgical resection and/or a drainage procedure – even though it may be technically challenging – may be the only way to achieve lasting resolution.

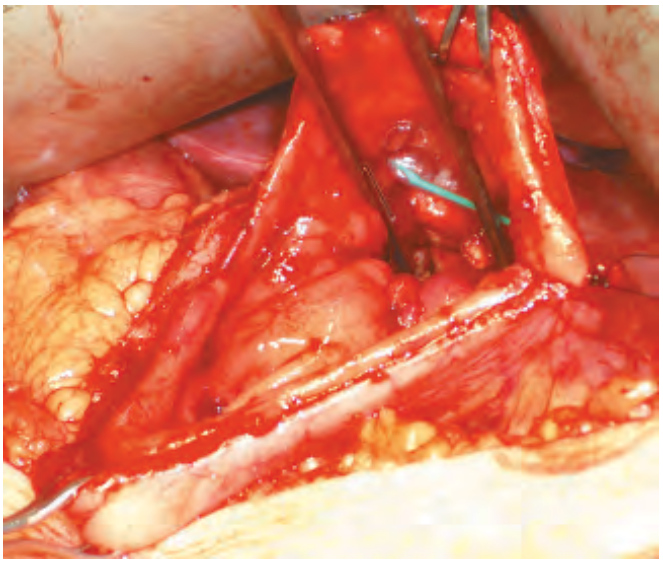

Figure 68.28 Cystgastrostomy for the pancreatic pseudocyst shown in Figure 68.10. The anterior wall of the stomach has been opened and the edges drawn back, held by Babcock's forceps. An opening has been made through the posterior wall of the stomach into the pseudocyst, and the tips of the dissecting forceps are in the cavity of the pseudocyst, which is lined by slough and granulation tissue. The tip of a nasogastric tube is visible. A running stitch will next be placed along the edges of this opening, suturing the full thickness of the posterior gastric wall to the capsule of the pseudocyst.

Summary box 68.8

Distinguishing a pseudocyst from a cystic neoplasm

- History
- Appearance on computed tomography and ultrasound (US)
- Fine needle aspiration of fluid, preferably under endoscopic US guidance:
  - Carcinoembryonic antigen (high level in mucinous tumours)
  - Amylase (level usually high in pseudocysts but occasionally in tumours)
  - Cytology

Outcomes and follow-up of acute pancreatitis

The overall mortality from acute pancreatitis has remained at 10–15% over the past 20 years. There is a clear responsibility before the patient is discharged to determine the aetiology of the attack of pancreatitis, and the causes listed in *Summary box 68.5* must be looked for and excluded. Failure to remove a predisposing factor could lead to a second attack of pancreatitis,

William Wayne Babcock, 1872–1963, surgeon, Philadelphia, PA, USA.

which could be fatal. A proportion of patients in the idiopathic group who suffer repeated attacks may prove to have biliary microlithiasis, which can be identified only by bile sampling at ERCP or by endoscopic ultrasound. In a patient who has gallstone pancreatitis, the gallbladder and gallstones should be removed as soon as the patient is fit to undergo surgery and, preferably, before discharge from hospital.

Chronic pancreatitis

Chronic pancreatitis is a progressive inflammatory disease in which there is irreversible destruction of pancreatic tissue. Its clinical course is characterised by severe pain and, in the later stages, exocrine and endocrine pancreatic insufficiency. In the early stages of its evolution, it is frequently complicated by attacks of acute pancreatitis, which are responsible for the recurrent pain that may be the only clinical symptom. The incidence of chronic pancreatitis in several European, North American and Japanese studies ranges from 2 to 10 new cases per 100 000 population per year, with a prevalence of around 13 cases per 100 000, although there are suspicions that the prevalence is actually higher. In certain parts of the world, such as southern India, the prevalence is much higher (100–200 per 100 000). The disease occurs more frequently in men (male:female ratio of 4:1), and the mean age of onset is about 40 years.

Aetiology and pathology

High alcohol consumption is the most frequent cause of chronic pancreatitis, accounting for 60–70% of cases, but only 5–10% of people with alcoholism develop chronic pancreatitis. The exact mechanism of how alcohol causes chronic inflammation in these patients is unclear; genetic and metabolic factors may be at play.

Other causes include pancreatic duct obstruction resulting from stricture formation after trauma, after acute pancreatitis, or even occlusion of the duct by pancreatic cancer. Congenital abnormalities, such as pancreas divisum and annular pancreas, if associated with papillary stenosis, are rare causes of chronic pancreatitis.

Hereditary pancreatitis, CF, infantile malnutrition and a large unexplained idiopathic group make up the remainder. Normally, if trypsinogen does become prematurely activated within the pancreas, it is inhibited by *SPINK1* and then gets destroyed. Hereditary pancreatitis is an autosomal dominant disorder with an 80% penetrance, associated with a gain-of-function mutation in the cationic trypsinogen gene (*PRSS1*) on chromosome 7, which leads to production of a degradation-resistant form of trypsin. A loss-of-function mutation in *SPINK1* also predisposes to idiopathic pancreatitis. Some patients with idiopathic chronic pancreatitis have mutations in the *CFTR* gene. Idiopathic chronic pancreatitis accounts for approximately 30% of cases and has been subdivided into early-onset and late-onset forms.

The importance of hereditary pancreatitis and pancreatitis occurring at a young age is that there is a markedly increased risk of developing pancreatic cancer, particularly if the patient smokes tobacco. Hyperlipidaemia and hypercalcaemia can lead to chronic pancreatitis.

Tropical pancreatitis is a form of idiopathic pancreatitis that begins at a young age and is associated with a high incidence of diabetes mellitus and stone formation. This has been described in Kerala, in southern India, as well as in resource-poor countries in Asia, Africa and central America. Malnutrition, ingestion of cyanogenic glycosides in cassava, and exposure to hydrocarbons released by kerosene or paraffin lamps have been proposed as possible mechanisms for tropical pancreatitis.

Autoimmune pancreatitis has been described relatively recently. Features include diffuse enlargement of the pancreas, and diffuse and irregular narrowing of the main pancreatic duct. It may occur in association with other autoimmune diseases, as a multisystem disorder, or may affect the pancreas alone. There may be changes in the biliary tree (autoimmune cholangiopathy) as well. The changes may be confused with neoplasia. Autoantibodies may be present, and levels of the immunoglobulin subtype IgG4 are elevated.

At the onset of the disease when symptoms have developed, the pancreas may appear normal. Later, the pancreas enlarges and becomes hard as a result of fibrosis. The ducts become distorted and dilated with areas of both stricture formation and ectasia. Calcified stones weighing from a few milligrams to 200 mg may form within the ducts. The ducts may become occluded with a gelatinous proteinaceous fluid and debris, and inflammatory cysts may form. Histologically, the lesions affect the lobules, producing ductular metaplasia and atrophy of acini, hyperplasia of duct epithelium and interlobular fibrosis.

Clinical features

Pain is the outstanding symptom in the majority of patients. The site of pain depends to some extent on the main focus of the disease. If the disease is mainly in the head of the pancreas, then epigastric and right subcostal pain is common, whereas if it is limited to the left side of the pancreas, left subcostal and back pain are the presenting symptoms. In some patients, the pain is more diffuse. Radiation to the shoulder can occur. Nausea is common during attacks, and vomiting may occur. The pain is often dull and gnawing. Severe flare-ups of pain may be superimposed on background discomfort. All the complications of acute pancreatitis can occur with chronic pancreatitis. Weight loss is common, because the patient does not feel like eating. The pain prevents sleep and time off work is frequent. The number of hospital admissions for acute exacerbations is a pointer towards the severity of the disease. Analgesic use and abuse is frequent. This, too, gives an indication of the severity of the disability. The patient's lifestyle is gradually destroyed by pain, analgesic dependence, weight loss and inability to work. Loss of exocrine function leads to steatorrhoea in more than 30% of patients with chronic pancreatitis. Loss of endocrine function and the development of diabetes are not uncommon, and the incidence increases as the disease progresses. Complications frequently bring the patient to the attention of the surgeon. Infection is not infrequent, possibly related to the diabetes mellitus.

Investigations

Only in the early stages of the disease will there be a rise in serum amylase. Tests of pancreatic function merely confirm

the presence of pancreatic insufficiency or that more than 70% of the gland has been destroyed.

Pancreatic calcifications may be seen on abdominal X-ray (see **Figure 68.18**). CT or MRI scan will show the outline of the gland, the main area of damage and the possibilities for surgical correction (**Figure 68.29**; see also **Figure 68.7**). Calcification is seen very well on CT but not on MRI. An MRCP will identify the presence of biliary obstruction and the state of the pancreatic duct (**Figure 68.30**). The use of intravenous secretin during the study may demonstrate a pancreatic duct stricture that is not apparent on a standard MRCP, but a normal-looking pancreas on CT or MRI does not rule out chronic pancreatitis. ERCP is the most accurate way of elucidating the anatomy of the duct and, in conjunction with the whole organ morphology, can help to determine the type of operation required, if operative intervention is indicated (**Figures 68.15 and 68.17**). Histologically proven chronic pancreatitis can, however, occur in the setting of normal findings on pancreatography. EUS can also be very useful. Sonographic findings characteristic of chronic pancreatitis include the presence of stones, visible side branches, cysts, lobularity, an irregular main pancreatic duct, hyperechoic foci and strands, dilatation of the main pancreatic duct and hyperechoic margins of the main pancreatic duct. The presence of four or more of these features is highly suggestive of chronic pancreatitis.

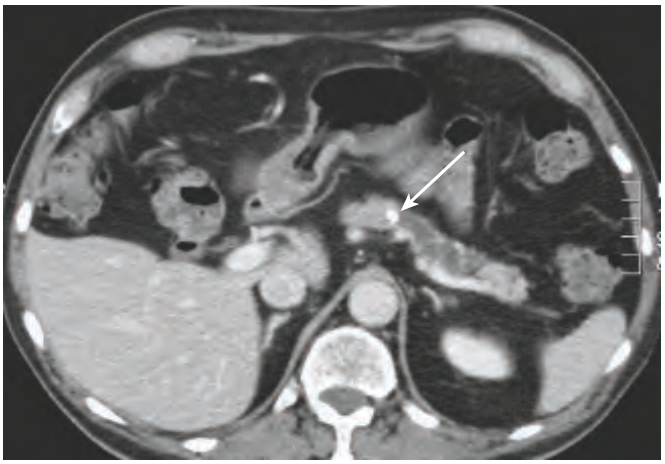

Figure 68.29 Computed tomography scan in a patient with chronic pancreatitis. A stone (arrow) is obstructing the main pancreatic duct in the body of the gland. The duct is markedly dilated upstream of the obstruction.

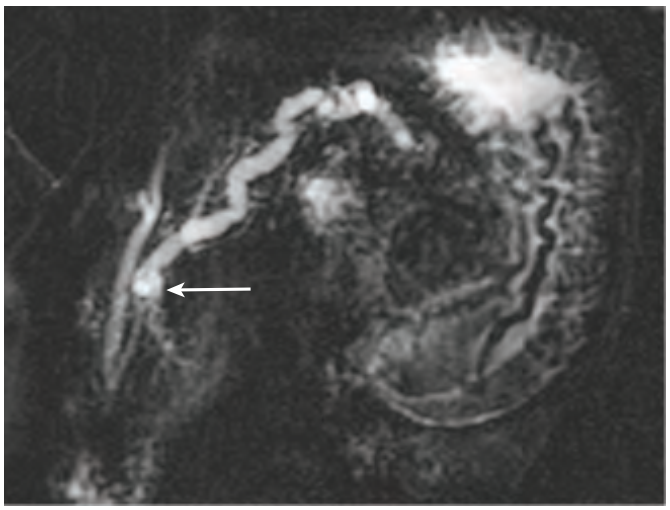

Figure 68.30 Magnetic resonance cholangiopancreatography in a patient with chronic pancreatitis, showing a stricture of the pancreatic duct in the body of the gland (arrow), with dilatation upstream.

Treatment

Most patients can be managed with medical measures. There is no single therapeutic agent that has been shown to relieve symptoms (*Summary box 68.9*).

Summary box 68.9

Medical treatment of chronic pancreatitis

Treat the addiction

- Help the patient to stop alcohol consumption and tobacco smoking
- Involve a dependency counsellor or a psychologist

Alleviate abdominal pain

- Eliminate obstructive factors (duodenum, bile duct, pancreatic duct)
- Escalate analgesia in a stepwise fashion
- Refer to a pain management specialist
- For intractable pain, consider CT/EUS-guided coeliac axis block

Nutritional and pharmacological measures

- Diet: low in fat and high in protein and carbohydrates
- Pancreatic enzyme supplementation with meals
- Correct malabsorption of the fat-soluble vitamins and vitamin B12
- Micronutrient therapy with methionine, vitamins C & E, selenium (may reduce pain and slow disease progression)
- Steroids (only in autoimmune pancreatitis, for relief of symptoms)
- Medium-chain triglycerides in patients with severe fat malabsorption (they are directly absorbed by the small intestine without the need for digestion)
- Reducing gastric secretions may help

Treat diabetes mellitus

Endoscopic, radiological or surgical interventions are indicated mainly to relieve obstruction of the pancreatic duct, bile duct or the duodenum, or in dealing with complications (e.g. pseudocyst, abscess, fistula, ascites or variceal haemorrhage). Decompressing an obstructed pancreatic duct can provide pain relief in some patients (the assumption is that ductal hypertension causes the pain).

Endoscopic pancreatic sphincterotomy might be beneficial in patients with papillary stenosis and a high sphincter pressure and pancreatic ductal pressure. Patients with a dominant pancreatic duct stricture and upstream dilatation may benefit by placement of a stent across the stricture. The stent should be left in for no more than 4–6 weeks as it will block. The complication rate is high, and less than two-thirds of patients experience pain relief, but those who do get relief may benefit from a surgical bypass. Pancreatic duct stones may

be extracted at ERCP, and this may sometimes be combined with extracorporeal shock wave lithotripsy. Pseudocysts may be drained internally under EUS guidance. Percutaneous or transgastric drainage of pseudocysts under ultrasound or CT guidance may be performed.

The role of surgery is to overcome obstruction and remove mass lesions. Some patients have a mass in the head of the pancreas, for which either a pancreatoduodenectomy or a Beger procedure (duodenum-preserving resection of the pancreatic head) is appropriate. If the duct is markedly dilated, then a longitudinal pancreatojejunostomy or Frey procedure can be of value (**Figure 68.31**). The natural evolution of the disease may not be altered significantly, but around half the patients get long-term pain relief. The rare patient with disease limited to the tail will be cured by a distal pancreatectomy. Patients with intractable pain and diffuse disease may plead for a total pancreatectomy in the expectation that removing the offending organ will relieve their pain. However, one should keep in mind that pancreatic function and quality of life are significantly impaired after this procedure, and the operative mortality rate is not trivial. Moreover, there is no guarantee of pain relief (approximately a third of patients get resolution, a third show some benefit, and a third see no benefit at all). Total pancreatectomy and islet autotransplantation has been reported in selected patients, but it is difficult to demonstrate any overall benefit.

Prognosis

Chronic pancreatitis is a difficult condition to manage. Patients often suffer a gradual decline in their professional, social and personal lives. The pain may abate after a surgical or percutaneous intervention, but tends to return over a period of time. In a proportion of patients, the inflammation may gradually burn out over a period of years, with disappearance of the pain, leaving only the exocrine and endocrine insufficiencies. Development of pancreatic cancer is a risk in those who have had the disease for more than 20 years. New symptoms or a change in the pattern of symptoms should be investigated and malignancy excluded.

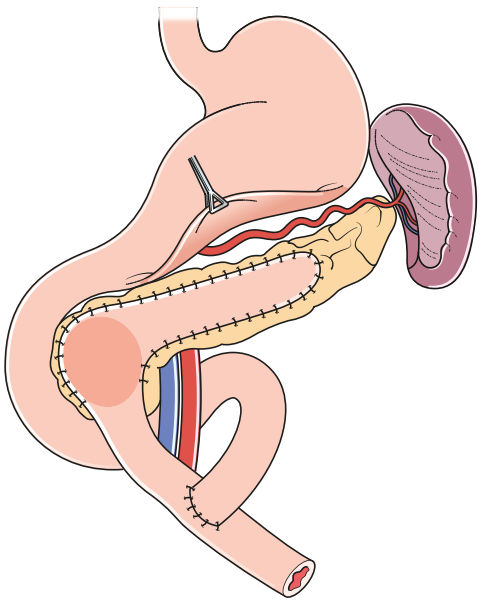

Figure 68.31 Pancreatojejunostomy. The pancreatic duct is opened longitudinally, and a loop of jejunum is sutured to the duct. In the Frey procedure, the superficial part of the head of the pancreas is removed to achieve drainage.

Sphincter of Oddi dysfunction

Separate mention is warranted of this condition, which should be considered in the differential diagnosis of chronic biliary or pancreatic pain. The sphincter of Oddi is 6–10 mm long and lies within the duodenal wall. A part of it encircles the common channel, and then there are separate biliary and pancreatic components (see **Figure 68.5**). In most mammals the bile duct and pancreatic duct have separate openings into the duodenum. The one other animal that has a sphincter anatomy very similar to that of humans is the Australian possum. Sphincter of Oddi dyskinesia or dysfunction (SOD) is a clinical syndrome in which pain, biochemical abnormalities and dilatation of the bile duct and/or pancreatic duct are attributed to abnormal function of the sphincter of Oddi. The true incidence of SOD is unknown. Females are more commonly affected than males. SOD may result from stenosis of the sphincter, or from dysmotility. Scarring or stenosis of the sphincter can result from passage of stones, pancreatitis or prior endoscopic sphincterotomies.

There are two clinical types of SOD. Biliary-type SOD is characterised by biliary pain, which may be accompanied by abnormally raised liver enzymes and/or dilation of the bile duct and/or evidence of delayed emptying on biliary scintigraphy. It may be a cause of persistent post-cholecystectomy symptoms. A predominance of pancreatic problems, especially recurrent episodes of acute pancreatitis, is known as pancreatic-type SOD. Each type of SOD is further divided into types I, II and III (*Table 68.7*). This classification helps to predict the underlying pathology and the likelihood of successful treatment. Type I disease is thought to result from a fixed stenosis and responds best to therapy. An episodic dysmotility is the presumed underlying abnormality in the other types and often does not respond as well to treatment.

Biliary type SOD should be considered and excluded in patients with the post-cholecystectomy syndrome. Pancreatic type SOD should be excluded in patients with recurrent acute pancreatitis of unexplained aetiology. The role of SOD in chronic pancreatitis is unclear. A careful history is essential. CT and MRCP can demonstrate dilatation of the biliary and pancreatic ducts. MRCP with intravenous secretin injection can particularly demonstrate pancreatic duct dilatation due to raised sphincter pressures. EUS may achieve the same end. Quantitative cholescintigraphy (HIDA scan) may demonstrate delayed biliary transit. The gold standard for diagnosing SOD is ERCP with manometry of the biliary and pancreatic sphincters, though many would say that this is not essential for diagnosis of type I SOD. ERCP with manometry

Charles Frederick Frey, b.1929, Professor of Surgery, The University of California, Davids, CA, USA.

TABLE 68.7 Milwaukee classification of sphincter of Oddi (SOD) dysfunction.

1. Biliary type SOD:
Type I: Typical biliary type pain Liver enzymes (AST, ALT or ALP) >2 times normal limit documented on at least 2 occasions during episodes of pain Dilated CBD >12 mm in diameter Prolonged biliary drainage time (>45 min)*
Type II: Biliary type pain, and One or two of the above criteria
Type III: Biliary type pain only
2. Pancreatic type SOD:
Type I: Pancreatic type pain Amylase and/or lipase >2 times upper normal limit on at least 2 occasions during episodes of pain Dilated pancreatic duct (head >6 mm, body >5 mm) Prolonged pancreatic drainage time (>9 min)*
Type II: Pancreatic type pain, and One or two of the above criteria
Type III: Pancreatic type pain only

* difficult to measure and often eschewed in clinical practice

is indicated if the pain disabling, noninvasive investigations have not shown structural abnormalities and conservative therapy has not helped. The variables customarily assessed at manometry are basal pressure and amplitude, duration, frequency, and propagation pattern of the phasic waves. Basal sphincter pressure higher than 40 mm Hg is the manometric criterion used to diagnose SOD.

Endoscopic sphincterotomy is the treatment of choice for type I SOD. The question of whether dual sphincterotomies (biliary and pancreatic) should be carried out remains unanswered. There is however a particularly high risk of post-ERCP pancreatitis (30% or more), though placement of a pancreatic stent at the time of the procedure appears to reduce this risk. Such treatments are best carried out in tertiary units by expert gastroenterologists. For patients with type II SOD, manometry should be done before considering sphincterotomy, and the results of sphincterotomy are less consistent. Patients with type III SOD are even more difficult, with response rates to sphincterotomy ranging from 8% to 65%. Medical therapy should be tried before proceeding to manometry. Proton pump inhibitors, spasmolytic drugs, calcium blockers (nifedipine), and psychotropic agents have all been tried with varying degrees of success. Injection of botulinum toxin (which can cause a chemical sphincterotomy for up to 3 months) or placement of a pancreatic stent (these are usually removed after 6 weeks) do not provide lasting relief, but can be used to identify patients who may benefit from a sphincterotomy.

A recent study in patients with abdominal pain after cholecystectomy and suspected SOD casts doubt on the efficacy of endoscopic sphincterotomy. In patients undergoing ERCP with manometry, sphincterotomy versus sham did not reduce disability due to pain. Manometry results were not associated with the outcome. No clinical subgroups appeared to benefit from sphincterotomy more than others.

In a small subgroup of patients who have experienced significant but short-lived relief with sphincterotomy or stenting, surgical transduodenal sphincteroplasty may be considered. But the long-term results of surgical sphincteroplasty are often poor. In exceptional circumstances, where the pancreatic head is badly scarred and sphincteroplasty has failed or is unlikely to succeed, there may be grounds for surgical resection of the pancreatic head.

CARCINOMA OF THE PANCREAS

Pancreatic cancer is the sixth leading cause of cancer death in the UK, and the incidence is 10 cases per 100 000 population per year. Worldwide, it constitutes 2–3% of all cancers and, in the USA, is the fourth highest cause of cancer death. The incidence has declined slightly over the last 25 years. There is no simple screening test; however, patients with an increased inherited risk of pancreatic cancer (*Table 68.8*) should be referred to specialist units for screening and counselling.

TABLE 68.8 Risk factors for the development of pancreatic cancer.

Demographic factors
Age (peak incidence 65–75 years)
Male gender
Black ethnicity
Environment/lifestyle
Cigarette smoking
Genetic factors and medical conditions
Family history
Two first-degree relatives with pancreas cancer: relative risk increases 18- to 57-fold
Germline BRCA2 mutations in some rare high-risk families
Hereditary pancreatitis (50- to 70-fold increased risk)
Chronic pancreatitis (5- to 15-fold increased risk)
Lynch syndrome (HNPCC)
Ataxia telangiectasia
Peutz–Jeghers syndrome
Familial breast–ovarian cancer syndrome
Familial atypical multiple mole melanoma
Familial adenomatous polyposis – risk of ampullary/duodenal carcinoma
Diabetes mellitus

HNPCC, hereditary non-polyposis colorectal cancer.

Henry T Lynch, b.1928, Professor of Preventative Medicine, Creighton University, Omaha, NE, USA.
John Law Augustine Peutz, 1886–1968, Chief Specialist for Internal Medicine, St. John's Hospital, The Hague, The Netherlands.
Harold Joseph Jeghers, 1904–1990, Professor of Internal Medicine, The New Jersey College of Medicine and Dentistry, Jersey City, NJ, USA.

Pathology

More than 85% of pancreatic cancers are ductal adenocarcinomas. The remaining tumours constitute a variety of pathologies with individual characteristics. Endocrine tumours of the pancreas are rare. These are covered in Chapter 52.

Ductal adenocarcinomas arise most commonly in the head of the gland. They are solid, scirrhous tumours, characterised by neoplastic tubular glands within a markedly desmoplastic fibrous stroma. Fibrosis is also a characteristic of chronic pancreatitis, and histological differentiation between tumour and pancreatitis can cause diagnostic difficulties. Ductal adenocarcinomas infiltrate locally, typically along nerve sheaths, along lymphatics and into blood vessels. Liver and peritoneal metastases are common. Proliferative lesions in the pancreatic ducts can precede invasive ductal adenocarcinoma. These are termed pancreatic intraepithelial neoplasia or PanIN, and can demonstrate a range of structural complexity and cellular atypia.

Cystic tumours of the pancreas may be serous or mucinous. Serous cystadenomas are typically found in older women, and are large aggregations of multiple small cysts, almost like bubblewrap. They are benign. Mucinous tumours, on the other hand, have the potential for malignant transformation. They include mucinous cystic neoplasms (MCNs) and intraductal papillary mucinous neoplasms (IPMNs). MCNs are seen in perimenopausal women, show up as multilocular thick-walled cysts in the pancreatic body or tail, and, histologically, contain an ovarian-type stroma. IPMNs are more common in the pancreatic head and in older men, but an IPMN arising from a branch duct can be difficult to distinguish from an MCN. IPMNs arising within the main duct are often multifocal and have a greater tendency to prove malignant. Thick mucus seen extruding from the ampulla at ERCP is diagnostic of a main duct IPMN. Mucinous tumours can be confused with pseudocysts (see *Summary box 68.8*). Occasionally, lymphoepithelial cysts, lymphangiomas, dermoid cysts and intestinal duplication cysts can show up in the pancreas. Solid pseudopapillary tumour is a rare, slowly progressive but malignant tumour, seen in women of childbearing age, and manifests as a large, part-solid, part-cystic tumour.

Tumours arising from the ampulla or from the distal common bile duct can present as a mass in the head of the pancreas, and constitute around a third of all tumours in that area. Adenomas of the ampulla of Vater are diagnosed at endoscopy as polypoid submucosal masses covered by a smooth epithelium. They can harbour foci of invasive carcinoma; the larger the adenoma, the greater the risk. Biopsies taken at endoscopy may not always include the malignant focus. Endoscopic surveillance, endoscopic resection or even surgical transduodenal ampullary excision should be considered (**Figure 68.32**). Patients with familial adenomatous polyposis (FAP) can present with multiple duodenal polyps. Malignant transformation in a duodenal polyp is a significant cause of mortality in these patients, mandating endoscopic follow-up and pancreatoduodenectomy in selected patients with high-grade dysplasia within the polyp.

Ampullary adenocarcinomas often present early with biliary obstruction. Their natural history is distinctly more favourable compared with pancreatic ductal adenocarcinoma. Ampullary carcinomas are relatively small when diagnosed, which may account for their better prognosis. Occasionally, other malignant neoplasms can arise at the ampulla, such as carcinoid tumours and high-grade neuroendocrine carcinomas.

Clinical features

Jaundice secondary to obstruction of the distal bile duct is the most common symptom that draws attention to ampullary and pancreatic head tumours. It is characteristically painless jaundice but may be associated with nausea and epigastric discomfort. Pruritus, dark urine and pale stools with steatorrhoea are common accompaniments of jaundice. In the absence of jaundice, symptoms are often non-specific, namely vague discomfort, anorexia and weight loss, and are frequently dismissed by both patient and doctor. Upper abdominal symptoms in a recently diagnosed diabetic, especially in one above 50 years of age, with no family history or obesity, should raise suspicion. Occasionally, a patient will present with an unexplained attack of pancreatitis; all such patients should have follow-up imaging of the pancreas. Tumours of the body and tail of the gland often grow silently, and present at an advanced unresectable stage. Back pain is a worrying symptom, raising the possibility of retroperitoneal infiltration.

On examination, there may be evidence of jaundice, weight loss, a palpable liver and a palpable gall bladder. Courvoisier first drew attention to the association of an enlarged

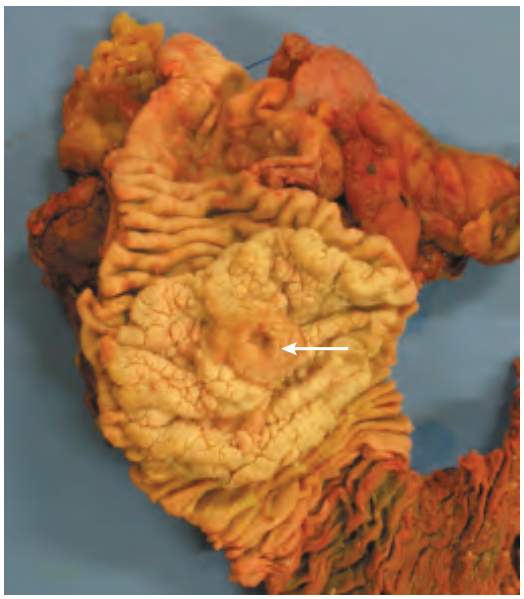

Figure 68.32 A large ampullary adenoma that turned into an adenocarcinoma; the arrow indicates the ampulla. Photograph taken after resection in the form of a pancreatoduodenectomy (courtesy of Dr Joanne Chin-Aleong).

Ludwig Courvoisier, 1843–1918, surgeon, Basel, Switzerland, was one of the first surgeons to remove stones from the common bile duct.

gall bladder and a pancreatic tumour in 1890, when he noted that, when the common duct is obstructed by a stone, distension of the gall bladder (which is likely to be chronically inflamed) is rare; when the duct is obstructed in some other way, such as a neoplasm, distension of the normal gall bladder is common. Other signs of intra-abdominal malignancy should be looked for with care, such as a palpable mass, ascites, supraclavicular nodes and tumour deposits in the pelvis; when present, they indicate a grim prognosis.

Investigation

In a jaundiced patient, the usual blood tests and ultrasound scan should be performed. Ultrasound will determine if the bile duct is dilated. If it is, and there is a genuine suspicion of a tumour in the head of the pancreas, the preferred test is a contrast-enhanced CT scan (see **Figure 68.8**). In the majority of instances, this should establish if there is a tumour in the pancreas and if it is resectable. The presence of hepatic or peritoneal metastases, lymph node metastases distant from the pancreatic head, or encasement of the superior mesenteric, hepatic or coeliac artery by tumour are clear contraindications to surgical resection. Tumour size, continuous invasion of the duodenum, stomach or colon, and lymph node metastases within the operative field are not contraindications. If the tumour abuts or minimally invades the portal or superior mesenteric vein, this is not a contraindication to surgery (as part of the vein can be resected if necessary), but complete encasement and occlusion of the vein is. MRI and MR angiography can provide information comparable to CT.

ERCP and biliary stenting should be carried out if there is any suggestion of cholangitis, if there is diagnostic doubt (small ampullary lesions may not be seen on CT, and ERCP is the best way to identify them) or if there is likely to be a delay between diagnosis and surgery and the patient is deeply jaundiced with distressing pruritus. It relieves the jaundice and can also provide a brush cytology or biopsy specimen to confirm the diagnosis (see **Figures 68.13**, **68.14** and **68.19**). Otherwise, however, preoperative ERCP and biliary stenting is not mandatory in patients with resectable disease; there is evidence to suggest that it is associated with a slightly higher incidence of infective complications after surgery. The prothrombin time should be checked, and clotting abnormalities should be corrected with vitamin K or fresh-frozen plasma prior to ERCP. If a stent is placed in a patient who may undergo resection, it should be a plastic stent or a covered metal stent, as these can be easily pulled out during surgery. If a naked metal self-expanding stent is placed (that will get embedded in its position), it should be a relatively short one that does not extend too high up the bile duct towards the biliary confluence.

EUS is useful if CT fails to demonstrate a tumour, if tissue diagnosis is required prior to surgery (e.g. a mass has developed on a background of chronic pancreatitis and a distinction needs to be made between inflammation and neoplasia), if vascular invasion needs to be confirmed, or in separating cystic tumours from pseudocysts (**Figure 68.33**; see also **Figure 68.20**). Transduodenal or transgastric FNA or Trucut biopsy performed under EUS guidance avoids spillage of tumour cells into the peritoneal cavity. Percutaneous transperitoneal biopsy of potentially resectable pancreatic tumours should be avoided as far as possible. Histological confirmation of malignancy is desirable but not essential, particularly if the imaging clearly demonstrates a resectable tumour. The lack of a tissue diagnosis should not delay appropriate surgical therapy. In patients judged to have unresectable disease, tissue diagnosis should be obtained prior to starting palliative therapy.

Diagnostic laparoscopy prior to an attempt at resection can spare a proportion of patients an unnecessary laparotomy by identifying small peritoneal and liver metastases. It can be combined with laparoscopic ultrasonography. The tumour marker CA19-9 is not highly specific or sensitive, but a baseline level should be established; if it is initially raised, it can be useful later in identifying recurrence.

Management

At the time of presentation, more than 85% of patients with ductal adenocarcinoma are unsuitable for resection because the disease is too advanced. If imaging shows that the tumour is potentially resectable, the patient should be considered

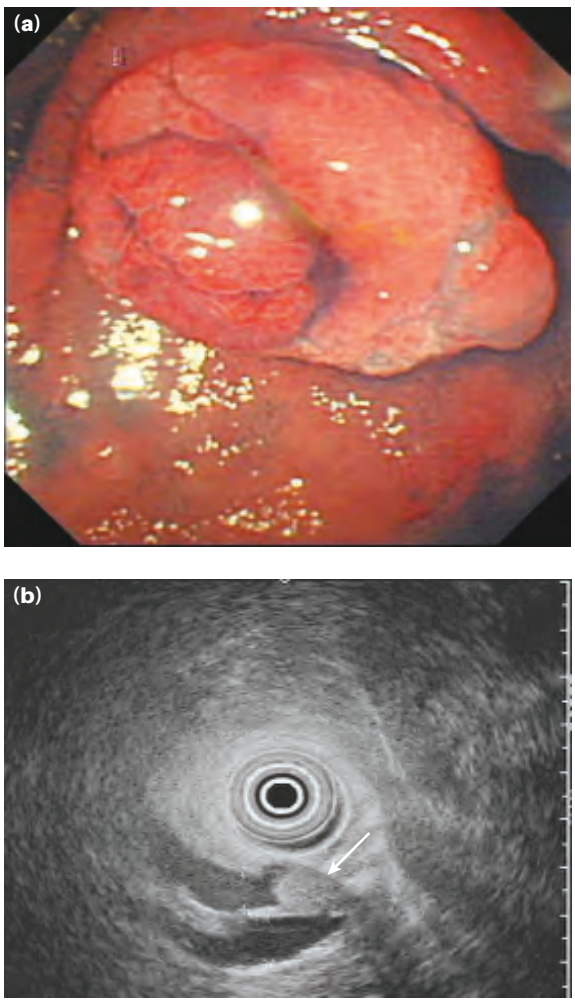

Figure 68.33 **(a)** Carcinoma of the ampulla as seen at endoscopy. **(b)** Appearance of the same tumour (arrow) on endoscopic ultrasound (courtesy of Dr Peter Fairclough).

for surgical resection, as that offers the only (albeit small) chance of a cure. Comorbidities should be taken carefully into account. Biological rather than chronological age should be the consideration. If a cystic tumour is encountered, no matter how large, surgical resection should be considered, as it carries a reasonable chance of cure. Tumours of the ampulla have a good prognosis and should, if at all possible, be resected. Some of the rare tumours and the neuroendocrine lesions should also be resected if at all possible. For those patients who have inoperable disease, palliative treatment should be offered.

Surgical resection

The standard resection for a tumour of the pancreatic head or the ampulla is a pylorus-preserving pancreatoduodenectomy (PPPD). This involves removal of the duodenum and the pancreatic head, including the distal part of the bile duct. The original pancreatoduodenectomy as proposed by Whipple included resection of the gastric antrum. Preserving the antrum and the pylorus is thought to result in a more physiological outcome with no difference in survival or recurrence rates. The Whipple procedure is now reserved for situations in which the entire duodenum has to be removed (e.g. in FAP) or where the tumour encroaches on the first part of the duodenum or the distal stomach and a PPPD would not achieve a clear resection margin. Total pancreatectomy is warranted only in situations where one is dealing with a multifocal tumour (e.g. a main duct IPMN), or the body and tail of the gland are too inflamed or too friable to achieve a safe anastomosis with the bowel. The PPPD procedure includes a local lymphadenectomy. Extended lymphadenectomy has not been shown to be beneficial in improving survival and is associated with increased morbidity. If the tumour is adherent to the portal or superior mesenteric vein, but can still be removed by including a patch or a short segment of vein in the resection, with an appropriate reconstruction of the vessel, then that should be done. This is not associated with an increase in the morbidity or mortality of the procedure, and the outcomes are similar.

For tumours of the body and tail, distal pancreatectomy with splenectomy is the standard. Infiltration of the splenic artery or vein by the tumour is not a contraindication to resection. When resecting the pancreatic tail for a benign lesion, one may attempt to preserve the spleen if possible. When removing the spleen, prior vaccinations against pneumococci, meningococci and *Haemophilus influenzae* B should be administered, and subsequent antibiotic prophylaxis given (see Chapter 66).

While the majority of pancreatic resections continue to be performed via the open approach, there is evidence that the laparoscopic and robotic approaches are also feasible and may yield comparable results. Laparoscopic pancreatic resections are technically challenging, pose additional demands on operating room time and equipment, and involve a significant learning curve for the surgeon and the entire team. Distal pancreatectomy, especially for smaller tumours, lends itself more easily to the laparoscopic approach than a pancreatic head resection.

PANCREATODUODENECTOMY

The patient's coagulation screen should be checked preoperatively and adequate hydration ensured. The patient should be aware of the diagnosis, the gravity of the operation and the risks involved. The operation has three distinct phases:

- exploration and assessment;
- resection;
- reconstruction.

A cholecystectomy is performed. The bile duct and hepatic artery are exposed, removing the lymphatic tissue in this area. Exposure of the hepatic artery enables division of the gastroduodenal artery and visualisation of the portal vein. The distal part of the gastric antrum is mobilised. The duodenum and right colon are mobilised from the retroperitoneal tissues. The superior mesenteric vein is exposed inferior to the pancreatic neck. Careful dissection into the plane between the vein and the pancreatic substance (see **Figure 68.2**) will reveal whether the tumour is adherent to the vein. At this juncture, a decision has to be made whether to proceed to the next phase of resection or not. If resection is to be performed, the fourth part of the duodenum is dissected and freed from the ligament of Treitz so that the upper jejunum can be brought into the supracolic compartment. The jejunum is divided 20–30 cm downstream from the duodenojejunal flexure, and the mesentery of the proximal jejunum is detached. The first part of the duodenum is divided. The neck of the pancreas is divided, and then the uncinate process is separated from the superior mesenteric vein and artery working up towards the upper bile duct, which is divided, releasing the specimen (**Figure 68.34**). Retroperitoneal lymph nodes within the operative field are completely removed with the specimen. Reconstruction is carried out as in **Figure 68.35**. The pancreatic stump, the divided bile duct and the duodenal stump are anastomosed on to the jejunum, in that order. Some surgeons prefer to anastomose the pancreas to the posterior wall of the stomach instead; others prefer to create a separate Roux loop of the jejunum and anastomose the pancreas to that. The operation should take between 3 and 6 hours. Blood loss should be low, and transfusion is often not necessary. The patients are usually nursed in a high-dependency area for the first 24–48 hours after surgery. Prolonged nasogastric drainage is unnecessary, and early feeding can be commenced.

Resection for pancreatic cancer should be carried out in specialist units. There is a clear correlation between higher caseload volume and lower hospital mortality and morbidity.

Allen Oldfather Whipple, 1881–1963, Director of Surgical Services, The Presbyterian Hospital, and Professor of Surgery, Columbia University, New York, NY, USA, began to perform two-stage pancreatoduodenectomies in 1934 and shortened the procedure into a one-stage process in 1940. Alessandro Codivilla (1861–1912) and Walter Kausch (1867–1928) had performed the operation before him, but Whipple was the surgeon who established pancreatoduodenectomy as an operation.

Wenzel Treitz, 1819–1872, Professor of Anatomy and Pathology, at Krakow, Poland, and later at Prague, The Czech Republic. He was involved in the struggle for Czech nationalism and at 52 committed suicide by taking potassium cyanide.

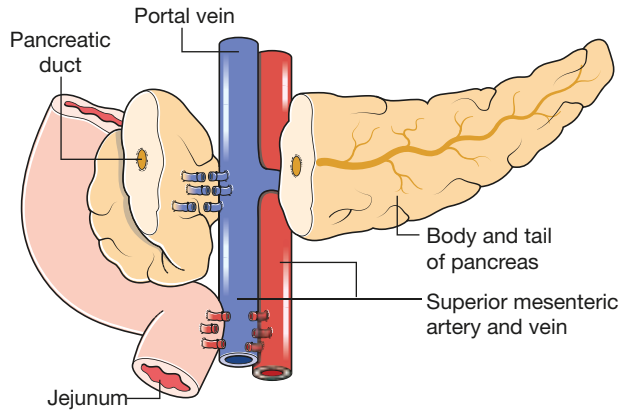

Figure 68.34 Resection of the head of the pancreas in a pylorus-preserving pancreatoduodenectomy.

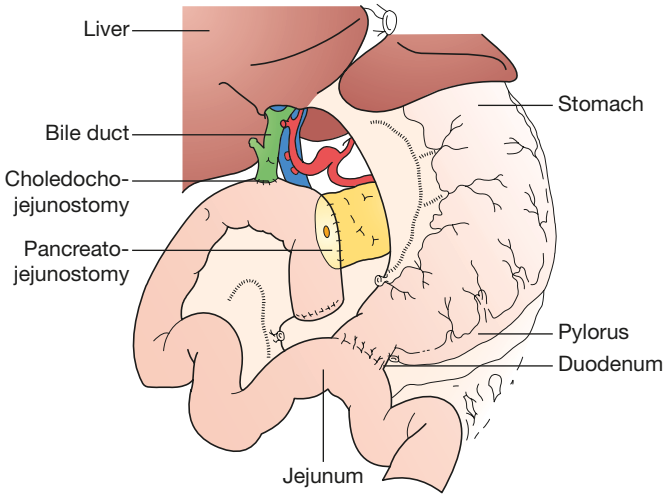

Figure 68.35 Reconstruction after a pylorus-preserving pancreatoduodenectomy.

PPPD should carry a mortality of no more than 3–5%. The morbidity remains high, with some 30–40% of patients developing a complication in the postoperative period. These complications are usually infective, but a leak from the anastomosis between the pancreas and the bowel is known to occur in at least 10% of patients, and this may give rise to major complications. Octreotide may be administered in the perioperative period to suppress secretion and reduce the likelihood of a leak, but the evidence for its efficacy is still debatable. Following surgical resection, the pathological tumour–node–metastasis stage should be documented.

ADJUVANT THERAPY

At the beginning of this century, the reported 5-year survival following resection of a pancreatic adenocarcinoma ranged from 7% to 25% (around 10% for most centres). The median survival was 11–20 months. Considering that, at best, 15% of patients had resectable disease to begin with, this meant only two or three out of 100 patients with this disease could expect to survive to 5 years. Moreover, recurrences could and did show up even beyond the 5-year cut-off. The high recurrence rate following resection inevitably led to the consideration of adjuvant treatments to improve outcome. In a large multicentre European study (ESPAC-1) reported in 2004, adjuvant radiotherapy or chemoradiotherapy was shown to confer no advantage, but chemotherapy with 5-fluorouracil (5-FU) provided an overall benefit; median survival with chemotherapy was 20 months compared with 16 months without. Another trial (ESPAC-3) showed that gemcitabine works equally well. A further trial (ESPAC-4), of gemcitabine alone versus gemcitabine with capecitabine (a fluorouracil that can be taken orally) has indicated that the latter regimen can push the median survival above 2 years and the 5-year survival close to 30%. Most patients with resected ductal adenocarcinoma are now offered 6 months of adjuvant chemotherapy with gemcitabine and/or 5-FU. Some centres continue to offer chemoradiotherapy, particularly in patients with involved (R1) resection margins, and further trials of adjuvant chemoradiation are in progress.

It should be emphasised, however, that these depressing statistics apply to ductal adenocarcinomas. Patients with resected ampullary tumours have a 5-year survival of 40%, and cystic tumours and neuroendocrine tumours can often be cured by surgical resection.

Palliation

The median survival of patients with unresectable, locally advanced, non-metastatic pancreatic cancer is 6–10 months and, in patients with metastatic disease, it is 2–6 months.

If unresectable disease is found in the course of a laparotomy that was commenced with the intent to resect, a choledochoenterostomy and a gastroenterostomy should be carried out to relieve (or pre-empt) jaundice and duodenal obstruction. The bile duct may be anastomosed to the duodenum, or to a loop of jejunum. It is preferable to use the bile duct rather than the gall bladder. Cholecystojejunostomy is easier to perform, but the bile must then drain through the cystic duct, which is narrow and, if inserted low into the bile duct, is vulnerable to occlusion by tumour growth. A coeliac plexus block can also be administered. A transduodenal Trucut biopsy of the tumour should be obtained.

In patients found to have unresectable disease on imaging, jaundice is relieved by stenting at ERCP (**Figure 68.36a**). Stents may be made of plastic or self-expanding metal mesh. Plastic stents are cheaper but tend to occlude faster and, if the patient is likely to have a longer life expectancy, a metal stent can be used. If the patient is not a suitable candidate for endoscopic biliary stenting, a percutaneous transhepatic stent can be placed (**Figure 68.36b**). Obstruction of the duodenum occurs in approximately 15% of cases. If this occurs early in the course of the disease, surgical bypass by gastrojejunostomy is appropriate but, if it is late in the course of the disease, then the use of expanding metal stents inserted endoscopically is preferable, as many of these patients have prolonged delayed gastric emptying following surgery (**Figure 68.36c**). If both biliary and duodenal metal stents are to be placed endoscopically, the biliary one should be placed first.

If no operative procedure is undertaken, an EUS-guided or percutaneous biopsy of the tumour should be performed before consideration of chemotherapy or chemoradiation.

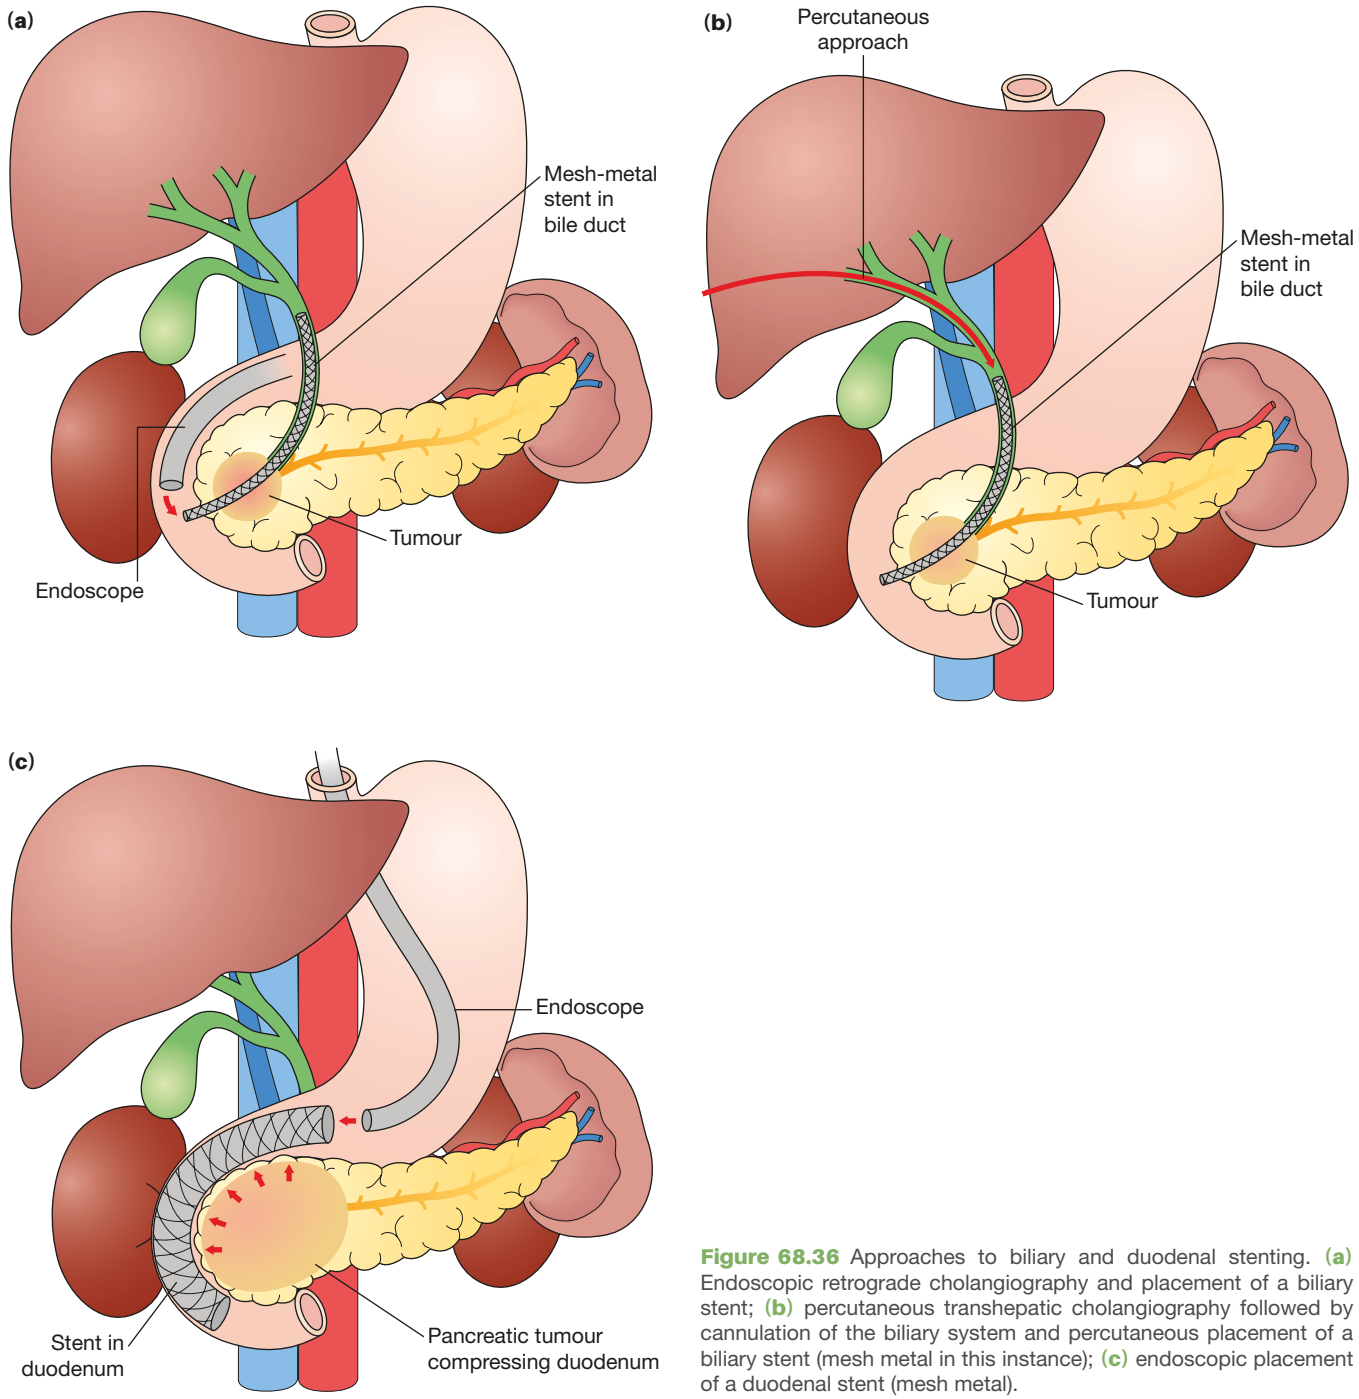

Figure 68.36 Approaches to biliary and duodenal stenting. **(a)** Endoscopic retrograde cholangiography and placement of a biliary stent; **(b)** percutaneous transhepatic cholangiography followed by cannulation of the biliary system and percutaneous placement of a biliary stent (mesh metal in this instance); **(c)** endoscopic placement of a duodenal stent (mesh metal).

Lymphomas of the pancreas are rare and constitute less than 3% of all pancreatic cancers. These respond to chemoradiotherapy and surgical resection is not indicated. For patients with ductal adenocarcinoma, 5-FU or gemcitabine will produce a remission in 15–25%, while the remainder will receive no benefit from the therapy. Better tumour responses are now being achieved with multiagent chemotherapy regimens such as the combination of fluorouracil, irinotecan, oxaliplatin, and leucovorin (FOLFIRINOX) and gemcitabine plus albumin-bound paclitaxel particles (nab-paclitaxel). However the 2–5 months' increase in median survival with these regimens has to be offset against the higher toxicity and cost. No long-term cures have been described with chemotherapy or radiotherapy.

Attempts to downstage unresectable disease with chemotherapy or chemoradiation and render it resectable are rarely successful. In a very small proportion of patients who have been deemed unresectable due to major vascular involvement and do not have metastatic disease, attempts have been made to downstage the tumour with one of the newer combination

chemotherapy regimens, sometimes with chemoradiation thrown in, to try to render them resectable. Such neoadjuvant therapies should ideally be considered within a clinical trial.

Steatorrhoea is treated with enzyme supplementation. Diabetes mellitus, if it develops, is treated with oral hypoglycaemics or insulin as appropriate, and pain with either analgesics or an appropriate nerve block.

Summary box 68.10

Palliation of pancreatic cancer

Relieve jaundice and treat biliary sepsis

- Surgical biliary bypass
- Stent placed at ERCP or percutaneous transhepatic cholangiography

Improve gastric emptying

- Surgical gastroenterostomy
- Duodenal stent

Pain relief

- Stepwise escalation of analgesia
- Coeliac plexus block
- Transthoracic splanchnicectomy

Symptom relief and quality of life

- Encourage normal activities
- Enzyme replacement for steatorrhoea
- Treat diabetes

Consider chemotherapy

Chapter 69

The small intestine

Learning objectives

To appreciate:
- The basic anatomy and physiology of the small intestine
- The range of conditions that may affect the small intestine

To understand:
- The aetiology and pathology of common small intestinal conditions
- The principles of investigation of small intestinal symptoms
- The importance of non-surgical management of small intestinal problems
- The principles of small intestinal surgery
- That complex intestinal problems are best managed by a multidisciplinary team
- The management of acute surgical problems of the intestines

ANATOMY OF THE SMALL INTESTINE

Although the duodenum is anatomically indistinguishable from the small intestine, it is subject to some specific pathologies and surgical therapies; therefore, in purely surgical terms it may be regarded as a distinct entity and is covered in Chapter 63. The length of the small bowel varies from 300 to 850 cm between the duodenojejunal (DJ) flexure to the ileocaecal valve (Figure 69.1). It is notoriously difficult to establish the length of the small intestine, and estimates gathered at surgery, at postmortem and during radiological investigations may vary widely, even in the same individual. In addition, there is considerable inter-individual variability and the small intestine has been said to be longer in men.

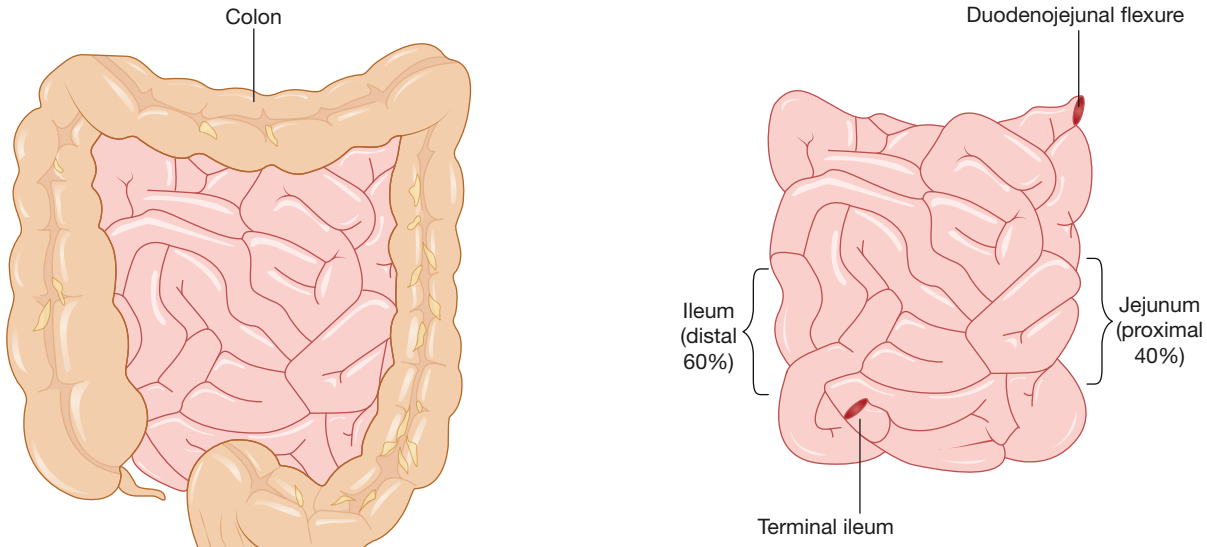

Figure 69.1 Portions of the small bowel and their relations to the colon.

The proximal 40% of the small intestine is referred to as the jejunum; the remainder is the ileum. There is no clear demarcation between jejunum and ileum, but the small bowel does change gradually in character from proximal to distal. The jejunum tends to have a wider diameter and a thicker wall, with more prominent mucosal folds (valvulae conniventes), while the ileum has a thicker, more fatty mesentery with more complex arterial arcades. The ileum also contains larger aggregates of lymph nodes (Peyer's patches), which can occasionally become lead points in intussusception in childhood.

The small intestine has a very rich blood supply, derived from the superior mesenteric artery, while venous drainage is via the portal venous system, into which the superior mesenteric vein drains blood rich in nutrients after a meal. This arrangement facilitates processing of the nutrients by the liver, into which the portal vein drains in turn. The lymphatic drainage of the small intestine follows the arterial supply.

The small intestine has a rich autonomic innervation arising from the splanchnic nerves, which contribute a dense network of sympathetic fibres around the superior mesenteric artery and its branches. Referred pain from the small intestine is usually felt in the periumbilical region (T10). The blood and nerve supply to the small intestine runs in the attached mesentery, which originates on the posterior abdominal wall and runs obliquely downwards to the right between the duodenojejunal flexure to the left of the second lumbar vertebra and the right sacroiliac joint.

Summary box 69.1

Important features of small bowel anatomy

- Comprises jejunum and ileum
- Has valvulae conniventes
- Blood supply from superior mesenteric artery

PHYSIOLOGY OF THE SMALL INTESTINE

The principal function of the small intestine is the digestion of food and the absorption of nutrients, water and electrolytes. Carbohydrates and proteins are broken down in the intestinal lumen by pancreatic enzymes, but the final hydrolysis takes place at the brush border of the jejunum, after which they are absorbed. Fats are digested chiefly by the actions of pancreatic lipase and bile salts. The products of fat digestion, fatty acids and monoglycerides, separate from bile salts in the jejunum and are absorbed for further processing. The jejunum is the principal site for digestion and absorption of fluid, electrolytes, iron, folate, fat, protein and carbohydrate, but the absorption of bile salts and vitamin B12 only occurs in the terminal ileum, where there are specific transporters. If the jejunum is resected, the ileum can assume all the required absorptive functions, but resection of the terminal ileum will result in a diminished bile salt pool, B12 deficiency and may lead to deficiency of the fat-soluble vitamins A, D, E and K.

The small intestine plays an important role in the metabolism of plasma lipoproteins, as it is the main site of synthesis of high-density, low-density and very low-density lipoproteins (HDL, LDL, VLDL). These particles transport most of the absorbed dietary fat to the systemic circulation via the lymph. The small bowel also synthesises intestinal hormones such as glucagon-like peptides GLP-1 and 2, peptide YY and motilin, which interact with the enteric nervous system to modulate intestinal function, growth and differentiation.

INFLAMMATORY BOWEL DISEASE

By definition, the term 'inflammatory bowel disease' is reserved for conditions characterised by the presence of idiopathic intestinal inflammation, while conditions such as infective or ischaemic enteritis are excluded. Crohn's disease (CD) is the only known 'inflammatory bowel disease' affecting the small intestine.

Crohn's disease (regional enteritis)

The label 'Crohn's disease' (CD) became attached to a chronic inflammatory disease of the ileum following a key publication by Crohn and colleagues in 1932. CD is characterised by a chronic full-thickness inflammatory process that can affect any part of the gastrointestinal tract from the lips to the anal margin. It is most common in North America and Northern Europe with an annual incidence of 8 per 100 000. Prevalence rates of around 145 per 100 000 have been reported in the UK. Over the last four decades, the incidence appears to have increased three-fold, thought to possibly be a consequence of environmental factors, improved diagnostic modalities, or both. It is slightly more common in women than in men, and is most commonly diagnosed between the ages of 25 and 40 years. There is a second peak of incidence around the age of 70 years. In those countries with high prevalence of CD, the groups with the highest prevalence seem to be Caucasian, notably American Whites and Northern Europeans, whereas it is less common, even in high prevalence countries, in those originating from Central Europe and less prevalent still in those originating from South America, Asia and Africa. CD seems to be especially prevalent (three- to five-fold higher) in the Ashkenazi Jewish population, although interestingly, the prevalence of CD in the Jewish population in Israel is lower than that in Europe or the United States, suggesting that environmental factors are also important.

Aetiology

The aetiology of CD is incompletely understood but is thought to involve a complex interplay of genetic and environmental factors. Although CD shares some features with chronic

Valvulae conniventes describes a fold of mucous membrane that passes across two-thirds of the bowel circumference.
Johann Conrad Peyer, 1653–1712, Professor of Logis, Rhetoric and Medicine, Schaffausen, Switzerland, described the lymph follicles in the intestine in 1677.

infection, no causative organism has ever been demonstrated. An intriguing similarity to Johne's disease of cattle, a chronic inflammatory enteropathy resulting from infection with *Mycobacterium paratuberculosis*, suggests that CD in man may share a similar aetiology. Some studies of tissue affected by CD have identified mycobacterial DNA more frequently in patients with CD than in controls, but others have been less conclusive and, importantly, randomised controlled trials have failed to show a significant therapeutic benefit of treating CD with antituberculous drugs.

A wide variety of foods have been implicated, in particular a diet high in refined foodstuffs, but none conclusively. An association with high levels of sanitation in childhood has been suggested. Smoking increases the relative risk of CD three-fold and is certainly an exacerbating factor after diagnosis, contrary to the protective effect seen in ulcerative colitis (UC). Smoking cessation has a beneficial effect on disease activity that is comparable to that of very strong medical therapies, such as the antitumour necrosis factor drugs, and is therefore an essential component in the management of CD.

Genetic factors are also clearly extremely important. Approximately 10% of patients have a first-degree relative with the disease, and concordance has been shown to approach 50% in monozygotic twins. Inheritance is thought to involve multiple genes with low penetrance. The *NOD2/CARD15* gene has excited particular interest as variants of this gene have been shown to have strong associations with CD. Genetic manipulation of these genes in mice seems to induce the development of a disease resembling CD and abnormalities of these genes have been shown to be present in some members of families with a particularly high incidence of CD. It should be noted, however, that the vast majority of individuals with CD have no abnormalities of these genes. Since these genes are involved in intracellular recognition of bacteria, their discovery provides potentially valuable insight into the pathogenesis of CD, as a disease in which the relationship between the gut mucosa and the normal gut bacteria becomes deranged, resulting in uncontrolled intestinal inflammation.

Pathogenesis

As in UC, increased gut mucosal permeability appears to develop at a relatively early stage of the disease. This may lead to increased passage of luminal antigens, which then induce a cell-mediated inflammatory response. This results in the release of proinflammatory cytokines, such as interleukin-2 and tumour necrosis factor, which coordinate local and systemic inflammatory responses. It has been suggested that CD is associated with a defect in suppressor T-cells, which usually act to prevent escalation of the inflammatory process. As in UC, however, it remains unclear whether the proposed increase in intestinal permeability is a cause or consequence of the disease process. Studies of intestinal permeability in healthy and apparently unaffected first-degree relatives of patients with CD have also, however, suggested that gut permeability is increased, suggesting that a global, and potentially genetically determined increase in gut permeability, combined perhaps with an abnormal immune-mediated response to colonisation of the gut with some subspecies of the normal enteric microflora, may initiate the disease.

Pathology

The terminal ileum is most commonly involved (65%), either in isolation or in combination with colonic disease. Colitis alone occurs in up to a one-third of cases and the remainder are patients with more proximal small bowel involvement. The stomach and duodenum are affected in around 5%, but perianal lesions are common, affecting up to 50–75% of patients. Perianal disease occurs in 25% per cent of patients with small bowel disease, but in 75% of patients with Crohn's colitis.

Macroscopically, resection specimens show fibrotic thickening of the intestinal wall with narrowing of the lumen and fat wrapping (encroachment of mesenteric fat around the bowel, **Figure 69.2**). There is usually dilated bowel just proximal to the stricture and deep mucosal ulcerations with linear or snake-like patterns in the strictured area itself. Oedema in between the ulcers gives rise to a cobblestone appearance of the mucosa. The transmural inflammation (which is a characteristic feature of CD) may lead to segments of bowel becoming adherent to each other and to surrounding structures, inflammatory masses with mesenteric abscesses and fistulae into adjacent organs. The serosa is usually opaque, with thickening of the mesentery and enlarged mesenteric lymph nodes. CD is characteristically discontinuous, with inflamed areas separated by normal intestine, so-called 'skip' lesions.

Microscopically, there are focal areas of chronic inflammation involving all layers of the intestinal wall with lymphoid aggregates. Non-caseating giant cell granulomas are found in 60% of patients and when present clearly allow a confident diagnosis of CD. They are most common in anorectal disease.

A first-degree relative, defined as the individual's parents, siblings or children.
Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, along with Leon Ginzburg and Gordon Oppenheimer, described regional ileitis in 1932.

Multifocal arterial occlusions are found in the muscularis propria, which is thickened. There may be nerve cell hyperplasia and there is deep, fissuring ulceration within affected areas. Characteristically, and unlike in UC, there may be completely normal areas immediately next to areas of severe inflammation.

Clinical features

Presentation depends on the pattern of disease. Occasionally, CD presents acutely with ileal inflammation and symptoms and signs resembling those of acute appendicitis, or even with free perforation of the small intestine, resulting in a local or diffuse peritonitis. CD may present with fulminant colitis but this is considerably less common than in UC.

Summary box 69.2

Differences between ulcerative colitis (UC) and Crohn's disease (CD)

- UC affects the colon; CD can affect any part of the gastrointestinal tract, but particularly the small and large bowel
- UC is a mucosal disease, whereas CD affects the full thickness of the bowel wall
- UC produces confluent disease in the colon and rectum, whereas CD is characterised by skip lesions
- CD more commonly causes stricturing and fistulation
- Granulomas may be found on histology in CD, but not in UC
- CD is often associated with perianal disease, whereas this is unusual in UC
- CD affecting the terminal ileum may produce symptoms mimicking appendicitis, but this does not occur in UC
- Resection of the colon and rectum cures the patient with UC, whereas recurrence is common after resection in CD

CD more commonly presents with features of chronicity. Small bowel CD is often characterised by abdominal colicky pain, which may be postprandial, and mild diarrhoea extending over many months occurring in bouts. A tender mass may be palpable in the right iliac fossa. Intermittent fevers, secondary anaemia and weight loss are common. After months of repeated attacks characterised by acute inflammation, the affected area of intestine begins to narrow with fibrosis, causing more chronic obstructive symptoms. Children developing the illness before puberty may have retarded growth and sexual development. With progression of the disease, adhesions and transmural fissuring, intra-abdominal abscesses and fistulae may develop.

Fistulation may occur into adjacent loops of bowel (enteroenteric or interloop fistulae). Occasionally, the (healthy) sigmoid loop may become adherent to the affected terminal ileum, resulting in ileosigmoid fistulation. The fistula tracks in such cases are usually small and the profuse diarrhoea that results from ileosigmoid fistulation is due primarily to bacterial overgrowth (attributable to colonisation of the small bowel with colonic flora) rather than passage of small bowel content into the colon. Fistulation may also occur into the bladder (ileovesical) or the female genital tract and, less commonly, the duodenum. Fistulation into the abdominal wall (enterocutaneous fistulation) may also develop spontaneously, but it far more commonly occurs as a complication of abdominal surgery (see below).

Colonic CD presents with symptoms of colitis and proctitis as described for UC (Chapter 70), although toxic megacolon is much less common.

Many patients with CD present with perianal problems. In the presence of active disease, the perianal skin appears bluish. Superficial ulcers with undermined edges are relatively painless and can heal with bridging of epithelium. Deep cavitating ulcers are usually found in the upper anal canal; they can be painful and cause perianal abscesses and fistulae, discharging around the anus and sometimes forwards into the genitalia. Fistulation through the posterior wall of the vagina may lead to rectovaginal fistula and continuous leakage of gas and/or faeces per vaginam.

The rectal mucosa is often spared in CD and may feel normal on rectal examination. If it is involved, however, it will feel thickened, nodular and irregular. Perianal disease is frequently associated with dense, fibrous stricturing at the anorectal junction. Incontinence may develop as a result of destruction of the anal sphincter musculature because of inflammation, abscess formation, fibrotic change and repeated episodes of surgical drainage. In severe cases, the perineum may become densely fibrotic, rigid and covered with multiple discharging openings (watering-can perineum).

Each patient with CD should have their disease phenotype (manifestations) classified according to the Montreal classification. This is important as it allows an overview of disease progression in the individual patient over time, and it enables group comparisons and evaluations. The Montreal classification specifies age of onset, location and behaviour. As discussed above, the behaviour of CD can be dominated by inflammation without stricturing or penetration, stricturing or penetration (causing phlegmons, abscesses and fistulae).

EXTRAINTESTINAL MANIFESTATIONS

The extraintestinal manifestations of CD are similar to those that occur in UC and are outlined in Summary box 69.3. Primary sclerosing cholangitis is relatively rare in CD, compared with UC. Gallstones are common, as an inflamed or excised terminal ileum leads to reduced absorption of bile salts. Amyloidosis is common at postmortem examination, but is rarely symptomatic. 'Metastatic' CD can occur in the vagina and/or skin with nodular ulcers, which demonstrate non-caseating granulomas when biopsied. Such 'cutaneous' CD can be virtually indistinguishable macroscopically from hidradenitis suppurativa.

Investigations

LABORATORY

A full blood count should be performed, as anaemia is common and usually multifactorial. It may result from the anaemia of chronic disease, or from iron deficiency as a result of blood loss or malabsorption. Vitamin B12 deficiency may occur as a consequence of terminal ileal disease or resection. Folate deficiency may also result from diffuse small bowel disease or

  - Primary sclerosing cholangitis
  - Chronic active hepatitis
  - Sacroiliitis

resection. Active inflammatory disease is usually associated with a fall in serum albumin, magnesium, zinc and selenium. Acute phase protein measurements (C-reactive protein and orosomucoid) and the erythrocyte sedimentation rate may correlate with disease activity.

Finding an elevated concentration in the stools of calprotectin, a specific marker of inflammation, may support a diagnosis of CD in patients with new onset of persistent gastrointestinal symptoms. It can also be used to monitor disease activity in the long-term management of established CD.

ENDOSCOPY

Colonoscopic examination may be normal or show patchy inflammation. Characteristically, there are areas of normal mucosa in between areas of inflammation that are irregular and ulcerated, with a mucopurulent exudate. The earliest findings are of aphthous ulcers surrounded by a rim of erythematous mucosa. These become larger and deeper with increasing severity of disease. There may be stricturing, and it is important to exclude malignancy at these sites by multiple and often repeated mucosal biopsies. An irregular Crohn's stricture with polypoid mucosa may be almost macroscopically indistinguishable from malignancy. The terminal ileum may be ulcerated and strictured. In patients who have had previous ileocaecal resection and anastomosis, recurrent disease usually presents first with aphthous ulceration just proximal to the anastomosis. Interval colonoscopy is therefore important in the follow-up after surgery for CD.

Upper gastrointestinal symptoms may require upper gastrointestinal endoscopy, which may reveal deep longitudinal ulcers and cobblestoning of mucosa in the duodenum, stomach or, rarely, in the oesophagus.

Enteroscopy may reveal jejunal ulceration and stricturing. Capsule endoscopy should not be undertaken where there is a suspicion of stricture, because of the possibility of the capsule becoming stuck in the narrow segment. A biodegradable test capsule can be used if this is a source of concern. Capsule endoscopy has a useful role in those patients with evidence of chronic gastrointestinal symptoms or blood loss where no evidence of ulceration can be found with more conventional endoscopic assessment.

IMAGING

High-resolution ultrasound in expert hands can demonstrate inflamed and thickened bowel loops, as well as fluid collections and abscesses. The small intestine is traditionally imaged by a small bowel enema (**Figure 69.3**). This is performed by instilling contrast into the small bowel via a nasoduodenal tube, and will show up areas of stricturing and prestenotic dilatation. The involved areas tend to be narrowed, irregular and, sometimes, when a length of terminal ileum is involved, there may be the 'string sign' of Kantor (**Figure 69.3**).

Computed tomography (CT) scans with oral contrast are widely used in the investigation of abdominal symptoms and can demonstrate fistulae, intra-abdominal abscesses and bowel thickening or dilatation. Magnetic resonance imaging (MRI) is useful in assessing complex perianal disease and, more recently, has been shown to be an excellent method for investigating the small bowel. MR enterography (oral contrast) or enteroclysis (contrast administered via nasoduodenal tube) is particularly effective at demonstrating small bowel stricturing and avoids the need for repeated exposure to large

doses of ionising radiation in young patients (**Figure 69.4**). A labelled white cell scan is occasionally of value to determine whether or not a segment of bowel is actively inflamed and guide decisions on medical treatment.

In patients with enterocutaneous fistulae, fistulography will be required to demonstrate the anatomy and complexity of the fistulae and allow adequate planning for future surgery.

Treatment

MEDICAL TREATMENT

Steroids Steroids are the traditional method for inducing remission in CD, and remain important when rapid remission is required. They induce remission in 70–80% of cases with moderate to severe disease. They should be used in short courses only and tapered when a response has been achieved. They reduce inflammation and are therefore ineffective in fibrostenotic disease, where the symptoms relate mainly to obstruction. Steroids can also be used as topical agents in the rectum where the benefits include reduced systemic bioavailability, but long-term use can still cause adrenal suppression. More recently, oral steroid formulations such as budesonide have been devised, to ensure that the steroid moiety is removed in the portal circulation, reducing systemic side effects. Steroids should not be used for maintenance therapy for CD and are usually replaced with immunomodulatory agents (see below) in order to minimise the risk of side effects associated with long-term steroid use.

Aminosalicylates Colonic symptoms can be treated by 5-ASA agents in a similar manner to that in UC. These agents have limited efficacy in small bowel CD.

Antibiotics Metronidazole and ciprofloxacin may be used, particularly for periods of a few weeks at a time, especially in perianal disease. Long-term use of metronidazole is to be especially avoided, as there is a risk of peripheral neuropathy. Ciprofloxacin also has significant side effects when used in the long term, such as Achilles tendinitis and tendon rupture. Antibiotics may also be used to decrease systemic symptoms resulting from an inflammatory mass or an abscess. In general, however, a confirmed abscess should be treated by percutaneous drainage and/or surgery as antibiotics alone will not treat a Crohn's mass effectively.

Immunomodulatory agents Azathioprine is used for its additive and steroid-sparing effects and currently represents standard maintenance therapy. It is a purine analogue, which is metabolised to 6-mercaptopurine (6-MP) and works by inhibiting cell-mediated immune responses. 6-MP may be given directly for the same effects. Approximately 10% of people have deficient thiopurine methyltransferase (TPMT) and 1 in 300 people have no enzyme activity, causing inefficient metabolism of 6-MP. The resulting supra-pharmacological concentrations may cause severe adverse effects such as myelosuppression. Testing TPMT activity is usually undertaken before commencing treatment.

Cyclosporin also acts by inhibiting cell-mediated immunity. Short-course intravenous cyclosporin treatment is associated with 80% remission; however, there is relapse after completion of treatment in many cases.

Monoclonal antibody therapy Several commercially available agents have been developed based on monoclonal antibodies targeting tumour necrosis factor alpha and other key pro-inflammatory mediators.

Infliximab, a murine chimeric monoclonal antibody, was the first available monoclonal antibody for the treatment of CD. This needs to be administered as an intravenous infusion and is typically given every 8 weeks for maintenance of remission.

Adalimumab, an entirely human monoclonal antibody, is an alternative to infliximab. This is administered subcutaneously every 1–2 weeks, depending on response, and most patients can self-administer this agent.

Third-generation monoclonal antibody therapies include integrin antibodies vedulizumab and etrolizumab. Both prevent leucocyte migration preferentially in the gastrointestinal tract and may therefore have fewer side effects than the earlier monoclonal antibodies, although they are both currently in limited use.

The roles of monoclonal antibodies have expanded from initially being used exclusively in the most severe cases of CD when other therapies failed, to having a more central role in the management of moderate to severe CD. They are currently widely used for induction and maintenance of remission. Furthermore, there is evidence that early and aggressive use of these agents in patients at high risk for early recrudescent disease after surgery (for example, penetrating phenotype, early mucosal inflammation or aphthous ulceration at follow-up colonoscopy) may reduce the need for subsequent surgery.

These agents also appear to be effective treatments for perianal disease. Recent studies have suggested, however, that while they may reduce the inflammation associated with

the process of fistulation and can achieve healing of fistula openings, the fistula tracks may remain patent and cessation of therapy is usually associated with a high risk of reactivation of the fistulae.

Overall, monoclonal antibodies are expensive forms of treatment that are associated with a small but definable risk of overwhelming bacterial infection and specific malignancies over the long term. Active infection, tuberculosis and a past history of malignancy are specific contraindications.

Nutritional support It is essential that nutritional status is evaluated in all patients with CD. Nutritional support is frequently required. Patients with moderate nutritional impairment will require nutritional supplementation and severely malnourished patients may require enteral tube or even intravenous feeding. Anaemia, hypoproteinaemia and electrolyte, vitamin and metabolic bone problems must all be addressed. Elemental diet or parenteral nutrition can induce remission in up to 80% of patients, an effect comparable to steroids. However, almost all patients relapse rapidly after cessation of therapy.

Summary box 69.4

Principles of management of Crohn's disease (CD)

- Close liaison between physician and surgeon is crucial
- Medical therapy should always be considered as an alternative to surgery, although surgery should not be delayed when a clear indication for surgery exists
- Patients must be optimised as far as possible prior to surgery, and this may require preoperative total parenteral nutrition
- CD is a chronic relapsing disease with a high likelihood of reoperation; the surgeon must take every reasonable effort to preserve bowel length and sphincter function

ENDOSCOPIC DILATATION IN CROHN'S DISEASE

Although penetrating disease will often require surgical resection (see below under Surgery), stricturing may be amenable to endoscopic treatment, provided the strictures can be reached with an endoscope and negotiated with a guidewire. This may be accomplished by enteroscopy or colonoscopy, depending on the site of the stricture. Dilatation of an inflamed or ulcerated stricture is contraindicated because of the risks of perforation, but balloon dilatation of fibrostenotic disease may result in substantial symptomatic improvement and obviate the need for surgery in selected cases.

INDICATIONS FOR SURGERY

Surgical resection will not cure CD. Surgery therefore focuses on managing the complications of the disease. As many of these indications for surgery may be relative, joint management by an aggressive physician and a conservative surgeon is ideal (see Summary box 69.4). CD is a complicated condition and decisions regarding management are best made jointly by members of a multidisciplinary team.

Complications or manifestations of CD for which surgery is usually appropriate include the following:

- recurrent intestinal obstruction;
- persistent or, less commonly, massive acute bleeding;
- free perforation of the bowel;
- failure of medical therapy;
- steroid dependent disease;
- intestinal fistula;
- perianal disease (abscess, fistula, stenosis);
- malignant change (notably in the colon and less commonly as a complication of small bowel disease).

TOP-DOWN APPROACH TO MANAGEMENT OF CROHN'S DISEASE

Traditionally, active Crohn's disease is treated in a 'step-up' approach where newer, more aggressive therapies are added only when more established and less toxic therapies have failed. Thus, active ileocolic CD may be treated initially with a thiopurine, adding steroids and then a monoclonal antibody only if and when required. Some centres instead advocate a top-down approach, where rapid remission is obtained by initiating therapy with a monoclonal antibody agent (unless contraindicated), often in combination with a thiopurine. Studies suggest advantages mainly in the form of rapid remission, steroid sparing and increased rates of mucosal healing.

Whether surgical resection should be part of a top-down approach is currently being debated. While surgery carries perioperative risks, these have been reduced during the past decades with the development of perioperative enhanced-recovery protocols and laparoscopic surgery. It has been suggested that the balance of risk and benefit between surgical resection and non-operative treatment, typically involving long-term medical therapy, is finely balanced and requires more detailed evaluation.

SURGERY FOR CROHN'S DISEASE

Population-based studies show that roughly 70% of patients with CD will require a bowel resection in the first decade after diagnosis, and 40% will require a further resection in the decade following their index resection. Recent population-based data in the era of monoclonal antibodies suggest that the incidence of surgery may be falling, but nevertheless still remains substantial.

Since surgery does not cure CD, the fundamental principle is to preserve healthy gut and to maintain adequate function. The whole of the gastrointestinal tract should be examined carefully at surgery and intestinal resection kept to the minimum required to treat the local consequences of disease. In laparoscopic surgery, it may be difficult to fully assess the full length of the small intestine. Up-to-date and accurate preoperative small bowel imaging is therefore paramount, particularly in laparoscopic surgery for CD.

Occasionally, unsuspected ileitis is diagnosed during the course of an operation for suspected appendicitis. Determining whether to resect the ileum in this situation is a complex clinical decision that should be made by a senior surgeon. This decision involves an assessment of the likelihood that the ileitis is an expression of CD rather than of another aetiology such as *Yersinia* infection; an assessment of

the likelihood of remission with medical therapy rather than surgery; and an assessment of the rest of the small bowel for presence of additional sites of inflammation. Thus, it would be advisable to surgically resect a mass caused by penetrating CD of the terminal ileum, as such complex disease is unlikely to resolve with medical therapy. On the other hand, it would be controversial in the current era of monoclonal therapy to resect uncomplicated terminal ileitis found during an emergency procedure for suspected appendicitis, as uncomplicated Crohn's ileitis is likely to respond to medical therapy. Many cases fall in between these two extremes, requiring a considered decision.

A further consideration is whether to perform an appendicectomy when terminal ileitis is found. There is a risk of fistulation in the setting of CD, so unless the appendix itself is grossly inflamed with a healthy base, isolated appendicectomy should be avoided in this setting.

The course of CD after surgery is unpredictable, but recrudescence (a better term than 'recurrence', as surgery never cures CD) is common. Symptomatic recrudescence does not seem to be related to the presence of disease at the resection line. The cumulative probability of recrudescence requiring surgery for ileal disease is approximately 20, 40, 60 and 80% at 5, 10, 15 and 20 years, respectively, after a previous resection.

Surgery for CD is technically demanding as the involved mesentery is thickened and oedematous and healing may be impaired. The patient may be malnourished, immunosuppressed or suffer from sepsis (and potentially all three). Decision-making regarding the timing and nature of surgery to be undertaken is the key to satisfactory outcome of surgical treatment, and frequently requires experience and considerable discussion with other health professional and, most importantly, the patient. A key decision has to be made whether to anastomose the apparently healthy bowel ends after macroscopically apparent disease has been resected, as anastomotic leaks and fistulation represent a considerable problem after surgery for CD. Intra-abdominal septic complications are more common if one or more of the following risk factors are present:

- current high-dose steroid therapy (≥10 mg prednisolone for ≥4 weeks before surgery);
- current preoperative monoclonal antibody therapy;
- preoperative significant weight loss (>10% premorbid weight);
- pre-existing abdominal sepsis (notably abscess or fistula);
- serum albumin <32 g/L.

If any these risk factors are present (and particularly if more than one risk factor is present as the risks appear to be additive), one should consider exteriorising the bowel and planning a delayed anastomosis when the risk factor has been corrected.

Ileocaecal or colonic resections can be undertaken laparoscopically, with the potential advantage of smaller incisions and potentially shorter recovery time. Reoperative surgery is technically demanding and studies suggest that ileosigmoid or ileoduodenal adhesions and fistulae can be difficult to safely dissect laparoscopically and conversion to laparotomy may be advisable in this setting.

A range of operations is performed for CD, depending on the pattern of disease – the most common are outlined below:

- Ileocaecal resection is the usual procedure for terminal ileal disease, with a primary anastomosis between the ileum and the ascending or transverse colon, depending on the extent of the disease.
- Segmental resection of short segments of small or large bowel strictures can be performed.
- Colectomy and ileorectal anastomosis may be undertaken for colonic CD with rectal sparing and a normal anus.
- Subtotal colectomy and ileostomy for Crohn's colitis accounts for 8% of such procedures for acute colonic disease. The indications are similar to those for UC.
- Temporary loop ileostomy. This can be used either in patients with acute distal CD, allowing remission and later restoration of continuity, or in patients with severe perianal or rectal disease.
- Proctectomy and proctocolectomy. Many patients with severe anal disease failing to respond to medical treatment will eventually require a permanent colostomy. When this occurs in a setting of severe colonic disease, proctocolectomy and permanent ileostomy may be required.
- Strictureplasty. Strictured areas of CD (**Figure 69.5**) can be treated by strictureplasty, a local widening procedure, to avoid small bowel resection and is thus an important bowel sparing technique (**Figure 69.6**). Strictureplasty is particularly useful for the treatment of fibrostenotic disease, when there is little or no active inflammation in the involved segment. Multiple strictureplasties can be performed and strictureplasty can be combined with resection.

Anal disease should be treated conservatively by simple drainage of abscesses and the use of setons through fistulae to avoid sphincter injury. Infliximab or adalimumab therapy may be combined with seton insertion in the early phase of management of perianal fistulae. Once the fistula has dried up, typically after 2–3 doses, the seton can be removed. Laying open of fistulae (fistulotomy), commonly performed for fistulae resulting from the common cryptoglandular perianal

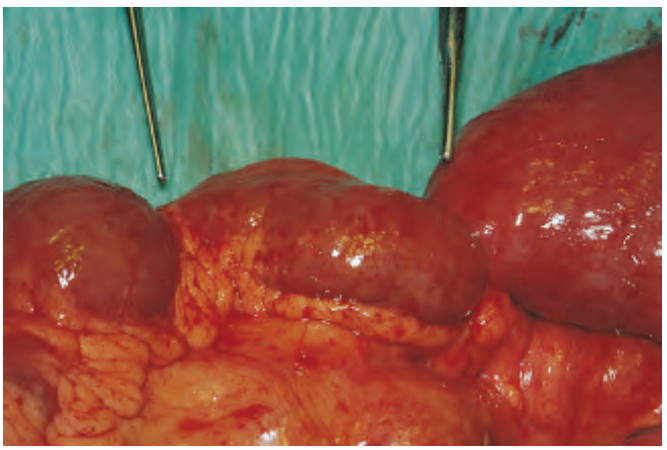

Figure 69.5 Small bowel strictures in Crohn's disease with dilatation between strictures.

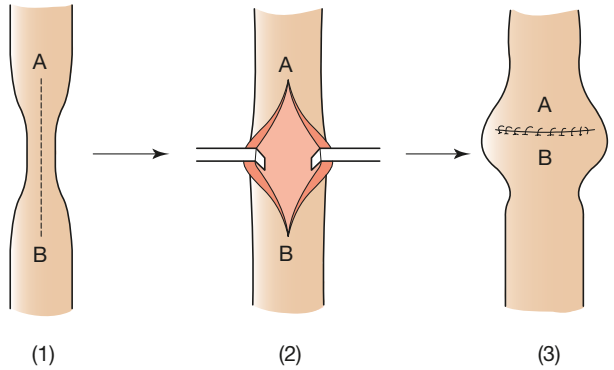

Figure 69.6 Heineke–Mikulicz strictureplasty. (1) A strictured length of intestine is incised along its length. (2) The bowel is opened and the walls are retracted as shown. (3) The bowel is resutured transversely to widen the narrowed segment. Other types of strictureplasty are also used.

abscess, should be avoided in CD as the wound edges heal very slowly or not at all.

INFECTIVE ENTERITIS

Campylobacteriosis

Infection with *Campylobacter jejuni* (a gram-negative rod with a distinctive spiral shape) is the most common form of bacterial gastroenteritis in the UK, typically acquired from eating infected poultry. It causes diarrhoea and abdominal pain and may mimic an acute abdomen. Severe cases may resemble UC, with rectal bleeding and colorectal ulceration, causing diagnostic difficulty. The organism is very sensitive and may take several days to isolate on stool culture. Toxic dilatation and even disintegrative colitis have rarely been reported to occur. Treatment is generally supportive as the condition usually resolves without antibiotics. It is a notifiable disease.

Yersiniosis

Yersinia enterocolitica is a gram-negative rod that can infect the terminal ileum, appendix, ascending colon and mesenteric lymph nodes, and can cause a granulomatous inflammatory process that mimics CD. *Yersinia* typically causes a fever and gastroenteritis, but may persist and cause a terminal ileitis, which, on occasion, may perforate. The diagnosis may be made on stool culture, but is more often confirmed serologically. If discovered at laparotomy, the terminal ileum and mesenteric nodes will look thickened and inflamed and a lymph node biopsy can be taken for diagnostic purposes. The disease is normally self-limiting, but responds to treatment with cotrimoxazole or chloramphenicol.

Salmonellosis, typhoid and paratyphoid

Salmonella are a family of gram-negative rods that can cause a range of enteric infections. *Salmonella* gastroenteritis is typically caused by *S. enteritidis* from poultry, and is most often a self-limiting illness comprising headache, fever and watery diarrhoea. When severe, antibiotics and hospitalisation and intravenous fluids may be needed. The diagnosis is based on stool culture. *Shigella* and enteropathogenic strains of *E. coli* may cause similar diarrhoeal illnesses.

Typhoid fever is caused by *S. typhi* and presents with fever and abdominal pain after an incubation period of 10–20 days. Over the next week, the patient can develop distension, diarrhoea, splenomegaly and characteristic 'rose spots' on the abdomen caused by a vasculitis. Typhoid is a systemic infection and diagnosis of typhoid is confirmed by culture of blood or stool. Treatment is by antibiotics, usually chloramphenicol. A number of surgical complications can result, including paralytic ileus, intestinal haemorrhage, free ileal perforation and cholecystitis.

In addition, invasion of the systemic circulation, which is a characteristic feature of salmonellosis, may cause severe gram-negative sepsis, resulting in septic shock. Some patients develop metastatic sepsis, including septic arthritis and osteomyelitis, meningitis, encephalitis, disseminated intravascular coagulation and pancreatitis.

Perforation of a typhoid ulcer characteristically occurs during the third week of the illness, although it is sometimes the first clinical sign of the disease. The ulcer is parallel to the long axis of the gut and is usually situated in the distal ileum. Perforation requires surgery to wash out and close the ulcer and intestinal resection is usually avoided. In unstable patients, notably with evidence of septic shock, the bowel should be exteriorised and the perforation closed after recovery. Paratyphoid infection (with *S. paratyphi*) resembles typhoid fever and is treated in a similar manner.

Tuberculosis of the intestine

Tuberculosis, like CD, can affect any part of the gastrointestinal tract from the mouth to the anus. The sites affected most often are the ileum, proximal colon and peritoneum. There are two principal disease presentations.

Ulcerative tuberculosis

Ulcerative tuberculosis develops secondary to pulmonary tuberculosis and arises as a result of swallowing tubercle bacilli. Multiple ulcers, lying transversely, develop in the terminal ileum and the overlying serosa is thickened, reddened and covered in tubercles. Patients typically present with diarrhoea and weight loss, although subacute obstruction and even local perforation and fistula formation can occur. A barium follow-through or CT examination fails to show filling of the lower ileum, caecum and the ascending colon as a result of narrowing of the ulcerated segment (**Figure 69.7**).

A course of antituberculous chemotherapy usually leads to cure, provided the pulmonary tuberculosis is adequately treated. Surgery is usually undertaken only in the rare event of a perforation or complete intestinal obstruction.

Hyperplastic tuberculosis

This is caused by the ingestion of *Mycobacterium tuberculosis* by patients with a high resistance to the organism. The infection usually occurs in the ileocaecal region, although solitary and multiple lesions in the lower ileum are also sometimes

Figure 69.7 Ileocaecal tuberculosis. Absent ascending colon and caecum with dilatation of terminal ileum (courtesy of Dr VK Kapoor, Delhi, India).

seen. The infection establishes itself in lymphoid follicles, and the resulting chronic inflammation causes thickening of the intestinal wall and narrowing of the lumen. There is early involvement of the regional lymph nodes, which may caseate. Unlike in CD, abscess and fistula formation are rare.

Patients usually present with attacks of abdominal pain and intermittent diarrhoea. There is incomplete ileal obstruction, leading to stasis and bacterial overgrowth. This in turn causes steatorrhoea, anaemia and loss of weight. Patients may present with a mass in the right iliac fossa and vague ill health. The differential diagnosis is that of an appendix mass, lymphoma, carcinoma of the caecum, CD, tuberculosis or actinomycosis. A barium follow-through or small bowel enema will show a long narrow filling defect in the terminal ileum (which may result in a differential diagnosis of CD). CT will also demonstrate the narrowed segment with proximal distension and the associated lymphadenopathy. When the diagnosis is clear and the patient has not yet developed obstructive symptoms, treatment with chemotherapy is advised and may be curative. Where obstruction is present, or the possibility of CD or lymphoma require clarification, ileocaecal resection is often required.

Actinomycosis

Abdominal actinomycosis is rare. It is caused by infection with *Actinomyces israelii* and infection usually develops several weeks after an apparently straightforward perforated appendicitis. An abscess develops and spreads to the retroperitoneal tissues and the adjacent abdominal wall, eventually becoming the seat of multiple indurated discharging sinuses. At first, the discharge from the sinuses is thin, watery and inoffensive, but it may later become thicker and malodorous. Secondary fistulation may occur and the tissues may become extensively indurated and woody. In contrast to tuberculosis, however, mesenteric lymph nodes are not involved and the lumen of the intestine is not narrowed. Haematogenous spread via the portal vein may lead to multiple liver abscesses.

Pus should be sent for bacteriological examination, which will reveal the characteristic sulphur granules. Penicillin or cotrimoxazole treatment is required and should be prolonged and in high dosage.

Human immunodeficiency virus

Human immunodeficiency virus (HIV) infection is associated with a number of proctological problems, as discussed in Chapter 73. Intestinal complications are common after the development of AIDS when opportunistic organisms can cause gastroenteritis (see Summary box 69.5.). HIV1 may also cause a specific enteropathy. Treatment is directed towards the relevant organism and surgery should be avoided if possible.

Summary box 69.5

Opportunistic intestinal infections in patients with AIDS

  - Giardia
- Fungal
  - *Candida albicans*

TUMOURS OF THE SMALL INTESTINE

Small bowel tumours are rare and in total account for less than 10% of gastrointestinal neoplasia.

James Israel, 1848–1926, first found sulphur granules in pus from a discharging sinus in a man's neck. Later, he became a famous Berlin urologist.

Benign

The majority of small bowel neoplasms are benign, comprising adenomas, lipomas, haemangiomas and neurogenic tumours. They are frequently asymptomatic and identified incidentally, but can present with intussusception, small bowel obstruction and bleeding that may cause anaemia or may even be overt. Where these lesions do cause anaemia, the cause can be difficult to diagnose, as CT or small bowel contrast studies do not show them easily. Capsule endoscopy or small bowel endoscopy has been used successfully where the facilities exist. Symptomatic lesions can be treated by small bowel resection and anastomosis.

Peutz–Jeghers syndrome

This is an autosomal dominant disease characterised by melanosis of the mouth and lips, with multiple hamartomatous (benign tumour-like malformation resulting from faulty development in an organ) polyps in the small bowel and colon (**Figure 69.8**). Melanin spots can also occur on the digits and perianal skin. The gene *STK11* on chromosome 19 has been found in a proportion of patients with this condition. Long-term follow-up of the original family described by Peutz has shown reduced survival as a consequence of complications of bowel obstruction and the development of a range of cancers. It is logical to perform regular colonic surveillance and encourage female patients to attend breast and cervical screening. Despite the increased risk of malignancy in general, malignant change in the polyps themselves rarely occurs and the polyps can be left alone unless they are the cause of symptoms. Resection may be indicated, however, for heavy and persistent or recurrent bleeding or intussusception. Polyps may be removed by enterotomy or, at laparotomy, snared via a colonoscope introduced via an enterotomy. Heavily involved segments of small intestine may occasionally be resected.

Figure 69.8 Melanin spots on the lips of a patient afflicted with Peutz–Jeghers syndrome (courtesy of Major PCM Manta, Indian Medical Service).

Malignant

Small bowel malignancy is rare and classically presents late, most often diagnosed after surgery for small bowel obstruction. Four types will be considered, which account for over 99% of small bowel malignancies: adenocarcinoma, carcinoid tumours, lymphomas and mesenchymal tumours (gastrointestinal stromal tumours [GIST]).

Adenocarcinoma

Small bowel adenocarcinoma is more often found in the jejunum than the ileum and although the aetiology is unknown, it is more common in patients with CD, coeliac disease, familial adenomatous polyposis, hereditary non-polyposis colon cancer and Peutz–Jeghers syndrome. The tumours present with anaemia, overt gastrointestinal bleeding, intussusception or obstruction. Prognosis is poor, particularly in patients with CD, in whom these tumours often present late, because the symptoms are commonly mistaken for those of CD and treated conservatively. When suspected, the advised surgical treatment is a resection of 5 cm of non-involved bowel either side of the lesion and the affected mesentery (**Figure 69.9**). A right hemicolectomy is likely to be required for tumours of the distal ileum.

Carcinoid tumours

These neuroendocrine tumours occur throughout the gastrointestinal tract, most commonly in the appendix, ileum and rectum in decreasing order of frequency. Appendicular carcinoid tumours are commonly noted as an incidental finding at appendicectomy, and are said to occur in approximately 2% of appendices removed surgically. The tumour arises from Kulchitsky cells at the base of intestinal crypts (of Lieberkuhn). The primary is usually small, although significant lymph node metastases can occur. In up to one-third of cases of small bowel carcinoids, the tumours are multiple. They

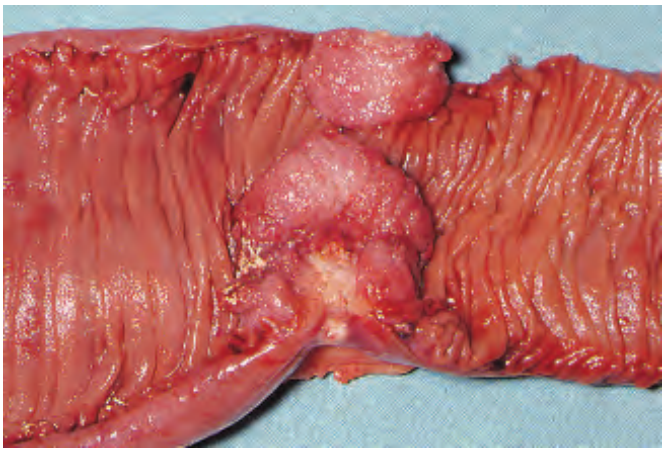

Figure 69.9 Small bowel adenocarcinoma.

may produce dense fibrosis in the surrounding tissues, resulting in distortion and scarring of the bowel and associated mesentery, giving them a characteristic radiological appearance. Carcinoid tumours can produce a number of vasoactive peptides, most commonly 5-hydroxytryptamine (serotonin), but also histamine, prostaglandins and kallikrein. When they metastasise to the liver, the 'carcinoid syndrome' can become evident, because the vasoactive substances escape the filtering actions of the liver. The clinical syndrome itself consists of reddish-blue cyanosis, flushing attacks, diarrhoea, borborygmi, asthmatic attacks and, eventually, pulmonary and tricuspid stenosis (see *Summary box 69.6*). Classically, the flushing attacks are induced by alcohol.

Summary box 69.6

Carcinoid syndrome

- Diarrhoea
- Bronchospasm
- Facial/upper chest flushing
- Palpitations
- Tricuspid regurgitation

Surgical resection is usually sufficient for patients with primary disease, but the incidence of recurrence is significant. The extent of disease can be assessed preoperatively using octreotide scanning, which may detect otherwise clinically unapparent primary and secondary tumours. Plasma markers of tumour bulk, such as chromogranin A concentrations, may be useful markers of disease recurrence, as well as of prognostic value.

Hepatic resection can be carried out in patients with metastatic disease. The treatment has been transformed by the use of octreotide (a somatostatin analogue), which reduces both flushing and diarrhoea, and octreotide cover is usually used in patients with a carcinoid syndrome who have surgery to prevent a carcinoid crisis resulting from liberation of vasoactive substances following handling of the tumour. Carcinoid tumours generally grow more slowly than most metastatic malignancies and patients may live with the syndrome of metastatic disease for many years. They are not usually sensitive to chemo- or radiotherapy.

Lymphoma

Small bowel lymphoma may be primary or, more commonly, secondary to systemic lymphoma. The incidence of small bowel lymphoma is increased in patients with CD and immunodeficiency syndromes. The classification of lymphoma is beyond the scope of this chapter but a number of points are worth noting briefly. It is rare for Hodgkin's lymphoma to affect the small bowel and most western-type lymphomas are non-Hodgkin's B-cell lymphomas. They usually present with anaemia, bleeding, perforation, anorexia and weight loss.

T-cell lymphoma develops in patients with coeliac disease. It usually presents with worsening of the patient's diarrhoea, pyrexia of unknown origin and local obstructive symptoms. Mediterranean lymphoma is found mostly in North Africa and the Middle East and is often widespread at diagnosis. Burkitt's lymphoma can aggressively affect the ileocaecal region, particularly in children. The mainstay of treatment for these conditions is chemotherapy; however, surgery may be required for obstruction, perforation or bleeding.

Gastrointestinal stromal tumours

Gastrointestinal stromal tumours (GISTs) are mesenchymal tumours and the distinction between benign or malignant types is difficult even on histological examination. Increased size and high levels of c-kit (CD117) staining are associated with malignant potential. GISTs are found most commonly in the stomach, but can be found in other parts of the gut. They occur most commonly in the 50- to 70-year age group. Although the cause is unknown, patients with neurofibromatosis have an increased risk of developing these types of tumour. Patients may be asymptomatic and the tumour may present as an incidental mass on a CT scan. Symptoms include lethargy, pain, nausea, haematemesis or melaena. Surgery is the most effective way of treating GISTs, as the tumour is radioresistant and is not sensitive to conventional chemotherapy. Glivec® (imatinib) is a tyrosine kinase inhibitor that has been shown to be effective in advanced cases and may also have a role in adjuvant treatment.

CONNECTIVE TISSUE DISORDERS

Intestinal diverticulae

Diverticulae (hollow out-pouchings) are a common structural abnormality that can occur from the oesophagus to the rectosigmoid junction (but not usually in the rectum). Small bowel diverticulae may be congenital or acquired. In congenital diverticulae, all three coats of the bowel are present in the wall of the diverticulum (e.g. Meckel's diverticulum).

Acquired diverticulae

These invariably develop in the jejunum and arise from the mesenteric side of the bowel as a result of mucosal herniation at the point of entry of the blood vessels. There is thus no muscularis layer present in the wall. Jejunal diverticulae can vary in size and are frequently multiple. They are commonly asymptomatic and present as an incidental finding at surgery or on radiological imaging (**Figure 69.10**). However, they can result in malabsorption, as a result of bacterial stasis, or present as an acute abdominal emergency if they become inflamed or perforate. Bleeding from a jejunal diverticulum is a rare complication (compared with sigmoid diverticular disease). Elective resection of an affected small bowel segment that is causing malabsorption can be effective, provided there

Thomas Hodgkin, 1798–1866, lecturer in morbid anatomy and curator of the museum, Guy's Hospital, London, UK, described lymphadenoma in 1832.
Johann Friedrich Meckel (the younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany, described the diverticulum in 1809.

Figure 69.10 Jejunal diverticula.

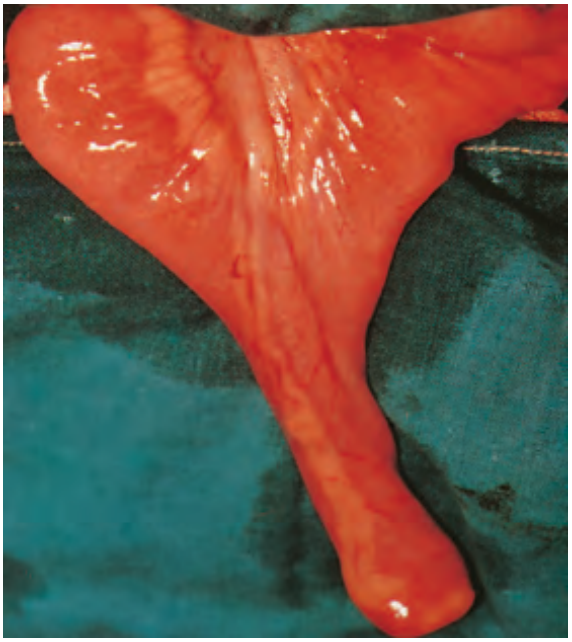

Figure 69.11 Meckel's diverticulum.

is only a limited amount of jejunum affected by the condition. If perforated jejunal diverticulitis is found at emergency laparotomy, a small bowel resection should be performed and a decision made between anastomosis and stoma formation. This will depend on the degree of contamination, physiological stability and local resources for managing a patient with a high output jejunostomy.

Complications resulting from extensive jejunal diverticulosis can be extremely difficult to treat. In severe cases, much of the proximal small intestine may be involved, effectively precluding resection. Prolonged antibiotic therapy for bacterial overgrowth may be preferable, and antibiotics (metronidazole, ciprofloxacin, rifaximin) are frequently rotated in an attempt to avoid the development of antibiotic resistance. Limited resection, leaving remaining segments of affected jejunum, may be feasible, but may also fail to deal adequately with bacterial overgrowth, recurrent attacks of inflammation or bleeding.

Meckel's diverticulum

A Meckel's diverticulum is a persistent remnant of the vitellointestinal duct and is present in about 2% of the population. It is found on the antimesenteric side of the ileum, commonly approximately 60 cm from the ileocaecal valve and is classically 5 cm long (**Figure 69.11**). A Meckel's diverticulum is a congenital diverticulum. It contains all three coats of the bowel wall and has its own blood supply. It may be vulnerable to obstruction and inflammation in the same way as the appendix; indeed, when a normal appendix is found at surgery for suspected appendicitis, a Meckel's diverticulum should be looked for by examining the small bowel, particularly if free fluid or pus is found. In approximately 20% of cases, the mucosa of a Meckel's diverticulum contains heterotopic epithelium of gastric, colonic or pancreatic type. The presence of heterotopic mucosa may predispose to the development of complications. The vast majority of Meckel's diverticulae are asymptomatic and Meckel's diverticulum is notoriously difficult to see with contrast radiology. Meckel's diverticulum may, however, present clinically in the following ways:

- Haemorrhage. If gastric mucosa is present, peptic ulceration can occur and present as painless dark rectal bleeding or melaena. If the stomach, duodenum and colon are excluded as a source of bleeding by endoscopy, radioisotope scanning with technetium-99m may demonstrate a Meckel's diverticulum.
- Diverticulitis. Meckel's diverticulitis presents like appendicitis, although if perforation occurs the presentation may resemble a perforated duodenal ulcer.
- Intussusception. A Meckel's diverticulum can be the lead point for ileoileal or ileocolic intussusception.
- Chronic ulceration. Pain is felt around the umbilicus, as the site of the diverticulum is midgut in origin.
- Intestinal obstruction. A band between the apex of the diverticulum and the umbilicus (also part of the vitellointestinal duct) may cause obstruction directly, or by predisposing to the development of a volvulus around it.
- Perforation. (**Figure 69.12**).

When found in the course of abdominal surgery, a Meckel's diverticulum can safely be left alone, provided it has a wide mouth and is not thickened. When there is doubt, it can be resected. The finding of a Meckel's diverticulum in an inguinal or femoral hernia has been described as 'Littre's hernia'.

Alexis Littre, 1658–1726, surgeon and lecturer in Anatomy, Paris, France, described Meckel's diverticulum in a hernial sac in 1700, 81 years before Meckel was born.

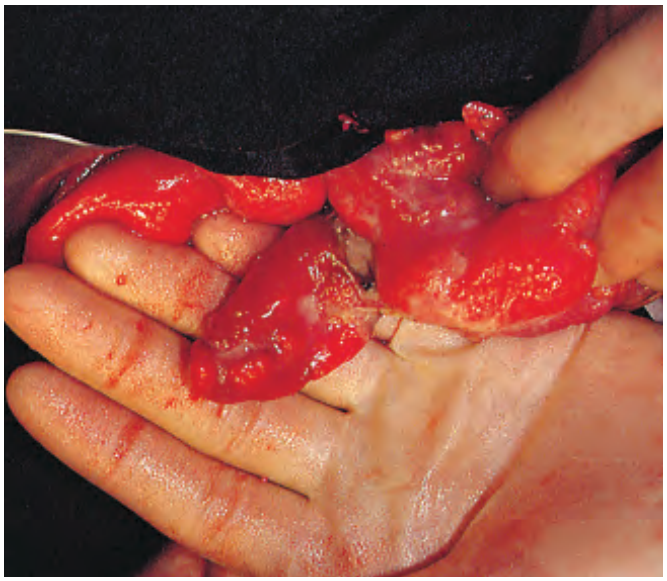

Figure 69.12 Gangrenous Meckel's diverticulitis.

Summary box 69.7

Features of Meckel's diverticulum

- Remnant of vitellointestinal duct
- Occurs in 2% of patients, 2 inches (5 cm) long, 2 feet (60 cm) from the ileocaecal valve, 20% heterotopic epithelium
- Should be looked for when a normal appendix is found at surgery for suspected appendicitis
- If a Meckel's is found incidentally at surgery, it can be left provided it has a wide mouth and is not thickened
- Can be source of gastrointestinal bleeding if it contains ectopic gastric mucosa

Meckel's diverticulectomy

A broad-based Meckel's diverticulum should not be amputated at its base and invaginated (as for an appendix), as there is the risk of stricture and of leaving heterotopic epithelium behind. It is safer simply to excise the diverticulum, either by resecting it and suturing the defect at its base, or with a linear stapler-cutter. If the base of the diverticulum is indurated, it is on balance more logical to perform a limited small bowel resection of the involved segment followed by an anastomosis.

VASCULAR ANOMALIES OF THE INTESTINE

Mesenteric ischaemia

Mesenteric vascular disease may be classified as acute intestinal ischaemia – with or without occlusion – venous, chronic arterial, central or peripheral. The superior mesenteric vessels are the visceral vessels most likely to be affected by embolisation or thrombosis, with the former being most common. Occlusion at the origin of the superior mesenteric artery (SMA) is almost invariably the result of thrombosis, whereas emboli tend to lodge at the origin of the middle colic artery. Inferior mesenteric involvement is usually clinically silent because the collateral circulation is better.

Possible sources for embolisation of the SMA include the left atrium in atrial fibrillation, the left ventricle after mural myocardial infarction, vegetations on mitral and aortic valves associated with endocarditis and an atheromatous plaque from an aortic aneurysm. Primary thrombosis is associated with atherosclerosis and vasculitides, including conditions such as thromboangitis obliterans and polyarteritis nodosa. Primary thrombosis of the superior mesenteric veins may occur in association with factor V Leiden, portal hypertension, portal pyaemia and sickle cell disease and in women taking the oral contraceptive pill. A specific form of 'non-occlusive mesenteric ischaemia' may complicate critical illness, possibly due to alterations in splanchnic blood flow.

Irrespective of whether the occlusion is arterial or venous, haemorrhagic infarction occurs. The mucosa is especially sensitive to ischaemic injury because of its high metabolic activity. The intestine and its mesentery become swollen and oedematous, especially with venous occlusion. Blood-stained fluid exudes into the peritoneal cavity and bowel lumen. The changes develop rapidly and irreversible injury, ranging in severity from mucosal necrosis and sloughing, to full-thickness infarction usually occurs within a few hours at most. If the main trunk of the SMA is involved, the infarction usually covers an area from just distal to the DJ flexure to the splenic flexure. Usually, a branch of the main trunk is implicated and the area of infarction is less.

Clinical features

The most important clue to an early diagnosis of acute mesenteric ischaemia is the sudden onset of severe abdominal pain in a patient with atrial fibrillation or atherosclerosis. The pain is typically in the central abdomen and out of all proportion to the physical findings. Persistent vomiting and defaecation occur early, with the subsequent passage of altered blood. Abdominal tenderness may be mild initially, with rigidity being a late feature. Shock, with features of both hypovolaemia and sepsis, rapidly ensues.

Investigation

Investigation will usually reveal a profound neutrophil leucocytosis with an absence of gas in the lumen of the thickened small intestine on abdominal radiographs and CT scans. Gas may be present within the intestinal wall and occasionally in the mesenteric and portal veins.

Treatment

Treatment should be tailored to the individual. In conjunction with full resuscitation, laparotomy with embolectomy via the ileocolic artery or revascularisation of the SMA by vascular bypass may be considered in early cases. Anticoagulation should be implemented early in the postoperative period. However, the condition is usually diagnosed late in the disease process and the mortality rate is extremely high. In the young, all affected bowel should be resected, whereas in the elderly or infirm the situation may be deemed incurable.

After extensive enterectomy, it is usual for patients to require intravenous alimentation. The young, however, may sometimes develop sufficient intestinal digestive and absorptive function to lead relatively normal lives. In selected cases, consideration may be given to small bowel transplantation.

Chronic small intestinal ischaemia

Chronic small intestinal ischaemia almost invariably results from atherosclerosis and affects the proximal superior mesenteric and coeliac vessels. Patients classically present with symptoms of severe central abdominal pain that comes on within 30–60 minutes of eating (mesenteric angina). Weight loss and diarrhoea due to malabsorption may also occur. The condition may be difficult to diagnose and is often overlooked initially, the symptoms being mistaken for those of peptic ulcer disease or irritable bowel syndrome. The presence of significant vascular disease on visceral angiography is common in elderly patients and in those with severe vascular disease, and should not necessarily be assumed to indicate that abdominal symptoms are attributable to chronic ischaemia. Treatment is usually by selective visceral angiography, with stenting/angioplasty and, where this is not possible, bypass surgery. Smoking cessation in imperative and patients are usually anticoagulated.

STOMAS

A colostomy (or ileostomy) stoma is an artificial opening made in the colon (or small intestine) to divert faeces and flatus out-side the abdomen where they can be collected in an external appliance. Depending on the purpose for which the diversion has been necessary, a stoma may be temporary or permanent.

Summary box 69.8

Stomas

- May be colostomy or ileostomy
- May be temporary or permanent
- Temporary or defunctioning stomas are usually fashioned as loop stomas
- An ileostomy is spouted; a colostomy is flush
- Ileostomy effluent is usually liquid, whereas colostomy effluent is usually solid
- Ileostomy patients are more likely to develop fluid and electrolyte problems
- An ileostomy is usually sited in the right iliac fossa
- End-colostomy is usually sited in the left iliac fossa
- Whenever possible, patients should be counselled and sited by a stoma care nurse before operation

Loop ileostomy

A loop ileostomy is often used for defunctioning a low rectal anastomosis or an ileal pouch. A knuckle of ileum is exteriorised through a skin trephine in the right iliac fossa. An incision is made in the distal part of the knuckle, and this is then pulled over the top of the more proximal part to create a spout on the proximal side of the loop with a flush distal side still in continuity. This allows near perfect defunctioning, but also the possibility of restoration of continuity, by taking down the spout and reanastomosing the partially divided ileum.

The advantages of a loop ileostomy over a loop colostomy are the ease with which the bowel can be brought to the surface and the relative absence of odour. Care is needed when the ileostomy is closed, so that suture line obstruction does not occur. Closure of a loop ileostomy can be a technically challenging procedure, particularly if there are dense adhesions resulting from previous surgery.

End ileostomy

An end ileostomy is formed after a subtotal colectomy without anastomosis, when it may later be reversed, or may be permanent after a panproctocolectomy. The ileum is normally brought through the rectus abdominis muscle. Careful attention to the terminal ileal mesentery should be taken to ensure that it is not too bulky. The use of a spout was originally described by Bryan Brooke; this should project some 2–4 cm from the skin surface (**Figure 69.13**). A disposable appliance is placed over the ileostomy so that it is a snug fit at skin level.

There may be an 'ileostomy flux' while the ileum adapts to the loss of the colon. While ileostomy output can amount to 4 or 5 litres per day, losses of 1–2 litres are more common. A consistent ileostomy output in excess of 1.5 litres is usually associated with dehydration and sodium depletion in the absence of intravenous therapy. The stools thicken in a few weeks and are semisolid in a few months. The help, skill and advice of the stoma care nurse specialist are essential. Modern appliances have transformed stoma care, and skin problems are unusual (**Figure 69.14**). Complications of an ileostomy include prolapse, retraction, stenosis, bleeding, fistula and parastomal hernia.

Stoma bags and appliances

Stoma output is collected in disposable adhesive bags. Ileostomy appliances tend to be drainable bags, which are left

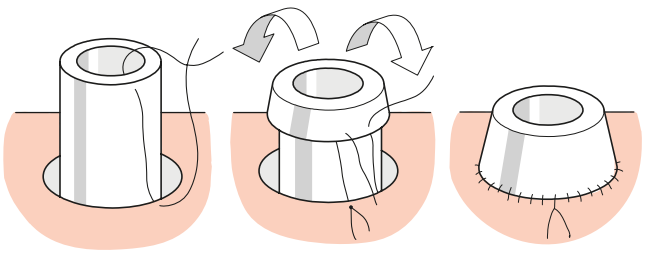

Figure 69.13 Ileostomy formation. Suturing the free extremity of the proximal ileum to the skin edges after eversion to form a spout (after Brooke).

Bryan Nicholas Brooke, 1915–1998, Professor of Surgery, St George's Hospital, London, UK.

Figure 69.14 Spouted ileostomy in the right iliac fossa.

in place for 48 hours, while colostomy appliances are simply changed two or three times each day. A wide range of such bags is currently available. Many now incorporate an adhesive backing, which can be left in place for several days. In most hospitals, a stoma care service is available to offer advice to patients, to acquaint them with the latest appliances and to provide the appropriate psychological and practical help.

Complications of stomas

Stoma complications are underestimated and common. On occasion, these complications require surgical revision. Sometimes, this can be achieved with an incision immediately around the stoma, but on occasion reopening the abdomen and freeing up the stoma may be necessary. Repair of parastomal hernias is particularly technically challenging and the recurrence rate is high. Simple suture of the parastomal hernia is associated with an almost 100% risk of recurrence and transfer to the opposite side of the abdomen, or insertion of a piece of prosthetic material within the abdominal wall around the stoma may be necessary.

Summary box 69.9

Stoma complications

- Skin irritation
- Prolapse
- Retraction
- Ischaemia
- Stenosis
- Parastomal hernia
- Bleeding
- Fistulation

CONDITIONS CAUSING MALABSORPTION

Coeliac disease

Coeliac disease is the most common cause of malabsorption in the UK with a stated prevalence of 1:1800, although this may be an underestimate. It is characterised by a hypertrophic small bowel mucosa with atrophic villi and deep crypts. It is thought that the loss of surface area and brush border enzymes results in malabsorption.

Coeliac disease is caused by an abnormal immune response to gluten, a cereal protein, although the exact mechanism remains unclear. There is a genetic component, as the disease is more common in first-degree relatives and has an association with HLA B8. In children, coeliac disease presents with steatorrhoea and growth retardation. In adults, it may result in diarrhoea and weight loss but many patients simply present with an iron deficiency anaemia. Some patients develop a characteristic skin rash (dermatitis herpetiformis)

The diagnosis is usually made after an endoscopic duodenal biopsy allows pathological examination of mucosa. The antiendomysial antibody tests have a very high sensitivity and specificity for coeliac disease, but a duodenal biopsy is usually indicated to confirm the diagnosis. The biopsy usually shows flattening of the mucosa, marked inflammatory changes and characteristic findings of intraepithelial lymphocytes.

Patients with coeliac disease may develop an acute inflammatory condition of the small intestine (ulcerative jejunoileitis) and have an increased risk of small bowel lymphoma and adenocarcinoma.

The main treatment for coeliac disease is the withdrawal of gluten from the diet by avoiding wheat, rye and barley. Surgery does not usually play a role in the management of coeliac disease and is primarily reserved for resection of malignancy.

Bacterial overgrowth

The small intestine can become colonised with bacteria normally confined to the colon if there is stasis resulting in delayed bacterial clearance (blind loop syndrome, Figure 69.15). Similar complications may result from chronic small bowel obstruction, jejunal diverticulosis and ileosigmoid fistulation

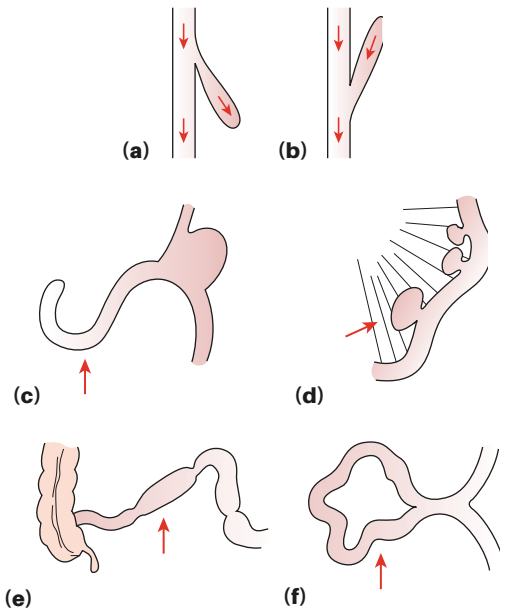

Figure 69.15 Common types of blind loop: **(a)** self-filling: deficiency occurs; **(b)** self-emptying: no deficiency occurs; **(c)** long afferent loop stasis in Pólya gastrectomy; **(d)** jejunal diverticula; **(e)** intestinal stricture causing stasis; **(f)** 'stenosis–anastomosis loop' syndrome.

(see above). If overgrowth occurs in the upper small intestine, the defect is chiefly of fat absorption; if in the lower intestine, there is vitamin B12 deficiency. There is usually relatively little effect on carbohydrate or protein metabolism. Stasis results in an abnormal bacterial flora, which prevents adequate breakdown of fat. Sometimes, the only manifestation is anaemia, resulting from vitamin B12 deficiency but, if steatorrhoea occurs, other serious malabsorption features may follow, including glossitis, osteomalacia, paraesthesia and peripheral neuropathy.

Improvement normally follows after intermittent therapy with oral antibiotics; metronidazole, ciprofloxacin, tetracycline and rifaximin are commonly used. Definitive treatment is surgical when the anatomical abnormality can be corrected, but this is not always possible.

ENTEROCUTANEOUS FISTULA

An abnormal connection between the small intestine and the skin can occur as a result of fistulating CD, radiotherapy or abdominal trauma, but the condition most commonly follows a surgical complication – either a leak from an anastomosis or an inadvertent enterotomy during dissection. At least 50% of small bowel enterocutaneous fistulae develop after surgery in which no small bowel has been resected, as a result of injury to the intestine following division of adhesions. The frequency of this complication has been shown to increase with the number of previous laparotomies. Management of patients with enterocutaneous fistulae can be very challenging, especially when the fistula output is high (usually defined as >500 mL of effluent/day). The majority of fistulae can be expected to heal spontaneously, provided there is no distal obstruction or disease at the fistula site. Reasons for failure of spontaneous healing also include epithelial continuity between the gut and the skin and an associated complex abscess.

The management of fistulas is based on well-established principles ('SNAP', see Summary box 69.10). An early return to theatre to try and treat the problem definitively in a septic, malnourished patient is doomed to failure.

Infected collections are best identified at CT (**Figure 69.16**) and can be drained percutaneously. Skin protection is important, as small bowel effluent is caustic. Nutritional support must include fluid and electrolytes, which can be lost in high quantities from a proximal fistula, as well as carbohydrates, protein, fat and vitamins. Judgements have to be made between enteral and parenteral feeding – enteral feeding has advantages but if the fistula is proximal or high output, total parenteral nutrition will be required. Defining anatomy is best done after careful discussion with the radiologist – a sequence of contrast studies (follow-through, fistulogram and enema) may well be required to define bowel length and plan a surgical strategy. Surgery can be extremely technically demanding, and an anastomosis should not be fashioned in the presence of continuing intra-abdominal sepsis or when the patient is hypoalbuminaemic (<32 g/dL).

SHORT BOWEL SYNDROME

Intractable diarrhoea with impaired absorption of nutrients following resection or bypass of the small intestine, ultimately leading to progressive malnutrition, is referred to as 'short bowel syndrome'. The most common causes of short bowel syndrome are resection resulting from the management of CD and its complications (which accounts for almost half of cases), mesenteric vascular thrombosis, radiation enteritis and tumours. Although features of short bowel syndrome usually appear when there is less than 200 cm of small bowel, the length and nature of the remaining intestine are also important. In general, diseases which result in short bowel syndrome tend to preferentially affect the distal small intestine, and there is some evidence that the ileum, with its tighter intercellular junctions and consequently better fluid absorptive capacity, can assume the functions of a missing jejunum, but not *vice versa*. While the ileocaecal valve used to be considered important with regard to preservation of absorptive function, it is more likely that this is a reflection of the associated preservation of the distal ileum and right colon than the valve itself.

Patients with an intact colon are relatively protected from the effects of massive small bowel resection because of the ability of the colon to absorb not only fluid and electrolytes, but a modest amount of nutrient energy. Patients with as little as 100–200 cm of jejunum anastomosed to an intact colon may therefore be able to maintain satisfactory macronutrient, fluid and electrolyte status, although they will, of course, be at risk of fat-soluble and B12 vitamin deficiencies and will also generally need oral nutritional supplements of trace elements, vitamins and minerals. Some (but not all) patients with

50–100 cm of small intestine and an intact colon will need long-term parenteral nutrition, as will almost all patients with 50 cm or less of jejunum anastomosed to an intact colon. In contrast, most patients with less than 200 cm of small intestine ending in a jejunostomy will require regular infusions of parenteral fluid and electrolytes, and almost all of those with less than 100 cm of small bowel ending in a jejunostomy will require long-term parenteral nutrition.

Medical management of patients with short bowel syndrome relies on the use of antidiarrhoeal agents (loperamide and codeine phosphate), drugs to reduce diarrhoea related to bile-salt malabsorption (colestyramine) and enteral and parenteral vitamin and trace element supplements. Although there has also been interest in the use of drugs to promote intestinal adaptation, such as growth hormone, glutamine and, most recently, glucagon-like peptide 2 agonists, the mainstay of treatment for short bowel syndrome remains home parenteral nutrition (HPN). The development of this treatment in the late 1960s enabled the majority of patients with short bowel syndrome to enjoy a reasonably good quality of life, with long-term survival related principally to the underlying disease. HPN is, however, expensive and demanding and patients with short bowel syndrome receiving HPN are at risk from catheter-related complications (notably catheter-related sepsis and occlusion), as well as metabolic complications (fibrotic liver disease, gallstones, metabolic bone disease and kidney stones).

Surgical procedures designed to improve the surface area or reduce the speed of transit of the remaining small intestine (and thus improve absorptive capacity) have shown some promise in children, but their place in managing adults with established short bowel syndrome is currently unclear. In some patients, the loss of venous access resulting from the complications of long-term intravenous feeding or the development of progressive liver dysfunction may represent indications for small bowel transplantation. The results of small bowel transplantation have progressively improved and 5-year patient survival now exceeds 80% in some centres.

Chapter 70

The large intestine

Learning objectives

To appreciate:
- The basic anatomy and physiology of the large intestine
- The range of conditions that may affect the large intestine

To understand:
- The aetiology and pathology of common large intestinal conditions
- The principles of investigation of large intestinal symptoms
- The importance of non-surgical management of large intestinal problems
- The principles of colonic surgery
- That complex intestinal problems are best managed by a multidisciplinary team
- The management of acute surgical problems of the intestines

ANATOMY OF THE LARGE INTESTINE

The large intestine begins at the ileocaecal valve and extends to the anus. It is divided into the caecum, ascending colon, hepatic flexure, transverse colon with attached greater omentum, splenic flexure, descending colon, sigmoid and rectum. The large intestine is approximately 1.5 m long, but can be straightened at endoscopy so the caecum can be reached with 70 cm of colonoscope.

The colon is distinguished from the small bowel by having fat-filled peritoneal tags known as appendices epiploicae and the taenia coli. These are three flat bands of longitudinal muscle that run from the appendix base to the rectosigmoid junction. They act to pull the colon into its sacculated state, producing a series of haustrations. Distended small and large intestine can be distinguished on an abdominal radiograph as the small bowel has complete transverse markings caused by the valvulae conniventes, while the colon has incomplete lines from the sacculation caused by the taeniae. The important posterior relations of the caecum and ascending colon are the right ureter, right gonadal vessels and duodenum and these must be protected at surgery. The left ureter, left gonadal vessels and tail of the pancreas must be protected when operating on the left colon.

The blood supply of the large intestine is derived from branches of the superior mesenteric artery from the caecum to the distal transverse colon and the inferior mesenteric artery and its branches more distally. Adjacent branches anastomose so there is usually a complete vascular supply along the colon, named the marginal artery of Drummond. This vessel is often the key blood supply to the vascular arcades, ensuring adequate perfusion of a colonic anastomosis, but blood flow in the 'watershed' area of the splenic flexure representing the junction between the superior and inferior mesenteric supply may be tenuous. Sudden occlusion of the inferior mesenteric artery may leave the area of the splenic flexure poorly perfused, leading to an ischaemic colitis. Venous and lymphatic drainage of the colon follows the arterial supply and venous drainage is into the portal system. High ligation of the artery supplying a segment of colon will therefore also remove the draining lymph nodes, a key technical point in cancer surgery. The nerve supply to the large intestine is derived from the splanchnic nerves via a dense sympathetic plexus surrounding the superior and inferior mesenteric arteries. Visceral pain from the part of the colon supplied by the superior mesenteric artery is thus felt, like that of the small intestine, in the periumbilical region, while pain from the colon distal to that point is felt suprapubically.

Valvulae conniventes describes a fold of mucous membrane that passes across two-thirds of the bowel circumference.
David Drummond, 1852–1932, English physician.

PHYSIOLOGY OF THE LARGE INTESTINE

The principle function of the colon is absorption of water; 1000 mL of ileal content enters the caecum every 24 hours, of which only approximately 200 mL is excreted as faeces. Sodium absorption is efficiently accomplished by an active transport system, while chloride and water are absorbed passively. Fermentation of dietary fibre in the colon by the normal colonic microflora leads to the generation of short chain fatty acids, which are an important metabolic fuel for the colonic mucosa. Diversion of the faecal stream may lead to inflammatory changes in the colon downstream (diversion colitis). Absorption of nutrients including glucose, fatty acids, amino acids and vitamins can also take place in the colon.

Colonic motility is variable. In general, faecal residue reaches the caecum 4 hours after a meal and the rectum after 24 hours. Passage of stool is not orderly because of mixing within the colon, so it is not uncommon for residue from a single meal to still be passed 4 days later.

TUMOURS OF THE LARGE INTESTINE

Benign

The term 'polyp' is a clinical description of any protrusion of the mucosa. It encompasses a variety of histologically different tumours (*Table 70.1*). Polyps can occur singly, synchronously in small numbers or as part of a polyposis syndrome.

Adenomatous polyps

Adenomatous polyps vary from a tubular adenoma (**Figure 70.1**), rather like a berry on a stalk, to the villous adenoma, a flat spreading lesion. Villous tumours can cause diarrhoea, mucus discharge and, occasionally hypokalaemia and hypoalbuminaemia. The risk of malignancy developing in an adenoma increases with size; there is a 10% risk of cancer in a 1-cm diameter tubular adenoma, whereas almost one-third of large (>3 cm) colonic adenomas will have an area of invasive malignancy within them. Adenomas larger than 5 mm in diameter are usually excised because of their malignant potential. Snare polypectomy is usually possible for colonic polyps but larger sessile polyps may require endoscopic mucosal resection after infiltration of a solution containing dilute adrenaline. Larger rectal adenomas may require transanal resection or, where the adenoma is too high, transanal endoscopic microsurgery or resection via transanal placement of laparoscopic instruments. Extensive villous lesions of the rectum may require argon beam ablation when the patient is frail but symptomatic.

TABLE 70.1 Classification of intestinal polyps.

Inflammatory	Inflammatory polyps (pseudopolyps in UC)	
Metaplastic	Metaplastic or hyperplastic polyps	
Hamartomatous	Peutz–Jeghers polyp

		Villous
	Adenocarcinoma	
	Carcinoid tumour	

UC, ulcerative colitis.

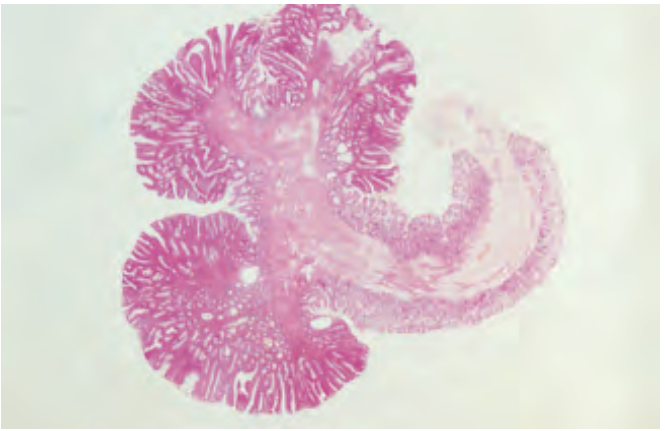

Figure 70.1 Pedunculated adenomatous polyp of the large intestine, longitudinal section (courtesy of Dr P Millard, John Radcliffe Hospital, Oxford, UK).

Familial adenomatous polyposis

Familial adenomatous polyposis (FAP) is defined clinically by the presence of more than 100 colorectal adenomas, but is also characterised by duodenal adenomas and multiple extraintestinal manifestations (*Summary box 70.1*). Over 80% of cases come from patients with a positive family history. The remainder arise as a result of new mutations in the adenomatous polyposis coli (APC) gene on the short arm of chromosome 5. FAP is inherited as an autosomal dominant condition and is consequently equally likely in men and women. The lifetime risk of colorectal cancer is 100% in patients with FAP. FAP can also be associated with benign mesodermal tumours such as desmoid tumours and osteomas. Epidermoid cysts can also occur (Gardner's syndrome); desmoid tumours in the abdomen spread locally to involve the intestinal mesentery and, although non-metastasising, they may become unresectable. Up to 50% of patients with FAP have congenital hypertrophy of the retinal pigment epithelium (CHRPE), which can be used to screen affected families if genetic testing is unavailable.

CLINICAL FEATURES

Polyps are usually visible on sigmoidoscopy by the age of 15 years and will almost always be visible by the age of 30 years. Carcinoma of the large bowel develops 10–20 years after the onset of the polyposis. If there are no adenomas by the age of 30 years, FAP is unlikely. If the diagnosis is made during

Eldon John Gardner, 1909–1989, geneticist, The University of Utah, Salt Lake City, UT, USA, described this syndrome in 1950.

Summary box 70.1

Extracolonic manifestations of FAP

- Endodermal derivatives
  - Adenomas and carcinomas of the duodenum, stomach, small intestine, thyroid and biliary tree
  - Fundic gland polyps
  - Hepatoblastoma
- Ectodermal derivatives
  - Epidermoid cysts
  - Pilomatrixoma
  - Congenital hypertrophy of the retinal pigment epithelium (CHRPE)
  - Brain tumours
- Mesodermal derivatives
  - Desmoid tumours
  - Osteomas
  - Dental problems

adolescence, surgery is usually deferred to the age of 17 or 18 years unless symptoms develop. Malignant change is rare before the age of 20 years. Examination of blood relatives, including cousins, nephews and nieces, is essential; a family tree should be constructed and a register of affected families maintained. Referral to a medical geneticist is essential. If over 100 adenomas are present at colonoscopy, the diagnosis can be made confidently (**Figure 70.2**).

Summary box 70.2

Features of FAP

- Autosomal dominant inherited disease due to mutation of the *APC* gene
- More than 100 colonic adenomas are diagnostic
- Prophylactic surgery is indicated to preventing colorectal cancer
- Polyps and malignant tumours can develop in the duodenum and small bowel

Figure 70.2 Familial adenomatous polyposis.

TREATMENT

The aim of surgery in FAP is to prevent the development of colorectal cancer. The surgical options are:

1. colectomy with ileorectal anastomosis (IRA);
2. restorative proctocolectomy with an ileal pouch–anal anastomosis (RPC);
3. total proctectomy and end ileostomy.

The patient is almost always young and likely to prefer to avoid a permanent stoma and so the choice is normally between the first two options. The advantage of an IRA is that it avoids the temporary stoma frequently required for an RPC and avoids the potential compromise to sexual function accompanying proctectomy. It is also has a lower morbidity and mortality. However, the rectum requires regular surveillance. Even with optimal surveillance of the rectal remnant, up to 10% of patients will develop invasive malignancy within a 30-year follow up period. Restorative proctocolectomy has the advantage of removing the whole colon and rectum. However, there is a pouch failure rate of approximately 10%. In addition, and particularly where a stapled anastomosis has been created, there remains a small but definite incidence of cancer developing in the small strip of rectal mucosa between the pouch and the dentate line. Some advocate complete mucosectomy of the residual cuff and a transanal anastomosis, although this may result in worse function. In experienced hands a laparoscopic approach to these operations can be successful, with swifter recovery and improved cosmesis.

POSTOPERATIVE SURVEILLANCE

Because of the risk of further tumour formation, follow-up is important and takes the form of rectal/pouch surveillance, with biopsy of the cuff recommended yearly. Gastroscopies are also carried out to detect upper gastrointestinal tumours (notably duodenal adenomas). Despite this, lifespan is reduced because of the development of duodenal and ampullary cancers and complications of desmoid tumours.

Hereditary non-polyposis colorectal cancer (Lynch syndrome)

Hereditary non-polyposis colorectal cancer (HNPCC) is characterised by an increased risk of colorectal cancer and also cancers of the endometrium, ovary, stomach and small intestine. It is an autosomal dominant condition caused by a mutation in one of the DNA mismatch repair genes. The most commonly affected genes are *MLH1* and *MSH2*. The lifetime risk of developing colorectal cancer is 80%, and the mean age of diagnosis is 45 years. Most cancers develop in the proximal colon. Females have a 30–50% lifetime risk of developing endometrial cancer.

DIAGNOSIS

HNPCC can be diagnosed by genetic testing or by the Amsterdam II criteria:

- three or more family members with an HNPCC-related cancer (colorectal, endometrial, small bowel, ureter, renal

pelvis), one of whom is a first-degree relative of the other two;
- two successive affected generations;
- at least one colorectal cancer diagnosed before the age of 50 years;
- FAP excluded;
- tumours verified by pathological examination.

Patients with HNPCC are offered regular endoscopic surveillance. The small intestine may also be radiologically assessed but this is of unproven benefit.

Malignant – colorectal cancer

Epidemiology

In the UK, colorectal cancer is the second most common cause of cancer death. Approximately 35 000 patients are diagnosed with colorectal cancer every year in the UK. Approximately one-third of these tumours are in the rectum and two-thirds in the colon. The burden of disease is similar in men and women. Colorectal cancer occurs less frequently in the resource-poor world than in resource-rich countries.

Aetiology

The accepted model of colorectal cancer development is that it arises from adenomatous polyps after a sequence of genetic mutations influenced by environmental factors. This adenoma–carcinoma sequence is based on strong observational evidence as outlined in *Summary box 70.3*. The adenoma–carcinoma sequence is not a simple stepwise progression of mutations but a complicated array of multiple genetic alterations, ultimately resulting in an invasive tumour. Mutations of the adenomatous polyposis coli (APC) gene occur in two-thirds of colonic adenomas and are thought to develop early in the carcinogenesis pathway. K-ras mutations result in activation of cell signalling pathways and are more common in larger lesions, suggesting that that they are later events in mutagenesis. The p53 gene is frequently mutated in carcinomas but not in adenomas and therefore thought to be a marker of invasion.

Summary box 70.3

Evidence for adenoma–carcinoma sequence

- The prevalence of adenomas and carcinomas is very similar – carcinoma patients are about 5 years older
- The distribution of adenomas in the colon is the same as that of cancers (70% left sided)
- When small cancers are studied they almost always have adjacent adenomatous tissue
- Adenomas are found in one-third of specimens resected for colorectal cancer
- Sporadic adenomas are identical to the adenomas of FAP, which is associated with a 100% chance of colorectal adenocarcinoma unless treated
- Larger adenomas are more likely to be dysplastic and to have higher grades of dysplasia than small adenomas
- Incidence of colorectal cancer falls within a screening programme that involves colonoscopy and polypectomy

There has been much interest in the association between diet and colon cancer. Worldwide, the prevalence of colorectal cancer is closely associated with intake of red meat and particularly processed meat products (haem and N-nitroso compounds). These adversely affect DNA in the colorectal mucosa. A protective effect of dietary fibre is also suggested by epidemiological studies. The hypothesis is that increased roughage is associated with reduced colonic transit times, and this in turn reduces the exposure of the mucosa to dietary carcinogens. Increased risk for colorectal cancer has also been associated with dietary animal fat, smoking and alcohol. Cholecystectomy may marginally increase the risk of right-sided colon cancer and inflammatory bowel disease is a well-recognized risk factor (see below).

Pathology

Macroscopically, the tumour may take one of four forms (**Figure 70.3**). The annular variety tends to give rise to obstructive symptoms, whereas the others present more commonly with bleeding. Most large bowel cancers arise from the left colon, notably the rectum (38%), sigmoid (21%), and descending colon (4%). Cancer of the caecum (12%) and ascending colon (5%) are less common, but may be gradually increasing in incidence. Cancer of the transverse colon (5.5%), flexures (2–3%) and appendix (0.5%) are relatively uncommon. Microscopically, the neoplasm is a columnar cell adenocarcinoma. Origin from a benign polyp may be evident in early cases, before the benign architecture is destroyed by malignant infiltration.

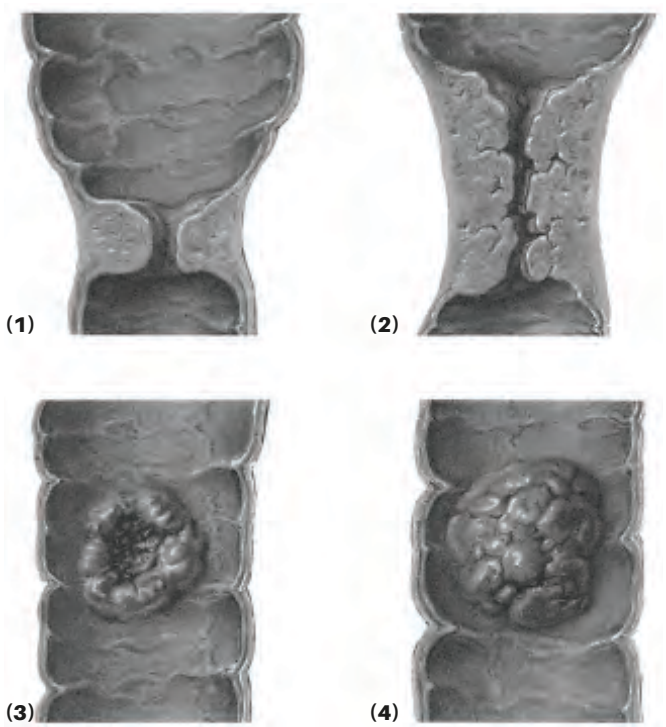

Figure 70.3 The four common macroscopic varieties of carcinoma of the colon: (1) annular; (2) tubular; (3) ulcer; (4) cauliflower.

Spread

Colonic cancer can spread locally or via the lymphatics, bloodstream or transcoelomically across the peritoneal cavity. Direct spread may be longitudinal or radial. Radial spread may be retroperitoneal into the ureter, duodenum and posterior abdominal wall muscles or intraperitoneal into adjacent organs or the anterior abdominal wall.

In general, involvement of the lymph nodes by the tumour progresses from those closest to the bowel along the course of lymphatics to central nodes. However, this orderly process does not always occur. Haematogenous spread is most commonly to the liver via the portal vein. One-third of patients will have liver metastases at the time of diagnosis and 50% will develop them at some point, accounting for the majority of deaths. The lung is the next most common site; metastasis to ovary, brain, kidney and bone is less common. Colorectal cancer can spread from the serosa of the bowel or via subperitoneal lymphatics to other structures within the peritoneal cavity, including peritoneum, ovary and omentum.

Staging colon cancer

A variety of staging systems are described for colorectal cancer based on pathological reporting to predict prognosis and guide adjuvant treatment. Dukes' classification was originally described for rectal tumours but has been adopted for histopathological reporting of colon cancer. Although it is simple and widely recognised (*Summary box 70.4*) the more detailed TNM system is regarded as the international standard (*Summary box 70.5*).

Summary box 70.4

Dukes' staging for colorectal cancer

- A: invasion of but not breaching the muscularis propria
- B: breaching the muscularis propria but not involving lymph nodes
- C: lymph nodes involved.

Dukes himself never described a stage D, but this is often used to describe metastatic disease

Summary box 70.5

TNM classification for colonic cancer

- T Tumour stage
  - T1 Into submucosa
  - T2 Into muscularis propria
  - T3 Into pericolic fat or subserosa but not breaching serosa
  - T4 Breaches serosa or directly involving another organ
- N Nodal stage
  - N0 No nodes involved
  - N1 1-3 nodes involved
  - N2 Four or more nodes involved
- M Metastases
  - M0 No metastases
  - M1 Metastases

Clinical features

Carcinoma of the colon typically occurs in patients over 50 years of age and is most common in the 8th decade of life. Emergency presentation occurs in 20% of cases and is associated with a considerably worse prognosis, even when matched for disease stage. A careful family history should be taken. Those with first-degree relatives who have developed colorectal cancer before the age of 45 years may be part of one of the colorectal cancer familial syndromes. Tumours of the left side of the colon usually present with a change in bowel habit or rectal bleeding, while proximal lesions typically present later, with iron deficiency anaemia or a mass (**Figure 70.4**). Patients commonly present with metastatic disease. Lesions of the flexures may present with vague upper abdominal symptoms for many months before symptoms suggestive of colonic disease appear.

Investigation of colon cancer

SCREENING

Colon cancer is suited to screening as prognosis is better for early stage disease and polypectomy allows the prevention of cancer development. In the UK, a screening programme has been introduced based on faecal occult blood testing of people aged 60–69 years, followed by colonoscopy in those who test positive. A guaiac-based test is used, which detects peroxidase-like activity of faecal haematin. Studies have suggested a 15–20% reduction in colorectal cancer specific mortality in the screened population. Flexible sigmoidoscopy can also be used as the initial screening tool, with a similar reduction in colorectal cancer specific mortality.

ENDOSCOPY

The 60-cm, fibreoptic, flexible sigmoidoscope is increasingly being used in 'one-stop' rectal bleeding clinics. The patient is prepared with an enema and sedation is not usually necessary. It is usually possible to assess the bowel up to the splenic flexure, which will detect up to 70% of cancers and almost all that cause fresh rectal bleeding (**Figure 70.5**). Colonoscopy is the investigation of choice if colorectal cancer is suspected,

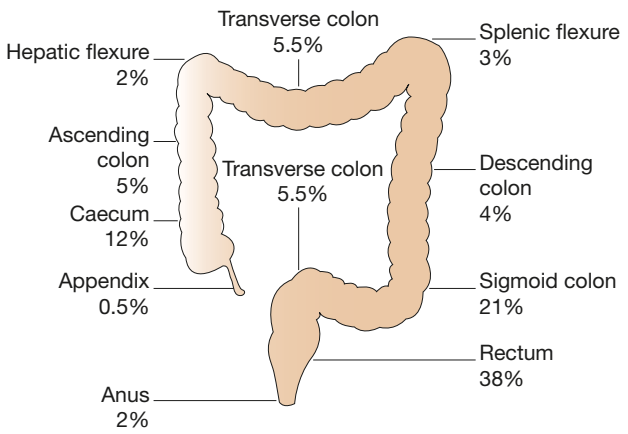

Figure 70.4 Distribution of colorectal cancer by site.

Cuthbert Esquire Dukes, 1890–1977, pathologist, St Mark's Hospital, London, UK. The original Dukes' classification in 1932 gave three stages, A–C.

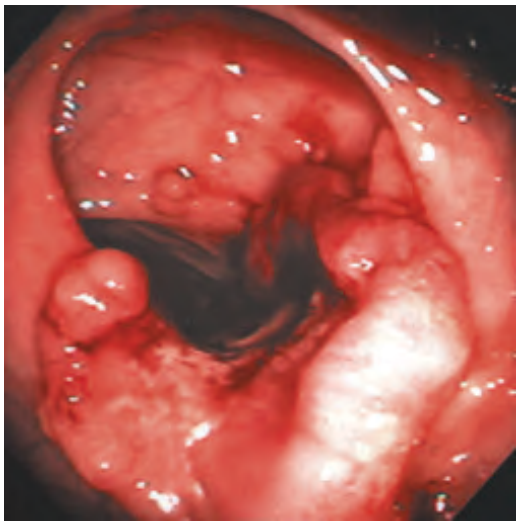

Figure 70.5 A cancer seen at colonoscopy.

provided the patient is fit enough to undergo the mechanical bowel preparation required. It has the advantage of not only picking up a primary cancer but also having the ability to detect synchronous polyps or other carcinomas, which occur in 3–5% of cases. There is a small risk of perforation (1:1000).

RADIOLOGY

Double-contrast barium enema has traditionally been used and shows a cancer of the colon as a constant irregular filling defect, often described as looking like an apple-core (**Figure 70.6**). False positives occur in 1–2% of cases and false negatives in 7–9% of cases. It has now been largely replaced by computed tomography (CT) virtual colonoscopy, which is extremely sensitive in picking up polyps down to a size of 6 mm (**Figure 70.7**). It has the advantage of being less

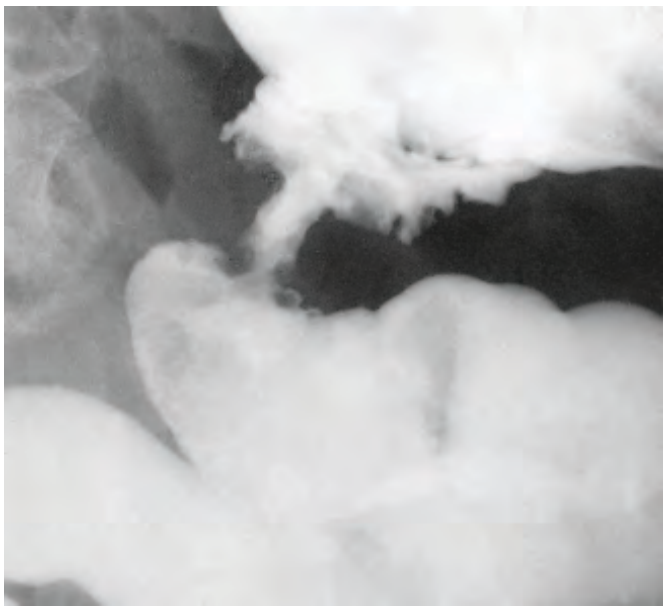

Figure 70.6 Barium enema showing a carcinoma of the sigmoid colon. It may have an 'apple core' appearance (i.e. a short, irregular stenosis with sharp shoulders at each end).

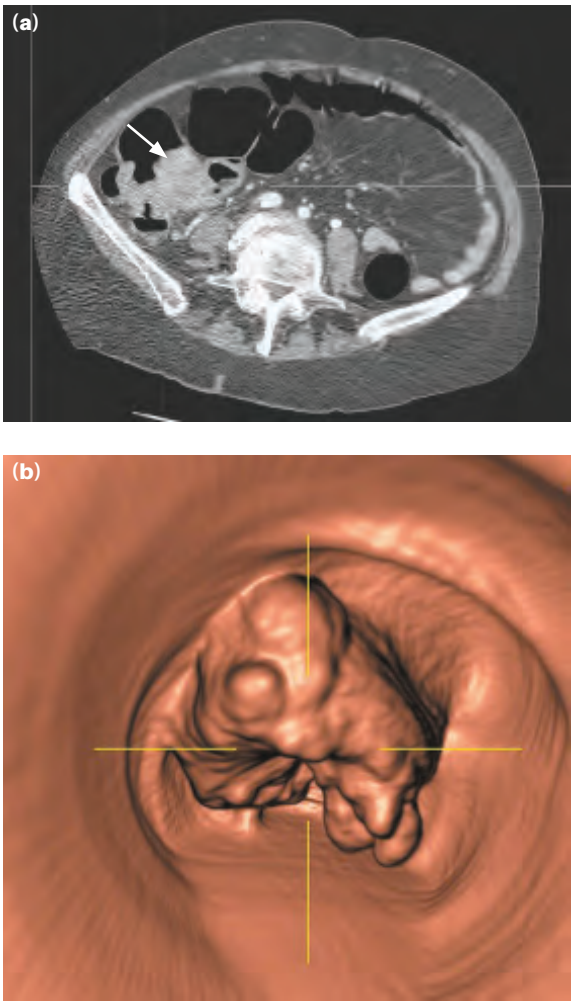

Figure 70.7 Virtual colonoscopy of the right colon. **(a)** Computed tomography scan of the abdomen showing a caecal tumour (arrow). **(b)** Formatted 'virtual' image of the same lesion as in **(a)** (courtesy of Dr A Slater, John Radcliffe Hospital, Oxford, UK).

invasive than colonoscopy but if a biopsy is required, an endoscopy will still be needed. CT is used as a diagnostic tool in patients with palpable abdominal masses. Spiral CT of the chest, abdomen and pelvis now represents the standard means of staging colorectal cancer, although chest x-ray and liver ultrasound are alternatives if CT is not readily available. Rectal cancer usually requires additional staging for local spread, using magnetic resonance imaging.

Surgical treatment

PREOPERATIVE PREPARATION

Mechanical bowel preparation has fallen out of favour in surgery for colon cancer, with little evidence of benefit and some of an increased rate of wound infection. It currently remains in use largely for low rectal resection, where unprepared bowel may be associated with a higher infection rate. Anti-embolism stockings should be fitted and the patient started on prophylactic subcutaneous low molecular weight heparin. If available, manual compression boots are used perioperatively. Intravenous prophylactic antibiotics are given immediately

before the start of surgery, to reduce the risk of surgical site infection. A single dose of antibiotics covering bowel organisms is as effective as multiple doses. In all cases where a stoma seems likely, careful preoperative counselling and marking of an appropriate site by an enterostomal therapist is essential.

OPERATIONS

The operations described are designed to remove the primary tumour and its draining locoregional lymph nodes. It is unusual to find unsuspected metastases at laparotomy (or laparoscopy) after CT staging, but the presence of peritoneal metastases may predicate a palliative strategy with a segmental resection and less aggressive lymphadenectomy. The use of stapling and hand-suturing techniques for colonic anastomoses have been compared, and there is probably little difference in leak rate. It is more important that healthy bowel, free of tension or distal obstruction, is used to construct an anastomosis and that patients are adequately nourished and free from active infection if anastomotic leakage is to be avoided.

Right hemicolectomy Carcinoma of the caecum or ascending colon (Figure 70.8) is treated by right hemicolectomy (Figure 70.9). At open surgery the peritoneum lateral to the ascending colon is incised, and the incision is carried around the hepatic flexure. The right colon and mesentery are elevated, taking care not to injure the ureter, gonadal vessels or the duodenum. The ileocolic artery is ligated close to its origin from the superior mesenteric artery ('high-tie') and divided. Where the right colic artery has a separate origin from the superior mesenteric artery (around 10% of patients) this is separately ligated. The mesentery of the distal 20 cm of ileum and the mesocolon as far as the proximal third of the transverse colon is divided. The greater omentum is divided up to the point of intended division of the transverse colon. When it is clear that there is an adequate blood supply at the resection margins, the right colon is resected, and an anastomosis is fashioned between the ileum and the transverse colon. If the tumour is at the hepatic flexure the resection must be extended further along the transverse colon and will involve dividing the right branch of the middle colic artery.

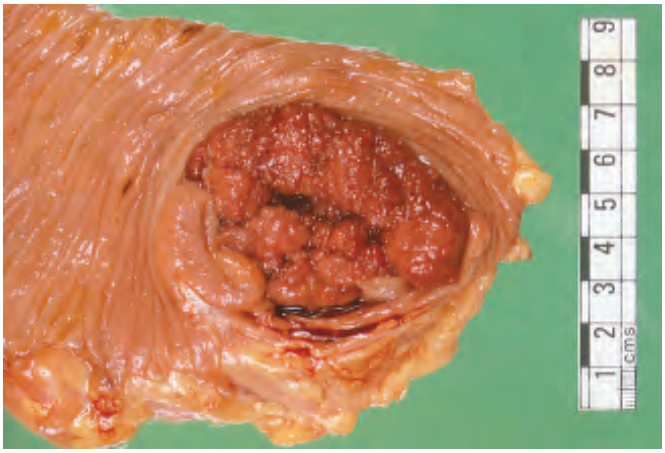

Figure 70.8 Large villous tumour of the caecum with malignant change.

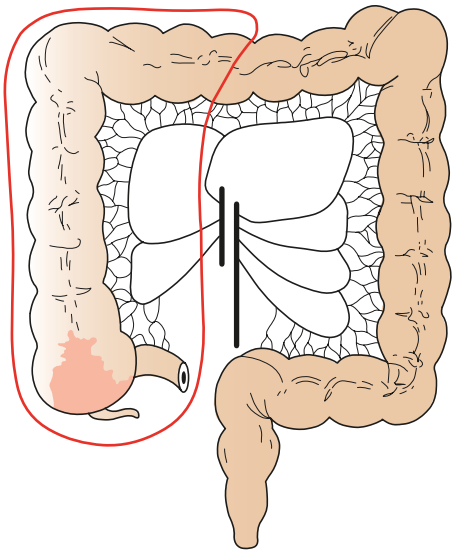

Figure 70.9 Schematic showing right hemicolectomy.

Extended right hemicolectomy Carcinomas of the transverse colon and splenic flexure are most commonly treated by an extended right hemicolectomy. The extent of the resection is from the right colon to the descending colon. The mobilisation is as for a right hemicolectomy but dissection continues to take down the splenic flexure and the whole transverse mesocolon is ligated. Some surgeons prefer to perform a left hemicolectomy for a splenic flexure cancer.

Left hemicolectomy This is the operation of choice for descending colon and sigmoid cancers (Figure 70.10). The left half of the colon is mobilised completely along the 'white line' that marks the lateral attachment of the mesocolon. As the sigmoid mesentery is mobilised, the left ureter and gonadal vessels must be identified and protected. The splenic flexure may be mobilised by extending the lateral dissection

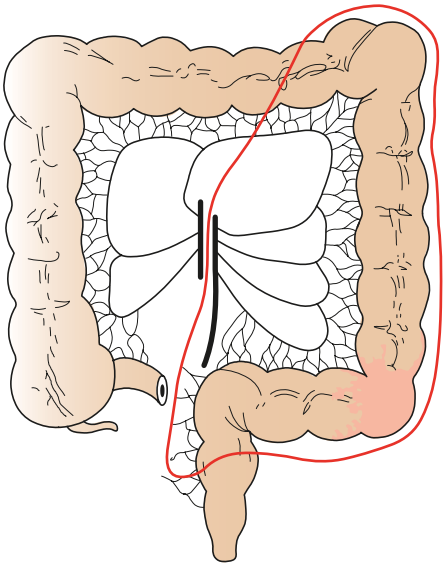

Figure 70.10 Schematic showing left hemicolectomy.

from below and completed by entering the lesser sac. The inferior mesenteric artery below its left colic branch, together with the related paracolic lymph nodes, is included in the resection by ligating the inferior mesenteric artery close to its origin ('high-tie'). For full mobility the inferior mesenteric vein is also ligated and divided at the lower border of the pancreas. The bowel and mesentery can then be resected to allow a tension-free anastomosis. A temporary diverting stoma may be fashioned upstream, usually by formation of a loop ileostomy. This is usually undertaken if the anastomosis is below the peritoneal reflection of the rectum, because healing is more likely to be impaired distally.

Laparoscopic surgery Laparoscopic surgery for colon cancer has been shown to have equivalent overall and cancer-related outcomes to open surgery. Lymph node harvests are equivalent to open surgery and initial concerns about reports of port site recurrence have been dispelled as the world experience has grown. In the UK, the National Institute for Health and Care Excellence has stated that laparoscopic colorectal surgery should be offered to suitable patients. Operation times are longer but wound infection rates, blood loss and postoperative pain scores are lower than for open surgery. The costs of laparoscopic surgery are, however, generally higher and this may particularly relevant where funds are limited.

It is not possible to palpate lesions, so if laparoscopic surgery is planned it is useful to tattoo the lesion at prior colonoscopy. The laparoscopic operation has particular advantages if performed in a medial to lateral manner – that is starting the dissection by controlling and dividing the major vascular pedicles and only taking the lateral peritoneal reflection once the mesocolon is completely free. Specimen retrieval and bowel anastomosis can then be performed via small incisions. Dedicated training in laparoscopic colorectal surgery is important, as there is a relatively long learning curve.

Emergency surgery

In the UK, 20% of patients with colonic cancer will present as an emergency, the majority with obstruction, but occasionally with haemorrhage or perforation. If the lesion is right sided, it is usually possible to perform a right hemicolectomy and anastomosis in the usual manner. If there has been perforation with substantial contamination or if the patient is unstable, it may be advisable to bring out an ileocolostomy rather than forming an anastomosis. For a left-sided lesion the decision lies between a Hartmann's procedure or resection and anastomosis. Where endoscopic and radiological facilities are present an obstructing left-sided lesion can be treated with an expanding metal stent (**Figure 70.11**). This has the advantage of converting an emergency operation with a high chance of a stoma to a situation that can be managed semi-electively by resection and anastomosis. Although early studies cast doubt on the benefits of colorectal stenting, more recently evidence has emerged that stenting leads to a reduction in stoma rates.

Figure 70.11 Abdominal radiograph demonstrating a colonic stent in position ((arrow) courtesy of Dr D Kasir, Hope Hospital, Salford, UK)

Postoperative care

After colonic surgery patients should be closely monitored, as there is a small incidence of postoperative bleeding. Antithrombosis measures should be continued as discussed in the preoperative section and are currently recommended for 28 days postoperatively. There is no advantage to placing intra-abdominal drains after colonic surgery. Wound infections are relatively common after colonic surgery and may well be more frequent than the 10% usually quoted. Anastomotic leaks occur in 4–8% of ileocolic or colocolic anastomoses. The possibility should be borne in mind in any patient not progressing as expected or with unexplained cardiac abnormalities, fever or worsening abdominal pain. Early investigation with contrast enhanced CT scan is appropriate. In the presence of sepsis or peritonitis, early return to theatre and taking down the leaking anastomosis with the formation of stomas is usually advised.

Prolonged nasogastric drainage, intravenous fluid therapy and cautious introduction of oral fluid and diet represented traditional postoperative practice. Enhanced recovery programmes have been shown to reduce length of hospital stay from 10–14 days to as little as 2–3 days, by modulating the surgical stress response and reducing post-operative ileus. It is important to appreciate that these programmes require multiple interventions to be instituted and considerable time, effort and education from the surgical, anaesthetic and ward teams.

Henri Albert Antoine Hartmann, 1860–1952, Professor of Clinical Surgery in the Faculty of Medicine, University of Paris, France.

Summary box 70.6

Key elements of an enhanced recovery programme

- Preadmission counselling
- Avoidance of mechanical bowel preparation
- Preoperative carbohydrate loading
- Avoidance of preoperative dehydration
- No nasogastric tubes
- Short, transverse incisions (or laparoscopic procedure)
- Short-acting anaesthetic drugs
- Avoidance of perioperative fluid/salt overload
- Thoracic epidurals
- Avoidance of opiate analgesia
- Maintenance of perioperative temperature
- Prevention of postoperative nausea and vomiting
- Early mobilisation
- Early introduction of oral fluids/diets/supplements
- Early removal of urinary catheters
- Continual audit of outcomes

Adjuvant therapy

In most patients with colon cancer there is little clear benefit of preoperative chemotherapy, although trials in selected patient groups with locally advanced disease are ongoing. There is evidence that adjuvant chemotherapy improves outcome after surgery in patients with node-positive disease (Dukes C).

Metastatic disease

Hepatic metastases can be resected and series have demonstrated 5-year survival of over 30% in resectable disease. Liver surgeons are increasingly aggressive in treatment and the only absolute limitation on what can be resected relates to leaving behind sufficient functioning liver, although this clearly has to be moderated by patient factors. It is important not to biopsy potentially resectable hepatic metastases as this may cause tumour dissemination. Imaging will usually correctly identify colorectal metastases and assess patients suitable for liver resection (**Figure 70.12**). The role of chemotherapy and the timing of colonic and hepatic surgery in synchronous metastases is still a matter of debate and such cases should be carefully discussed by a multidisciplinary team. Isolated lung metastases may occasionally be suitable for resection but they are more commonly accompanied by metastases elsewhere. In patients with widespread disease, palliative chemotherapy is offered alongside symptomatic treatment and support by a palliative care team.

Prognosis

Overall 5-year survival for colorectal cancer is approximately 50%. The most important determinant of prognosis is tumour stage and, in particular, lymph node status. Patients with disease confined to the bowel wall (Dukes stage A) will usually have cure by surgical resection alone and over 90% will have disease-free survival at 5 years. Spread beyond the bowel wall (Dukes B) reduces 5-year survival to approximately 60–70%. Patients with lymph node metastases (Dukes C) have a 5-year survival of 30%, while fewer than 10% of patients presenting with metastatic disease at the outset will be alive 5 years later.

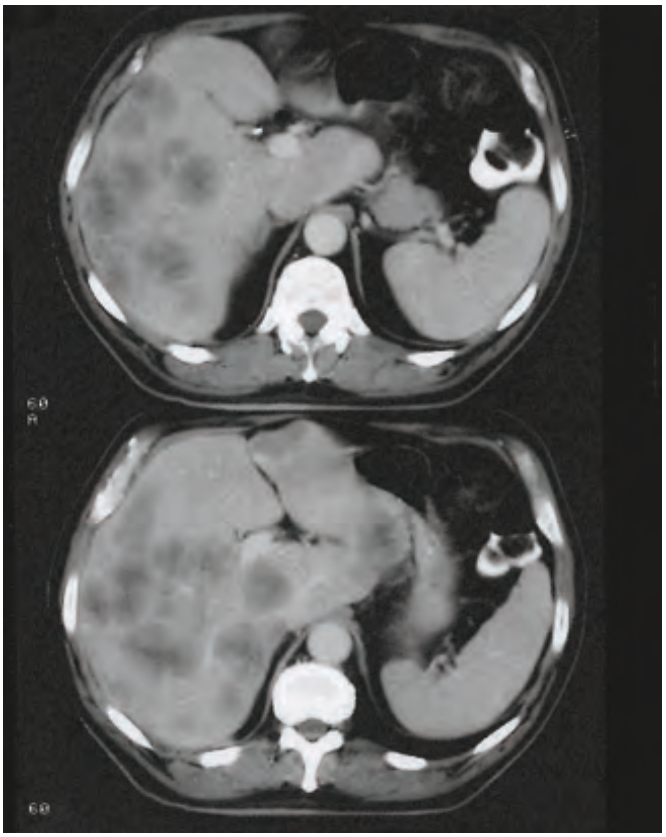

Figure 70.12 Computed tomography scan of the liver showing multiple metastases from carcinoma of the colon.

Colorectal cancer follow-up

Since the advent of safe liver resection for metastases the outcome benefit of follow-up has been clearly demonstrated. Follow-up aims to identify synchronous bowel tumours (present in 3%) that were not picked up at the time of original diagnosis due to emergency presentation or incomplete assessment. Similarly, 3% of patients will develop a metachronous (at a different time) colonic cancer and surveillance colonoscopy is designed to diagnose these. Up to a half of all patients with colorectal cancer will develop liver metastases at some point and regular imaging of the liver (by ultrasound and CT scan) and measurement of carcinoembryonic antigen (CEA) is designed to diagnose this early, in order to allow curative metastectomy. Trials of the optimum follow-up pathway have suggested that CEA measurement alone can be as effective as regular imaging.

INFLAMMATORY BOWEL DISEASE

The term 'inflammatory bowel disease' is reserved for conditions characterised by the presence of idiopathic intestinal inflammation (i.e. ulcerative colitis [UC] and Crohn's disease [CD]. Although the availability of population genetics and

molecular biology has contributed to our understanding of the pathogenesis of inflammatory bowel disease, the aetiology remains unclear.

Ulcerative colitis

UC is a disease of the rectum and colon with extraintestinal manifestations. The incidence is 10 per 100 000 per year in the UK with a prevalence of 160 per 100 000 population. UC affects men and women equally in early life, although it is said to be more common in males in later life. It is most commonly diagnosed between the ages of 20 and 40. UC is far more common in the USA and Western Europe but relatively rare in the Far East and tropics. Asians who spent their childhood before the age of 14 in Asia have a much lower incidence of UC than Asians born and raised in the UK, suggesting an important effect of environmental exposure in childhood.

Aetiology

The cause of UC is unknown. There is clearly a genetic contribution, as 10–20% of patients have a first-degree relative with inflammatory bowel disease. Patients with severe colitis have a reduction in the number of anaerobic bacteria and in the variability of bacterial strains in the colon, but no causative link with any specific organism has been identified. Unlike CD, smoking seems to have a protective effect in UC and has even been the basis of therapeutic trials of nicotine. Relapses are occasionally said to be associated with periods of stress, but personality and psychiatric profiles in patients with UC are the same as those of the normal population.

Pathology

In virtually all cases the disease starts in the rectum and extends proximally in continuity. Colonic inflammation is diffuse, confluent and superficial, primarily affecting the mucosa and superficial submucosa. 'Pseudopolyposis' occurs in almost one-quarter of cases. Stricturing in UC is very unusual (unlike CD) and should prompt urgent assessment because of the possibility of coexisting carcinoma. A small proportion of patients develop irregular mucosal swellings (dysplasia-associated lesions or mass [DALMs]), which are highly predictive of coexisting carcinoma.

Histological examination reveals an increase in inflammatory cells in the lamina propria and the crypts of Lieberkuhn and there are 'crypt abscesses'. There is depletion of goblet cell mucin. With time, precancerous changes can develop (dysplasia). High-grade dysplasia is regarded as an indication for surgery as 40% of colectomy specimens in which high-grade dysplasia was detected will have evidence of a colorectal cancer. In contrast, optimum management of low-grade dysplasia is currently controversial. Ten to twenty per cent of patients with low-grade dysplasia will have a cancer at colectomy. The progression rate of low-grade dysplasia to invasive cancer is unclear and many cancers in patients with low-grade dysplasia probably develop without high-grade dysplasia.

Symptoms

Clinical presentation depends in large part on the extent of disease. If confined to the rectum (proctitis), there is usually no systemic upset and extra-alimentary manifestations are rare. The main symptoms are rectal bleeding, tenesmus and mucous discharge. The disease remains confined to the rectum in 90% of cases but proctitis may extend proximally. Colitis is almost always associated with bloody diarrhoea and urgency. Severe and/or extensive colitis may result in anaemia, hypoproteinaemia and electrolyte disturbances. Pain is unusual. Children with poorly controlled colitis may have impaired growth. The more extensive the disease the more likely extraintestinal manifestations are to occur. Extensive colitis is also associated with systemic illness, characterised by malaise, loss of appetite, and fever.

Classification of colitis severity

The assessment of severity of UC is determined by frequency of bowel action and the presence of systemic signs of illness:

- Mild disease is characterized by fewer than four stools daily, with or without bleeding. There are no systemic signs of toxicity.
- Moderate disease corresponds to more than four stools daily, but with few signs of systemic illness. There may be mild anaemia. Abdominal pain may occur. Inflammatory markers, including erythrocyte sedimentation rate and C-reactive protein, are often raised.
- Severe disease corresponds to more than six bloody stools a day and evidence of systemic illness, with fever, tachycardia, anaemia and raised inflammatory markers. Hypoalbuminaemia is common and an ominous finding.
- Fulminant disease is associated with more than 10 bowel movements daily, fever, tachycardia, continuous bleeding, anaemia, hypoalbuminaemia, abdominal tenderness and distension, the need for blood transfusion and, in the most severe cases, progressive colonic dilation ('toxic megacolon'). This is a very significant finding, suggestive of disintegrative colitis, and an indication for emergency surgery if colonic perforation is to be avoided.

Extraintestinal manifestations

Arthritis occurs in around 15% of patients and is typically a large joint polyarthropathy, affecting knees, ankles, elbows and wrists. Sacroiliitis and ankylosing spondylitis are 20 times more common in patients with UC than the general population and are associated with the HLA-B27 genotype. Sclerosing cholangitis is associated with UC and can progress to cirrhosis and hepatocellular failure. Patients with UC and sclerosing cholangitis are also at a significantly greater risk of development of large bowel cancer. Cholangiocarcinoma is an extremely rare association and its frequency is not influenced by colectomy. The skin lesions erythema nodosum and pyoderma gangrenosum are associated with UC and both normally resolve with good colitis control. The eyes can also be affected by uveitis and episcleritis.

Acute colitis

Approximately 5% of patients present with severe acute (fulminant) colitis. Intensive medical treatment leads to remission in 70% but the remainder require urgent surgery. Toxic dilatation should be suspected in patients who develop severe

abdominal pain and confirmed by the presence on a plain abdominal radiograph of a colon with a diameter of more than 6 cm (Figure 70.13). A reduction in stool frequency is not always a sign of improvement in patients with severe UC, and a falling stool frequency, abdominal distension and abdominal pain (resulting from progression of the inflammatory process through the colonic wall) are strongly suggestive of disintegrative colitis and impending perforation. Plain abdominal radiographs should be obtained daily in patients with severe colitis, and a progressive increase in colon diameter despite medical therapy is an indication for urgent surgery. Colonic perforation is a grave complication with a mortality rate of 40%. Steroids may mask the physical signs. Severe haemorrhage is uncommon (1–2%) but may occasionally require urgent surgical intervention.

Cancer risk in colitis

The risk of cancer in ulcerative colitis increases with duration of disease. At 10 years from diagnosis it is approximately 1%, increasing to 10–15% at 20 years and 20% at 30 years. Patients with pancolitis (defined as the presence of inflammation proximal to the splenic flexure) of more than ten years duration should be entered into screening programmes in order to detect clinically silent dysplasia, which is predictive of increased cancer risk. The value of screening programmes remains somewhat controversial, however, with most UC patients who develop cancer (approximately 3.5% of all patients) presenting with their tumours in-between attendances for screening colonoscopy. Carcinoma is more likely to occur if the whole colon is involved (Figure 70.14) or if the disease started early in life. Malignant change, often atypical and high grade, may occur at many sites at once. Colonoscopic surveillance with dye-spray (chromo-endoscopy) or multiple biopsies every 10 cm is undertaken to look for subtle mucosal abnormalities, which can occur in flat mucosa, or a DALM.

Investigations

ENDOSCOPY AND BIOPSY

Rigid/flexible sigmoidoscopy can detect proctitis in the clinic; the mucosa is hyperaemic and bleeds on touch, and there may be a purulent exudate. Where there has been remission and relapse, there may be regenerative mucosal nodules or pseudopolyps. Later, tiny ulcers may be seen that appear to coalesce. Colonoscopy and biopsy has a key role in diagnosis and management:

1 to establish the extent of inflammation, although colonoscopy is contraindicated in severe acute colitis because of the risk of colonic perforation;
2 to distinguish between UC and Crohn's colitis (although this can be exceptionally difficult, *Table 70.2*);
3 to monitor the response to treatment;
4 to assess longstanding cases for malignant change.

Figure 70.13 Fulminating ulcerative colitis with toxic dilatation of the transverse colon.

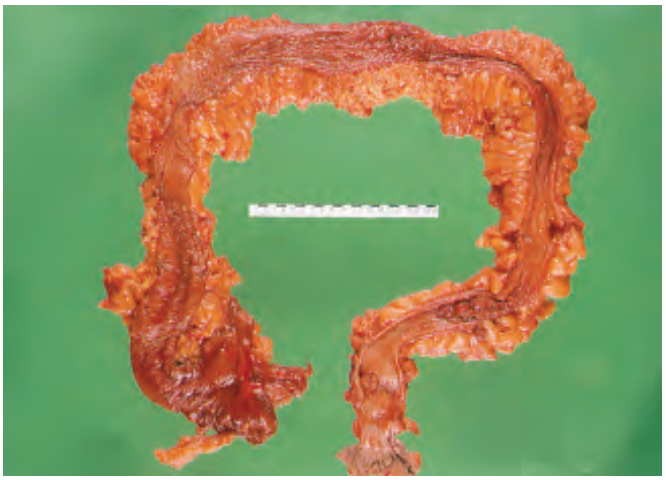

Figure 70.14 Resection specimen from a patient with long-standing ulcerative colitis showing a narrow tubular colon with areas of cancerous change in the rectum and sigmoid (courtesy of Dr B Warren, John Radcliffe Hospital, Oxford, UK).

RADIOLOGY

A plain abdominal film may indicate the severity of disease in the acute setting and is particularly valuable in demonstrating the development of toxic megacolon. Barium enema has largely been replaced by CT, although a contrast study will

TABLE 70.2 Distinguishing ulcerative colitis (UC) and Crohn's disease (CD).

	UC	CD
Macroscopic		
Distribution	Colon/rectum	Anywhere in the gastrointestinal tract
Rectum	Always involved	Often spared
Perianal disease	Rare	Common
Fistula formation	Rare	Common
Stricture	Rare	Common
Microscopic		
Layers involved	Mucosa/submucosa	Full thickness
Granulomas	No	Common
Fissuring	No	Common
Crypt abscesses	Common	Rare

show a featureless colon. CT findings in pancolitis may show significant thickening of the colonic wall, as well as inflammatory stranding in the colonic mesentery (Figure 70.15).

BACTERIOLOGY

A stool specimen should be sent for microbiological analysis when UC is suspected, in order to exclude infective colitides, notably *Campylobacter*, which may be very difficult to distinguish from acute severe UC. *Clostridium difficile* colitis may need to be considered in populations at risk of this disease (see below).

Treatment

Effective treatment of UC requires a multidisciplinary approach to management. This involves the gastroenterologist, nurses, nutritionist, enterostomal therapists and, occasionally, clinical psychologists and social workers as well as the surgeon.

Summary box 70.7

Principles of management of ulcerative colitis

- Many patients can be adequately maintained for years on medical therapy
- Toxic dilatation must be suspected in any colitic patient who develops severe abdominal pain; missed colonic perforation is associated with a high mortality
- Colitic patients are at increased risk of developing cancer; those with pancolitis of long duration are most at risk

MEDICAL TREATMENT

Medical therapy is based on anti-inflammatory agents. The 5-aminosalicylic acid (5-ASA) derivatives can be given topically (per rectum) or systemically. They act as inhibitors of the cyclo-oxygenase enzyme system and are formulated to protect the aspirin-related drug from degradation before reaching the colon. They can be used long term as maintenance therapy.

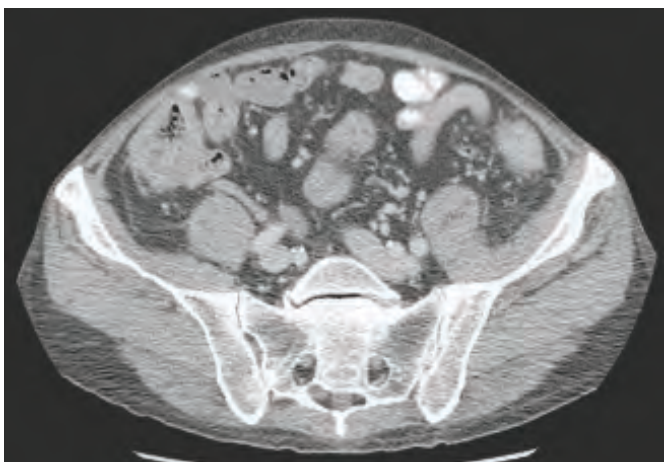

Figure 70.15 Computed tomography scan demonstrating colitis with thickened colonic wall and inflammatory stranding in the mesentery (courtesy of Dr D Kasir, Hope Hospital, Salford, UK).

Corticosteroids are the mainstay of treatment for 'flare-ups', either topically or systemically, and have a widespread anti-inflammatory action. The immunosuppressive drugs azathioprine and cyclosporin can be used to maintain remission and as 'steroid-sparing' agents. The monoclonal antibodies infliximab and adalimumab both act against antitumour necrosis factor alpha, which has a central role in inflammatory cascades. Most recently, vedolizumab, which blocks integrins, has been used as 'rescue therapy' for severe colitis, to try and avoid emergency colectomy.

ACUTE COLITIS

Patients with a mild attack usually respond to a course of oral prednisolone. A moderate attack often responds to oral prednisolone, twice-daily steroid enemas and 5-ASA. Failure to achieve remission as an outpatient is an indication for admission. Severe attacks of UC occur in up to 10% of patients and are emergencies, requiring hospital admission. Regular assessment of vital signs, weight and the abdomen is required. A stool chart should be kept and a plain abdominal radiograph is taken daily and inspected for dilatation of the transverse colon. The presence of mucosal islands or intramural gas on plain radiographs, increasing colonic diameter or a sudden increase in pulse and temperature may indicate a colonic perforation. Fluid and electrolyte balance is maintained, anaemia corrected and adequate nutrition is provided, sometimes intravenously in severe cases. The patient is treated with intravenous hydrocortisone four times daily, as well as rectal steroids. If there is failure to gain an improvement within 48 hours of commencing high-dose intravenous steroids, then surgery should be considered and it is certainly advisable if there has been no improvement within 3–5 days. Regular and joint review by gastroenterologist and surgeon is essential to identify patients who are failing to make anticipated progress and to ensure that surgery is neither inappropriately delayed nor undertaken. Gastroenterologists will use azathioprine, cyclosporin or infliximab in severe acute attacks to attempt to induce remission.

INDICATIONS FOR SURGERY

The greatest likelihood of a patient with UC requiring surgery is during the first year after diagnosis. The overall risk of colectomy is 20%. Indications for surgery in UC are:

- severe or fulminating disease failing to respond to medical therapy;
- chronic disease with anaemia, frequent stools, urgency and tenesmus;
- steroid-dependent disease – here, the disease is not severe but remission cannot be maintained without substantial doses of steroids;
- inability of the patient to tolerate medical therapy required to control the disease (steroid psychosis or other side effects, azathioprine-induced pancreatitis), such that remission cannot be maintained;
- neoplastic change: patients who have severe dysplasia or carcinoma on review colonoscopy;
- extraintestinal manifestations;
- rarely, severe haemorrhage or stenosis causing obstruction.

OPERATIVE TREATMENT FOR UC

Emergency In the emergency situation, (or for a patient who is malnourished or on steroids), the 'first aid' procedure is a subtotal colectomy and end ileostomy. The rectosigmoid stump is left long and can either be brought out as a mucous fistula or closed just beneath the skin. This operation has the advantages that the patient avoids a pelvic operation while unwell, that colonic histology can be assessed and restorative surgery can be contemplated at a later date when the patient is no longer on steroids and has fully recovered. The mesentery is divided close to the bowel and the omentum should be preserved if possible. Dissection of the left colon is continued to divide the sigmoid at a level that will comfortably reach the skin as a mucous fistula. The temptation to close the rectal stump and leave it stapled off in the pelvis should be avoided if at all possible. The diseased rectum may disintegrate, causing a pelvic abscess and severe sepsis, with potentially fatal consequences. Allowing the rectal remnant to discharge through the mucous fistula not only minimises the risk of this serious complication but may also allow the delivery of a high-dose topical steroid or 5-ASA compound, via the mucous fistula, into the isolated rectum. An emergency subtotal colectomy can be performed laparoscopically, provided the surgeon and theatre team has adequate experience.

Elective surgery The indications for elective surgery include:

1. failure of medical therapy/steroid dependence;
2. growth retardation in the young;
3. extraintestinal disease (polyarthropathy and pyoderma gangrenosum respond to colectomy);
4. malignant change.

In the elective setting four operations are available – all of these can be successfully performed laparoscopically in experienced hands:

1. subtotal colectomy and ileostomy (as in an emergency);
2. proctocolectomy and permanent end ileostomy;
3. restorative proctocolectomy with ileoanal pouch;
4. subtotal colectomy and ileorectal anastomosis.

Segmental resections are not recommended as even when the right side is not obviously involved there is a high recurrence rate in the remaining colon. Subtotal colectomy with ileostomy is performed electively for a frail patient, a patient who cannot be weaned from steroids and when there is doubt as to whether the colitis may represent CD. A pouch, a completion proctectomy and even an ileorectal anastomosis can be considered at a future date.

Proctocolectomy and ileostomy This operation removes all the colon and rectum, removing any risk of colorectal neoplasia or colitic symptoms, but it leaves a permanent stoma. It has a lower complication rate compared with a pouch procedure, although the perineal wound can be problematic (10% fail to heal) and stoma problems are common. It is indicated for patients who are not candidates for restorative surgery due to sphincter problems or patient preference. The colectomy is performed as above. Provided there is no concern regarding rectal cancer, a close rectal dissection may be performed to minimise damage to the pelvic nerves, avoiding erectile and bladder dysfunction. An intersphincteric excision of the anus is undertaken, which results in a smaller perineal wound and fewer healing problems. A permanent end ileostomy is formed. The position of the ileostomy should be carefully chosen by the patient with the help of a stoma care nurse specialist.

Restorative proctocolectomy with an ileoanal pouch (Parks) In this operation, a pouch is made out of ileum (Figure 70.16) as a substitute for the rectum and sewn or stapled to the anal canal. This avoids a permanent stoma. It is reserved for patients with adequate anal sphincters and

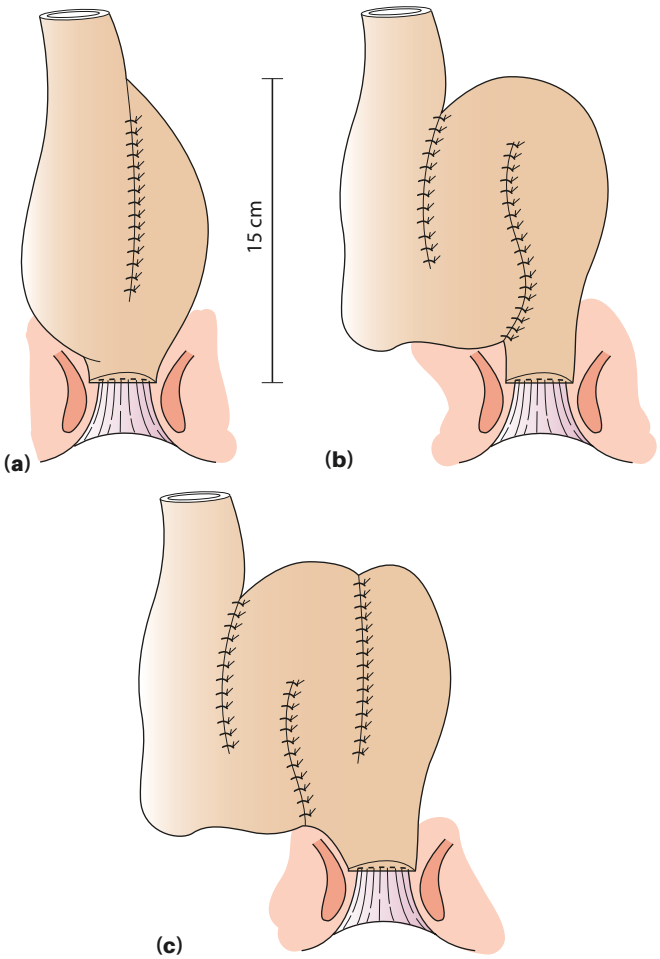

Figure 70.16 Ileoanal anastomosis with pouch. A substitute rectum is made from joined folds of ileum to form an expanded pouch of small intestine. The pouch is then joined directly to the anus at the level of the dentate line, all other rectal mucosa having been removed. Three ways of forming a pouch are illustrated: **(a)** a simple reversed 'J'; **(b)** an 'S' pouch; **(c)** a 'W' pouch.

Sir Alan Guyatt Parks, 1920–1982, surgeon, St Mark's Hospital and the London Hospital, London, UK, former President of the Royal College of Surgeons of England.

should be avoided if CD is a possibility. Various pouch designs have been described, but the 'J' is the most popular and the most easily made using staplers (Figure 70.17). There is some controversy over the correct technique for ileoanal anastomosis. In the earliest operations, the mucosa from the dentate line up to mid-rectum was stripped off the underlying muscle, but it is now known that a long muscle cuff is not needed. Although mucosectomy of the upper anal canal with an anastomosis at the dentate line is claimed to remove all of the at-risk mucosa and any problem of subsequent cancer, it may also increase the risk of incontinence with nocturnal seepage. The alternative is an anastomosis double-stapled to the top of the anal canal, preserving the upper anal mucosa. Continence appears to be better, but there is a theoretical risk of leaving inflamed mucosa behind. The procedure can be carried out in stages and a covering loop ileostomy is virtually always used.

Complications include pelvic infection (usually resulting from a leak at the ileoanal anastomosis or, in a J pouch, from the top of the 'J'), postoperative small bowel obstruction (which may occur in as many as 10–15% of patients) and pouch vaginal fistula. Frequency of evacuation is determined by pouch volume, completeness of emptying, reservoir inflammation and intrinsic small bowel motility, but is typically between three and eight evacuations in each 24-hour period. Increased frequency, urgency and faecal incontinence are common (20%, 5% and 5%, respectively), but usually reduce with time. Approximately 50% of patients with ileoanal pouches have a very good quality of life, whereas 35% of patients are less satisfied but choose to retain their pouches. Pouch function is so poor in 15% that the pouch is removed. The main reasons for failure are pelvic infection (50%), poor function (30%) and pouchitis or inflammation of the pouch (10%). It is also important for women of reproductive age to be advised that they may suffer from reduced fertility, as well as vaginal dryness, due to denervation of the secretory glands of the vaginal mucosa. Women who have not completed their families may elect for a colectomy with ileostomy and a pouch later.

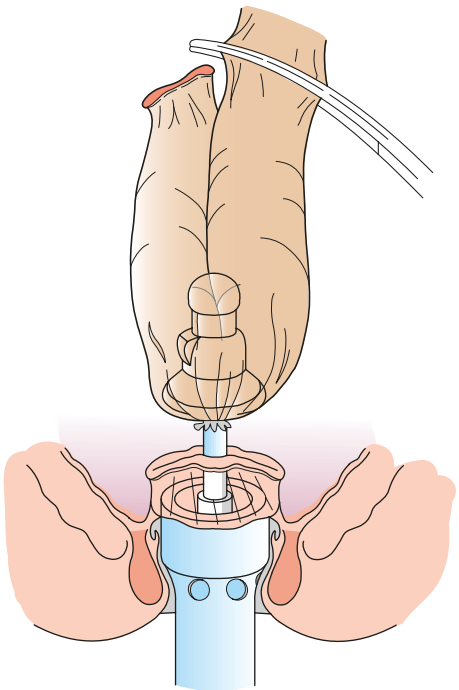

Figure 70.17 Stapled 'J' pouch with stapler creating a pouch–anus anastomosis.

Pouchitis describes an inflammatory condition, which may affect 30% of patients with an ileoanal pouch for colitis. It is characterised not only by the presence of inflammation in the pouch (which is common and frequently asymptomatic) but also by symptoms of pouch dysfunction (increased frequency, tenesmus, bleeding, purulent discharge) and systemic illness (malaise, fever, raised inflammatory markers). The cause of pouchitis is unknown but it appears to relate to inflammatory bowel disease (pouchitis does not usually occur in pouches created for other indications). Alterations in bacteria flora may be relevant as pouchitis usually responds to a short course of antibiotic therapy, notably with metronidazole or ciprofloxacin and can be followed by maintenance with probiotics.

Colectomy and ileorectal anastomosis This procedure is occasionally performed in UC if there is minimal rectal inflammation. A very considerable percentage (at least 50%) of patients with a quiescent rectum after total colectomy will develop significant mucosal inflammation in the rectum once the faecal stream has been re-established. Although rectal inflammation can be controlled with medical treatment, functional results may be disappointing. If the rectum is preserved, then annual rectal inspection is advocated. Although this procedure has the advantage of avoiding a stoma and the risk to sexual function associated with rectal dissection, it has largely fallen out of favour due to the ongoing risk of persisting inflammation and malignancy in the retained rectum.

Indeterminate colitis

Ten percent of patients with colitis present with histological features that make their disease difficult to characterise. Such patients may be said to have an 'indeterminate colitis'. Indeterminate colitis is, therefore, an indication by a pathologist that the nature of the underlying colitis (and therefore the likely course of the illness) is unclear. While the clinical history may suggest the diagnosis in some cases (for example, a history of recurrent perianal sepsis and fistulation would make a diagnosis of CD more likely), in others it may remain unclear whether a patient has UC or CD. In such cases, it may still be appropriate to offer a pouch after detailed informed consent, but the risks of pouch failure appear to be significantly higher (up to 25–30%) and patients should be advised accordingly.

Crohn's disease of the colon

CD affecting the small bowel is discussed in Chapter 69. Colonic involvement is found in 30% of patients with CD, frequently in association with perianal disease and it may coexist with small bowel pathology. Colonic CD presents

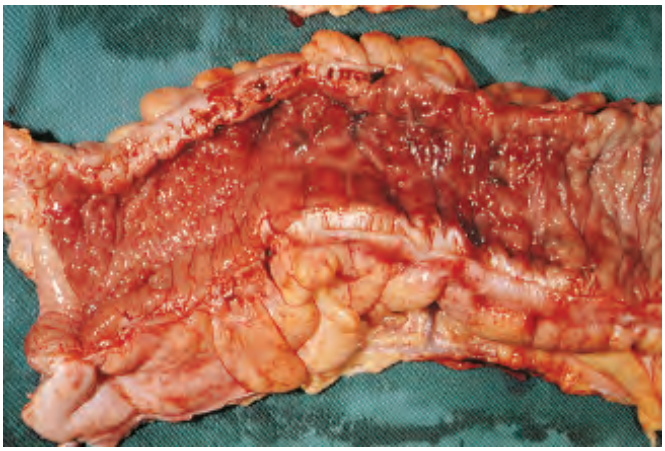

Figure 70.18 Colonic Crohn's disease. Note the normal mucosa on either side of the inflammatory stricture (courtesy of Dr B Warren, John Radcliffe Hospital, Oxford, UK).

with symptoms of colitis and proctitis as described for UC, although toxic megacolon is much less common (**Figure 70.18**). Colonic strictures may form just as are seen in small bowel CD. Endoscopic dilatation may be performed in expert hands as an alternative to surgical resection. Distinguishing between CD and UC is often difficult and requires clinical and pathological patterns to be combined. The presence of skip lesions, rectal sparing, non-caseating granulomas or perianal disease will point to CD.

Colonoscopic examination may be normal or show patchy inflammation. There will be areas of normal colon or rectum in between areas of inflamed mucosa that are irregular and ulcerated, with a mucopurulent exudate. The earliest appearances are aphthous ulcers surrounded by a rim of erythematous mucosa. These become larger and deeper with increasing severity of disease. There may be stricturing, and it is important to exclude malignancy in these sites. An irregular Crohn's stricture with polypoid mucosa may be almost indistinguishable from malignancy.

Treatment

There is great overlap in the treatment of Crohn's colitis and UC. Disease activity can be controlled with 5-ASA compounds and flare-ups treated with steroids. Rectal agents can be particularly effective if the disease activity is localised to the rectum. Immunomodulatory agents are frequently used, particularly if there is evidence of CD activity in large and small bowel.

Although CD is usually regarded as a contraindication to pouch surgery, the other options (panproctocolectomy or total colectomy with ileorectal anastomosis) are frequently appropriate and there may be considerable rectal sparing in CD, justifying the latter. Where the diagnosis of CD is firmly established, segmental rather than total colectomy may be appropriate.

INFECTIONS OF THE LARGE INTESTINE

Campylobacter

Infection with *Campylobacter jejuni* (a gram-negative rod with a distinctive spiral shape) is the commonest form of gastroenteritis in the UK, typically acquired from eating infected poultry. It causes diarrhoea and abdominal pain. Severe cases may resemble UC. The organism may take several days to isolate on stool culture. Treatment is supportive as it usually resolves without antibiotics, but severe colitis and even perforation may occur. It is a notifiable disease.

Intestinal amoebiasis

Entamoeba histolytica has a worldwide distribution and is transmitted mainly in contaminated drinking water. It can cause colonic ulcers, which are described as 'bottlenecked' because they have considerably undermined edges. The ulcers typically also have a yellow necrotic floor, from which blood and pus exude. In the majority of cases they are confined to the distal sigmoid colon and the rectum. Clinically amoebiasis can mimic UC, most commonly causing bloody diarrhoea, but more severe colonic complications can occur, including severe haemorrhage, stricture formation or perforation. A pericolitis is not uncommon and results in adhesions and may cause intestinal obstruction. Amoebiasis may cause liver abscesses or an amoebic mass ('amoeboma') of the caecum or sigmoid which is difficult to distinguish from a carcinoma. Surgery is fraught with danger as the bowel is extremely friable.

Endoscopic biopsies or fresh hot stools are examined to look for the presence of amoebae (**Figure 70.19**). It is important to emphasise, however, that the presence of the parasite does not indicate that it is pathogenic. It is especially important to exclude amoebic infection in patients suspected of having UC. Treatment is by metronidazole in the acute setting,

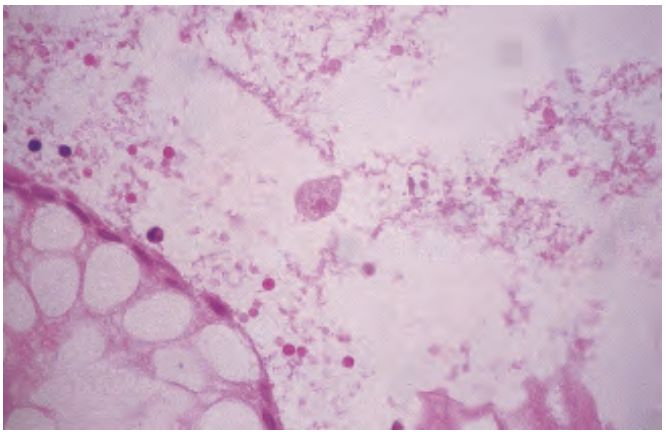

Figure 70.19 An amoeba in a rectal biopsy.

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, along with Leon Ginzburg and Gordon Oppenheimer described regional ileitis in 1932.

three times daily for 7–10 days. Diloxanide furoate is effective against chronic infections associated with the passage of cysts in stools.

Salmonellosis, typhoid and paratyphoid

Salmonella are a family of gram-negative rods that can cause a range of enteric infections. Salmonella gastroenteritis is typically caused by *S. enteritidis* from poultry, and is most often a self-limiting illness comprising headache, fever and watery diarrhoea. When severe, antibiotics and indeed hospitalisation and intravenous fluids may be needed. The diagnosis is based on stool culture. *Shigella* and enteropathogenic strains of *E. coli* may cause similar diarrhoeal illnesses.

Typhoid fever is caused by *S. typhi* and presents with fever and abdominal pain after a 10–20-day incubation period. Over the next week, the patient can develop distension, diarrhoea, splenomegaly and characteristic 'rose spots' on the abdomen caused by a vasculitis. A number of surgical complications can result:

- paralytic ileus;
- intestinal haemorrhage;
- perforation;
- cholecystitis.

In addition, invasion of the systemic circulation, which is a characteristic feature of salmonellosis, may cause severe gram-negative sepsis and septic shock may develop. Some patients may develop metastatic sepsis, including septic arthritis and osteomyelitis, meningitis, encephalitis and pancreatitis.

Human immunodeficiency virus (HIV)

Intestinal complications are common after the development of AIDS when opportunistic organisms can cause gastroenteritis (*Summary box 70.8*). HIV1 may also cause a specific enteropathy. Treatment is directed towards the responsible organism and surgery should be avoided.

Clostridium difficile

Clostridium difficile is a toxin-producing gram-positive bacillus that is an increasing concern in many hospitals. Although normally present in around 2% of the population, it proliferates after antibiotic treatment (especially cephalosporins). Clinically, *C. difficile* infection presents with diarrhoea, abdominal pain and fever. Infection may progress to pseudomembranous colitis, so called because on visualisation of the bowel, plaques of inflammatory exudate between oedematous mucosa are seen. Diagnosis is usually made by detection of the toxin in stool samples, rather than by culture. Treatment is by metronidazole or vancomycin alongside supportive care.

Summary box 70.8

Opportunistic intestinal infections in patients with AIDS

- Bacteria
  - Salmonella
  - Shigella
  - Yersinia
  - Campylobacter
  - *Mycobacterium avium intracellulare* (MAI)
- Viral
  - Cytomegalovirus
- Protozoa
  - Cryptosporidium
  - Giardia
- Fungal
  - *Candida albicans*

If the colitis does not settle, an emergency subtotal colectomy and ileostomy may be necessary.

Colonic diverticula

Diverticula (hollow out-pouchings) are a common structural abnormality. They can be classified as:

1. Congenital. All three coats of the bowel are present in the wall of the diverticulum (e.g. Meckel's diverticulum).
2. Acquired. There is no muscularis layer present in the diverticulum (e.g. sigmoid diverticular disease).

Diverticula are found in the left colon in around 75% of over 70 year olds in the Western world. The condition is overwhelmingly found in the sigmoid but can affect the whole colon. Interestingly, in South-East Asia right-sided diverticular disease is more common. Diverticula are most often asymptomatic (diverticulosis) and found incidentally, but they can present clinically with sepsis or haemorrhage.

Aetiology

Epidemiological studies indicate that diverticular disease is a consequence of a refined Western diet, deficient in dietary fibre. The combination of altered collagen structure with ageing, disordered motility and increased intraluminal pressure, most notably in the narrow sigmoid colon, results in herniation of mucosa through the circular muscle at the points where blood vessels penetrate the bowel wall. The rectum has a complete muscular coat and a wider lumen and is thus very rarely affected. Diverticular disease is rare in Africa and Asia where the diet is high in natural fibre.

Complications of diverticular disease

The majority of patients with diverticula are asymptomatic but historical studies suggest that somewhere between 10 and 30% will have symptomatic complications (*Summary box 70.9*). These complications are:

Johann Friedrich Meckel (the younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany, described the diverticulum in 1809.

1 Pain and inflammation (diverticulitis).
2 Perforation: most often contained leading to pericolic abscess formation but occasionally leading to generalised peritonitis.
3 Intestinal obstruction: progressive fibrosis can cause stenosis of the sigmoid and large bowel obstruction or loops of small intestine can adhere to an inflamed sigmoid, resulting in small bowel obstruction.
4 Haemorrhage: diverticular disease may present with profuse and recurrent) colonic haemorrhage due to erosion of vessels adjacent to a diverticulum.
5 Fistula formation (colovesical, colovaginal, enterocolic, colocutaneous): occurs in 5% of cases, colovesical fistulation is most commonly seen.

Summary box 70.9

Complications of diverticular disease

- Diverticulitis
- Abscess
- Peritonitis
- Intestinal obstruction
- Haemorrhage
- Fistula formation

Clinical features

In mild cases, symptoms such as distension, flatulence and a sensation of heaviness in the lower abdomen may be indistinguishable from those of irritable bowel syndrome. These symptoms are thought to result from a combination of increased luminal pressure affecting wall tension and increased visceral hypersensitivity. Surgical treatment is rarely, if ever appropriate for diverticular disease in the absence of complications.

Diverticulitis typically presents as persistent lower abdominal pain, usually in the left iliac fossa. There may be accompanying diarrhoea or constipation. The lower abdomen is tender, especially on the left, but occasionally also in the right iliac fossa if the sigmoid loop lies across the midline. The sigmoid colon may be tender and thickened on palpation and rectal examination may reveal a tender mass if an abscess has formed. Distinguishing between diverticulitis and abscess formation is difficult on clinical grounds alone and radiological imaging is essential. Generalised peritonitis as a result of free perforation presents in the typical manner with systemic upset and generalised tenderness and guarding.

Haemorrhage from colonic diverticula is typically painless and profuse. Bleeding from the sigmoid will be bright red with clots, whereas right-sided bleeding will be darker. Torrential bleeding is fortunately rare and, in fact, more commonly due to angiodysplasia, but diverticular bleeding may persist or recur requiring transfusion and resection. The presentation of a fistula resulting from diverticular disease depends on the site. The most common colovesical fistula results in recurrent urinary tract infections and pneumaturia (flatus in the urine) or even faeces in the urine. Colovaginal fistulae are more common after hysterectomy. Colocutaneous fistulation is rare in the absence of prior intervention (e.g. radiological drainage). Rarely, diverticular disease may perforate into the retroperitoneum, leading to a psoas abscess, and even groin fistulation.

Classification of contamination

The degree of infection has a major impact on outcome in acute diverticulitis. Patients with inflammatory masses have a lower mortality than those with perforation (3% versus. 33%). Classification systems have been developed for acute diverticulitis to try and rationalise the literature, the most commonly used being the Hinchey classification (*Table 70.3*).

Radiology

Plain radiographs can demonstrate a pneumoperitoneum. Spiral CT has excellent sensitivity and specificity for identifying bowel wall thickening, abscess formation and extraluminal disease and has revolutionised the assessment of complicated diverticular disease (**Figure 70.20**). On identification of abscesses in stable patients, drainage may be carried out percutaneously, avoiding the need for laparotomy/laparoscopy. Contrast studies and endoscopy are usually avoided for 6 weeks after an acute attack for fear of causing perforation. They are used subsequently, however, to exclude a coexisting carcinoma and assess the extent of diverticular disease. Contrast examination or CT can demonstrate a fistula.

Colonoscopy

Endoscopic assessment may demonstrate the necks of diverticula within the bowel lumen (**Figure 70.21**). A narrowed

TABLE 70.3 Hinchey classification of complicated diverticulitis.

Grade I	Mesenteric or pericolic abscess
Grade II	Pelvic abscess
Grade III	Purulent peritonitis
Grade IV	Faecal peritonitis

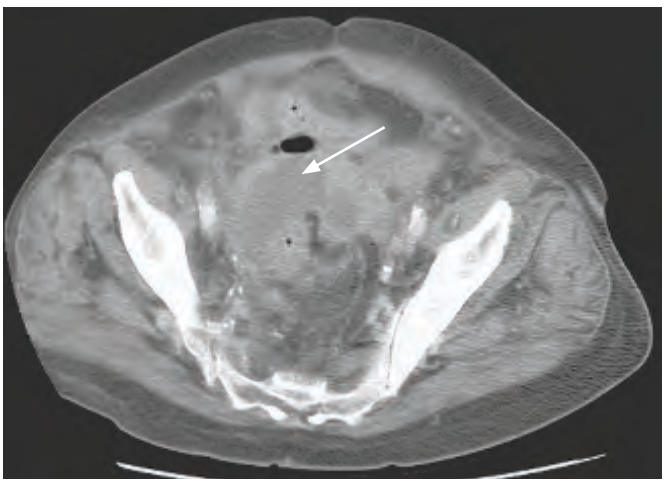

Figure 70.20 Computed tomography scan demonstrating an abscess associated with diverticulitis (arrow) (courtesy of Dr D Kasir, Hope Hospital, Salford, UK)

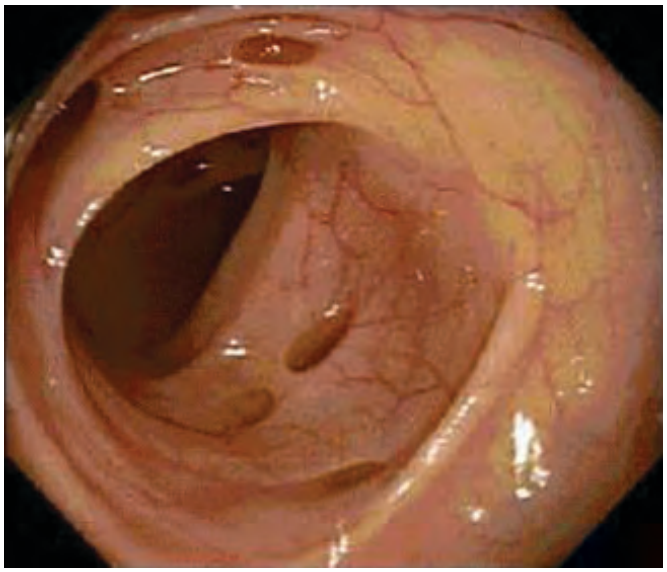

Figure 70.21 Colonoscopic view of sigmoid diverticula. Note the mouths of diverticula between the hypertrophied colonic walls.

area of diverticular disease may be impassable because of the severity of disease and there is a significant risk of endoscopic perforation. Colonoscopy in these circumstances requires judgement and experience. Biopsies may be taken if possible and corroboration with barium enema or CT virtual colonoscopy is required. Excluding a carcinoma may not always be possible and may represent an indication for resection.

Management

Patients are frequently recommended to take a high-fibre diet and bulk-forming laxatives, although the evidence for their effectiveness in diverticulosis or after an attack of diverticulitis is limited. Antispasmodics may have a role if recurrent pain is a problem. Acute diverticulitis is treated by intravenous antibiotics (to cover gram-negative bacilli and anaerobes) alongside appropriate resuscitation and analgesia. Nil by mouth to 'rest the bowel' and catheterisation to reduce the risk of colovesical fistulation are often advocated, but there is little evidence to support these practices. A CT scan can confirm the diagnosis and assess for complications. After the acute attack has subsided the bowel should be investigated by endoscopy, barium enema or CT virtual colonoscopy. Some pericolic abscesses can be drained percutaneously. A diameter of 5 cm is frequently regarded as the cut off between an abscess likely to settle with antibiotics and one likely to require intervention.

Operative procedures for diverticular disease

The aim of emergency surgery is to control peritoneal infection; indications are generalised peritonitis and failure to respond to optimum medical management. Laparotomy for diverticular disease in the acute setting has considerable risk with mortality in most series of 15% and, in the case of faecal peritonitis, mortality approaches 50%. Alongside operative technique, resuscitation, anaesthesia and postoperative management should be optimised.

Laparotomy and thorough washout of contamination are performed and then a choice has to be made between a Hartmann's procedure (sigmoid resection with formation of left iliac fossa colostomy and closure of the rectal stump) and resection with colonic washout and anastomosis (with consideration of a defunctioning loop ileostomy). Primary anastomosis should be used selectively but is appealing in a young fit patient without gross contamination or overwhelming sepsis. However, this is a relatively rare scenario and the majority of emergency operations for perforated diverticular disease are Hartmann's procedures (**Figure 70.22**). There is good evidence that simple defunctioning with a proximal stoma is associated with higher mortality than a resection. There may be a role for emergency laparoscopy in diverticular disease with washout if there is no faecal contamination (i.e. Hinchey grade III or less), allowing sigmoid resection to be avoided, but this remains somewhat controversial as some trials have suggested a higher mortality.

Elective surgery is usually undertaken for management of complications. Diverticular fistulae can only be cured by resecting the affected bowel, although a defunctioning stoma can ameliorate symptoms. In colovesical fistula the sigmoid can often be pinched off the bladder and the sigmoid resected. If an anastomosis is performed, it is wise to place an omental pedicle between the bowel and bladder to prevent recurrent

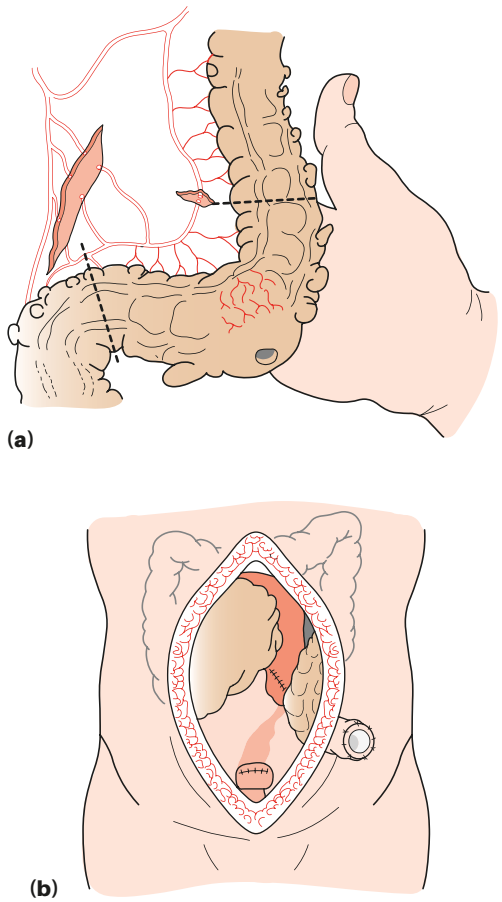

Figure 70.22 **(a)** Perforated sigmoid diverticular disease. **(b)** The Hartmann procedure – oversewn rectal stump and left iliac fossa colostomy.

fistulation. These procedures can be technically challenging and ureteric stents are commonly required to reduce the risk of ureteric injury. Partial cystectomy may be required and assistance from a urological surgeon is often very helpful

Haemorrhage from diverticular disease should be distinguished from angiodysplasia. It usually responds to conservative management and only occasionally requires resection. Where available, angiography is helpful to localise bleeding points. On-table lavage and colonoscopy may be necessary to localise the bleeding site. If the source cannot be located, then subtotal colectomy and ileostomy may be the safest option.

Indications for surgery in an elective setting, in the absence of complications of the disease, are controversial. There are undoubtedly a small number of patients with recurrent attacks who should be offered an elective sigmoid colectomy (with anastomosis). This could be performed laparoscopically in experienced hands with a likely swifter recovery as well as improved cosmesis. Cohort studies suggest that in patients under 50 years old admitted with diverticulitis, 25% will have a further episode. This may be used as an argument for offering elective resection but equally suggests that 75% will not get another severe attack. Many surgeons would discuss the pros and cons of elective surgery after two emergency admissions, although general health must be carefully considered. There has been an increasing tendency, in recent years, to treat even patients with recurrent attacks of diverticulitis conservatively in the absence of complications.

Summary box 70.10

Principles of surgical management of diverticular disease

- Hartmann's procedure is the safest option in emergency surgery
- Primary anastomosis can be considered in selected patients
- Elective resection may be offered for recurrent attacks
- Definitive treatment of colovesical fistula will require resection

VASCULAR ANOMALIES OF THE INTESTINE

Angiodysplasia

Angiodysplasia is a vascular malformation that commonly causes haemorrhage from the colon in patients over the age of 60. The malformations consist of dilated tortuous submucosal veins.

Clinical features

In the majority of cases, the symptoms are subtle and patients can present with anaemia. About 10–15% have brisk bleeds, which may present as melaena or significant rectal bleeding. Many patients in whom rectal bleeding has been attributed to diverticular disease have probably bled from angiodysplasia. There is an association with aortic stenosis (Heyde's syndrome).

Investigation

Colonoscopy may show the characteristic lesion in the right colon. The lesions are only a few millimetres in size and appear as reddish, raised areas at endoscopy. Selective superior and inferior mesenteric angiography shows the site and extent of the lesion by a 'blush' of contrast, provided bleeding is above 1 mL/minute. If this fails, a technetium-99m (99mTc)-labelled red cell scan may confirm and localise the source of haemorrhage.

Treatment

The first principle is to stabilise the patient. Following this, the bleeding needs to be localised. Colonoscopy may allow cauterisation to be carried out and an argon laser can be helpful. In severe uncontrolled bleeding, surgery becomes necessary. On-table colonoscopy is carried out to confirm the site of bleeding. Angiodysplastic lesions are sometimes demonstrated by transillumination through the caecum (**Figure 70.23**). If it is still not clear exactly which segment of the colon is involved, then a subtotal colectomy may be necessary.

Ischaemic colitis

Ischaemia of the colon typically results from thrombosis or embolism. Sudden embolic events present with severe pain out of proportion to the degree of peritonism, bloody diarrhoea, haemodynamic instability and shock. Resuscitation and laparotomy are required with resection of gangrenous

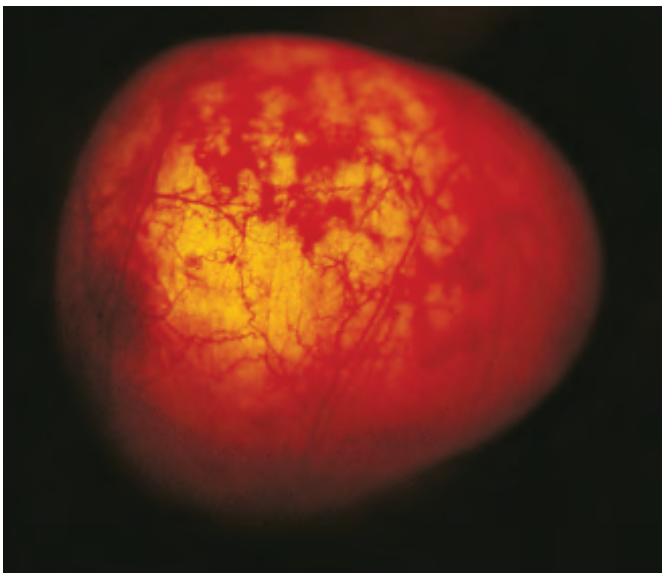

Figure 70.23 Angiodysplasia of the caecum demonstrated by transillumination with a colonoscope intraoperatively.

Edward Heyde, American internist, published his findings on the association between aortic valve stenosis and angiodysplasia in a letter to the *New England Journal of Medicine* in 1958.

bowel and exteriorisation of viable bowel ends. Mortality is extremely high. Thrombotic occlusion usually occurs in the context of global atherosclerosis and the presentation tends to be less dramatic with abdominal pain and rectal bleeding. A plain abdominal radiograph may show 'thumb-printing' and endoscopy may demonstrate haemorrhagic oedema. The left colon and, in particular, the splenic flexure are usually the worst affected. Symptoms usually settle spontaneously. In some cases, ulceration at the splenic flexure associated with ischaemic colitis may heal with stricturing and present with subsequent large bowel obstruction.

COLOSTOMIES

A colostomy (or ileostomy) stoma is a planned opening made in the colon (or small intestine) to divert faeces and flatus to the abdominal wall where they can be collected in an external appliance. Depending on the purpose for which the diversion has been necessary, a stoma may be temporary or permanent.

Loop colostomy

A transverse loop colostomy has in the past been used to defunction an anastomosis after an anterior resection. It is now less commonly employed, as it is difficult to manage and potentially disrupts the marginal arterial supply to the anastomosis. Loop transverse colostomies are also particularly prone to prolapse. A loop ileostomy is now more commonly used.

A loop left iliac fossa colostomy is still sometimes used to prevent faecal peritonitis developing following traumatic injury to the rectum, to facilitate the operative treatment of a high anal fistula, for incontinence and to defunction an obstructing low rectal cancer prior to long course chemoradiotherapy.

A temporary loop colostomy is made by bringing a mobilised loop of colon to the surface, where it is held in place by a plastic bridge passed through a mesenteric window. Once the abdomen has been closed, the colostomy is opened, and the edges of the colonic incision are sutured to the adjacent skin margin (Figure 70.24). When firm adhesion of the colostomy to the abdominal wall has taken place, the bridge can be removed.

Following healing of the distal lesion for which the temporary stoma was constructed, the colostomy can be closed. It is usual to perform a contrast examination (proctogram) to check that there is no distal obstruction or continuing problem at the site of previous surgery. Colostomy closure is most easily and safely accomplished if the stoma is mature, typically after the colostomy has been established for at least 2 months. Closure is usually possible with a circumstomal incision, which avoids a full laparotomy, but it is important for patient and surgeon to consider the risks of closure carefully as it does involve a bowel anastomosis. In some cases, a full laparotomy may be required for safe closure of the stoma.

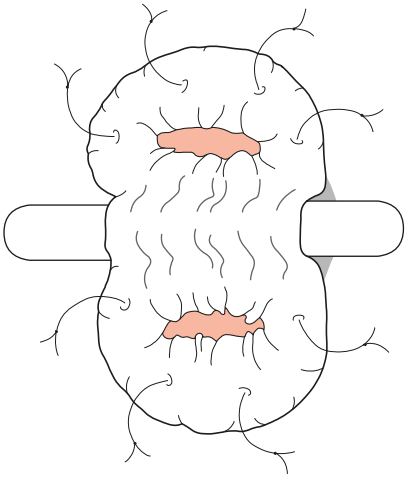

Figure 70.24 Temporary (loop) colostomy opened over a rod, and immediate suture of the colon wall to surrounding skin (alternatively, a skin bridge is used).

End colostomy

This is formed after an abdominoperineal excision of the rectum or as part of a Hartmann's procedure, bringing the divided colon through a left iliac fossa trephine in rectus abdominis and skin. The colonic margin is then sutured to the adjoining skin.

The point at which the colon is brought to the surface must be carefully selected to allow a colostomy bag to be applied without impinging on the anterior-superior iliac spine. The best site is usually through the lateral edge of the rectus sheath (Figure 70.25).

Stoma bags and appliances

Stoma output is collected in disposable adhesive bags. Colostomy appliances are simply changed two or three times each day. A wide range of such bags is currently available. In most hospitals, a stoma care service is available to offer advice to patients, to acquaint them with the latest appliances and to provide the appropriate psychological and practical help.

Summary box 70.11

Stomas

- May be colostomy or ileostomy
- May be temporary or permanent
- Temporary or defunctioning stomas are usually fashioned as loop stomas
- An ileostomy is spouted; a colostomy is flush
- Ileostomy effluent is usually liquid whereas colostomy effluent is usually solid
- Ileostomy patients are more likely to develop fluid and electrolyte problems
- An ileostomy is usually sited in the right iliac fossa
- End-colostomy is usually sited in the left iliac fossa
- Whenever possible patients should be counselled and sited by a stoma care nurse before operation

Figure 70.25 A colostomy in the left iliac fossa.

Complications of stomas

Stoma complications are underestimated and common (*Summary box 70.12*). On occasion these complications may require surgical treatment. Sometimes, this can be achieved with an incision immediately around the stoma but on occasion reopening the abdomen and freeing up the stoma may be necessary. Repair of parastomal hernias is particularly technically challenging and the recurrence rate is high. Simple suture is associated with an almost 100% risk of recurrence and transfer to the opposite side of the abdomen, or insertion of a piece of prosthetic material within the abdominal wall around the stoma may be necessary. There is some evidence that stoma trephine reinforcement with mesh at the time of initial stoma formation may reduce the incidence of parastomal herniation, which may be as high as 50% over the long term.

Summary box 70.12

Stoma complications

- Skin irritation
- Prolapse
- Retraction
- Ischaemia
- Stenosis
- Parastomal hernia
- Bleeding
- Fistulation

FUNCTIONAL ABNORMALITIES

Constipation

There is no single definition of constipation; however, a bowel frequency of less than one every 3 days is commonly considered to be abnormal. Constipation is an extremely prevalent complaint in western society and some patients are greatly disabled by abdominal pain, distension, reliance on laxatives and difficulty with defaecation.

Drugs and a range of illnesses can result in constipation (*Summary boxes 70.13*, *70.14*). Altering medication or addition of laxatives can be helpful for drug-related constipation and correction of underlying illness is clearly ideal where possible.

Summary box 70.13

Drugs that can cause constipation

- Benzodiazepines
- Carbamazepine
- Chlorpromazine
- Cholestyramine
- Iron
- Opiates, particularly codeine and morphine
- Tricyclic antidepressants
- Statins

Summary box 70.14

Illnesses associated with constipation

- Neurological conditions
- Parkinson's disease
- Multiple sclerosis
- Diabetic nephropathy
- Spinal cord lesion
- Endocrine conditions
- Hypothyroidism
- Hypercalcaemia

There remains a group of patients with constipation who do not have any structural, pharmacological or other pathology to explain their symptoms. Some will have obstructed defaecation (a syndrome of impaired rectal emptying associated with pelvic floor dysfunction). Others will have slow colonic transit, a disorder usually seen in women, which may have been present since childhood or may suddenly follow abdominal or pelvic surgery. Some patients have a combination of both conditions.

Investigation

It is important to exclude a structural abnormality (notably large bowel obstruction) by conventional investigation (colonoscopy, CT virtual colonoscopy or barium enema) before diagnosing a functional bowel disorder.

Whole-gut transit time can be measured by asking the patient to stop all laxatives and take a capsule containing radiopaque markers (**Figure 70.26**). Retention of more than 80% of the shapes, 120 hours after ingestion, is abnormal.

Defaecating proctography may demonstrate impaired pelvic floor relaxation, rectal intussusception and/or rectocoele if they are causing obstructed defaecation. Anorectal manometry may confirm an abnormal pattern of straining in patients with obstructed defaecation, with failure to reduce (or even inappropriately increase) anal canal pressures on bearing down.

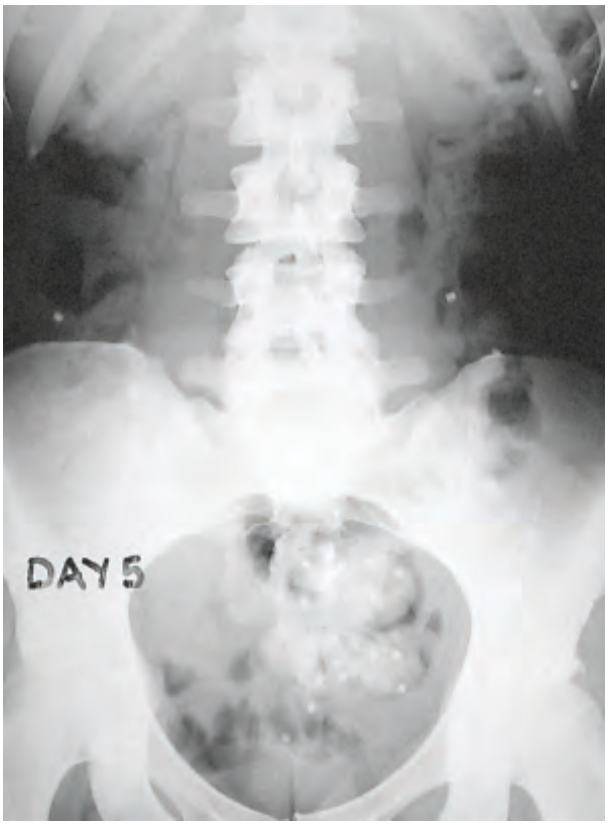

Figure 70.26 Whole-gut transit studied using radiopaque markers. More than 80% should have passed by day 5, demonstrating delayed transit here (courtesy of Dr D Nolan, John Radcliffe Hospital, Oxford, UK).

Treatment of slow colonic transit and obstructed defaecation

Dietary fibre This is the first-line treatment for mild constipation. Constipation only resolves after several weeks of therapy, which usually needs to be continued in the long term.

Laxatives It is important that patients do not fall into a cycle of laxative abuse. A number of types are available including bulk, osmotic and stimulant agents.

New agents Newer agents such as prucalopride, which selectively activates serotonin (5HT-4) receptors, may have a role in chronic constipation.

Rectal irrigation Rectal irrigation may improve quality of life in some patients, who can be trained to do this for themselves using commercially available kits.

Biofeedback This involves training in pelvic floor function. It has been shown to be effective in up to 50% of patients with obstructed defaecation.

Sacral nerve stimulation Although primarily used for the treatment of faecal incontinence, sacral neuromodulation has recently been suggested to be of value in the treatment of obstructed defaecation.

Surgery The results of surgery are relatively poor. Surgery is justified only after careful evaluation and when appropriate medical options have been exhausted. Total colectomy and ileorectal anastomosis is the preferred procedure for slow transit constipation but the results are unpredictable.

Complications include intermittent small bowel obstruction (60%), further surgery (30%), constipation (25%), diarrhoea (25%) and incontinence (10%). Patients need to be carefully selected for surgery and psychological evaluation may be of benefit. An ileostomy may be required in some cases.

Obstructed defaecation may be amenable to surgical treatment if there is evidence of rectal intussusception or a sizeable rectocele. These can be corrected by a ventral mesh rectopexy and repair (transrectal or transvaginal), respectively. If there is coexisting evidence of impaired pelvic floor relaxation, the results of surgical treatment tend to be disappointing.

Irritable bowel syndrome

The term irritable bowel syndrome (IBS) covers a range of symptoms with a functional basis. Clinical features are variable but abdominal discomfort, bloating, irregularity of bowel habit and passage of mucus are common. By definition, the symptoms of pain have to have been present for at least 3 days per month for at least the 3 previous months in the 6-month period prior to diagnosis (Rome criteria). IBS is common and symptoms have been said to occur in up to 20% of the population.

Colonic investigations are typically performed to rule out organic disease (colonoscopy, barium enema or CT virtual colonoscopy) but are, by definition, normal.

Treatment of IBS is difficult. Many patients benefit from reassurance and symptomatic treatment; dietary modifications, including fibre for constipation and avoidance of fermentable carbohydrates, reduction of caffeine and nicotine intake, may be of value. Antidiarrhoeals and antispasmodic agents are commonly prescribed, but the evidence of benefit is poor. There is some evidence of benefit for low-dose tricyclic antidepressants but patients are often reluctant to use them. Psychological treatments, including hypnotherapy and cognitive behavioural therapy, may be beneficial. Surgery is contraindicated.

Chapter 71

Intestinal obstruction

Learning objectives

To understand:

- The pathophysiology of dynamic and adynamic intestinal obstruction
- The cardinal features on history and examination
- The causes of small and large bowel obstruction
- The indications for surgery and other treatment options in bowel obstruction

CLASSIFICATION

Intestinal obstruction may be classified into two types:

- **Dynamic**, in which peristalsis is working against a mechanical obstruction. It may occur in an acute or a chronic form (Figure 71.1).
- **Adynamic**, in which there is no mechanical obstruction; peristalsis is absent or inadequate (e.g. paralytic ileus or pseudo-obstruction).

Summary box 71.1

Causes of intestinal obstruction

Dynamic

- Intraluminal
  - Faecal impaction
  - Foreign bodies
  - Bezoars
  - Gallstones
- Intramural
  - Stricture
  - Malignancy
  - Intussusception
  - Volvulus
- Extramural
  - Bands/adhesions
  - Hernia

Adynamic

- Paralytic ileus
- Pseudo-obstruction

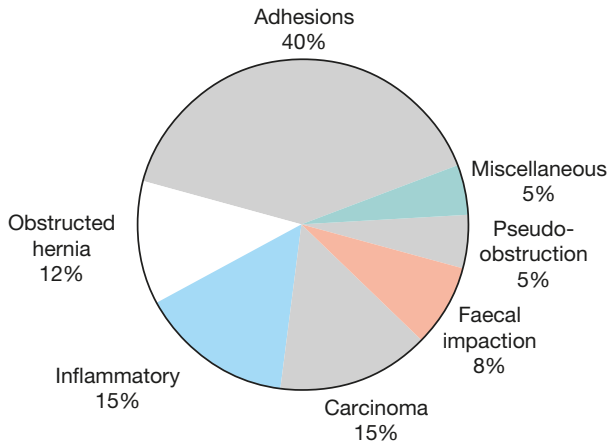

Figure 71.1 Pie chart showing the common causes of intestinal obstruction and their relative frequencies.

PATHOPHYSIOLOGY

Irrespective of aetiology or acuteness of onset, in dynamic (mechanical) obstruction the bowel proximal to the obstruction dilates and the bowel below the obstruction exhibits normal peristalsis and absorption until it becomes empty and collapses. Initially, proximal peristalsis is increased in an attempt to overcome the obstruction. If the obstruction is not relieved, the bowel continues to dilate; ultimately there is a reduction in peristaltic strength, resulting in flaccidity and paralysis.

The distension proximal to an obstruction is caused by two factors:

- **Gas**: there is a significant overgrowth of both aerobic and anaerobic organisms, resulting in considerable gas

production. Following the reabsorption of oxygen and carbon dioxide, the majority is made up of nitrogen (90%) and hydrogen sulphide.

- **Fluid**: this is made up of the various digestive juices. (saliva 500 mL, bile 500 mL, pancreatic secretions 500 mL, gastric secretions 1 litre – all per 24 hours). This accumulates in the gut lumen as absorption by the obstructed gut is retarded. Dehydration and electrolyte loss are therefore due to:
  - reduced oral intake;
  - defective intestinal absorption;
  - losses as a result of vomiting;
  - sequestration in the bowel lumen;
  - transudation of fluid into the peritoneal cavity.

STRANGULATION

It is important to appreciate that the consequences of intestinal obstruction are not immediately life-threatening unless there is superimposed strangulation. When strangulation occurs, the blood supply is compromised and the bowel becomes ischaemic.

Summary box 71.2

Causes of strangulation

Direct pressure on the bowel wall

- Hernial orifices
- Adhesions/bands

Interrupted mesenteric blood flow

- Volvulus
- Intussusception

Increased intraluminal pressure

- Closed-loop obstruction

Ischaemia from direct pressure on the bowel wall from a constricting band such as a hernial orifice is easy to understand.

Distension of the obstructed segment of bowel results in high pressure within the bowel wall. This can happen when only part of the bowel wall is obstructed as seen in Richter's hernias. Venous return is compromised before the arterial supply. The resultant increase in capillary pressure leads to impaired local perfusion and once the arterial supply is impaired, haemorrhagic infarction occurs. As the viability of the bowel is compromised, translocation and systemic exposure to anaerobic organisms and endotoxin occurs.

The morbidity and mortality associated with strangulation are largely dependent on the duration of the ischaemia and its extent. Elderly patients and those with comorbidities are more vulnerable to its effects. Although in strangulated external hernias the segment involved is often short, any length of ischaemic bowel can cause significant systemic effects secondary to sepsis and obstruction proximal to the obstruction can result in significant dehydration. When bowel involvement is extensive circulatory failure is common.

Closed-loop obstruction

This occurs when the bowel is obstructed at both the proximal and distal points (Figure 71.2). The distension is principally confined to the closed loop; distension proximal to the obstructed segment is not typically marked.

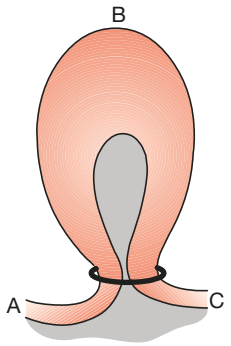

Figure 71.2 Distension. Closed-loop obstruction with no proximal (A) or distal (C) distension and impending strangulation (B).

A classic form of closed-loop obstruction is seen in the presence of a malignant stricture of the colon with a competent ileocaecal valve (present in up to one-third of individuals). This can occur with lesions as far distally as the rectum. The inability of the distended colon to decompress itself into the small bowel results in an increase in luminal pressure, which is greatest at the caecum, with subsequent impairment of blood flow in the wall. Unrelieved, this results in necrosis and perforation (Figure 71.3).

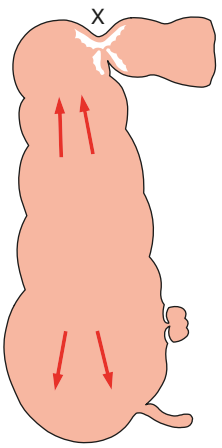

Figure 71.3 Carcinomatous stricture (X) of the hepatic flexure: closed-loop obstruction.

August Gottlieb Richter, 1742–1812, lecturer in surgery, Göttingen, Germany, described this form of hernia in 1777.

SPECIAL TYPES OF MECHANICAL INTESTINAL OBSTRUCTION

Internal hernia

Internal herniation occurs when a portion of the small intestine becomes entrapped in one of the retroperitoneal fossae or in a congenital mesenteric defect.

The following are potential sites of internal herniation (all are rare):

- the foramen of Winslow;
- a defect in the mesentery;
- a defect in the transverse mesocolon;
- defects in the broad ligament;
- congenital or acquired diaphragmatic hernia;
- duodenal retroperitoneal fossae – left paraduodenal and right duodenojejunal;
- caecal/appendiceal retroperitoneal fossae – superior, inferior and retrocaecal;
- intersigmoid fossa.

Internal herniation in the absence of adhesions is rare and a preoperative diagnosis is unusual. The standard treatment of an obstructed hernia is to release the constricting agent by division. This should not be undertaken in cases of herniation involving the foramen of Winslow, mesenteric defects and the paraduodenal/duodenojejunal fossae as major blood vessels run in the edge of the constriction ring. The distended loop in such circumstances must first be decompressed (minimising contamination) and then reduced.

Obstruction from enteric strictures

Small bowel strictures usually occur secondary to tuberculosis or Crohn's disease. Malignant strictures associated with lymphoma are uncommon, whereas carcinoma and sarcoma are rare. Presentation is usually subacute or chronic. Standard surgical management consists of resection and anastomosis. Resection is important to establish a histological diagnosis as this can be uncertain clinically. In Crohn's disease, strictureplasty may be considered in the presence of short multiple strictures without active sepsis.

Bolus obstruction

Bolus obstruction in the small bowel may be caused by gallstones, food, trichobezoar, phytobezoar, stercoliths and worms.

Gallstones

This type of obstruction tends to occur in the elderly secondary to erosion of a large gallstone directly through the gall bladder into the duodenum. Classically, there is impaction about 60 cm proximal to the ileocaecal valve. The patient may have recurrent attacks as the obstruction is frequently incomplete or relapsing as a result of a ball-valve effect. The characteristic radiological sign of gallstone ileus is Rigler's triad, comprising: small bowel obstruction, pneumobilia and an atypical mineral shadow on radiographs of the abdomen. The presence of two of these radiological signs has been considered pathognomic of gallstone ileus and is encountered in 40–50% of the cases (note than pneumobilia is common following endoscopic retrograde cholangiopancreatography (ERCP) with sphincterotomy). At laparotomy, the stone is milked proximally away from the site of impaction. It may be possible to crush the stone within the bowel lumen; if not, the intestine is opened at this point and the gallstone removed. If the gallstone is faceted, a careful check for other enteric stones should be made. The region of the gall bladder should not be explored.

Food

Bolus obstruction may occur after partial or total gastrectomy when unchewed articles can pass directly into the small bowel. Fruit and vegetables are particularly liable to cause obstruction. The management is similar to that for gallstone, with intraluminal crushing usually being successful.

Trychobezoars and phytobezoars

These are firm masses of undigested hair ball and fruit/vegetable fibre respectively. The former is due to persistent hair chewing or sucking, and may be associated with an underlying psychiatric abnormality. Predisposition to phytobezoars results from a high fibre intake, inadequate chewing, previous gastric surgery, hypochlorhydria and loss of the gastric pump mechanism. When possible, the lesion may be kneaded into the caecum; otherwise open removal is required. A preoperative diagnosis is difficult even with high-resolution computed tomography (CT) scanning.

Stercoliths

These are usually found in the small bowel in association with a jejunal diverticulum or ileal stricture. Presentation and management are identical to that of gallstones.

Worms

Ascaris lumbricoides may cause low small bowel obstruction, particularly in children, the institutionalised and those near the tropics (**Figure 71.4**). An attack may follow the initiation of antihelminthic therapy. Debility is frequently out of proportion to that produced by the obstruction. If worms are not seen in the stool or vomitus the diagnosis may be indicated by eosinophilia or the sight of worms within gas-filled small bowel loops on a plain radiograph (Naik). At laparotomy it may be possible to knead the tangled mass into the caecum; if not it should be removed. Occasionally, worms may cause

Vinod C Naik, a doctor from Nansari, India.

Figure 71.4 Obstruction of the small intestine due to *Ascaris lumbricoides* (courtesy of Asal Y Izzidien, Nenavah, Iraq).

a perforation and peritonitis, especially if the enteric wall is weakened by such conditions as ameobiasis.

Obstruction by adhesions and bands

Adhesions

In Western countries where abdominal operations are common, adhesions and bands are the most common cause of intestinal obstruction. The lifetime risk of requiring an admission to hospital for adhesional small bowel obstruction susequent to abdominal surgery is around 4% and the risk of requiring a laparotomy around 2%. Adhesions start to form within hours of abdominal surgery. In the early postoperative period, the onset of such a mechanical obstruction may be difficult to differentiate from paralytic ileus.

The causes of intraperitoneal adhesions are shown in *Table 71.1*. Any source of peritoneal irritation results in local fibrin production, which produces adhesions between apposed surfaces. Early fibrinous adhesions may disappear when the cause is removed or they may become vascularised and be replaced by mature fibrous tissue.

There are several factors that may limit adhesion formation.

TABLE 71.1 The common causes of intra-abdominal adhesions.

Acute inflammation	Sites of anastomoses, reperitonealisation of raw areas, trauma, ischaemia
Foreign material	Talc, starch, gauze, silk
Infection	Peritonitis, tuberculosis
Chronic inflammatory conditions	Crohn's disease
Radiation enteritis	

Summary box 71.3

Prevention of adhesions

Factors that may limit adhesion formation include:

- Good surgical technique
- Washing of the peritoneal cavity with saline to remove clots
- Minimising contact with gauze
- Covering anastomosis and raw peritoneal surfaces

Laparoscopic technique

Numerous substances have been instilled in the peritoneal cavity to prevent adhesion formation, including hyaluronidase, hydrocortisone, silicone, dextran, polyvinylpropylene (PVP), chondroitin and streptomycin, anticoagulants, antihistamines, non-steroidal anti-inflammatory drugs and streptokinase. Currently, no single agent or combination of agents has been convincingly shown to be effective.It is hoped that with the more widespread use of laparoscopic surgery the incidence of intra-abdominal adhesions will reduce.

Adhesions may be classified into various types by virtue of whether they are early (fibrinous) or late (fibrous) or by underlying aetiology. From a practical perspective there are only two types – 'easy' flimsy ones and 'difficult' dense ones.

Postoperative adhesions giving rise to intestinal obstruction usually involve the lower small bowel and almost never involve the large bowel.

Bands

Usually only one band is culpable. This may be:

- congenital, e.g. obliterated vitellointestinal duct;
- a string band following previous bacterial peritonitis;
- a portion of greater omentum, usually adherent to the parietes.

Acute intussusception

This occurs when one portion of the gut invaginates into an immediately adjacent segment; almost invariably, it is the proximal into the distal.

The condition is encountered most commonly in children, with a peak incidence between 5 and 10 months of age. About 90% of cases are idiopathic but an associated upper respiratory tract infection or gastroenteritis may precede the condition. It is believed that hyperplasia of Peyer's patches in the terminal ileum may be the initiating event. Weaning, loss of passively acquired maternal immunity and common viral pathogens have all been implicated in the pathogenesis of intussusception in infancy.

Children with intussusception associated with a pathological lead point such as Meckel's diverticulum, polyp, duplication, Henoch–Schönlein purpura or appendix are usually older than those with idiopathic disease. After the age of

Johann Conrad Peyer, 1653–1712, Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland, described the lymph follicles in the intestine in 1677.
Johann Friedrich Meckel, (The Younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany, described the diverticulum in 1809.
Eduard Heinrich Henoch, 1820–1910, Professor of Diseases of Children, Berlin, Germany, described this form of purpura in 1868.
Johann Lucas Schönlein, 1793–1864, Professor of Medicine, Berlin, Germany, gave his account of this disease in 1837.

2 years, a pathological lead point is found in at least one-third of affected children. Adult cases are invariably associated with a lead point, which is usually a polyp (e.g. Peutz–Jeghers syndrome), a submucosal lipoma or other tumour.

Pathology

An intussusception is composed of three parts (**Figure 71.5**):

- the entering or inner tube (intussusceptum);
- the returning or middle tube;
- the sheath or outer tube (intussuscipiens).

The part that advances is the apex, the mass is the intussusception and the neck is the junction of the entering layer with the mass.

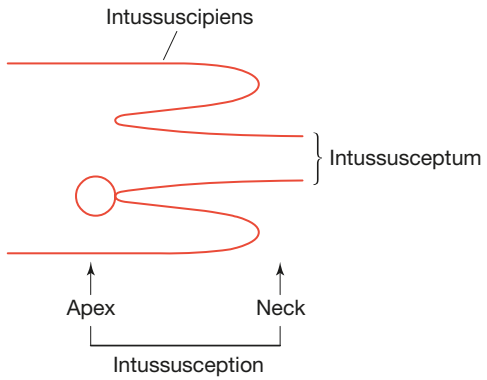

Figure 71.5 Mechanism and nomenclature of intussusception.

Intussusception may be anatomically defined according to the site and extent of invagination (*Table 71.2*). In most children, the intussusception is ileocolic. In adults, colocolic intussusception is more common. The degree of ischaemia is dependent on the tightness of the invagination, which is usually greatest as it passes through the ileocaecal valve. On CT scanning the target sign may be evident and if present is pathognomonic. It is worth noting that, rarely, intussusception has been noted on CT scanning in asymptomatic adults.

TABLE 71.2 Types of intussusception in children (after RE Gross) (*n* = 702).

	Percentage of series
Ileoileal	5
Ileocolic	77
Ileoileocolic	12
Colocolic	2
Multiple	1
Retrograde	0.2
Others	2.8

Summary box 71.4

Intussusception

- Most common in children
- Adult cases are secondary to intestinal pathology, e.g. polyp, Meckel's diverticulum
- Ileocolic is the commonest variety
- Can lead to an ischaemic segment
- Radiological reduction is indicated in most paediatric cases
- Adults require surgery

Volvulus

A volvulus is a twisting or axial rotation of a portion of bowel about its mesentery. The rotation causes obstruction to the lumen (>180° torsion) and if tight enough also causes vascular occlusion in the mesentery (>360° torsion). Bacterial fermentation adds to the distension and increasing intraluminal pressure impairs capillary perfusion. Mesenteric veins become obstructed as a result of the mechanical twisting and thrombosis results and contributes to the ischaemia.

Volvuli may be primary or secondary. The primary form occurs secondary to congenital malrotation of the gut, abnormal mesenteric attachments or congenital bands. Examples include volvulus neonatorum, caecal volvulus and sigmoid volvulus. A secondary volvulus, which is the more common variety, is due to rotation of a segment of bowel around an acquired adhesion or stoma.

Summary box 71.5

Volvulus

- May involve the small intestine, caecum or sigmoid colon; neonatal midgut volvulus secondary to midgut malrotation is life-threatening
- The commonest spontaneous type in adults is sigmoid
- Sigmoid volvulus can be relieved by decompression per anum
- Surgery is required to prevent or relieve ischaemia

Volvulus neonatorum

This occurs secondary to intestinal malrotation (see Chapter 9) and is potentially catastrophic.

Sigmoid volvulus

This is uncommon in Europe and the USA but more common in Eastern Europe and Africa. Indeed, it is the most common cause of large bowel obstruction in the indigenous black African population. Rotation nearly always occurs in the anticlockwise direction. The predisposing clinical features are summarised in **Figure 71.6**. Other predisposing factors include a high-residue diet and constipation. In

John Law Augustine Peutz, 1886–1968, Chief Specialist for Internal Medicine, St. John's Hospital, The Hague, The Netherlands.
Harold Joseph Jeghers, 1904–1990, Professor of Internal Medicine, New Jersey College of Medicine and Dentistry, Jersey City, NJ, USA.

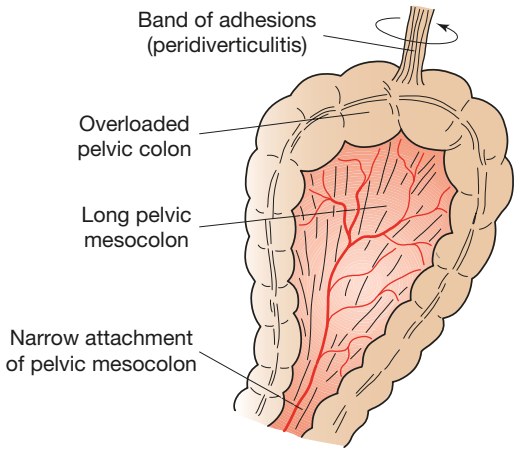

Figure 71.6 Causes predisposing to volvulus of the sigmoid colon. Idiopathic megacolon usually precedes the volvulus in African people.

western populations, the condition is seen most often in elderly patients with chronic constipation; comorbidities are common and chronic psychotropic drug use is associated with this condition. Younger patients present earlier and the prognosis is inversely related to the duration of symptoms. Presentation can be classified as:

- **Fulminant**: sudden onset, severe pain, early vomiting, rapidly deteriorating clinical course;
- **Indolent**: insidious onset, slow progressive course, less pain, late vomiting.

Compound volvulus

This is a rare condition also known as ileosigmoid knotting. The long pelvic mesocolon allows the ileum to twist around the sigmoid colon, resulting in gangrene of either or both segments of bowel. The patient presents with acute intestinal obstruction, but distension is comparatively mild. Plain radiography reveals distended ileal loops in a distended sigmoid colon. At operation, decompression, resection and anastomosis are required.

CLINICAL FEATURES OF INTESTINAL OBSTRUCTION

Dynamic obstruction

The diagnosis of dynamic intestinal obstruction is based on the classic quartet of pain, distension, vomiting and absolute constipation. Obstruction may be classified clinically into two types:

- small bowel obstruction – high or low;
- large bowel obstruction.

The nature of the presentation will also be influenced by whether the obstruction is:

- complete;
- incomplete.

A complete small bowel obstruction has all the cardinal features. In cases of complete large bowel obstruction there is often a surprising lack of preceeding symptoms. Both small and large bowel obstruction can present with more chronic symptoms in which the symptoms are intermittent or the obstruction is incomplete. Incomplete obstruction is also referred to as partial or subacute.

Summary box 71.6

Features of obstruction

- In **high small bowel obstruction**, vomiting occurs early, is profuse and causes rapid dehydration. Distension is minimal with little evidence of dilated small bowel loops on abdominal radiography
- In **low small bowel obstruction**, pain is predominant with central distension. Vomiting is delayed. Multiple dilated small bowel loops are seen on radiography
- In **large bowel obstruction**, distension is early and pronounced. Pain is less severe and vomiting and dehydration are later features. The colon proximal to the obstruction is distended on abdominal radiography. The small bowel will be dilated if the ileocaecal valve is incompetent.

Summary box 71.7

Cardinal clinical features of acute obstruction

- Abdominal pain
- Distension
- Vomiting
- Absolute constipation

Presentation will be further influenced by whether the obstruction is:

- simple – in which the blood supply is intact;
- strangulating/strangulated – in which there is interference to blood flow.

The common causes of intestinal obstruction in Western countries and their relative frequencies are shown in **Figure 71.1**. The underlying mechanisms are shown in *Summary box 71.2*.

The clinical features vary according to:

- the location of the obstruction;
- the duration of the obstruction;
- the underlying pathology;
- the presence or absence of intestinal ischaemia.

Late manifestations of intestinal obstruction that may be encountered include dehydration, oliguria, hypovolaemic shock, pyrexia, septicaemia, respiratory embarrassment and peritonism. In all cases of suspected intestinal obstruction, the hernial orifices must be examined.

Pain

Pain is the first symptom encountered; it occurs suddenly and is usually severe. It is colicky in nature and usually centred on the umbilicus (small bowel) or lower abdomen (large bowel).

The pain coincides with increased peristaltic activity. With increasing distension, the colicky pain is replaced by a mild and more constant diffuse pain. If there is no ischaemia and the obstruction persists over several days, pain reduces and can disappear.

The development of severe pain is suggestive of the presence of strangulation, especially if that severe pain is continuous. Beware the patient whose pain is not controlled with intravenous opiates. Colicky pain may not be a significant feature in postoperative simple mechanical obstruction and pain does not usually occur in paralytic ileus.

Vomiting

The more distal the obstruction, the longer the interval between the onset of symptoms and the appearance of nausea and vomiting. As obstruction progresses the character of the vomitus alters from digested food to faeculent material, as a result of the presence of enteric bacterial overgrowth.

Distension

In the small bowel the degree of distension is dependent on the site of the obstruction and is greater the more distal the lesion. Visible peristalsis may be present (**Figure 71.7**). This can sometimes be provoked by 'flicking' the abdominal wall. Distension is a later feature in colonic obstruction and may be minimal or absent in the presence of mesenteric vascular occlusion.

Constipation

This may be classified as absolute (i.e. neither faeces nor flatus is passed) or relative (where only flatus is passed). Absolute constipation is a cardinal feature of complete intestinal obstruction. Some patients may pass flatus or faeces after the onset of obstruction as a result of the evacuation of the distal bowel contents. The administration of enemas should be avoided in cases of suspected obstruction. This merely stimulates evacuation of bowel contents distal to the obstruction and confuses the clinical picture.

The rule that absolute constipation is present in intestinal obstruction does not apply in:

- Richter's hernia;
- gallstone ileus;
- mesenteric vascular occlusion;
- functional obstruction associated with pelvic abscess;
- all cases of partial obstruction (in which diarrhoea may occur).

Figure 71.7 Visible peristalsis. Intestinal obstruction due to a strangulated right femoral hernia, to which the arrow points.

Other manifestations

Dehydration

Dehydration is seen most commonly in small bowel obstruction because of repeated vomiting and fluid sequestration. It results in dry skin and tongue, poor venous filling and sunken eyes with oliguria. The blood urea level and haematocrit rise, giving a secondary polycythaemia.

Hypokalaemia

Hypokalaemia is not a common feature in simple mechanical obstruction. An increase in serum potassium, amylase or lactate dehydrogenase may be associated with the presence of strangulation, as may leucocytosis or leucopenia.

Pyrexia

Pyrexia in the presence of obstruction is rare and may indicate:

- the onset of ischaemia;
- intestinal perforation;
- inflammation or abscess associated with the obstructing disease.

Hypothermia indicates septicaemic shock or neglected cases of long duration.

Abdominal tenderness

Localised tenderness indicates impending or established ischaemia. The development of peritonism or peritonitis indicates overt infarction and/or perforation. In cases of large bowel obstruction, it is important to elicit these findings in the right iliac fossa as the caecum is most vulnerable to ischaemia.

Bowel sounds

High-pitched bowel sounds are present in the vast majority of patients with intestinal obstruction. Normal bowel sounds are of negative predictive value. Bowel sounds may be scanty or absent if the obstruction is longstanding and the small bowel has become inactive.

Clinical features of strangulation

It is vital to distinguish strangulating from non-strangulating intestinal obstruction because the former is a surgical emergency. The diagnosis is almost entirely clinical.

Summary box 71.8

Clinical features of strangulation

- Constant pain, severe pain
- Tenderness with rigidity and peritonism
- Shock

In addition to the features above, it should be noted that:

- The presence of shock suggests underlying ischaemia, especially if the shock is resistant to simple fluid resuscitation.
- In impending or established strangulation, pain is never completely absent.
- The presence and character of any local tenderness are of great significance and, however mild, tenderness requires frequent reassessment.
- Generalised tenderness and the presence of rigidity indicate the need for early laparotomy.
- In cases of intestinal obstruction in which pain persists despite conservative management, even in the absence of the above signs, strangulation should be presumed.
- When strangulation occurs in an external hernia, the lump is tense, tender and irreducible and there is no expansile cough impulse. Skin changes with erythema or purplish discolouration are associated with underlying ischaemia (**Figures 71.8** and **71.9**).

Clinical features of intussusception

The classical presentation of intussusception is with episodes of screaming and drawing up of the legs in a previously well male infant. The attacks last for a few minutes and recur repeatedly. During attacks the child appears pale; between episodes he may be listless. Vomiting may or may not occur at the outset but becomes conspicuous and bile-stained with time. Initially, the passage of stool may be normal, whereas, later, blood and mucus are evacuated – the 'redcurrant jelly' stool.

Whenever possible, examination should be undertaken between episodes of colic, without disturbing the child. Classically, the abdomen is not initially distended; a lump that hardens on palpation may be discerned but this is present in only 60% of cases (**Figure 71.10**). There may be an associated feeling of emptiness in the right iliac fossa (the sign of Dance). On rectal examination, blood-stained mucus may be found on the finger. Occasionally, in extensive ileocolic or colocolic intussusception, the apex may be palpable or even protrude from the anus.

Unrelieved, progressive dehydration and abdominal distension from small bowel obstruction will occur, followed by peritonitis secondary to gangrene. Rarely, natural cure may occur as a result of sloughing of the intussusception.

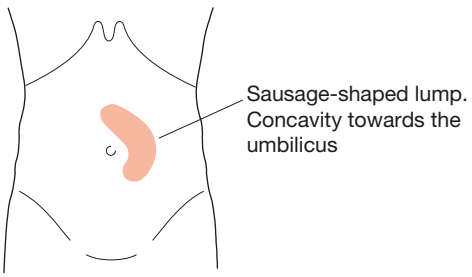

Figure 71.10 The physical signs as recorded by Hamilton Bailey in a typical case of intussusception in an infant.

Differential diagnosis

ACUTE GASTROENTERITIS

Although abdominal pain and vomiting are common in acute gastroenteritis, with occasional blood and mucus in the stool,

Henry Hamilton Bailey, 1894–1961, surgeon, The Royal Northern Hospital, London, UK.
Jean Baptiste Hippolyte Dance, 1797–1832, physician, Hôpital Cochin, Paris, France.

diarrhoea is a leading symptom and faecal matter or bile is always present in the stool.

HENOCH–SCHÖNLEIN PURPURA

Henoch–Schönlein purpura is associated with a characteristic rash and abdominal pain; intussusception may occur.

RECTAL PROLAPSE

This may be easily differentiated by the fact that the projecting mucosa can be felt in continuity with the perianal skin whereas in intussusception the finger may pass indefinitely into the depths of a sulcus.

Clinical features of volvulus

Volvulus of the small intestine

This may be primary or secondary and usually occurs in the lower ileum. It may occur spontaneously in African people, particularly following the consumption of a large volume of vegetable matter, whereas in western countries it is usually secondary to adhesions passing to the parietes or female pelvic organs.

Caecal volvulus

This may occur as part of volvulus neonatorum or *de novo* and is usually a clockwise twist. It is more common in females in the 4th and 5th decades and usually presents acutely with the classic features of obstruction. Ischaemia is common. At first the obstruction may be partial, with the passage of flatus and faeces. In 25% of cases, examination may reveal a palpable tympanic swelling in the midline or left side of the abdomen. The volvulus typically results in the caecum lying in the left upper quadrant. The diagnosis is not usually made preoperatively.

Sigmoid volvulus

The symptoms are of large bowel obstruction. Presentation varies in severity and acuteness, with younger patients appearing to develop the more acute form. Abdominal distension is an early and progressive sign, which may be associated with hiccough and retching. Constipation is absolute. In the elderly, a more chronic form may be seen. In some patients the grossly distended torted left colon is visible through the abdominal wall

IMAGING

Erect abdominal films are no longer routinely obtained and the radiological diagnosis is based on a supine abdominal film (**Figure 71.11**). An erect film may subsequently be requested when further doubt exists.

When distended with gas, the jejunum, ileum, caecum and remaining colon have a characteristic appearance in adults and older children that allows them to be distinguished radiologically.

Figure 71.11 Gas-filled small bowel loop; patient supine.

Summary box 71.9

Radiological features of obstruction (on plain x-ray)

- The obstructed small bowel is characterised by straight segments that are generally central and lie transversely. No/minimal gas is seen in the colon
- The jejunum is characterised by its valvulae conniventes, which completely pass across the width of the bowel and are regularly spaced, giving a 'concertina' or ladder effect
- Ileum – the distal ileum has been piquantly described by Wangensteen as featureless
- Caecum – a distended caecum is shown by a rounded gas shadow in the right iliac fossa
- Large bowel, except for the caecum, shows haustral folds, which, unlike valvulae conniventes, are spaced irregularly, do not cross the whole diameter of the bowel and do not have indentations placed opposite one another

In intestinal obstruction, fluid levels appear later than gas shadows as it takes time for gas and fluid to separate (**Figure 71.12**). These are most prominent on an erect film. In adults, two inconstant fluid levels – one at the duodenal cap and the other in the terminal ileum – may be regarded as normal. In infants (less than 1 year old), a few fluid levels in the small bowel may be physiological. In this age group it is difficult to distinguish large from small bowel in the presence of obstruction, because the characteristic features seen in adults are not present or are unreliable.

During the obstructive process, fluid levels become more conspicuous and more numerous when paralysis has occurred. When fluid levels are pronounced, the obstruction is advanced. In the small bowel, the number of fluid levels is directly proportional to the degree of obstruction and to its site, the number increasing the more distal the lesion.

Owen Harding Wangensteen, 1898–1981, Professor of Surgery, The University of Minnesota, Minneapolis, MN, USA.

Figure 71.12 Fluid levels with gas above; 'stepladder pattern'. Ileal obstruction by adhesions; patient erect.

In patients without evidence of strangulation there is a role for other imaging modalities. A recent systematic review and meta-analysis of the diagnostic and therapeutic role of 50–100mL water-soluble contrast agent in adhesive small bowel obstruction included 14 prospective studies. The appearance of contrast in the colon 4–24 hours after administration had a sensitivity of 96% and a specificity of 98% in predicting resolution of small bowel obstruction. If contrast does not reach the colon, sugery is required in about 90% of patients. Administration of a water-soluble agent was also effective in reducing the need for surgey (OR 0.62; $p = 0.007$) and shortening hospital stay.

In contrast, low colonic obstruction does not commonly give rise to small bowel fluid levels unless advanced, whereas high colonic obstruction may do so in the presence of an incompetent ileocaecal valve. Colonic obstruction is usually associated with a large amount of gas in the caecum. A limited water-soluble enema should be undertaken to differentiate large bowel obstruction from pseudo-obstruction. A barium follow-through is contraindicated in the presence of acute obstruction and may be life-threatening.

The CT scan is now used very widely to investigate all forms of intestinal obstruction. It is highly accurate and its only limitations are in diagnosing ischaemia. Two CT scan findings may be used in clinical practice when looking for intestinal ischaemia: reduced enhanced bowel wall is highly predictive of ischaemia and absence of mesenteric fluid is a reliable finding to rule out strangulation. It is important to remember that even with the best imaging techniques, the diagnosis of strangulation remains a clinical one.

Key points:

- Reduced bowel wall enhancement on CT increases the probability of strangulation 11-fold.
- Absence of mesenteric fluid on CT decreases the probability of strangulation 6-fold.
- The clinical reliability of other CT signs is doubtful for predicting strangulation.

Impacted foreign bodies may be seen on abdominal radiographs. It is noteworthy that gas-filled loops and fluid levels in the small and large bowel can also be seen in established paralytic ileus and pseudo-obstruction. The former can, however, normally be distinguished on clinical grounds whereas the latter can be confirmed radiologically. Fluid levels may also be seen in nonobstructing conditions such as gastroenteritis, acute pancreatitis and intra-abdominal sepsis.

Imaging in intussusception

A plain abdominal field usually reveals evidence of small or large bowel obstruction with an absent caecal gas shadow in ileocolic cases. A soft tissue opacity is often visible in children. A barium enema may be used to diagnose the presence of an ileocolic intussusception (the claw sign) (**Figure 71.13**) but does not demonstrate small bowel intussusception. An abdominal ultrasound scan has a high diagnostic sensitivity in children, demonstrating the typical doughnut appearance of concentric rings in transverse section. CT scanning is currently considered the most sensitive radiological method to confirm intussusception, with a reported diagnostic accuracy of 58–100%. The characteristic features of CT scan include a 'target'- or 'sausage'- shaped soft-tissue mass with a layering effect; mesenteric vessels within the bowel lumen are also typical.

Imaging in volvulus

- In **caecal volvulus**, radiological abnormalities are identifiable in nearly all patients, but are often nonspecific, with caecal dilatation (98–100%), single air-fluid level

Figure 71.13 'Claw' sign of iliac intussusception. The barium in the intussusception is seen as a claw around a negative shadow of the intussusception (courtesy of RS Naik, Durg, India).

(72–88%), small bowel dilatation (42–55%) and absence of gas in distal colon (82–91%) reported as the most common abnormalities. A barium enema may be used to confirm the diagnosis if there are no concerns about ischaemia, with an absence of barium in the caecum and a bird beak deformity. CT scanning is replacing barium enema as the imaging of choice in these less urgent cases.

- In **sigmoid volvulus**, a plain radiograph shows massive colonic distension. The classic appearance is of a dilated loop of bowel; the two limbs are seen running diagonally across the abdomen from right to left, with two fluid levels seen, one within each loop of bowel (if an erect film is taken).
- In **volvulus neonatorium**, the abdominal radiograph shows a variable appearance. Initially, it may appear normal or show evidence of duodenal obstruction but, as the intestinal strangulation progresses, the abdomen becomes relatively gasless.

TREATMENT OF ACUTE INTESTINAL OBSTRUCTION

There are three main measures used to treat acute intestinal obstruction.

Summary box 71.10

Treatment of acute intestinal obstruction

- Gastrointestinal drainage via a nasogastric tube
- Fluid and electrolyte replacement
- Relief of obstruction
- Surgical treatment is necessary for most cases of intestinal obstruction but should be delayed until resuscitation is complete, provided there is no sign of strangulation or evidence of closed-loop obstruction

The first two steps are always necessary before attempting the surgical relief of obstruction and are the mainstay of postoperative management.

Summary box 71.11

Principles of surgical intervention for obstruction

Management of:

- The segment at the site of obstruction
- The distended proximal bowel
- The underlying cause of obstruction

Supportive management

Nasogastric decompression is achieved by the passage of a nonvented (Ryle) or vented (Salem) tube. The tubes are normally placed on free drainage with 4-hourly aspiration but may be placed on continuous or intermittent suction. As well as facilitating decompression proximal to the obstruction, they are essential to reduce the risk of subsequent aspiration during induction of anaesthesia and post-extubation.

The basic biochemical abnormality in intestinal obstruction is sodium and water loss, and therefore the appropriate replacement is Hartmann's solution or normal saline. The volume required varies and should be determined by clinical haematological and biochemical criteria.

Antibiotics are not mandatory but many clinicians initiate broad-spectrum antibiotics early in therapy because of bacterial overgrowth. Antibiotic therapy is mandatory for all patients undergoing surgery for intestinal obstruction.

Surgical treatment

The timing of surgical intervention is dependent on the clinical picture. There are several indications for early surgical intervention.

Summary box 71.12

Indications for early surgical intervention

- Obstructed external hernia
- Clinical features suspicious of intestinal strangulation
- Obstruction in a 'virgin' abdomen

The classic clinical advice that 'the sun should not both rise and set' on a case of unrelieved acute intestinal obstruction was based on the concern that intestinal ischaemia would develop while the patient was waiting for surgery. If there is complete obstruction, but no evidence of intestinal ischaemia, it is reasonable to defer surgery until the patient has been adequately resuscitated. Where obstruction is likely to be secondary to adhesions, conservative management may be continued for up to 72 hours in the hope of spontaneous resolution.

If the site of obstruction is unknown, adequate exposure is best achieved by a midline incision. Assessment is directed to:

- the site of the obstruction;
- the nature of the obstruction;
- the viability of the gut.

In cases of small bowel obstruction, the first manoeuvre is to deliver the distended small bowel into the wound. This

John Alfred Ryle, 1889–1950, Regius Professor of Physic, The University of Cambridge, and later Professor of Social Medicine, The University of Oxford, UK, introduced the Ryle's tube in 1921.
Henri Albert Charles Antoine Hartmann, 1860–1952, Professor of Clinical Surgery, The Faculty of Medicine, The University of Paris, France.

permits access to the site of obstruction. The small bowel should be covered with moist swabs and the weight of the fluid-filled bowel supported such that the blood supply to the mesentery is not impaired.

Operative decompression should be performed whenever possible. This reduces pressure on the abdominal wound, reducing pain and improving diaphragmatic movement. The simplest and safest method is to insert a large-bore orogastric tube and to milk the small bowel contents in a retrograde manner to the stomach for aspiration. All volumes of fluid removed should be accurately measured and appropriately replaced. It is important to ensure that the stomach is empty at the end of the procedure to prevent postoperative aspiration.

Rarely, decompression using Savage's decompressor within a seromuscular purse-string suture may be required. Its benefits should be balanced against the potential risk of septic complications from spillage and the risk of leakage from the suture line postoperatively. The type of surgical procedure required will depend upon the cause of obstruction – division of adhesions (enterolysis), excision, bypass or proximal decompression.

Following relief of obstruction, the viability of the involved bowel should be carefully assessed (*Table 71.3*). Although frankly infarcted bowel is obvious, the viability status in many cases may be difficult to discern. If in doubt, the bowel should be wrapped in hot packs for 10 minutes with increased oxygenation and then reassessed. The state of the mesenteric vessels and pulsation in adjacent arcades should be sought. Viability is also confirmed by colour, sheen and peristalsis. If, at the end of this period, there is still uncertainty about gut viability, the gut should be resected if this does not result in short bowel syndrome. If the patient is septic such that they require inotropic therapy or would require postoperative level 3 intensive care treatment following resection, consideration should be given to raising both ends of the bowel as stomas. This is not only safe but also allows regular assessment of the bowel.

Intestinal ischaemia/reperfusion injury has been described following reperfusion of ischaemic bowel with remote lung injury resulting from the release of inflammatory mediators. This should be borne in mind when dealing with ischaemic bowel. For example if there is a volvulus with established infarction, detorsion should be avoided until the affected mesentery has been clamped and thus reperfusion injury prevented. When no resection has been undertaken or there are multiple ischaemic areas (mesenteric vascular occlusion), a second-look laparotomy at 24–48 hours may be required.

Special attention should always be paid to the sites of constriction at each end of an obstructed segment. If of doubtful viability they should be infolded by the use of a seromuscular suture and can also be covered with omentum (**Figures 71.14 and 71.15**).

The surgical management of massive infarction is dependent on the patient's overall prognostic criteria. In the elderly, infarction of the small bowel from the duodenojejunal flexure to the right colon may be considered incurable, whereas in the young, with the potential for long-term intravenous alimentation and small bowel transplantation, a policy of excision may be justified.

Whenever the small bowel is resected, the exact site of resection, the length of the resected segment and that of the residual bowel should be recorded.

As laparoscopic surgery is now so common, it is important to note that small bowel obstruction and strangulation occur in relation to port site hernias. The risk of port site herniation is related to older age, higher body mass, trocar diameter and extension of the port site for tissue extraction. For laparoscopic cholecystectomy, the hernia rate is reported to be around 2%. Obstruction and strangulation have even been reported through 5-mm port sites. Complications from these hernias may present in the early postoperative period and as a Richter's hernia. They can be easily overlooked and careful examination of port sites in patients with small bowel obstruction is essential.

TABLE 71.3 Differentiation between viable and non-viable intestine.

	Viable	Non-viable
Circulation	Dark colour becomes lighter Visible pulsation in mesenteric arteries	Dark colour remains No detectable pulsation
General appearance	Shiny	Dull and lustreless
Intestinal musculature	Firm	Flabby, thin and friable
	Peristalsis may be observed	No peristalsis

Figure 71.14 Band adhesion causing closed-loop obstruction.

Paul Thwaites Savage, formerly surgeon, The Whittington Hospital, London, UK.

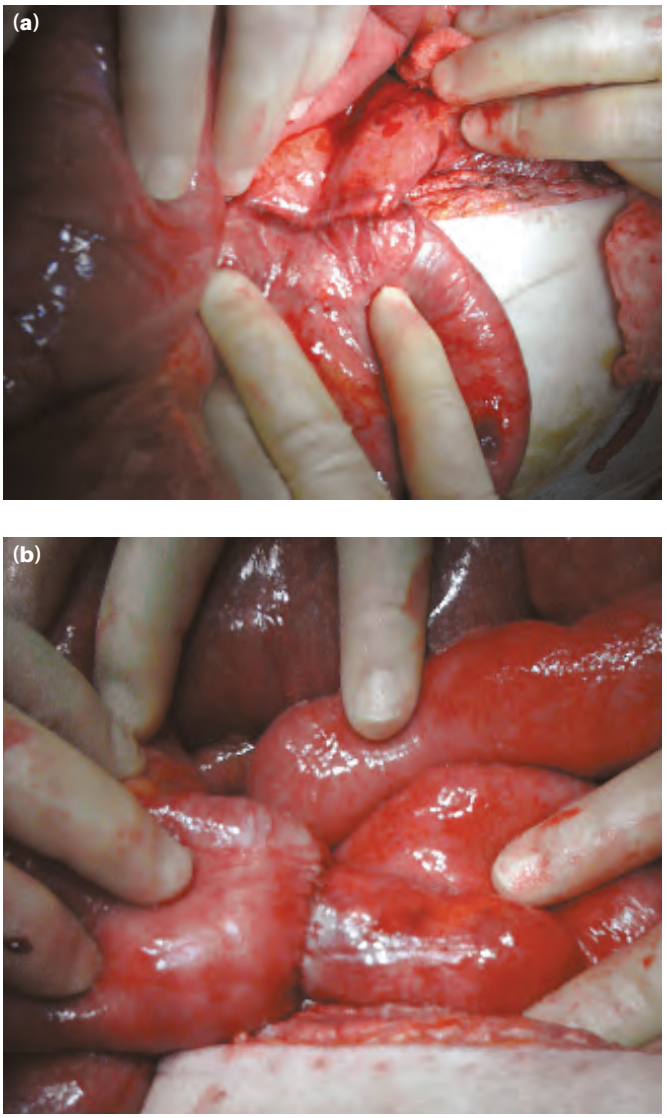

Figure 71.15 (a, b) Wall injury resulting from band compression, oversewn with an absorbable seromuscular suture.

Treatment of adhesions

Initial management is based on intravenous rehydration and nasogastric decompression; occasionally, this treatment is curative. Although an initial conservative regimen is considered appropriate, regular assessment is mandatory to ensure that strangulation does not occur. Conservative treatment should not usually be prolonged beyond 72 hours.

When laparotomy is required, although multiple adhesions may be found, only one may be causative. If there is absolute certainty that this is the cause of the obstruction, this should be divided and the remaining adhesions can be left *in situ* unless severe angulation is present. Division of these adhesions will only cause further adhesion formation.

When obstruction is caused by an area of multiple adhesions, the adhesions should be freed by sharp dissection from the duodenojejunal junction to the caecum. Following the release of band obstruction, the constriction sites that have suffered direct compression should be carefully assessed and, if they show residual colour changes, invaginated with a seromuscular suture (**Figure 71.15**).

Laparoscopic adhesiolysis may be considered in highly selected cases of small bowel obstruction. This is classed as an advanced laparoscopic procedure and should only be undertaken by surgeons with advanced laparoscopic skills.

Summary box 71.13

Treatment of adhesive obstruction

- Initially treat conservatively provided there are no signs of strangulation; should rarely continue conservative treatment for longer than 72 hours
- At operation, divide only the causative adhesion(s) and limit dissection
- Repair serosal tears; invaginate (or resect) areas of doubtful viability
- Laparoscopic adhesiolysis in the hands of advanced laparoscopic practitioners

Treatment of recurrent intestinal obstruction caused by adhesions

Several procedures may be considered in the presence of recurrent obstruction including:

- repeat adhesiolysis (enterolysis) alone;
- Noble's plication operation;
- Child–Phillips transmesenteric plication;
- intestinal intubation.

The latter three operations are now very rarely performed and can probably be consigned to the history books (they have never been required by the author).

Postoperative intestinal obstruction

Differentiation between persistent paralytic ileus and early mechanical obstruction may be difficult in the early postoperative period. Mechanical obstruction is more likely if the patient has regained bowel function postoperatively which subsequently stops. Obstruction is usually incomplete and the majority settle with continued conservative management. Postoperative intra-abdominal sepsis is a potent cause of postoperative obstruction; CT scanning with oral contrast is of particular value in the assessment of the postoperative abdomen. Instant gastrografin enemas are also of value.

Thomas Benjamin Noble, 1895–1965, surgeon, The Community Hospital, Indianapolis, IN, USA.
Richard V Phillips, surgeon, Albuquerque, NM, USA.

Treatment of intussusception

In the infant with ileocolic intussusception, after resuscitation with intravenous fluids, broad-spectrum antibiotics and nasogastric drainage, non-operative reduction can be attempted using an air or barium enema. Successful reduction can only be accepted if there is free reflux of air or barium into the small bowel, together with resolution of symptoms and signs in the patient. Non-operative reduction is contraindicated if there are signs of peritonitis or perforation, there is a known pathological lead point or in the presence of profound shock. In experienced units, more than 70% of intussusceptions can be reduced non-operatively. Strangulated bowel and pathological lead points are unlikely to reduce. Perforation of the colon during pneumatic or hydrostatic reduction is a recognised hazard but is rare. Recurrent intussusception occurs in up to 10% of patients after non-operative reduction.

Surgery is required when radiological reduction has failed or is contraindicated. After resuscitation, a transverse right-sided abdominal incision provides good access. Reduction is achieved by gently compressing the most distal part of the intussusception toward its origin (**Figure 71.16**), making sure not to pull. The last part of the reduction is the most difficult (**Figure 71.17**). After reduction, the terminal part of the small bowel and the appendix will be seen to be bruised and oedematous. The viability of the whole bowel should be checked carefully. An irreducible intussusception or one complicated by infarction or a pathological lead point requires resection and primary anastomosis.

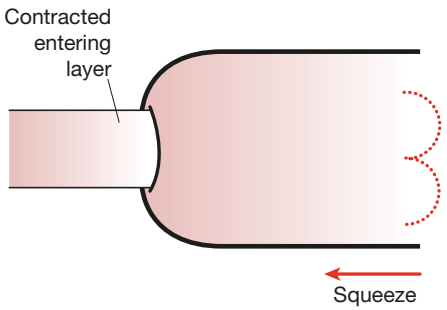

Figure 71.16 Diagram showing the method used to reduce an intussusception.

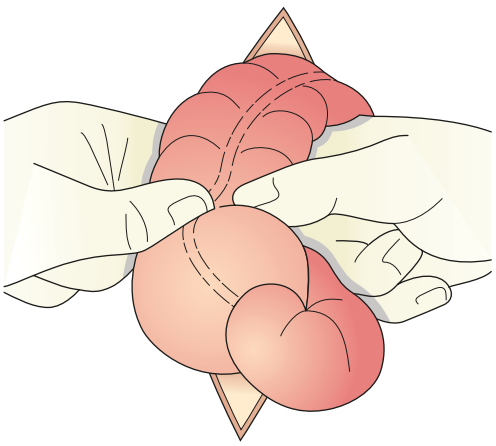

Figure 71.17 Reducing the terminal part of the intussusception (after RE Gross).

Acute intestinal obstruction of the newborn

Neonatal intestinal obstruction has many potential causes. Congenital atresia and stenosis are the most common. Intestinal malrotation with midgut volvulus, meconium ileus, Hirschprung's disease, imperforate anus, necrotising enterocolitis and an incarcerated inguinal hernia may also be responsible. Many of these conditions are discussed in Chapter 9.

Intestinal atresia

Duodenal atresia and stenosis are the commonest forms of intestinal obstruction in the newborn (see Chapter 9). Jejunal or ileal atresias are next in frequency whereas colonic atresia is rare. The possibility of multiple atresias makes intraoperative assessment of the whole small and large bowel mandatory. As with all congenital anomalies, associated malformations are common and should be excluded.

There are four main types of jejunal/ileal atresia, ranging from an obstructing membrane with continuity of the bowel wall, through blind-ended segments of bowel separated by a fibrous cord or V-shaped mesenteric defect (including the so called apple-peel atresia) (**Figure 71.18**), to multiple atresias ('string of sausages'). The obstructed proximal bowel is at risk of perforation, which may happen prenatally causing meconium peritonitis in the fetus.

Small bowel atresias present with intestinal obstruction soon after birth. Bilious vomiting is the dominant feature in jejunal atresia whereas abdominal distension is more

Figure 71.18 Apple-peel jejunal bowel atresia with obstructed proximal jejunum and collapsed distal ileum coiled round a remnant ileocolic artery (courtesy of MD Stringer, Leeds, UK).

Harald Hirschsprung, 1830–1916, physician, The Queen Louise Hospital for Children, Copenhagen, Denmark, described congenital megacolon in 1887.

prominent with ileal atresia. A small amount of pale meconium may be passed despite the atresia.

Plain abdominal radiographs show a variable number of dilated loops of bowel and fluid levels according to the level of obstruction. In a stable infant, a contrast enema may be required to clarify the cause of a distal bowel obstruction.

SURGERY

Duodenal atresia is corrected by a duodenoduodenostomy. In most cases of jejunal/ileal atresia, the distal end of the dilated proximal small bowel is resected and a primary end-to-end anastomosis is possible. If the proximal bowel is extremely dilated it may need to be tapered to the distal bowel before anastomosis. Occasionally, a temporary stoma is required before definitive repair.

Meconium ileus

Cystic fibrosis is almost always the underlying cause of this condition. Meconium is normally kept fluid by the action of pancreatic enzymes. In meconium ileus the terminal ileum becomes filled with thick viscid meconium, resulting in progressive intestinal obstruction. A sterile meconium peritonitis may have occurred *in utero*.

Visibly dilated loops of bowel are often palpable in the newborn with meconium ileus. An abdominal radiograph may show a dilated small intestine with mottling. Fluid levels are generally not seen. Unlike ileal atresia there is no abrupt termination of the gas-filled intestine. A contrast enema shows an unused microcolon. As the condition is caused by an autosomal recessive genetic defect, a family history may be present. Further assessment includes gene mutation analysis and, beyond the neonatal period, a sweat test, which shows elevated sodium and chloride levels (>70 mmol/L).

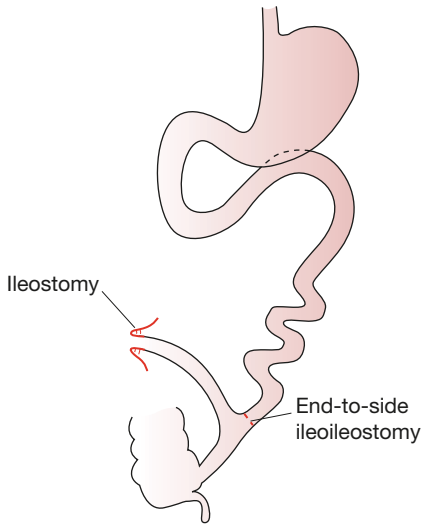

Figure 71.19 Bishop–Koop operation. This shows the completed procedure after a grossly distended ileum has been resected. Because intestinal continuity is preserved, early closure of the ileostomy is not essential.

Uncomplicated meconium ileus may respond to treatment with a hyperosmolar gastrografin enema; this draws fluid into the gut lumen and also has detergent properties, which help to liquefy the meconium. Infants treated in this way need extra intravenous fluids to compensate for fluid shifts. Meconium ileus complicated by intestinal perforation, volvulus or atresia, or unresponsive to enemas, demands surgery. Various surgical procedures are used including intestinal resection and temporary stoma formation, resection and primary anastomosis, and, in uncomplicated cases, enterotomy and irrigation of the bowel. The Bishop–Koop operation (**Figure 71.19**) with its irrigating stoma is now only rarely used.

TREATMENT OF ACUTE LARGE BOWEL OBSTRUCTION

Large bowel obstruction is usually caused by an underlying carcinoma or occasionally diverticular disease, and presents in an acute or chronic form. The condition of pseudo-obstruction should always be considered and excluded by a limited contrast study or CT scan to confirm organic obstruction.

After full resuscitation, the abdomen should be opened through a midline incision. Care should be taken to ensure that the loss of tamponade of the abdominal wall does not lead to increased caecal distension and rupture (this starts with splitting along the line of the taenia coli on the antimesenteric border). Distension of the caecum will confirm large bowel involvement. Identification of a collapsed distal segment of the large bowel and its sequential proximal assessment will readily lead to identification of the cause. As surgery for malignant bowel cancer is technically challenging, wherever possible a suitably trained surgeon should perform the procedure. When a removable lesion is found in the caecum, ascending colon, hepatic flexure or proximal transverse colon, an emergency right hemicolectomy should be performed. A primary anastomosis is safe if the patient's general condition is reasonable. If the lesion is irremovable (this is rarely the case) a proximal stoma (colostomy or ileostomy if the ileocaecal valve is incompetent) or ileotransverse bypass should be considered. Obstructing lesions at the splenic flexure should be treated by an extended right hemicolectomy with ileodescending colonic anastomosis.

For obstructing lesions of the left colon or rectosigmoid junction, immediate resection should be considered unless there are clear contraindications.

Summary box 71.14

Management of left-sided large bowel obstruction

Contraindications to immediate resection include:

- Inexperienced surgeon
- Moribund patient
- Advanced disease

Harry C Bishop, 1921–2009, Professor of Surgery, University of Philadelphia, PA, USA.
Charles Everett Koop, 1916–2013, paediatric surgeon and public health administrator, served as the 13th Surgeon General of the United States (1982–1989).

In rare instances, or when caecal perforation is imminent, additional time to improve the patient's clinical condition can be bought by performing an emergency caecostomy (or ileostomy in the presence of an incompetent ileocaecal valve).

In the absence of senior clinical staff it is safest to bring the proximal colon to the surface as a colostomy. When possible the distal bowel should be brought out at the same time (Paul–Mikulicz procedure) to facilitate subsequent closure. In the majority of cases, the distal bowel will not reach and is closed and returned to the abdomen (Hartmann's procedure). A second-stage colorectal anastomosis can be planned when the patient is fit.

If an anastomosis is to be considered using the proximal colon, in the presence of obstruction, it must be decompressed and cleaned by an on-table colonic lavage.

In the palliative situation, where there is advanced incurable disease, the patient is unfit for major surgery or a combination of the two, insertion of a self-expanding metal stent (SEMS) has been demonstrated to be preferable to surgery; there is now good evidence of reduced mortality and morbidity and stoma formation. Technical and clinical success rates for stenting are of the order of 80–90%.

For patients with potentially curative disease, stenting as a bridge to surgery (usually performed 1–4 weeks poststenting) has been shown to reduce stoma formation but not to reduce postoperative mortality, and the long-term oncological effects of stenting are still uncertain. The current recommendation is that stenting as a bridge to surgery in patients with potentially curative disease should only be used in patients with a high risk of postoperative morbidity and mortality (**Figure 71.20**).

Treatment of caecal volvulus

At operation the volvulus is usually found to be ischaemic and needs resection. If viable, the volvulus should be reduced. Sometimes, this can only be achieved after decompression of the caecum using a needle. Further management consists of fixation of the caecum to the right iliac fossa (caecopexy) and/or a caecostomy. Recurrence of volvulus after caecopexy has been reported in up to 40% of cases.

Treatment of sigmoid volvulus

Flexible sigmoidoscopy or rigid sigmoidoscopy and insertion of a flatus tube should be carried out to allow deflation of the gut. The tube should be secured in place with tape for 24 hours and a repeat x-ray taken to ensure that decompression has occurred. Success, as long as ischaemic bowel is excluded, will resolve the acute problem.

In young patients, an elective sigmoid colectomy is required. It is reasonable not to offer any further treatment following successful endoscopic decompression in the elderly as there is a high death rate (~80% at two years) from causes other than recurrent volvulus. In elderly patients with co-morbidities and recurrent episodes of volvulus, the options are resection or two-point fixation with combined endoscopic/percutaneous tube insertion (gastrostomy tubes are frequently used for this purpose). Failure results in an early laparotomy, with untwisting of the loop and per anum decompression (**Figure 71.21**).

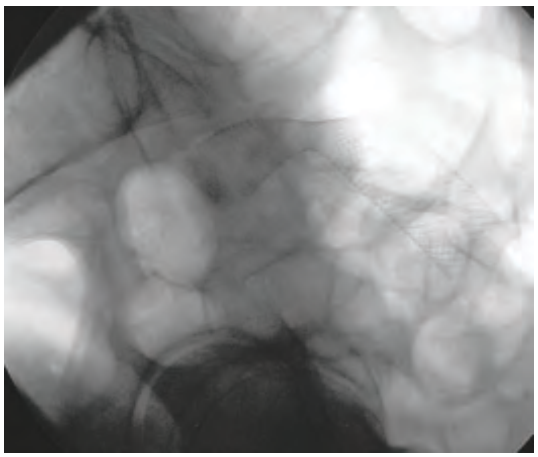

Figure 71.20 X-ray of a stent inserted for malignant colonic obstruction.

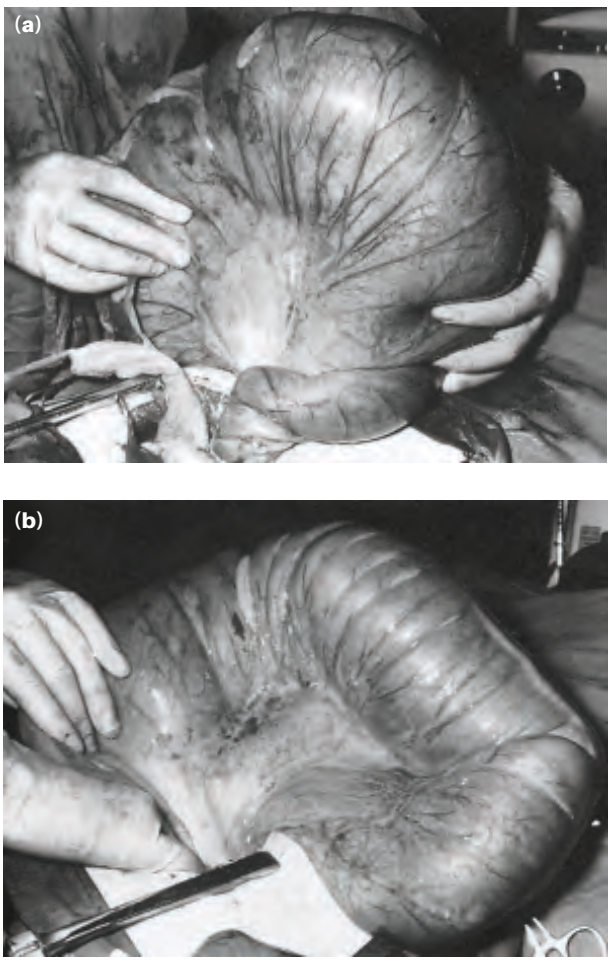

Figure 71.21 Volvulus of the sigmoid colon **(a)** before and **(b)** after untwisting (courtesy of SU Rahman, Manchester, UK).

Frank Thomas Paul, 1851–1941, surgeon, The Royal Infirmary, Liverpool, UK.
Johann von Mikulicz-Radecki, 1850–1905, Professor of Surgery, Breslau, Germany, (now Wroclaw, Poland).

When the bowel is viable, fixation of the sigmoid colon to the posterior abdominal wall may be a safer manoeuvre in inexperienced hands. Resection is preferable if it can be achieved safely. A Paul–Mikulicz procedure is useful, particularly if there is suspicion of impending gangrene (Figure 71.22); an alternative procedure is a sigmoid colectomy and, when anastomosis is considered unwise, a Hartmann's procedure with subsequent reanastomosis can be carried out.

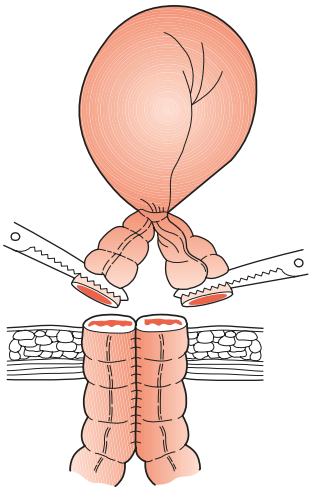

Figure 71.22 The Paul–Mikulicz operation applied to volvulus of the pelvic colon.

CHRONIC LARGE BOWEL OBSTRUCTION

The symptoms of chronic intestinal obstruction may arise from two sources – the cause and the subsequent obstruction.

The causes of obstruction may be organic:

- intraluminal (rare) – faecal impaction;
- intrinsic intramural – strictures (Crohn's disease, ischaemia, diverticular), anastomotic stenosis;
- extrinsic intramural (rare) – metastatic deposits (ovarian), endometriosis, stomal stenosis;

or functional:

- Hirschsprung's disease, idiopathic megacolon, pseudo-obstruction.

The symptoms of chronic obstruction differ in their predominance, timing and degree from acute obstruction. In functional cases, the symptoms may have been present for months or years. Constipation appears first. It is initially relative and then absolute, associated with distension. In the presence of large bowel disease, the point of greatest distension is in the caecum, and this is heralded by the onset of pain. Vomiting is a late feature and therefore dehydration is less severe. Examination is unremarkable, save for confirmation of distension, which can be profound (Figure 71.23) and the onset of peritonism in late cases. Rectal examination may confirm the presence of faecal impaction or a tumour.

Figure 71.23 Gross functional distension.

Investigation

Plain abdominal radiography confirms the presence of large bowel distension. All such cases should be investigated by a subsequent single-contrast water-soluble enema study, CT scan or endoscopic assessment to rule out functional disease.

Organic disease requires decompression with either a laparotomy or stent. Stomal stenosis can usually be managed at the abdominal wall level (Figure 71.24). Surgical management after resuscitation depends on the underlying cause and the relevant chapters in this book should be consulted.

Functional disease requires colonoscopic decompression in the first instance and conservative management. Intestinal perforation can occur in patients with functional obstruction. Those at risk have such gross distension that the abomen is rigid on palpation.

Summary box 71.15

Principles of investigation of possible large bowel obstruction

- In the presence of large bowel obstruction, a single-contrast water-soluble enema or CT should be undertaken to exclude a functional cause

ADYNAMIC OBSTRUCTION

Paralytic ileus

This may be defined as a state in which there is failure of transmission of peristaltic waves secondary to neuromuscular failure (i.e. in the myenteric (Auerbach's) and submucous

Leopold Auerbach, 1828–1897, Professor of Neuropathology, Breslau, Germany, (now Wroclaw, Poland), described the myenteric plexus in 1862.

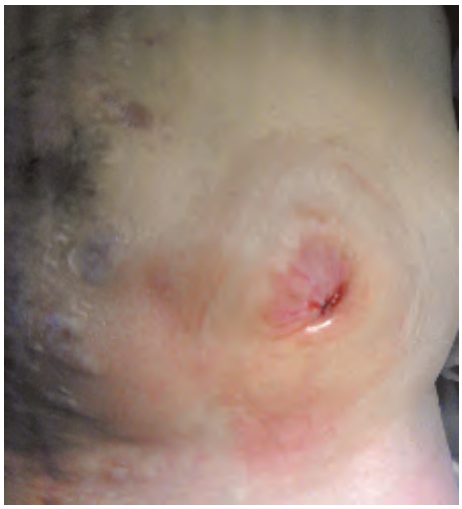

Figure 71.24 Stomal stenosis causing large bowel obstruction.

(Meissner's) plexuses). The resultant stasis leads to accumulation of fluid and gas within the bowel, with associated distension, vomiting, absence of bowel sounds and absolute constipation.

Varieties

The following varieties are recognised:

- **Postoperative**: a degree of ileus usually occurs after any abdominal procedure and is self-limiting, with a variable duration of 24–72 hours. Postoperative ileus may be prolonged in the presence of hypoproteinaemia or metabolic abnormality (see below).
- **Infection**: intra-abdominal sepsis may give rise to localised or generalised ileus.
- **Reflex ileus**: this may occur following fractures of the spine or ribs, retroperitoneal haemorrhage or even the application of a plaster jacket.
- **Metabolic**: uraemia and hypokalaemia are the most common contributory factors.

Clinical features

Paralytic ileus takes on a clinical significance if, 72 hours after laparotomy:

- there has been no return of bowel sounds on auscultation;
- there has been no passage of flatus.

Abdominal distension becomes more marked and tympanitic. Colicky pain is not a feature. Distension increases pain from the abdominal wound. In the absence of gastric aspiration, effortless vomiting may occur. Radiologically, the abdomen shows gas-filled loops of intestine with multiple fluid levels (if an erect film is felt necessary).

Management

Nasogastric tubes are not required routinely after elective intra-abdominal surgery. Paralytic ileus is managed with the use of nasogastric suction and restriction of oral intake until bowel sounds and the passage of flatus return. Electrolyte balance must be maintained. The use of an enhanced recovery programme with early introduction of fluids and solids is, however, becoming increasingly popular.

Specific treatment is directed towards the cause, but the following general principles apply:

- If a primary cause is identified this must be treated.
- Gastrointestinal distension must be relieved by decompression.
- Close attention to fluid and electrolyte balance is essential.
- There is no convincing evidence for the use of prokinetic drugs to treat postoperative adynamic ileus.
- If paralytic ileus is prolonged CT scanning is the most effective investigation; it will demonstrate any intra-abdominal sepsis or mechanical obstruction and therefore guide any requirement for laparotomy. Otherwise the decision to take a patient back to theatre in these circumstances is always difficult. The need for a laparotomy becomes increasingly likely the longer the bowel inactivity persists, particularly if it lasts for more than seven days or if bowel activity recommences following surgery and then stops again.

Pseudo-obstruction

This condition describes an obstruction, usually of the colon, that occurs in the absence of a mechanical cause or acute intra-abdominal disease. It is associated with a variety of syndromes in which there is an underlying neuropathy and/or myopathy and a range of other factors.

Small intestinal pseudo-obstruction

This condition may be primary (i.e. idiopathic or associated with familial visceral myopathy) or secondary. The clinical picture consists of recurrent subacute obstruction. The diagnosis is made by the exclusion of a mechanical cause. Treatment consists of initial correction of any underlying disorder. Metoclopramide and erythromycin may be of use.

Colonic pseudo-obstruction

This may occur in an acute or a chronic form. The former, also known as Ogilvie's syndrome, presents as acute large bowel obstruction. Abdominal radiographs show evidence of colonic obstruction, with marked caecal distension being a common feature. Indeed, caecal perforation is a well-recognised complication. The absence of a mechanical cause requires urgent confirmation by colonoscopy or a single-contrast water-soluble barium enema or CT. Once confirmed, pseudo-obstruction requires treatment of any identifiable cause. If this is ineffective, intravenous neostigmine should be given (1 mg intravenously), with a further 1 mg given intravenously within a few minutes if the first dose is ineffective. During this procedure, it is best to sit the patient on a

Georg Meissner, 1829–1905, Professor of Physiology, Gottingen, Germany, described the submucous plexus of the alimentary tract in 1852.
Sir William Heneage Ogilvie, 1887–1971, surgeon, Guy's Hospital, London, UK.

Summary box 71.16

Factors associated with pseudo-obstruction

- Metabolic
  - Diabetes
  - Hypokalaemia
  - Uraemia
  - Myxodoema
  - Intermittent porphyria
- Severe trauma (especially to the lumbar spine and pelvis)
- Shock
  - Burns
  - Myocardial infarction
  - Stroke
- Idiopathic
- Septicaemia
- Postoperative (for example fractured neck of femur)
- Retroperitoneal irritation
  - Blood
  - Urine
  - Enzymes (pancreatitis)
  - Tumour
- Drugs
  - Tricyclic antidepressants
  - Phenothiazines
  - Laxatives
- Secondary gastrointestinal involvement
  - Scleroderma
  - Chagas' disease

commode. Electrocardiograph (ECG) monitoring is required and atropine should be available. If neostigmine is not effective, colonoscopic decompression should be peformed. Caecal perforation can occur in pseudo-obstruction. Abdominal examination should pay attention to tenderness and peritonism over the caecum and as with mechanical obstruction, caecal perforation is more likely if the caecal diameter is 14 cm or greater. Surgery is associated with high morbidity and mortality and should be reserved for those with impending perforation when other treatments have failed or perforation has occurred.

Rarely, an endoscopically placed tube colostomy is used as a vent for patients with a chronic unremitting condition.

Chapter 72

The vermiform appendix

Learning objectives

To understand:

- The aetiology and surgical anatomy of acute appendicitis
- The clinical signs and differential diagnoses of appendicitis
- The investigation of suspected appendicitis
- Evolving concepts in management of acute appendicitis
- Basic surgical techniques, both open and laparoscopic
- The management of postoperative problems
- Tumours of the appendix and pseudomyxoma peritonei

INTRODUCTION

The importance of the vermiform appendix in surgery results primarily from its propensity for inflammation, which results in the clinical syndrome known as acute appendicitis. Acute appendicitis is the most common cause of an 'acute abdomen' in young adults and, as such, the associated symptoms and signs have become a paradigm for clinical teaching. Appendicitis is sufficiently common that appendicectomy (termed appendectomy in North America) is the most frequently performed urgent abdominal operation and is often the first major procedure performed by a surgeon in training. Advances in modern radiographic imaging have improved diagnostic accuracy; however, the diagnosis of appendicitis remains essentially clinical, requiring a mixture of observation, clinical acumen and surgical science and as such it remains an enigmatic challenge and a reminder of the art of surgical diagnosis. Although much more uncommon, the appendix also has a propensity to the formation of tumours which, despite humble and innocuous beginnings, may disseminate widely with dramatic clinical consequences.

Aside from its tendancy to cause surgical pathology the appendix, long thought to be a vistigial organ, may also have important roles in both immune function and maintaining the gut microbiota. The putative role of the appendix in the pathogenesis of ulcerative colitis (appendicectomy seems to be protective) for example, may be explained by its interaction with the intestinal flora and gut immune function.

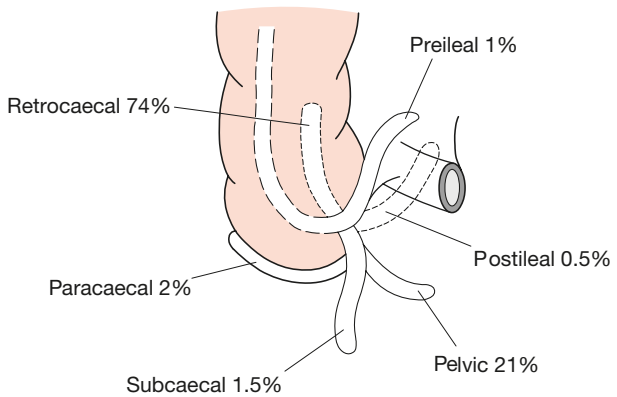

Figure 72.1 The various positions of the appendix (after Sir C Wakeley, London, formerly PRCS).

ANATOMY

The vermiform appendix is present only in humans, certain anthropoid apes and the wombat. It is a blind muscular tube with mucosal, submucosal, muscular and serosal layers. Morphologically, it is the undeveloped distal end of the large caecum found in many lower animals. At birth, the appendix is short and broad at its junction with the caecum, but differential growth of the caecum produces the typical tubular structure by about the age of 2 years (Condon). During childhood, continued growth of the caecum commonly rotates the appendix into a retrocaecal but intraperitoneal position (Figure 72.1). In approximately one-quarter of cases, rotation of the appendix does not occur, resulting in a pelvic, subcaecal or paracaecal position. Occasionally, the tip of the appendix becomes extraperitoneal, lying behind the caecum or ascending colon. Rarely, the caecum does not migrate

A wombat is a nocturnal, burrowing Australian marsupial.
Robert E Condon, 1929–2015, Emeritus Professor of Surgery, The Medical College of Wisconsin, WI, USA.

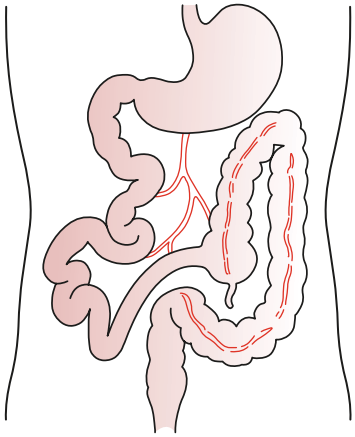

Figure 72.2 Left-sided caecum and appendix due to intestinal malrotation (after Findley and Humphreys).

during development to its normal position in the right lower quadrant of the abdomen. In these circumstances, the appendix can be found near the gall bladder or, in the case of intestinal malrotation, in the left iliac fossa, causing diagnostic difficulty if appendicitis develops (**Figure 72.2**).

The position of the base of the appendix is constant, being found at the confluence of the three taeniae coli of the caecum, which fuse to form the outer longitudinal muscle coat of the appendix. At operation, use can be made of this to find an elusive appendix, as gentle traction on the taeniae coli, particularly the anterior taenia, will lead the operator to the base of the appendix.

The mesentery of the appendix or mesoappendix arises from the lower surface of the mesentery or the terminal ileum and is itself subject to great variation. Sometimes, as much as the distal one-third of the appendix is bereft of mesoappendix. Especially in childhood, the mesoappendix is so transparent that the contained blood vessels can be seen (**Figure 72.3**). In many adults, it becomes laden with fat, which obscures these vessels. The appendicular artery, a branch of the lower division of the ileocolic artery, passes behind the terminal ileum to enter the mesoappendix a short distance from the base of the appendix. It then comes to lie in the free border of the mesoappendix. An accessory appendicular artery may be present but, in most people, the appendicular artery is an 'end-artery', thrombosis of which results in necrosis of the appendix (synonym: gangrenous appendicitis). Four, six or more lymphatic channels traverse the mesoappendix to empty into the ileocaecal lymph nodes.

Microscopic anatomy

The appendix varies considerably in length and circumference. The average length is between 7.5 and 10 cm. The lumen is irregular, being encroached on by multiple longitudinal folds of mucous membrane lined by columnar cell intestinal mucosa of colonic type (**Figure 72.4**). Crypts are present but are not numerous. In the base of the crypts lie argentaffin cells (Kulchitsky cells), which may give rise to carcinoid tumours (see below). The appendix is the most frequent site for carcinoid tumours, which may present with appendicitis due to occlusion of the appendiceal lumen. The submucosa contains numerous lymphatic aggregations or follicles. While no discernible change in immune function results from appendicectomy, the prominence of lymphatic tissue in the appendix of young adults seems to be important in the aetiology of appendicitis (see below).

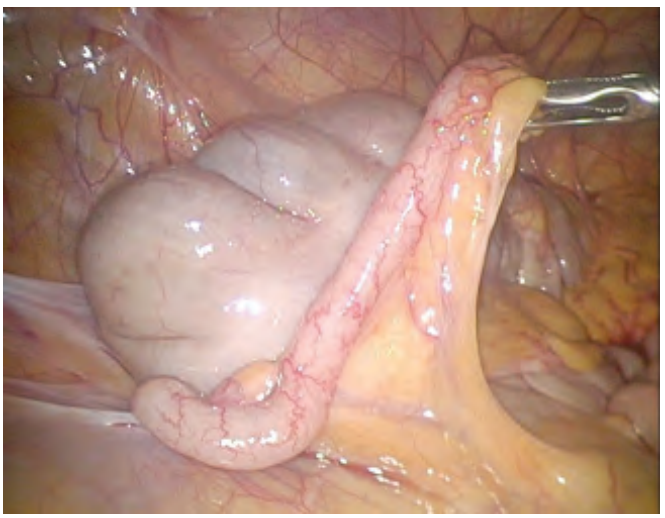

Figure 72.3 Laparoscopic view of a normal appendix with mesoappendix displaying the appendicular artery.

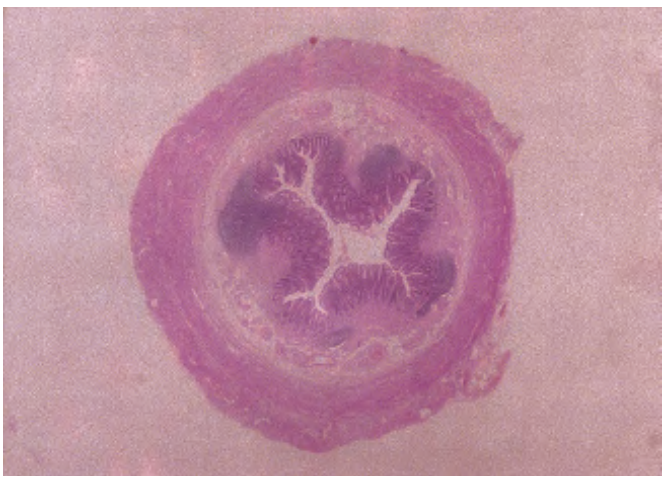

Figure 72.4 Normal vermiform appendix. The narrow lumen is bounded by mucosa, which may be arranged in folds. There is usually abundant lymphoid tissue in the mucosa, especially in younger individuals. This may encroach on and further narrow the lumen. The mucosa is bounded by a relatively thin muscularis mucosa (courtesy of Dr P Kelly, FRCPath, Dublin, Ireland).

Nikolai Kulchitsky, 1856–1925, Professor of Histology, Kharkov, Ukraine, who left Russia after the Revolution of 1917 and later worked at University College, London, UK. He described these cells in 1897.

ACUTE APPENDICITIS

While there are isolated reports of perityphlitis (fatal inflammation of the caecal region) from the late 1500s, recognition of acute appendicitis as a clinical entity is attributed to Reginald Fitz, who presented a paper to the first meeting of the Association of American Physicians in 1886 entitled 'Perforating inflammation of the vermiform appendix'. Soon afterwards, Charles McBurney described the clinical manifestations of acute appendicitis including the point of maximum tenderness in the right iliac fossa that now bears his name.

The incidence of appendicitis seems to have risen greatly in the first half of this century, particularly in Europe, America and Australasia, with up to 16% of the population undergoing appendicectomy. In the past 30 years, the incidence has fallen dramatically in these countries, such that the individual lifetime risk of appendicectomy is 8.6% and 6.7% among males and females, respectively.

Acute appendicitis is relatively rare in infants and becomes increasingly common in childhood and early adult life, reaching a peak incidence in the teens and early 20s. After middle age, the risk of developing appendicitis is quite small. The incidence of appendicitis is equal among males and females before puberty. In teenagers and young adults, the male–female ratio increases to 3:2 at age 25; thereafter, the greater incidence in males declines.

Aetiology

There is no unifying hypothesis regarding the aetiology of acute appendicitis. Decreased dietary fibre and increased consumption of refined carbohydrates may be important. As with colonic diverticulitis, the incidence of appendicitis is lowest in societies with a high dietary fibre intake. In resource-poor countries that are adopting a more refined western-type diet, the incidence continues to rise. This is in contrast to the dramatic decrease in the incidence of appendicitis in western countries observed in the past 30 years. No reason has been established for these paradoxical changes; however, improved hygiene and a change in the pattern of childhood gastrointestinal infection related to the increased use of antibiotics may be responsible.

While appendicitis is clearly associated with bacterial proliferation within the appendix, no single organism is responsible. A mixed growth of aerobic and anaerobic organisms is usual. The initiating event causing bacterial proliferation is controversial. Obstruction of the appendix lumen has been widely held to be important, and some form of luminal obstruction, either by a faecolith (**Figure 72.5**) or a stricture, is found in the majority of cases.

A faecolith (sometimes refered to as an appendicolith) is composed of inspissated faecal material, calcium phosphates, bacteria and epithelial debris (**Figure 72.6**). Rarely, a foreign body is incorporated into the mass. The incidental finding of a faecolith is a relative indication for prophylactic

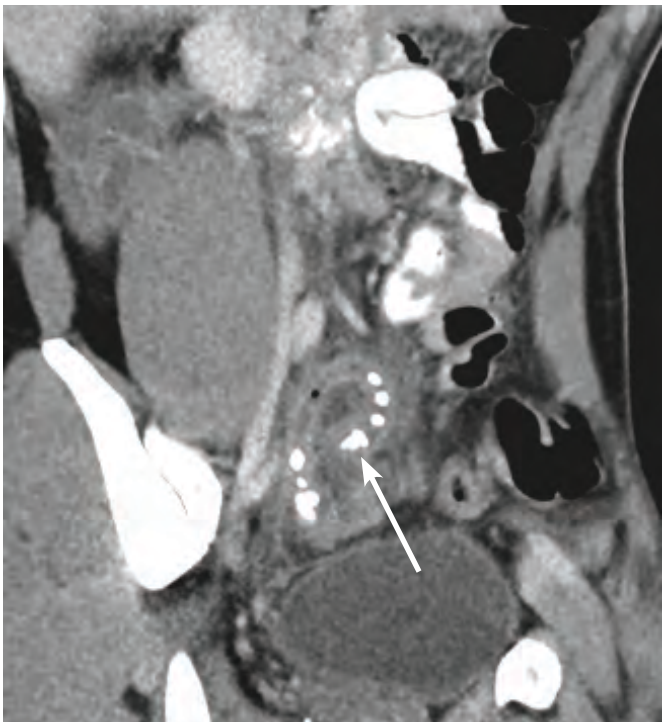

Figure 72.5 Coronal reformat of a computed tomography scan of the abdomen obtained with oral and intravenous contrast, demonstrating an inflamed, enhancing and enlarged appendix that is curled in the midline extending towards the pelvis (arrow). It contains multiple radiopaque appendicoliths. There is extensive periappendiceal fat stranding (courtesy of Dr P MacMahon, FRCR, Dublin, Ireland).

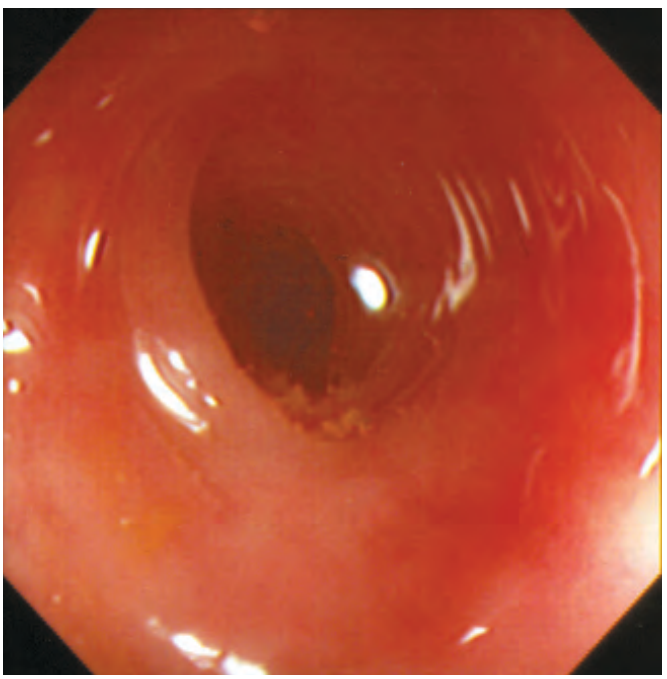

Figure 72.6 Colonoscopic view of the lumen of the appendix showing intraluminal debris (courtesy of Professor D Winter, FRCSI, Dublin, Ireland).

Reginald Heber Fitz, 1843–1913, Professor of Medicine, Harvard University, Boston, MA, USA.
Charles McBurney, 1854–1913, Professor of Surgery, Columbia College of Physicians and Surgeons, New York, NY, USA. In 1889 McBurney published a paper on appendicitis in which he stated 'I believe that in every case the seat of greatest pain "determined by the pressure of one finger" has been very exactly between an inch and a half and two inches from the anterior spirious process of the ilium on a straight line drawn from that process to the umbilicus.'

appendicectomy or an interval appendicetomy in a patient treated conservatively. A fibrotic stricture of the appendix usually indicates previous appendicitis that resolved without surgical intervention. Obstruction of the appendiceal orifice by tumour, particularly carcinoma of the caecum, is an occasional cause of acute appendicitis in middle-aged and elderly patients. Intestinal parasites, particularly *Oxyuris vermicularis* (pinworm), can proliferate in the appendix and occlude the lumen.

Pathology

Obstruction of the appendiceal lumen seems to be essential for the development of appendiceal gangrene and perforation. However, in many cases of early appendicitis, the appendix lumen is patent despite the presence of mucosal inflammation and lymphoid hyperplasia. Occasional clustering of cases among children and young adults suggests an infective agent, possibly viral, which initiates an inflammatory response. Seasonal variation in the incidence is also observed, with more cases occurring between May and August in northern Europe than at other times of the year.

Lymphoid hyperplasia narrows the lumen of the appendix, leading to luminal obstruction. Once obstruction occurs, continued mucus secretion and inflammatory exudation increase intraluminal pressure, obstructing lymphatic drainage. Oedema and mucosal ulceration develop with bacterial translocation to the submucosa. Resolution may occur at this point either spontaneously or in response to antibiotic therapy. If the condition progresses, further distension of the appendix may cause venous obstruction and ischaemia of the appendix wall. With ischaemia, bacterial invasion occurs through the muscularis propria and submucosa, producing acute appendicitis (Figure 72.7). Finally, ischaemic necrosis of the appendix wall produces gangrenous appendicitis, with free bacterial contamination of the peritoneal cavity. Alternatively, the greater omentum and loops of small bowel become adherent to the inflamed appendix, walling off the spread of peritoneal contamination and resulting in a phlegmonous mass or paracaecal abscess. Rarely, appendiceal inflammation resolves, leaving a distended mucus-filled organ termed a mucocele of the appendix.

It is the potential for diffuse peritonitis that is the great threat of acute appendicitis. Peritonitis occurs as a result of free migration of bacteria through an ischaemic appendicular wall, frank perforation of a gangrenous appendix or delayed perforation of an appendix abscess. Factors that promote this process include extremes of age, immunosuppression, diabetes mellitus and faecolith obstruction of the appendix lumen, a free-lying pelvic appendix and previous abdominal surgery that limits the ability of the greater omentum to wall off the spread of peritoneal contamination. In these situations, a rapidly deteriorating clinical course is accompanied by signs of diffuse peritonitis and systemic sepsis syndrome.

Summary box 72.1

Risk factors for perforation of the appendix

- Extremes of age
- Immunosuppression
- Diabetes mellitus
- Faecolith obstruction
- Pelvic appendix
- Previous abdominal surgery

Clinical diagnosis

History

The classical features of acute appendicitis begin with poorly localised colicky abdominal pain. This is due to mid-gut visceral discomfort in response to appendiceal inflammation and obstruction. The pain is frequently first noticed in the periumbilical region and is similar to, but less intense than,

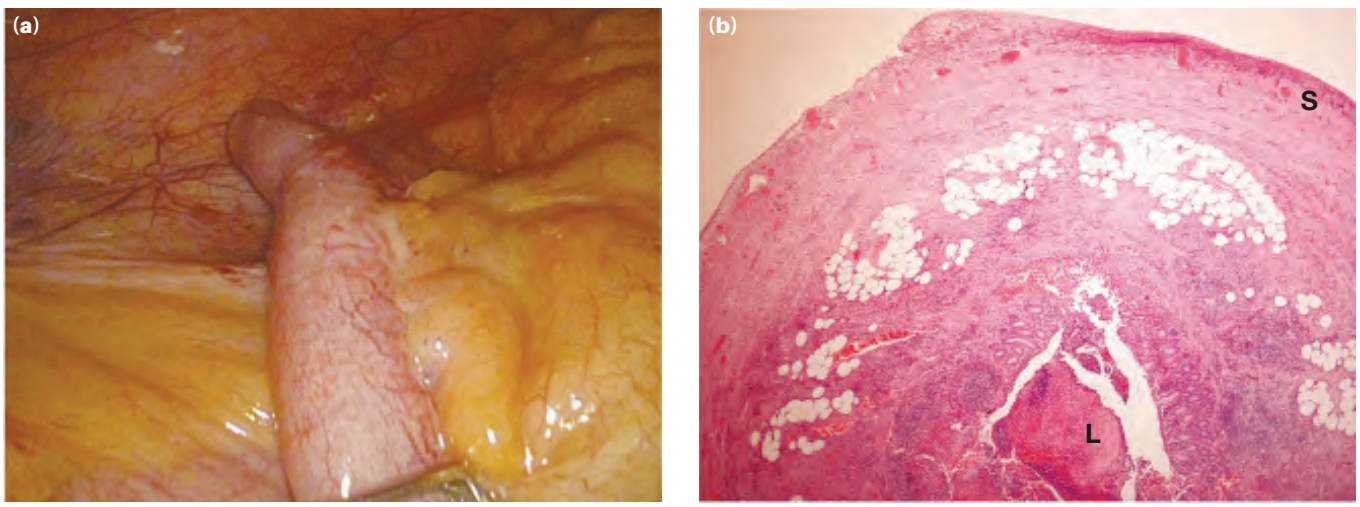

Figure 72.7 Acutely inflammed appendix with purulent exudate extending to the mesoappendix in a 28-year-old male as seen at laparoscopy (a) and a photomicrograph (original magnification ×20) from the same patient showing the appendix with pus-filled lumen (L) and inflammation extending to inflamed serosa (S) (courtesy of Professor C O'Keane, FFPath, FRCPI, Dublin, Ireland).

the colic of small bowel obstruction. Central abdominal pain is associated with anorexia, nausea and usually one or two episodes of vomiting that follow the onset of pain (Murphy). Anorexia is a useful and constant clinical feature, particularly in children. The patient often gives a history of similar discomfort that settled spontaneously. A family history is also useful as up to one-third of children with appendicitis have a first-degree relative with a similar history.

Summary box 72.2

Symptoms of appendicitis

- Periumbilical colic
- Pain shifting to the right iliac fossa
- Anorexia
- Nausea

With progressive inflammation of the appendix, the parietal peritoneum in the right iliac fossa becomes irritated, producing more intense, constant and localised somatic pain that begins to predominate. Patients often report this as an abdominal pain that has shifted and changed in character. Typically, coughing or sudden movement exacerbates the right iliac fossa pain.

The classic visceral–somatic sequence of pain is present in only about half of those patients subsequently proven to have acute appendicitis. Atypical presentations include pain that is predominantly somatic or visceral and poorly localised. Atypical pain is more common in the elderly, in whom localisation to the right iliac fossa is unusual. An inflamed appendix in the pelvis may never produce somatic pain involving the anterior abdominal wall, but may instead cause suprapubic discomfort and tenesmus. In this circumstance, tenderness may be elicited only on rectal examination and is the basis for the recommendation that a rectal examination should be performed on every patient who presents with acute lower abdominal pain.

During the first 6 hours, there is rarely any alteration in temperature or pulse rate. After that time, slight pyrexia (37.2–37.7°C) with a corresponding increase in the pulse rate to 80 or 90 is usual. However, in 20% of patients there is no pyrexia or tachycardia in the early stages. In children, a temperature greater than 38.5°C suggests other causes (e.g. mesenteric adenitis [see below]).

Typically, two clinical syndromes of acute appendicitis can be discerned, *acute catarrhal* (*non-obstructive*) appendicitis and *acute obstructive* appendicitis, the latter characterised by a more acute course. The onset of symptoms is abrupt and there may be generalised abdominal pain from the start. The temperature may be normal and vomiting is common, so the clinical picture may mimic acute intestinal obstruction.

Signs

The diagnosis of appendicitis rests more on thorough clinical examination of the abdomen than on any aspect of the history or laboratory investigation. The cardinal features are those of an unwell patient with low-grade pyrexia, localised abdominal tenderness, muscle guarding and rebound tenderness. Inspection of the abdomen may show limitation of respiratory movement in the lower abdomen. The patient is then asked to point to where the pain began and where it moved (the pointing sign). Gentle superficial palpation of the abdomen, beginning in the left iliac fossa and moving anticlockwise to the right iliac fossa, will detect muscle guarding over the point of maximum tenderness, classically McBurney's point. Asking the patient to cough or gentle percussion over the site of maximum tenderness will elicit rebound tenderness.

Summary box 72.3

Clinical signs in appendicitis

- Pyrexia
- Localised tenderness in the right iliac fossa
- Muscle guarding
- Rebound tenderness

Deep palpation of the left iliac fossa may cause pain in the right iliac fossa, Rovsing's sign, which is helpful in supporting a clinical diagnosis of appendicitis. Occasionally, an inflamed appendix lies on the psoas muscle, and the patient, often a young adult, will lie with the right hip flexed for pain relief (the psoas sign). Spasm of the obturator internus is sometimes demonstrable when the hip is flexed and internally rotated. If an inflamed appendix is in contact with the obturator internus, this manoeuvre will cause pain in the hypogastrium (the obturator test; Zachary Cope). Cutaneous hyperaesthesia may be demonstrable in the right iliac fossa, but is rarely of diagnostic value.

Summary box 72.4

Signs to elicit in appendicitis

- Pointing sign
- Rovsing's sign
- Psoas sign
- Obturator sign

John Benjamin Murphy, 1857–1916, Professor of Surgery, Northwestern University, Chicago, IL, USA.
Neils Thorkild Rovsing, 1862–1937, Professor of Surgery, Copenhagen, Denmark.
Sir Vincent Zachary Cope, 1881–1975, surgeon, St. Mary's Hospital, London, UK.

Special features, according to position of the appendix

Retrocaecal

Rigidity is often absent, and even application of deep pressure may fail to elicit tenderness (silent appendix), the reason being that the caecum, distended with gas, prevents the pressure exerted by the hand from reaching the inflamed structure. However, deep tenderness is often present in the loin, and rigidity of the quadratus lumborum may be in evidence. Psoas spasm, due to the inflamed appendix being in contact with that muscle, may be sufficient to cause flexion of the hip joint. Hyperextension of the hip joint may induce abdominal pain when the degree of psoas spasm is insufficient to cause flexion of the hip.

Pelvic

Occasionally, early diarrhoea results from an inflamed appendix being in contact with the rectum. When the appendix lies entirely within the pelvis, there is usually complete absence of abdominal rigidity, and often tenderness over McBurney's point is also lacking. In some instances, deep tenderness can be made out just above and to the right of the symphysis pubis. In either event, a rectal examination reveals tenderness in the rectovesical pouch or the pouch of Douglas, especially on the right side. Spasm of the psoas and obturator internus muscles may be present when the appendix is in this position. An inflamed appendix in contact with the bladder may cause frequency of micturition. This is more common in children.

Postileal

In this case, the inflamed appendix lies behind the terminal ileum. It presents the greatest difficulty in diagnosis because the pain may not shift, diarrhoea is a feature and marked retching may occur. Tenderness, if any, is ill defined, although it may be present immediately to the right of the umbilicus.

Special features, according to age

Infants

Appendicitis is relatively rare in infants under 36 months of age and, for obvious reasons, the patient is unable to give a history. Because of this, diagnosis is often delayed, and thus the incidence of perforation and postoperative morbidity is considerably higher than in older children. Diffuse peritonitis can develop rapidly because of the underdeveloped greater omentum, which is unable to give much assistance in localising the infection.

Children

It is rare to find a child with appendicitis who has not vomited. Children with appendicitis usually have complete aversion to food.

The elderly

Gangrene and perforation occur much more frequently in elderly patients. Elderly patients with a lax abdominal wall or obesity may harbour a gangrenous appendix with little evidence of it, and the clinical picture may simulate subacute intestinal obstruction. These features, coupled with coincident medical conditions, produce a much higher mortality for acute appendicitis in the elderly.

The obese

Obesity can obscure and diminish all the local signs of acute appendicitis and the clinician may have to rely on imaging to establish the diagnosis. Laparoscopy is particularly useful in the obese patient as it may obviate the need for a large abdominal incision.

Pregnancy

Appendicitis is the most common extrauterine acute abdominal condition in pregnancy, with a frequency of 1:1500–2000 pregnancies. Diagnosis is complicated by delay in presentation as early non-specific symptoms are often attributed to the pregnancy. Obstetric teaching has been that the caecum and appendix are progressively pushed to the right upper quadrant of the abdomen as pregnancy develops during the second and third trimesters. However, pain in the right lower quadrant of the abdomen remains the cardinal feature of appendicitis in pregnancy. Fetal loss occurs in 3–5% of cases, increasing to 20% if perforation is found at operation.

Differential diagnosis

Although acute appendicitis is the most common abdominal surgical emergency, the diagnosis can be extremely difficult at times. There are a number of common conditions that it is wise to consider carefully and, if possible, exclude. The differential diagnosis differs in patients of different ages; in women, additional differential diagnoses are diseases of the female genital tract (*Table 72.1*).

Children

The diseases most commonly mistaken for acute appendicitis are acute gastroenteritis and mesenteric lymphadenitis. In mesenteric lymphadenitis, the pain is colicky in nature and cervical lymph nodes may be enlarged. It may be impossible to clinically distinguish Meckel's diverticulitis from acute appendicitis. The pain is similar; however, signs may be central or left sided. Occasionally, there is a history of antecedent abdominal pain or intermittent lower gastrointestinal bleeding.

It is important to distinguish between acute appendicitis and intussusception. Appendicitis is uncommon before the age of 2 years, whereas the median age for intussusception is 18 months. A mass may be palpable in the right lower quadrant, and the preferred treatment of intussusception is reduction by careful barium enema.

James Douglas, 1715–1742, anatomist and midwife who practised in London, UK, described this pouch in 1730.
Johann Friedrich Meckel, 1781–1883, Professor of Anatomy and Surgery, Halle, Germany.

TABLE 72.1 Differential diagnosis of acute appendicitis.

Children	Adult	Adult female	Elderly
Gastroenteritis	Regional enteritis	Mittelschmerz	Diverticulitis
Mesenteric adenitis	Ureteric colic	Pelvic inflammatory disease	Intestinal obstruction
Meckel's diverticulitis	Perforated peptic ulcer	Pyelonephritis	Colonic carcinoma
Intussusception	Torsion of testis	Ectopic pregnancy	Torsion appendix epiploicae
Henoch–Schönlein purpura	Pancreatitis	Torsion/rupture of ovarian cyst	Mesenteric infarction
Lobar pneumonia	Rectus sheath haematoma	Endometriosis	Leaking aortic aneurysm

Henoch–Schönlein purpura is often preceded by a sore throat or respiratory infection. Abdominal pain can be severe and can be confused with intussusception or appendicitis. There is nearly always an ecchymotic rash, typically affecting the extensor surfaces of the limbs and on the buttocks. The face is usually spared. The platelet count and bleeding time are within normal limits. Microscopic haematuria is common.

Lobar pneumonia and pleurisy, especially at the right base, may give rise to right-sided abdominal pain and mimic appendicitis. Abdominal tenderness is minimal, pyrexia is marked and chest examination may reveal a pleural friction rub or altered breath sounds on auscultation. A chest radiograph is diagnostic.

Adults

Terminal ileitis in its acute form may be clinically indistinguishable from acute appendicitis unless a doughy mass of inflamed ileum can be felt. An antecedent history of abdominal cramping, weight loss and diarrhoea suggests regional ileitis rather than appendicitis. The ileitis may be non-specific, due to Crohn's disease (**Figure 72.8**) or *Yersinia* infection. *Yersinia enterocolitica* causes inflammation of the terminal ileum, appendix and caecum with mesenteric adenopathy. If suspected, serum antibody titres are diagnostic, and treatment with intravenous tetracycline is appropriate. If *Yersinia* infection is suspected at operation, a mesenteric lymph node should be excised and divided, with half submitted for microbiological culture (including tuberculosis) and half for histological examination.

Ureteric colic does not commonly cause diagnostic difficulty, as the character and radiation of pain differs from that of appendicitis. Urinalysis should always be performed, and the presence of red cells should prompt a supine abdominal radiograph. Renal ultrasound or intravenous urogram is diagnostic.

Right-sided acute pyelonephritis is accompanied and often preceded by increased frequency of micturition. It may cause difficulty in diagnosis, especially in women. The leading features are tenderness confined to the loin, fever (temperature 39°C) and possibly rigors and pyuria.

In perforated peptic ulcer, the duodenal contents pass along the paracolic gutter to the right iliac fossa. As a rule, there is a history of dyspepsia and a very sudden onset of pain that starts in the epigastrium and passes down the right paracolic gutter. In appendicitis, the pain starts classically in the umbilical region. Rigidity and tenderness in the right iliac fossa are present in both conditions but, in perforated duodenal ulcer, the rigidity is usually greater in the right hypochondrium. An erect chest radiograph will show gas under the diaphragm in 70% of patients. An abdominal computed tomography (CT) examination is valuable when there is diagnostic difficulty.

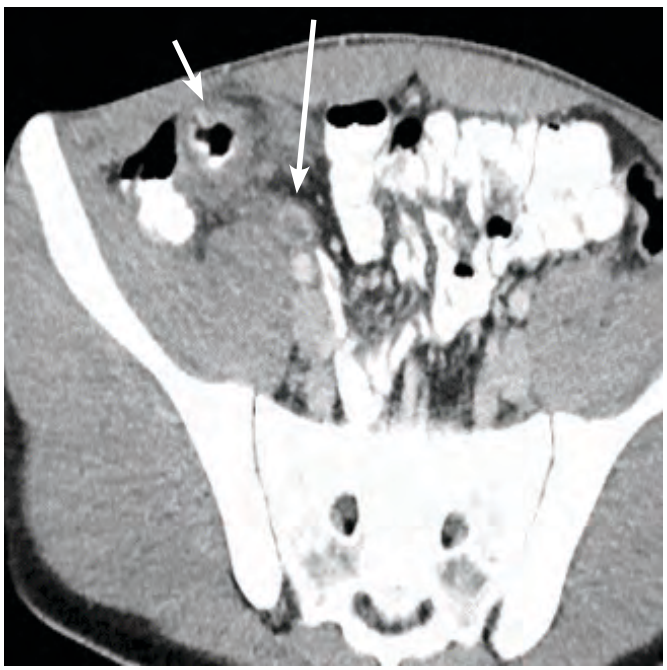

Figure 72.8 First presentation in a 19-year-old male with terminal ileitis, later confirmed to be Crohn's disease. Short arrow demonstrates abnormally thickened and inflamed terminal ileum. Long arrow indicates wall enhancement and enlargement of the appendix, indicating secondary acute appendicitis (courtesy of Dr P MacMahon, FRCR, Dublin, Ireland).

Eduard Heinrich Henoch, 1820–1910, Professor of Diseases of Children, Berlin, Germany, described this form of purpura in 1868.
Johann Lucas Schönlein, 1793–1864, Professor of Medicine, Berlin, Germany, described this form of purpura in 1837.
Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.
Alexandre Emile Yersin, 1863–1943, bacteriologist, Paris, France.

Testicular torsion in a teenage or young adult male is easily missed. Pain can be referred to the right iliac fossa, and shyness on the part of the patient may lead the unwary to suspect appendicitis unless the scrotum is examined in all cases.

Acute pancreatitis should be considered in the differential diagnosis of all adults suspected of having acute appendicitis and, when appropriate, should be excluded by serum or urinary amylase measurement.

Rectus sheath haematoma is a relatively rare but easily missed differential diagnosis. It usually presents with acute pain and localised tenderness in the right iliac fossa, often after an episode of strenuous physical exercise. Localised pain without gastrointestinal upset is the rule. Occasionally, in an elderly patient, particularly one taking anticoagulant therapy, a rectus sheath haematoma may present as a mass and tenderness in the right iliac fossa after minor trauma.

Adult female

It is in women of childbearing age that pelvic disease most often mimics acute appendicitis. A careful gynaecological history should be taken in all women with suspected appendicitis, concentrating on menstrual cycle, vaginal discharge and possible pregnancy. The most common diagnostic mimics are pelvic inflammatory disease (PID), Mittelschmerz, torsion or haemorrhage of an ovarian cyst and ectopic pregnancy.

PELVIC INFLAMMATORY DISEASE

PID comprises a spectrum of diseases that include salpingitis, endometritis and tubo-ovarian sepsis. The incidence of these conditions is increasing, and the diagnosis should be considered in every young adult female. Typically, the pain is lower than in appendicitis and is bilateral. A history of vaginal discharge, dysmenorrhoea and burning pain on micturition is a helpful differential diagnostic point. The physical findings include adenexal and cervical tenderness on vaginal examination. When suspected, a high vaginal swab should be taken for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* culture, and the opinion of a gynaecologist should be obtained. Treatment is usually a combination of ofloxacin and metronidazole for 14 days. Transvaginal ultrasound can be particularly helpful in establishing the diagnosis. When serious diagnostic uncertainty persists, diagnostic laparoscopy should be undertaken.

MITTELSCHMERZ

Midcycle rupture of a follicular cyst with bleeding produces lower abdominal and pelvic pain, typically midcycle. Systemic upset is rare, a pregnancy test is negative and symptoms usually subside within hours. Occasionally, diagnostic laparoscopy is required. Retrograde menstruation may cause similar symptoms.

TORSION/HAEMORRHAGE OF AN OVARIAN CYST

This can prove a difficult differential diagnosis. When suspected, pelvic ultrasound and a gynaecological opinion should be sought. If encountered at operation, untwisting of the involved adnexa and ovarian cystectomy should be performed, if necessary, in women of childbearing years. Documented visualisation of the contralateral ovary is an essential medico-legal precaution prior to oophorectomy for any reason.

ECTOPIC PREGNANCY

It is unlikely that a ruptured ectopic pregnancy, with its well-defined signs of haemoperitoneum, will be mistaken for acute appendicitis, but the same cannot be said for a right-sided tubal abortion or, still more, for a right-sided unruptured tubal pregnancy. In the latter, the signs are very similar to those of acute appendicitis except that the pain commences on the right side and stays there. The pain is severe and continues unabated until operation. Usually, there is a history of a missed menstrual period, and a urinary pregnancy test may be positive. Severe pain is felt when the cervix is moved on vaginal examination. Signs of intraperitoneal bleeding usually become apparent, and the patient should be questioned specifically regarding referred pain in the shoulder. Pelvic ultrasonography should be carried out in all cases in which an ectopic pregnancy is a possible diagnosis.

Elderly

DIVERTICULITIS

In some patients with a long sigmoid loop, the colon lies to the right of the midline and it may be impossible to differentiate between diverticulitis and appendicitis. Abdominal CT scanning is particularly useful in this setting and should be considered in the management of all patients over the age of 60 years. A trial of conservative management with intravenous fluids and antibiotics is often appropriate, with a low threshold for laparoscopy or exploratory laparotomy in the face of deterioration or lack of clinical response. Right-sided diverticulitis is unusual and may be clinically indistinguishable from appendicitis. Abdominal CT scanning is particularly useful in making the distinction. As with left-sided diverticulatis, treament should be conservative with intravenous antibiotics with recourse to laparoscopy or laparotomy in the face of clinical deterioration

INTESTINAL OBSTRUCTION

The diagnosis of intestinal obstruction is usually clear; the subtlety lies in recognising acute appendicitis as the occasional cause in the elderly. As with diverticulitis, intravenous fluids, antibiotics and nasogastric decompression should be instigated, with early resort to laparotomy.

CARCINOMA OF THE CAECUM

When obstructed or locally perforated, carcinoma of the caecum may mimic or cause obstructive appendicitis in adults. A history of antecedent discomfort, altered bowel habit or unexplained anaemia should raise suspicion. A mass may be palpable (see below) and an abdominal CT scan diagnostic.

Rare differential diagnoses

Preherpetic pain of the right 10th and 11th dorsal nerves is localised over the same area as that of appendicitis. It does not shift and is associated with marked hyperaesthesia. There is no intestinal upset or rigidity. The herpetic eruption may be delayed for 3–8 hours.

Tabetic crises are now rare. Severe abdominal pain and vomiting usher in the crisis. Other signs of tabes confirm the diagnosis.

Spinal conditions are sometimes associated with acute abdominal pain, especially in children and the elderly. These may include tuberculosis of the spine, metastatic carcinoma, osteoporotic vertebral collapse and multiple myeloma. The pain is due to compression of nerve roots and may be aggravated by movement. There is rigidity of the lumbar spine and intestinal symptoms are absent.

The abdominal crises of porphyria and diabetes mellitus need to be remembered. A urinalysis should be undertaken in every abdominal emergency. In cyclical vomiting of infants or young children, there is a history of previous similar attacks and abdominal rigidity is absent. Acetone is found in the urine but is not diagnostic as it may accompany starvation.

Typhlitis or leukaemic ileocaecal syndrome is a rare but potentially fatal enterocolitis occurring in immunosuppressed patients. Gram-negative or clostridial (especially *Clostridium septicum*) septicaemia can be rapidly progressive. Treatment is with appropriate antibiotics and haematopoietic factors. Surgical intervention is rarely indicated.

Investigation

The diagnosis of acute appendicitis is essentially clinical; however, a decision to operate based on clinical suspicion alone can lead to the removal of a normal appendix in 15–30% of cases. The premise that it is better to remove a normal appendix than to delay diagnosis does not stand up to close scrutiny, particularly in the elderly. A number of clinical and laboratory-based scoring systems have been devised to assist diagnosis. The most widely used is the Alvarado score (*Table 72.2*). A score of 7 or more is strongly predictive of acute appendicitis.

In patients with an equivocal score (5–6), abdominal ultrasound or contrast-enhanced CT examination further reduces the rate of negative appendicectomy. Abdominal ultrasound examination is more useful in children and thin adults, particularly if gynaecological pathology is suspected, with a diagnostic accuracy in excess of 90% (**Figure 72.9**). Modern CT is both sensitive and specific (approximately 95%) in the diagnosis of acute appendicitis (**Figure 72.10**) and worldwide there has been a steady increase in its use for this purpose. In the United States, for example, the majority of patients will undergo CT prior to surgery. CT has been shown to reduce the rate of negative appendicectomy without an associated increased perforation rate (due to delay in diagnosis) and may be cost-effective due to shorter hospital stay. While the diagnostic accuracy of modern CT scanning for appendicitis is well established, radiation exposure and the theoretical carcinogenic effect are a concern. Low-dose protocols, which reduce the radiation dose to the patient by up to 80%, can be as reliable as standard dose scanning and may be more appropriately applied when considering a diagnosis of acute appendicitis, particularly in the younger adult (Kim).

Contrast-enhanced standard dose CT is especially useful in patients in whom there is diagnostic uncertainty, particularly older patients, where acute diverticulitis, intestinal obstruction and neoplasm are likely differential diagnoses.

Summary box 72.5

Preoperative investigations in appendicitis

- Routine
  - Full blood count
  - Urinalysis
- Selective
  - Pregnancy test
  - Urea and electrolytes
  - Supine abdominal radiograph
  - Ultrasound of the abdomen/pelvis
  - Contrast-enhanced abdomen and pelvic computed tomography scan
  - Consider low-dose protocol in young adults

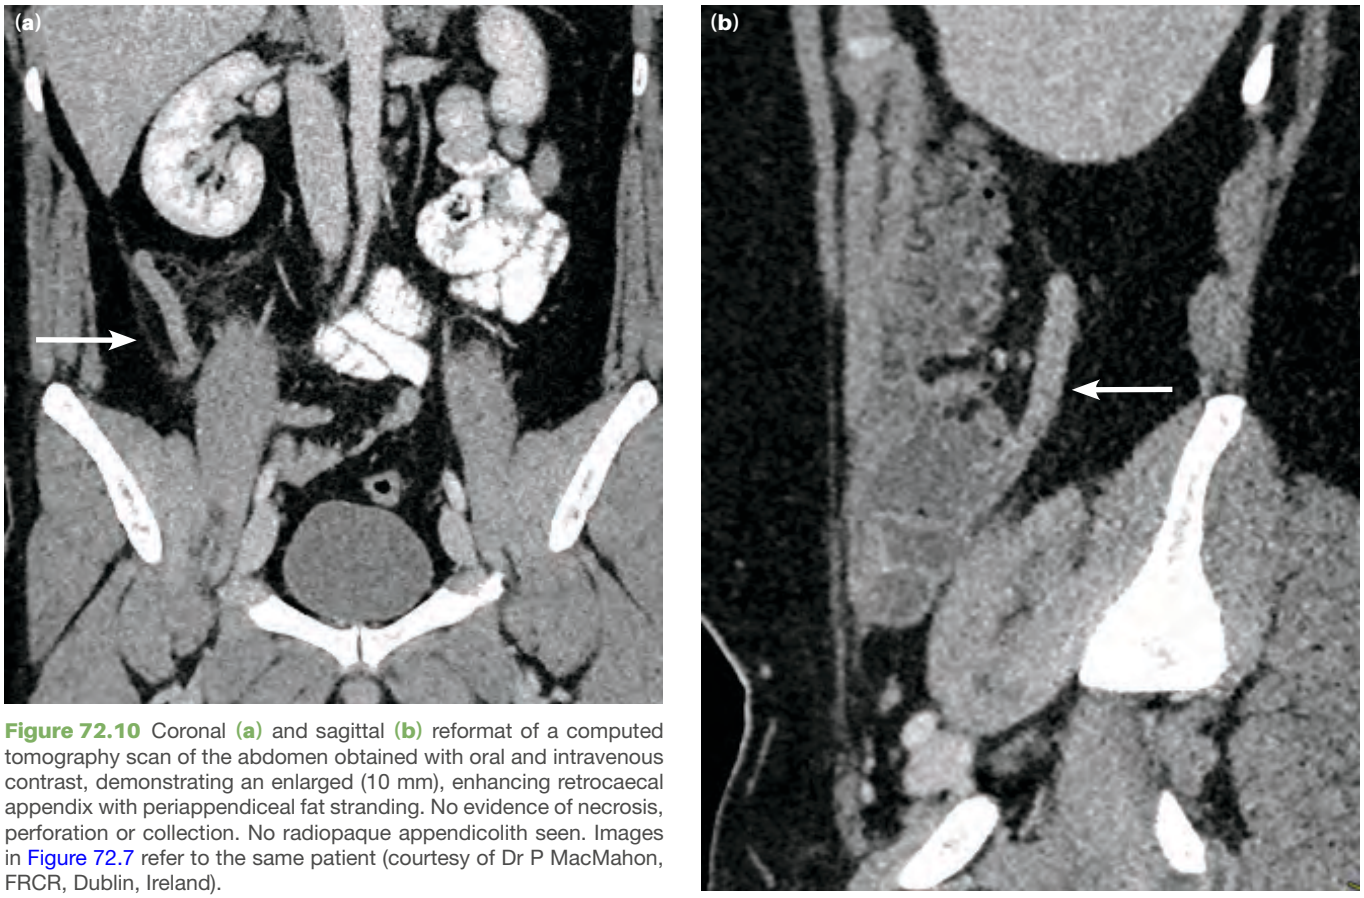

Figure 72.10 Coronal **(a)** and sagittal **(b)** reformat of a computed tomography scan of the abdomen obtained with oral and intravenous contrast, demonstrating an enlarged (10 mm), enhancing retrocaecal appendix with periappendiceal fat stranding. No evidence of necrosis, perforation or collection. No radiopaque appendicolith seen. Images in Figure 72.7 refer to the same patient (courtesy of Dr P MacMahon, FRCR, Dublin, Ireland).

Treatment

Non-operative management

While surgery remains the standard teaching, there is an emerging body of literature to support a trial of conservative mangement in patients with uncomplicated (absence of appendicolith, perforation or abscess) appendicitis. Treatment is bowel rest and intravenous antibiotics, often metronidazole and 3rd generation cephalosprin. More recently, ertapenem has been used in this setting and has the benefit of broad antimicrobial cover administered as a single daily dose. The available data indicate initial successful outcomes in more than 90% of patients with CT confirmed appendicitis; however, approximately one-quarter of patients initially treated conservatively will require surgery within 1 year for recurrent appendicitis (Salminen). Subsequent surgery, if needed, tends to be uncomplicated. This approach may be considered in the well patient with limited signs or those with high operative risk (multiple co-morbidities). As with conservative treatment of an appendix mass, patients over the age of 40 should be followed up to ensure there is no underlying malignancy (see below).

Operative management

The traditional treatment for acute appendicitis is appendicectomy. While there should be no unnecessary delay, all patients, particularly those most at risk of serious morbidity, benefit by a short period of intensive preoperative preparation. Intravenous fluids, sufficient to establish adequate urine output (catheterisation is needed only in the very ill), and appropriate antibiotics should be given. There is ample evidence that in the absence of purulent peritonitis, a single peroperative dose of antibiotics reduces the incidence of postoperative wound infection. When peritonitis is suspected, therapeutic intravenous antibiotics to cover gram-negative bacilli as well as anaerobic cocci should be given. Hyperpyrexia in children should be treated with salicylates in addition to antibiotics and intravenous fluids. With appropriate use of intravenous fluids and parenteral antibiotics, a policy of deferring appendicectomy after midnight to the first case on the following morning does not increase morbidity. However, when acute obstructive appendicitis is recognised, operation should not be deferred longer than it takes to optimise the patient's condition.

Appendicectomy

Claudius Amyand successfully removed an acutely inflamed appendix from the hernial sac of a boy in 1736. The first surgeon to perform deliberate appendicectomy for acute appendicitis was Lawson Tait in May 1880. The patient recovered; however, the case was not reported until 1890. Meanwhile,

Claudius Amyand, 1685–1740, surgeon, St. George's Hospital, London, UK.
Robert Lawson Tait, 1845–1899, surgeon, The Hospital for Diseases of Women, Birmingham, UK.

Thomas Morton was the first to diagnose appendicitis, drain the abscess and remove the appendix with recovery, publishing his findings in 1887.

Appendicectomy should be performed under general anaesthetic with the patient supine on the operating table and may be undertaken using either an open or laparoscopic approach. When the appropriate equipment and expertise are available and cost allows, the laparoscopic approach is advantageous. The initial laparoscopy allows the diagnosis to be established and may reduce the negative appendicectomy rate. Furthermore, the patient may benefit from the quicker recovery afforded by a minimally invasive approach, the rate of wound infection is lower (when compared with open surgery) and, contrary to initial concerns, the incidence of postoperative pelvic collection does not appear to be increased (van Rossem). There remains much variability in the operative approach to appendicitis. In the United Kingdom, for example, despite the widespread familiarity with and availability of laparoscopy, an initial laparoscopic approach is performed in only two-thirds of patients and the negative appendicectomy rate remains high (20%).

When a laparoscopic technique is used, the bladder must be empty (ensure that the patient has voided before leaving the ward). Prior to preparing the entire abdomen with an appropriate antiseptic solution, the right iliac fossa should be palpated for a mass. If a mass is felt, it may, on occasion, be preferable to adopt a conservative approach (see below). Draping of the abdomen is in accordance with the planned operative technique, taking account of any requirement to extend the incision or convert a laparoscopic technique to an open operation.

CONVENTIONAL APPENDICECTOMY

When the preoperative diagnosis is considered reasonably certain, the incision that is widely used for appendicectomy is the so-called gridiron incision (gridiron: a frame of crossbeams to support a ship during repairs). The gridiron incision (described first by McArthur) is made at right angles to a line joining the anterior superior iliac spine to the umbilicus, its centre being along the line at McBurney's point (**Figure 72.11**). If better access is required, it is possible to convert the gridiron to a Rutherford Morison incision (see below) by cutting the internal oblique and transversus muscles in the line of the incision.

In recent years, a transverse skin crease (Lanz) incision has become more popular, as the exposure is better and extension, when needed, is easier. The incision, appropriate in length to the size and obesity of the patient, is made approximately 2 cm below the umbilicus centred on the mid-clavicular–mid-inguinal line (**Figure 72.12**) When necessary, the incision may be extended medially, with retraction or suitable division of the rectus abdominis muscle.

When the diagnosis is in doubt, particularly in the presence of intestinal obstruction, a lower midline abdominal incision is to be preferred over a right lower paramedian incision. The latter, although widely practised in the past, is difficult to extend, more difficult to close and provides poorer access to the pelvis and peritoneal cavity.

Rutherford Morison's incision is useful if the appendix is para- or retrocaecal and fixed. It is essentially an oblique muscle-cutting incision with its lower end over McBurney's point and extending obliquely upwards and laterally as necessary. All layers are divided in the line of the incision.

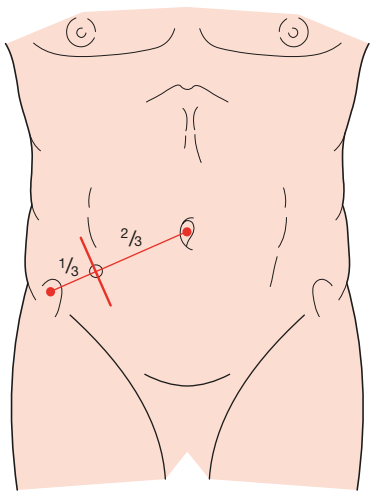

Figure 72.11 Gridiron incision for appendicitis, at right angles to a line joining the anterior superior iliac spine and umbilicus, centred on McBurney's point (courtesy of Professor M Earley, FRSCI, Dublin, Ireland).

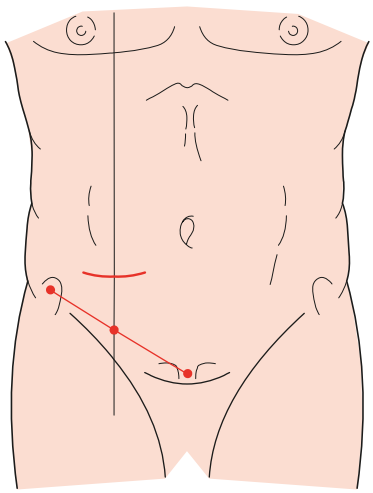

Figure 72.12 Transverse or skin crease (Lanz) incision for appendicitis, 2 cm below the umbilicus, centred on the mid-clavicular–mid-inguinal line (courtesy of Professor M Earley, FRSCI, Dublin, Ireland).

Lewis Linn McArthur, 1858–1934, surgeon, St. Luke's Hospital, Chicago, IL, USA.
James Rutherford Morison, 1853–1939, Professor of Surgery, The University of Durham, Durham, UK.
Otto Lanz, 1865–1935, surgeon, Amsterdam, The Netherlands.

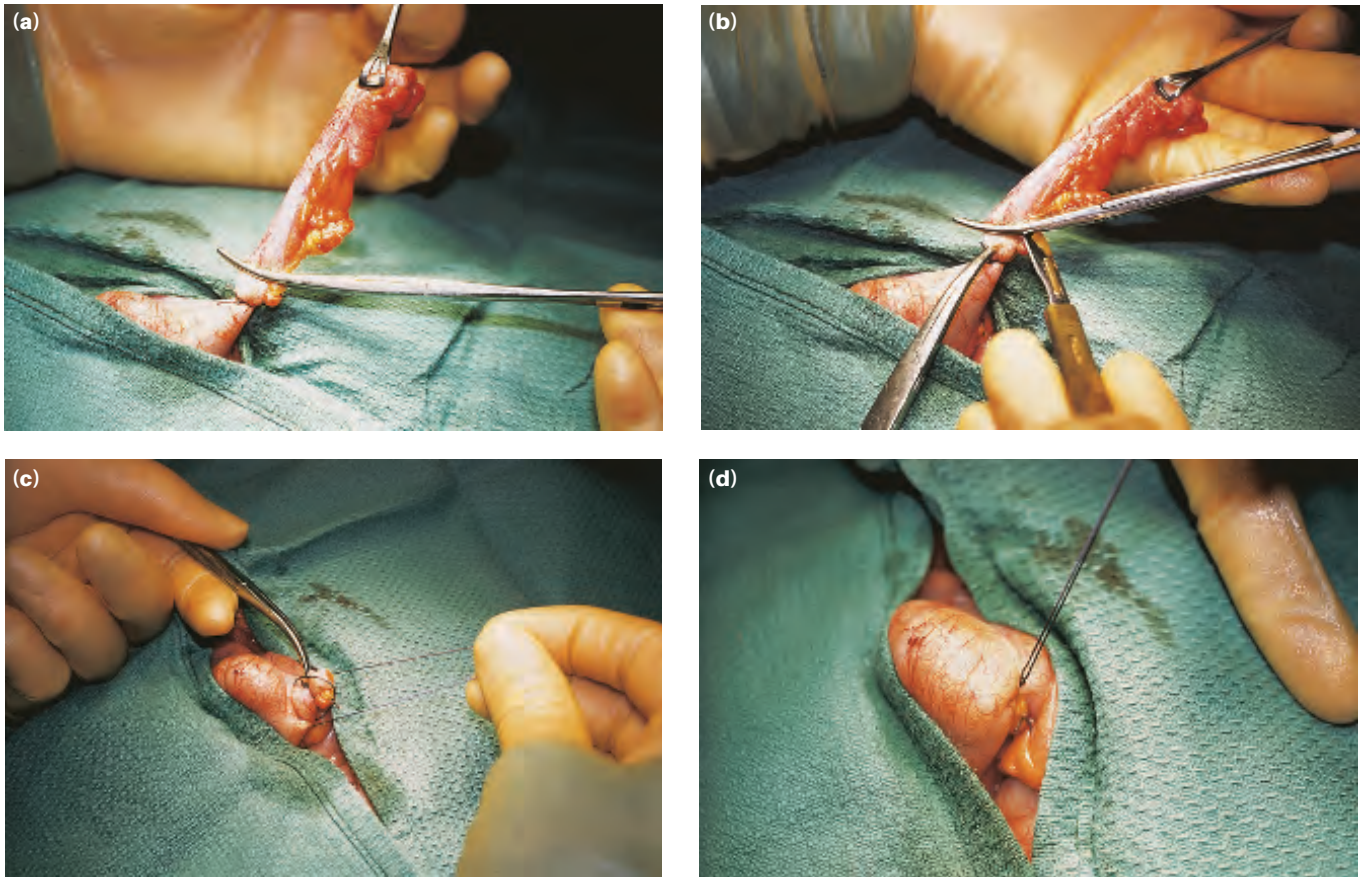

Figure 72.13 Appendicectomy. **(a)** The mesoappendix divided between artery forceps and ligated. **(b)** The appendix crushed and ligated at its base and about to be divided. **(c)** 'Z' suture inserted prior to inversion of the appendiceal stump. **(d)** The appendiceal stump inverted, the 'Z' suture having been tied.

REMOVAL OF THE APPENDIX

The caecum is identified by the presence of taeniae coli and, using a finger or a swab, the caecum is withdrawn. A turgid appendix may be felt at the base of the caecum. Inflammatory adhesions must be gently broken with a finger, which is then hooked around the appendix to deliver it into the wound. The appendix is conveniently controlled using a Babcock or Lane's forceps applied in such a way as to encircle the appendix and yet not damage it. The base of the mesoappendix is clamped in artery forceps, divided and ligated (**Figure 72.13a**). When the mesoappendix is broad, the procedure must be repeated with a second or, rarely, a third artery forceps. The appendix, now completely freed, is crushed near its junction with the caecum in artery forceps, which is removed and reapplied just distal to the crushed portion. An absorbable 2/0 ligature is tied around the crushed portion close to the caecum. The appendix is amputated between the artery forceps and the ligature (**Figure 72.13b**). An absorbable 2/0 or 3/0 purse-string or 'Z' suture may then be inserted into the caecum about 1.25 cm from the base (**Figure 72.13c**). The stitch should pass through the muscle coat, picking up the taeniae coli. The stump of the appendix is invaginated (**Figure 72.13d**) while the purse-string or 'Z' suture is tied, thus burying the appendix stump. Many surgeons believe invagination of the appendiceal stump is unnecessary.

METHODS TO BE ADOPTED IN SPECIAL CIRCUMSTANCES

When the caecal wall is oedematous, the purse-string suture is in danger of cutting out. If the oedema is of limited extent, this can be overcome by inserting the purse-string suture into more healthy caecal wall at a greater distance from the base of the appendix. Occasions may arise when, because of the extensive oedema of the caecal wall, it is better not to attempt invagination.

When the base of the appendix is inflamed, it should not be crushed, but ligated close to the caecal wall just tightly enough to occlude the lumen, after which the appendix is amputated and the stump invaginated. Should the base of the appendix be gangrenous, neither crushing nor ligation should be attempted. Two stitches are placed through the caecal wall close to the base of the gangrenous appendix, which is amputated flush with the caecal wall, after which these stitches are tied. Further closure is effected by means of a second layer of interrupted seromuscular sutures. An alternative but more costly option when the appendix base is compromised is to resect the appendix with a cuff of healthy caecum using a single firing of a linear stapling device.

William Wayne Babcock, 1872–1963, surgeon, Philadelphia, PA, USA.
Sir William Arbuthnot Lane, 1856–1943, surgeon, Guy's Hospital, London, UK.

RETROGRADE APPENDICECTOMY

When the appendix is retrocaecal and adherent, it is an advantage to divide the base between artery forceps. The appendiceal vessels are then ligated, the stump ligated and invaginated, and gentle traction on the caecum will enable the surgeon to deliver the body of the appendix, which is then removed from base to tip. Occasionally, this manoeuvre requires division of the lateral peritoneal attachments of the caecum.

LAPAROSCOPIC APPENDICECTOMY

The most valuable aspect of laparoscopy in the management of suspected appendicitis is as a diagnostic tool, particularly in women of childbearing age. The placement of operating ports may vary according to operator preference and previous abdominal scars. Typically, a pneumoperitoneum is established using an open infraumbilical approach. This umbilical port serves as the camera port with two working ports inserted under direct vision, the first suprapublically and second in the left lower quadrant. An alternative to this standard multiport approach is single incision laparoscopic appendicectomy (SILA) using a single multiple access port inserted at the umbilicus. SILA is associated with longer operating times and has not been shown to offer an advantage with respect to postoperative pain or hospital stay when compared with standard techniques, but may have a superior cosmetic outcome. Irrespective of the approach, the operator stands to the patient's left and faces a screen placed at the patient's right. A moderate Trendelenburg tilt with elevation of the right side of the operating table improves exposure and assists delivery of loops of small bowel from the pelvis. The appendix is found in the conventional manner by identification of the caecal taeniae and is controlled using a laparoscopic tissue-holding forceps. Occassionally, it is necessary to divide the peritoneal attachments and mobilise the caecum in order to adequately expose the appendix. By elevating the appendix, the mesoappendix is then displayed. A dissecting forceps, hook or scissors diathermy is used to dissect the mesoappendix (**Figure 72.14a**) and expose the appendicular vessels, which may be coagulated or ligated using a clip applicator (**Figure 72.14b**). The appendix, free of its mesentery, can be ligated at its base with an absorbable loop ligature (**Figure 72.14c**) or a linear stapling device, divided (**Fig. 72.14d**) and removed in a

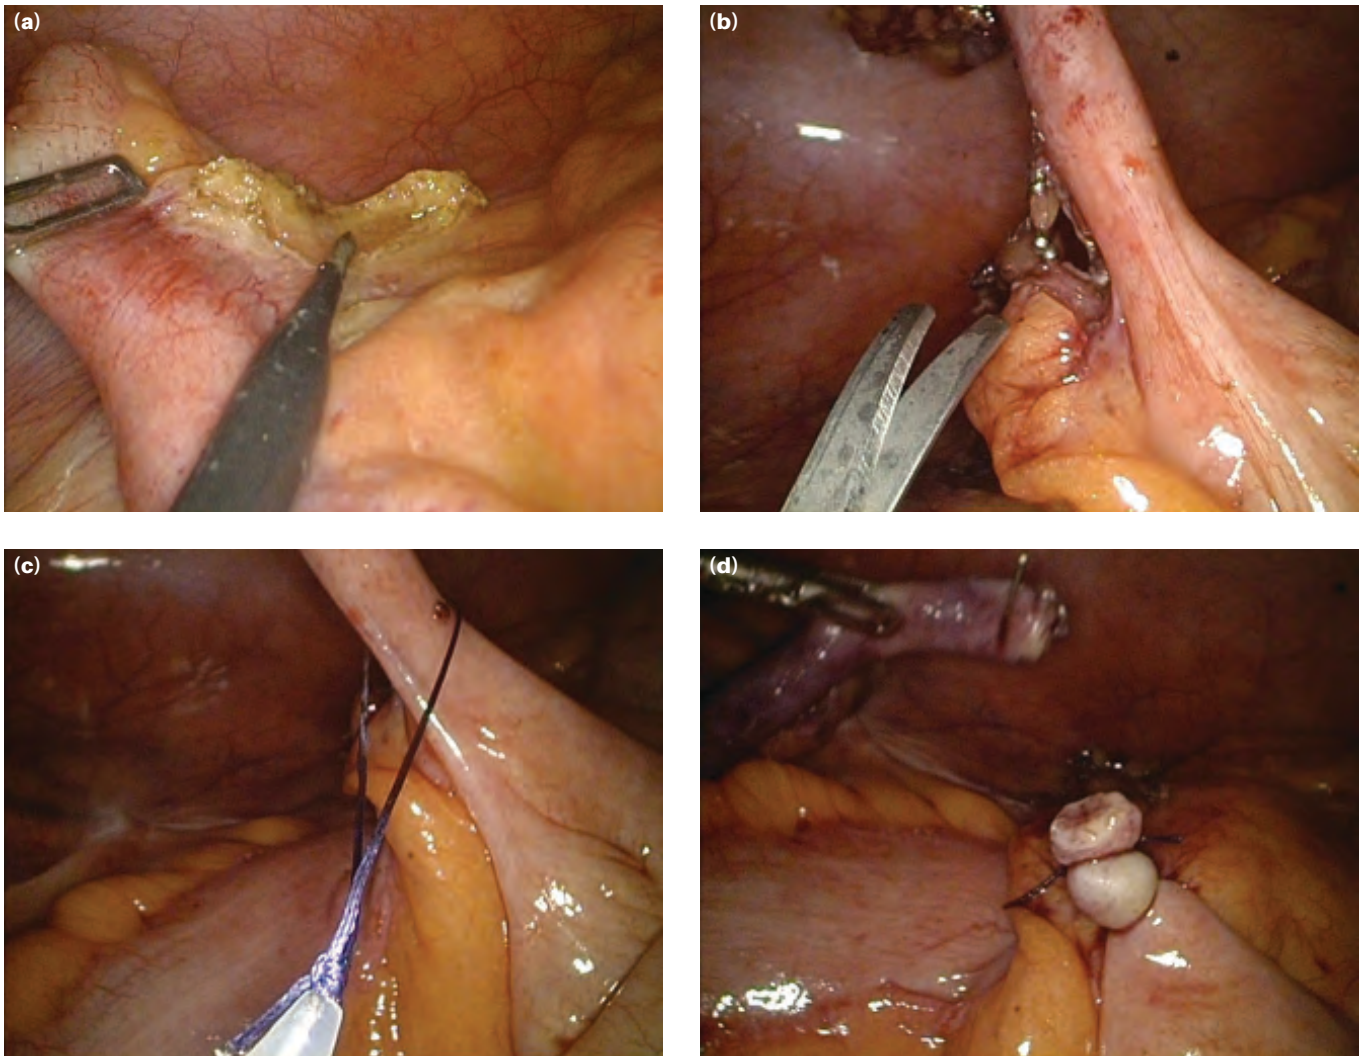

Figure 72.14 Laparoscopic appendicectomy. **(a)** Hook diathermy dissection of the mesoappendix. **(b)** The appendicular artery, ligated with clips, is divided. **(c)** The appendix base is ligated with absorbable ties. **(d)** Appendicectomy complete.

specimen bag through one of the operating ports. It is not usual to invert the stump of the appendix. Absorbable sutures are used to close the fascia at the umbilicus and at any port sites greater than 5 mm, and the small skin incisions may be closed with subcuticular sutures.

Problems encountered during appendicectomy

A NORMAL APPENDIX IS FOUND

This demands careful exclusion of other possible diagnoses, particularly terminal ileitis, Meckel's diverticulitis and tubal or ovarian causes in women. It is usual to remove the appendix to avoid future diagnostic difficulties, even though the appendix is macroscopically normal, particularly if a skin crease or gridiron incision has been made. A case can be made for preserving the macroscopically normal appendix seen at diagnostic laparoscopy, although approximately one-quarter of seemingly normal appendices show microscopic evidence of inflammation.

THE APPENDIX CANNOT BE FOUND

The caecum should be mobilised, and the taeniae coli should be traced to their confluence on the caecum before the diagnosis of 'absent appendix' is made.

AN APPENDICULAR TUMOUR IS FOUND

Small tumours (under 2.0 cm in diameter) can be removed by appendicectomy; larger tumours should be treated by a right hemicolectomy (see below).

AN APPENDIX ABSCESS IS FOUND AND THE APPENDIX CANNOT BE REMOVED EASILY

This eventuality is rare in the era of modern diagnositic imaging. Percutaneous drainage of the abscess and intravenous antibiotic treatment is to be preferred. If found at operation, the abscess should be drained and intravenous antibiotics administered. Very rarely in the face of a frankly necrotic appendix, a caecectomy or partial right hemicolectomy is required. (The first recorded operation for an appendix abscess was by Henry Hancock of Charing Cross Hospital, London, in 1848.)

Appendicitis complicating Crohn's disease

Occasionally, a patient undergoing surgery for acute appendicitis is found to have concomitant Crohn's disease of the ileocaecal region. Providing that the caecal wall is healthy at the base of the appendix, appendicectomy can be performed without increasing the risk of an enterocutaneous fistula. Rarely, the appendix is involved with the Crohn's disease. In this situation, a conservative approach may be warranted, and a trial of intravenous corticosteroids and systemic antibiotics can be used to resolve the acute inflammatory process.

Appendix abscess

Failure of resolution of an appendix mass or continued spiking pyrexia usually indicates that there is pus within the phlegmonous appendix mass. Ultrasound or abdominal CT scan may identify an area suitable for the insertion of a percutaneous drain. Rarely this is unsuccessful and laparotomy though a midline incision is indicated.

Pelvic abscess

Pelvic abscess formation is an occasional complication of appendicitis and can occur irrespective of the position of the appendix within the peritoneal cavity. The most common presentation is a spiking pyrexia several days after appendicitis; indeed, the patient may already have been discharged from hospital. Pelvic pressure or discomfort associated with loose stool or tenesmus is common. Rectal examination reveals a boggy mass in the pelvis, anterior to the rectum, at the level of the peritoneal reflection. Pelvic ultrasound or CT scan will confirm. Traditionally, treatment has been through transrectal drainage under general anaesthetic; however, increasing availablity of radiologically guided percutaneous drainage has reduced the need considerably.

Management of an appendix mass

If an appendix mass is present and the condition of the patient is satisfactory, the standard treatment is the conservative Ochsner–Sherren regime. This strategy is based on the premise that the inflammatory process is already localised and that inadvertent surgery is difficult and may be dangerous. It may be impossible to find the appendix and, occasionally, a faecal fistula may form. For these reasons, it is wise to observe a non-operative programme but to be prepared to operate should clinical deterioration occur.

Summary box 72.6

Criteria for stopping conservative treatment of an appendix mass

- A rising pulse rate
- Increasing or spreading abdominal pain
- Increasing size of the mass

Careful recording of the patient's condition and the extent of the mass should be made and the abdomen regularly re-examined. It is helpful to mark the limits of the mass on the abdominal wall using a skin pencil. A contrast-enhanced CT examination of the abdomen should be performed and antibiotic therapy instigated. An abscess, if present, should be drained radiologically. Temperature and pulse rate should be recorded 4-hourly and a fluid balance record maintained. Clinical deterioration or evidence of peritonitis is an indication for early laparotomy. Clinical improvement is usually evident within 24–48 hours. Failure of the mass to resolve should raise suspicion of a carcinoma or Crohn's disease. Using this regime, approximately 90% of cases resolve without incident. The need for interval appendicectomy in this

Albert John Ochsner, 1858–1925, Professor of Clinical Surgery, The University of Illinois College of Medicine, Chicago, IL, USA.
James Sherren, 1872–1945, surgeon, The London Hospital, London, UK.

cohort is much debated. The great majority of patients will not develop recurrent appendicitis; however; recently published studies have identified higher than expected rates of underlying appendiceal neoplasm in those patients who do go on to interval appendicectomy, particularly those patients over the age of 40. At the very least, follow-up CT should be performed to ensure complete resolution of findings and patients should undergo colonoscopy.

Postoperative complications

Postoperative complications following appendicectomy are relatively uncommon and reflect the degree of peritonitis that was present at the time of operation and intercurrent diseases that may predispose to complications.

Summary box 72.7

Check-list for unwell patient following appendicectomy

- Examine the wound and abdomen for an abscess
- Consider a pelvic abscess and perform a rectal examination
- Examine the lungs – pneumonitis or collapse
- Examine the legs – consider venous thrombosis
- Examine the conjunctivae for an icteric tinge and the liver for enlargement, and enquire whether the patient has had rigors (pylephlebitis)
- Examine the urine for organisms (pyelonephritis)
- Suspect subphrenic abscess

Wound infection

Wound infection is the most common postoperative complication, occurring in 5–10% of all patients. This usually presents with pain and erythema of the wound on the fourth or fifth postoperative day, often soon after hospital discharge. Treatment is by wound drainage and antibiotics when required. The organisms responsible are usually a mixture of gram-negative bacilli and anaerobic bacteria, predominantly *Bacteroides* species and anaerobic streptococci.

Intra-abdominal abscess

Approximately 8% of patients following appendectomy will develop a postoperative intra-abdominal abscess. In an era of hospital discharge 24–48 hours following appendectomy, patients should be advised prior to discharge that a spiking fever, malaise and anorexia developing 5–7 days after operation is suggestive of an intraperitoneal collection and that urgent medical advice should be obtained. Interloop, paracolic, pelvic and subphrenic sites should be considered. Abdominal ultrasonography and CT scanning greatly facilitate diagnosis and allow percutaneous drainage (**Figure 72.15**). Laparotomy should be considered in patients suspected of having intra-abdominal sepsis but in whom imaging fails to show a collection, particularly those with continuing ileus.

Ileus

A period of adynamic ileus is to be expected after appendicectomy, and this may last a number of days following removal of a gangrenous appendix. Ileus persisting for more than 4 or 5 days, particularly in the presence of a fever, is indicative of

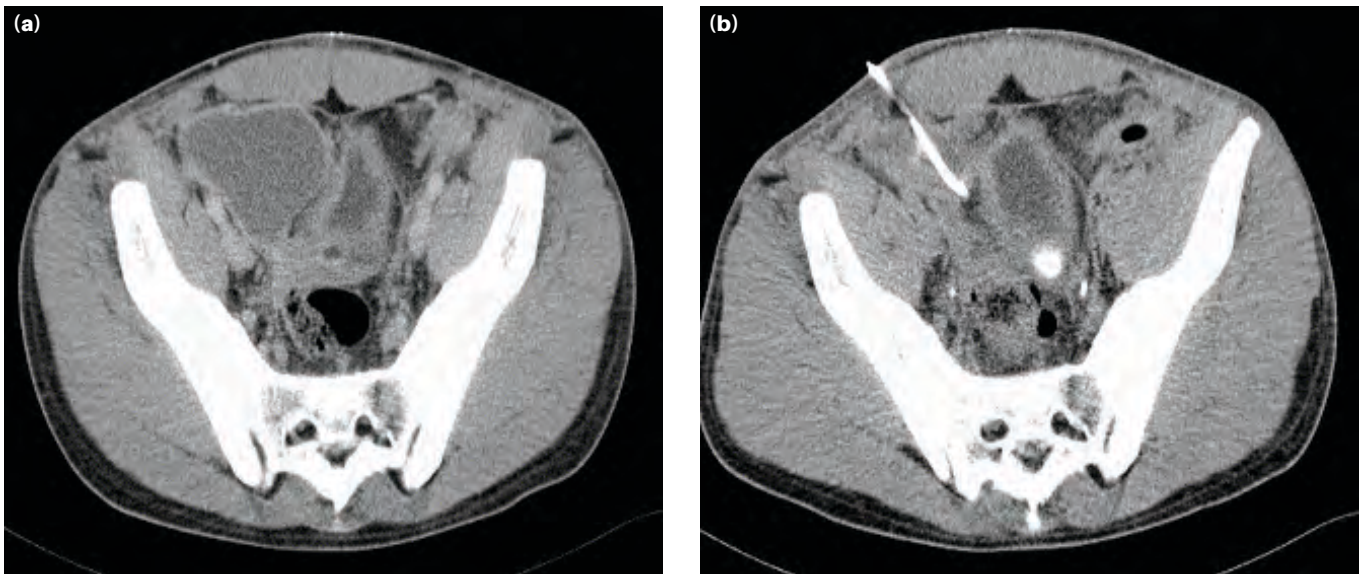

Figure 72.15 **(a)** Rim enhancing collection in the right iliac fossa, 1 week following open appendicectomy for perforated appendicitis. **(b)** Successful radiological drainage with resolution of the abscess (courtesy of Dr P MacMahon, FRCR, Dublin, Ireland).

continuing intra-abdominal sepsis and should prompt further investigation (see above). Rarely, early during postoperative recovery, a Richter's type of hernia may occur at the site of a laparoscopic port insertion and may be confused with a postoperative ileus. A CT scan is usually definitive.

Respiratory

In the absence of concurrent pulmonary disease, respiratory complications are rare following appendicectomy. Adequate postoperative analgesia and physiotherapy, when appropriate, reduce the incidence.

Venous thrombosis and embolism

These conditions are rare after appendicectomy, except in the elderly and in women taking the oral contraceptive pill. Appropriate prophylactic measures should be taken in such cases.

Portal pyaemia (pylephlebitis)

This is a rare but very serious complication of gangrenous appendicitis associated with high fever, rigors and jaundice. It is caused by septicaemia in the portal venous system and leads to the development of intrahepatic abscesses (often multiple). Treatment is with systemic antibiotics and percutaneous drainage of hepatic abscesses as appropriate. A screen for underlying thrombophilia should be considered.

Faecal fistula

Leakage from the appendicular stump occurs rarely, but may follow if the encircling stitch has been put in too deeply or if the caecal wall was involved by oedema or inflammation. Occasionally, a fistula may result following appendicectomy in Crohn's disease.

Figure 72.16 Axial computed tomography in a 20-year-old male with recurrent lower abdominal pain, demonstrating some fatty submucosal deposition in a thickened mildly enlarged appendix but without surrounding inflammatory change (arrow), findings suggestive of chronic appendicitis (courtesy of Dr P MacMahon, FRCR, Dublin, Ireland).

Adhesive intestinal obstruction

This is the most common late complication of appendicectomy. At operation, a single band adhesion is often found to be responsible. Occasionally, chronic pain in the right iliac fossa is attributed to adhesion formation after appendicectomy. In such cases, laparoscopy is of value in confirming the presence of adhesions and allowing division.

RECURRENT ACUTE APPENDICITIS

Rarely, inflammation of the appendix may present as a chronic condition characterised by recurrent episodes of lower abdominal pain. Recurrent appendicitis is thought to arise as a consequence of incomplete self-limiting obstruction of the appendix lumen (**Figure 72.16**). The attacks vary in intensity and may occur every few months, and the majority of cases ultimately culminate in severe acute appendicitis. If a careful history is taken from patients with acute appendicitis, many remember having had milder but similar attacks of pain. The appendix in these cases is thickened and shows fibrosis indicative of previous inflammation (**Figure 72.17**).

NEOPLASMS OF THE APPENDIX AND PSEUDOMYXOMA PERITONEI

Neoplasms of the appendix are found in 1% of appendicectomy specimens, with the vast majority being an incidental finding. Most tumours involving the appendix may be classified as either carcinoid or epithelial, with the latter group accounting for approximately three-quarters of all cases.

Figure 72.17 Excised appendix showing the point of luminal obstruction with distal fibrosis.

August Gottlieb Richter, 1742–1812, lecturer in Surgery, Göttingen, Germany.

Carcinoid tumour (synonym: argentaffinoma):

Carcinoid tumours arise in argentaffin tissue (Kulchitsky cells of the crypts of Lieberkühn) and are most common in the vermiform appendix. Carcinoid tumour is found once in every 300–400 appendices subjected to histological examination. In many instances, the appendix had been removed because of symptoms of subacute or recurrent appendicitis. The tumour can occur in any part of the appendix, but it is frequently found in the distal third. The neoplasm feels moderately hard and, on sectioning the appendix, it can be seen as a yellow tumour between the intact mucosa and the peritoneum. Microscopically, the tumour cells are small, arranged in small nests within the muscle and have a characteristic pattern using immunohistochemical stain for chromogranin B (**Figure 72.18**). Unlike carcinoid tumours arising in other parts of the intestinal tract, carcinoid tumour of the appendix rarely gives rise to metastases.

Treatment

Appendicectomy has been shown to be sufficient treatment unless the caecal wall is involved, the tumour is 2 cm or more in size or involved lymph nodes are found, when right hemicolectomy is indicated.

Epithelial tumours of the appendix:

Epithelial neoplasms are found in 0.6% of appendicectomy specimens. Numerous classifications systems have been proposed leading to much confusion and difficulty when comparing treatment modalities and outcomes. Recently, following a modified Delphi consultation process, a group of international experts proposed an updated classification system for appendiceal epithelial neoplasms (Carr). Tumours may be classified as mucinous or non-mucinous (intestinal type) and according to the degree of cytologic atypia and architectural features (infiltrative versus pushing invasion) (*Table 72.3*). Goblet cell carcinoid, a rare tumour of the appendix, which shows both gland forming and neuroendocrine features, has now been reclassified as goblet cell tumour and may be of a mucinous or non-mucinous subtype. The relevance of appendiceal epithelial tumours, particularly when of the mucinous subtype (**Figure 72.19**), lies in their propensity to disseminate causing the syndrome known as pseudomyxoma peritonei (PMP).

Figure 72.19 Low-grade appendiceal mucinous neoplasm with mucoceole formation that had redistributed causing secondary low-grade mucinous carcinoma peritonei, mainly of the ovary.

Johann Nathaniel Lieberkühn, 1711–1756, physician and anatomist, Berlin, Germany, described these glands in 1745.

Pseudomyxoma peritonei

PMP is a rare condition typified by progressive peritoneal tumour deposits, mucinous ascites, omental cake and ovarian involvement in females (**Figure 72.20**). The vast majority of cases arise as a result of perforation of a mucinous appendiceal tumour. This association was first described by Fraenkel in 1901. Patients typically present with progressive and massive abdominal distension, anorexia and symptoms of bowel dysfunction. The condition is invariably fatal without intervention. Traditionally, PMP was thought to have an incidence of one per million per year, but it is now thought to be at least double that. The overall risk of developing pseudomyxoma following removal of an appendix harbouring epithelial tumour is approximately 9%, with the risk varying according to the tumour subtype and the mode of presentation. Following removal of a non-mucinous neoplasm the risk of PMP is as low as 3%, while it may be as high as 30–50% in the case of a mucinous adenocarcinoma of the appendix. PMP is classified according to the degree of cytological atypia within the peritoneal deposits (*Table 72.4*) and its grading may differ from that of the causative appendiceal tumour.

TABLE 72.4 Classification of pseudomyxoma peritonei (adapted from Carr *et al*., 2016).

Acellular mucin
Low-grade mucinous carcinoma peritonei
High-grade mucinous carcinoma peritonei
High-grade mucinous carcinoma peritonei with signet ring cells

TREATMENT – APPENDICEAL EPITHELIAL TUMOUR WITHOUT PMP

In patients with an incidental finding of an epithelial neoplasm and no current evidence of established PMP, subsequent treatment is dependent on the degree of cytological atypia within the primary tumour and the estimated future risk of developing PMP.

Patients with low-grade epithelial neoplasms and no evidence of mucin or epithelial cells beyond the appendix are thought to be at low, but not negligible, risk of future PMP development. A colonoscopy should be performed to exclude associated colonic epithelial lesions and patients entered into

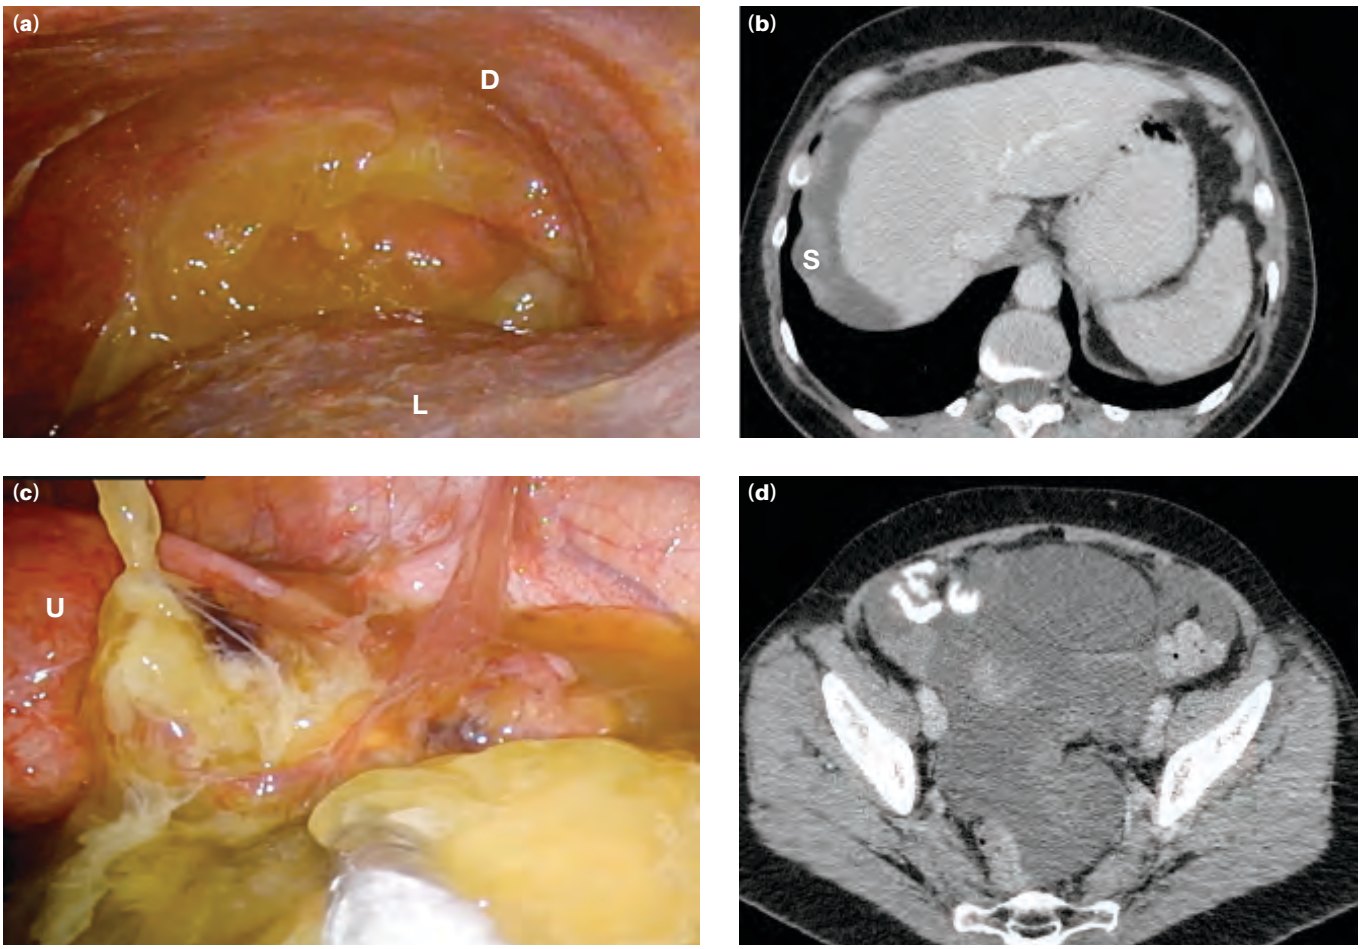

Figure 72.20 Pseudomyxoma peritonei secondary to a high-grade mucinous neoplasm of the appendix as seen at laparoscopy and computed tomography (CT). **(a, b)** Mucinous tumour of the right hemidiaphragm (D) and liver capsule (L) causing characteristic scalloping (S) at CT. **(c, d)** Mucinous tumour filling the pelvis posterior to the uterus (U) with the corresponding CT findings (courtesy of Dr C Cronin, FRCR, Dublin, Ireland).

a surveillance protocol for at least 5 years. Surveillance may take the form of clinical review, annual low-dose abdominopelvic CT scan and appendix-related tumour markers (CEA, CA 199, CA 125).

Patients with high-grade tumour, invasive adenocarcinoma or goblet cell tumour and/or those with epithelial cell containing mucin outside the appendix are at higher risk of nodal involvement and subsequent development of PMP. According to current paradigms, such patients should be approached in a similar fashion to patients with established PMP and consideration given to right hemicolectomy with prophylactic regional (right parietal) peritonectomy, omentectomy and intraperitoneal chemotherapy. Consideration should also be given to performing bilaterral salpingo-ophorectomy, although in patients of childbearing age the decision making is complex.

TREATMENT – ESTABLISHED PMP

The standard accepted treatment for established PMP is cytoreductive surgery (CRS) combined with heated intraperitoneal chemotherapy HIPEC (Sugarbaker). This approach combines multiple peritonectomy procedures with multivisceral resections as required to achieve a complete surgical clearance of the tumour (complete cytoreduction), which is augmented by HIPEC to eradicate presumed residual microscopic disease. The combined operation can take in excess of 10 hours and may require total abdominopelvic peritonectomy, greater and lesser omentectomy, bilaterral salpingo-ophorectomy, hysterectomy, cholecystectomy, splenectomy, partial gastrectomy, colectomy and anterior resection of the rectum. The largest reported series of CRS/HIPEC for PMP comes from Basingstoke, UK (Moran). In their experience involving more than 1000 patients, a complete cytoreduction was achieved in approximately 75% of patients with the remainder undergoing maximal tumour debulking. Although a potentially morbid procedure, in experienced centres the operative mortality rate following CRS/HIPEC is less than 2% with major postoperative morbidity occuring in 15% of patients. Following a complete cytoreduction 5- and 10-year survival rates of 87% and 70%, respectively, can be achieved. Poorer outcomes are seen in males, patients with elevated tumour markers and following resection of tumour showing high-grade or invasive features.

Chapter 73

The rectum

Learning objectives

To understand:

- The anatomy of the rectum and its relationship to surgical disease and its treatment
- The pathology, clinical presentation, investigation, differential diagnosis and treatment of diseases that affect the rectum

To appreciate:

- That carcinoma of the rectum is common and can present with symptoms similar to benign disease. Careful evaluation is required
- The principles involved in the management of rectal pathologies

ANATOMY

Surgical anatomy

The rectum begins where the tinea coli of the sigmoid colon join to form a continuous outer longitudinal muscle layer at the level of the sacral promontory. The rectum follows the curve of the sacrum, and ends at the anorectal junction. The puborectalis muscle encircles the posterior and lateral aspects of the junction, creating the anorectal angle (normally 120°). The rectum has three lateral curvatures; the upper and lower are convex to the right, and the middle is convex to the left. On the luminal aspect, these three curves are marked by semicircular folds (Houston's valves).

The adult rectum is approximately 12–18 cm in length and is conventionally divided into three equal parts: the upper third, which is mobile and has a peritoneal covering anteriorly and laterally; the middle third, where the peritoneum covers only the anterior and part of the lateral surfaces; and the lowest third, which lies deep in the pelvis below the peritoneal reflection.

The lower third of the rectum is separated by distinct fascial layers from the prostate/vagina anteriorly (Denonvilliers' fascia), and from the coccyx and lower two sacral vertebrae posteriorly (Waldeyer's fascia) (*Table 73.1*). These fascial layers are surgically important as they act as barriers to malignant invasion and form the anatomical envelope for total mesorectal excision (TME) to achieve complete oncological clearance of rectal cancer.

Summary box 73.1

Anatomy of the rectum

- The rectum measures approximately 15 cm in length
- It is divided into lower, middle and upper thirds
- The blood supply consists of superior, middle and inferior rectal vessels
- The lymphatic drainage follows the blood supply. The principal route of drainage is upwards along the superior rectal vessels to the para-aortic nodes, although the lower rectum can drain to lymphatics along the lateral pelvic side walls

TABLE 73.1 Anatomical relations of the rectum.

	Relation
Anterior	Bladder Seminal vesicles and prostate (males) Denonvillier's fascia (males) Pouch of Douglas and rectovaginal septum (females) Uterus and cervix (females) Ureters
Lateral	Lateral ligaments and middle rectal artery Obturator internus muscle and side wall of pelvis Pelvic autonomic plexus Levator ani muscle
Posterior	Sacrum and coccyx Waldeyer's fascial condensation Superior rectal artery and lymphatics Hypogastric nerves

John Houston, 1802–1845, physician, City of Dublin Hospital and Lecturer in Surgery, Dublin, Ireland.
Charles Pierre Denonvilliers, 1808–1872, Professor of Anatomy and later of Surgery, Paris, France.
Heinrich Wilhelm Gottfried Waldeyer-Hartz, 1836–1921, Professor of Pathological Anatomy, Berlin, Germany.

Embryology

The embryological hindgut forms the upper rectum, while the lower rectum is derived from the cloaca and is surrounded by extraperitoneal connective tissue. The primitive gut tube is suspended dorsally by a mesentry throughout its length, to form the mesorectum. The muscular layers of the rectum are derived from the mesenchyme that accompanies the endodermal part of the anorectum, with the inner circular layer preceding the outer longitudinal layer in the 7th week of embryonic development.

The levator ani muscles and external anal sphincter muscles form within the surrounding mesenchyme and grow to make contact with each other and with bundles of smooth muscle cells from the outer longitudinal layer of the rectal wall. A layer of undifferentiated mesenchyme separates the rectal muscle layers from the levator ani muscle and the muscle layer of the future anal canal.

Blood supply

The superior rectal artery is the direct continuation of the inferior mesenteric artery and is the main arterial supply of the rectum (**Figure 73.1**). The arteries and their accompanying lymphatics lie within the loose fatty tissue in the mesorectum, surrounded by a sheath of connective tissue (the mesorectal fascia). The middle rectal artery arises on each side from the internal iliac artery and passes to the rectum in the lateral ligaments. It is usually small and often only present on one side, and divides into several branches. The inferior rectal artery arises on each side from the internal pudendal artery as it enters Alcock's canal. It hugs the inferior surface of the levator ani muscle as it crosses the roof of the ischiorectal fossa to enter the anal muscles.

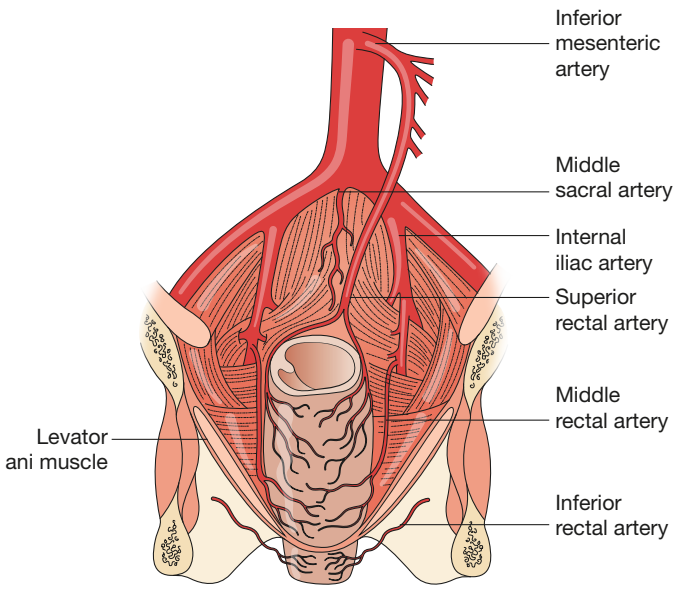

Figure 73.1 Blood supply to the rectum. The main blood supply comes from the superior rectal arteries, supplemented by middle rectal arteries in 20% of cases. The inferior rectal arteries are derived from the pudendal vessels and supply the anal canal and lower rectum.

Venous drainage

The superior haemorrhoidal veins draining the upper half of the anal canal above the dentate line pass upwards to become the rectal veins; these unite to form the superior rectal vein, which later becomes the inferior mesenteric vein. This forms part of the portal venous system and ultimately drains into the splenic vein. Middle rectal veins exist but are small, unimportant channels unless the normal paths are blocked.

Lymphatic drainage

The lymphatics of the rectal mucosa communicate freely with those of the muscle layers. The usual drainage flow is upwards, and only to a limited extent laterally and downwards. For this reason, surgical clearance of malignant disease concentrates mainly on achieving wide resection of proximal lymph nodes. However, if the usual upward routes are blocked, for example by metastatic disease, the flow can reverse and it is possible to find involved lymph nodes on the side walls of the pelvis (along the middle rectal vessels) or even in the inguinal region (along the inferior rectal artery).

CLINICAL FEATURES OF RECTAL DISEASE

Symptoms

Rectal diseases are common and can occur at any age. The symptoms of many of them overlap. In general, inflammatory conditions affect younger age groups, while tumours occur in the middle-aged and elderly.

Summary box 73.2

Main symptoms of rectal disease

- Fresh bleeding per rectum
- Altered bowel habit with loose stool
- Mucus discharge
- Tenesmus
- Prolapse
- Proctalgia (pain)

Bleeding

This is often painless and bright red in colour and should be carefully investigated at any age.

Altered bowel habit

Early morning stool frequency (spurious diarrhoea) is a symptom of rectal carcinoma, while blood-stained, frequent, loose stools characterise the inflammatory diseases.

Discharge

Mucus and pus are associated with rectal inflammation.

Tenesmus

Often described by the patient as 'I feel I want to go but nothing happens', this is normally an ominous symptom of rectal

cancer, but can occur with other rectal conditions and is a common symptom of rectal prolapse.

Prolapse

This usually indicates either mucosal or full-thickness rectal wall protrusion from the anus. Internal prolapse or intussusception refers to a telescoping of the rectum into itself without protrusion from the anus.

Pain: 'proctalgia'

This is usually a severe and episodic pain resulting from spasm of the levator ani muscle. It may last for a few seconds to minutes then recur, or it can be constant.

Signs

To examine the rectum the patient is most conveniently positioned in the left lateral (Sims) position.

Inspection

Visual examination of the anus precedes rectal examination, to exclude the presence of anal disease, e.g. fissure or fistula. Evidence of rectal prolapse or abnormal pelvic floor descent can be elicited by asking the patient to strain.

Digital examination

The index finger used with gentleness and precision remains a valuable test for rectal disease (Figure 73.2). The anal sphincters are assessed for anatomical integrity, resting tone and squeeze. In females, a rectocoele may be palpable as a herniation of the anterior rectal wall into the vagina. Tumours in the lower and middle thirds of the rectum can usually be felt. On removal, the finger should be examined for mucus, pus or blood. It is useful to note the normal, as well as the abnormal, findings on digital examination e.g. the prostate in the male. Digital findings can be recorded as intraluminal (e.g. blood, pus), intramural (e.g. tumours, granular areas, strictures) or extramural (e.g. enlarged prostate, uterine fibroids). Intramural lesions can be described as fixed, tethered or mobile.

Proctoscopy

This procedure can be used to inspect the anus, anorectal junction and lower rectum. A lubricated proctoscope is inserted through the anus to provide views of the lower rectum and anal canal (Figure 73.3). Biopsy can be performed of any suspicious areas, provided it is above the sensitive anoderm. Proctoscopy is particularly useful for assessing the presence of haemorrhoids.

Sigmoidoscopy

In the past, the sigmoidoscope was a rigid stainless steel instrument of variable diameter and normally 25 cm in length, but this has been replaced by disposable plastic instruments. The rectum must be empty for proper inspection. Direct inspection of the rectal mucosa may alert the clinician to inflammation or tumours. This procedure can be performed in the outpatient setting.

FLEXIBLE SIGMOIDOSCOPE

This is used as a supplement to rigid sigmoidoscopy or when views proximal to the rectum are required (Figure 73.4). The lower bowel needs to be cleaned out with preliminary enemas. In addition to the rectum, the whole sigmoid colon up to the splenic flexure is within visual reach. Flexible sigmoidoscopy is indicated to investigate underlying causes of fresh rectal bleeding or other bowel symptoms when full visualisation of the colon by colonoscopy is not required.

Summary box 73.3

INJURIES

The rectum or anal canal may be injured in a number of ways, all of which are uncommon:

- by falling in a sitting posture onto a pointed object;
- penetrating injury (including gunshots) to the buttocks;
- sexual assault or sexual activity involving anal penetration;
- by the fetal head during childbirth, especially forceps-assisted.

Diagnosis

The anus should be inspected and the abdomen palpated. If abdominal rigidity or tenderness is present, early laparoscopy or laparotomy is indicated. A water-soluble contrast enema may help in delineating the injury, but a computed tomographic (CT) scan is often preferred and will provide additional information on other pelvic injuries, such as accompanying urethral injury.

Treatment

The rectum is examined under general anaesthetic with a finger and a sigmoidoscope. If penetrating injury is confirmed, laparotomy or laparoscopy is required. If an intraperitoneal rupture of the rectum is found, the perforation is closed with sutures and the rectum defunctioned with a stoma. In the event that the rectal injury cannot be repaired, a Hartmann's procedure may need to be performed. If the rectal injury is below the peritoneal reflection, wide drainage from below is indicated, with rectal washout and a defunctioning colostomy. Care must be taken to preserve sphincter function during debridement of the perineal wounds. Antibiotic cover must be provided against both aerobic and anaerobic organisms.

FOREIGN BODIES IN THE RECTUM

The variety of foreign bodies that have found their way into the rectum is hardly less remarkable than the ingenuity displayed in their removal (Figure 73.5). The difficulty lies in the creation of a vacuum effect when trying to extract the object through the anus. If insurmountable difficulty is experienced in grasping any foreign body in the rectum, laparotomy is usually necessary. The object can be pushed from above into the assistant's fingers in the rectum, or removed by means of a rectotomy in a proximal area of the rectum. If there is considerable laceration of the mucosa, a temporary colostomy is advisable.

Summary box 73.4

Injuries to the rectum are serious and invariably require surgery

- A temporary colostomy is often necessary
- There is a serious risk of associated necrotising fasciitis, and broad-spectrum antibiotics are mandatory
- There may be associated bladder or urethral damage

PROLAPSE

Mucosal prolapse

The mucous membrane and submucosa of the rectum protrude outside the anus for approximately 1–4 cm. When the prolapsed mucosa is palpated between the finger and the thumb, it is evident that it is composed of no more than a double layer of mucous membrane. This distinguishes mucosal prolapse from full-thickness prolapse where the entire rectal wall exits from the anal canal.

In infants

The direct downward course of the rectum, due to the as-yet undeveloped sacral curve, predisposes infants to this condition.

In children

Mucosal prolapse often commences after an attack of diarrhoea, or from loss of weight and consequent loss of fat in the ischiorectal fossa. It may also be associated with cystic

Summary box 73.5

Rectal prolapse

- It may be mucosal or full thickness
- If full thickness, the whole wall of the rectum is included
- It commences as a rectal intussusception
- In children, the prolapse is usually mucosal and should be treated conservatively
- In the adult, the prolapse is often full thickness and is frequently associated with incontinence
- Surgery is necessary for full-thickness rectal prolapse
- The operation is performed either via the perineum or via the abdomen

fibrosis, neurological disorder, Hirschsprung's disease, rectal polyps and maldevelopment of the pelvis.

In adults

The condition in adults is often associated with third-degree haemorrhoids, when it is referred to as mucohaemorrhoidal prolapse (Figure 73.6). In the female, a torn perineum, and in the male straining from urethral obstruction, predispose to mucosal prolapse. In old age, both mucosal and full-thickness prolapse are associated with weakness of the sphincter mechanism. Partial prolapse may follow an operation for fistula-in-ano where a large portion of muscle has been divided. Here, the prolapse is usually localised to the damaged quadrant and is seldom progressive.

Treatment

IN INFANTS AND YOUNG CHILDREN

- **Digital repositioning**. The parents are taught to replace the protrusion, and any underlying causes are addressed.
- **Submucosal injection or banding**. If digital repositioning fails after a 6-week trial, injection of 5% phenol in almond oil or rubber band ligation is carried out under general anaesthetic (Figure 73.7).

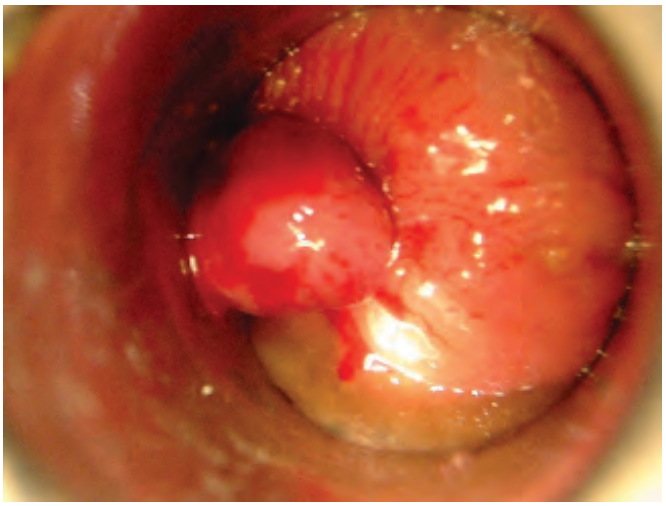

Figure 73.7 Through a proctoscope, a rubber band is applied to an area of mucohaemorrhoidal prolapse.

IN ADULTS

- **Local treatments**. Submucosal injections of phenol in almond oil or the application of rubber bands may be successful in cases of mucosal prolapse.
- **Excision of the prolapsed mucosa**. When the prolapse is unilateral, the redundant mucosa can be excised or, if circumferential, an endoluminal stapling technique or internal Delorme's procedure can be used.

Full-thickness prolapse

Complete rectal prolapse (synonym: procidentia) is less common than the mucosal variety. The protrusion consists of all layers of the rectal wall and is usually associated with a weak pelvic floor and/or chronic straining. The prolapse is thought to commence as an intussusception of the rectum, which descends to protrude outside the anus. The process starts with the anterior wall of the rectum, where the supporting tissues are weakest, especially in women. It is more than 4 cm and commonly as much as 10–15 cm in length (Figure 73.8). On

Figure 73.6 Mucohaemorrhoidal prolapse of the anorectum.

Figure 73.8 Full-thickness rectal prolapse. The whole bowel wall protrudes through the anus.

palpation between the finger and thumb, the prolapse feels much thicker than mucosal prolapse, and consists of a double thickness of the entire wall of the rectum. Any prolapse over 5 cm in length will contain anteriorly, between its layers, a pouch of peritoneum. When large, the peritoneal pouch may contain small intestine or bladder. The anal sphincter is characteristically patulous and gapes widely on straining to allow the rectum to prolapse. Complete prolapse is uncommon in children but may occur as a result of malnutrition. In adults, it can occur at any age, but it is more common in the elderly and sometimes in patients with anorexia nervosa. Women are affected six times more often than men, and it is commonly associated with other pelvic organ prolapse. In approximately 50% of adults, faecal incontinence is also a feature. Complications of rectal prolapse include rectal ulceration and bleeding, incontinence and even incarceration with strangulation of the rectum.

Differential diagnosis

In the case of a child with abdominal pain, the anus should be examined to exclude rectal prolapse as a cause. This should also be distinguished from intussusception protruding from the anus.

Treatment

Surgery is required for full-thickness rectal prolapse, and the operation can be performed via a perineal or abdominal approach. Abdominal operations can be by an open or laparoscopic approach. Abdominal rectopexy, either laparoscopic or open, has a lower rate of recurrence (<10%), but when the patient is elderly and very frail a perineal operation is usually safer, and if necessary can be performed under regional anaesthetic blockade. As an abdominal procedure risks damage to the pelvic autonomic nerves, resulting in possible sexual dysfunction, a perineal approach may be preferred in young men.

PERINEAL APPROACH

These procedures have been used most frequently:

- **Thiersch operation**. In this procedure, a steel wire, or silastic or nylon tape, is placed around the anal canal. It has become largely obsolete owing to problems with chronic perineal sepsis, anal stenosis and obstructed defaecation.
- **Delorme's operation**. In this procedure, the rectal mucosa is stripped circumferentially from the rectum over the length of prolapse (**Figure 73.9**). The underlying muscle is plicated with a series of sutures, so that the rectal muscle is concertinaed towards the anal canal. The excess rectal mucosa is excised and a mucosal anastomosis performed. The resulting effect is to reduce the prolapse as a plicated ring of muscle above the anal canal. This operation may be preferred in patients with short segment full rectal prolapse, but recurrence rates are high, in the region of 30% over 5 years.

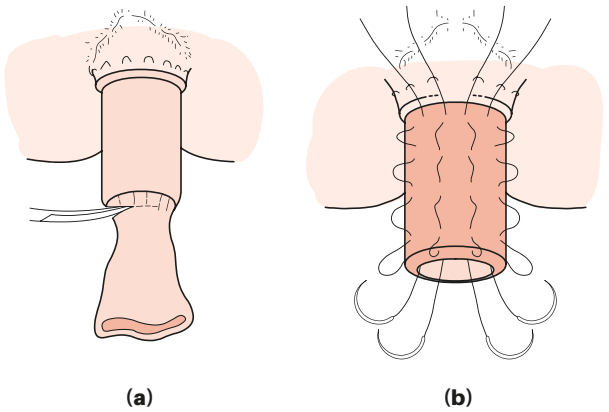

Figure 73.9 Delorme's procedure for rectal prolapse. **(a)** The mucosa is stripped from the muscular gut tube. **(b)** Interrupted sutures are used to plicate the muscular gut tube and reduce the prolapse. The operation is concluded by suturing the mucosa. Redrawn with permission from Keighley MRB, Williams NS. *Surgery of the anus, rectum and colon*. London: WB Saunders, 1999.

- **Altemeier's procedure**. In this procedure, the rectum is prolapsed through the anal canal and a full-thickness resection performed, incorporating any associated colonic prolapse. Restoration of colorectal continuity can be performed by either a hand-sewn or stapled anastomosis. This is the procedure of choice in patients presenting with incarcerated and strangulated prolapse. It is a good alternative perineal procedure to the Delorme's operation, particularly following recurrence. However, it is often complicated by poor bowel control with faecal soiling secondary to loss of the rectal reservoir. Recurrence rates range from 0 to 20%.

The advantages of a perineal approach include minimal postoperative pain, early mobility and low levels of morbidity. However, given the higher recurrence rates when compared with the abdominal operations, it is best reserved for patients at high risk of complications when undergoing a major operation.

ABDOMINAL APPROACH

The principle of all abdominal operations for rectal prolapse is to fix the rectum in its normal anatomical position. Many variations have been described, including inserting a sheet of polypropylene mesh between the rectum and the sacrum, hitching up the rectosigmoid junction with a Teflon sling to the front of the sacrum, or simply suturing the mobilised rectum to the sacrum using four to six interrupted non-absorbable sutures – so-called 'sutured rectopexy'. Currently, the technique is most often performed laparoscopically, reducing the operative trauma, limiting the time in hospital and broadening its indication for higher-risk patients.

As an abdominal rectopexy may lead to severe constipation, some surgeons recommend combining this procedure

Karl Thiersch, 1822–1895, Professor of Surgery, Leipzig, Germany.
Edmond Delorme, 1847–1929, Professor of Surgery, Val-de-Grace Military Hospital, Paris, France.
William Altemeier, 1910–1983, Professor of Surgery, Cincinnati, USA.

with resection of the sigmoid colon, so-called 'resection rectopexy'. Recently, a laparoscopic anterior mesh rectopexy has gained favour. In this procedure, the plane between the rectum and vagina (or prostate) is dissected, and a strip of mesh sutured to the anterior rectum and posterior vaginal vault. The upper end of the mesh is secured to the sacral promontory with sutures or tacks, thus re-suspending the rectum and preventing prolapse (Figure 73.10).

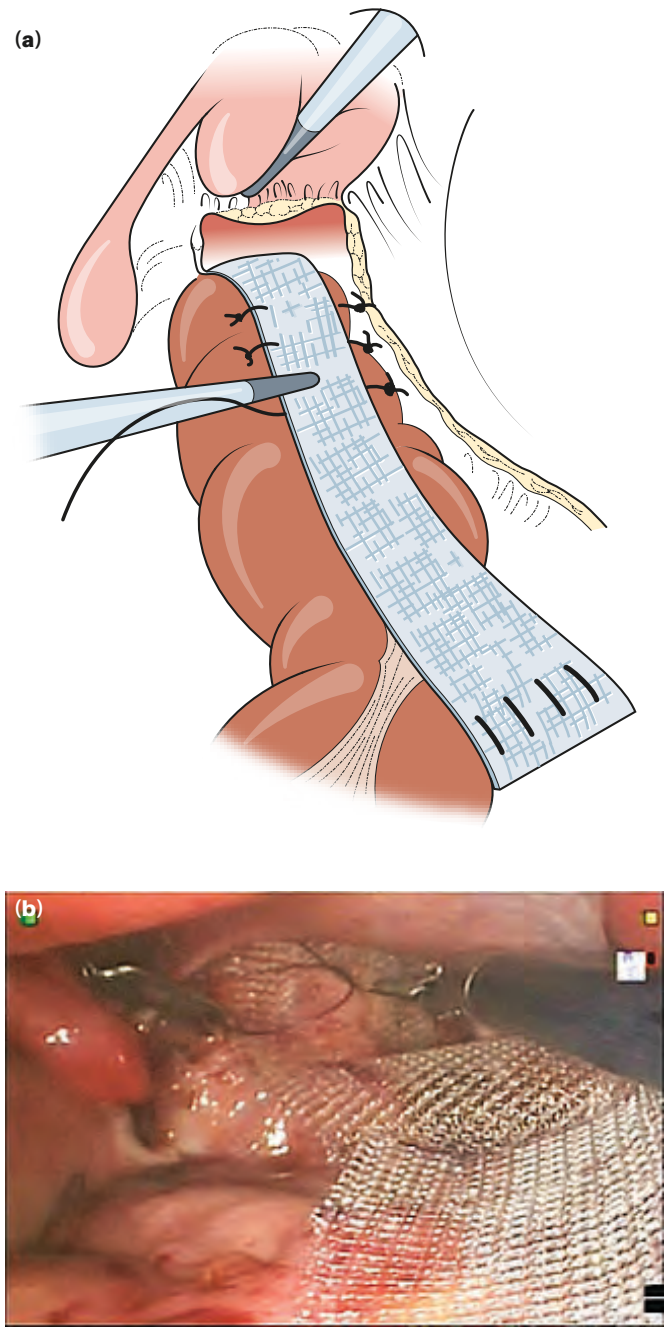

Figure 73.10 (a) Laparoscopic ventral mesh rectopexy: a prosthetic mesh is sutured to the front of the lower rectum and used to resuspend the rectum by securing the proximal end of the mesh to the sacral promontory. (b) Intraoperative image of a robotic ventral mesh rectopexy showing suturing of the mesh to the anterior rectum after dissection of the rectovaginal septum.

RECTAL EVACUATION DISORDER, RECTAL INTUSSUSCEPTION AND SOLITARY RECTAL ULCER SYNDROME (SRUS)

Rectal evacuation disorder (RED) is becoming a more commonly diagnosed problem and is complex in aetiology and treatment. Symptoms consist of a difficulty in emptying despite persistent straining and a feeling of incompleteness in the process. Rectal intussusception is often a component of RED whereby the rectal wall infolds on itself to produce an internal prolapse during straining. Solitary rectal ulcer syndrome may also be another associated manifestation of RED. Classically, SRUS takes the form of an ulcer on the anterior wall of the rectum, situated around 8 cm from the anal verge. In this form, it can be mistaken for rectal carcinoma or inflammatory bowel disease, particularly Crohn's disease. It may heal, leaving a polypoid appearance. Proctographic studies may indicate accompanying rectal intussusception or anterior rectal wall prolapse. Histology will confirm the diagnosis. The condition is difficult to treat. Symptomatic relief from bleeding and discharge may sometimes be achieved by controlling any associated straining with recoordination of defaecation using biofeedback therapy. Transanal stapled resection of the intussusception (STARR procedure) or resuspension of the rectum by abdominal rectopexy may be beneficial. In rare cases, rectal excision may be required with or without stoma.

PROCTITIS

The patient is usually middle-aged and complains of defaecatory frequency with the passage of loose motions, often with blood mixed in the stools. Inflammation is sometimes limited to the rectum; in other cases, it is associated with a similar condition in the colon (proctocolitis). The inflammation can be acute or chronic. Although the patient has a frequent, intense desire to defaecate, the amount of faeces passed at any time is small. Acute proctitis is usually accompanied by malaise and pyrexia. On rectal examination, there may be tenderness and blood on the glove. Proctoscopy is seldom sufficient and sigmoidoscopy is the more valuable method of examination. If the diagnosis is confirmed, colonoscopy with multiple biopsies is mandatory to determine the extent of the inflammatory process. Skilled pathological assessment is required to establish and classify the underlying pathology. Stool cultures should be sent routinely to exclude infective causes. If biopsy and histology are unable to establish an underlying inflammatory aetiology, the condition is frequently termed non-specific proctitis, but may herald a subsequent diagnosis of inflammatory bowel disease (ulcerative colitis or Crohn's disease).

Treatment is usually medical and tailored to the underlying pathology. Non-specific colitis may be self-limiting, but treatment with topical 5-aminosalicylic acid (5-ASA) compounds in the form of suppositories or foam enemas is usually effective. In resistant cases, oral steroids may have to be used.

Summary box 73.6

Proctitis

- May be non-specific or related to a specific infective agent
- Non-specific proctitis usually remains confined to the distal bowel, but can involve the proximal colon
- Symptoms include defaecatory frequency, loose stools, bleeding and tenesmus
- Endoscopic assessment with biopsy is required to establish the diagnosis
- Treatment usually involves medical management

Ulcerative proctocolitis

Proctitis is present in most cases of ulcerative colitis, and the degree of rectal involvement may influence the type of operative procedure (see Chapter 70).

Proctitis due to Crohn's disease

Crohn's disease can occasionally affect the rectum, although classically it is spared. Sigmoidoscopic appearances differ from those in non-specific proctitis. The inflammatory process tends to be patchy rather than confluent, and there may be fissuring, ulceration or even a cobblestone appearance. Rectal Crohn's disease is often associated with severe perineal disease characterised by fistulation, fissuring and haemorrhoids. Coexistent disease is often present in the rest of the colon or small bowel, or both.

Radiation proctitis

Radiation therapy is used in the treatment of cervical, prostate and rectal cancers. It can produce acute radiation proctitis with bleeding, pain, diarrhoea and defaecatory frequency. Most symptoms settle within a few weeks, but some patients develop chronic proctitis with symptoms appearing months or even decades after the radiation exposure.

Proctitis due to specific infections

Clostridium difficile

An acute form of proctocolitis caused by infection with *Clostridium difficile* can follow broad-spectrum antibiotics. A membrane can sometimes be seen on sigmoidoscopy ('pseudomembranous' colitis).

Bacillary dysentery

The appearance is that of an acute purulent proctitis with multiple small, shallow ulcers.

Amoebic dysentery

The infection is more likely to be chronic, with exacerbations after a long period of symptom improvement. Proctoscopy and sigmoidoscopy are not painful. The appearance of an amoebic ulcer is described in Chapter 70.

Tuberculous proctitis

This is nearly always associated with active pulmonary tuberculosis or tuberculous ulceration of the anus. Submucous rectal abscesses burst and leave ulcers with an undermined edge. A hypertrophic type of tuberculous proctitis occurs in association with tuberculous peritonitis or tuberculous salpingitis. This type of tuberculous proctitis requires biopsy for confirmation of the diagnosis.

Gonococcal proctitis

Gonococcal proctitis occurs in both sexes as the result of rectal coitus and, in the female, from direct spread from the vulva. In the acute stage, the mucous membrane is hyperaemic, and thick pus can be expressed as the proctoscope is withdrawn. In the early stages, the diagnosis can be readily established by bacteriological examination but, later, when the infection is mixed, it is more difficult to recognise. Systemic treatment is so effective that local treatment is unnecessary.

Lymphogranuloma venereum

The modes of infection are similar to those of gonococcal proctitis but, in the female, chlamydial infection spreading from the cervix uteri via lymphatics to the pararectal lymph nodes is common. The proctological findings are similar to those of gonococcal proctitis. The diagnosis of lymphogranuloma venereum should be suspected when the inguinal lymph nodes are greatly enlarged, although nodal enlargement may be subsiding by the time proctitis commences.

Acquired immunodeficiency syndrome

Acquired immunodeficiency syndrome (AIDS) due to human immunodeficiency virus (HIV) may present with a particularly florid type of proctitis. In such patients, unusual organisms including cytomegalovirus (CMV), herpes simplex virus and parasites such as *Cryptosporidium* are often found.

'Strawberry' lesion of the rectosigmoid

This results from infection by *Spirochaeta vincenti* and *Bacillus fusiformis*. The leading symptom is diarrhoea, often scantily blood stained. Occasionally, the diagnosis can be made by the demonstration of the specific organisms in the stools. More often, sigmoidoscopy is required. The characteristic lesion is a thickened, somewhat raised mucosa, with superficial ulceration in the region of the rectosigmoid. The inflamed mucous membrane oozes blood at numerous pinpoints, giving the appearance of an over-ripe strawberry. A swab should be taken and examined for Vincent's and fusiform organisms. Swabs from the gums and throat are also advisable.

Jean Hyacinthe Vincent, 1862–1950, Professor of Epidemiology, Val-de-Grace Military Hospital, Paris, France.

Rectal bilharziasis

Rectal bilharziasis is caused by *Schistosoma mansoni*, which is endemic in many tropical and subtropical countries, and particularly in the Nile Delta. In stage 1, a cutaneous lesion develops at the site of entrance of the cercariae (parasites of freshwater snails). Stage 2 is characterised by pyrexia, urticaria and a high eosinophilia. Both these stages are frequently overlooked. Stage 3 results from deposition of the ova in the rectum (much more rarely in the bladder; Chapter 77) and is manifested by bilharzial dysentery. On examination in the later stages, papillomas are frequently seen. The papillomas, which are sessile or pedunculated, contain the ova of the trematode, the life cycle of which resembles that of *Schistosoma haematobium*. Untreated, the rectum becomes festooned, and prolapse of the diseased mucous membrane is usual. Multiple fistulae-in-ano are prone to develop.

The primary treatment is systemic and should be undertaken by a specialist in tropical medicine. When the papillomas persist in spite of treatment, they should be treated by local destruction.

Proctitis due to herbal enemas

This is a well-known clinical entity to those practising in tropical Africa. Following an enema consisting of a concoction of ginger, pepper and bark, administered by a traditional healer, a virulent proctitis sets in. Pelvic peritonitis frequently supervenes. Not infrequently, a complete gelatinous cast of the mucous membrane of the rectum is extruded. Very large doses of morphine, together with antibiotics, often prevent a fatal outcome if commenced early. Temporary colostomy is often advisable.

RECTAL POLYPS

The rectum, along with the sigmoid colon, is the most frequent site of polyps (and cancers) in the gastrointestinal tract. Adenomatous polyps of the colon and rectum have the potential to become malignant. The chance of developing invasive cancer is enhanced if the polyp is more than 1 cm in diameter. Removal of all polyps is recommended to allow complete histological diagnosis and exclude carcinoma. This is best done using endoscopic biopsy or snare polypectomy techniques. If one or more rectal polyps are discovered on sigmoidoscopic examination, a colonoscopy must be performed because further polyps are frequently found in the colon.

The rectum shares the same spectrum of polyps as the colon. Polyps are described in terms of their appearance (pedunculated, sessile, flat) or histological composition (tubular, villous, tubulovillous).

Polyps relevant to the rectum

Hyperplastic polyps

These are small, pinkish, sessile polyps, 2–4 mm in diameter and frequently multiple. They are common and generally harmless.

Tubular adenomas

Tubular adenomas, or mixed tubulovillous adenomas, are the most common type of polyp. They have the potential to turn malignant, particularly if over 1 cm in diameter.

Villous adenomas

These have a characteristic frond-like appearance. They may be very large, occupying much of the circumference of the rectum. These tumours have an increased tendency to become malignant. Rarely, the profuse mucus discharge from these tumours, which is rich in potassium, causes electrolyte and fluid losses (**Figure 73.11**).

Serrated adenomas

These polyps are more commonly found in the right colon, but may be present in the rectum. They are typically sessile lesions that have a distinct microscopic architecture and can give rise to cancers through an alternative 'serrated' pathway.

Familial adenomatous polyposis

This autosomal dominant inherited condition is characterised by the development of multiple rectal and colonic adenomas around puberty. It is due to mutation in the adenomatous polyposis coli (*APC*) gene, allowing genetic testing in the 75% of families in which a mutation can be identified. A colonoscopy and biopsy will confirm the diagnosis. As this condition is premalignant, total colectomy is usually recommended within 10 years of disease onset. This may take the form of pan-proctocolectomy with permanent ileostomy. Rectal preservation may be an option if the rectal polyp load is not too severe, with colectomy and ileorectal anastomosis, but continuous rectal surveillance for synchronous polyps will

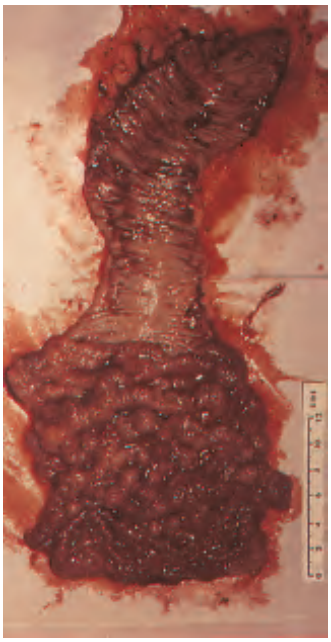

Figure 73.11 Large villous adenoma that occupied the lower half of the rectum and caused hypokalaemia.

Theodor Maximillan Bilharz, 1825–1862, Professor of Zoology, Cairo, Egypt.

be required. The alternative, if restoration of gastrointestinal continuity is desired, is to undertake restorative proctocolectomy with ileal pouch–anal anastomosis (see Chapter 70).

Inflammatory pseudopolyps

These are oedematous islands of mucosa. They are usually associated with colitis in the UK, but most inflammatory diseases (including tropical diseases) can cause them. They are more likely to cause radiological difficulty, as the sigmoidoscopic appearance is usually associated with obvious signs of active or quiescent inflammation.

Juvenile polyp

This is a bright red, glistening pedunculated sphere ('cherry tumour'), which is found in infants and children. Occasionally, it persists into adult life. It can cause bleeding, or pain if it prolapses during defaecation. It often separates itself, but can be removed easily with forceps or a snare. A solitary juvenile polyp has virtually no tendency to malignant change, but should be treated if it is causing symptoms. It has a unique histological structure with large mucus-filled spaces covered by a smooth surface of thin rectal cuboidal epithelium (**Figure 73.12**). The rare autosomal dominant inherited syndrome juvenile polyposis does carry an increased risk of malignancy. It is characterised by multiple polyps and a positive family history.

Treatment of rectal polyps

All polyps should be biopsied or removed for histological analysis to exclude cancer. A range of techniques can be used to remove rectal polyps, dependent on their size and location. The majority of polyps less than 1 cm in size are benign and are amenable to endoscopic polypectomy. Polyps greater than 1 cm in size have a 10% chance of harbouring a malignancy. Submucosal infiltration with saline or colloid solution can give an indication of invasive malignancy, with cancers exhibiting tethering to submucosal tissues and failing to 'lift'. Most polyps of 2 cm in size or less can be safely removed by endoscopic mucosal resection (EMR) (**Figure 73.13**). Larger polyps are more difficult to remove by EMR and may require a transanal procedure, such as transanal endoscopic microsurgery (TEMS).

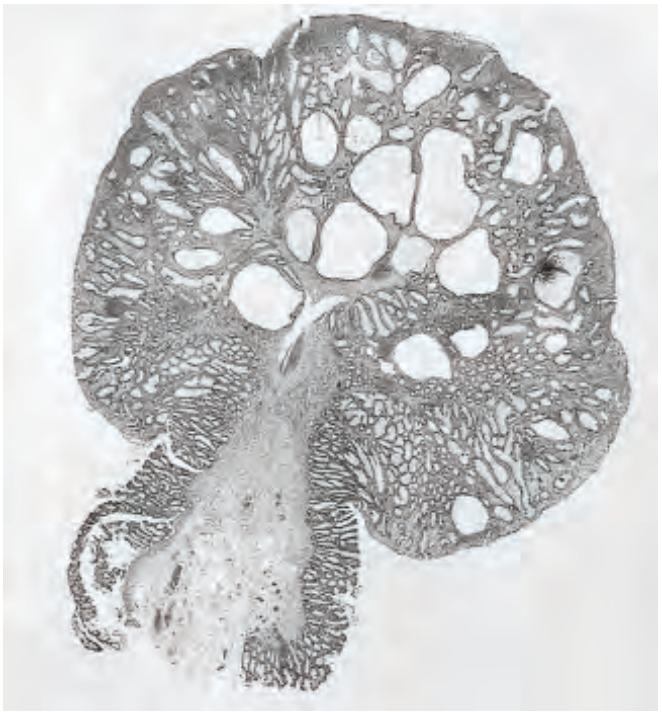

Figure 73.12 Microscopic appearance of a juvenile polyp.

Summary box 73.7

Polyps in the rectum

- Adenomas are the most frequent histological type
- Villous adenomas may be extensive and undergo malignant change more commonly than tubular adenomas
- All adenomas must be removed to avoid malignant change
- All patients must undergo colonoscopy to determine whether further polyps are present
- Most polyps can be removed by endoscopic techniques, but sometimes major surgery is required

BENIGN RECTAL LESIONS

Endometrioma

Endometrioma is rare and may be misdiagnosed as a carcinoma. The focus of the ectopic endometrial tissue produces either a constricting lesion of the rectosigmoid or a tumour invading the rectum from the rectovaginal septum. The latter variety gives rise to a tender submucous elevation of the rectal wall. Endometrioma usually occurs between 20 and 40 years of age. Dysmenorrhoea and rectal bleeding (particularly coinciding with the menses) are the main symptoms. On sigmoidoscopy, endometriosis involving the rectosigmoid junction usually presents as a stricture, with the mucous membrane intact. Hormonal manipulation is the first-line therapy, but sometimes total abdominal hysterectomy and bilateral salpingo-oophorectomy and even bowel resection are required. The laparoscopic approach for resecting deep rectal endometriosis is becoming popular. Isolated endometrial deposits may be treated by diathermy ablation or local 'discectomy' incorporating the rectal wall.

Haemangioma

Haemangioma of the rectum is an uncommon cause of serious haemorrhage. The symptoms may mimic ulcerative colitis, and the diagnosis is often delayed, or it may be mistaken for a carcinoma. Selective angiography and embolisation may be helpful, but excision of the rectum is sometimes required.

Gastrointestinal stromal tumour (GIST)

Smooth-muscle tumours of the rectum are rare. If the mitotic rate is high, and if there is variation in nuclear number, size

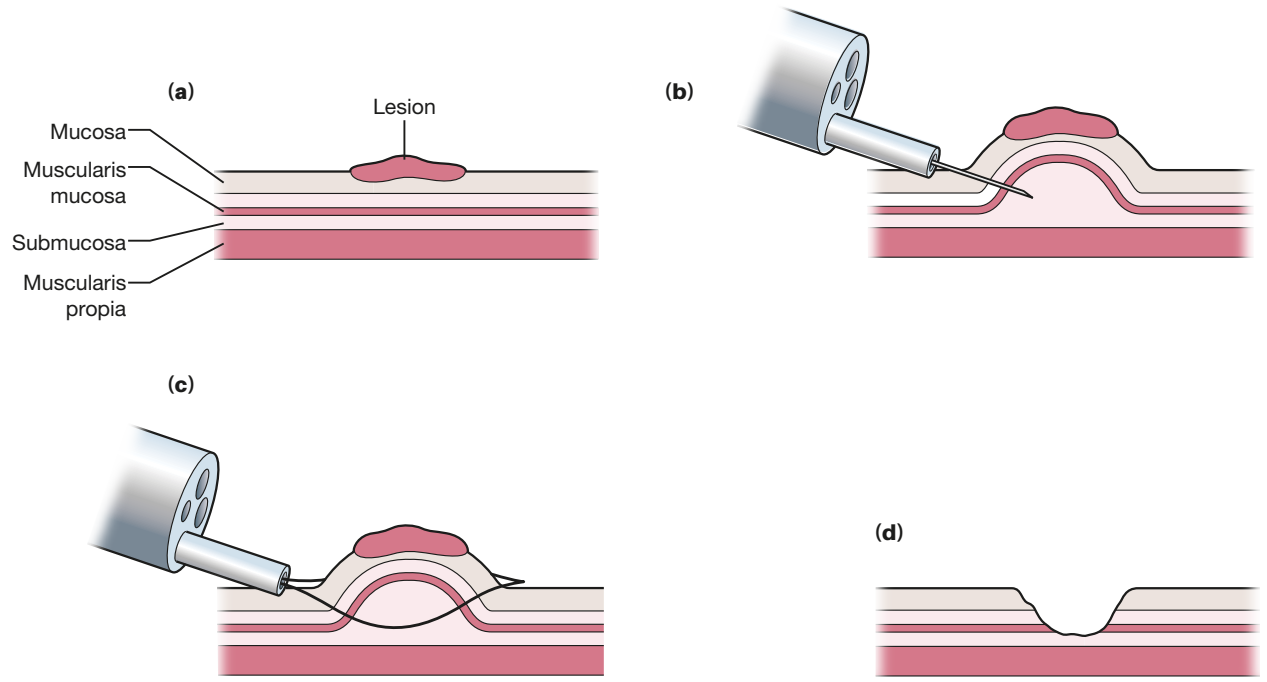

Figure 73.13 Endoscopic mucosal resection. The polyp is identified **(a)** and infiltration performed **(b)** to lift it from the underlying muscle layer. A diathermy snare is passed over the raised lesion **(c)** to achieve complete excision **(d)**.

and shape, hyperchromasia and frequent bizarre cells, these tumours are likely to metastasise. In these circumstances, they should be classified as malignant gastrointestinal stromal tumours (formerly leiomyosarcomas). The uncertainty in their behaviour means that treatment should, whenever possible, be radical excision.

Neuroendocrine tumours

Neuroendocrine tumours (NET) of the rectum comprise 19% of all gastrointestinal NET. They are classified into well-differentiated (grades 1 and 2) and poorly differentiated (grade 3) tumours. Both tumour mitotic index and Ki-67 expression are important factors for histopathological classification. Grade 3 tumours include both small- and large-cell NET. The majority of rectal NET are grade 1, also known as carcinoid tumours, with relatively good prognosis. These tumours are usually small (1–2 cm), solitary and clinically indolent. On the contrary, poorly differentiated grade 3 NETs are rare but very aggressive and metastasise at an early stage, with reported incidence of between 0.1 and 3.9% of all colorectal malignancies. Treatment of NET depends on the size of the tumour, its depth of invasion and the presence or absence of metastasis. Small lesions (1 cm) can often be treated locally, either endoscopically or transanally. However, larger lesions (>2 cm) require formal oncological resection. Adjuvant therapy is indicated only for metastatic disease.

CARCINOMAS

Globally, colorectal cancer is the second most common malignancy, affecting more than 1 million people every year and resulting in around 715,000 deaths. It is the second most common cancer in women and the third most common cancer in men, being the fourth most common cause of cancer death after lung, stomach, and liver cancer. In Western countries the incidence is rising, with an overall 14% increase since the 1970s, but with the largest increase (20%) seen in males. Risk factors include diet, obesity, smoking and lack of physical exercise. Most colorectal cancers are due to old age, with around 60% of cases affecting patients 70 years or older. The rectum is the most frequently involved site, accounting for approximately one-third of the cancers.

Pathogenesis

Colorectal cancer originates from premalignant precursor lesions in the epithelial lining of the colon or rectum in a stepwise progression that results in increasing dysplasia due to an accumulation of genetic abnormalities. In spontaneous colorectal cancer, as compared to hereditary cancers, this is referred to as the adenoma–carcinoma sequence. More than 75–95% of colorectal cancers occur in people with little or no genetic risk. People with inflammatory bowel disease are at an increased risk, which increases with the duration of the disease, and accounts for 2% of cancers each year. Those with a

family history in two or more first-degree relatives have a two- to three-fold greater risk of disease and this group accounts for about 20% of all cases. A number of genetic syndromes are also associated with higher rates of colorectal cancer. The most common is hereditary nonpolyposis colorectal cancer (HNPCC or Lynch syndrome), which accounts for 3% of people with colorectal cancer. Other syndromes include Gardner syndrome and familial adenomatous polyposis (FAP).

The most common abnormality found in colorectal cancer is mutation in the Wnt signaling pathway, which increases cell signalling activity. The mutations can be inherited or acquired. The most commonly mutated gene is the *APC* gene, which results in accumulation of the β-catenin protein. β-catenin activates the transcription of various proto-oncogenes that are responsible for normal cell renewal and differentiation, but when overexpressed can cause cancer. Many other mutations, other than in the Wnt signaling pathway, are found in colorectal cancer, and include mutations in the *TP53* gene that controls normal cell division and death, and mutations in genes responsible for programmed cell death, such as the gene encoding transforming growth factor (TGF)-β and *DCC* (deleted in colorectal cancer). Other genetic abnormalities include overexpression of oncogenes, including genes encoding the proteins KRAS (Kirsten rat sarcoma homologue), RAF (rapidly accelerated fibrosarcoma) and PI3K (phosphoinositide 3-kinase), which lead to increased cell proliferation, and inactivation of tumour suppressor genes, such as *PTEN* (phosphatase and tensin homologue), which normally inactivates the PI3K signalling pathway.

In addition to gene mutations, colorectal cancers frequently exhibit epigenetic alterations – cellular or physiological effects resulting from external or environmental factors that switch genes on or off. Epigenetic alterations can affect hundreds of genes and include changes in the expression of microRNAs (miRNA), hypermethylation or hypomethylation of CpG islands of protein-encoding genes, and alterations in histones and chromosomal architecture, all of which can influence gene expression.

Clinical features

Carcinoma of the rectum can occur early in life, but the age of presentation is usually above 55 years, when the incidence rises rapidly. Often, the early symptoms are so insignificant that the patient does not seek advice for 6 months or more, and the diagnosis is often delayed in younger patients as the symptoms are attributed to benign causes. Initial rectal examination and a low threshold for investigating persistent symptoms are essential.

Summary box 73.8

Early symptoms of rectal cancer

- Bleeding per rectum
- Tenesmus
- Early morning diarrhoea

Bleeding

Bleeding is the earliest and most common symptom. Typically, the bleeding is bright red in colour and painless. It can be mixed with the motions or separate in the toilet bowel. It can be indistinguishable from haemorrhoidal bleeding, which is the most common differential diagnosis, particularly in younger patients.

Tenesmus

The patient experiences a sensation of needing to evacuate the rectum but is unable to pass a motion. This is an important early symptom and is almost invariably present in patients with tumours of the lower half of the rectum. The patient may endeavour to empty the rectum several times a day (spurious diarrhoea), often with the passage of flatus and a little blood-stained mucus ('bloody slime').

Alteration in bowel habit

There is frequently a change in bowel habit, with a tendency to more frequent defaecation and the passage of looser stool. A patient who has to get up early in order to defaecate, or one who passes blood and mucus in addition to faeces ('early-morning bloody diarrhoea'), is usually found to be suffering from carcinoma of the rectum. Although a change to looser stools is more common, patients with a stenosing carcinoma at the rectosigmoid junction may complain of increasing constipation.

Pain

Pain is a late symptom, but pain of a colicky character may accompany advanced tumours of the rectosigmoid, owing to a degree of obstruction. Advanced cancers invading outside the mesorectum may infiltrate the prostate or bladder anteriorly or the sacral plexus posteriorly, giving rise to severe, intractable pain.

Weight loss

Weight loss is also a late symptom and is almost always associated with metastatic disease.

Investigation

Abdominal examination

Abdominal examination is normal in early cases. Occasionally, in patients with stenosing tumours at the rectosigmoid junction, signs of subacute large bowel obstruction may be present, with abdominal distension. If large-volume liver metastases are present, an enlarged liver may be palpable along with other signs, such as cachexia. Occasionally, it may be possible to elicit ascites if there is widespread peritoneal dissemination.

Rectal examination

In many cases where the neoplasm is situated within 7–8 cm of the anal verge it can be felt on digital rectal examination as an elevated, irregular and hard endoluminal mass. When the centre ulcerates, a shallow depression will be felt with raised and everted edges. An attempt should be made to determine

whether the neoplasm is mobile, tethered or fixed, and to estimate the distance of the lower margin from the top of the anal sphincter complex: these factors are important in assessing resectablility and methods of reconstruction following excisional surgery. In females, a vaginal examination may be useful if involvement of the posterior vaginal wall is suspected. Digital rectal examination also affords the opportunity to evaluate the anal sphincter complex, which is important in cases where resection and low anastomosis are being considered.

Rigid sigmoidoscopy

Rigid sigmoidoscopy can be performed in the outpatient clinic and is useful to identify the neoplasm and possibly obtain biopsies. However, it requires the rectum to be empty of faeces and may require a prior rectal enema, which may not be practical in the outpatient setting. As colonoscopy is almost always required to visualise the whole colorectum, it is often easier and safer to obtain biopsies at this time.

Colonoscopy

A colonoscopy is required in most patients to exclude a synchronous tumour, be it an adenoma or carcinoma. If a proximal adenoma is found, it can be conveniently snared and removed via the colonoscope. If a synchronous carcinoma is present, the operative strategy is likely to change. If a full colonoscopy is not possible, for example where there is a stenosing cancer, a CT colonography or barium enema can be performed.

Differential diagnosis

Many colorectal lesions can give rise to diagnostic difficulty. For example, it may be difficult to distinguish an inflammatory stricture or amoebic granuloma on macroscopic appearance. Similarly, endometriomas, carcinoid tumours and solitary rectal ulcers can be mistaken for adenocarcinoma. Benign adenomas can be distinguished from malignant lesions based on the appearance of their mucosal 'pit-patterns', as highlighted with the 'dye-spray' colonoscopy technique. Biopsy and histological analysis remain the mainstay of diagnosis, accepting that there may be diagnostic limitations caused by sampling errors due to small biopsy samples being unrepresentative of the larger lesion.

Summary box 73.9

Diagnosis and assessment of rectal cancer

All patients with suspected rectal cancer should undergo:

- Digital rectal examination
- Full colorectal visualisation preferably by colonoscopy with biopsy or computed tomography (CT) colonography or barium enema

All patients with proven rectal cancer require staging by:

- Imaging of the chest, abdomen and pelvis, preferably by CT
- Local pelvic imaging by magnetic resonance imaging and/or endoluminal ultrasound

Types of carcinoma spread

Local spread

Local spread occurs circumferentially rather than in a longitudinal direction. After the muscular coat has been penetrated, the growth spreads into the surrounding mesorectum, but is initially limited by the mesorectal fascia. If penetration occurs anteriorly, the prostate, seminal vesicles or bladder become involved in the male; in the female, the vagina or the uterus is invaded. In either sex, if the penetration is lateral, a ureter may become involved, while posterior penetration may reach the sacrum and the sacral plexus. Downward spread for more than a few centimetres is rare.

Lymphatic spread

Lymphatic spread from a carcinoma of the rectum above the peritoneal reflection occurs almost exclusively in an upward direction. Below that level, the lymphatic spread is still upwards, but when the neoplasm lies within the field of the middle rectal artery, primary lateral spread to the pelvic wall lymphatics occurs in around 20% of cases. Downward spread is exceptional, with drainage along the subcutaneous lymphatics to the groins being confined, for practical purposes, to the lymph nodes draining the perianal rosette and the epithelial lining of the distal 1–2 cm of the anal canal.

Metastasis at a higher level than the main trunk of the superior rectal artery occurs late in the disease. A radical operation should ensure that the high-lying lymph nodes are removed by ligating the inferior mesenteric artery at its origin from the aorta. Atypical and widespread lymphatic permeation can occur with highly undifferentiated neoplasms.

Venous spread

The principal sites for blood-borne metastases are liver (34%), lungs (22%) and adrenals (11%). The remaining 33% are divided among the many other locations where secondary carcinomatous deposits tend to lodge, including the brain.

Peritoneal dissemination

This may follow penetration of the peritoneal coat by a high-lying rectal carcinoma.

Stages of progression

Dukes classified carcinoma of the rectum into three stages (**Figure 73.14**).

Dukes' staging

- **A**: The growth is limited to the rectal wall (15%). The prognosis is excellent (>90% 5-year survival).
- **B**: The growth extends to the extrarectal tissues, but without metastasis to the regional lymph nodes (35%). The prognosis is reasonable (70% 5-year survival).
- **C**: There are secondary deposits in the regional lymph nodes (50%). These are subdivided into C1, in which the local pararectal lymph nodes alone are involved, and C2, in which the nodes accompanying the supplying blood vessels to their origin from the aorta are involved. This does not take into account cases that have metastasised

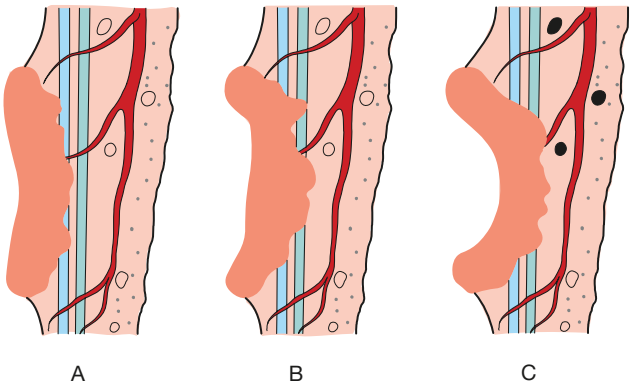

Figure 73.14 Dukes' original classification of colorectal cancer. A: the cancer is confined to the submucosa. B: the cancer penetrates the muscularis propria. C: involvement of the draining lymph nodes.

beyond the regional lymph nodes or by way of the venous system. The prognosis is poor (40% 5-year survival).

A stage D is often included, which was not described by Dukes. This stage signifies the presence of widespread metastases, usually hepatic. Other staging systems have been developed (e.g. Astler–Coller, TNM) to improve prognostic accuracy, with the tumour–node–metastasis (TNM) classification now recognised internationally as the optimum staging classification.

TNM staging – 'radiological staging'

Pretreatment magnetic resonance imaging (MRI) is the evaluation of choice in rectal cancer, helping to guide both surgical and oncological management.

T represents the extent of local spread:

- TX: primary tumour cannot be assessed;
- T0: no evidence of primary tumour;
- Tis: carcinoma *in situ* – intraepithelial or invasion of lamina propria;
- T1: tumour invades submucosa;
- T2: tumour invades muscularis propria;
- T3: tumour invades through the muscularis propria into pericolorectal tissues;
- T4a: tumour penetrates to the surface of the visceral peritoneum;
- T4b: tumour directly invades or is adherent to other organs or structures.

N describes nodal involvement:

- NX: regional lymph nodes cannot be assessed;
- N0: no regional lymph node metastasis;
- N1: metastasis in 1–3 regional lymph nodes:
  - N1a: metastasis in 1 regional lymph node
  - N1b: metastasis in 2–3 regional lymph nodes
  - N1c: tumour deposit(s) in the subserosa, mesentery or nonperitonealised pericolic or perirectal tissues without regional nodal metastasis;
- N2: metastasis in 4 or more regional lymph nodes:
  - N2a: metastasis in 4–6 regional lymph nodes
  - N2b: metastasis in 7 or more regional lymph nodes.

M indicates the presence of distant metastases:

- M0: no distant metastasis;
- M1: distant metastasis:
  - M1a: metastasis confined to one organ or site (for example liver, lung, ovary, non-regional node)
  - M1b: metastases in more than one organ/site or the peritoneum.

Histological grading

In the great majority of cases, carcinoma of the rectum is an adenocarcinoma, derived from malignant transformation of the columnar rectal epithelium. The more the tumour cells retain normal shape and arrangement (well-differentiated), the less aggressive the behaviour. Conversely, the more cells of an undifferentiated type, the more aggressive the behaviour. Other poor prognostic features include vascular and perineural invasion, the presence of an infiltrating (rather than pushing) margin and tumour budding. In a small number of cases, the tumour is a primary mucoid carcinoma. The mucus lies within the cells, displacing the nucleus to the periphery, like the seal of a signet ring. Signet-ring carcinomas are rapidly growing, metastasise early and have a poor prognosis.

Summary box 73.10

Pathology and staging of rectal cancer

- Tumours are adenocarcinomas and are well, moderately or poorly differentiated
- They spread by local, lymphatic, venous and transperitoneal routes
- Circumferential local spread is the most important and dictates management
- Lymphatic spread follows the blood supply of the rectum in a cephalad direction via the superior rectal vessels to the paraaortic nodes, but in low rectal cancer can also involve the lateral pelvic lymph nodes
- The TNM classification is the internationally recognised staging system

Treatment

Surgical excision of the tumour is the conventional management option, provided this can be achieved with clear oncological margins and acceptable risk of morbidity and mortality. However, the management of rectal cancer has become increasingly complex, because of the various surgical techniques available and the range of neoadjuvant and adjuvant options. As a result, the management of rectal cancer needs to be within the multidisciplinary team setting, involving surgeons, radiologists, oncologists, pathologists and specialty nurses.

Before treatment can be planned, it is necessary to assess:

- the fitness of the patient;
- the extent of spread of the tumour.

Assessment of spread should include CT of the chest, abdomen and pelvis to exclude distant metastases (**Figure 72.15**). Ultrasonography of the liver and a chest radiograph

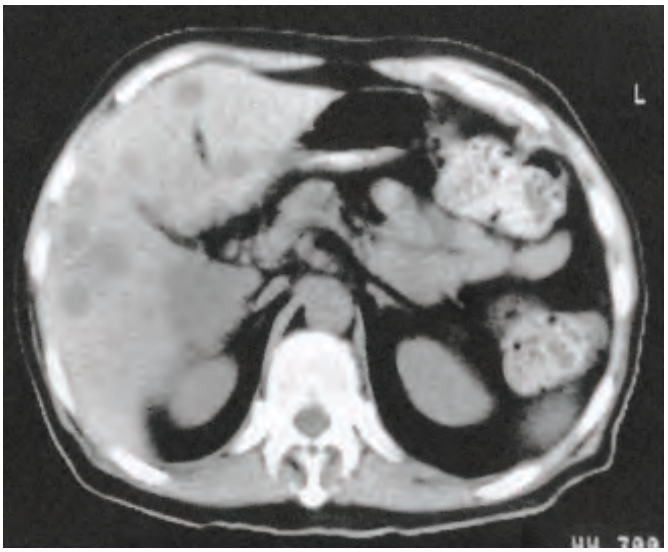

Figure 73.15 Computed tomography scan of the abdomen in a patient with rectal cancer, showing multiple liver metastases.

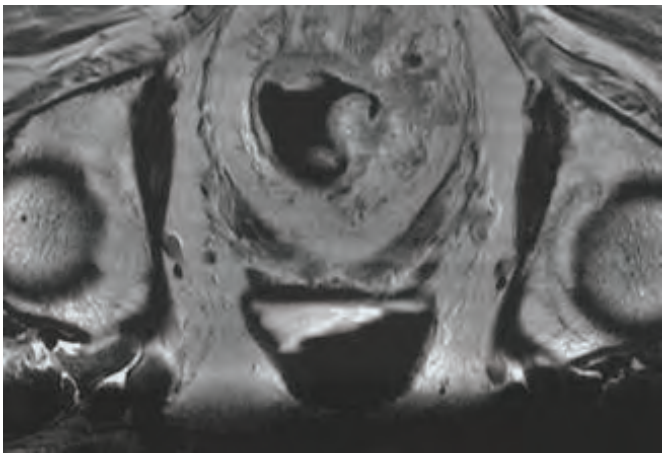

Figure 73.17 Magnetic resonance imaging scan of the pelvis showing extensive T3 rectal cancer involving the left mesorectum.

are decreasingly used alternatives. Positron emission tomography (PET) scanning can be helpful in identifying metastases if imaging is otherwise equivocal.

Endoluminal ultrasound, performed using a probe placed in the rectal lumen, can be used to assess the local spread of low rectal cancers (**Figure 73.16**), and is particularly useful in patients being considered for transanal endoluminal excision. CT is not particularly accurate in local staging; this is usually performed using MRI, which allows assessment of the circumferential resection margin and lymph node status (**Figure 73.17**).

Principles of surgical treatment

Radical excision of the rectum, together with the mesorectum and associated lymph nodes, should be the aim in most cases. In the presence of widespread metastases, other means of palliation should be considered, such as endoluminal stenting or external beam radiotherapy, although there may still be a role for palliative resection. The presence of liver metastases does not necessarily rule out the feasibility of cure: the results of surgery for liver metastases have greatly improved, with long-term survival being achieved in over a third of patients.

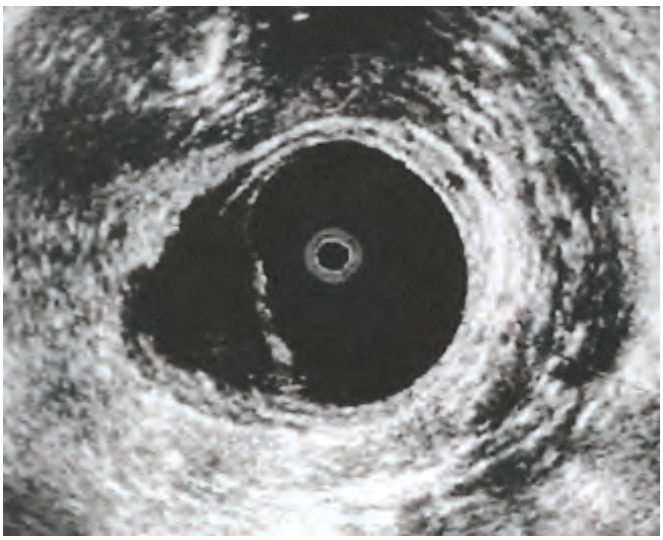

Figure 73.16 Endorectal ultrasound. The probe is in the rectal lumen and shows a rectal tumour invading through the rectal wall.

When a tumour appears to be locally advanced (i.e. invading a neighbouring structure or threatening to breach the circumferential resection margin), the use of neoadjuvant (preoperative) radiotherapy or chemoradiotherapy is usually considered. Long-course chemoradiotherapy is given as 5 fractions of radiotherapy combined with chemotherapy over a 6-week period. The aim is to down-stage the cancer and increase the chances of a complete resection with clear oncological margins. Alternatively, preoperative 'short-course' (5 days) radiotherapy can be used if the resection margins are not threatened but the cancer is still at high risk for local recurrence (e.g. peri-rectal lymph node involvement).

Increasingly, there is a trend for 'watch-and-wait' management in cancers that have shown a complete clinical response to long-course chemoradiotherapy (about 20%). If there is no evidence of residual cancer on clinical examination, biopsy or radiological imaging, patients are offered intense surveillance in the hope that they may have been cured of the disease and spared the morbidity of resectional surgery. Some 30% of cases will recur on a 'watch-and-wait' policy, but most can be salvaged by surgical resection.

There is also growing enthusiasm for 'organ-preserving' surgical techniques in early T1 and even T2 cancers with good prognostic features. This usually involves full-thickness excision of the cancer using TEMS (**Figure 73.18**). Alternative 'organ-preserving' techniques involve the use of brachytherapy and contact radiotherapy, but these are currently reserved for patients unfit for radical resection, or as a means of palliation.

When radical excision is possible, the aim should be to restore gastrointestinal continuity and continence by preserving the anal sphincter whenever feasible. A sphincter-saving operation (anterior resection) is usually possible for tumours whose lower margin is ≥2 cm above the anorectal junction. Although removal of the rectum and anus with a permanent

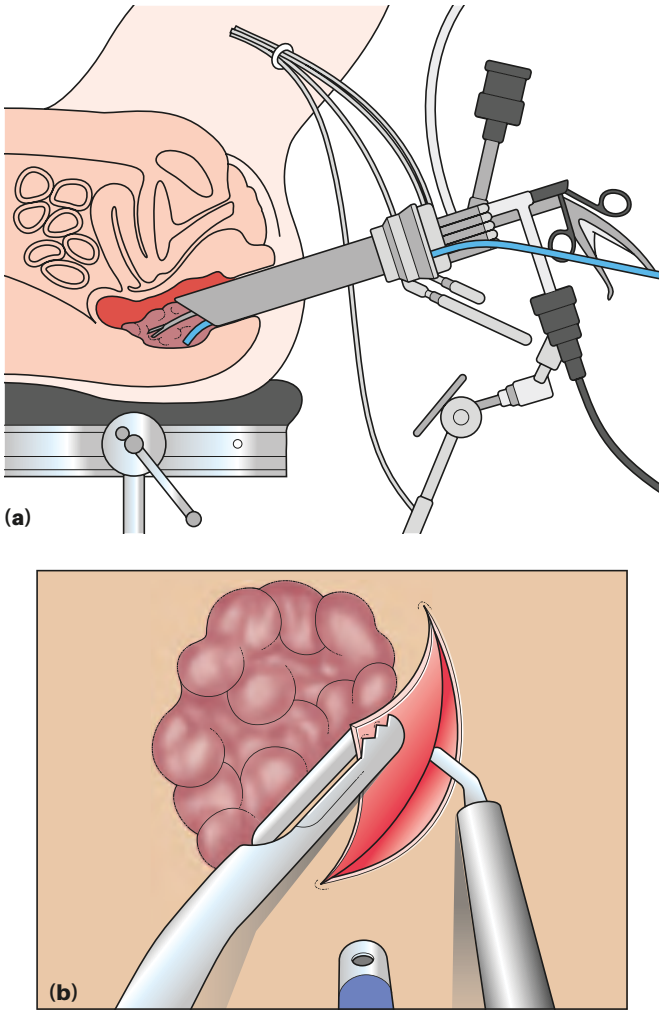

Figure 73.18 Transanal endoscopic microsurgery. **(a)** An operating sigmoidoscope is inserted through the anal canal to visualise the lesion and enable passage of a laparoscope and instruments. **(b)** A full-thickness local excision is performed. The defect is closed or, alternatively, may be left open if the peritoneum is not breached.

colostomy (abdominoperineal excision) was often required for tumours of the lower third of the rectum in the past, the introduction of the stapled anastomosis and chemoradiotherapy down-staging has enabled many more patients to be treated by a sphincter-saving procedure. The principles of anterior resection involve radical excision of the cancer along with its complete mesorectal envelope, combined with high proximal ligation of the inferior mesenteric lymphovascular pedicle. Once the left colon and rectum have been mobilised, the distal rectum is divided at least 1 cm (and preferably more) below the distal cancer margin and the specimen removed. Rectosigmoid cancers and those in the upper third of the rectum are removed by 'high anterior resection', in which the rectum and mesorectum are taken to a margin of at least 3 cm distal to the tumour, and a colorectal anastomosis is performed. For tumours in the middle and lower thirds of the rectum, complete removal of the rectum and mesorectum is required, i.e. total mesorectal excision (TME). Restoration of continuity is usually performed using a stapling technique, which might involve an end-to-end, side-to-end or colopouch construction in low cancers (**Figure 73.19**). The retention of at least a part of the rectum in high anterior resection results in better postoperative function, with less risk of anterior resection syndrome, a condition characterised by defaecatory urgency, incontinence and incomplete evacuation, secondary

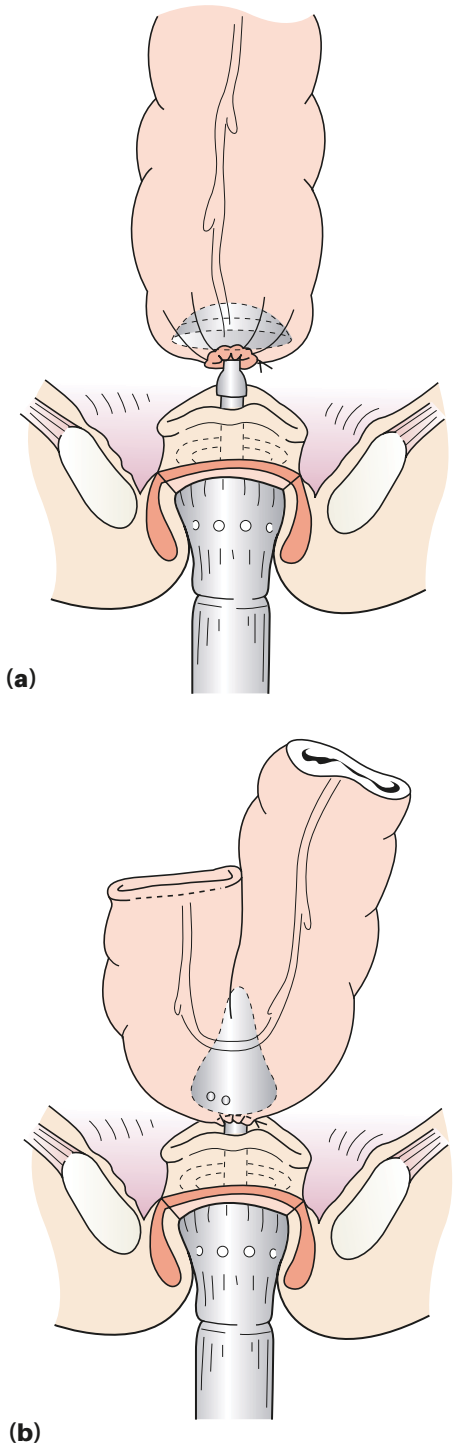

Figure 73.19 Low anterior resection by the double stapling method. The rectum has been excised, and the distal anorectal stump has been transected with a transverse stapling device. A circular stapling gun is used to construct **(a)** a straight low coloanal anastomosis, or **(b)** a colopouch–anus anastomosis.

to removal of the normal rectal reservoir. In cancers situated below the peritoneal reflection it is usual practice to defunction the anastomosis with a temporary stoma because of the higher risk of anastomotic leak. Although a defunctioning stoma does not prevent anastomotic leak, it does mitigate against septic complications should a leak occur.

Summary box 73.11

Surgery for rectal cancer

- Surgery is the mainstay of curative therapy
- The primary resection consists of rectal resection performed by total mesorectal excision
- Most cases can be treated by anterior resection, with the colorectal anastomosis being achieved with a circular stapling gun
- A smaller group of low, extensive tumours require an abdominoperineal excision with a permanent colostomy
- Preoperative radiotherapy with or without chemotherapy can be used to down-stage the cancer and reduce local recurrence
- Adjuvant chemotherapy can improve survival in node-positive disease
- Liver resection in carefully selected patients offers the best chance of cure for single or well-localised liver metastases

Preoperative preparation

The bowel is usually prepared by mechanical cleansing using a combination of diet, purgatives and enemas to reduce intraoperative contamination and the risk of surgical site infection. This approach is now used more selectively, with many surgeons reserving full bowel preparation for those undergoing a low anterior resection.

All patients should see a stoma care nurse preoperatively and be sited for a temporary or permanent ileostomy or colostomy. They must also be counselled as to the complications of the procedure, and particularly about the risks of pelvic autonomic nerve damage causing bladder and sexual disturbance, especially impotence in males.

Prophylactic systemic antibiotics are usually given perioperatively to reduce the risk of surgical site infection. In Europe, this usually takes the form of broad-spectrum antibiotics given intravenously at induction of anaesthesia. In the USA, antibiotic prophylaxis is more frequently administered as a course of oral antibiotics given preoperatively, and there is some evidence to suggest that this may be beneficial in reducing the risk of septic complications, including anastomotic leak.

Summary box 73.12

Preoperative preparation

- Counselling and siting of stomas
- Correction of anaemia and electrolyte disturbance
- Group and save of blood
- Bowel preparation
- Deep vein thrombosis prophylaxis
- Prophylactic antibiotics

Local operations

Early rectal cancers (T1 and good prognosis T2) may be amenable to local transanal excision, preserving much of the rectal reservoir and therefore near normal function. Histological analysis of the specimen is then used to assess the adequacy of excision with respect to the probability of positive lymph nodes being left behind. This may range from 10% in T1 cancers to 20% in T2 cancers and clinical judgement, along with in-depth conversation with the patient, is required to determine whether local excision has achieved a sufficient chance of oncological cure or whether a further radical resection is required.

Local excision is usually performed with one of the commercially available transanal laparoscopic systems or with equipment modified from taTME procedures (see below). A full-thickness excision of the lesion is performed and the defect closed with sutures or else left open. There is a limit to the height of lesion that can be resected, with more proximal lesions in the upper rectum being difficult.

Anterior resection

There has been a move to extend sphincter-saving operations to treat most tumours of the middle and lower thirds of the rectum, thus lowering the abdominoperineal excision rate and the need for permanent colostomy. There is also an increasing trend to use laparoscopic techniques for anterior resection, with patient benefits including less pain, quicker recovery from surgery and improved cosmesis. The evidence suggests that laparoscopic anterior resection is as safe as open surgery in terms of short- and long-term complications and oncological outcomes. More recently, robotic assistance has been employed with the da Vinci robotic surgical system (Intuitive Surgical Inc., Sunnyvale, CA, USA) (**Figure 73.20**). Although this adds significant cost to the procedure, there may be some benefit in terms of a reduced need to convert to open surgery, and therefore more patients benefiting from a minimally invasive approach. The operation performed is the same whether the procedure is undertaken by open, laparoscopic or robotic surgery, with the difference being in the extent of abdominal access trauma (laparotomy wound versus 'keyhole' incisions).

In open surgery, a midline abdominal incision is made and full laparotomy performed to detect synchronous pathologies, including evidence of intra-abdominal cancer spread. The sigmoid and descending colon are freed by dividing the peritoneal reflection on the left side, and mobilised to the midline on their mesentery, protecting the left ureter and testicular/ovarian vessels. The splenic flexure is mobilised to gain sufficient left colonic length to allow tension-free colorectal anastomosis. Rectal dissection is performed in the embryological planes (total mesorectal excision, TME) with preservation of the autonomic nerves, which course over the pelvic brim (sympathetic nerves) and exit from the pelvic plexuses (parasympathetic nerves) to supply the pelvic floor, and the urogenital organs (**Figure 73.21**). Once rectal dissection has reached the anorectal junction (low anterior resection), or at least 3 cm below the cancer (high anterior resection), the rectum is divided, usually with the aid of a stapling device.

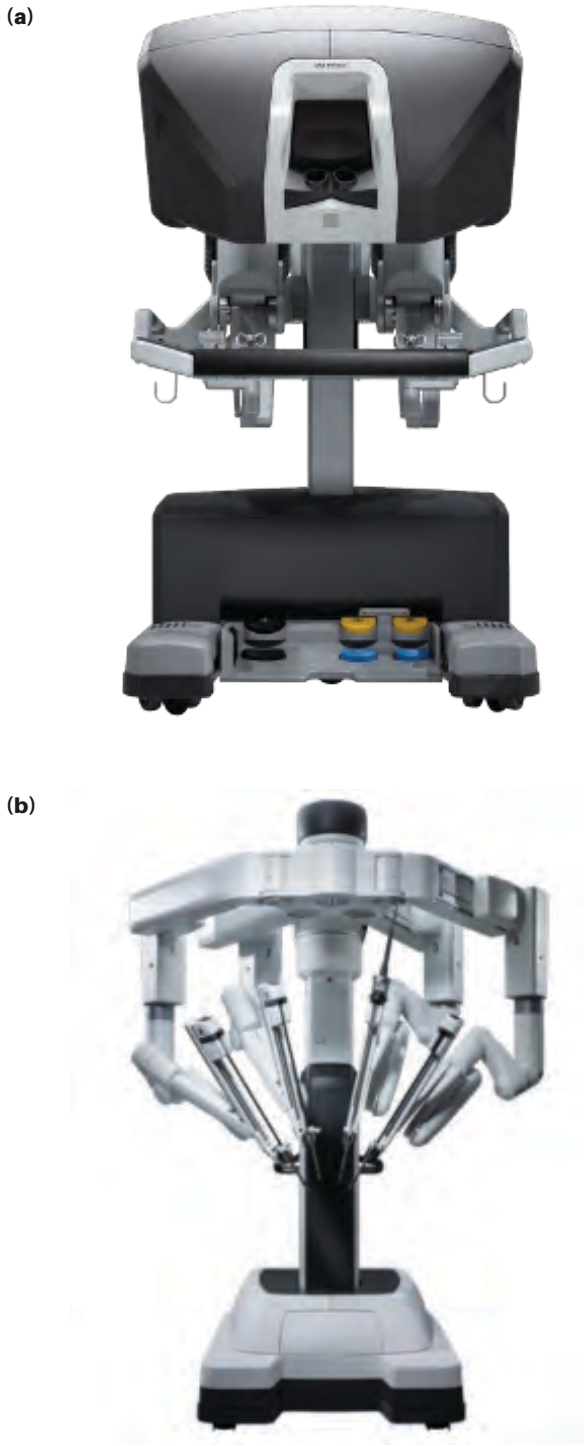

Figure 73.20 da Vinci Xi Robotic Surgical System: **(a)** surgeon console; **(b)** patient cart. Reproduced with kind permission from Intuitive Surgical Inc. http://www.intuitivesurgical.com/company/media/images/da-vinci-xi/

The mesocolon is divided at the site of the proposed division of the colon and the trunk of the inferior mesenteric artery is ligated and divided at its origin from the aorta (high-tie). Resection of the specimen is completed by division of the bowel at the point to be used for the proximal anastomosis.

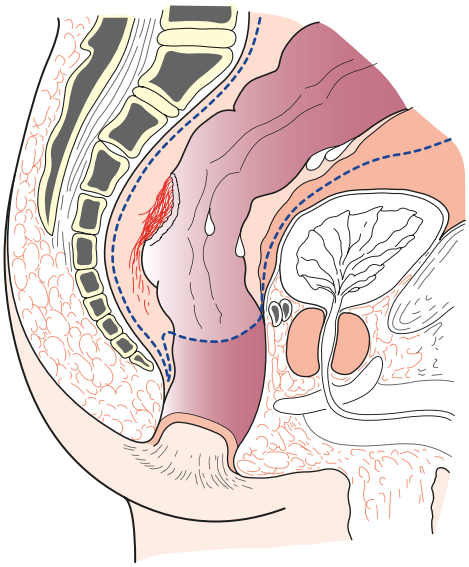

Figure 73.21 Plane of dissection for total mesorectal excision.

Restoration of bowel continuity is usually achieved by means of a stapled anastomosis. The simplest way of achieving this is by using a 'double stapling' technique, whereby a stapling gun is passed transanally to anastomose the stapled ends of the proximal colon and rectal stump. Alternatively, a 'single stapled' anastomosis may be performed in which purse-string sutures are applied to the proximal colon and rectal stump and anastomosed using a single firing of a staple gun inserted transanally. In cases where the anastomosis is very low (coloanal anastomosis) it may be necessary to perform a hand-sewn anastomosis.

Laparoscopic and robotic anterior resection follow the above general principles, but with abdominal access through the use of four or five abdominal ports and carbon dioxide pneumoperitoneum. The dissection usually follows a medial-to-lateral approach, i.e. dissection and high ligation of the vascular pedicle followed by lateral mobilisation of the colon, then rectal resection. A small laparotomy wound is still required to extract the specimen, unless transanal specimen extraction is possible, and restoration of bowel continuity is performed by the usual stapling techniques.

Transanal total mesorectal excision (taTME)

There is growing interest in reducing the trauma of anterior resection by undertaking total endoluminal excision of the rectum: transanal TME (taTME). This builds on the principles of laparoscopic surgery, with an air-tight anal device used to provide transanal insufflation and access for laparoscopic instruments. The operation proceeds by placing a purse-string suture below the distal level of the tumour and incising the bowel wall to enter the mesorectal plane. Dissection then proceeds using a 'bottom-up' approach to accomplish TME. It is usual for this procedure to be undertaken as a combined operation, with synchronous 'top-down' laparoscopic resection by an abdominal operator who mobilises the left colon, takes down the splenic flexure and does some of the upper rectal dissection.

Initial results have shown that taTME is safe, with short-term oncological outcomes, in terms of pathological quality of the resection specimen and circumferential resection margins, comparable to those of traditional laparoscopic and open techniques.

Hartmann's operation

This is an option in elderly and frail patients in whom there is concern about poor anal sphincter function and postoperative incontinence or the viability of an anastomosis. Colorectal excision follows the same principles as outlined above, but the rectal stump is stapled closed and the proximal colon exteriorised as a permanent end colostomy.

Abdominoperineal excision of the rectum

This operation is still required for some tumours of the lower third of the rectum which are unsuitable for a sphincter-saving procedure. Traditionally, the procedure was performed by two surgeons operating simultaneously, one via the abdomen and the other via the perineum, with the patient in the Trendelenburg lithotomy position. More recently, there has been a shift to completing the abdominal procedure first (with the patient in the Lloyd-Davies position, in which the legs are in supports set lower than the lithotomy position), and then placing the patient either in a prone jack-knife or Lloyd-Davies position and completing the operation via the perineum. The aim is to produce a complete resection of the rectum and mesorectum along with cylindrical excision of the extralevator component. This achieves wide excision at the level of the pelvic floor, increasing complete resection rates and reducing local perforation and the risk of local recurrence.

The abdominal procedure is carried out laparoscopically or via a midline laparotomy, and is performed in the same way as an anterior resection, except that dissection stops before the pelvic floor is reached (at the level of the seminal vesicles in men or the cervix in women), to avoid 'coning down' onto the tumour at the level of the pelvic floor. Perineal dissection is achieved through a circumanal incision which is deepened into the ischiorectal fossae and out towards the attachment of the levator muscles to the pelvic side wall (**Figure 73.22**). The dissection is extended posteriorly by incising Waldeyer's fascia, which is a thick condensation of pelvic fascia lying between the rectum and the sacrum. Some surgeons routinely remove the coccyx to improve access and surgical margins. Anteriorly, the plane between the rectum and the prostate in the male or between the rectum and the vagina in the female is developed, with particular care to avoid the membranous urethra in the male. A catheter within it should be palpated so that it can be avoided. The posterior wall of the vagina can be excised with the rectum if an advanced anterior tumour is present. Resection is completed when the perineal dissection reaches the abdominal dissection, with the specimen retrieved through the perineal wound. An end colostomy is formed in the left iliac fossa and the wounds closed with drains to the pelvis.

Oswald Vaughan Lloyd-Davies, 1905–1987, surgeon, St Mark's Hospital and The Middlesex Hospital, London, UK.

Endoluminal stenting

An increasingly used alternative for patients with an obstructing carcinoma is placement of an endoluminal stent, which can be done endoscopically, often with fluoroscopic guidance. This can either be used as a palliative procedure, or to relieve obstruction and permit elective rather than emergency surgery to be undertaken. Only rectosigmoid and upper rectal tumours are suitable for stenting, because stent impingement on the anorectum in low cancers causes symptoms of tenesmus.

Palliative colostomy

This is indicated only in cases giving rise to intestinal obstruction, or where the rectal cancer is not resectable. It can be performed by either an open or laparoscopic approach. In some cases a defunctioning colostomy is required in advanced cancers to prevent obstruction during down-staging chemoradiotherapy.

More extensive operations

When carcinoma of the rectum has spread to contiguous organs, the radical operation can often be extended to remove these structures *en bloc*. Thus, in the male, in whom spread is usually to the bladder or prostate, a cystectomy or prostatectomy may be required in combination with anterior resection to achieve complete oncological clearance. In the female, the uterus acts as an oncological barrier, preventing spread from the rectum to the bladder. Accordingly, a hysterectomy can be undertaken in addition to excision of the rectum. Pelvic evisceration for carcinoma of the rectum is usually only justifiable when the surgeon is confident that the cancer can be completely removed with negative resection margins.

Pelvic exenteration

The aim is to remove pelvic organs involved in the malignant process, and may involve a partial exenteration (posterior exenteration, including rectum and posterior vagina/uterus) or complete (including rectum and urogenital organs) (**Figure 73.23**). Exenteration may be necessary for advanced local disease, but more commonly for disease recurrence. It involves a large excision of the pelvic floor, leaving a sizeable perineal defect that has to be reconstructed using a plastic surgical procedure. Rectus abdominus or gluteal flaps can be used to fill the empty pelvis. Special care must be taken to suture the perineal skin accurately, and to avoid pressure necrosis by nursing the patient on alternate sides. Excision of the bladder will require the formation of an ileal conduit in addition to a colostomy.

Liver resection

Single or multiple well-localised liver metastases can now be resected with relatively low mortality and morbidity. Provided the patients are carefully selected, a reasonable long-term survival rate can be achieved (approximately 40%). Such surgery is usually carried out in a specialised liver unit, and may be performed synchronously at the time of anterior resection or else as a delayed procedure.

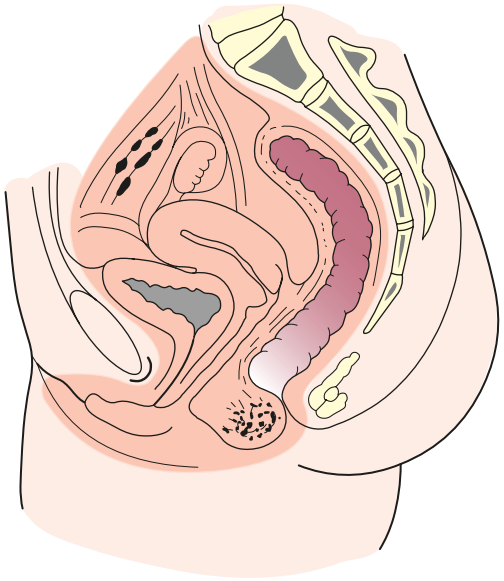

Figure 73.23 Radical pelvic exenteration, indicating the extent of the dissection and the viscera removed (shaded dark pink). Redrawn with permission from Keighley MRB, Williams NS. *Surgery of the anus, rectum and colon*. London: WB Saunders, 1999.

Radiotherapy

Adjuvant radiotherapy is now commonly used in the treatment of rectal cancer. It may be given preoperatively (neoadjuvant) and less commonly postoperatively (adjuvant). In the neoadjuvant setting, radiotherapy is used to either 'sterilise' the operative field in cancers with suspected lymphovascular involvement, or to down-stage locally advanced cancers with threatened circumferential resection margins. In the former instance, radiotherapy is often given as a 'short course' over 5 days with immediate surgery some 7–10 days later. On occasion, short-course radiotherapy can be combined with a delay before surgery (up to 12 weeks) to allow cancer regression. When radiotherapy is used to down-stage a cancer, it is often combined with chemotherapy (chemoradiotherapy) and given over a period of 6 weeks with a 6-week recovery period before surgery. Some 20% of cancers treated with chemoradiotherapy will show a complete pathological response, with a further 25–30% showing a partial response. Unfortunately, it is not yet possible to determine prior to treatment which patients will respond and therefore to tailor treatment accordingly.

Occasionally, radiotherapy is used to palliate unresectable cancers that are causing symptoms due to pain, obstruction or bleeding.

Alternative radiotherapy regimens include the Papillon technique in which intracavity radiation is directed to the cancer in the form of 'contact radiotherapy' or else delivered by brachytherapy techniques. To date, the application of these techniques has been restricted to selected cases, usually in patients unfit for more radical surgery.

Chemotherapy

Chemotherapy is either given in combination with radiotherapy (chemoradiotherapy) to down-stage a cancer prior

to surgical resection, or else in the postoperative setting to reduce the risk of disseminated disease. 5-Fluorouracil (5-FU) based regimens remain the first-line therapy and are associated with a 10% improvement in disease-free survival in patients with node-positive rectal cancer. Second-line therapies include oxaliplatin and irinotecan, and biological agents such as cetuximab.

Results of surgery for rectal cancer

In specialised centres, the resectability rate for rectal cancer may be as high as 95%, with an operative mortality of less than 5%. Overall, the 5-year survival rate is about 50% and has not changed appreciably over the last decade. Survival rates are influenced by TNM/Dukes' stage, with node-positive patients doing worse than those with node-negative lesions. However, with the introduction of national bowel cancer screening programmes, there is a shift to an earlier stage of disease presentation and consequently improved survival.

LOCAL RECURRENCE

Local recurrence after rectal excision is a major problem. The patient may be asymptomatic with recurrence diagnosed as part of a surveillance programme, including regular measurements of blood carcinoembryonic antigen (CEA) and cross-sectional radiological imaging. The presence of symptoms is often a poor prognostic feature. Persistent pelvic pain, which may radiate down the legs, is indicative of nerve root involvement and will preclude further surgery. Bladder symptoms may occur or there may be fistulating disease onto the perineum. Most local recurrences are situated extrarectally and are therefore not readily diagnosed on endoscopy examination and biopsy. CT and MRI scan are the best means for detecting local recurrence, but PET-CT is increasingly being used to differentiate metabolically active cancer recurrence from metabolically inactive scar tissue. Local recurrence rates vary between 2 and 25% and are higher after abdominoperineal excision than after sphincter-saving resection. High quality primary surgery with preservation of the mesorectal 'package' and a clear circumferential resection margin are the most important factors in preventing local recurrence.

Overall, 80% of local recurrences develop within 2 years following surgery, and are very difficult to treat. If the patient is radiotherapy naïve then preoperative chemoradiotherapy will be beneficial. Surgical exenteration offers the only hope of cure and may involve a partial sacrectomy, with significant morbidity.

Chapter 74

The anus and anal canal

Learning objectives

To understand

- The anatomy of the anus and anal canal and their relationship to surgical disease and its treatment
- The pathology, clinical presentation, investigation, differential diagnosis and treatment of diseases that affect the anus and anal canal
- That anal disease is common and its treatment tends to be conservative, although surgery may be required
- That any damage to the anus, including too aggressive or inappropriate surgery, may render the patient permanently disabled

ANATOMY AND PHYSIOLOGY

Surgical anatomy

The anal canal commences at the level where the rectum passes through the pelvic diaphragm and ends at the anal verge. The muscular junction between the rectum and anal canal can be felt with the finger as a thickened ridge – the anorectal 'bundle' or 'ring'.

Anal canal anatomy

The anorectal ring

The anorectal ring marks the junction between the rectum and the anal canal (**Figure 74.1**). It is formed by the joining of the puborectalis muscle (**Figure 74.2**), the deep external sphincter, conjoined longitudinal muscle and the highest part of the internal sphincter. The anorectal ring can be clearly felt digitally, especially on its posterior and lateral aspects.

The puborectalis muscle

Puborectalis, part of the funnel-shaped muscular pelvic diaphragm, maintains the angle between the anal canal and rectum and hence is an important component in the continence mechanism (**Figure 74.2**). The muscle derives its nerve supply from the sacral somatic nerves, and is functionally indistinct from the external anal sphincter. The position and length of the anal canal, as well as the angle of the anorectal junction, depend to a major extent on the integrity and strength of the puborectalis muscle sling. It gives off fibres that contribute to the longitudinal muscle layer.

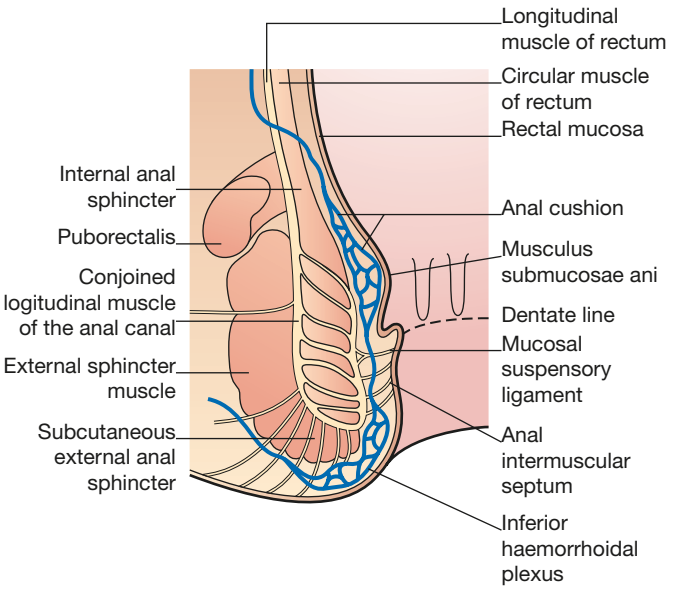

Figure 74.1 Relevant anatomy of the anus. (Redrawn with permission from Mann CV. *Surgical treatment of haemorrhoids*. London: Springer, 2002.)

The external sphincter

The external sphincter forms the bulk of the anal sphincter complex and, although traditionally it has been subdivided into deep, superficial and subcutaneous portions, it is a single muscle (Goligher), which is variably divided by lateral extensions from the longitudinal muscle layer. Some of its fibres are attached posteriorly to the coccyx, whereas anteriorly they fuse with the perineal muscles. Being a somatic voluntary muscle, the external sphincter is red in colour and is innervated by the pudendal nerve.

John Cedric Goligher, 1912–1998, Professor of Surgery, University of Leeds, Leeds, UK.

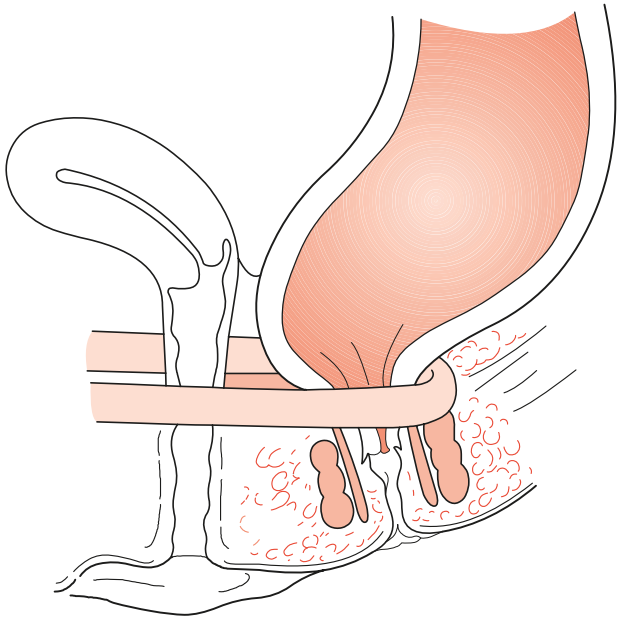

Figure 74.2 The disposition of the puborectalis muscle. Note how it maintains the rectoanal angle.

The intersphincteric plane

Between the external sphincter muscle laterally and the longitudinal muscle medially exists a potential space, the intersphincteric plane. This plane is important as it contains intersphincteric anal glands (see below) and is also a route for the spread of pus, which occurs along the extensions from the longitudinal muscle layer. The plane can be opened up surgically to provide access for operations on the sphincter muscles.

The longitudinal muscle

The longitudinal muscle is a direct continuation of the smooth muscle of the outer muscle coat of the rectum, augmented in its upper part by striated muscle fibres originating from the medial components of the pelvic floor. Most of the muscle continues caudally before splitting into multiple terminal septa that surround the muscle bundles of the subcutaneous portion of the external sphincter, to insert into the skin of the lowermost part of the anal canal and adjacent perianal skin. Milligan and Morgan named the most medial of these septa, passing around the inferior border of the internal sphincter, the 'anal intermuscular septum'. As it descends, however, it gives off fibres that pass medially across the internal sphincter to reach the submucosal space, and laterally across the external sphincter and ischiorectal space to reach the fascia of the pelvic side walls. As well as providing a supportive mesh for the anal canal and other muscular components, its ramifications provide potential pathways for the spread of infection. During defaecation, its contraction widens the anal lumen, flattens the anal cushions, shortens the anal canal and everts the anal margin; subsequent relaxation allows the anal cushions to distend and thus contribute to an airtight seal.

The internal sphincter

The internal sphincter is the thickened (2–5 mm) distal continuation of the circular muscle coat of the rectum, which has developed special properties and which is in a tonic state of contraction. This involuntary muscle commences where the rectum passes through the pelvic diaphragm and ends above the anal orifice, its lower border palpable at the intersphincteric groove, below which lie the most medial fibres of the subcutaneous external sphincter, and separated from it by the anal intermuscular septum. When exposed during life, it is pearly-white in colour and its circumferentially placed fibres can be seen clearly. Although innervated by the autonomic nervous system, it receives intrinsic non-adrenergic and non-cholinergic (NANC) fibres, stimulation of which causes release of the neurotransmitter nitric oxide, which induces internal sphincter relaxation.

The epithelium and subepithelial structures

The pink columnar epithelium lining the rectum extends through the anorectal ring into the surgical anal canal. Passing downwards the mucous membrane becomes cuboidal and redder in colour (Figure 74.3), whereas above the anal valves it is plum coloured. Just below the level of the anal valves there is an abrupt, albeit wavy, transition to stratified squamous epithelium, which is parchment coloured. This wavy junction constitutes the dentate line. The dentate line is a most important landmark both morphologically and surgically, representing the site of fusion of the proctodaeum and postallantoic gut, and being the site of the crypts of Morgagni (synonym: anal crypts, sinuses). The latter are small pockets between the inferior extremities of the columns of Morgagni through which anal ducts that communicate with deeper placed anal glands open into the anal lumen. The squamous epithelium lining the lower anal canal is thin and shiny and is known as the anoderm; it differs from the true skin in that it has no epidermal appendages, i.e. hair and sweat glands. At the dentate line, the anoderm is

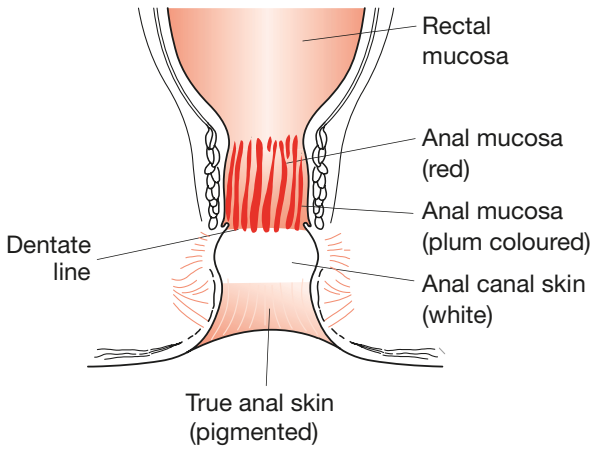

Figure 74.3 The lining membrane of the anal canal (after Sir Clifford Naunton Morgan, London).

Edward Thomas Campbell Milligan, 1886–1972, surgeon, St Mark's Hospital, London, UK.
Sir Clifford Naughton Morgan, 1901–1986, surgeon, St Mark's Hospital and St Bartholomew's Hospital, London, UK.

attached more firmly to deeper structures. The mucosa and submucosa above the dentate line is uneven and thrown into folds, the so called anal cushions. There are variations in the numbers and positions of these cushions but there are usually three, corresponding to those seen in later life. These are described classically as occupying the left lateral, right posterior and right anterior positions, and they continue proximally as the primary rectal foldings. Secondary foldings (the rectal columns of Morgagni) lie both over and between the primary folds. This area is the caudal limit of the so-called epithelial transitional zone, below which the stratified squamous epithelium is richly innervated by sensory nerve endings serving several modalities including touch, pain and temperature. The bulk of the anal cushions themselves, situated in the upper part of the anal canal, receive only visceral afferent innervation and, although there is perception of stretching, sensitivity to noxious stimuli is much more blunted than distally.

Between the epithelial layer and the internal sphincter lies the submucosa, consisting of vascular, muscular and connective tissue supportive elements. From the longitudinal muscle, medial extensions cross the internal anal sphincter and form part of the supporting meshwork of the submucosa, blending with the true submucosal smooth muscle layer and thereby supporting the mucosa itself. Parks described the increased density of fibres that insert into the mucosa of the anal crypts at the level of the dentate line, termed the 'mucosal suspensory ligament'. One feature of this structure is that it separates the superior (portal) and inferior (systemic) haemorrhoidal plexuses; another, is that the mucosa is more firmly tethered to underlying tissues at this level than above. It is important to appreciate that the meshwork of supporting tissues (muscle fibres and connective tissue) within the subepithelial space is intimately linked to deeper structures within the anal sphincter complex, including the internal sphincter, longitudinal muscle layer and external anal sphincter, and indeed structures beyond the sphincter complex. With age, the smooth muscle component of this mesh is reduced and muscle fibres are gradually replaced with fibroelastic connective tissue, which in turn becomes fragmented.

Blood supply

In addition to the meshwork support of the lining of the anal canal, the subepithelial space contains venous dilatations supported by the same fibroelastic connective tissue and smooth muscle scaffolding. Debate has centred on the nature of the vascular component of haemorrhoids, but the seminal anatomical studies of Thomson have clarified this issue. Venous dilatations are seen in the submucosa both above and below the level of the dentate line; they are much more numerous above although tend to be larger below. The historical description of the blood supply to the upper anal canal as constant, with bifurcation of the main trunk of the superior rectal artery into right and left branches and with subsequent division of the former into anterior and posterior divisions, thereby determining the sites of haemorrhoids around the anal circumference, was questioned by Thomson. He demonstrated that the divisions of the superior rectal artery were not constant and that, furthermore, the anal submucosa in a proportion of his specimens received a blood supply from the middle and inferior rectal arteries. He was also able to show the presence of free communications between tributaries of the superior, middle and inferior rectal veins, as well as tiny direct arteriovenous communications with the submucosal venous dilatations. These communications have been shown both histologically and radiologically, and the oxygen tension of the blood contained within the venous dilatations (as well as the colour) is more arterial than venous.

Venous drainage

The anal veins are distributed in a similar fashion to the arterial supply. The upper half of the anal canal is drained by the superior rectal veins, tributaries of the inferior mesenteric vein and thus the portomesenteric venous system, and the middle rectal veins, which drain into the internal iliac veins. The inferior rectal veins drain the lower half of the anal canal and the subcutaneous perianal plexus of veins; they eventually join the internal iliac vein on each side.

Lymphatic drainage

Lymph from the upper half of the anal canal flows upwards to drain into the postrectal lymph nodes and from there goes to the para-aortic nodes via the inferior mesenteric chain. Lymph from the lower half of the anal canal drains on each side, first into the superficial and then into the deep inguinal group of lymph glands. However, if the normal flow is blocked, e.g. by tumour, the lymph can be diverted into the alternative route.

Summary box 74.1

Anal canal anatomy

- The internal sphincter is composed of circular, non-striated involuntary muscle supplied by autonomic nerves
- The external sphincter is composed of striated voluntary muscle supplied by the pudendal nerve
- Extensions from the longitudinal muscle layer support the sphincter complex
- The space between sphincters is known as the intersphincteric plane
- The superior part of the external sphincter fuses with the puborectalis muscle, which is essential for maintaining the anorectal angle, necessary for continence
- The lower part of the anal canal is lined by sensitive squamous epithelium
- Blood supply to the anal canal is via superior, middle and inferior rectal vessels
- Lymphatic drainage of the lower half of the anal canal goes to inguinal lymph nodes

The anal glands

Anal glands (which are not vestigial remnants of sexual scent glands) may be found in the submucosa and intersphincteric space (**Figure 74.4**), and normally number between 0 and 10 in an individual. They drain via ducts into the anal sinuses at the level of the dentate line. Not all sinuses have a duct draining into them and, occasionally, more than one gland can discharge into the same sinus. Their function is unknown although they secrete mucin (distinct from that secreted by the rectal epithelium), which perhaps lubricates the anal canal to ease defaecation. The importance of intersphincteric anal glands is that they are widely considered to be the potential source of anal sepsis, either acute, presenting as perianal, ischiorectal or even pelvic sepsis, or chronic, presenting as a cryptoglandular (non-specific) anal fistula.

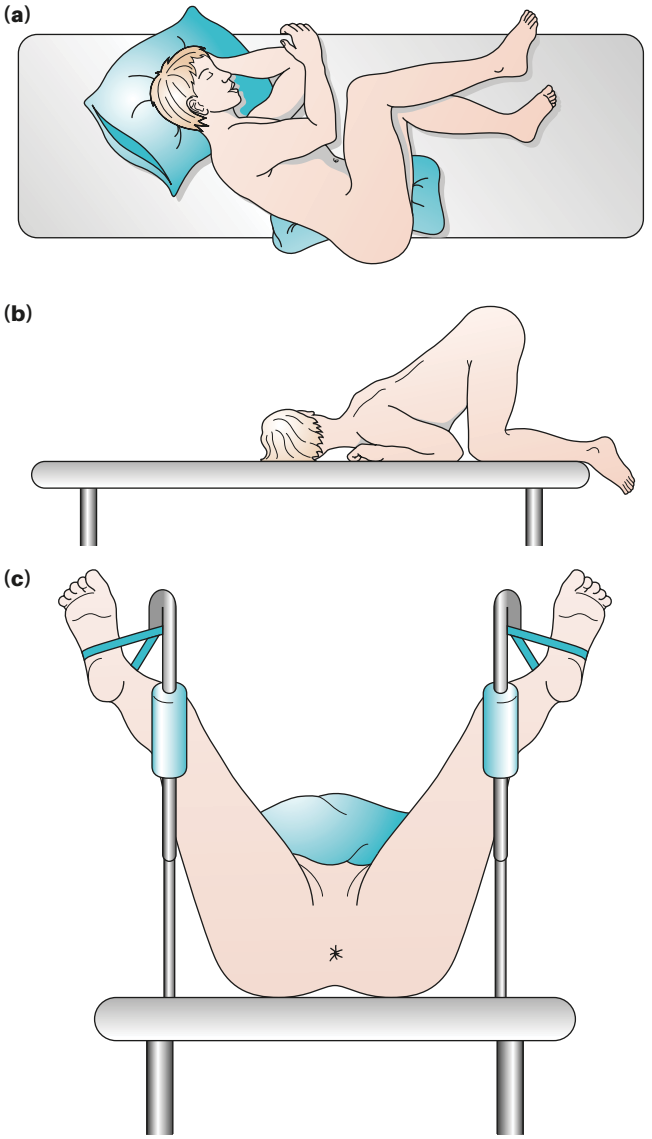

Figure 74.5 **(a)** The left lateral; **(b)** knee–elbow and lithotomy **(c)** positions for examination. (Redrawn with permission from Mann CV. *Surgical treatment of haemorrhoids*. London: Springer, 2002.)

EXAMINATION OF THE ANUS

Careful clinical examination will be diagnostic in the vast majority of patients complaining of anal symptoms, but it requires a relaxed patient who is informed of what the examination will entail, a private environment, a chaperone (for the security of both parties) and good light. Most commonly, the patient is examined in the left lateral (Sims) position with the buttocks overlying the edge of the examination couch and with the axis of the torso crossing, rather than parallel with, the edge of the couch. Alternatively, in younger patients, the prone jack-knife or knee–elbow positions may be used (**Figure 74.5**). The examining couch should be of sufficient height to allow easy inspection and access for any necessary manoeuvres. A protective glove should be worn.

Inspection

The buttocks are gently parted to allow inspection of the anus and perineum: the presence of any skin lesions and whether they are confined to the perineum or evident elsewhere on general examination, e.g. psoriasis, lichen planus, or on genital examination, e.g. warts, candidiasis, lichen sclerosus et atrophicus, the vesicles of herpes simplex virus (HSV); evidence of anal leakage; whether the anus is closed or patulous; and the position of the anus and perineum at rest and on bearing down (the latter may reveal prolapse of haemorrhoids or even the rectum). Pain on parting the buttocks, perhaps

James Marion Sims, 1813–1883, gynaecological surgeon, the State Hospital for Women, New York, USA, introduced this position to give access to the anterior vaginal wall during operations for the closure of vesicovaginal fistulae.

together with the presence of a sentinel tag, may indicate the presence of an underlying fissure, but may also prompt the need for examination under anaesthesia to exclude more suspicious pathology, for example squamous cell carcinoma of the anal canal.

Digital examination with the index finger

With an adequately lubricated index finger, the soft tissues around the anus are palpated for induration, tenderness and subcutaneous lesions. The index finger is then introduced gently into the anal canal along its posterior aspect. At the apex of the canal, the sling of puborectalis is felt posteriorly; supralevator induration feels bony hard and is more easily appreciated if unilateral. The posterior surface of the prostate gland with its median sulcus can be palpated anteriorly in male patients; in female patients, the uterine cervix can be palpated. The presence of any distal intrarectal, intra-anal or extraluminal mass is recorded. Sphincter length, resting tone and voluntary squeeze are assessed. On withdrawal, the examining finger is inspected for the presence of mucus, blood or pus and to identify stool colour.

Proctoscopy

Proctoscopy, performed with the patient in the same position, allows a detailed inspection of the distal rectum and anal canal (**Figure 74.6**). Minor procedures can also be carried out through this instrument, e.g. treatment of haemorrhoids by injection or banding (see below) and biopsy. Asking the patient to bear down on slow withdrawal of the proctoscope may reveal a descending intussusception.

Sigmoidoscopy

Although sigmoidoscopy is strictly an examination of the rectum (see Chapter 73), it should always be carried out even when an anal lesion has been confirmed. Rectal pathology, e.g. colitis or carcinoma, is frequently associated with an anal lesion, e.g. fissure or haemorrhoids. Not infrequently, rectal pathology is found that is independent of the anal lesion and which requires treatment.

Summary box 74.2

Examination of anal canal

- A rectal examination is essential for any patient with anorectal and/or bowel symptoms – 'If you don't put your finger in, you might put your foot in it'
- A proctosigmoidoscopy is essential in any patient with bowel symptoms, and particularly if there is rectal bleeding

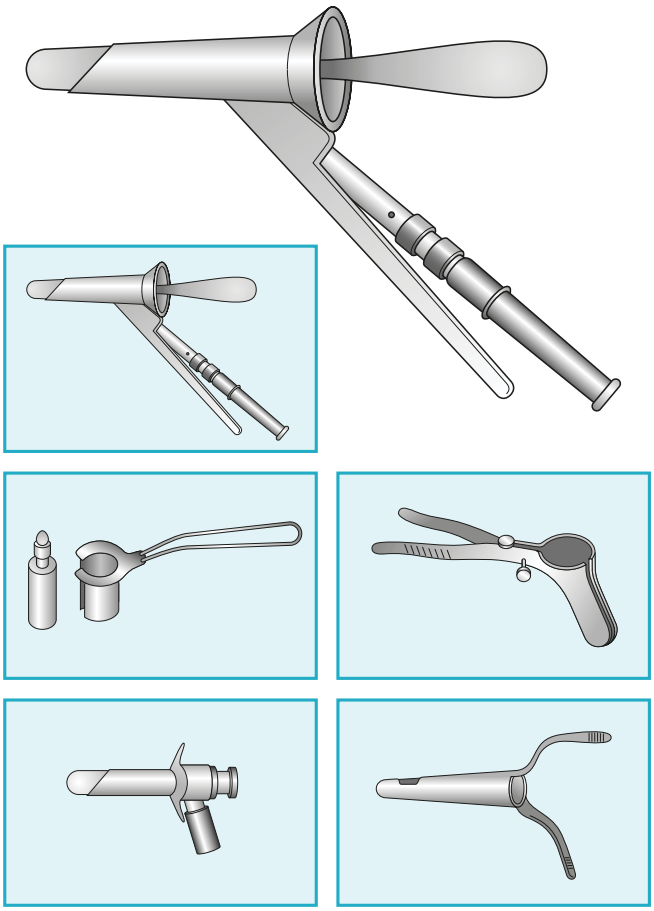

Figure 74.6 Various types of proctoscope. (Redrawn with permission from Mann CV. *Surgical treatment of haemorrhoids*. London: Springer, 2002.)

PHYSIOLOGICAL ASPECTS OF THE ANAL SPHINCTERS AND PELVIC FLOOR, AND SPECIAL INVESTIGATIONS

Anal continence and defaecation are highly complex processes that necessitate the structural and functional integrity of the cerebral, autonomic and enteric nervous systems, the gastrointestinal tract (especially the rectum) and the pelvic floor and anal sphincter complex, any of which may be compromised and lead to disturbances of function of varying severity. The sphincter mechanism provides the ultimate barrier to leakage and its integrity can be assessed fairly simply and objectively in the physiology laboratory (Swash and Henry). Perineal position and degree of descent on straining (markers of pelvic floor and pudendal nerve function) can be quantified, and functional anal canal length, resting tone (reflective predominantly of internal sphincter activity) and squeeze increment (reflective of external sphincter function)

Michael Swash, formerly Professor of Neurology, St Bartholomew's and The Royal London Hospital, London, UK.
Michael Meldrum Henry, surgeon, The Chelsea and Westminster Hospital, London, UK.

can be measured by a variety of simple manometric techniques (Figure 74.7). The structural integrity of the sphincters can be visualised with endoluminal ultrasound (Figure 74.8), and neuromuscular function can be measured by assessment of conduction velocity along the pudendal nerve on each side, or, more painfully, by needle electromyogram (EMG) studies (Figures 74.9 and 74.10). In the elderly especially, but also in younger patients, disorders relating to rectal sensorimotor dysfunction can lead to 'overflow' of rectal contents through what may be an otherwise normal sphincter. The dynamics of defaecation can also be assessed radiologically by evacuation proctography, in which radio-opaque pseudostool is inserted into the rectum and the patient asked to rest, squeeze and then bear down to evacuate the rectal contents under real-time imaging. Proctography can be combined with synchronous EMG and pressure studies (Williams) (Figure 74.11) to yield more information about possible reasons (mechanical (rectocoele, intussusception) or functional (anismus, lack of effort)) for disordered defaecation in an individual. More recently, the use of dynamic magnetic resonance (MR) proctography has become more widespread, although studies in which the subject is asked to evacuate in the supine position may be less physiological than those in which the subject adopts a sitting position within an open magnet. When compared with evacuation proctography, MR proctography under-reports intussusception and the size of rectocele; also significantly fewer patients are able to evacuate the contrast. Results of all physiological and imaging tests have to be compared with a robust normal range and within the context of the patient's symptoms, and are used to guide rational rather than empirical treatment strategies.

CONGENITAL ABNORMALITIES

Early in embryonic life there is a common chamber – the cloaca – into which the hind gut and the allantois open. This endodermlined chamber is separated from the surface ectoderm of the embryo by the cloacal membrane. The cloaca becomes divided into two parts, dorsal (rectum) and ventral

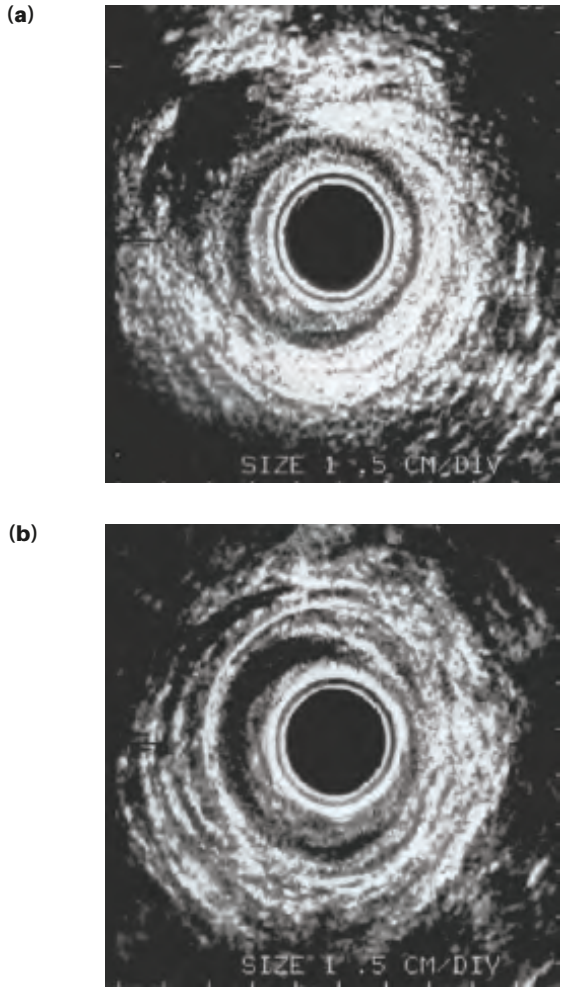

Figure 74.8 Endoanal ultrasonography: **(a)** external anal sphincter defect caused by obstetric injury; **(b)** internal anal sphincter defect postsphincterotomy.

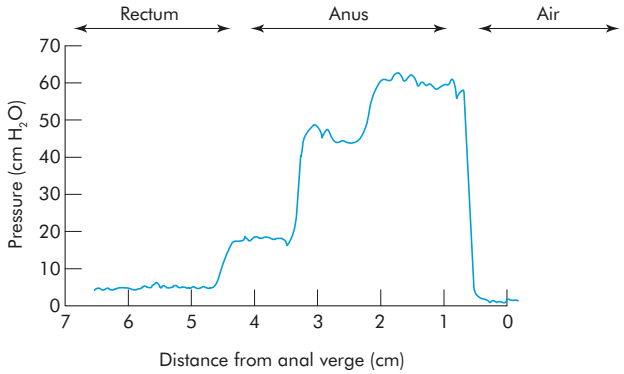

Figure 74.7 A typical, normal 'pull-through' manometric study of the anal canal (3.5 cm long; maximal pressure approximately 60 cmH_2O).

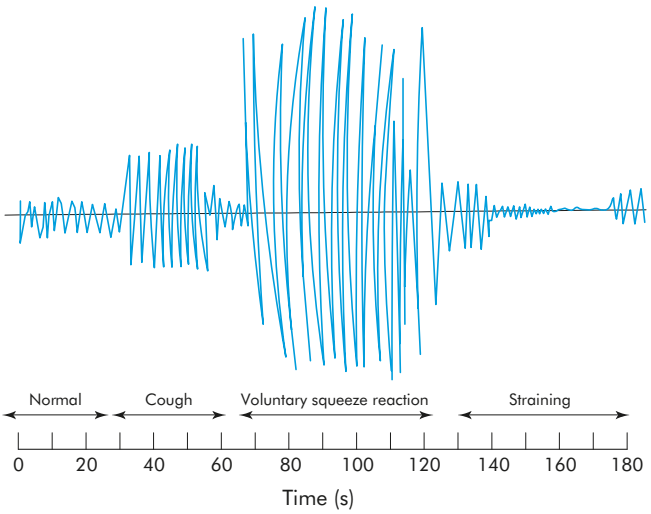

Figure 74.9 A typical, normal electromyographic study of the external sphincter during various activities.

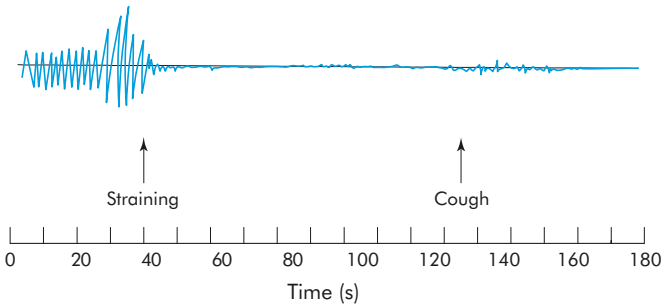

Figure 74.10 An electromyographic study of the external sphincter showing prolonged inhibition on straining and absent cough reflex. This is typical of a denervated patulous sphincter.

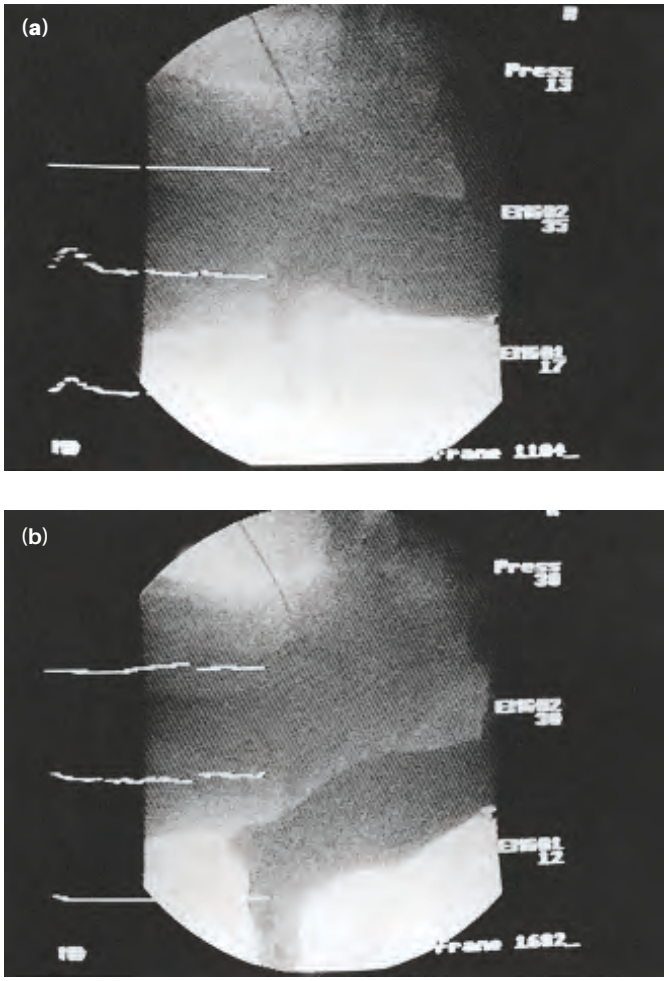

Figure 74.11 Integrated dynamic proctography: **(a)** at rest; **(b)** during evacuation. Visualisation of the rectum is achieved using barium-impregnated 'synthetic stool'. The effects of straining and evacuation on the electromyographic activity of the sphincter muscles and intrarectal pressure can be simultaneously recorded (Williams).

(urogenital sinus), by the downgrowth of a septum. The dorsal part of the cloacal membrane, known as the anal membrane, is thus composed of an outer layer of ectoderm and an inner layer of endoderm. Resorption of this anal membrane by the eighth week of embryonic life creates the anal canal.

Imperforate anus

Imperforate anus (strictly, it should be anal 'agenesis' or 'atresia') has historically been divided into two main groups – high and low – depending on the level of termination of the rectum in relation to the pelvic floor. Treatment and prognosis are influenced by any associated abnormalities of the sacrum and genitourinary systems. In both sexes, low defects embrace rectoperineal fistula (**Figure 74.12**), covered anus and anal

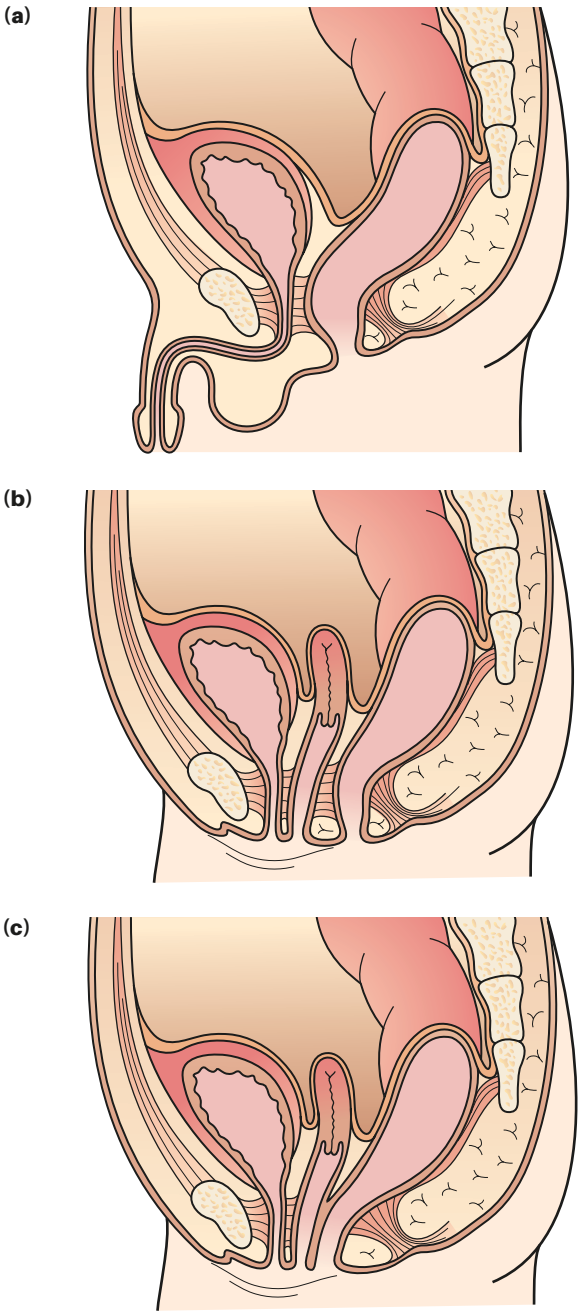

Figure 74.12 Low anorectal malformations: **(a)** rectoperineal fistula in a boy; **(b)** rectoperineal fistula in a girl (anterior anus); **(c)** rectovestibular fistula. (Courtesy of Alberto Pena and Springer-Verlag. From Pena A. *Atlas of surgical management of anorectal malformations*. Copyright Springer-Verlag, 1990.)

Alberto Pena, contemporary, Professor of Pediatric Surgery, Schneider Children's Hospital, New York, NY, USA.

membrane. The most frequent defect in boys with imperforate anus is one in which the distal rectum is sited within the puborectalis sling but terminates as a fistula into the bulbar urethra (**Figure 74.13**) (see also Chapter 9, **Figure 9.32**) or prostatic urethra above the main anal sphincter complex. Boys with a fistula into the bladder neck (a high defect) have the poorest prognosis because of the underdevelopment of the sacrum and pelvic and anal musculature. The most common defect in girls is a rectovestibular fistula, in which the fistula opens into the posterior vestibule (not the vagina) (**Figure 74.12**). The finding of a single perineal orifice indicates a persistent cloaca in which the rectum, vagina and urinary tract form a confluence (**Figure 74.13**); the longer the common channel, the greater the likelihood of more complex defects, including vaginal and uterine septation, duplication or atresia. An anterior anus, although not imperforate, is not fully located within the sphincter mechanism and is regarded as part of the spectrum of anorectal malformations (**Figure 74.12**).

Clinical management

Careful perineal examination will usually provide the most important clues about the neonate's type of malformation. The presence of meconium on the perineum indicates a low defect and meconium in the urine is evidence of a urinary tract fistula. During the first 24 hours, the baby should receive intravenous fluids and antibiotics, and should be evaluated for associated congenital anomalies. By 24 hours, the distal limit of air within the rectum, seen on a lateral prone radiograph, indicates the distance between the rectal stump and perineum (**Figure 74.14**).

Treatment

Low anomalies with a perineal fistula can be treated by an anoplasty. More complex malformations require early colostomy, with definitive repair performed several months later. This may involve posterior sagittal anorectoplasty (PSARP, Pena), with or without transabdominal mobilisation of the left colon and division of any communication with the urinary tract. In girls with a cloaca and long common channel, urinary and vaginal reconstruction is also required. Postoperatively, a programme of anal dilatation is instituted, and any residual colostomy is closed at a later date. Ultimate bowel function (voluntary bowel movements, continence, constipation) is related to the type of anorectal abnormality and the presence of associated defects, especially sacral.

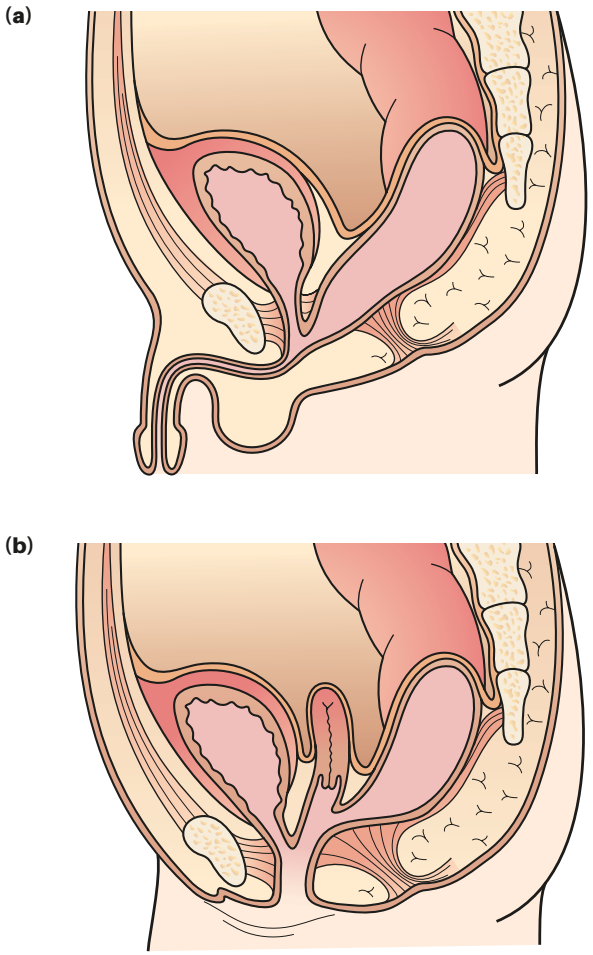

Figure 74.13 More complex anorectal malformations: **(a)** rectobulbar fistula; **(b)** cloacal malformation. (Courtesy of Alberto Pena and Springer-Verlag. From Pena A. *Atlas of surgical management of anorectal malformations*. Copyright Springer-Verlag, 1990.)

Summary box 74.3

Imperforate anus

- A rare congenital disorder
- Classified as being high or low depending on the site of the rectal termination in relation to the pelvic floor
- Low defects: relatively easy to correct but prone to constipation
- High defects: more difficult to correct and prone to faecal incontinence

Postanal dermoid

The space in front of the lower part of the sacrum and coccyx may be occupied by a soft, cystic swelling – a postanal dermoid cyst. Hidden in the hollow of the sacrum it is unlikely to be discovered unless a sinus communicating with the exterior is present or it develops as a result of inflammation. Such a cyst usually remains asymptomatic until adult life, when it is prone to becoming infected. Exceptionally, because of its size, it gives rise to difficulty in defaecation. The cyst is easily palpable on rectal examination.

Differential diagnosis

Especially in a child, an anterior sacral meningocele must be excluded. This enlarges when the child cries and is frequently associated with paralysis of the lower limbs and incontinence. When a discharging sinus is present, a postanal dermoid will probably be mistaken for a pilonidal sinus or even an anal fistula. Pressure over the sacrococcygeal region with a finger in the rectum may cause a flow of sebaceous material, and injection of contrast media followed by radiography reveals a bottle-necked cyst in front of the coccyx.

Treatment

Treatment involves complete excision of the cyst and, if present, the sinus. In the case of large cysts, it is necessary to remove the coccyx to gain access. The coccyx should also be removed *en bloc* in any child with a presacral dermoid because of the risk of sacrococcygeal teratoma.

Postanal dimple (synonym: fovea coccygea)

A dimple in the skin beneath the tip of the coccyx, sometimes amounting to a short blind pit, is noticed from time to time in the course of a clinical examination and is of no consequence.

Pilonidal sinus

The term pilonidal sinus describes a condition found in the natal cleft overlying the coccyx, consisting of one or more, usually non-infected, midline openings, which communicate with a fibrous track lined by granulation tissue and containing hair lying loosely within the lumen. A common affliction amongst the military, it has been referred to as 'jeep disease'.

Aetiology and pathology

Although acquired theories of development are better accepted than the more historical congenital theories, exact mechanisms of development are speculative. Evidence that supports the theory of the origin of pilonidal sinuses as acquired, can be summarised as follows:

- Interdigital pilonidal sinus is an occupational disease of hairdressers, the hair within the interdigital cleft or clefts being the customers'. Pilonidal sinuses of the axilla and umbilicus have also been reported.
- The age incidence of the appearance of pilonidal sinus (82% occur between the ages of 20 and 29 years) is at variance with the age of onset of congenital lesions.
- Hair follicles have almost never been demonstrated in the walls of the sinus.
- The hairs projecting from the sinus are dead hairs, with their pointed ends directed towards the blind end of the sinus.
- The disease mostly affects men, in particular hairy men.
- Recurrence is common, even though adequate excision of the track is carried out.

It is thought that the combination of buttock friction and shearing forces in that area allows shed hair or broken hairs which have collected there to drill through the midline skin, or that infection in relation to a hair follicle allows hair to enter the skin by the suction created by movement of the buttocks, so creating a subcutaneous, chronically infected, midline track. From this primary sinus, secondary tracks may spread laterally, which may emerge at the skin as granulation tissue-lined, discharging openings. Usually, but not invariably (when diagnosis may be confused with anal fistula or hidradenitis suppurativa), the sinus runs cephalad. Carcinoma arising in chronic pilonidal disease has been described but is exceedingly rare.

Clinical features

The condition is seen much more frequently in men than women, usually after puberty and before the fourth decade of life, and is characteristically seen in dark-haired individuals rather than those with softer blond hair (Oldham). Patients complain of intermittent pain, swelling and discharge at the base of the spine but little in the way of constitutional symptoms. There is often a history of repeated abscesses that have burst spontaneously or which have been incised, usually away from the midline. The primary sinus may have one or many openings, all of which are strictly in the midline between the level of the sacrococcygeal joint and the tip of the coccyx.

Conservative treatment

As the natural history of the condition is usually one of regression, in those whose symptoms are relatively minor, simple

A jeep is a small military, general purpose, vehicle with hard springing, which gives its occupants a very bouncy ride when driven over rough terrain.
James Bagot Oldham, 1899–1977, surgeon, the United Liverpool Hospitals, Liverpool, UK.

cleaning out of the tracks and removal of all hair, with regular shaving of the area and strict hygiene, may be recommended.

Treatment of an acute exacerbation (abscess)

If rest, baths, local antiseptic dressings and the administration of a broad spectrum antibiotic fail to bring about resolution, the abscess should be drained through a small longitudinal incision made over the abscess and off the midline, with thorough curettage of granulation tissue and hair. This procedure may or may not be associated with complete resolution.

Surgical treatment of chronic pilonidal disease

The multitude of surgical procedures advocated to eradicate pilonidal disease, combined with the lack of prospective trials, attests to the lack of overall superiority of one method over the others. Time spent off work and perceived recurrence rates, but more usually surgeon preference, influence the choice of method, which includes the laying open of all tracks with or without marsupialisation, the excision of all tracks with or without primary closure and the excision of all tracks and then closure by some other means designed to avoid a midline wound (Limberg procedure, Z-plasty, Karydakis procedure (**Figure 74.15**)). Bascom's procedure involves an incision lateral to the midline to gain access to the sinus cavity, which is rid of hair and granulation tissue (**Figure 74.16**), and excision and closure of the midline pits (**Figure 74.17**). The lateral wound is left open (**Figure 74.18**). Irrespective of procedure, postoperative wound care is important and centres around elimination of hair (ingrown, local or other) from the wound. The search for an ideal surgical treatment modality for pilonidal disease is still ongoing, the most essential characteristic being tension-free healing.

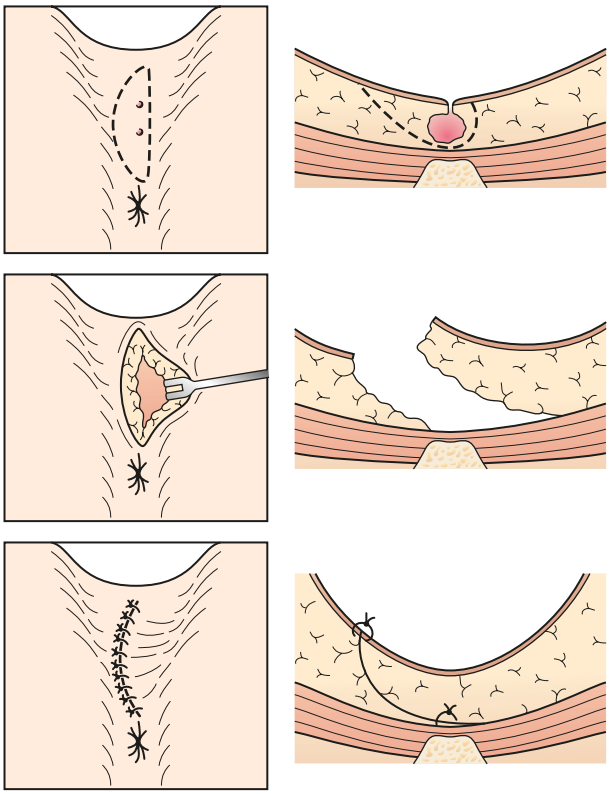

Figure 74.15 Karydakis's operation for pilonidal sinus. A semilateral incision is made around the sinus complex, the diseased component excised and the flap mobilised to allow tension-free closure of the wound off the midline. Col Dr George E Karydakis, surgeon, Athens, Greece.
John U Bascom, 1925–2013, American surgeon, formerly of Eugene, OR, USA.

Recurrent pilonidal sinus

Three possibilities account for this disappointment:

- part of the sinus complex has been overlooked at the primary operation;
- new hairs enter the skin or the scar;
- there is persistence of a midline wound caused by shearing forces and scarring; in this situation, revisional surgery may include re-excision followed by wound closure and obliteration of the natal cleft, either by myocutaneous rotational buttock flap or cleft closure (Bascom).

ANAL INCONTINENCE

Aetiology

As continence is dependent upon the structural and functional integrity of both the neurological pathways and the gastrointestinal tract, the risk factors for anal incontinence are many. Patients complaining of the involuntary loss of rectal contents require a comprehensive assessment of the nature and severity of symptoms; past history, especially of gastrointestinal disease, neurological conditions, obstetric events and anal surgery; and careful clinical examination (in the elderly, incontinence is often one of overflow secondary to rectal impaction, and proctitis may lead to such an irritable rectum that even the strongest sphincter is occasionally overwhelmed). A combination of history and examination will usually be diagnostic, but special investigations are then usually required to clarify the exact cause, including exclusion of an underlying malignancy, and to direct management.

Sphincteric causes of incontinence may be classified as structural, in which there is disruption (or atrophy) of part of the sphincter muscles, neuropathic (previously termed idiopathic), in which the nerve supply to the sphincters is damaged, usually by chronic straining or complicated vaginal delivery (prolonged second stage), or a combination of the two. The commonest causes of sphincteric disruption are obstetric damage, anal surgery (following haemorrhoidectomy, dilatation or sphincterotomy for anal fissure, and fistulotomy for anal fistula) and trauma (including anal intercourse, forced or otherwise).

In general, conservative measures to reduce symptoms are employed initially. These may be in the form of stool bulking or constipating agents, nurse-led bowel retraining including specific biofeedback programmes, or anal plugs, which expand within and thus seal the anal canal. Failure of such measures and severity of symptoms may result in selection for surgery.

Operations to reunite divided sphincter muscles

In situations in which there is a discrete disruption of the sphincters, the ends of the divided muscle are found and reunited by a double overlap repair (**Figure 74.19**). Short-term results are good, with reports of 75–80% improvement in symptoms at first follow–up. This reduces with time to 50% or less 5–10 years after surgery.

Summary box 74.4

Causes of anal incontinence

Congenital/childhood

- Anorectal anomalies
- Spina bifida
- Hirschsprung's disease
- Behavioural

Acquired/adulthood

- Diabetes mellitus
- Cerebrovascular accident
- Parkinson's disease
- Multiple sclerosis
- Spinal cord injury
- Other neurological conditions:
  - Myotonic dystrophy
  - Shy–Drager syndrome
  - Amyloid neuropathy
- Gastrointestinal infection
- Irritable bowel syndrome
- Metabolic bowel disease
- Inflammatory bowel disease
- Megacolon/megarectum
- Anal trauma
- Abdominal surgery:
  - Small bowel resection
  - Colonic resection
- Pelvic surgery:
  - Hysterectomy
  - Rectal excision
- Pelvic malignancy
- Pelvic radiotherapy
- Rectal prolapse
- Rectal evacuatory disorder:
  - Mechanical, e.g. rectocoele, intussusception
  - Functional, i.e. pelvic floor dyssynergia
- Anal surgery:
  - Haemorrhoidectomy
  - Surgery for fistula
  - Surgery for fissure
  - Rectal disimpaction
- Obstetric events

General

- Ageing
- Dependence of nursing care
- Obesity
- Psychobehavioural factors
- Intellectual incapacity
- Drugs:
  - Primary constipating and laxative agents
  - Secondary effects

Operations to reef the external sphincter and puborectalis muscle

If the sphincter muscles are stretched and patulous (as they often are in old age and in cases of rectal prolapse) they may

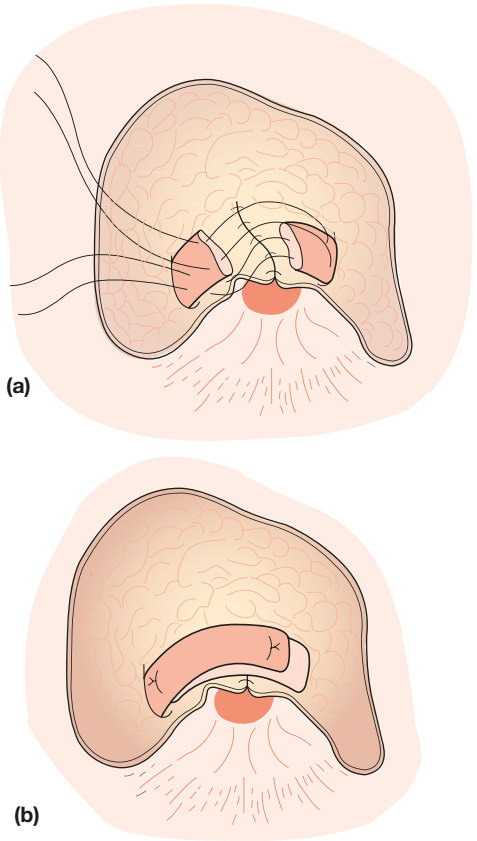

Figure 74.19 Direct sphincter repair in which **(a)** the sphincter defect is excised and **(b)** the remaining muscle is overlapped. (Redrawn with permission from Mann CV, Glass RE. *Surgical treatment of anal incontinence*. New York: Springer, 1991.)

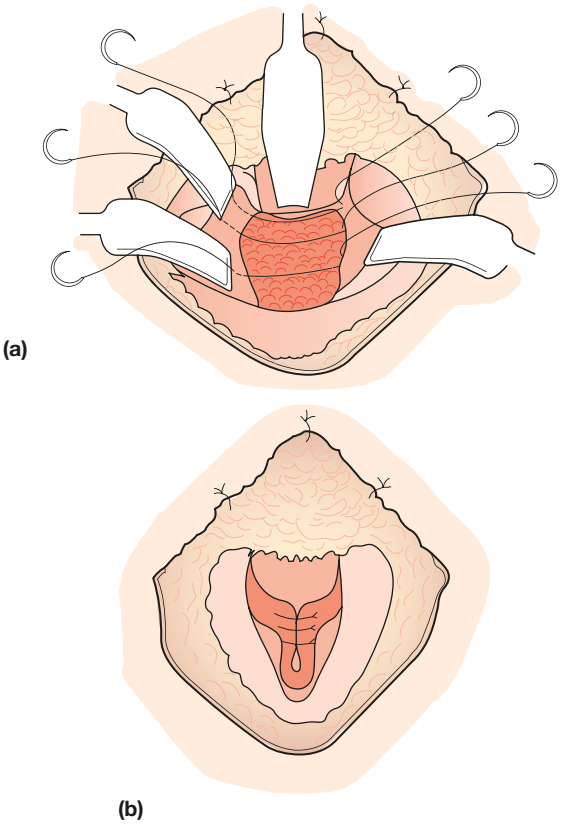

Figure 74.20 Postanal repair in which **(a)** the sphincter muscle is plicated posterior to the anal canal, thus restoring the anorectal angle; **(b)** the completed repair. (Redrawn with permission from Mann CV, Glass RE. *Surgical treatment of anal incontinence*. New York: Springer, 1991.)

be tightened by a postanal repair, which, through the use of darns of absorbable material to narrow down and plicate the external sphincter and the puborectalis sling (Figure 74.20), aims to recreate the anorectal angle and to restore length to the anal canal and strength to the anal sphincter. The approach is usually through the intersphincteric plane. The operation is now much less popular because long-term outcomes have been reported as poor.

Operations to augment the anal sphincters

If the degree of sphincter disruption or weakness is such that restoration of function cannot be achieved by direct means, the sphincter can be augmented by using muscle transposed from nearby (gluteus maximus or gracilis) or by using an artificial sphincter. Transposition of the gracilis muscle around the anal canal is followed by electrical stimulation, with conversion from a fast-twitch to a less fatiguable slow-twitch muscle by an implanted pacemaker (Williams) (Figure 74.21). Because of its magnitude this technique is performed only in highly selected and motivated patients, most of whom have had more conventional treatment that has failed to cure their incontinence; it is effective in approximately 60% of patients in the long term. A simpler means of augmenting the sphincter, developed initially for urinary incontinence, is the placement of an inflatable silastic cuff around the anal canal. When evacuation is required the cuff is deflated by squeezing a small balloon positioned in the scrotum or labia, the balloon being attached to a subcutaneous reservoir (Figure 74.22). However, because this device is a foreign body that exerts pressure on the bowel wall, erosion and infection have been found to be common problems. To reduce the risk of septic complications the operation should be covered by antibiotics active against both aerobic and anaerobic organisms. A newer magnetic sphincter (Fenix) is being implanted as part of a national trial in the UK (Safari trial; Fenix versus sacral nerve stimulator), the results of which should be available within the next 2 years. Paradoxically, all of these methods used to treat incontinence may be associated with difficulties in rectal evacuation.

Again, as a result of prior use in urinary incontinence, sacral nerve stimulation has been used to treat faecal incontinence, with encouraging short- and medium-term results. Rather than any direct action on sphincter strength, this technique appears to work by sensorimotor neurophysiological modulation of the hindgut through electrical stimulation of the sacral nerve roots via a needle positioned through one of the posterior sacral foramina (Figure 74.23). The advantage of this technique is its relatively non-invasive nature, causes no additional damage to the sphincter, as well as the fact that its effects can be tested by temporary stimulation

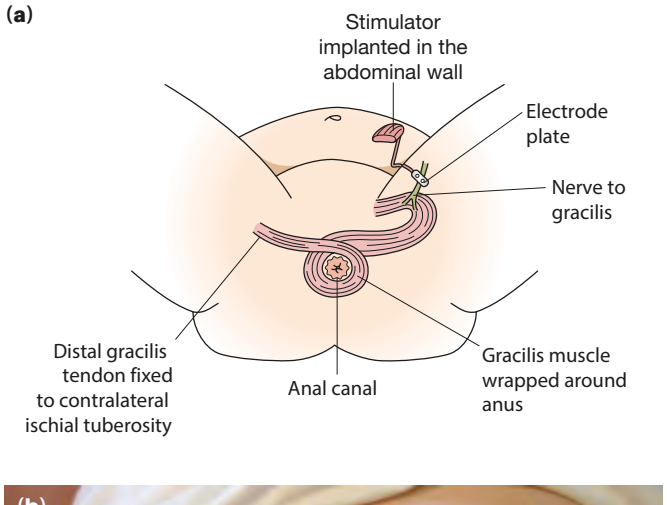

Figure 74.21 **(a)** The electrically stimulated gracilis neosphincter or dynamic graciloplasty. **(b)** Hand-held radiotelemetry controller, which allows the patient to turn the stimulator on and off.

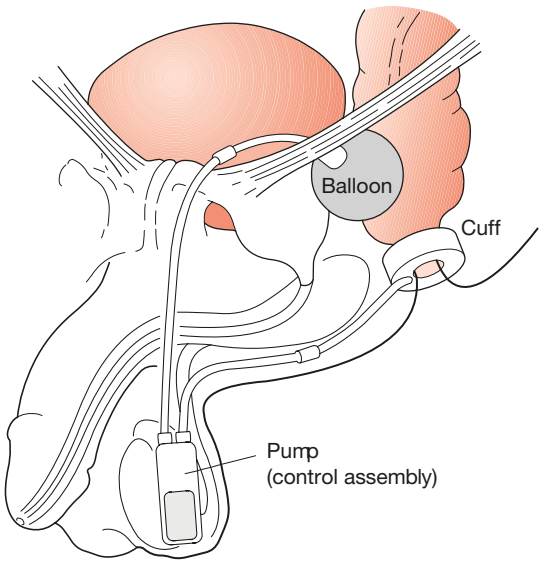

Figure 74.22 Artificial bowel sphincter. A cuff is placed around the anal canal. An inflatable pump control assembly is placed in the scrotum and the balloon reservoir is placed under the symphysis pubis.

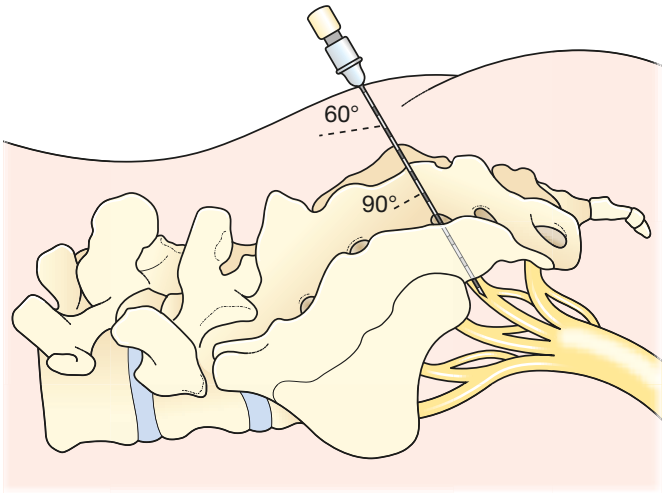

Figure 74.23 Diagram showing the placement of the electrode through a sacral foramen in sacral nerve stimulation.

using an external stimulator before the expensive permanent pacemaker is implanted. A much cheaper and less invasive novel technique to treat faecal incontinence, again mediated through neuromodulation, is percutaneous posterior tibial nerve stimulation (PTNS). Results from a prospective comparative study suggest that there is no benefit in faecal incontinence over placebo effect .

For some patients, and in those in whom quality of life remains poor despite attempts at restoring continence, a colostomy can provide relief from a condition that is both disabling and socially isolating.

ANAL FISSURE

Definition

An anal fissure (synonym: fissure-*in-ano*) is a longitudinal split in the anoderm of the distal anal canal (Figure 74.24), which extends from the anal verge proximally towards, but not beyond, the dentate line.

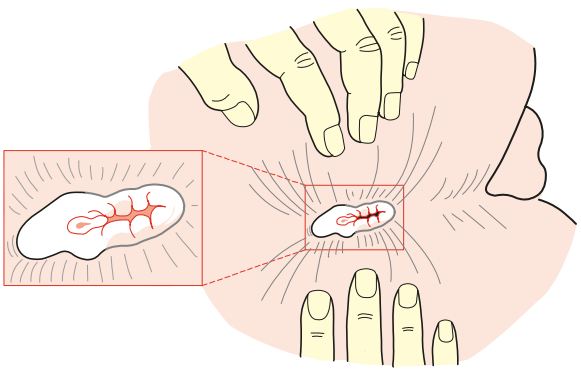

Figure 74.24 The appearance of an anal fissure. If the buttocks are gently parted, the presence of an anal fissure can usually be detected as an ulcer of variable depth with the skin tag and an anal papilla. (Redrawn with permission from Keighley MRB, Williams NS. *Surgery of the anus, colon and rectum*, 2nd edn. Philadelphia: WB Saunders, 1999.)

Aetiology

The cause of an anal fissure, and particularly the reason why the posterior midline is so frequently affected, is not completely understood. Classically, acute anal fissures arise from the trauma caused by the strained evacuation of a hard stool or, less commonly, from the repeated passage of diarrhoea. The location in the posterior midline perhaps relates to the exaggerated shearing forces acting at that site at defaecation, combined with a less elastic anoderm endowed with an increased density of longitudinal muscle extensions in that region of the anal circumference. Anterior anal fissure is much more common in women and may arise following vaginal delivery. Perpetuation and chronicity may result from repeated trauma, anal hypertonicity and vascular insufficiency, either secondary to increased sphincter tone or because the posterior commisure is less well perfused than the remainder of the anal circumference.

Clinical features

Although simple epithelial splits, acute anal fissures are, because of their location involving the exquisitely sensitive anoderm, characterised by severe anal pain associated with defaecation, which usually resolves spontaneously after a variable time only to recur at the next evacuation, as well as the passage of fresh blood, normally noticed on the tissue after wiping. Chronic fissures are characterised by a hypertrophied anal papilla internally and a sentinel tag externally (both consequent upon attempts at healing and breakdown), between which lies the slightly indurated anal ulcer overlying the fibres of the internal sphincter. When chronic, patients may also complain of itching secondary to irritation from the sentinel tag, discharge from the ulcer or discharge from an associated intersphincteric fistula, which has arisen through infection penetrating via the fissure base. Although most sufferers are young adults, the condition can affect any age, from infants to the elderly. Men and women are affected equally. Anterior fissures account for about 10% of those encountered in women (and many of these may occur postpartum) but only 1% in men. A fissure sited elsewhere around the anal circumference or with atypical features should raise the suspicion of a specific aetiology, and the inability to be able to conduct an adequate examination in the clinic should prompt early examination under anaesthesia, with biopsy and culture to exclude Crohn's disease, tuberculosis, sexually transmitted or human immunodeficiency virus (HIV)-related ulcers (syphilis, *Chlamydia*, chancroid, lymphogranuloma venereum, HSV, cytomegalovirus, Kaposi's sarcoma, B-cell lymphoma) and squamous cell carcinoma.

Treatment

After confirmation of the diagnosis in the clinic or under anaesthesia, with exclusion of secondary causes of anal ulceration, conservative management should result in the healing of almost all acute and the majority of chronic fissures. Emphasis must be placed on normalisation of bowel habits such that the passage of stool is less traumatic. The addition of fibre to the diet to bulk up the stool, stool softeners and adequate water intake are simple and helpful measures. Warm baths and topical local anaesthetic agents relieve pain; however, providing patients with anal dilators is usually associated with low compliance and consequently little effect. The mainstay of current conservative management is the topical application of pharmacological agents that relax the internal sphincter, most commonly nitric oxide donors (Scholefield); by reducing spasm, pain is relieved, and increased vascular perfusion promotes healing. Such agents include glyceryl trinitrate (GTN) 0.2% applied two to three times per day to the anal margin (although this may cause headaches) and diltiazem 2% applied twice daily. An alternative medical treatment is Botox (10–100 units) in either divided or a single dose. The cure rate using any of these options is approximately 50% although the headache rate with GTN ointment has been reported to be as high as 30%, which limits its acceptability by patients.

Summary box 74.5

Anal fissure

- Acute or chronic
- Ischaemic ulcer in the midline of the anal canal
- Ectopic site suggests a more sinister cause

Symptoms:

- Pain on defaecation
- Bright-red bleeding
- Mucus discharge
- Constipation

Operative measures

Historically, under regional or general anaesthesia, forceful manual (four- or eight-digit) sphincter dilatation was used to reduce sphincter tone; however, this was achieved in an uncontrolled fashion with potential disruption at multiple sites of the internal (and even external) sphincter. The risk of incontinence following this procedure has now made it unpopular, although more conservative controlled stretching is still practised in young men with very high sphincter tone.

Fissure healing can also be achieved by a posterior division of the exposed fibres of the internal sphincter in the fissure base, but this is associated with prolonged healing, as well as passive anal leakage thought mainly to be due to the resulting keyhole gutter deformity; however, it may be indicated if there is an associated intersphincteric fistula.

Lateral anal sphincterotomy

In this operation, the internal sphincter is divided away from the fissure itself – usually either in the right or the left lat-

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA.
Moritz Kaposi, 1837–1902, Professor of Dermatology, Vienna, Austria, described pigmented sarcoma of the skin in 1872.
John Howard Scholefield, contemporary, Professor of Surgery, The University of Nottingham, Nottingham, UK.

eral positions (Notaras). The procedure can be carried out using an open or a closed method, under local, regional or general anaesthesia, and with the patient in the lithotomy or prone jack-knife position. The distal internal sphincter is palpated with a bivalved speculum at the intersphincteric groove. In the closed method, a small longitudinal incision is made over this, and the submucosal and intersphincteric planes are carefully developed to allow precise division of the internal sphincter with a knife or scissors to the level of the apex of the fissure; the wound is then closed with absorbable sutures. Alternatively, either plane can be entered using a scalpel (no. 11 blade), with the blade advanced parallel to the sphincter and then rotated such that the sharp edge faces the internal sphincter, which can then be divided along its distal third. Pressure should be applied to the wound for a few minutes to prevent haematoma formation. In the open technique, the anoderm overlying the distal internal sphincter is divided longitudinally to expose the sphincter, which is divided, and the wound is closed with absorbable sutures. Although the fissure needs no specific attention, problematic papillae and external tags can be excised concomitantly.

Early complications of sphincterotomy include haemorrhage, haematoma, bruising, perianal abscess and fistula. Despite low recurrence rates, the most important complication is incontinence of a variable nature and severity, which may affect up to 30% of patients, particularly women, who have weaker, shorter sphincter complexes and in whom there may already have been covert sphincter compromise incurred by childbirth.

Anal advancement flap

The recognition of the risk to continence following internal sphincterotomy has led some to advocate a different approach, especially in women and those with normal or low resting anal pressures, developed from the treatment of anal stenosis. After excision of the edges of the fissure and, if necessary, its base overlying the internal sphincter, an inverted house-shaped flap of perianal skin is carefully mobilised on its blood supply and advanced without tension to cover the fissure, and then sutured with interrupted absorbable sutures (**Figure 74.25**). The patient is maintained on stool softeners and bulking agents postoperatively, and usually also on topical sphincter relaxants; minor breakdown of one anastomotic edge does not herald ultimate failure. The technique appears to work irrespective of sphincter hypertonicity or patient gender.

Summary box 74.6

Treatment of an anal fissure

- Conservative initially, consisting of stool-bulking agents and softeners, and chemical agents in the form of ointments designed to relax the anal sphincter and improve blood flow
- Surgery if above fails, consisting of lateral internal sphincterotomy or anal advancement flap

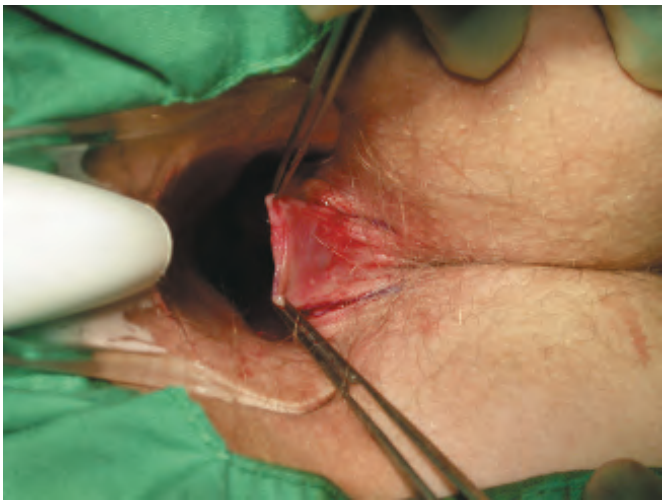

Figure 74.25 Mobilised skin flap prior to suturing intra-anally over the debrided and freshened posterior fissure base.

Hypertrophied anal papilla

Anal papillae occur at the dentate line and are remnants of the ectodermal membrane that separated the hindgut from the proctodaeum. As these papillae are present in 60% of patients examined proctologically, they should be regarded as normal structures. Anal papillae can become elongated, as they frequently do in the presence of an anal fissure. Occasionally, an elongated anal papilla may be the cause of pruritus. An elongated anal papilla associated with pain and/or bleeding at defaecation is sometimes encountered in infancy. Haemorrhage into a hypertrophied anal papilla can cause sudden rectal pain. A prolapsed papilla may become nipped by contraction of the sphincter mechanism after defaecation. Occasionally, a red oedematous papilla is encountered, with local pain and a purulent discharge from the associated crypt. This condition of 'cryptitis' may be cured by laying open the mouth of the infected anal gland and excising the papilla. Troublesome papillae may be simply excised.

Proctalgia fugax

This problem is characterised by attacks of severe pain arising in the rectum, recurring at irregular intervals and apparently unrelated to organic disease. The pain is described as cramp-like, often occurs when the patient is in bed at night, usually lasts only for a few minutes and disappears spontaneously. It may follow straining at stool, sudden explosive bowel action or ejaculation. It seems to occur more commonly in patients suffering from anxiety or undue stress, and it is also said to afflict young doctors. The pain may be unbearable – it is possibly caused by segmental cramp in the pubococcygeus muscle. It is unpleasant and incurable but is fortunately harmless and gradually subsides. If patients have frequent attacks, they may benefit from amitryptiline. Salbutamol inhalers have been

Mitchell James Notaras, surgeon, Barnet General Hospital, Barnet, UK.

suggested as treatment for acute attacks. A more chronic form of the disease has been termed the 'levator syndrome' and can be associated with severe evacuatory dysfunction. Biofeedback techniques have been used to help such patients; in the past, some surgeons tried severing the puborectalis muscle, but this can cause incontinence and should never be carried out. If this is being consider an acceptable alternative is Botox into the puborectalis muscle.

HAEMORRHOIDS

The prevalence of haemorrhoids when patients are assessed proctoscopically far outweighs the prevalence of symptoms, and the term should only be used when patients have symptoms referable to them. Occasionally, patients with portal hypertension develop rectal varices, but these should not be confused with haemorrhoids as the consquences may be disastrous. Internal haemorrhoids (Greek: *haima* = blood, *rhoos* = flowing; synonym: piles, Latin: *pila* = a ball) are symptomatic anal cushions and characteristically lie in the 3, 7 and 11 o'clock positions (with the patient in the lithotomy position). In addition, haemorrhoids may be observed between the main pile masses, in which case they are internal haemorrhoids at the secondary position. External haemorrhoids relate to venous channels of the inferior haemorrhoidal plexus deep in the skin surrounding the anal verge and are not true haemorrhoids; they are usually only recognised as a result of a complication, which is most typically a painful solitary acute thrombosis. External haemorrhoids associated with internal haemorrhoids ('interoexternal piles') result from progression of the latter to involve both haemorrhoidal plexuses, and are best thought of as being external extensions of internal haemorrhoids. Secondary internal haemorrhoids arise as a result of a specific condition, although the mechanisms involved may be the same as those involved in the formation of primary internal haemorrhoids. The most important cause, albeit relatively uncommon, is carcinoma of the anorectum (**Figure 74.26**) but there may be other causes, which may be categorised as follows:

- local, e.g. anorectal deformity, hypotonic anal sphincter;
- abdominal, e.g. ascites;
- pelvic, e.g. gravid uterus, uterine neoplasm (fibroid, carcinoma of the uterus or cervix), ovarian neoplasm, bladder carcinoma;
- neurological, e.g. paraplegia, multiple sclerosis.

Primary internal haemorrhoids

Theories of development

PORTAL HYPERTENSION AND VARICOSE VEINS

Misconceptions concerning the vascular anatomy of the anal canal (specifically the lack of appreciation of communications between portal and systemic systems and the 'normality' of venous dilatations) led to theories of development of primary internal haemorrhoids that lasted for several centuries. Man's upright posture (we know little about haemorrhoidal problems in animals), lack of valves in the portal venous system and raised abdominal pressure were thought to contribute to the development of anal varicosities. If raised portal venous pressure were indeed the cause, one would expect a high incidence in subjects suffering from portal hypertension; however, although such patients have a higher incidence of anorectal varices, these are a separate anatomical and clinical entity from haemorrhoids, which are seen no more frequently than in those without cirrhosis, portal hypertension and oesophageal varices.

OTHER VASCULAR CAUSES

Historically, some considered haemorrhoids to be haemangiomatous or to result from changes in the erectile tissue that forms part of the continence mechanism, such as hyperplasia of the 'corpus cavernosum recti'.

INFECTION

Repeated infection of the anal lining, secondary to trauma at defaecation, has been postulated as a cause of weakening and erosion of the walls of the veins of the submucosa. This hypothesis is difficult to accept, as one of the truly incredible properties of the anal canal is its resistance to infection, as well as the ability of its mucosa to heal after surgical intervention despite the torrent of microorganisms passing over it.

DIET AND STOOL CONSISTENCY

Much emphasis has been placed on the role of constipation in the development of haemorrhoids and, indeed, much of the management of sufferers involves attempts to 'normalise' bowel habits. A fibre-deficient diet results in a prolonged gut transit time, which is associated with the passage of smaller, harder stools that require more straining to expel. The presence of a hard faecal mass in the rectum could obstruct venous

Figure 74.26 Carcinoma of the rectum associated with haemorrhoids, a not infrequent diagnostic pitfall.

return, resulting in engorgement of the anal veins with the act of straining at stool or sitting for prolonged periods on the lavatory with a relaxed perineum, causing a disturbance of vascular flow. However, the epidemiological pattern of constipation is different from that of haemorrhoidal disease and, indeed, an association has been demonstrated between haemorrhoids and diarrhoeal disorders.

ANAL HYPERTONIA

The association between raised anal canal resting pressure and haemorhoids is well known, but whether anal hypertonia causes symptoms attributable to haemorrhoids or whether anal cushion hypertrophy causes anal hypertonia is a subject of debate. The fact that surgical haemorrhoidectomy restores resting pressures to the normal range is not absolute evidence that the pile masses themselves are the cause of the hypertonia. It should be remembered, however, that there are a significant proportion of patients who suffer haemorrhoidal symptoms in whom the anal canal is relatively patulous, and there is mucosal prolapse, which is associated with perineal descent and pudendal neuropathy.

AGEING

In contrast to the anal cushion of early life, with age, the supporting structures show a higher proportion of collagen than muscle fibres and are fragmented and disorganised. Presumably, these changes arise over time with continued use of the anal canal for defaecation; however, similar changes are noted histologically in surgically excised haemorrhoids in younger patients.

CURRENT VIEW

Shearing forces acting on the anus (for a variety of reasons) lead to caudal displacement of the anal cushions and mucosal trauma. With time, fragmentation of the supporting structures (a normal consequence of ageing but perhaps accelerated in those with haemorrhoids) leads to loss of elasticity of the cushions such that they no longer retract following defaecation.

Clinical features

Bleeding, as the name haemorrhoid implies, is the principal and earliest symptom. The nature of the bleeding is characteristically separate from the motion and is seen either on the paper on wiping or as a fresh splash in the pan. Very rarely, the bleeding may be sufficient to cause anaemia. Pain is not commonly associated with the bleeding and its presence should make the clinician alert to the possibility of another diagnosis; however, pain may result from congestion of pile masses below a hypertonic sphincter. Some patients describe the feeling of 'passing ground glass' as they are defaecating and itching is another common symptom. Piles associated with bleeding alone are called first-degree haemorrhoids.

Patients may complain of true 'piles', lumps that appear at the anal orifice during defaecation and which return spontaneously afterwards (second-degree haemorrhoids), piles that have to be replaced manually (third-degree haemorrhoids) (**Figure 74.27**) or piles that lie permanently outside (fourth-degree haemorrhoids). By this stage there is often a significant cutaneous component to the pile masses, which arise through repeated congestion and oedema. In addition to the main symptoms of pain and prolapse, patients may complain of anal irritation, which may occur as a result of mucus secretion from the caudally displaced rectal mucosa, minor leakage through a now imperfect anal seal or difficulties in cleaning after defaecation because of the irregularity of the anal verge.

Summary box 74.7

Haemorrhoids: clinical features

- Haemorrhoids or piles are symptomatic anal cushions
- They are more common when intra-abdominal pressure is raised, e.g. in obesity, constipation and pregnancy
- Classically, they occur in the 3, 7 and 11 o'clock positions with the patient in the lithotomy position
- Symptoms of haemorrhoids:
  - Bright-red, painless bleeding
  - Mucus discharge
  - Prolapse
  - Pain only on prolapse

Complications

Profuse haemorrhage is not rare. The bleeding mainly occurs externally but it may continue internally after the bleeding haemorrhoid has retracted or has been returned. In these circumstances the rectum is found to contain blood.

Summary box 74.8

Four degrees of haemorrhoids

- First degree – bleed only, no prolapse
- Second degree – prolapse but reduce spontaneously
- Third degree – prolapse and have to be manually reduced
- Fourth degree – permanently prolapsed

Figure 74.27 Third-degree haemorrhoids (courtesy of CV Mann, The Royal London Hospital, London, UK).

Summary box 74.9

Complications of haemorrhoids

- Strangulation and thrombosis (**Figure 74.28**)
- Ulceration
- Gangrene
- Portal pyaemia
- Fibrosis

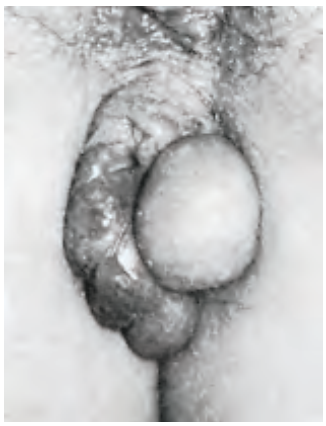

Figure 74.28 An attack of piles. Prolapsed strangulated piles, as commonly seen, on the left. A less common mass on the right with fibrofatty covering.

TREATMENT OF COMPLICATIONS

Strangulation, thrombosis and gangrene. In these cases, it was formerly believed that surgery would promote portal pyaemia. However, if adequate antibiotic cover is given from the start, this is not found to be so, and immediate surgery can be justified in some patients. The other risk if surgery is performed at this stage, that of postoperative stenosis, has resulted in many surgeons adopting a conservative approach, reviewing the situation much later and carrying out haemorrhoidectomy only if necessary. Besides adequate pain relief, bed rest with frequent hot baths and warm or cold saline compresses with firm pressure usually cause the pile mass to shrink considerably in 3–4 days (the author's preference is shrinkage through external application of small bags of frozen peas combined with the use of topical anaesthetic agents). An anal dilatation technique has in the past been used as an alternative treatment to surgery for painful 'strangulated' haemorrhoids. However, because of the risk of incontinence this is no longer advised.

Severe haemorrhage. The cause usually lies in a bleeding diathesis or the use of anticoagulants. If such causes are excluded, a local compress containing adrenaline solution, with an injection of morphine and blood transfusion if necessary, will usually suffice. However, after adequate blood replacement, ligation and excision of the piles may be required.

Management

Exclusion of other causes of rectal bleeding, especially colorectal malignancy, is the first priority. In the absence of a specific predisposing cause, important measures include attempts at normalising bowel and defaecatory habits: only evacuating when the natural desire to do so arises, adopting a defaecatory position to minimise straining, and the addition of stool softeners and bulking agents to ease the defaecatory act. Various proprietary creams can be inserted into the rectum from a collapsible tube fitted with a nozzle, at night and before defaecation. Suppositories are also useful.

In those with first- or second-degree piles whose symptoms are not improved by conservative measures, injection sclerotherapy (Mitchell), the submucosal injection of 5% phenol in arachis oil or almond oil, may be used. Any invasive treatment, however, must be with full agreement of the patient, who should be informed of the potential risks of such interventions. The aim is to create fibrosis, cause obliteration of the vascular channels and hitch up the anorectal mucosa. With the awake patient in the left lateral position and under direct vision with a proctoscope, about 5 mL of sclerosant is injected into the apex of the pile pedicle (**Figure 74.29**) using a disposable needle and syringe (**Figure 74.30**). The procedure is repeated for each pile and the patient reassessed after 8 weeks; if necessary, the injections are repeated. Pain upon injection means that the needle is in the wrong place and should be withdrawn. Injections that are too superficial are heralded by the rapid bulging of the musosa, which turns white; this leads to superficial ulceration but rarely serious septic sequelae. However, injections placed too deeply can have disastrous consequences, including pelvic sepsis, prostatitis, impotence and rectovaginal fistula.

For more bulky piles, banding has been shown to be efficacious, but it is associated with more discomfort. The Barron's bander is a commonly available device used to slip tight elastic bands onto the base of the pedicle of each haemorrhoid (**Figure 74.31**). The bands cause ischaemic necrosis of the piles, which slough off within 10 days; this may be associated with bleeding, about which the patient must be warned. As with sclerotherapy, three piles may be treated at one session, and the process may be repeated after several weeks if necessary. The techniques of cryotherapy (Lloyd Williams) and infrared photocoagulation (Leicester) are not often used nowadays.

Figure 74.29 Correct site (cross) for injecting a haemorrhoid (after WB Gabriel, London, UK).

Operations

INDICATIONS

The indications for haemorrhoidectomy include:

- third- and fourth-degree haemorrhoids;
- second-degree haemorrhoids that have not been cured by non-operative treatments;
- fibrosed haemorrhoids;
- interno-external haemorrhoids when the external haemorrhoid is well defined.

If there is any doubt about the diagnosis of haemorrhoids, examination under anaesthesia and, if indicated, biopsy, are necessary. The other strong indication for surgery is haemorrhoidal bleeding sufficient to cause anaemia. Beyond these, the indications summarised above are more relative than absolute, because in these situations surgery aims simply to improve symptoms and, of course, is not without risk. For instance, elderly multiparous women with hypotonic sphincters who are just continent before haemorrhoidectomy may find that the procedure results in frank incontinence, a far worse condition than that for which they originally sought help.

TECHNIQUE

It is usual for the patient to have been taking stool softeners in the days before surgery and a preoperative enema to empty the rectum is administered. The procedure is usually performed under general or regional anaesthesia with the patient in the lithotomy or prone jack-knife position. The perianal skin is shaved and a formal examination performed. Haemorrhoidectomy can be performed using an open or a closed technique. The open technique is most commonly used in the UK and is known as the Milligan–Morgan operation – named after the surgeons who described it. The closed technique is the popular technique in the USA. Both involve ligation and excision of the haemorrhoid, but in the open technique the anal mucosa and skin are left open to heal by secondary intention, and in the closed technique the wound is sutured.

- **Open technique**. The anoderm and subcutaneous tissues between the pile masses may be injected with dilute adrenaline (1:300 000 dilution) to reduce bleeding and aid preservation of the skin bridges left following excision. Artery forceps are applied to the skin-covered external components of the piles and traction exerted to reveal the internal components, which are also grasped by artery forceps. When held out by the assistant these pairs of artery forceps form a triangle (**Figure 74.32a**). The operator takes the left lateral pair of artery forceps in the palm of the hand and places the extended forefinger in the anal canal to support the internal haemorrhoid. In this way traction is applied to the skin of the anal margin. With scissors or cutting diathermy, a V-shaped cut is made through the skin and those fibres inserting into it around the skin-holding artery forceps. Traction by both operator and assistant, combined with careful dissection, will expose the lower border of the internal sphincter. The dissection proceeds up the anal canal, with the sides of the mucosal dissection converging towards the pile apex and with the internal sphincter visible and separate from the dissected pile (**Figure 74.32b**). A transfixion ligature of strong Vicryl is applied to the pedicle at this level (**Figure 74.32c**), the pile is excised well distal to the ligature and, after ensuring haemostasis, the ligature is cut long. Each haemorrhoid is dealt with in this manner, taking care to leave mucocutaneous bridges. If there are

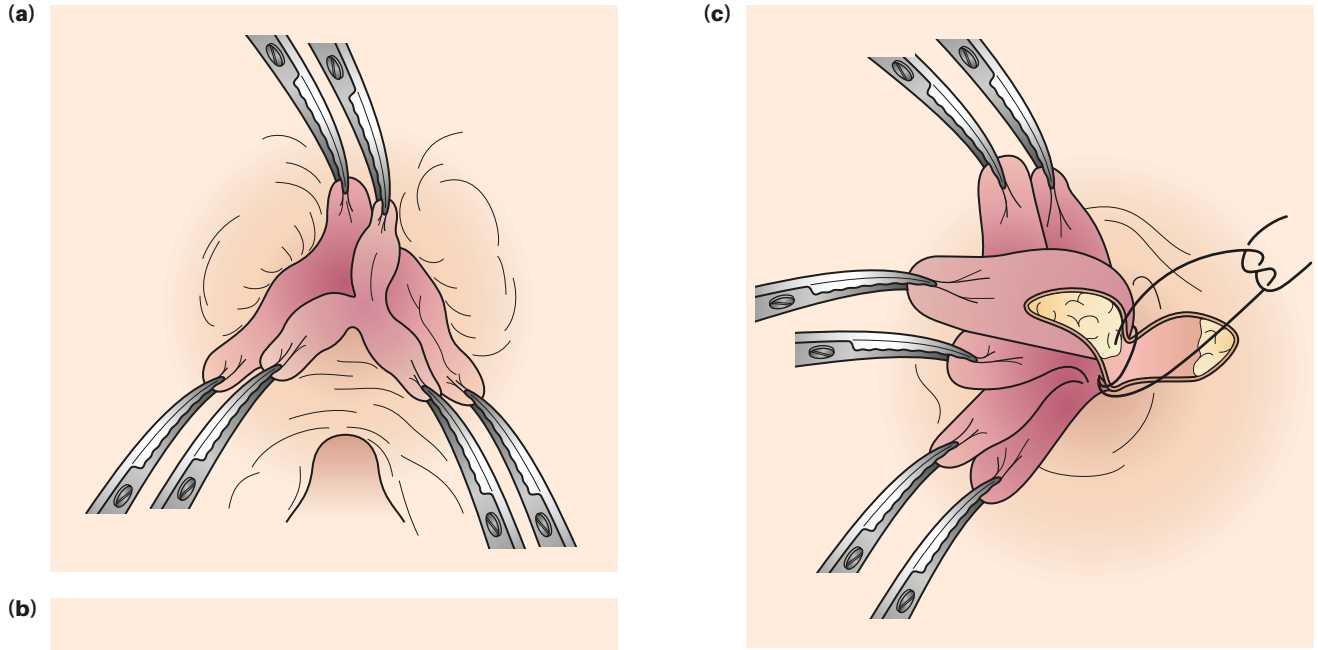

Figure 74.32 Ligation and excision of haemorrhoids. Open technique: **(a)** the artery forceps have been applied; **(b)** dissection of the left lateral pedicle; **(c)** transfixion of the pedicle. significant secondary haemorrhoids under these bridges they can be filleted out by scissor dissection. Haemostasis must be absolute at the end of the procedure, when a soft absorbable anal dressing is inserted. The margins of the skin wounds are trimmed so as not to leave overhanging edges (**Figure 74.33**). Bleeding subcutaneous arteries having been secured, the areas denuded of skin are dressed with three pieces of petroleum jelly gauze. A pad of gauze and wool and a firmly applied T-bandage complete the operation.

- **Closed technique**. The haemorrhoid is excised, together with the overlying mucosa, as illustrated in **Figure 74.34**. The haemorrhoid is dissected carefully from the underlying sphincter and haemostasis is achieved. The pedicle is transfixed and ligated with 3/0 Vicryl or Dexon. Any residual small haemorrhoids should be removed by filleting them out after undermining the edges of the cut mucosa. The mucosal defect is then closed completely with a continuous suture, using the same stitch that was employed to ligate the haemorrhoid pedicle. The remaining haemorrhoids are excised and ligated in a similar fashion, ensuring that there are adequate mucosal and skin bridges between each area of excision to avoid a subsequent stenosis.

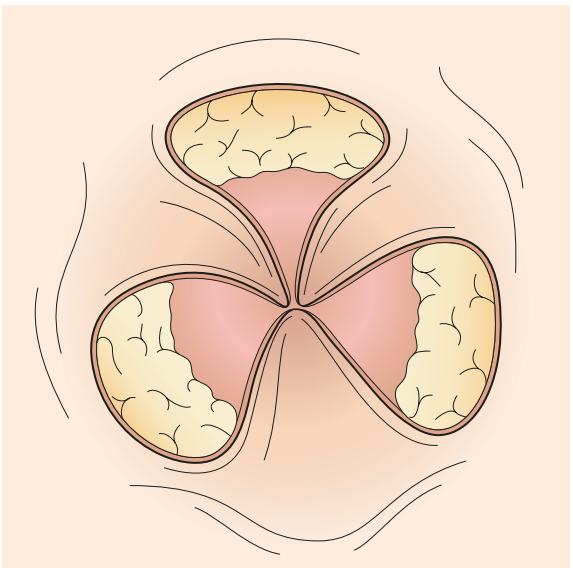

Figure 74.33 The appearance of the anus at the conclusion of the operation. (Note that to avoid stricture formation it is necessary to ensure that a bridge of skin and mucous membrane remains between each wound.) 'If it looks like a clover the trouble is over, if it looks like a dahlia, it is surely a failure.' (Reproduced with permission from Nicholls RJ, Dozois RR. *Surgery of the colon and rectum*. Edinburgh: Churchill Livingstone, 1997.)

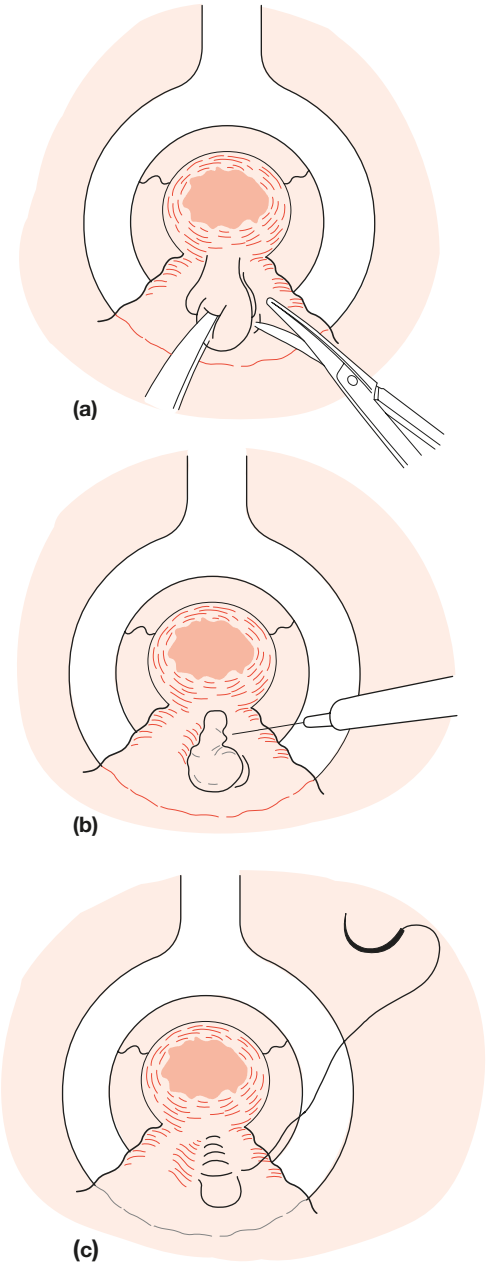

Figure 74.34 Closed technique of haemorrhoidectomy: **(a)** the haemorrhoidal tissue is excised; **(b)** bleeding is controlled by diathermy; **(c)** the defect is closed with a continuous suture after first undermining the anoderm on each side. (Redrawn with permission from Keighley MRB, Williams NS. *Surgery of the anus, colon and rectum*, 2nd edn. Philadelphia: WB Saunders, 1999.)

- **Stapled haemorrhoidopexy**. With the aim of symptom relief but preservation of the anal cushions, the technique of stapled haemorrhoidopexy (Longo), which utilises a purpose-designed stapling gun (PPH, Ethicon Inc.), has also been described and is widely used in Europe. This procedure excises a strip of mucosa and submucosa (together with the vessels travelling within them) circumferentially, well above the dentate line. Activation of the gun also simultaneously repairs the cut mucosa and submucosa by stapling the edges together (Figure 74.35). This procedure is quick to perform, and controlled trials suggest that it is less painful and less traumatic than conventional haemorrhoidectomy and, at least in the short term, it seems to be equally efficacious. However, evidence is emerging that the technique is associated with higher recurrence rates than following conventional haemorrhoidectomy, and associated with more additional surgery. The patient, after counselling, may or may not choose to accept a higher recurrence rate to take advantage of the short-term benefits.

TRANSANAL HAEMORRHOIDAL DEARTERIALISATION (THD) OR HAEMORRHOID ARTERY LIGATION OPERATION (HALO)

For the treatment of second- and third-degree haemorrhoids, some have recently advocated transanal Doppler-guided ligation of those vessels feeding the haemorrhoidal masses, to which others have added suture 'mucopexy' to deal with any prolapse. Long-term outcomes are unknown, but recurrence rates for fourth-degree haemorrhoids (certainly when additional procedures are not incorporated) are high. However, the complication rate and postoperative pain scores are better than with conventional surgery

- Haemorrhoidectomy

POSTOPERATIVE CARE

In these days of economic stringencies, the patient is discharged from hospital within 1–2 days of the operation. In many countries, the procedure is often performed on a day-care basis. The patient is instructed to take two warm baths each day and is given a bulk laxative to take twice daily, together with appropriate analgesia. There is some evidence that a 5-day course of oral metronidazole may reduce pain. Dry dressings are applied as necessary, a sterile sanitary towel usually being ideal. The patient is seen again 3–4 weeks after discharge and a rectal examination is performed. If there is evidence of stenosis, the patient is encouraged to use a dilator.

POSTOPERATIVE COMPLICATIONS

Postoperative complications may be early or late. Early complications include pain, which may require opiate analgesia; retention of urine, especially in men, which rarely may need

Antonio Longo, contemporary, surgeon, Sicily, Italy.

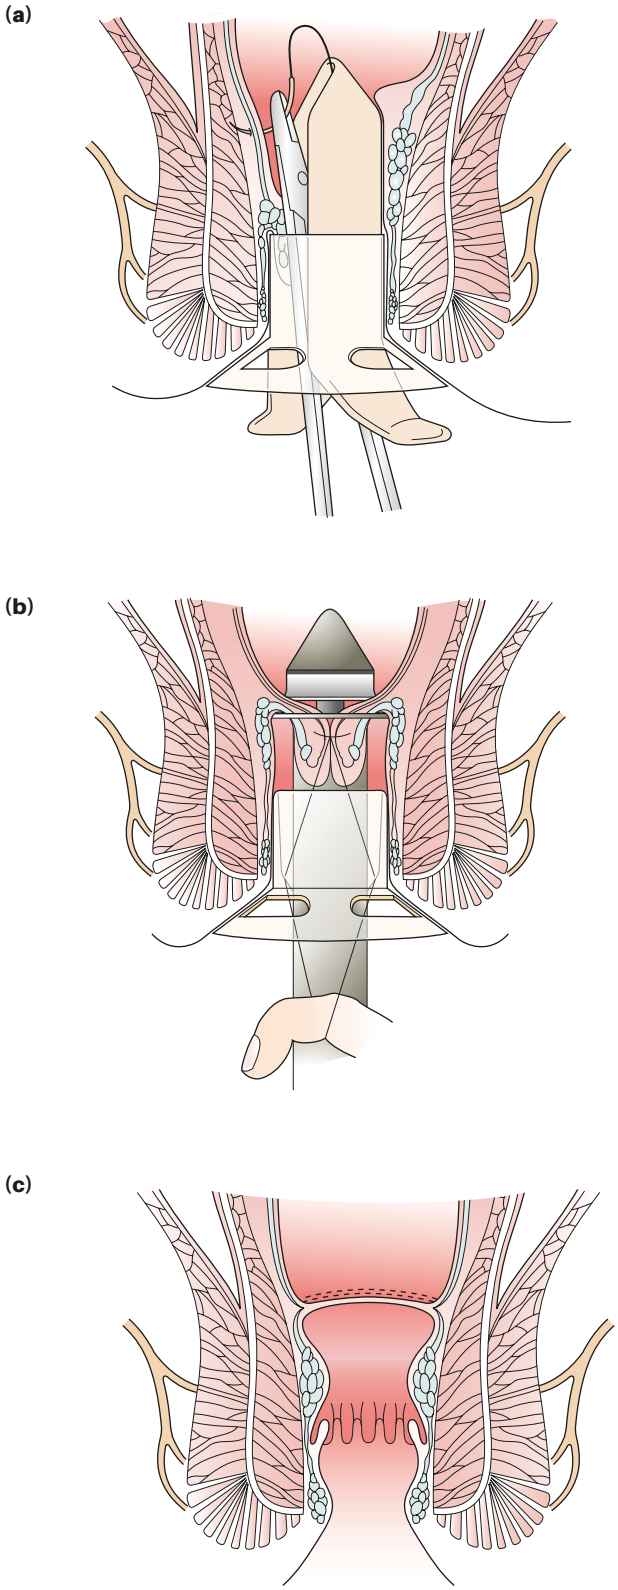

Figure 74.35 Stapled haemorrhoidectomy: **(a)** the purse-string suture is placed several centimetres above the dentate line; **(b)** the anvil of the fully opened stapling gun is inserted endoanally so that it is above the purse-string suture, which is then tied around the shaft of the gun. The gun is closed and fired; **(c)** after firing, a 3–4 cm strip of mucosa and submucosa containing the haemorrhoids is excised and the mucosal edges are simultaneously stapled together.

relief by catheterisation; and reactionary haemorrhage, which is much more common than secondary haemorrhage. The haemorrhage may be mainly or entirely concealed but will become evident on examining the rectum. If persistent following adequate analgesia, the patient must be taken to the operating theatre and the bleeding point secured by careful diathermy or under-running with a ligature on a needle, care being taken to avoid damage to the internal sphincter. Should a definite bleeding point not be found, the anal canal and rectum are packed.

Late postoperative complications include:

- **Secondary haemorrhage**. This is uncommon, occurring about the seventh or eighth day after operation. It is usually controlled by morphine but, if the haemorrhage is severe, an anaesthetic should be given and the bleeding controlled.
- **Anal stricture**, which must be prevented at all costs. A rectal examination at the postoperative review will indicate whether stricturing is to be expected. It may then be necessary to give a general anaesthetic and dilate the anus. After that, daily use of the dilator should give a satisfactory result.
- **Anal fissures and submucous abscesses**.
- **Incontinence**, especially if there has been inadvertent damage to the underlying internal sphincter. Although uncommon, this is obviously a very serious problem that is difficult to treat.

Summary box 74.11

Complications of haemorrhoidectomy

Early

- Pain
- Acute retention of urine
- Reactionary haemorrhage

Late

- Secondary haemorrhage
- Anal stricture
- Anal fissure
- Incontinence

External haemorrhoids

A thrombosed external haemorrhoid relates anatomically to the veins of the superficial or external haemorrhoidal plexus and is commonly termed a perianal haematoma. It presents as a sudden onset, olive-shaped, painful blue subcutaneous swelling at the anal margin and is usually consequent upon straining at stool, coughing or lifting a heavy weight (Figure 74.36). The thrombosis is usually situated in a lateral region of the anal margin. If the patient presents within the first 48 hours, the clot may be evacuated under local anaesthesia. Untreated it may resolve, suppurate, fibrose and give rise to a cutaneous tag, burst and the clot extrude, or continue bleeding. In the majority of cases, resolution or fibrosis occurs. Indeed, this condition has been called 'a 5-day, painful, self-curing lesion' (Milligan).

Figure 74.36 A thrombosed external haemorrhoid that has burst. There is also a mucosal prolapse, which is separate from the cutaneous lesion.

PRURITUS ANI

This is intractable itching around the anus, a common and embarrassing condition. Usually, the skin is reddened and hyperkeratotic and it may become cracked and moist.

Causes

The causes are numerous. A useful mnemonic is 'pus, polypus, parasites, piles, psyche':

- **Lack of cleanliness**, excessive sweating and wearing rough or woollen underclothing.
- An **anal or perianal discharge** that renders the anus moist. The causative lesions include an anal fissure, fistula-*in-ano*, prolapsed internal or external haemorrhoids, genital warts and excessive ingestion of liquid paraffin. A mucous discharge is an intense pruritic agent and a polyp can be the cause.
- A **vaginal discharge**, especially caused by *Trichomonas vaginalis* infection.
- **Parasitic causes**. Threadworms should be excluded, especially in young subjects. Children suffering from threadworms should wear gloves at night, lest they scratch the perianal region and are reinfested with ova by nail biting – 'parasites lost, parasites regained'. Scabies and pediculosis pubis may infest the anal region.
- **Epidermophytosis** is a common cause, especially if the skin between the toes is also infected; microscopic and cultural examinations are essential. Half-strength Whitfield's ointment quickly gives relief and is the sheet anchor of treatment.
- **Allergy** is sometimes the cause, in which case there is likely to be a history of other allergic manifestations, such as urticaria, asthma or hay fever. Antibiotic therapy may be the precipitating factor.
- **Skin diseases** localised to the perianal skin: psoriasis, lichen planus and contact dermatitis.
- **Bacterial infection**, such as intertrigo resulting from a mixed bacterial infection. Erythrasma caused by *Corynebacterium minutissimum* is responsible for some cases and its presence is detected by ultraviolet light, which induces a pink fluorescence.
- A **psychoneurosis**. It is alleged that in a few instances neurotic individuals become so immersed in their complaint that a pain–pleasure complex develops, the pleasure being the scratching. Possibly this is true, but such a syndrome should not be assumed without firm grounds for coming to this conclusion.
- **Diabetes** can sometimes present with pruritus ani, and the urine should be tested in all patients.

Treatment

The cause is treated. Symptomatic treatment includes the following:

- **Hygiene measures**. Cotton wool should be substituted for toilet paper. Soap is avoided and replaced by water alone, and the area pat-dried rather than rubbed. These measures alone, combined with wearing cotton underwear and the application of calamine lotion or zinc and castor oil, are all that is necessary to cure some cases. If there is much anal hair trapping the moisture and discharge, shaving can be very helpful.
- **Hydrocortisone**. In patients with dermatitis, and only in patients with dermatitis, the topical application of 0.5% or 1% prednisolone cream is often beneficial; sometimes after discontinuation of the therapy, the pruritus is liable to return, in which case 5% lidocaine hydrochloride (Xylocaine) ointment can be substituted for a time.
- **Strapping the buttocks** keeps moist opposing surfaces apart but is not well tolerated. If the moistness originates from anal discharge, a cotton wool anal plug will seal the anal orifice.

Operative treatment

This may be necessary for a concomitant lesion of the anorectum that is thought to initiate or contribute to the pruritus. Otherwise, surgery is not indicated.

Arthur Whitfield, 1867–1967, Professor of Dermatology, Kings College Hospital, London, UK. Whitfield's ointment is 'compound ointment of benzoic acid'.

Summary box 74.12

Pruritus ani

- Common
- Numerous causes including skin diseases, parasites (threadworm), anal discharge, allergies, diabetes
- Treat the cause if possible
- Symptomatic treatment is the mainstay

ANORECTAL ABSCESSES

Aetiology

Acute sepsis in the region of the anus is common. A fundamental distinction that has to be made is whether the sepsis is in that area by chance (simple boil, skin appendage infection) or whether it has arisen as a consequence of the presence of the anorectum, specifically the anal glands. Overall, anorectal sepsis is more common in men than women, although infections with skin-type organisms (and thus unrelated to fistula) are evenly distributed. The cryptoglandular theory of intersphincteric anal gland infection (Parks) holds that, upon infection of a gland, pus, which travels along the path of least resistance, may spread caudally to present as a perianal abscess, laterally across the external sphincter to form an ischiorectal abscess or, rarely, superiorly above the anorectal junction to form a supralevator intermuscular or pararectal abscess (depending on its relation to the longitudinal muscle), as well as circumferentially in any of the three planes: intersphincteric/intermuscular, ischiorectal or pararectal supralevator (**Figure 74.37**). Sepsis unrelated to anal gland infection may occur at the same or at other sites (**Figure 74.38**), including submucosal abscess (following haemorrhoidal sclerotherapy, which usually resolve spontaneously), mucocutaneous or marginal abscess (infected haematoma), ischiorectal abscess (foreign body, trauma, deep skin-related infection) and pelvirectal supralevator sepsis originating in pelvic disease. Underlying rectal disease, such as neoplasm and particularly Crohn's disease, may be the cause. Similarly, patients with generalised disorders, such as diabetes and acquired immunodeficiency syndrome (AIDS), may present with an anorectal abscess; in these patients, abscesses may run an aggressive course.

Presentation

A perianal abscess, confined by the terminal extensions of the longitudinal muscle, is usually associated with a short (2–3 day) history of increasingly severe, well-localised pain and a palpable tender lump at the anal margin. Examination reveals an indurated hot, tender perianal swelling. Patients with infection in the larger fatty-filled ischiorectal space, in which tissue tension is much lower, usually present later, with less well localised symptoms but more constitutional upset and fever. On examination, the affected buttock is diffusely swollen with widespread induration and deep tenderness. If sepsis is higher, deep rectal pain, fever and sometimes disturbed micturition may be the only features, with nothing evident on external examination but tender supralevator induration palpable on digital examination above the anorectal junction.

Caspar Bartholin, (Secundus), 1655–1709, Professor of Medicine, Anatomy and Physics, Copenhagen, Denmark, described these glands in 1677.
William Cowper, 1666–1709, London surgeon, described these glands in 1697.

Differential diagnosis

The only conditions with which an anorectal abscess is likely to be confused are abscesses connected with a pilonidal sinus, Bartholin's gland or Cowper's gland.

Management

Management of acute anorectal sepsis is primarily surgical, including careful examination under anaesthesia, sigmoidoscopy and proctoscopy, and adequate drainage of the pus. For perianal and ischiorectal sepsis (with an incidence of 60% and 30%, respectively), drainage is through the perineal skin, usually through a cruciate incision over the most fluctuant point, with excision of the skin edges to deroof the abscess (**Figure 74.39**). Pus is sent for microbiological culture (Grace) and tissue from the wall is sent for histological appraisal to exclude specific causes. With a finger in the anorectum to avoid creation of a false opening, the cavity is carefully curetted. A gentle search may be made for an underlying fistula if the surgeon is experienced, and, if obvious, a loose draining seton may be passed; injudicious probing in the acute stage is, however, potentially dangerous and may lead to a much more difficult situation. Unless by highly experienced hands, immediate fistulotomy should not be performed. After irrigation of the cavity, the wound is lightly tucked; antibiotics are prescribed if there is surrounding cellulitis and especially in those less resistant to infection, such as diabetics. If the pus subsequently cultures skin-type organisms, there will be no underlying fistula and the patient can be reassured. If gut flora are cultured, it is likely, but not inevitable, that there is an underlying fistula.

The management of supralevator sepsis is dependent upon its exact anatomy (within or outside the rectal wall) and its origin. Sepsis originating in pelvic disease necessitates appropriate management of the underlying cause (appendiceal, gynaecological, diverticular, Crohn's disease, malignancy), although intrarectal drainage may be apt to avoid creation of an extrasphincteric fistula. Cephalad extension of an intersphincteric fistula can be safely drained into the rectum, whereas supralevator extension of a transsphincteric fistula should be drained via the skin of the buttock. Rarely, a colostomy may be necessary to control severe sepsis, especially in the immunocompromised individual.

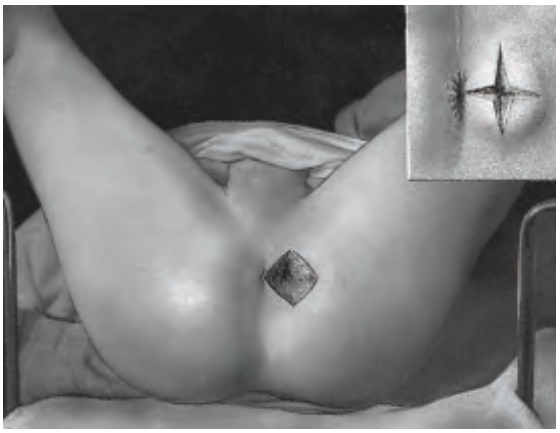

Figure 74.39 Incision of an ischiorectal abscess. The cavity is explored and, if septa exist, they should be broken down gently with a finger and the necrotic tissue lining the walls of the abscess removed by the finger wrapped in gauze. It is wise to biopsy the wall and send the pus for culture. Nothing further is done at this stage.

Summary box 74.13

Anorectal abscess

- Usually produces a painful, throbbing swelling in the anal region. The patient often has swinging pyrexia
- Subdivided according to anatomical site into perianal, ischiorectal, submucous and pelvirectal
- Underlying conditions include fistula-*in-ano* (most common), Crohn's disease, diabetes, immunosuppression
- Treatment is drainage of pus in first instance, together with appropriate antibiotics
- Always look for a potential underlying problem

FISTULA-*IN-ANO*

Aetiology

A fistula-*in-ano*, or anal fistula, is a chronic abnormal communication, usually lined to some degree by granulation tissue, which runs outwards from the anorectal lumen (the internal opening) to an external opening on the skin of the perineum or buttock (or rarely, in women, to the vagina). Anal fistulae may be found in association with specific conditions, such as Crohn's disease, tuberculosis, lymphogranuloma venereum, actinomycosis, rectal duplication, foreign body and malignancy (which may also very rarely arise within a longstanding fistula), and suspicion of these should be aroused if clinical findings are unusual. However, the majority are termed non-specific, idiopathic or cryptoglandular, and intersphincteric anal gland infection is deemed central to them.

Presentation

For reasons that are unknown, non-specific anal fistulae are more common in men than women. The overall incidence is about 9 cases per 100 000 population per year in western Europe, and those in their third, fourth and fifth decades of life are most commonly affected. Patients usually complain of intermittent purulent discharge (which may be bloody) and pain (which increases until temporary relief occurs when the pus discharges). There is often, but not invariably, a previous episode of acute anorectal sepsis that settled (incompletely) spontaneously or with antibiotics, or which was surgically drained. The passage of flatus or faeces through the external opening is suggestive of a rectal rather than an anal internal opening.

Roger Hew Grace, formerly Professor of Colorectal Surgery, The Royal Wolverhampton Hospital, Wolverhampton, UK.

Classification

The most widespread and useful classification of anal fistulae is that proposed by Parks, based on the centrality of intersphincteric anal gland sepsis (the internal opening is usually at the dentate line), which results in a primary track whose relation to the external sphincter defines the type of fistula and which influences management (**Figure 74.40**). Classifications based simply on level are less practical because they mean different things to different people, although the description of a fistula as high, indicating a high risk of incontinence if laid open, or low, with a lower but still some risk to function, is often used. Similarly, 'simple' and 'complex' are commonly used adjectives – complexity may be endowed by the level at which the primary track crosses the sphincters, the presence of secondary extensions or the difficulties faced in treatment. The vast majority of fistulae are intersphincteric or trans-sphincteric.

Intersphincteric fistulae (45%) do not cross the external sphincter (bar, for the purist, the most medial subcutaneous fibres running below the distal border of the internal sphincter); most commonly they run directly from the internal to the external openings across the distal internal sphincter, but may extend proximally in the intersphincteric plane to end blindly with or without an abscess, or enter the rectum at a second internal opening.

Trans-sphincteric fistulae (40%) have a primary track that crosses both internal and external sphincters (the latter at a variable level) and which then passes through the ischiorectal fossa to reach the skin of the buttock. The primary track may have secondary tracks arising from it, which often reach the roof of the ischiorectal fossa, which may rarely pass through the levators to reach the pelvis and which may spread circumferentially (horseshoe). Circumferential spread of sepsis may occur in the intersphincteric and pararectal planes, as well as in the ischiorectal plane.

Suprasphincteric fistulae are very rare, are thought by some to be iatrogenic and are difficult to distinguish from high-level trans-sphincteric tracks (for which, fortunately, management strategies are similar). Extrasphincteric fistulae run without specific relation to the sphincters and usually result from pelvic disease or trauma.

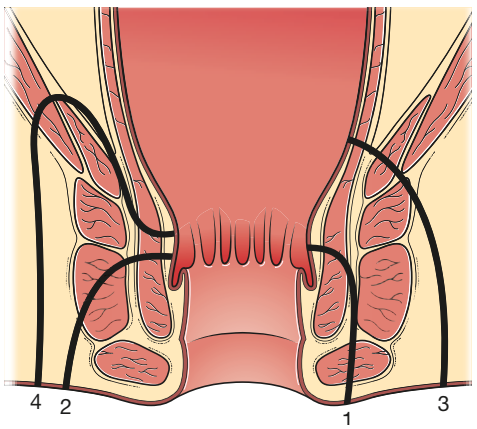

Figure 74.40 Types of anal fistula (Parks' classification): 1, intersphincteric; 2, trans-sphincteric; 3, suprasphincteric; 4, extrasphincteric primary tracks.

Clinical assessment

A full medical (including obstetric, gastrointestinal, anal surgical and continence) history and proctosigmoidoscopy are necessary to gain information about sphincter strength and to exclude associated conditions. The key points to determine are the site of the internal opening; the site of the external opening(s); the course of the primary track; the presence of secondary extensions; and the presence of other conditions complicating the fistula. Palpable induration between external opening and anal margin suggests a relatively superficial track, whereas supralevator induration suggests a primary track above the levators or high in the roof of the ischiorectal fossa, or a high secondary extension. Intersphincteric fistulae usually have an external opening close to the anal verge. Goodsall's rule (**Figure 74.41**), used to indicate the likely position of the internal opening according to the position of the external opening(s), is helpful but not infallible. The site of the internal opening may be felt as a point of induration or seen as an enlarged papilla. Probing in an awake patient is painful, unhelpful and can be dangerous. Full examination under anaesthesia should be repeated before surgical intervention. Dilute hydrogen peroxide, instilled via the external opening, is a very useful way of demonstrating the site of the internal opening; gentle use of probes (**Figure 74.42**) and a finger in the anorectum usually delineates primary and secondary tracks and their relations to the sphincters. Any concerns about fistula topography at clinical examination or examination under anaesthesia (more common after previous unsuccessful surgery) should prompt further investigations before surgical intervention.

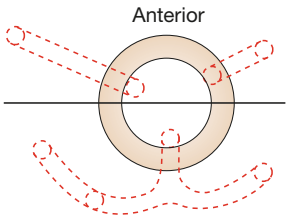

Figure 74.41 Goodsall's rule.

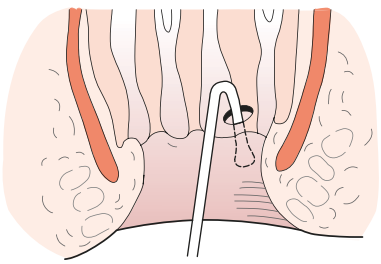

Figure 74.42 Retrograde probing of an anal canal sometimes reveals the internal orifice of the fistula.

David Henry Goodsall, 1843–1906, surgeon, St Mark's Hospital, London, UK.

Special investigations

A successful outcome after fistula surgery requires an accurate assessment of the fistula itself, the sphincter through which it passes and patient expectations (especially in terms of risk to continence). Clinical examination will give some indication of functional anal sphincter length, resting tone and voluntary squeeze; these may be more objectively assessed by manometry, whereas endoanal ultrasound gives useful information about sphincter integrity – the knowledge so gained may well influence surgical strategy. Endoanal ultrasound, especially with hydrogen peroxide, can also be used to delineate fistulae, although definition of sepsis outside or above the sphincters is limited by the probe's focal range and scarring makes interpretation difficult. Nonetheless, ultrasound, which is more accurate than clinical examination, is useful to determine whether a fistula is relatively straightforward or not. MRI is acknowledged to be the 'gold standard' for fistula imaging but it is limited by availability and cost and is usually reserved for difficult recurrent cases. The great advantage of MRI is its ability to demonstrate secondary extensions, which may be missed at surgery and which are the cause of persistence (**Figure 74.43**). Fistulography and computed tomography (CT) both have limitations but are useful techniques if an extrasphincteric fistula is suspected.

Surgical management

Patients with minimal symptoms, especially if they have compromised sphincters, may be managed expectantly. Eradication of sepsis requires surgery, the aim of which must be balanced with the preservation of continence. Most fistulae are relatively straightforward to deal with; however, a minority are extremely problematic and are not the realm of the 'occasional proctologist'. The multitude of strategies advocated attests to these difficult situations; comparisons between techniques are difficult to make because of the heterogeneity of patient groups, the variability in classification, the inapplicability of certain techniques in some situations, inadequate reporting of functional outcomes, inadequate follow-up and surgeon preference over-riding entry into prospective randomised trials.

Figure 74.43 Coronal magnetic resonance imaging scan (STIR sequence) demonstrating a primary track running up the right ischiorectal space (short arrow), which then crosses the sphincters to open into the anal canal just below the puborectalis. However, there is a blind secondary extension (long arrow) passing to the contralateral side in the roof of the left ischiorectal fossa (and involving the levators), which was missed at surgery and which was the cause of fistula persistence.

Fistulotomy

That the fistulous track must be laid open from its termination to its source was a rule promulgated by John of Arderne more than 600 years ago. Fistulotomy, or laying open, is the surest way of getting rid of a fistula, but, by definition, it involves division of all those structures lying between the external and internal openings. It is therefore applied mainly to intersphincteric fistulae and trans-sphincteric fistulae involving less than 30% of the voluntary musculature (but not anteriorly-placed fistulae in women); however, even then, it is not immune to postoperative defects in continence. After full examination under anaesthesia in the lithotomy or prone jack-knife position, during which the internal opening should have been identified, a grooved fistula probe is passed from the external to the internal opening (**Figure 74.44**), the amount of sphincter below and above the probe is noted and, if indicated, the track is laid open over the probe. Granulation tissue is curetted and sent for histological appraisal and the wound edges are trimmed. Secondary tracks, often identified as granulation tissue that persists despite curettage, should be laid open or drained. Marsupialisation reduces wound size and speeds up healing. Primary tracks crossing the external sphincter more deeply have been managed with good outcomes by fistulotomy and immediate reconstitution of the divided muscle – failure to eradicate all sepsis and subsequent breakdown of the repair, however, are very problematic. Alternatively, a staged fistulotomy may be carried out in which secondary tracks are laid open and only part of the sphincter enclosed by the primary track is divided, with the remainder encircled by a loose seton. After sufficient time for healing of the wound and fibrosis, the seton-enclosed track is divided at a second stage.

Fistulectomy

This technique involves coring out of the fistula, usually by diathermy cautery; it allows better definition of fistula anatomy than fistulotomy, especially the level at which the track crosses the sphincters and the presence of secondary extensions. If the sphincteric component of the fistula is deemed low enough to allow safe fistulotomy, then this may proceed (at the expense of longer healing times than conventional fistulotomy). If laying open is not advisable, then the sphincteric component can be managed by another method.

John of Arderne, 1307–1390, was the first English surgeon of note. He practised at Newark-upon-Trent, Nottinghamshire and, from 1370, in London, UK. He described his operation for the treatment of fistulae in about 1376.

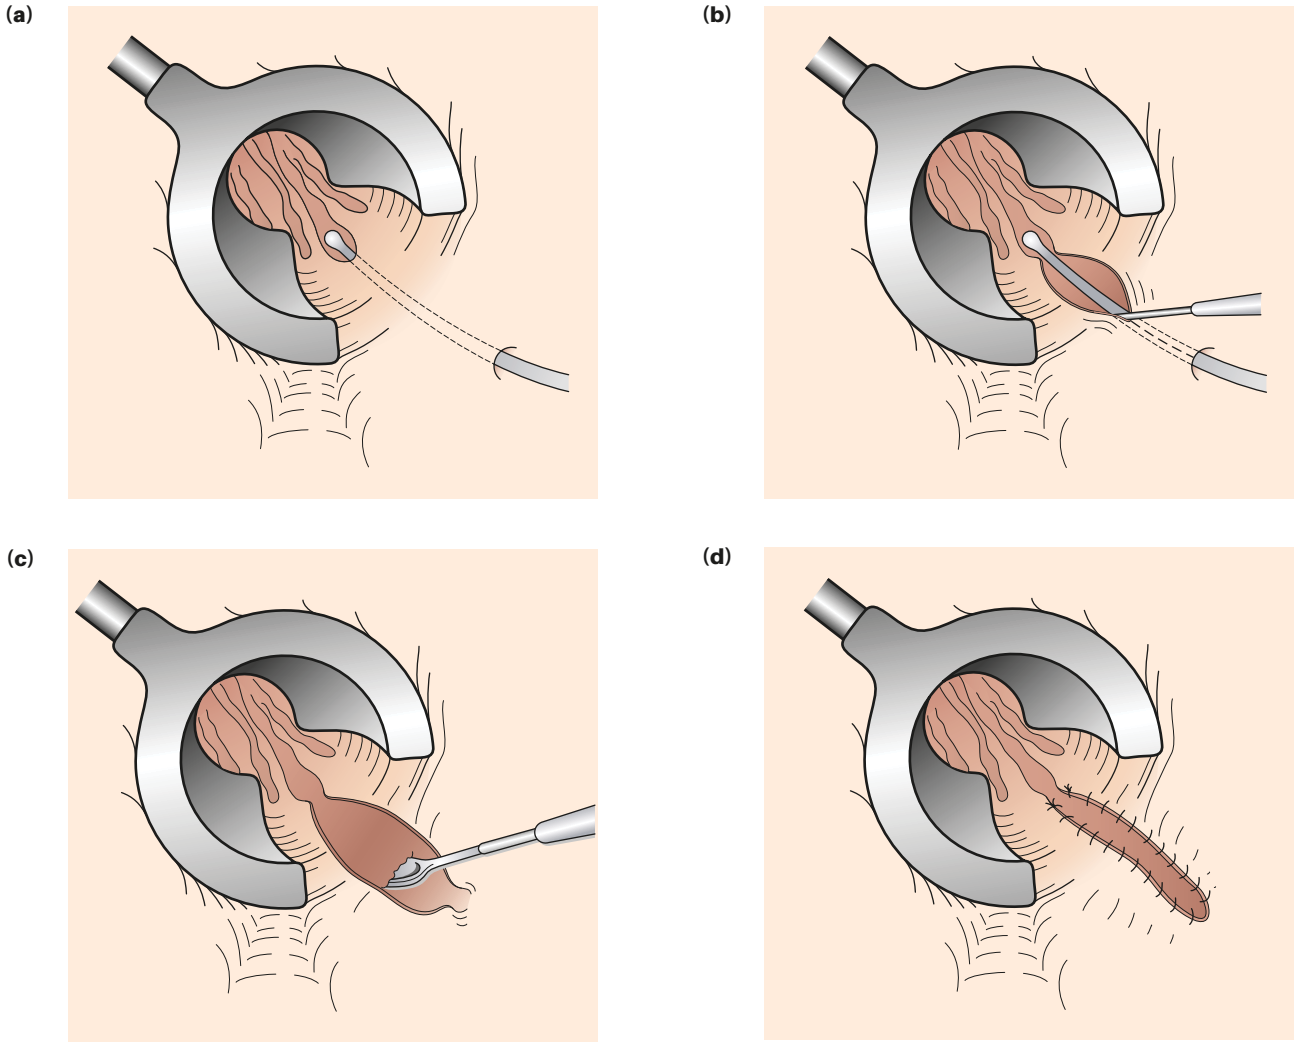

Figure 74.44 Fistulotomy. A grooved probe is passed from the external to internal openings **(a)** and the track laid open over the probe **(b)**. The track is curetted to remove granulation tissue **(c)**, the edges of the wound are trimmed and the wound may then be marsupialised **(d)**. (Reproduced with permission from Nicholls RJ, Dozois RR. *Surgery of the colon and rectum*. Edinburgh: Churchill Livingstone, 1997.)

Ligation of intersphincteric fistula tract

Ligation of intersphincteric fistula tract (LIFT) was first described in 2006 for trans-sphincteric fistulae. The technique involves disconnection of the internal opening from the fistula tract at the level of the intersphincteric plane and removal of the residual infected glands without diving any part of the sphincter complex. The tract is then ligated and divided, the internal part is removed and the external part of the track is curretted out and drained. Hence it is a sphincter-preserving procedure, thereby maintaining continence. Success in terms of healing have been quoted at anything from 47% to 95%.

Setons

Setons (Latin: *seta* = bristle) have been used in a variety of ways in fistula surgery and it is important for surgeons to be clear about what they are trying to achieve in a particular situation. **Loose** setons are tied such that there is no tension upon the encircled tissue; there is no intent to cut the tissue. A variety of materials have been used but the seton should be non-absorbable, non-degenerative and comfortable. **Tight** or **cutting** setons are placed with the intention of cutting through the enclosed muscle.

USES OF LOOSE SETONS

- For **long-term palliation** to avoid septic and painful exacerbations by establishing effective drainage; most often in Crohn's disease and in those with problematic fistulae not wishing to countenance the possibility of incontinence.
- Used **before 'advanced' techniques** (fistulectomy, advancement flap, cutting seton); acute sepsis and secondary extensions are eradicated and a loose seton is passed across the sphincteric component of the primary track to simplify the fistula and allow fibrosis.
- As part of a **staged fistulotomy**.
- As part of a therapeutic strategy to **preserve the external sphincter** in trans-sphincteric fistulae. Secondary tracks in the ischiorectal fossa are laid open. Access to the site

where the primary track crosses the external sphincter may sometimes necessitate division of the anococcygeal ligaments to reach the deep postanal space. The internal sphincter is laid open to the level of the internal opening (or higher if there is a cephalad intersphincteric extension) to eradicate the presumed source and the sepsis in the intersphincteric space. A seton is then passed along the residual track around the denuded external sphincter and tied loosely, and the wounds are dressed. Initial postoperative management includes daily wound irrigation and light wound redressing. The seton is left in place for 3 months and, if there is evidence of good healing, simply removed. Such a strategy certainly protects against the consequences of external sphincter division, with an incidence of healing in the short term of 50–60%.

USES OF CUTTING SETONS

Cutting setons aim to achieve the high fistula eradication rates associated with fistulotomy, but without the degree of functional impairment endowed by division of the sphincters at a single stage. The enclosed muscle is gradually severed ('cheese wiring through ice') such that the divided muscles do not spring apart, and the site of the fistula track is replaced by a thin line of fibrosis as it is brought down. Some recommend prior internal sphincter division, others incorporation of the internal sphincter within the cutting seton. A variety of seton material has been used, either elastic and 'self-cutting' or non-elastic and tightened at intervals, with the sphincter being divided at varying speeds. In eastern parts of the world the same aim has been achieved by chemical cautery using an Ayurvedic method, known in India as Kshara sutra, in which a specially prepared seton thread burns through the enclosed tissue. This out-patient method has been shown to be equivalent to one-stage fistulotomy in patients with intersphincteric and distal trans-sphincteric fistulae.

Advancement flaps

When the sphincter complex is not too indurated and adequate intra-anal access can be obtained, the advancement flap technique can be employed, which aims to preserve both anatomy and function. The principles are prior elimination of acute sepsis and secondary tracks, with ideally a direct track from internal to external openings; coring out of the entire track; and closure of the communication with the anal lumen with an adequately vascularised flap consisting of mucosa and internal sphincter, sutured without tension to the anoderm, well distant from the site of the (excised) internal opening. Modifications include flap orientation (proximally or distally based) and thickness (mucosal, partial or full-thickness internal sphincter), and treatment of the external wound.

Biological agents

The functional consequences of fistulotomy and the poorer eradication rates of sphincter-preserving techniques has led to a search for agents that essentially plug and seal the track and allow ingrowth of healthy tissue to replace it. Intuitively, success must depend on the biomaterial itself and the environment into which it is placed. The poor long-term results of fibrin glue probably result from its relatively rapid resorption, and thus inadequate time for host tissue incorporation. The variable short-term results associated with porcine small intestinal submucosa may reflect early extrusion, premature degradation within an infected field, or the protocol advocated for its use, which does not include meticulous eradication of secondary extensions, or the lining of the primary tack itself, whether epithelial or granulation tissue. Cross-linked porcine dermal collagen has also, more recently, been studied, but only short-term outcomes (albeit optimistic) are known. Research into biological agents must continue.

Summary box 74.14

Anorectal fistulae

- Are common and may be simple or complex
- Are classified according to their relationship to the anal sphincters
- May be associated with underlying disease such as tuberculosis or Crohn's disease
- Laying open is the surest method of eradication, but sphincter division may result in incontinence

HIDRADENITIS SUPPURATIVA

This is a chronic suppurative condition of apocrine gland-bearing skin, which is found in the axillae, submammary regions, nape of the neck, groin, mons pubis, inner thighs and sides of the scrotum, as well as the perineum and buttocks, and is a source of considerable physical and psychological morbidity. There is no confirmatory test or specific characteristic for diagnosis, which makes definition difficult. Acne, pilonidal sinus and chronic scalp folliculitis may coexist with hidradenitis suppurativa in the condition 'follicular occlusion tetrad'.

Pathology

Occlusion of gland ducts leads to bacterial proliferation, gland rupture and spread of infection and epithelial components into the surrounding soft tissue and to adjacent glands. Secondary infection (with *Staphylococcus aureus*, *Streptococcus milleri* and anaerobes) causes further local extension, skin damage and deformity, with multiple communicating subcutaneous fistulae. There is some evidence that the disease may be related to a relative androgen excess.

Presentation

The condition is not seen before puberty and rarely presents after the fourth decade of life. Overall, it is three times more

The Ayurvedic method is derived from the Ayurveda, the most ancient system of Hindu medicine, whose origin is ascribed to Brahma and dates from circa 1400 to 1200BC.

common in women than men, although anogenital disease is more common in men, and obesity is a common association. When affecting the perineum, lesions begin as multiple raised boils, with recurrent lesions within the same vicinity leading to sinus tract formation, bridged scarring and multiple points of discharge. Rarely, it may involve the anal canal anoderm but it does not extend above the dentate line or involve the sphincter muscles themselves.

Differential diagnosis

In the early stages distinction from furunculosis can be difficult. Crohn's disease, cryptoglandular fistula, pilonidal sinus, tuberculosis, actinomycosis, lymphogranuloma venereum and granuloma inguinale must be considered when later stages present.

Treatment

In the early stages, general measures, including weight reduction and antiseptic soaps, may be helpful. Antibiotics may induce remission but often the disease relapses and progresses, at which point surgery is indicated. Inadequate treatment may lead to prolonged morbidity, but any surgery should be less debilitating than the condition. Surgical intervention ranges from simple incision and drainage of acute sepsis to radical excision of all apocrine gland-bearing skin. Careful laying open of all tracts, possibly as a staged procedure according to anatomical location, is an option that appeals to many patients. Radical excision requires closure by skin graft or rotation flap and, occasionally, a defunctioning colostomy to allow healing.

CONDYLOMATA ACCUMINATA (ANAL WARTS)

There is increasing evidence that sexually-transmitted infection with human papillomavirus (HPV) forms the aetiological basis of anal and perianal warts, anal intraepithelial neoplasia (AIN) and squamous cell carcinoma of the anus. In areas of the world where sexual promiscuity (especially anal intercourse) is more common, and in immunocompromised individuals (HIV-infected individuals and transplant recipients), there have been dramatic increases in the incidence of these conditions over the last 30 years, most importantly of AIN and anal cancers. Similar virally-induced changes have been noted in the genital tracts of women (vulval intraepithelial neoplasia (VIN), cervical intraepithelial neoplasia (CIN) and cancers). It is essential to examine all areas of the genitalia and perineum in an affected person as there is often a field change with the virus affecting any squamous epithelium in that area. There are over 170 subtypes of HPV, but certain subtypes (16, 18, 31, 33) are associated with a greater risk of progression to dysplasia and malignancy. Squamous cell carcinoma (SCC) is associated with HPV (especially subtypes 16, 18, 31 or 33).

Condylomata accuminata is the most common sexually-transmitted disease encountered by colorectal surgeons and is most frequently observed in homosexual men. Associated warts on the penis and along the female genital tract are common.

Presentation

Many are asymptomatic but pruritus, discharge, bleeding and pain are usual presenting complaints. In the early stages, examination reveals separate pinkish-white warts close to the anal margin and also often on the anoderm within the distal anal canal. Later, the warts enlarge, coalesce and carpet the skin. Rarely, relentless growth results in giant condylomata (Buschke–Löwenstein tumour), which may obliterate the anal orifice. The diagnosis is aided by aceto-whitening upon application of acetic acid but confirmed by biopsy, which will also indicate the presence or absence of dysplasia.

Treatment

Because of the field effect endowed by viral skin infection, long-term resolution can be problematic. Careful serial application of 25% podophyllin to discrete warts on the perianal skin is often used; however, it cannot be used intra-anally. Surgical excision under local, regional or general anaesthesia involves raising and separating the lesions with local infiltration of dilute adrenaline, which allows more accurate scissor or electrocautery excision to maximise the preservation of normal skin.

ANAL INTRAEPITHELIAL NEOPLASIA

AIN (**Figure 74.45**) is a multifocal virally-induced dysplasia of the perianal or intra-anal epidermis, which is associated with HPV (most frequently subtypes 6, 11, 16 and 18; subtypes 6 and 11 are most often associated with warts and early AIN, whereas subtypes 16 and 18 account for more than 75% of anal cancers). The prevalence is <1% of the population

Figure 74.45 Extensive anal intraepithelial neoplasia, which extends intra-anally.

Abraham Buschke, 1868–1943, German dermatologist.
LW Löwenstein described this condition in 1939.

with a rising incidence especially in those areas where anoreceptive intercourse and HIV are prevalent. At-risk groups include patients with HIV as well as immunocompromised patients, women with a history of other genital intraepithlieal neoplasia (VIN and CIN) and patients with extensive anogenital condylomata. Patients may be asymptomatic and the diagnosis is often a histological surprise, although increasing numbers in high-risk groups are picked up on anal cytology. It is classified according to the degree of dysplasia on biopsy into AIN I, AIN II and AIN III, according to the lack of keratocyte maturation and extension of the proliferative zone from the lower third (AIN I) to the full thickness of the epithelium (AIN III), in the same manner as cervical or vulval dysplasia. The natural history is uncertain but progression from AIN II to AIN III to invasive carcinoma has been observed, notably in the immunocompromised. The term Bowen's disease should probably be avoided.

Presentation

Around 10% of AIN lesions are diagnosed by the pathologist after excision of abnormal skin lesions. Low-grade lesions may be raised and similar to anal condylomata; however, AIN III lesions are more often flat and may be white, grey, purple or brown in colour. Ulceration would suggest progression to invasive anal carcinoma. Patients' symptoms include pruritis, pain, bleeding and discharge. AIN is present in 28–35% of excised anal warts. Approximately 10% of AIN III lesions will progress to anal carcinoma at 5 years. Regression of AIN III rarely occurs, but AIN I and AIN II may regress. The association between AIN III and carcinoma is strengthened by the findings of AIN III in 80% of anal cancer biopsies.

Diagnosis and management

A high index of suspicion and targeted biopsy yields the diagnosis, whereas multiple (mapping) biopsies give an indication of the extent and overall severity of the disease. AIN II and III should be regularly monitored clinically and, if necessary, by repeat biopsy to exclude invasive disease. Specialised centres may offer colposcopy of the anus (anoscopy) utilising 5%acetic acid with Lugol's iodine to assess *in vivo* the dysplastic areas of the anus. The affected areas show up white and can be biopsied. Focal disease may be excised and local excision is effective for lesions <30% of the circumference of the anus. More widespread disease can be dealt with surgically by wide local excision and closure of the resultant defect by flap or skin graft, with or without covering colostomy (especially if there is intra-anal disease). However, for a condition with uncertain malignant potential, this approach should be used with caution as it carries with it significant morbidity. It is important to remember that female patients are at risk of other anogenital intraepithlieal neoplasia; it is recommended that those with AIN III have a yearly cervical smear test.

Topical imiquimod, 5% or oral retinoids have some effect on the progression of dysplasia and can cause regression by at least two histological grades. Other newer options may include anti-HPV treatment; vaccination may reduce the incidence long term.

NON-MALIGNANT STRICTURES – ANAL STENOSIS

Spasmodic

An anal fissure causes spasm of the internal sphincter. Rarely, a spasmodic stricture accompanies secondary megacolon, possibly as a result of the chronic use of laxatives.

Organic

Anal stenosis is a rare but serious complication of anorectal surgery, 90% are seen after haemorrhoidectomy. Other causes included trauma, inflammatory bowel disease, radiation treatment, sexually-transmitted disease, tuberculosis and some skin conditions, e.g scleroderma.

Postoperative stricture

This sometimes follows a haemorrhoidectomy performed incorrectly. Removal of excess anoderm and mucosa without adequate skin bridges can lead to scarring and structuring. Stenosis can be seen after stapled haemorrhoidopexy (0.8–5%) and low coloanal anastomoses, especially if a stapling gun is used, but these are really low rectal stenoses.

Irradiation stricture

This is an aftermath of irradiation and is particularly seen after chemoradiation for anal carcinoma, when a wide are of skin and anoderm are irradiated. It can be seen after irradiation for any pelvic tumours.

Senile anal stenosis

A condition of chronic internal sphincter contraction is sometimes seen in the elderly. Increasing constipation is present, with pronounced straining at stool. Faecal impaction is liable to occur. The muscle is rigid and feels like a tight rubber ring. There is no evidence of a fissure-*in*-*ano*. The treatment is dilatation at frequent intervals.

Lymphogranuloma inguinale

This is by far the most frequent cause of a tubular inflammatory stricture of the rectum and 80% of the sufferers are women. Frei's reaction is usually positive. This variety of rectal stricture is particularly common in black populations and may be accompanied by elephantiasis of the labia majora. In the early stages, antibiotic treatment may lead to cure. In advanced cases, excision of the rectum is required.

John Templeton Bowen, 1857–1941, Professor of Dermatology, Harvard University Medical School. Boston, MA, USA, described this intradermal precancerous skin lesion in 1912.

Wilhelm Sigmund Frei, 1885–1943, Professor of Dermatology, the State Hospital, Spandau, Berlin, who later settled in New York, NY, USA, described his test for lymphogranuloma inguinale in 1925.

Inflammatory bowel disease

Stricture of the anorectum may complicate Crohn's disease and, in this instance, the stricture is annular and often more than one is present. These stenoses are characterised by transmural scarring and inflammation. Occasionally, an anal stricture may occur in ulcerative colitis. Until a biopsy is obtained, a carcinoma should be suspected if a stricture is found.

Endometriosis

Endometriosis of the rectovaginal septum may present as a stricture. There is usually a history of frequent menstrual periods with severe pain during the first 2 days of the menstrual flow.

Neoplastic

When free bleeding occurs after dilatation of a supposed inflammatory stricture, carcinoma should be suspected (Grey Turner) and a portion of the stricture should be removed for biopsy. Sometimes in these cases, repeated biopsies show inflammatory tissue only. If, however, the symptoms show a marked progression, malignancy should be strongly suspected.

Clinical features

Increasing difficulty in defaecation is the leading symptom. The patient finds that increasingly large doses of aperients are required and, if the stools are formed, they are 'pipe-stem' in shape. In cases of inflammatory stricture, tenesmus, bleeding and the passage of mucopus are superadded. Sometimes the patient comes under observation only when subacute or acute intestinal obstruction has supervened.

Rectal examination

The finger encounters a sharply-defined shelf-like interruption of the lumen. If the calibre is large enough to admit the finger, it should be noted whether the stricture is annular or tubular. Sometimes this point can be determined only after dilatation. A biopsy of the stricture must be taken. Often the examination will be painful and needs to be performed under general anaesthesia when biopsies and gentle, graduated dilatation may be undertaken.

Treatment

Before starting treatment it is important to ascertain the cause of the stricture. If associated with Crohn's disease an anoplasty is contraindicated. Non-operative treatment is recommended for mild stenosis. The use of stool softeners and fibre supplements helps aid the passage of stools.

Prophylactic

The passage of an anal dilator during convalescence after haemorrhoidectomy greatly reduces the incidence of postoperative stricture. Efficient treatment of lymphogranuloma inguinale in its early stages should lessen the frequency of stricture from that cause.

Dilatation

Anal dilatation can be performed under general anaesthesia and then, by the patient, using an anal dilator. For anal and many rectal strictures, dilatation at regular intervals is all that is required.

Anoplasty

For severe anal stenosis, an anoplasty is used to replace loss of anal tissue. The stricture is incised and a rotation or advancement flap of skin and subcutaneous tissue replaces the defect and enlarges the anal orifice (**Figure 74.46**). This technique is particularly useful for postoperative strictures.

Colostomy

Colostomy must be undertaken when a stricture is causing intestinal obstruction and in advanced cases of stricture complicated by fistulae-*in-ano*. In selected cases, this can be followed by restorative resection of the stricture-bearing area. If this step is anticipated, a loop ileostomy is constructed.

Rectal excision and coloanal anastomosis

When the strictures are at, or just above, the anorectal junction and are associated with a normal anal canal, but irreversible changes necessitate removal of the area, excision can be followed by a coloanal anastomosis, with good functional results.

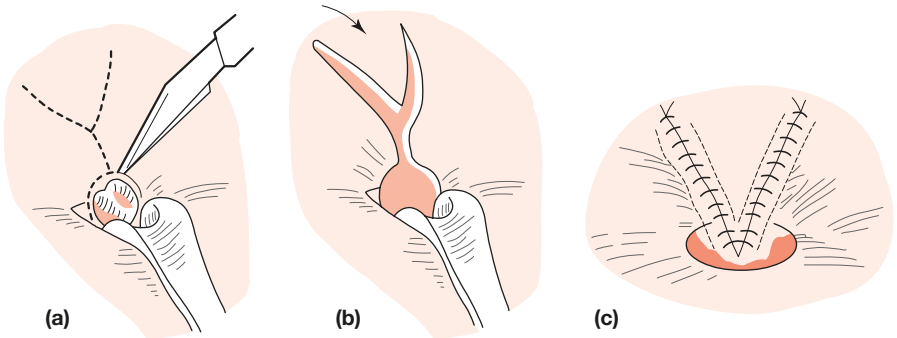

Figure 74.46 (a–c) Y–V advancement flap for anal stenosis.

George Grey Turner, 1877–1951, Professor of Surgery, University of Durham, Durham (1927–1934) and then at the Postgraduate Medical School, London, UK (1934–1945).

Summary box 74.15

Benign anal stricture

- May be spasmodic or organic
- May be iatrogenic, e.g. after haemorrhoidectomy or repair of imperforate anus
- Biopsy must be taken to rule out malignancy
- Can usually be managed by regular dilatation
- Severe anal stenosis may require surgical treatment by an anoplasty

MALIGNANT TUMOURS

Malignant lesions of the anus and anal canal

Anal malignancy is rare and accounts for less than 2% of all large bowel cancers. The crude incidence rate is 0.65 per 100 000. Those arising below the dentate line are usually squamous, whereas those above are variously termed basaloid, cloacogenic or transitional. Collectively they are known as epidermoid carcinomas, and account for >70% of anal malignancies; management and prognosis is similar for this group. Adenocarcinomas are the next commonest. Other tumours include melanoma, lymphoma, and sarcoma.

Squamous cell carcinoma

Although rare, the incidence of anal SCC is rising, with a direct association with HPV infection, AIN and immunosuppression. In the UK in 2012, there were over 1200 new anal cancer cases, with a male:female ratio of 1:2 and 307 deaths from anal cancer. Anal SCC is associated with HPV (especially subtypes 16, 18, 31 or 33) in 70–90% of cases (Figure74.47). Patients at increased risk are those with HIV infection, recipients of organ transplants (renal transplant patients have a 100-fold increased risk) and those with a past history of cancers at 'sexually accessible' sites (usually genital). Pain and bleeding are the most common symptoms and the disease is thus often initially misdiagnosed as a benign condition, highlighting the need for a level of suspicion and adequate examination. A mass, pruritus or discharge is less common. Advanced tumours may cause faecal incontinence by invasion of the sphincters and, in women, anterior extension may result in anovaginal fistulation. On examination, anal margin tumours look like malignant ulcers. There may be associated HPV lesions. Anal canal tumours are palpable as irregular indurated tender ulceration. Sphincter involvement may be evident.

MANAGEMENT

Historically, early anal margin tumours were treated by local excision and anal canal tumours by abdominoperineal excision of the rectum. Nowadays, primary treatment is by chemoradiotherapy (combined modality therapy (CMT); Nigro), the chemotherapy usually including a combination of 5-fluorouracil (5-FU) with mitomycin C or cisplatin. Metastases are rare at presentation (5%) and treatment is aimed at local control. Initial staging involves a clinical examination and biopsy of the primary tumour as well as examination of inguinal nodes. Local staging is by MRI scanning and CT is used to assess lungs and abdomen for metasatic spread. Positron emission tomography (PET) CT may help in equivocal inguinal node assessment. The surgeon has an important role in management: initial diagnosis is surgical; small marginal tumours are still best treated by local excision; radical surgery is indicated in those with persistent or recurrent disease following CMT; and a defunctioning stoma may be indicated for those in whom treatment and disease regression is associated with radionecrosis, incontinence or fistula. Despite good results with chemoradiotherapy, 20–25% of patients will have local disease relapse. After thorough assessment, these patients may require radical abdominoperineal resection, including excision of the posterior wall of the vagina in 70% of women and reconstruction of the perineum using myocutaneous flaps.

Figure 74.47 Neglected papillomas of the anus that have become malignant.

Other anal malignancies

Adenocarcinomata within the anal canal are usually extensions of distal rectal cancers. Rarely, adenocarcinoma may arise from anal glandular epithelium or develop within a long-standing (usually complex) anal fistula; treatment is as for low rectal cancers (i.e. abdominoperineal excision of the rectum (APER) with or without previous radiotherapy or chemoradiotherapy) but prognosis is less good. Melanocytes can be found in the transitional zone of the anal canal. Malignant melanoma of the anus is very rare and usually presents as a bluish-black soft mass that may mimic a thrombosed external

Norman D Nigro, 1912–2009, surgeon, Wayne State University, Detroit, MI, USA.

pile, although it may be amelanotic (Figure 74.48). The prognosis, irrespective of treatment, is extremely poor. Perianal Paget's disease is exceedingly rare.

Figure 74.48 Malignant melanoma of the anal canal (courtesy of Mr B Thomas, Kalushi, Zambia).

Summary box 74.16

Anal cancer

- Uncommon tumour, which is usually a squamous cell carcinoma
- Associated with human papilloma virus
- More prevalent in patients with human immunodeficiency virus infection
- May affect the anal verge or anal canal
- Lymphatic spread is to the inguinal lymph nodes
- Treatment is by chemoradiotherapy in the first instance
- Major ablative surgery is required if the above fails

PART 12

Genitourinary

Chapter 75

Urinary symptoms and investigations

Learning objectives

- To understand the significance of pain relating to urinary tract pathology
- To understand the difference between renal pain and ureteric colic
- To understand the definitions of common lower urinary tract symptoms
- To be able to select the appropriate diagnostic tests to establish a diagnosis of urinary tract disease

PAIN

Pain is a common urological symptom and can be due to pathology in any of the component parts of the urinary tract. **Pain passing urine** is called **dysuria** and refers to the discomfort localised to the outlet of the bladder which is experienced during voiding – typically described as a sensation akin to passing razor blades or glass. Most commonly, dysuria is due to an infection in the lower urinary tract but can be a symptom of more serious pathology such as bladder cancer or carcinoma in situ (CIS) of the bladder especially in an older male smoker with haematuria.

Renal pain is usually caused by distension of the renal capsule and is felt as a constant, gnawing pain in the loin/renal angle. **Ureteric colic** (often incorrectly referred to as renal colic) is different from renal pain and is typified by the lateralised, colicky pain experienced by someone who has a ureteric calculus. Ureteric colic can radiate to the groin or lower still to the testicle/labium but does not radiate to the back of the leg. Ureteric colic can be caused by something other than a stone in the ureter, such as a blood clot or, rarely, a sloughed renal papilla. If the history is carefully taken, it will be apparent that some patients simultaneously experience both ureteric colic and renal pain.

Disease processes in the bladder, e.g. infection or inflammation, can produce **suprapubic pain**. Suprapubic bladder pain, which is experienced when the bladder is full and is relieved by micturition, is typical of interstitial cystitis, an idiopathic benign inflammatory disorder of the bladder typically seen in middle-aged females (see Chapter 77).

Testicular pain is a common symptom in men, especially in early middle-age. Sudden severe testicular pain in younger men (<40 years old) should be treated as a medical emergency and the patient assessed so that a diagnosis of acute testicular torsion can be excluded. The time interval from the onset of pain to the diagnosis of suspected testicular torsion should not influence whether scrotal exploration is performed as torsion/detorsion may be occurring and the testis may still be salvageable after a delayed time interval. Hydrocoeles and epididymal cysts usually do not cause significant pain but can have an increasing pressure effect as they enlarge. A dragging sensation in the scrotum which gets worse towards the end of the day is typical of the discomfort associated with a varicocoele, often on the left side. Typically, testicular tumours in young males are not associated with significant pain. Investigation of testicular pain in the young adult male/middle-aged male is frequently negative, resulting in a highly unsatisfactory diagnostic label of 'idiopathic testicular pain' which is subsequently managed with the input of other clinicians, most commonly pain management specialists. Patients undergoing vasectomy are routinely counselled of the approximate 10% risk of testicular pain in the short term following surgery but more importantly the 1% chance of chronic testicular pain in the longer term.

Perineal pain is often a feature of a complex of symptoms typically seen in middle-aged men who, by a process of exclusion, are diagnosed as suffering from acute or chronic

Summary box 75.1

Pain from the urinary tract

- Renal pain is not synonymous with renal colic
- Renal colic is a misnomer and should be referred to as ureteric colic
- Renal pain can be distinguished from ureteric colic by careful history taking
- Renal pain and ureteric colic may be experienced simultaneously
- Ureteric colic may radiate to the groin/testicle/labium
- Ureteric colic does not radiate to the chest or the back of the leg

prostatitis. With prostatitis, perineal pain may be accompanied by suprapubic pain, low back pain which radiates to the legs, penile pain as well as frequency of micturition and dysuria. Perineal pain is an ominous symptom after previous treatment for a pelvic malignancy, often signifying recurrent pelvic disease.

LOWER URINARY TRACT SYMPTOMS (LUTS)

The International Continence Society (ICS) provides the internationally accepted definitions for symptoms relating to lower urinary tract function:

- **Frequency** is the complaint by the patient who considers that he/she voids too often during the day. The patient may report needing to void more frequently than is their usual habit or more frequently than they consider is socially acceptable.
- **Nocturia** is the complaint that the individual needs to wake at night at least once to void.
- **Strangury** is a sensation of constantly needing to void. Typically, the patient describes having to stand/sit for long periods with the sensation that micturition is imminent. Strangury is most commonly due to a lower urinary tract infection (UTI).
- **Urgency** is a sudden compelling desire to pass urine which is difficult to defer.
- **Urge incontinence (UI)** is involuntary urinary leakage, often large volume, immediately preceded by the sensation of urgency. Urgency and episodes of urge incontinence are often associated with an overactive bladder or a bladder neuropathy.
- **Stress incontinence** is involuntary urinary leakage which occurs when the intra-abdominal pressure rises. This is most common in females who have had vaginal deliveries who describe small-volume urinary leakage associated with activity such as coughing, laughing, sneezing or exercising.
- **Nocturnal enuresis** is involuntary loss of urine during sleep. A common cause in an elderly male is chronic retention of urine with overflow incontinence.
- **Hesitancy** is the term used when an individual describes difficulty in initiating micturition, resulting in a delay in the onset of voiding after the individual is ready to pass urine. This can be several seconds to several minutes and is often a symptom of bladder outlet obstruction.
- **Reduced urinary stream** is usually reported compared with previous performance or in comparison with the performance of others. This is often a symptom of bladder outlet obstruction.
- **Intermittency** is the term used when the individual describes urine flow which stops and starts, on one or more occasions, during micturition.
- **Straining** is the muscular effort used in order to initiate, maintain or improve the urinary stream.
- **Incomplete emptying** is the sensation that at the end of micturition bladder fullness persists.
- **Post micturition dribble (PMD)** is the term used when an individual describes the involuntary loss of urine immediately after he/she has finished passing urine. This is a common symptom in the ageing male when the bulbar urethra fails to empty itself of urine at the completion of micturition. PMD is a symptom which is not usually remedied by a transurethral resection of the prostate.

In general terms, LUTS are classified as either **storage LUTS** (frequency, nocturia, urgency and UI); **voiding LUTS** (hesitancy, a reduced stream, straining) or **post-micturitional LUTS** (incomplete emptying and PMD). Storage LUTS result from failure of the bladder to act as a functioning reservoir for urine and are commonly seen in patients with an overactive bladder or a bladder neuropathy. Voiding and post-micturitional LUTS are commonly seen in males with bladder outlet obstruction (BOO); however, a male with BOO may also have storage LUTS as the thickened detrusor muscle resulting from outlet obstruction becomes overactive, resulting in the combination of symptoms. The term 'prostatism' is now obsolete. LUTS are frequently investigated with urodynamics (see below).

Summary box 75.2

Lower urinary tract symptoms (LUTS)

- Are classified as storage, voiding or post-micturitional
- Storage LUTS are frequency, nocturia, urgency and urge incontinence
- Storage LUTS are typical of an overactive bladder
- Voiding LUTS are hesitancy, a reduced stream and straining
- Voiding LUTS are typical of bladder outlet obstruction
- Some patients may have storage and voiding LUTS in combination
- Are often investigated with urodynamics

HAEMATURIA

Haematuria occurs when there is blood in the urine. This is now classified as visible haematuria (VH) or non-visible haematuria (NVH). Older terminology referred to macroscopic (or frank or gross) haematuria and microscopic (or dipstick) haematuria. Enquiry should be made about the timing of the blood in relation to the urinary stream; initial (urethral pathology), throughout the stream (bladder or upper tracts), or terminal (bladder neck or prostatic pathology), as well as degree of haematuria and its frequency. A patient with haematuria should be investigated regardless of whether they are taking anticoagulant therapy. The concern for the urologist is that the haematuria, especially if painless, is due to an underlying neoplasm of the urinary tract, usually a bladder or renal tumour. Causes of haematuria include **T**rauma, **I**nfection and **N**eoplasm (think of TIN) at all levels of the urinary tract. Haematuria in association with loin pain and a palpable loin mass defines the classic triad of symptoms and signs of a renal tumour although this triad is seen in less than 10% of patients presenting with a renal tumour.

Apart from young females with a proven UTI, most patients with haematuria, whether visible or non-visible, will

be investigated urgently at a haematuria clinic where they will have a renal ultrasound scan (USS) and a flexible cystoscopy as a minimum. The cancer detection rate depends on the degree of haematuria, being approximately 20% in those patients with visible haematuria but very much lower in those with non-visible haematuria (<5%).

Summary box 75.3

Haematuria

- Nowadays, is classified as visible haematuria (VH) or non-visible haematuria (NVH)
- A list of potential causes for haematuria can be rapidly generated by considering trauma (**T**), infection (**I**) and neoplasm (**N**) at all levels of the urinary tract from kidney to urethra
- Haematuria is investigated with a renal USS and a flexible cystoscopy as a minimum

Discolouration of the urine

Many drugs and foodstuffs have been reported to produce abnormal discolouration of the urine. Most colours have been reported but the most frequently encountered clinically are red/orange and brown. Clearly, haematuria is the commonest cause for red urine; however, the presence of haem in the urine also produces red discolouration and generates a positive dipstick test. Red urine discolouration due to haemoglobinuria may present in haemolytic disorders such as 'march haematuria', classically seen in dehydrated soldiers after prolonged marching. Likewise, myoglobinuria due to myocyte destruction, e.g. caused by rhabdomyolysis after crush injury, can also result in red discolouration of the urine. Disordered haem production, seen in porphyria, can result in red discolouration that may change to brown or purple with exposure to sunlight. Several medications can cause red/orange discolouration of the urine, most commonly rifampicin, isoniazid or phenazopyridine with tears and other bodily fluids generally also discoloured. Others include chlorpromazine, thioridazine, senna and laxatives containing a phenolphthalein component. Consumption of large quantities of beetroot can result in red discolouration of the urine. This discolouration is due to the excretion of betalain (betacyanin) pigments such as betanin. There is no direct genetic influence and no single gene variant that differentiates excreters from non-excreters.

The commonly used antibiotics nitrofurantoin and metronidazole can lead to the urine being discoloured brown. Brown urine due to high-circulating bilirubin is also a feature of obstructive jaundice.

LESS COMMON URINARY SYMPTOMS

Haematospermia

This refers to blood, which can be bright red or a brown colour, seen in the seminal fluid. It is most commonly due to benign inflammatory change in the prostate but occasionally can be the presenting symptom of a prostate cancer. A digital rectal examination (DRE) should be performed alongside a prostate-specific antigen (PSA) test and a transrectal US (TRUS) should be considered. In most cases, haematospermia is self-limiting.

Pneumaturia

This is air, or more correctly gas, in the urine. Patients typically describe frothy urine, bubbles in the urine or a stream which intermittently stops then starts again. The commonest cause is an underlying colovesical fistula, usually due to primary pathology in the rectum or sigmoid colon.

'The urethral syndrome'

In this condition, typically seen in young females, symptoms suggestive of a UTI are reported but with negative bacteriology. It is sometimes remedied by a simple cystoscopy and urethral dilatation.

SYMPTOMS RELATED TO THE EXTERNAL GENITALIA

Testis

A testis may be absent from the scrotum in patients with undescended or ectopic testes.

In boys <5 years, a common cause of testicular pain and swelling is a torted hydatid of Morgagni (appendix testis). Often in these young males the scrotal skin is transparent enough to allow visualisation of a small, bluish swelling at the superior pole of the testis. In a young male suspected of having a testicular torsion, examination of the **normal** i.e. **contralateral** testis may reveal a horizontal lie or 'clapper bell testis', raising the level of clinical suspicion. If torsion is suspected, immediate testicular exploration is mandatory and if confirmed, **bilateral** testicular fixation is performed.

Patients with Klinefelter's syndrome typically have bilateral small, firm testes in addition to the other signs typical of this condition.

A hydrocoele is an accumulation of fluid between the testis and the tunica vaginalis and in the younger male can be associated with a patent processus vaginalis. On opening into a hydrocoele, the fluid is typically a yellow colour. A testis which cannot be felt in a tense hydrocoele in the age groups at risk of testis cancer needs to be assessed by USS preoperatively.

Epididymis

Epididymal pathology is rare in the prepubertal male. In the sexually active male, acute epididymitis (often due to chlamydia) with significant pain and swelling needs to be distinguished from acute testicular torsion. If there is any doubt, scrotal exploration is undertaken. Tiny cysts are frequently

Giovanni Battista Morgagni, 1682–1771, Professor of Anatomy, University of Padua, Italy.
Harry Fitch Klinefelter, 1912–1990, American rheumatologist and endocrinologist, first described Klinefelter's syndrome in 1942.

detected in young males undergoing testicular USS but in the vast majority of patients these do not require attention.

Epididymal cysts can form similar scrotal swellings to hydrocoeles but can be distinguished by the fact that the testis can often be felt separately. They contain clear or white fluid. Both hydrocoeles and epididymal cysts transilluminate on clinical examination.

Genitourinary tuberculosis (TB) can result in bilateral nodular induration of the epididymes.

Spermatic cord

Ten per cent of males have a left-sided varicocoele and a smaller left testis. Masses are occasionally found associated with the spermatic cord, which on removal are found to be lipomas, mesotheliomas or sarcomas.

Prepuce (foreskin)

Phimosis occurs when the distal foreskin is tight and will not allow the foreskin to retract. **Paraphimosis** occurs when a poorly retractile foreskin becomes trapped in the retracted state and cannot be replaced. Significant oedema of the foreskin results, making replacement of the foreskin increasingly difficult. Depigmentation and scarring of the distal prepuce occurs in **balanitis xerotica obliterans (BXO)**.

Penis

Peyronie's disease is an idiopathic condition in which fibrosis develops in the corpora cavernosa of the penis. The 'plaque' of Peyronie's fibrosis is usually palpable in the midline anywhere from the base of the penis to just behind the corona. It gives rise to painful angulation of the penis on erection.

Penile fracture occurs when there is trauma to the erect penis. Classically, there is an audible crack and immediate penile detumescence and the patient presents with gross bruising of the penile shaft skin.

Glans penis

In the younger male, **genitourinary warts** due to human papilloma virus (HPV) infection may be observed. In the older male, red raised patches on the glans penis or the inner aspect of the prepuce due to **Zoon's balanitis** or CIS **(erythroplasia of Queyrat** or **Bowen's disease**) are distinguished only on penile biopsy.

Urethra

Hypospadias occurs when there is failure of the urethra to completely close on the ventral aspect and **epispadias** occurs when there is failure of closure on the dorsal surface. A **urethral diverticulum** in a female can be a cause for recurrent UTIs and is notable for its capacity to fill and empty at cystoscopy. A **urethral caruncle** is a minor prolapse of the urethral mucosa in a female and usually requires no treatment.

INVESTIGATION OF URINARY SYMPTOMS

Blood tests

Screening blood tests

Initial blood tests in a patient with potentially serious urinary tract pathology often start with screening blood tests such as full blood count (FBC) and urea and electrolytes (U&E). Anaemia accompanied by a diagnosis of a urinary tract malignancy is an adverse prognostic feature of renal cell carcinoma (RCC).

Serum biochemistry

Modern assessment of biochemical renal function not only involves reporting of serum levels of urea, creatinine and electrolytes but, in addition, involves the reporting of the estimated glomerular filtration rate (eGFR). Creatinine is an end-product of muscle catabolism and suffers from the disadvantage that eGFR can be wide ranging for a given serum creatinine level. For example, a serum creatinine level of 1.5 mg/dL (132 µmol/L) may correspond to a GFR from approximately 20 to 90 mL/min/1.73m^2. eGFR is nowadays recommended as the optimal method of reporting renal function in many countries. The Modification of Diet in Renal Disease (MDRD) study equation uses age, gender, race and standardised serum creatinine to estimate the GFR. When patients with a urological cancer are being considered for nephrotoxic cisplatin-based systemic chemotherapy, in general terms, the eGFR needs to be 50 mL/min or greater.

Patients with calculous disease routinely have serum calcium and uric acid levels checked to rule out a metabolic predisposition to stone formation.

Serum alkaline phosphatase may be elevated in patients with bone metastases due to a urological malignancy and is commonly seen in men with disseminated prostate cancer.

Summary box 75.4

Biochemical assessment of renal function

- eGFR is increasingly reported along with urea and creatinine as it is more informative of true renal function
- With both kidneys functioning normally, an individual has approximately 6 times the renal function needed to remain off dialysis
- Serum creatinine will remain normal with unilateral renal pathology but a normally functioning contralateral kidney

Johannes Jacobus Zoon, 1902–1958, Professor of Dermatology, University of Utrecht, the Netherlands, described Zoon's balanitis in 1952.
Louis Auguste Queyrat, 1856–1933, French dermatologist, described erythroplasia of Queyrat in 1911.
John Templeton Bowen, 1857–1940, American dermatologist, described Bowen's disease.

Tumour markers

Serum tumour markers are utilised in patients with prostate and testis cancer. As of 2017, no serum tumour markers exist in routine clinical practice for renal or bladder cancer.

Prostate-specific antigen

PSA is a glycoprotein produced by prostatic epithelial cells. It is responsible for liquefaction of seminal fluid and allows spermatozoa to swim freely. As a consequence of altered architecture of the prostate in conditions such as benign prostatic hyperplasia (BPH) and prostatitis as well as prostate cancer, PSA enters the bloodstream and is detected by a blood test. The commonly used PSA assays measure the total amount of PSA. PSA levels can be influenced by certain drugs, most notably 5-α-reductase inhibitors such as finasteride and dutasteride used to treat men with LUTS, but also by aspirin, statins and thiazide diuretics. The PSA needs to be multiplied by 2 in men who have been on a 5-α-reductase inhibitor for at least 6 months to give an approximation of the true PSA value. The PSA test can be significantly influenced by an active or recent UTI and the true PSA level only returns to baseline 6 weeks after treatment and eradication of an infective episode.

Summary box 75.5

Prostate-specific antigen

- Is not significantly altered by digital rectal examination
- Can be significantly altered by a UTI
- After an infective episode takes 6 weeks to return to baseline values
- Is artificially lowered in men taking 5-α-reductase inhibitors (finasteride, dutasteride)

In clinical practice, age-adjusted PSA values have been used for many years (*Table 75.1*), but recently have been called into question as they are highly variable and may reflect differences in demographics and clinical characteristics of a particular population.

The two largest randomised PSA-based screening trials, the European Randomised Study of Prostate Cancer (ERSPC) and the Prostate, Lung, Colorectal and Ovarian (PLCO) Study, have evaluated PSA testing among men aged 55–69 years with the indication for a biopsy being a PSA ≥3 ng/mL. Recommended prostate biopsy referral values are being realigned to the evidence emerging from these two studies. The new recommended referral value for men aged 50–69 years is 3 ng/mL. Further diagnostic evaluation should consider the man's history of comorbidities, ethnicity, family history and abnormal DRE findings prior to biopsy.

A large UK-based clinical study of serum PSA as a tool for identifying asymptomatic men with prostate cancer has recently reported 10-year outcome data (ProtecT trial). At present, screening men in the UK for prostate cancer using regular PSA testing is not routinely performed but men interested in having a PSA test can request this from their family practitioners.

Risk prediction models have been developed in recent years to assist clinicians and patients in predicting prostate cancer diagnosis, stage and prognosis. A number of these risk assessment tools are available online as a decision aid for an individual man to evaluate his own risk of prostate cancer. These include the Prostate Cancer Prevention Trial (PCPT) Risk Calculator and the ERSPC Risk Calculator.

For men newly diagnosed with prostate cancer, PSA assists with risk (of disease progression) stratification. It is also a useful marker of response to treatment and of disease recurrence after treatment.

PSA derivatives

Raised serum levels of PSA in men with BPH and prostatitis decrease the specificity of the PSA blood test as a cancer marker. In an effort to improve specificity of testing, PSA derivatives and PSA kinetics have been used but to date have had little impact in assisting with clinical decision making.

FREE PSA (FPSA), COMPLEXED PSA (CPSA) AND FREE/TOTAL PSA (F/TPSA)

Total PSA detectable in the serum consists of proteolytically active free PSA and complexed PSA. Free PSA constitutes 5–40% of total PSA and cPSA 60–95%. 60–90% of cPSA is bound to α-1-antichymotrypsin, 10–20% to α-2-macrogobulin and 1–5% to α-1-protease inhibitor. A lower percentage fPSA has been associated with prostate cancer and many studies have indicated its value in reducing the

TABLE 75.1 Age-specific reference ranges for prostate-specific antigen (PSA) values.

	PSA reference range (ng/mL)		
Age range (years)	Oesterling *et al.*[1]	Dalkin *et al.*[2]	DeAntoni *et al.*[3]
40–49	0.0–2.5 ng/mL	–	0.0–2.4 ng/mL
50–59	0.0–3.5 ng/mL	0.0–3.5 ng/mL	0.0–3.8 ng/mL
60–69	0.0–4.5 ng/mL	0.0–5.4 ng/mL	0.0–5.6 ng/mL
70–79	0.0–6.5 ng/mL	0.0–6.3 ng/mL	0.0–6.9 ng/mL

[1]Oesterling JE, Jacobsen SJ, Chute CG *et al*. Serum prostate-specific antigen in a community-based population of healthy men. Establishment of age-specific reference ranges. *JAMA* 1993; **270**(7): 860–4.
[2]Dalkin BL, Ahmann FR, Kopp JB. Prostate specific antigen levels in men older than 50 years without clinical evidence of prostatic carcinoma. *J Urol* 1993; **150**(6): 1837–9.
[3]DeAntoni EP, Crawford ED, Oesterling JE *et al*. Age- and race-specific reference ranges for prostate-specific antigen from a large community-based study. *Urology* 1996; **48**(2): 234–9.

number of negative prostate biopsies performed. Studies have varied in the threshold of percentage fPSA used, with cut-offs of 22%, 15% and 10% reported to be of clinical utility. Recent studies have indicated that there are, in fact, 3 forms of fPSA: inactive PSA, known as proPSA, and 2 other forms; BPSA (nicked PSA) and intact PSA (iPSA). BPSA and iPSA have been associated with benign disease of the prostate while proPSA has been found in prostate cancer tissue.

HUMAN KALLIKREIN-2 (HK2)

PSA in prostatic tissue, namely pPSA, is converted to mature PSA via activation of HK2 induced by a physiological process occurring in seminal fluid. HK2 is a protein belonging to the kallikrein family closely related to PSA and is a potential prostate cancer tumour marker.

PROSTATE HEALTH INDEX (PHI)

PHI is a mathematical equation demonstrating the probability of prostate cancer. The equation is formulated as p2PSA/fPSA×√tPSA. p2PSA is an isoform of fPSA. Higher PHI values have been associated with an increased probability of prostate cancer.

PSA kinetics

PSA DENSITY (PSAD)

This factors in the volume of the prostate and assumes contributions to the total PSA of normal prostate epithelium, BPH or prostate cancer to be 0.1 ng/mL, 0.3 ng/mL and 3.5 ng/mL. In clinical practice, PSAD has been found not to have a significant role.

PSA VELOCITY

PSA velocity (ng/mL/yr) has been defined as the annual absolute increase in tPSA. In the past, a velocity of >0.75 ng/mL/yr compared with baseline in those men with a PSA in the range 4–10 ng/mL has been considered suspicious but currently there is no consensus concerning a useful threshold.

PSA DOUBLING TIME

This is defined as the number of months it takes for a baseline PSA to double. It is clinically useful in determining the need for treatment initiation in men undergoing active surveillance and watchful waiting for prostate cancer and for determining the need for further treatment once first-line therapy has failed.

Other possible prostate cancer biomarkers

Recently, two promising urinary ribonucleic acid (RNA) biomarkers, prostate cancer antigen-3 (PCA-3) and the fusion gene TMPRSS2:ERG, have emerged.

Testis tumour markers

There are three serum tumour markers routinely used in the management of men with suspected testis cancer: alpha fetoprotein (αFP), beta human chorionic gonadotropin (βHCG) and lactate dehydrogenase (LDH). These markers sometimes provide insight into the likely histological subtype of germ cell tumour present and, in addition, contribute to the prognostication of testis cancer patients into good prognosis, intermediate prognosis and poor prognosis groups using a classification devised by the International Germ Cell Cancer Collaborative Group (IGCCCG) (see Chapter 80).

Urine-based tests

Urinalysis

Patients in both primary and secondary care settings will very often be screened for significant disease with a urine dipstick test. Urine is dipped with a stick on which there is a series of small chemical-containing pads designed to detect, typically, glucose, bilirubin, ketones, the specific gravity, blood, pH, protein, urobilinogen, nitrites and leucocyte esterase through colour changes which are detected using a bench-top analyser. A trace of blood on dipstick testing should be regarded as a negative test and should not prompt further evaluation of the patient.

Mid-stream specimen of urine (MSU)

A MSU is used to establish the diagnosis of a UTI and primarily allows identification of the responsible urinary pathogen and selection of the most appropriate antibiotic. Most MSUs will be processed in 2 stages with initial urine microscopy followed by urine culture only if appropriate. Normal urine contains small numbers of white blood cells (WBCs) and epithelial cells as indicated:

Normal values	
WBC	(0–40 × 10^6/L)
Epithelial cells	(0–55 × 10^6/L)

Early-morning urine (EMU)

EMU samples are sent on 3 consecutive days for Ziehl–Neelsen (ZN) staining and culture for acid-fast bacilli if genitourinary TB is suspected. Culture results take 6 weeks.

Voided urine cytology

Voided urine cytology is performed when a urinary tract malignancy, usually a urothelial carcinoma, is suspected, particularly in the setting of a normal cystoscopy. The test has the disadvantage of a high false-negative rate. Approximately 15% of low-grade transitional cell carcinomas produce positive voided urine cytology compared with approximately 50% of high-grade transitional cell tumours.

Endoscopy

Cystoscopy

To further evaluate urinary symptoms, the entire lining of the urinary tract can be directly visualised from the urethra and bladder (using a cystoscope) to the ureter and renal pelvis

Franz Ziehl, 1859–1926, German bacteriologist and a professor in Lübeck, Germany.
Friedrich Carl Adolf Neelsen, 1854–1898, German pathologist and professor at the Institute of Pathology, University of Rostock, Germany.

(semi-rigid ureteroscope), and finally the renal calyces (flexible ureteroscope). Cystoscopy can be undertaken either as a flexible cystoscopy (Figure 75.1) using local anaesthesia or rigid cystoscopy (Figures 75.1 and 75.2), preferably under a general anaesthetic. Telescopes with different fields of view are available (0°, 12°, 30° and 70° lenses are commonly used). In the operating theatre, most endoscopic procedures, including cystoscopy, require the urology stack (Figures 75.3 and 75.4). Insertion of the cystoscope sheath in some centres is performed with the obturator inserted rather than the telescope, which is then switched with the obturator once in the bladder.

Flexible cystoscopy is relatively poorly tolerated in young males. In the male, visualisation of the urethra during flexible cystourethroscopy is often completed on withdrawal of the scope providing there is no stricture in the urethra. Flexible cystoscopy can be performed as a rapid turnover procedure in the outpatient clinic. It is principally a diagnostic tool but a few minor procedures can be accomplished using the flexible cystoscope, such as insertion/removal of ureteric stents, small biopsies and diathermy/laser of small bladder lesions. The tip of most flexible cystoscopes deflects down 90° and upwards/backwards through 180° giving a 270° field of view. Full backward deflection of the flexible cystoscope allows what is referred to as the 'J manoeuvre' permitting excellent visualisation of the bladder neck region.

Figure 75.1 A rigid cystoscope (above) assembled with the telescope inside the outer sheath, demonstrating the working channel with the white plastic nipple below the light attachment. Below is the flexible cystoscope that simply needs to be connected to a light source and irrigation and is ready to use.

Figure 75.2 The components of a rigid cystoscope. From above down: the obturator for insertion into the outer sheath used in blind insertion of the cystoscope sheath – usually in females; the telescope to which the light cable is attached; the outer sheath containing 2 taps for irrigation and outflow with the bridge with a working channel for guidewires and ureteric catheters already engaged; cold cup biopsy forceps that will accommodate the telescope and fit down the outer sheath.

Figure 75.3 The urology 'stack'. In this stack, from above down, are the monitor (often on a telescopic arm), a video recording device, the light source which is on the camera to connect to the endoscope and a printer for capturing images. The endoflator (used for laparoscopic urological procedures) is hidden by the monitor in this image.

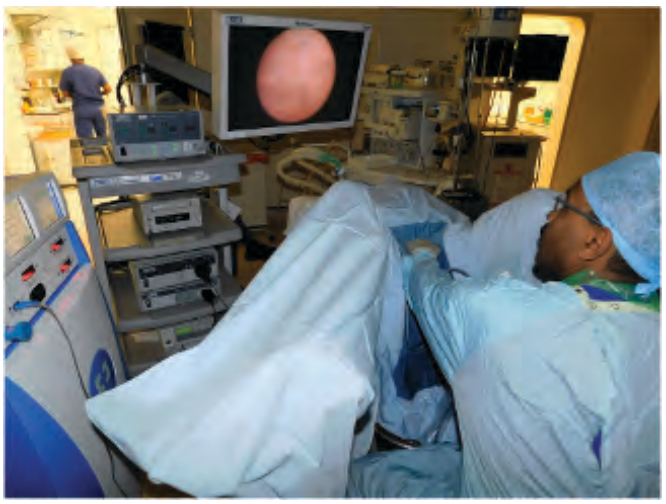

Figure 75.4 The urology stack in use in a patient under general anaesthetic about to undergo a transurethral resection of a bladder tumour.

More can be achieved with a rigid cystoscope under general anaesthetic (GA), especially in relation to instrumentation of the ureters.

In an effort to improve the diagnostic accuracy of cystoscopy, technological advances have produced narrow band imaging (NBI) and photodynamic diagnosis (PDD) combined with cystoscopy.

NBI is an optic enhancement technique which filters the white light into two different bandwidths, including blue (415 nm) and green (540 nm) spectrum. In the NBI mode, the light is strongly absorbed by haemoglobin and only penetrates the tissue superficially, which increases the identification of small capillaries and superficial tissue structures. Since bladder tumours are vascular structures, the tumours appear in brown or green colour against a white background using NBI (**Figure 75.5**).

With PDD, 60 to 90 minutes before the PDD procedure, a solution containing a drug with fluorescent properties is instilled into the bladder. The drug preferentially accumulates in rapidly proliferating cells such as tumour cells.

During the PDD procedure, the bladder is examined in blue light. The accumulated drug in the tumour cells is spectrally excited by this blue light and emits a pink fluorescence. The tumour cells are highlighted pink and stand out against the normal bladder tissue, which keeps its blue appearance (**Figure 75.6**). Bladder tumours and areas of CIS are easier to identify compared with white light cystoscopy.

Figures 75.7–75.13 show some normal anatomy as well as some of the pathology seen in the urethra and bladder on cystourethroscopy.

Summary box 75.6

Cystoscopy

- Can be performed either with a rigid cystoscope under general anaesthetic or a flexible cystoscope under local anaesthetic
- Flexible cystoscopy is principally a diagnostic procedure
- The diagnostic accuracy of cystoscopy has recently been improved by techniques such as NBI and PDD

CYSTOSCOPY AND RETROGRADE URETEROGRAMS

In patients in whom ureteric pathology is suspected (often stones or tumours), retrograde studies of the entire ureter and renal pelvis can be performed by insertion of a fine ureteric catheter into the ureteric orifice (via a cystoscope) followed by the injection of contrast material retrogradely into the ureter in an effort to confirm the diagnosis. Overexuberant injection of contrast can result in extravasation of contrast material into the retroperitoneum, especially when there is ureteric obstruction.

Ureteroscopy

Ureteroscopy can be performed as both a diagnostic procedure and a therapeutic procedure. A rigid or semi-rigid ureteroscope can be used in the ureter as far as the renal pelvis but to inspect or operate on the renal pelvis or renal calyces, a flexible ureteroscope is, generally, needed (**Figure 75.14**). The procedure is most often performed when pathology, commonly stones, strictures or tumours of the ureter, is suspected. The insertion of each of these instruments is facilitated by the use of a guidewire in the ureter and in most cases the ureter is best first outlined with radio-opaque contrast material using an image intensifier.

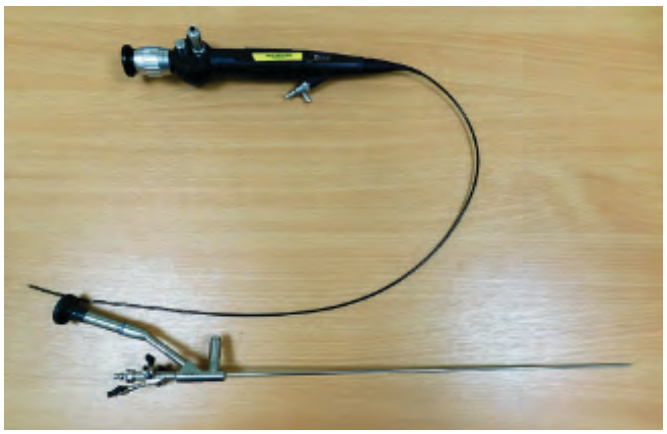

Figure 75.14 Examples of a flexible ureteroscope (above) and a semi-rigid ureteroscope (below).

Radiology

Urinary tract ultrasound scan (USS) (**Figure 75.15**)

Renal USS is used frequently in the investigation of patients with urinary problems and, in addition to selected use, is used to screen patients with recurrent UTIs and patients with both visible and non-visible haematuria. USS is extremely useful in the detection of hydronephrosis and can be used at the bedside to detect this in the emergency setting. It is useful in detecting renal parenchymal cysts, tumours, renal scarring, and angiomyolipomas (AML) as well as stones. Stones classically produce an acoustic shadow but USS is not the most sensitive imaging modality for detecting renal stones and some stones can be missed on USS. USS is the imaging modality most frequently used to assist with the insertion of a percutaneous nephrostomy (PCN), often placed by a radiologist when there is an obstructed (and/or infected) renal collecting system. USS is sometimes used to further characterise renal lesions detected by other modalities such as computed tomography (CT) or magnetic resonance imaging (MRI) and is a useful adjunct in clarifying whether some lesions on CT/MRI are haemorrhagic cysts or solid renal lesions.

USS is not particularly good for assessing ureters unless there is significant dilatation of the ureter or sizeable pathology in the ureter such as a stone. Soft tissue lesions in the ureter are difficult to detect by USS. USS can be used to detect pathology in the bladder and the bladder is routinely assessed in addition to the kidneys by USS in the haematuria clinic. USS can detect filling defects in the bladder in keeping with bladder tumours and, in addition, can detect bladder calculi, a thickened, trabeculated bladder wall in patients with bladder outlet obstruction and large bladder diverticula, and can be used to determine the residual volume after micturition.

In addition, USS is frequently employed to investigate men with scrotal swellings and has a role to play in the assessment of urethral stricture disease.

Summary box 75.7

Ultrasound scan

- Is frequently used to screen patients with suspected urological pathology
- Is frequently part of a haematuria clinic protocol
- Is an excellent method to detect hydronephrosis
- Can be performed at the bedside in the critically ill patient
- Recently has been combined with contrast enhancement in certain settings such as in the assessment of renal cysts

Transrectal ultrasound scan (TRUS)

TRUS is often performed in conjunction with biopsy of the prostate. Some manufacturers produce USS machines dedicated to USS of the prostate as shown in **Figure 75.16**. Most prostatic USS is performed using biplanar probes which give transverse as well as sagittal views of the prostate (**Figure 75.17**). The majority of men undergoing a TRUS and prostate biopsy have the procedure on account of a raised PSA or an abnormal digital rectal examination (DRE) or both. A bridging plan is needed for those patients on oral anticoagulant therapy. Patients can be biopsied while continuing on aspirin therapy. Patients require antibiotic prophylaxis with a regime such as ciprofloxacin orally in the hour before the procedure and IV gentamicin immediately before the procedure is undertaken. Patients are counselled concerning the risk of complications such as a UTI (5%), septicaemia (1%), haematuria, blood per rectum and haematospermia which can be prolonged. Prior to any biopsies, local anaesthetic is infiltrated around the apex of the prostate under USS guidance. During TRUS, a distinct peripheral zone (PZ) and transition zone (TZ) are evident (**Figure 75.17**); the volume of the prostate can be estimated and biopsies are taken if indicated. If the procedure is being performed for a raised PSA and the prostate looks normal on TRUS, systematic biopsies will be taken

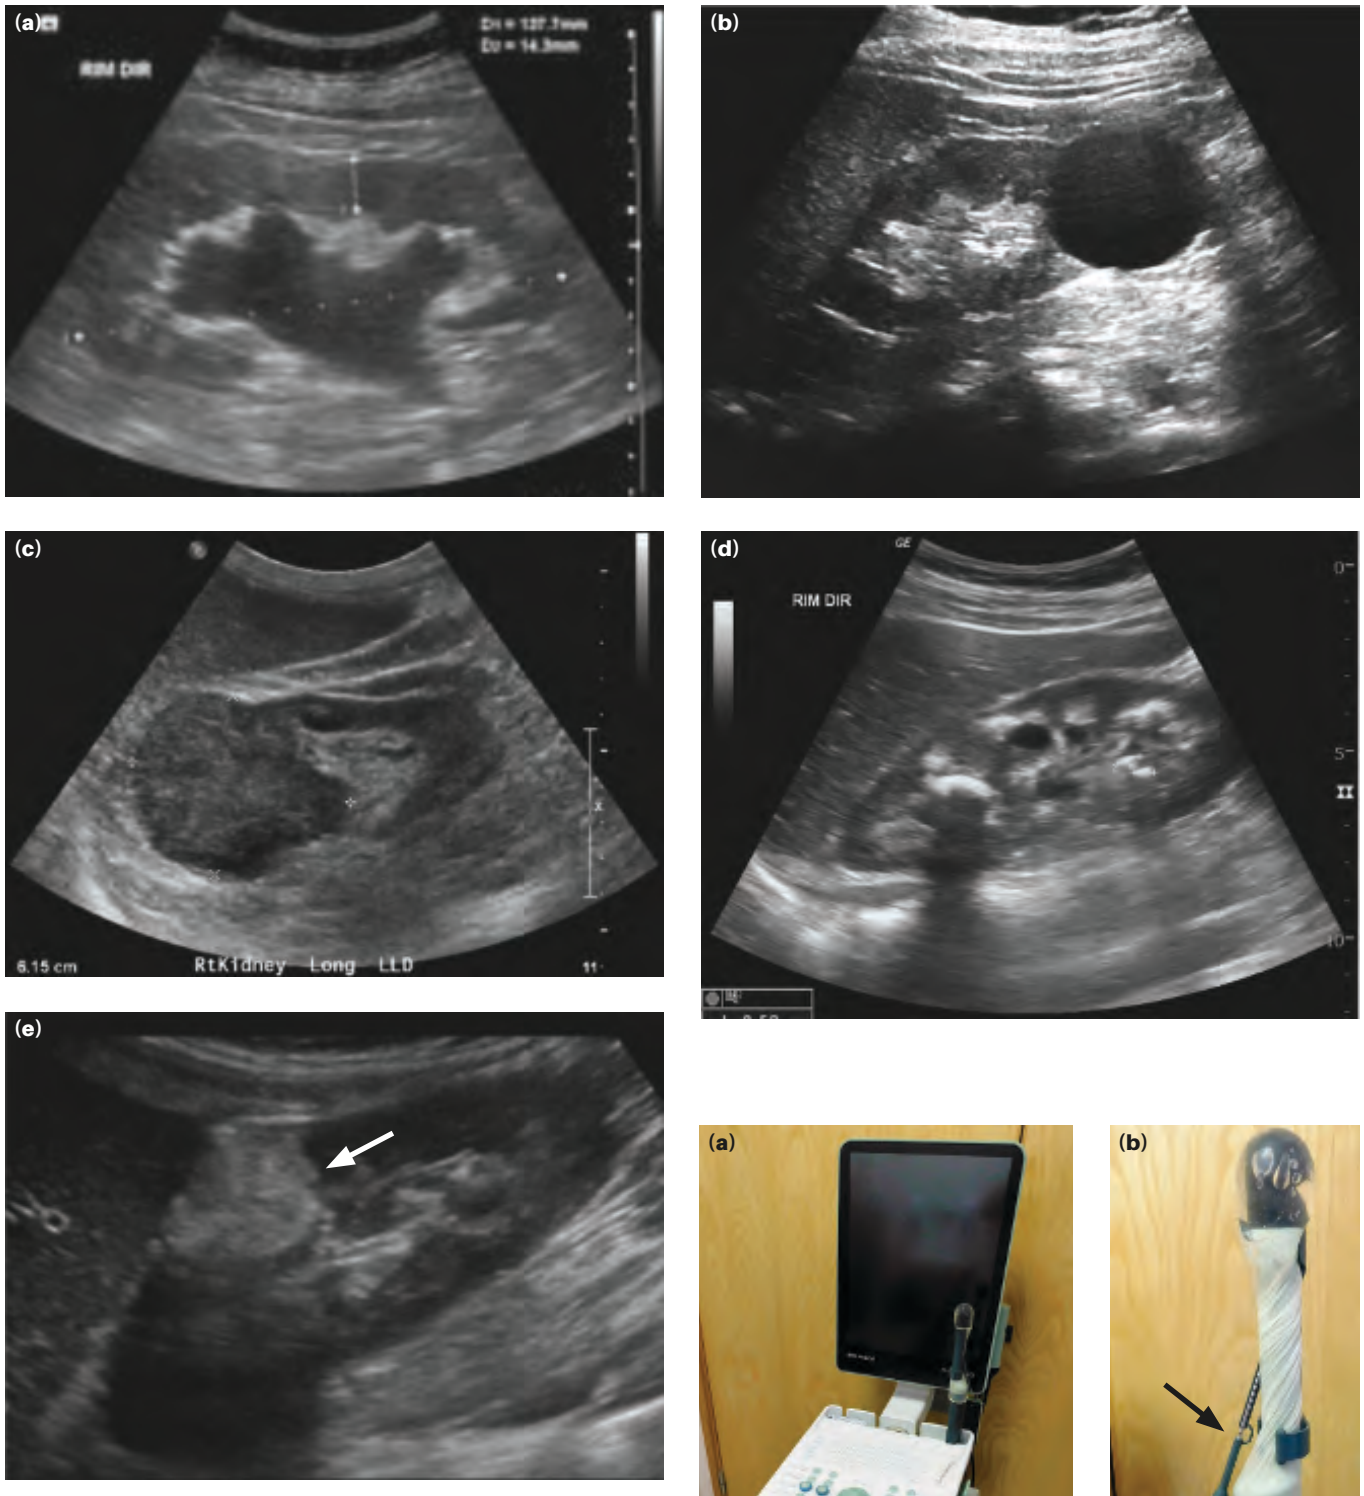

Figure 75.15 Ultrasound scan showing: **(a)** hydronephrosis (courtesy of Dr Bruno Di Muzio, Radiopaedia.org, rID: 21885); **(b)** renal cyst (courtesy of Dr Ian Bickle, Radiopaedia.org, rID: 21139); **(c)** renal tumour (courtesy of Wendy Boller); **(d)** medullary sponge kidney with renal calculi – note the stone gives rise to an acoustic window (courtesy of Dr Bruno Di Muzio, Radiopaedia.org, rID: 12141); **(e)** angiomyolipoma (arrow).

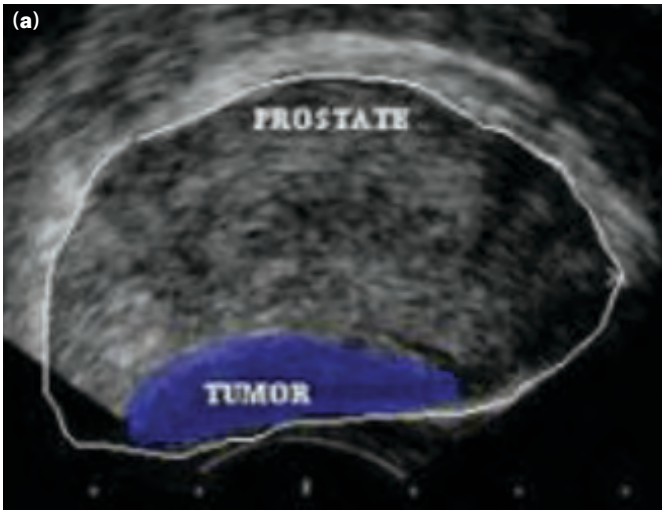
using a biopsy device as shown in Figure 75.18. The classic abnormality associated with prostate cancer is a hypoechoic area in the PZ (Figure 75.19) but this is rarely found in the absence of a palpable abnormality on DRE.

Transperineal template biopsies of the prostate

Transperineal template biopsies of the prostate (TPTBP) are increasingly used clinically and although they have not yet replaced TRUS-guided prostate biopsies as a first-line test, they may do this in the future. Currently, TPTBP are used



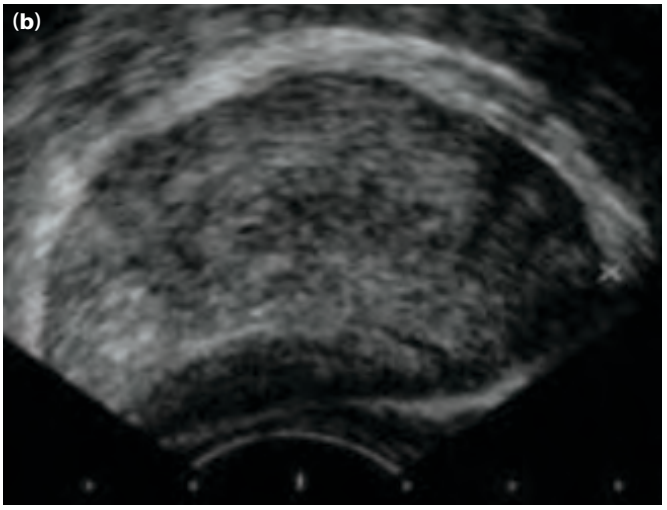


Figure 75.19 (a, b) A transverse image of the prostate on transrectal ultrasound scanning demonstrating the classic hypoechoic lesion in the peripheral zone, typical of a cancer.

to further evaluate men with a negative TRUS-guided prostate biopsy in whom the PSA trend remains suspicious, or younger men for whom a diagnosis of low-risk prostate cancer has been made and where it is important to exclude more significant disease in other parts of the prostate (most notably in the anterior aspects of the gland) not easily accessible via the transrectal route. TPTBP are usually performed under GA although there are reports that they can be done under local anaesthetic (LA). Typically, around 36 biopsies are obtained during TPTBP including from anterior aspects of the prostate which are impossible to sample during TRUS. TPTBP has a much lower risk of sepsis than TRUS-guided biopsies.

Summary box 75.8

Prostate biopsies

- TRUS has been the traditional method of guiding prostate biopsies
- TRUS-guided biopsies are increasingly being replaced by transperineal template biopsies of the prostate
- TPTBP have a much lower sepsis risk than TRUS biopsies
- TRUS biopsies are usually performed under local anaesthesia
- TPTBP are usually performed under general anaesthesia

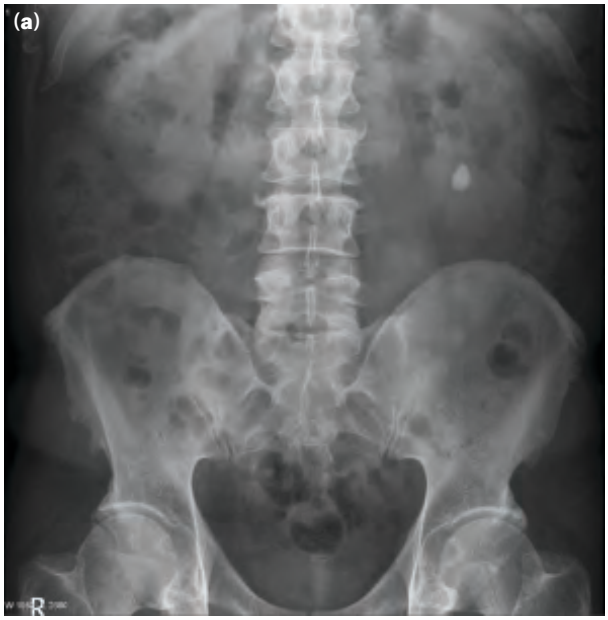

Figure 75.20 **(a)** Left lower pole renal stone on plain KUB x-ray (courtesy of Prof Frank Gaillard, Radiopaedia.org, rID: 12555). **(b)** A staghorn calculus in the left kidney (courtesy of Dr Natalie Yang, Radiopaedia.org, rID: 9733). **(c)** Right lower pole calculi and steinstrasse in the distal right ureter (arrow) (courtesy of Dr Ali Abougazia, Radiopaedia.org).

KUB x-ray (Figure 75.20)

This is a plain x-ray of the abdomen and pelvis that includes the regions of the body occupied by the **K**idneys, **U**reters and **B**ladder. In fact, not a huge amount is learned about these organs in the absence of pathology. In the normal setting, soft tissue outlines of the kidneys are commonly seen but normal ureters and bladder will not be seen. The commonest indication for a KUB is to screen patients for the presence of urinary tract calculi. Patients who have had a CT scan resulting in the diagnosis of a urinary tract calculus often have a supplementary KUB to determine if plain x-ray can be used in the subsequent follow-up of the patient. Phleboliths (thrombosed, calcified veins in the pelvis) can easily be mistaken for distal ureteric stones by the novice. KUB is also frequently used in the management of patients undergoing extracorporeal shockwave lithotripsy (ESWL) for urinary tract stones, to assess the outcome of treatment and to determine whether further treatment is necessary. Finally, a KUB is often used to check for correct positioning of a double-J ureteric stent.

Intravenous urography (IVU)

This is infrequently used nowadays and its primary indication in the investigation of patients with suspected urinary tract calculi has been superseded by non-contrast CT.

Computed tomography (CT) scan

A non-contrast CT scan is now the imaging modality of choice in the investigation of a patient with suspected urinary tract calculi (**Figure 75.21a**). Angiomyolipomas of the kidney have a characteristic appearance on CT (**Figure 75.21b**). Other variations of the CT scan include a contrast CT, a contrast CT with a urographic phase and a triple-phase CT.

A contrast CT scan of the chest/abdomen and pelvis is frequently used to stage patients with renal tumours (**Figure 75.22**), muscle-invasive bladder cancer and young men with testicular cancer. CT is less frequently used in men with prostate cancer but does have a role to play when lymph node disease is being assessed prior to treatment.

Summary box 75.9

Diagnosis of urinary tract stones

- Intravenous urography is obsolete in diagnosing urinary tract stones
- Non-contrast computed tomography scan is now the technique of choice for this diagnosis

In 1986, a classification of renal cysts based on CT criteria known as the Bosniak classification was devised. Nowadays, this classification can also be applied to MR imaging.

The Bosniak classification of renal cystic masses (**Figures 75.23 and 75.24**) is as outlined:

I Simple benign cysts with hairline thin walls (**Figure 75.24a**). The cysts do not contain septations, calcifications or solid components. There are no enhancing soft tissue components.

II Benign cystic lesions (**Figure 75.24b**). The cysts may have hairline thin septations with fine calcifications in the walls. Minimal enhancement of the hairline thin smooth wall may be seen. No enhancing soft tissue components are present. Non-enhancing high-attentuation cysts <3 cm in size are included.

IIF Complex cysts requiring follow-up imaging. These cysts are more complex and do not fit into category II or III. These cysts have an increased number of hairline septations or mild thickening of the wall and/or septations. No enhancing soft tissue components are present.

III Indeterminate masses (**Figure 75.24c**). The cystic lesions have thickened walls and septations that are irregular. The cyst walls or septations demonstrate enhancement.

IV Malignant cystic masses (**Figure 75.24d**). Thick and irregular walls and septations may be present but enhancing soft tissue components are seen, independent of wall or septal enhancement.

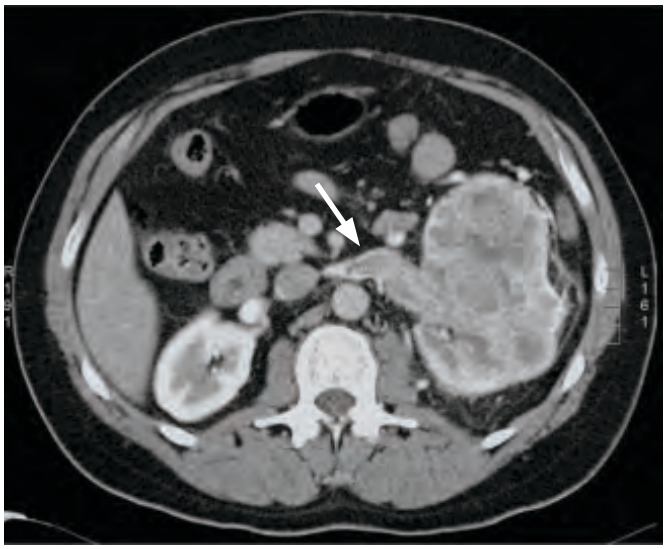

Figure 75.22 Computed tomography scan demonstrating a large left renal tumour with involvement of the left renal vein (arrow) (courtesy of Dr Laughlin Dawes, Radiopaedia.org, rID: 35937).

Morton A Bosniak, 1929–2016, Professor of Radiology, New York University (NYU) Langone School of Medicine, NY, USA.

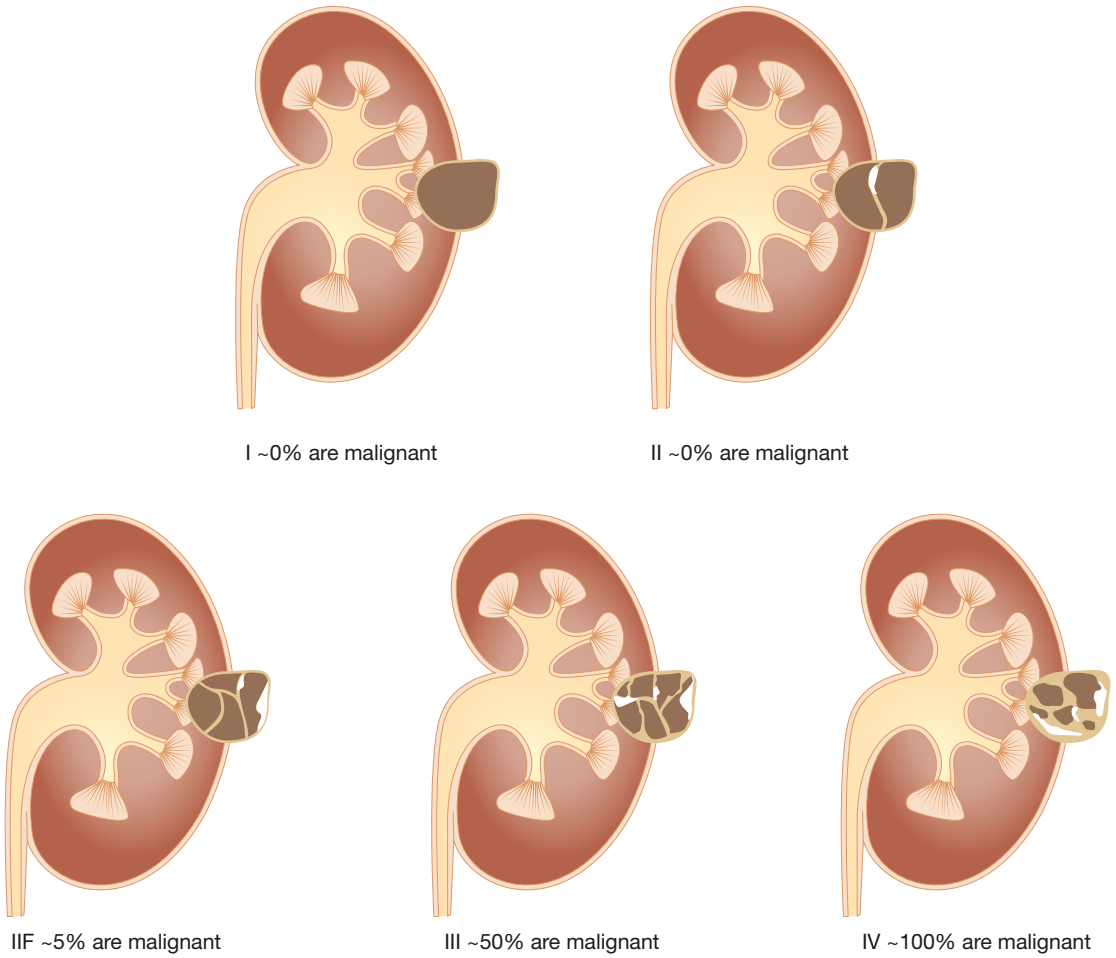

Figure 75.23 Bosniak classification of renal cysts.

Category I and II cysts do not require treatment and do not require follow-up imaging. Category IIF (F indicating need for follow-up) do require further imaging but the duration of this is uncertain. Some authors have suggested 1–2 years but others recommend longer. Category III cysts have a risk of malignancy of 30–100% and should undergo a biopsy to identify those patients requiring surgery. Category IV 'cysts' have an incidence of malignancy of 67–100% and surgical removal should be considered.

Magnetic resonance imaging (MRI)

MRI scanning has a significant role to play, either on its own or as an adjunct to other cross-sectional imaging modalities, in the staging of a number of urological cancers, but it has a central role in the investigation of men suspected of having prostate cancer. Modern MRI techniques in prostate cancer imaging apply the principles of multiparametric MRI (mpMRI), utilising anatomical imaging with standard MRI techniques (T1- and T2-weighted images) and functional imaging such as diffusion-weighted imaging (DWI) (for water molecules motion assessment) and dynamic contrast-enhanced (DCE) imaging (for tissue perfusion assessment after intravenous contrast administration) (**Figure 75.25**). The advantage of mpMRI is that multiple imaging parameters are combined to assign a degree of suspicion that a clinically significant cancer is present. A 5-point scoring system, called PI-RADS (Prostate Imaging-Reporting and Data System), is used to assign a likelihood (from 1: benign to 5: highly suspicious) that prostate cancer is present within the abnormality detected on mpMRI of the prostate.

mpMRI has a crucial role in the detection and localisation of cancer in men with a persistently elevated PSA but negative previous TRUS biopsy and in men with what is thought to be small-volume, low-risk (of progression) prostate cancer detected on TRUS biopsy who are considered for active surveillance to ensure a significant cancer has not been overlooked for biopsy. The identification of suspicious abnormalities on mpMRI allows subsequent targeted biopsy using novel technologies that utilise MRI during biopsy, and has a major impact on management. Increasingly however, MRI–TRUS fusion biopsies are being performed in a similar manner to TRUS biopsy, with MRI images imported into the specialised workstation to guide biopsy during TRUS.

Summary box 75.10

Magnetic resonance imaging (MRI)

- Is used to stage many urological cancers
- Multiparametric MRI has a significant role in the assessment of men with suspected prostate cancer
- mpMRI is increasingly used prior to prostate biopsy
- Pre-biopsy MRI permits selection of biopsy technique (TRUS v. TPTBP)
- Pre-biopsy MRI assists with targeting of biopsies

SPECT/CT and PET/CT

Single photon emission computed tomography (SPECT) and positron emission tomography (PET) are nuclear medicine imaging techniques that provide metabolic and functional information, unlike CT and MRI. They have both been combined with CT and MRI to provide detailed anatomical and metabolic information. Whereas, initially, separate machines were used to image the patient and the images were then fused, recent technological advances allow the one machine to acquire both sets of data.

Radionuclides used in PET scans are substances that are normally utilised by the particular organ/tissue of interest during metabolism, such as glucose, carbon or oxygen, attached to a radioactive substance. The most common radionuclide in clinical use is FDG (2-fluoro-2-deoxy-d-glucose).

PET/CT looks promising as a tool for the detection of distant metastases in bladder cancer. To date the technique has not been used frequently in those patients with renal cancer. In men with testis cancer, it is recommended in the follow-up of patients with seminoma with any residual mass.

Choline PET/CT using either 11C-choline or 18F-

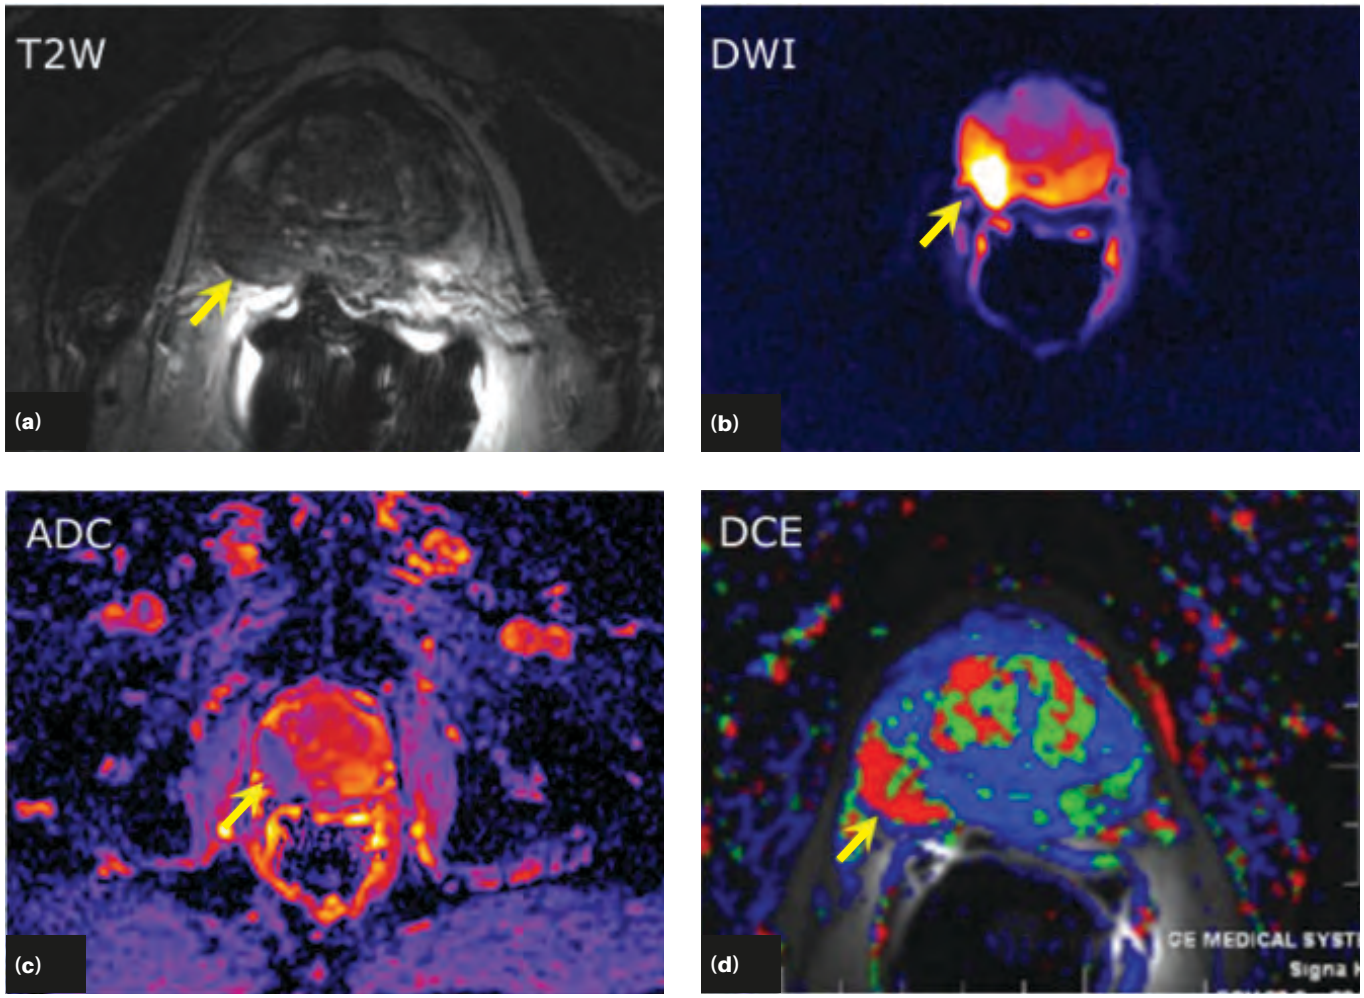

Figure 75.25 Multiparametric magnetic resonance images of a patient with prostate cancer. **(a)** T2-weighted. **(b)** Diffusion weighted (DWI). **(c)** Apparent diffusion coefficient (ADC). **(d)** Dynamic contrast enhanced (DCE). The tumour appears dark on the axial T2-weighted image (arrow); the corresponding area shows restricted diffusion on the DWI and ADC images as well as abnormal contrast enhancement on the DCE axial image (abnormal red colour coding of the tumour). (Images courtesy of Janet Cochrane Miller, Radiology Rounds, Massachusetts General Hospital.)

choline as the radiotracer have been increasingly used, especially in the assessment of metastatic disease in men with prostate cancer who have failed primary treatment and may be candidates for salvage therapy (Figure 75.26). A new radiotracer for PET/CT, 18F-fluciclovine, was approved by the Food and Drug Administration (FDA) in May 2016 for the diagnosis of suspected prostate cancer recurrence after primary therapy.

Bone scan (Figures 75.27 and 75.28)

A bone scan is most frequently used in patients with a urological malignancy when other imaging suggests there may be bone metastases present. It is also used in the routine staging of patients with high-risk prostate cancer, although there is a <5% chance of a bone scan being positive until the PSA is >40 ng/mL.

Dimercaptosuccinic acid (DMSA) renogram (Figure 75.29)

Tc-99m DMSA is a technetium radiopharmaceutical used in renal imaging to evaluate renal structure, especially in the paediatric population where it is used to detect renal scarring. DMSA is selected for evaluation of the renal cortex as it binds to proximal convoluted tubules in the renal cortex with slow renal excretion. This results in higher concentration and hence higher resolution on imaging. In addition, it allows better assessment of differential (split) renal function.

Diethylene-triamine-penta-acetate (DTPA) renogram

Tc-99m DTPA is another technetium radiopharmaceutical used in renal imaging. Previously it was used frequently in patients suspected of having a ureteropelvic junction (UPJ) obstruction but it has largely been superseded by the mercaptoacetyltriglycine (MAG3) renogram in such cases.

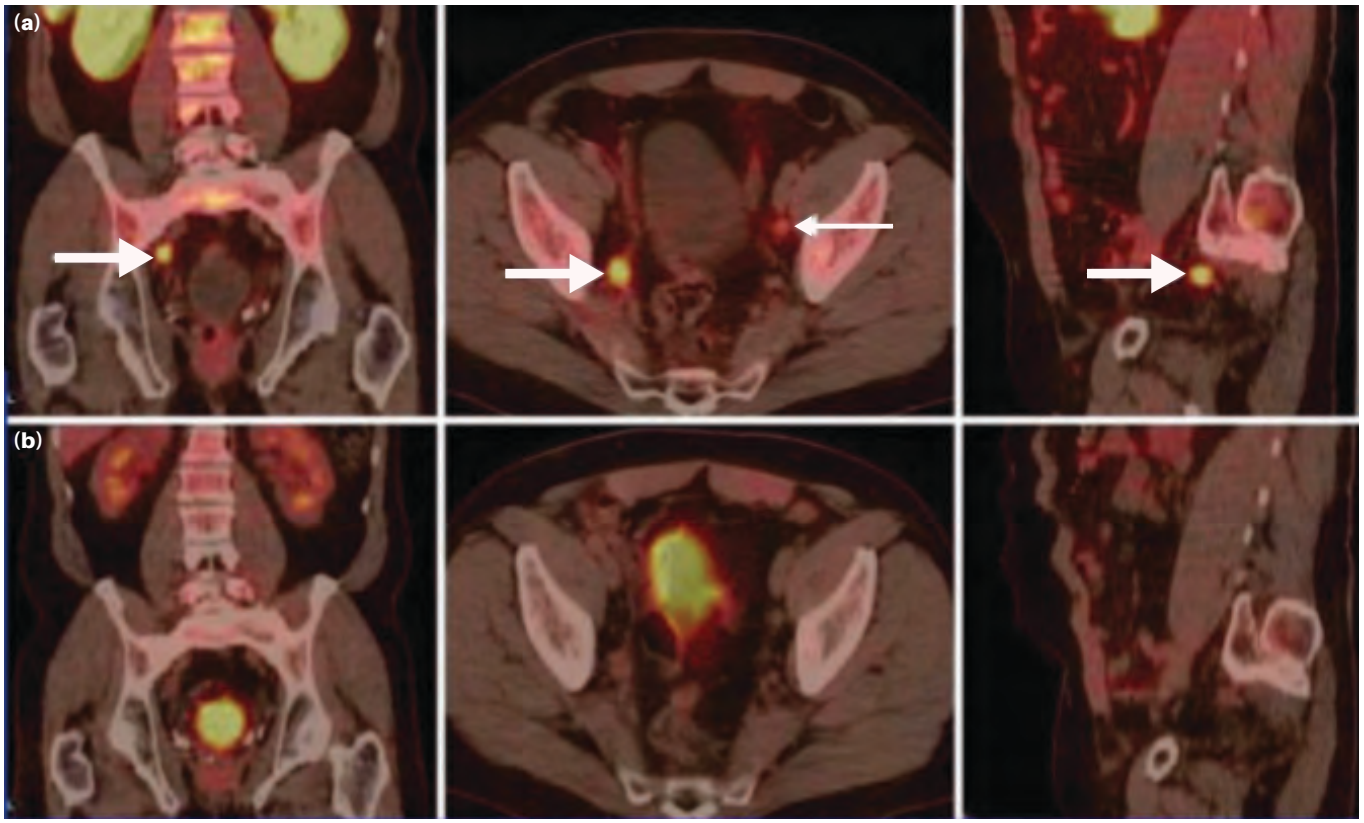

Figure 75.26 Fifty-five-year-old patient with increasing prostate-specific antigen level, 27 months after radical prostatectomy. Coronal (left), axial (middle) and sagittal (right) fused image projections of positron emission tomography/computed tomography (PET/CT) scans. **(a)** Focal 11C-choline uptake in right (large arrow) and left (thin arrow) iliac region revealed lymph node involvement. **(b)** This was not observed with 18F-FDG PET. Figure 75.28 Superscan with intense tracer uptake throughout the skeleton.

MAG3 renogram (Figures 75.30 and 75.31)

Tc-99m MAG3 is now the radiopharmaceutical of choice used in the assessment of patients with suspected upper urinary tract obstruction such as UPJO.

The shape of the renogram curve (following subtraction of background activity) is dependent on MAG3 uptake from the circulation to the kidney and secondly MAG3 elimination from the kidney into the bladder.

Classically, the normal MAG3 renogram curve has three phases (Figure 75.30):

1. The curve rises steeply upwards following intravenous tracer injection. This is indicative of the speed of tracer injection and its delivery to the kidneys (i.e. renal vascular supply).
2. A more gradual slope which represents renal handling of MAG3 (renal uptake by tubular secretion and glomerular filtration) and peaks between 2 and 5 minutes. The time taken for the curve to peak following tracer injection is referred to as Tmax. This may be delayed in patients with renovascular insufficiency, renal failure and obstruction.
3. Commences after the peak. It is associated with the emergence of tracer in the bladder and represents elimination (but also delivery) of tracer from the kidney.

After 3 minutes, both elimination and uptake are in competition, but the former subsequently dominates. It is this elimination curve that is dependent on the upper tract urodynamics. Renogram curves of a number of normal and pathological conditions are shown in Figure 75.31.

Bladder function assessment

Flow rate and US residual urine

Men with LUTS and females with recurrent UTIs or LUTS are frequently investigated with a **flow rate** and a **US residual urine** at the first clinic appointment (**Figures 75.32–75.34**). A peak flow rate (Q_{max}) in excess of 15 mL/s suggests significant bladder outlet obstruction is not present whereas a flow rate of <10 mL/s suggests BOO is present. A very low flow rate with a very protracted pattern of voiding is suggestive of a urethral stricture. Caution is required when interpreting the significance of a single high US residual volume and repeated tests often give a more representative picture of the degree of bladder emptying.

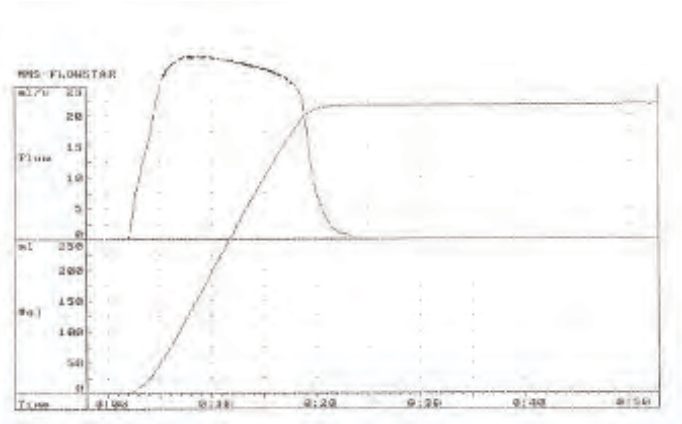

Figure 75.33 A flow study from a young healthy male patient showing a high volume, rapid void with excellent peak flow of 32 mL/s.

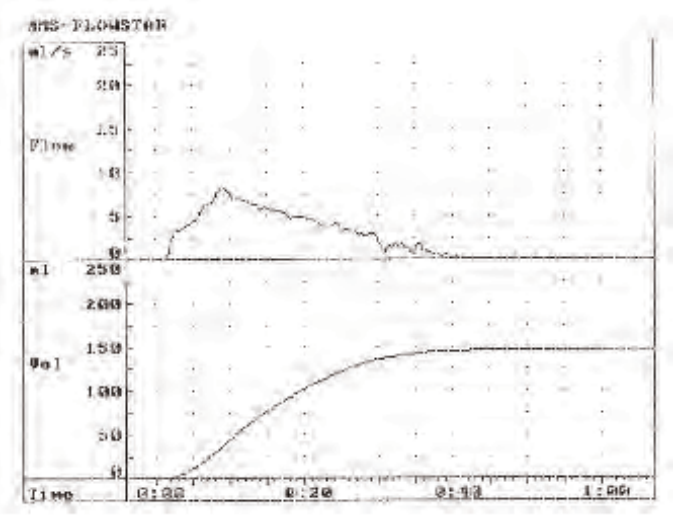

Figure 75.34 A flow study performed by a patient with bladder outlet obstruction showing a very reduced peak flow of urine (8.1 mL/s).

Urodynamics

A urodynamic evaluation provides information about bladder pressure and urine flow and as a consequence has been referred to as a pressure/flow study. A device for urodynamic assessment is shown in Figure 75.35. During urodynamics, fine catheters (or a dual-lumen catheter) are inserted through the urethra into the bladder to allow bladder filling and to record the intravesical pressure. The test is commonly performed to investigate male patients with LUTS and female patients with LUTS or incontinence. It is also commonly used in those patients with a suspected bladder neuropathy. There are 2 phases to the test; a filling phase during which fluid is instilled into the bladder at a constant rate, and a voiding phase when the patient is asked to void. Involuntary rises in the intravesical (detrusor) pressure during the filling phase with or without a desire to void are classical of an overactive bladder (Figure 75.36). High intravesical pressure during voiding with a reduced flow rate is typically seen in a man with bladder outlet obstruction (Figure 75.37). An atonic

Figure 75.35 A modern urodynamic machine.

bladder (no detrusor activity) is seen in diabetic neuropathy and in some patients following abdominoperineal excision of the rectum when damage to the pelvic nerve plexus has occurred. Detrusor-sphincter dyssynergia, when coordinated contraction of the detrusor muscle in conjunction with relaxation of the external sphincter, necessary to permit normal voiding, is lost, is often seen in neurological conditions such as multiple sclerosis (MS).

Specialised centres have facilities for ambulatory urodynamics when pressure/flow studies can be performed over several hours. A non-invasive system for urodynamics assessment, based on a small penile cuff and avoiding insertion of a catheter into the bladder, has been developed for males.

Summary box 75.11

Assessment of bladder function

- Simple tests are a flow rate and a US residual urine estimation
- Urodynamics provides a pressure/flow profile
- Urodynamics requires fine catheters to be inserted into the bladder and usually the rectum
- Urodynamics can assist with the selection of patients for surgery such as transurethral resection of the prostate (TURP) or anti-incontinence surgery
- A non-invasive technique in males using a penile cuff has a limited clinical role

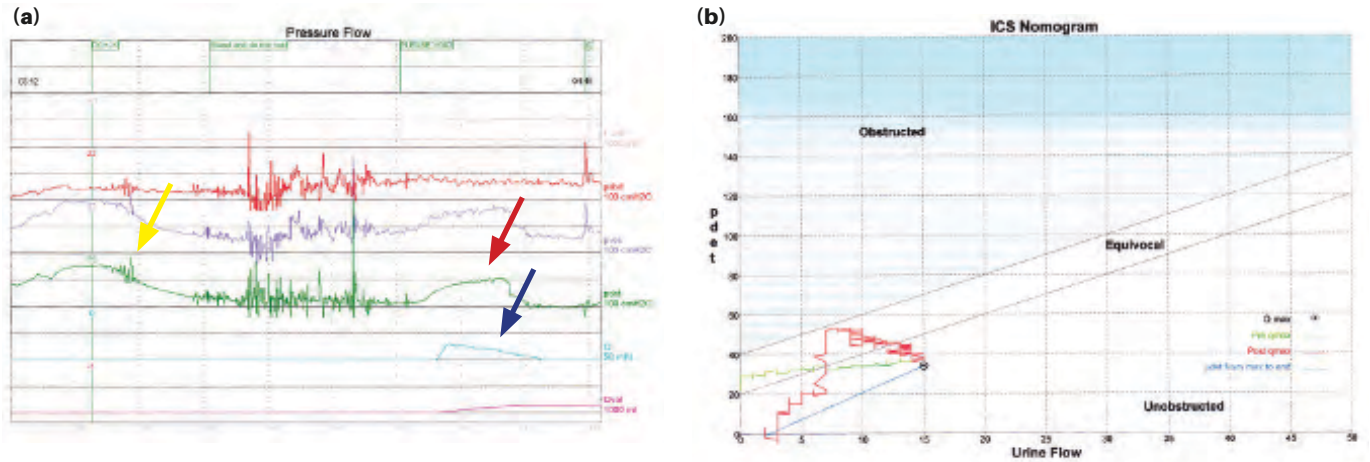

Figure 75.36 A urodynamic outcome **(a)** in a patient with an overactive bladder, demonstrating a rise in detrusor pressure during filling (yellow arrow), normal detrusor pressure during voiding (red arrow) and a good urinary flow (blue arrow). The Abrams-Griffiths nomogram **(b)** shows the patient is not obstructed.

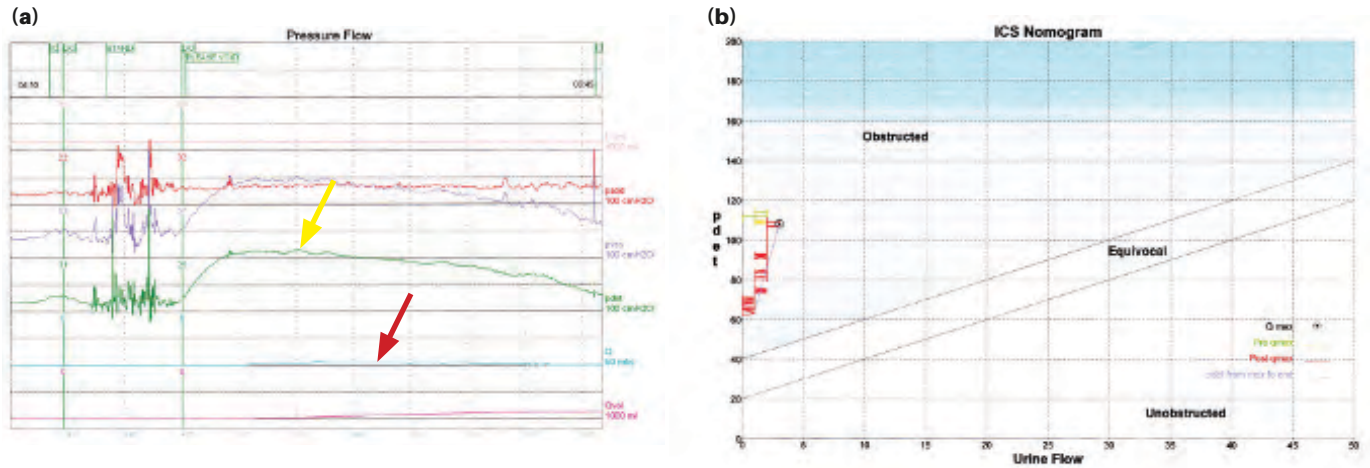

Figure 75.37 A urodynamic outcome **(a)** in a patient with bladder outlet obstruction, demonstrating a rise in detrusor pressure during voiding (yellow arrow) and a reduced urinary flow rate (red arrow). The Abrams-Griffiths nomogram **(b)** shows the patient is obstructed.

Chapter 76

Kidneys and ureters

Learning objectives

To recognise and understand:

- Important congenital abnormalities of the upper urinary tract
- Important cystic diseases of the kidney
- The management of sepsis in the upper urinary tract
- The pathophysiology of renal stone formation
- The management of urinary tract calculi
- The aetiology, presentation and surgical management of obstruction to the upper urinary tract
- The management of open and closed trauma to the kidney and ureter
- Important renal neoplasms and their presentation
- Surgery of upper urinary tract tumours

SURGICAL ANATOMY

The kidneys are surrounded by a distinct, well-defined envelope of perinephric fat. Nephrectomy is facilitated by staying at the true margin of the perinephric fat envelope. The perinephric fat is 'whiter' than colonic mesenteric fat as observed during a laparoscopic nephrectomy. At the renal hilum, the first structure encountered (i.e. the uppermost) is the renal vein, then the renal artery and lastly the renal pelvis. The right renal vein is much shorter than the left renal vein. The left renal vein is occasionally retroaortic. The right adrenal vein and right gonadal vein drain into the inferior vena cava (IVC) whereas the left adrenal and gonadal veins drain into the left renal vein. Gonadal veins can easily be confused for ureters – these structures are distinguished by pinching the ureter which contracts (vermiculation).

EMBRYOLOGY (FIGURE 76.1)

The urinary tract is formed from the cloaca and intermediate mesoderm in parallel with the early differentiation of the metanephric blastema which will ultimately form the kidney.

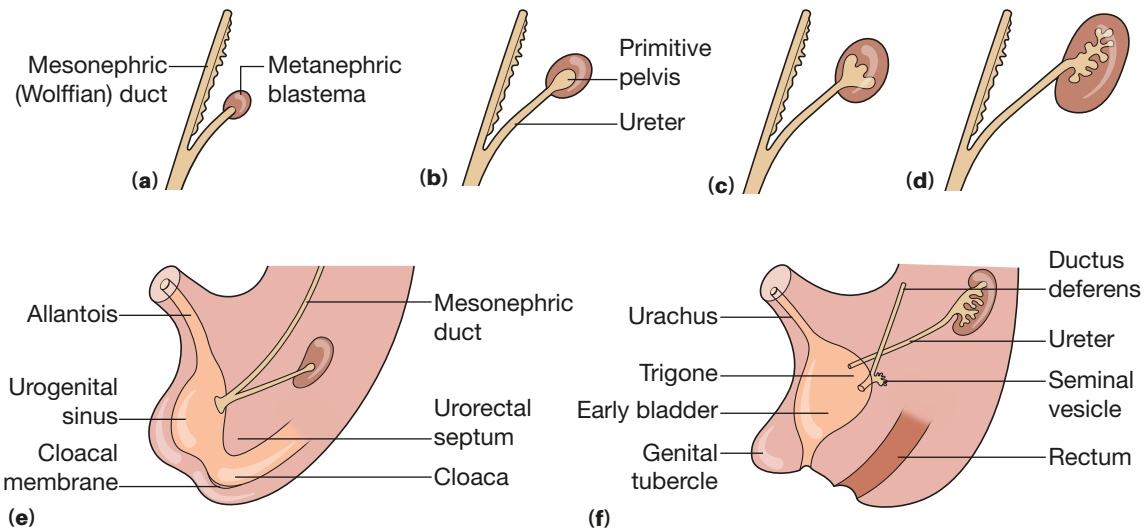

Figure 76.1 Development of the urinary tract. **(a–d)** The growth and development of the primitive ureter and pelvis, with elongation and branching of the ureteral tip and the formation of the calyces. The kidney ascends continuously as the fetus grows. **(e)** During weeks 5–6 of gestation, the cloaca grows and develops. **(f)** During weeks 8–9, the urogenital sinus grows and develops into the bladder and outflow tract.

In the 6-week-old embryo, the mesonephric (Wolffian) duct and the paramesonephric (Müllerian) ducts run in parallel. By week 7, in the male, the Müllerian duct starts to regress, and the Wolffian duct will eventually develop into the epididymis and the caudal part of the vas deferens. In the female, the Müllerian ducts fuse to form the uterovaginal cord which will develop into the vagina. As the urogenital tract develops, there is simultaneous development of the fetal kidney. The ureteric bud arises from the distal end of the Wolffian duct as an unbranched diverticulum and invades the adjacent metanephric mesenchyme, initiating the branching collecting system within the primitive kidney. If the ureteric bud fails to develop, the kidney will not form. Renal development is controlled by the function of a number of transcription factors including PAX-2 and WT1.

Summary box 76.1

Embryology

- Kidney develops from the metanephros
- Ureter sprouts from the mesonephric duct
- Mesonephric duct regresses in females
- Paramesonephric duct regresses in males

CONGENITAL ABNORMALITIES

Unilateral renal agenesis

Complete absence of one kidney occurs in 1 in 500–1000 births and results from failure of connection between the metanephric blastema and the ipsilateral ureteric bud. This condition is an autosomal dominant trait with incomplete penetrance. Typically, there is an absent ipsilateral ureter and the ipsilateral hemi-trigone is missing in the bladder. The remaining kidney is usually hypertrophic but may also be dysplastic. In addition, the ipsilateral testis and vas deferens are usually absent and in some patients the adrenal gland on the affected side is missing as well. Females with the condition may have an absent ovary or Fallopian tube. Renal agenesis is different from renal aplasia where there is a small dysplastic kidney.

Bilateral renal agenesis

Bilateral renal agenesis is incompatible with life. It is associated with pulmonary hypoplasia and Potter's facies due to oligohydramnios.

Multicystic disease

This results from congenital severe renal dysplasia in which the kidney is composed of a mass of various-sized cysts in a loose stroma. If bilateral it is incompatible with survival. It occurs in approximately 1 in 4500 births. It is mostly diagnosed on a prenatal ultrasound scan (USS) and is apparent as a palpable mass in the newborn. Previously, this was surgically excised but nowadays is treated conservatively as there is a tendency for the cystic kidney to regress. Atresia of the ipsilateral ureter is usual and contralateral pelvi-ureteric junction (PUJ) obstruction is common.

Ectopic kidney/crossed renal ectopia

The fetal kidney arises in the pelvis and ascends to attain its normal position. If this process fails to any degree, the kidney ends up being in a lower-than-normal position. During their ascent, the renal pelvis also rotates from facing anteriorly to facing more medially. The most common anomaly is for the renal pelvis to face anteriorly and the more ectopic the kidney, the more severe is the rotational abnormality. In the majority of cases of renal ectopia, both kidneys are fused. In crossed renal ectopia **(Figure 76.2)**, both kidneys are fused and are on the same side – one of the ureters, therefore, crosses the midline to enter the bladder on the correct side of the trigone.

Horseshoe kidney

In a horseshoe kidney **(Figures 76.3 and 76.4)**, the two renal units are low lying and the lower poles fuse to form an isthmus. Further ascent of the fused kidneys is prevented by the inferior mesenteric artery. This condition is detected in 1 in 1000 autopsies and has a male preponderance (2:1). Horseshoe kidneys have an unpredictable vascular supply from nearby major vessels. Horseshoe kidneys are prone to reflux, obstruction and stone formation.

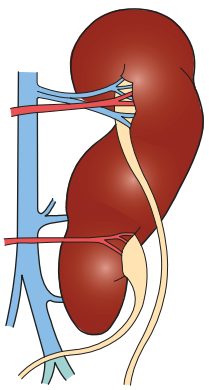

Figure 76.2 Crossed renal ectopia.

Kaspar Friedrich Wolff, 1733–1794, Professor of Anatomy and Physiology, St Petersburg, Russia, described the mesonephric duct and body in 1759.
Johannes Peter Müller, 1801–1858, German physiologist, described these ducts in 1830.
Gabriele Falloppio, 1523–1562, Italian anatomist and physician.
Edith Louise Potter, 1901–1993, American physician, described Potter's facies in 1946.

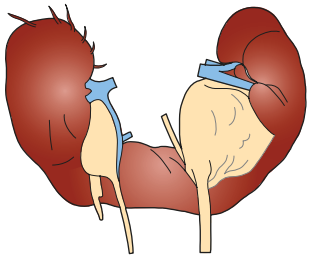

Figure 76.3 Horseshoe kidney. Note the ureters passing in front of the fused lower poles.

Figure 76.4 Urogram of a horseshoe kidney. Only rarely are all the calyces directed towards the spinal column.

Summary box 76.2

Horseshoe kidneys

- Are prone to pelvi-ureteric junction obstruction, infection and stones
- Can have anomalous vasculature which needs to be considered when planning surgery

Duplex renal pelvis and ureter (Figures 76.5 and 76.6)

Duplication of the ureter and renal pelvis is a common anomaly, with an incidence of approximately 1 in 150 births. Unilateral duplication is six times more common than bilateral and the left side is more commonly involved. The condition is more common in girls and the detection of duplication in a patient increases the risk in a sibling to 1 in 8.

Incomplete duplex ureters with a Y ureter arise if the ureteric bud bifurcates after its initial development from the mesonephric duct. Complete ureteric duplication occurs

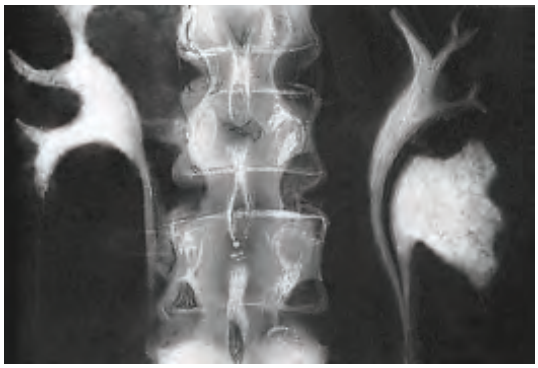

Figure 76.5 Urogram showing a left kidney with double pelvis.

Figure 76.6 Retrograde ureterogram showing a double ureter on the left.

when there are 2 separate ureteric buds – one in the normal position and the other in a low position. The normal bud ends in the correct site in the trigone of the bladder and is non-refluxing. The lower bud, which will drain the lower pole of the kidney, ends in the bladder with a more laterally placed ureteric orifice with a short submucosal tunnel. The lower pole ureter is, therefore, often associated with vesico-ureteric reflux (VUR).

If there are 2 ureteric buds and the second bud arises from a high position, the upper ureter is incorporated into the bladder, ending more distally and medial to the normal one. Thus, the upper pole ureter ends ectopically and due to obstruction or dysplasia is often associated with severe scarring of the upper pole moiety.

When detected in adults the condition is usually asymptomatic but children with duplex ureters often have VUR. Spontaneous resolution of VUR is less common in patients with duplex ureters compared with patients with single ureters.

Summary box 76.3

Duplex ureters

- Incidence 1 in 150
- Unilateral more common than bilateral
- More common in girls
- Can be complete or incomplete
- In children are associated with vesico-ureteric reflux

Summary box 76.4

Ectopic ureters

- Usually associated with duplex ureters
- More common in females
- Drain the upper pole of the kidney
- May cause incontinence in females
- Never cause incontinence in males

Ectopic ureters

Ectopic ureters are almost always associated with ureteric duplication and 10% are bilateral. There is a female:male ratio of 7:1. As indicated above, the ectopic ureter drains the upper pole of the kidney and inserts into the bladder more distally than normal and towards the bladder neck. In females, the ectopic ureter opens either into the urethra below the sphincter (Figure 76.7) or into the vagina. A female who voids normally but who has dribbled urine for as long as she can remember is typical of the patient with an ectopic ureter. In the male, the opening of the ureter is above the external urethral sphincter so the patient is continent. An ectopic ureteric orifice in a male at the apex of the trigone, in the posterior urethra, in a seminal vesicle or in an ejaculatory duct is likely to be functionally abnormal and infection is common.

A severely diseased or atrophic moiety is effectively treated by partial nephrectomy. A refluxing ureter may need re-implanting. An ectopic ureter in a female often drains hydronephrotic and chronically infected renal tissue and is best excised. Rarely, the incontinence can be cured and renal function preserved by re-implanting the ureter into the bladder.

Ureterocoele

A ureterocoele is a cystic enlargement of the intramural ureter, probably due to atresia of the ureteric orifice. Ureterocoeles affect females more often than males (4:1) and 10% are bilateral. The condition occurs almost exclusively in Caucasians. Similar to ectopic ureters, ureters with ureterocoeles frequently drain the upper pole and are often associated with dysplastic or non-functional renal tissue. In childhood, they usually present with infection. When large, they can obstruct the bladder neck or even the contralateral ureteric orifice. In adults, ureterocoeles typically present with stones in the lower ureter. The classic sign of a ureterocoele on excretion urography was of a 'cobra head' (Figure 76.8) but intravenous urography (IVU) is relatively infrequently undertaken nowadays. On cystoscopy, a bulging, translucent swelling involving the ureteric orifice is typical which fills with and empties of urine with ureteric peristalsis (Figure 76.9). The treatment of simple ureterocoeles is surgical excision with re-implantation of the ureter. Endoscopic incision is a relatively straightforward method of releasing a stone stuck in a ureterocoele but may result in subsequent ureteric reflux. Advanced unilateral cases with hydronephrosis or pyonephrosis may mean that nephrectomy is indicated.

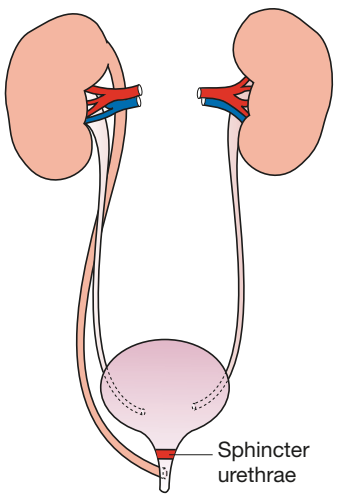

Figure 76.7 In women, one ureteric orifice may open below the sphincter, causing intractable incontinence of urine.

Figure 76.8 Cobra head appearance of a ureterocoele.

Figure 76.9 Ureterocoele on cystoscopy.

Congenital megaureter

In this uncommon condition, there is ureteric dilatation with or without obstruction. It may be bilateral and associated with other congenital abnormalities. The ureteric orifice looks normal on cystoscopy and a ureteric catheter passes easily. Most cases of megaureter with obstruction present in childhood with severe infections. Renal stones can easily form in the dilated systems. The exclusion of obstruction is often established only by an antegrade pressure-flow study (Whitaker test) in which a nephrostomy tube is placed in the renal pelvis and fluids infused at a rate of 10 mL/min.

Retrocaval ureter

Rarely, the right ureter passes behind the inferior vena cava rather than lying to its right side. This can lead to obstruction and the need to surgically move the ureter to lie anterior to the IVC.

Autosomal dominant polycystic kidney disease (ADPKD)

This is a multisystem disorder characterised by multiple bilateral renal cysts associated with cysts in other organs such as the liver, pancreas and arachnoid membranes. It is a genetic condition caused by mutation in one of two different genes (*PKD1* and *PKD2*) and is expressed in an autosomal dominant pattern, with variable expression. The ADPKD proteins, now known as polycystin-1 and polycystin-2, play a critical role in the normal function of the primary cilium that is essential to maintaining the differentiated phenotype of tubular epithelium. ADPKD occurs worldwide and in all races, with a prevalence of genetically affected individuals at birth of 1:400 to 1:1000. The disease does not usually manifest before the age of 30 years and in some patients it is never diagnosed.

Renal USS is used for pre-symptomatic testing of at-risk individuals. At least 3 (unilateral or bilateral) renal cysts and 2 cysts in each kidney are sufficient for a diagnosis of at-risk individuals aged 15–39 years.

The differential diagnosis of ADPKD includes autosomal recessive PKD, tuberous sclerosis complex, von Hippel–Lindau disease, renal cysts and diabetes syndrome (RCAD), orofaciodigital syndrome type 1, medullary sponge kidney and simple renal cysts.

Clinical manifestations of ADPKD are divided into renal and extrarenal.

Renal manifestations

RENAL SIZE

Renal size increases with age and renal enlargement eventually occurs in 100% of patients with ADPKD, resulting in some patients in a flank or abdominal mass. Cysts contain clear fluid, thick brown material or coagulated blood. Less florid examples are encountered unexpectedly at laparotomy or on abdominal imaging.

PAIN

Pain is commonly a dull loin ache. Haemorrhage into a cyst causes a more acute severe pain, as does passing a calculus from the diseased kidney.

HAEMATURIA AND CYST HAEMORRHAGE

Visible haematuria occurs in up to 40% of patients with ADPKD over the course of the disease. Cyst haemorrhage is a frequent complication with or without haematuria, depending on whether the cyst communicates with the collecting system.

URINARY TRACT INFECTION AND CYST INFECTION

Urinary tract infection is common in ADPKD but its incidence may have been overestimated as sterile pyuria is common in these patients.

NEPHROLITHIASIS

Renal stones occur in approximately 20% of patients with ADPKD. Most stones are composed of uric acid or calcium oxalate or both. Uric acid stones are more common in ADPKD than in stone formers without ADPKD. Stones can be difficult to diagnose on imaging in ADPKD on account of cyst wall and parenchymal calcification.

HYPERTENSION

Hypertension is the most common manifestation of ADPKD and a major contributor to renal disease progression and cardiovascular morbidity and mortality. After the age of 20 years, most patients are hypertensive.

Robert H Whitaker, former urologist, now lecturer at the University of Cambridge, Cambridge, UK.
Eugen von Hippel, 1867–1939, Professor of Ophthalmology in Göttingen, Germany, first described angiomas in the eye in 1904.
Arvid Vilhelm Lindau, 1892–1958, Swedish pathologist, described angiomas of the cerebellum and spine in 1927.

END-STAGE RENAL DISEASE

In most patients, renal function is maintained within normal limits until the 4th to 6th decade of life. Up to 80% of patients are alive with preserved renal function aged 50 years. Men tend to progress to renal failure more rapidly and require renal replacement therapy at a younger age than women. In recent years, a greater understanding of the pathophysiology of ADPKD has led to clinical trials of novel agents such as vasopressin antagonists, somatostatin analogues and mTOR inhibitors to prevent cystogenesis, cyst expansion and declining renal function.

Extrarenal manifestations

POLYCYSTIC LIVER DISEASE

Hepatic cysts are rare in children with ADPKD but thereafter their frequency increases with age. Cysts are usually asymptomatic but symptoms may occur due to a mass effect or due to cyst complications.

INTRACRANIAL ANEURYSMS

Intracranial aneurysms occur in approximately 10% of patients with ADPKD.

VALVULAR HEART DISEASE

Mitral valve prolapse is the most common valvular abnormality and has been demonstrated in up to 25% of patients with ADPKD by echocardiography.

Summary box 76.5

Autosomal dominant polycystic kidney disease

- Autosomal dominant condition
- Cysts may also occur in liver, pancreas and arachnoid membrane
- Usually does not manifest before 30 years of age
- Clinical manifestations are divided into renal and extrarenal
- Hypertension is the most common clinical manifestation
- Renal function declines after the 4th to 6th decade of life
- Men tend to progress to renal failure more rapidly than women

INFECTIONS

Urinary tract infections (UTIs) more commonly involve the lower urinary tract and are significantly more common in females. Infection at any level in the urinary tract is classified as uncomplicated or complicated. A complicated UTI is defined as an episode of infection with an increased risk of serious complications or treatment failure. Complicated UTIs may require different treatment type and duration compared with uncomplicated UTIs.

Acute pyelonephritis

Infection of the kidney (pyelonephritis) can arise in two ways:

- **Haematogenous infection** from a primary site in the tonsils, carious teeth or from cutaneous infections, particularly boils or a carbuncle. Renal tuberculosis occurs by bloodborne spread from lymph nodes in the neck, chest or abdomen.
- **Ascending infection** in the urinary tract is the most common route, and is most likely to occur when there is vesico-ureteric reflux. Urinary stasis and the presence of calculi are common contributory factors.

Acute pyelonephritis is more common in females, especially during childhood, at puberty, after intercourse and during pregnancy. Acute pyelonephritis is suggested by fever (temperature >38°C), rigors, flank pain, nausea and vomiting, and costovertebral angle tenderness. Cystitis symptoms may or may not be present. Symptoms may vary from a mild illness to a severe illness with septic shock, renal failure and a threat to life. Pyuria is almost always present. Both urine and blood are sent for culture. Imaging of the kidney is necessary in the hospitalised patient to rule out pyonephrosis, perirenal abscess and obstruction of the collecting system by renal calculi. A renal USS is often the imaging modality employed initially when the diagnosis is suspected. Alternatively, a contrast-enhanced computed tomography (CT) scan can be used and typically shows decreased opacification of the affected parenchyma, typically in patchy, wedge-shaped or linear distribution.

Escherichia coli and other gram-negative organisms are commonly responsible. In *E. coli* and streptococcal infections, the urine is acidic. *Proteus* and staphylococci split urea to form ammonia, which makes the urine alkaline and promotes the formation of calculi.

Summary box 76.6

Pyelonephritis

- More common in women
- Can be associated with septicaemia
- Associated with pyuria
- Should be treated initially with broad-spectrum antibiotics
- Is potentially fatal, especially if associated with obstruction of the urinary tract

Pyelonephritis complicating pregnancy

Pyelonephritis most often presents between 20 and 28 weeks of gestation with malaise, fever, loin pain and rigors. Not all women will have had lower urinary tract symptoms and pyelonephritis can also manifest in pregnancy as acute abdominal pain or may be detected only after presentation with premature labour. Pyelonephritis is more common in pregnant women with an underlying urological abnormality or diabetes and more often affects the right kidney, probably because the ureter is often more dilated on that side. Pyonephrosis and perirenal abscess are rare complications but should be suspected when treatment fails. Under such circumstances, a renal USS is indicated.

Hans Christian Gram, 1853–1938, Danish bacteriologist, developed Gram staining in 1884.

Urinary infection in childhood/ vesico-ureteric reflux

Symptomatic UTI occurs in 3–5% of girls and 1–2% of boys. In the age-group <3 months, it is more common in boys and in the age-group >1 year, it is more common in girls. The commonest underlying cause is urinary stasis due to VUR, detrusor-sphincter dyssynergia, poor bladder emptying habit or constipation. Other causes of stasis include stones, outlet obstruction or secondary to a neurological disorder such as spina bifida. It is recommended that all children be investigated after their first confirmed UTI.

The most important outcome of a UTI in a child is renal scarring secondary to renal parenchymal inflammation. Scarring can be detected (on IVU) in up to 20% of children who have had a UTI and can be detected in up to 37% of children if assessed with a dimercaptosuccinic acid (DMSA) scan. The maximal renal inflammatory response to infection is seen at 3–5 days, hence the need for prompt antibiotic treatment. Between 10 and 20% of children with renal scarring will develop hypertension. Chronic pyelonephritis (CPN) with renal failure is the commonest reason for renal transplant in children <19 years in the UK. VUR occurs in 1–2% of the asymptomatic paediatric population but in 30–40% of children with a UTI and is apparent in 90% of children with renal scarring on an IVU.

VUR is graded as follows:

- Grade I: reflux into the ureter.
- Grade II: reflux into the ureter and renal pelvis.
- Grade III: reflux is associated with mild/moderate dilatation on an IVU.
- Grade IV: additional blunting of fornices.
- Grade V: absent papillary impressions.

VUR is confirmed by a micturating cystogram and a DMSA scan is used to assess the degree of renal scarring. Grades I–III generally resolve spontaneously. Surgery (ureteric re-implantation, periureteric injections of Teflon or collagen) should be considered if episodes of acute PN recur despite antibiotic therapy or if severe reflux is accompanied by a surgically correctable malformation.

Summary box 76.7

Urinary tract infections (UTIs) in children

- In children > 1 year, more common in girls
- Principal cause is urinary stasis
- All children should be investigated after a single UTI
- VUR occurs in 30–40% of children with a UTI
- Renal scarring is a possible long-term consequence

Renal cortical abscess (carbuncle), corticomedullary abscess and perirenal abscess

A **renal cortical abscess** (carbuncle) is usually caused by *Staphylococcus aureus*, which reaches the kidney by haematogenous spread. A renal carbuncle is most commonly seen in diabetics, intravenous drug abusers, those debilitated by chronic disease and patients with acquired immunodeficiency. A **renal corticomedullary abscess**, in contrast, usually results from an ascending UTI in association with an underlying urinary tract abnormality, such as obstructive uropathy or VUR, and is usually caused by common uropathogens such as *E. coli* and other gram-negative bacilli. Such abscesses may extend deeply into the renal parenchyma, perforate the renal capsule and form a perirenal abscess. Treatment with antibiotics without drainage may be effective if the abscess is small and if the underlying urinary tract abnormality can be corrected. However in many cases, percutaneous drainage of pus is required to stabilise the patient. Two percutaneous drains may be needed, one to drain the perirenal collection and a second to decompress the collecting system of the kidney in the presence of obstruction. Formal open drainage of the abscess may be necessary if the pus is too thick to be drained by the percutaneous route.

Patients usually present with pyrexia, back or abdominal pain and costovertebral tenderness but they may have no urinary symptoms or findings if the abscess does not communicate with the collecting system, as often occurs with a cortical abscess. The clinical presentation may be insidious and non-specific. CT scan is the investigation of choice to establish the diagnosis and location of a renal or perirenal abscess. Empiric antibiotic therapy should be broad and cover *S. aureus* and other uropathogens causing complicated UTI.

Emphysematous pyelonephritis

Emphysematous pyelonephritis is a fulminant, necrotising, life-threatening variant of acute pyelonephritis caused by gas-forming organisms, including *E. coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa* and *Proteus mirabilis*. Up to 90% of cases occur in diabetic patients and urinary tract obstruction may be present. Symptoms are suggestive of pyelonephritis and there may be a loin mass. Gas can be detected on a plain film, on USS or more probably on a CT scan. Intravenous broad-spectrum antibiotics and percutaneous catheter drainage with relief of obstruction may be adequate for the less severely ill patient, but nephrectomy may be needed in the most severely ill patients with this condition.

Xanthogranulomatous pyelonephritis (XGP)

This is a poorly understood, uncommon but severe chronic destructive granulomatous inflammation of the renal

Theodor Escherich, 1857–1911, Professor of Paediatrics, Vienna, Austria, discovered the bacterium coli commune in 1886.
Theodor Albrecht Edwin Klebs, 1834–1913, German-Swiss Professor of Pathology.

parenchyma associated with obstruction and infection of the urinary tract. Patients with XGP are typically middle-aged women and have chronic symptoms such as flank pain, pyrexia and malaise. Flank tenderness, a palpable mass, and irritative voiding symptoms are common. The urine culture is usually positive for *E. coli*, other gram-negative bacilli or *S. aureus*. CT generally shows an enlarged, non-functioning kidney, often the presence of calculi and low-density masses (xanthomatous tissue) and, in some cases, involvement of adjacent structures. It can sometimes be difficult to distinguish XGP from neoplastic disease. Nephrectomy is usually the definitive treatment for the condition but is made more technically challenging the more the kidney is adherent to adjacent structures.

Tuberculosis (TB) of the urinary tract

Genitourinary tuberculosis (GUTB) accounts for 14% of non-pulmonary cases of TB. It is caused by dissemination of the organism through the bloodstream and is thus always secondary TB. There is either reinfection or reactivation of old TB.

Blood-borne organisms are deposited close to the glomeruli causing an inflammatory reaction. Macrophages react and granulomas are formed. If bacterial multiplication is checked, fibrous tissue is formed but if it is unchecked, tubercles result with later caseous necrosis. The healing process produces fibrous tissue and then calcium deposition follows. The lesions will eventually slough causing tuberculous bacilluria. The disease spreads through the collecting system and once a calyx is stenosed it is rare for the communication to be restored. Hypertension is rarely seen except when there is extensive renal destruction.

Involvement of the ureter is an extension of renal TB commonly seen at the vesico-ureteric junction.

Involvement of the bladder is again secondary to renal disease. It is seen around the ureteric orifice as inflammation, then bullous granulations and later as ulcers. It then progresses to the muscle which is replaced by fibrous tissue. Tubercles are infrequent.

Involvement of the testis is usually secondary to epididymitis. Spread to the epididymis is usually blood-borne.

The diagnosis is confirmed on a tuberculin test, or at least 3 consecutive early-morning specimens of urine are examined for acid-fast bacilli with a Ziehl–Neelsen stain and subsequently cultured.

CT is the most sensitive modality for visualising renal calcifications and CT urography is more sensitive at identifying all manifestations of renal tuberculosis:

- **Early:**
  - papillary necrosis (single or multiple) resulting in uneven caliectasis.
- **Progressive:**
  - multifocal strictures can affect any part of the collecting system;
  - generalised or focal hydronephrosis;
  - mural thickening and enhancement;
  - poorly enhancing renal parenchyma, either due to direct involvement or due to hydronephrosis.
- **End-stage:**
  - progressive hydronephrosis results in very thin parenchyma, mimicking multiple thin-walled cysts;
  - amorphous dystrophic calcification eventually involves the entire kidney (known as putty kidney).

Treatment involves short-course therapy as fewer organisms are involved compared with pulmonary TB and drugs tend to concentrate in the urine. Drugs such as pyrazinamide, isoniazid and rifampicin are used. Surgery for GUTB is increasing because although chemotherapy can successfully eradicate bacteria, the complications of infection remain. Surgery entails excision of dead tissue, e.g. partial nephrectomy or nephrectomy, and reconstructive surgery, e.g. for ureteric strictures, mainly distal ureteric, and surgery to the bladder such as augmentation cystoplasty.

Summary box 76.8

Genitourinary tuberculosis (TB)

- Is always either re-infection or reactivation of old TB
- Is a cause of sterile pyuria
- Spreads from the kidney to involve the distal ureters and bladder around the ureteric orifices
- Treatment involves short-course therapy
- Surgery is increasing for this condition

STONES

Aetiology

There are very many causes for urinary tract stone disease which can be classified into the following groups:

- idiopathic calcium urolithiasis;
- hypercalcaemic disorders;
- renal tubular syndromes;
- uric acid lithiasis;
- enzyme disorders;
- secondary urolithiasis;
- other factors.

Idiopathic calcium urolithiasis

In this condition, there is unexplained hypercalciuria but a normal serum calcium distinguishes this condition from primary hyperparathyroidism. It is classified as renal (more common in children) or absorptive (more common in adults). This is present in approximately 70% of patients with urinary tract stones. It often coexists with minimal hyperoxaluria, hyperuricosuria, inhibitor deficiency and incomplete renal tubular acidosis.

Franz Ziehl, 1857–1926, German bacteriologist and professor in Lübeck, Germany.
Friedrich Carl Adolf Neelsen, 1854–1894, German pathologist and professor at the Institute of Pathology, University of Rostock, Germany.

Hypercalcaemic disorders

PRIMARY HYPERPARATHYROIDISM

A parathyroid adenoma or chief cell hyperplasia results in overproduction of parathormone leading to increased synthesis of 1,25-dihydroxycholecalciferol which increases intestinal calcium absorption, renal tubular reabsorption and bone resorption. This is found in <5% of patients with radio-opaque stones. In the past, urologists sometimes performed the parathyroid surgery for their patients with renal stones but this is rarely the case nowadays.

PROLONGED IMMOBILISATION

With this, hypercalcaemia and hypercalciuria result from bone resorption.

MILK-ALKALI SYNDROME

The ingestion of large quantities of calcium, vitamin D and alkali may result in hypercalcaemia, alkalosis and possible renal impairment. The alkalosis compromises renal excretion of calcium, promoting hypercalcaemic-induced soft-tissue calcification (nephrocalcinosis and nephrolithiasis).

SARCOIDOSIS

The non-caseating granulomata produce 1,25-dihydroxycholecalciferol.

OTHER CAUSES

These include disseminated neoplastic disease, Cushing's disease and hyperthyroidism.

Renal tubular syndromes

RENAL TUBULAR ACIDOSIS (RTA)

There are 3 types of RTA but only type I is associated with stone formation, which is due to hypercalciuria and low urinary citrate excretion. Stones are composed of mainly pure calcium phosphate and nephrocalcinosis can occur.

CYSTINURIA

This results from an inherited defect (autosomal recessive) of amino acid transport in renal tubules and the gastrointestinal tract involving cystine, ornithine, lysine and arginine (COAL or COLA). Cystine stones are often multiple, are very hard and are radio-opaque. Family members should be screened with a sodium cyanide–nitroprusside test.

Uric acid lithiasis

Uric acid stones account for approximately 5–10% of urinary tract stones. Patients with uric acid stones either excrete excessive amounts of uric acid or have excessively acid urine and uric acid remains undissociated and insoluble at pH <5.5. Uric acid is an end-product of purine metabolism. Dietary purine and protein excesses may increase urinary uric acid excretion. Extensive cellular turnover in myeloproliferative diseases or in those receiving chemotherapy may result in increased uric acid production. Uric acid stones can also occur in patients with normal serum uric acid levels (idiopathic uric acid lithiasis). Low urine volume may contribute to uric acid stone disease, such as in patients with inflammatory bowel disease and ileostomies. Uric acid stones are hard, smooth, often multiple and are multifaceted. Pure uric acid stones are radiolucent but most uric acid stones contain some calcium and are consequently faintly radio-opaque.

Enzyme disorders

PRIMARY HYPEROXALURIA

This is an autosomal recessive disorder of glyoxalate metabolism. With type I there is a deficiency of alanine:glyoxalate aminotransferase, and with type II a deficiency of D-glycerate dehydrogenase. These enzyme deficiencies lead to an increased production of endogenous oxalate which results in nephrocalcinosis and nephrolithiasis. This condition often presents in childhood.

XANTHINURIA

This is a rare inherited deficiency of xanthine oxidase. Stone formation in these patients can be precipitated by allopurinol, a xanthine oxidase inhibitor.

2, 8-DIHYDROADENINURIA

This is an inherited deficiency of adenine phosphoribosyl transferase.

Secondary urolithiasis

SECONDARY HYPEROXALURIA

Increased oxalate absorption may occur after small bowel resection, or in patients with inflammatory bowel disease or chronic pancreatitis or who have a jejunoileal bypass. This results either from excess fat in the gut binding calcium, hence reducing the calcium available to bind oxalate, or exposure of colonic mucosa to bile salts with detergent properties increases its permeability to charged ions, including oxalate.

DIETARY EXCESS

Rhubarb, spinach, tea, cocoa, chocolate and pepper commonly increase urinary oxalate.

INFECTION

Urease-producing organisms, e.g. *Proteus*, *Pseudomonas* and *Staphylococcus*, break down urea to produce ammonia and CO_2. The urine becomes alkaline which promotes formation of struvite calculi (magnesium ammonium phosphate) which can grow to form a staghorn calculus. *E. coli* never causes struvite stones.

OBSTRUCTION AND STASIS

Delayed crystal washout leads to aggregation and stone formation.

MEDULLARY SPONGE KIDNEY

Up to 20% of patients with calcium stones may have this condition.

Harvey Williams Cushing, 1869–1939, American neurosurgeon, described Cushing's disease in 1912.

URINARY DIVERSION

These patients develop stones due to a combination of infection, acidosis and sometimes stasis.

DRUGS

Several drugs, commonly used, can increase the risk of stone formation. Acetazolamide stimulates renal tubular acidosis. Allopurinol may precipitate xanthine stones. Thiazide diuretics can result in uric acid stone formation.

Other factors

Other factors include:

- geography;
- climatic and seasonal factors;
- water intake;
- diet;
- occupation: especially sedentary jobs in hot environments.

Clinical features

Patients with acute ureteric colic pain represent one of the 3 common emergency admissions seen on urology wards (the other 2 being acute urinary retention and haematuria). Approximately 50% of patients present between the ages of 30 and 50 years. There is a slight male preponderance. Patients describe ureteric colic-type pain but may, in addition, describe renal pain (see Chapter 75 for the distinction between these two types of pain). Visible haematuria is rarely present but dipstick haematuria is a frequent accompaniment to the pain, such that if a patient does not have detectable dipstick haematuria other diagnoses need to be seriously considered – this is especially true in the elderly male presenting for the first time with pain suggestive of a urinary tract stone, in whom a leaking abdominal aortic aneurysm should always be considered and discounted. On account of the fact that other serious pathology can be wrongly attributed to a urinary tract stone, the diagnosis of a urinary tract calculus needs to be confirmed at the earliest opportunity with a non-contrast CT scan. A supplementary plain x-ray is often performed to assess if the stone(s) are radio-opaque and if plain x-rays can be used in the follow-up of a patient who is expected to pass a stone spontaneously. There are 5 recognised narrowings in the ureter which may present obstacles to a stone's passage through to the bladder and these are the PUJ, the point at which the ureter crosses the bifurcation of the common iliac artery, and 3 areas involving the distal ureter (**Figure 76.10**). Ninety percent of stones <5 mm in maximal dimension are likely to pass successfully. Controversy exists about the value of medical expulsive therapy using agents such as α-blockers and calcium channel blockers (such as nifedipine), with significant variation in whether they are routinely used to facilitate the passage of ureteric calculi.

Stone management

The management of urinary tract stones can be subdivided depending on whether the patient presents in the emergency or elective setting.

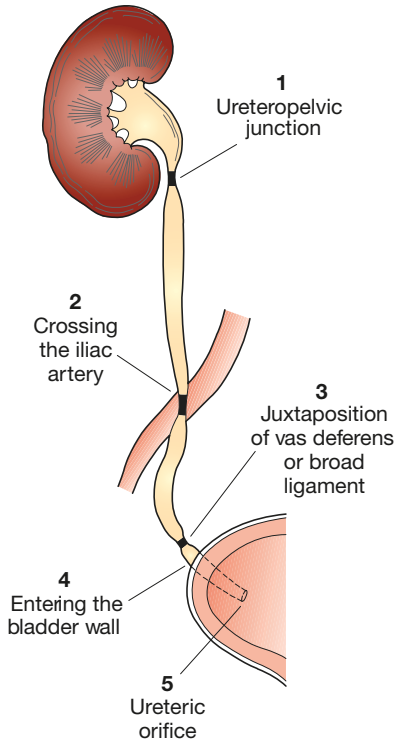

Figure 76.10 Normal anatomical narrowings (1–5) of the ureter.

Summary box 76.9

Urinary stones

- The commonest urinary tract stones are calcium oxalate
- Stones are best diagnosed on a non-contrast computed tomography kidney–ureter–bladder (KUB)
- Most stones <5 mm will pass spontaneously
- Medical expulsive therapy remains controversial
- Indications for surgical intervention are persistent pain, obstruction and infection

Emergency setting

A CT scan confirms the diagnosis and, as indicated above, small stones (<5 mm), especially in the distal ureter, are treated expectantly as they are likely to pass spontaneously. Medical expulsive therapy may be considered. The patient is usually given a non-steroidal anti-inflammatory drug such as diclofenac for pain relief and observed for further episodes of pain, but also temperature, pulse, blood pressure and white blood count are monitored for signs of developing infection and the estimated glomerular filtration rate (eGFR) is monitored for signs of a decline in renal function. It should be noted that the eGFR should remain within normal limits in the presence of a normal contralateral kidney with normal function. Frequent episodes of pain, signs of infection or a significant decline in renal function are the usual indications to intervene at an early stage.

In a patient requiring relatively urgent treatment for pain, the options are:

- *In situ* extracorporeal shockwave lithotripsy (ESWL).
- Cystoscopy and insertion of a ureteric stent as a temporising procedure.
- Primary ureteroscopic stone retrieval. Nowadays, the stone is usually treated with lasertripsy.

In a patient who is septic secondary to an obstructing urinary tract calculus, the options are:

- Insertion of a percutaneous nephrostomy (PCN) under local anaesthetic by an interventional radiologist.
- Cystoscopy and insertion of a ureteric stent.

When the patient is grossly unwell, insertion of a percutaneous nephrostomy, after the patient has been adequately resuscitated, is preferable to stent insertion as a ureteric stent may not adequately drain pus from a kidney and a PCN results in less manipulation and has a lower risk of producing septicaemia.

Elective setting

The options for surgical treatment are as follows:

EXTRACORPOREAL SHOCKWAVE LITHOTRIPSY (ESWL, ESL)

This is a non-invasive method of treating urinary tract stones by generating shockwaves outside the body which are focused on the stones. It was first used on a human in Germany in 1980. Different methods of generating shockwaves include spark gap, electromagnetic, piezoelectric and microexpulsive. Shockwaves generated using the spark-gap method need to be coordinated with the patient's electrocardiogram (ECG) to prevent cardiac arrhythmias. Stones can be localised for treatment using either fluoroscopy or USS. This is the common form of treatment these days for renal calculi and stones up to approximately 1.5 cm in size are suitable for this form of treatment. More than one treatment session may be needed to fully treat the stone, especially if it is sizeable. Prophylactic antibiotics are used to prevent infection as stones are often colonised by bacteria. Cystine stones are relatively resistant to ESWL due to their hardness. In addition to infection, ESWL may result in haematuria, parenchymal haemorrhage and even perirenal haematoma. A collection of stone fragments in a ureter after ESWL for a significant renal stone is given the German name of steinstrasse ('street of stones') (**Figure 76.11**). Contraindications to ESWL are obese patients, pregnant patients and patients taking oral anticoagulants.

Summary box 76.10

Extracorporeal shockwave lithotripsy

- Is the commonest method of treating urinary tract stones nowadays
- Several sessions of ESWL may be needed for complete stone fragmentation
- Stone fragments collecting in the distal ureter post ESWL are called Steinstrasse

Figure 76.11 Right lower pole calculi and steinstrasse in the distal right ureter (arrow).

URETEROSCOPY

Advances in the design of ureterorenoscopy have rendered the entire urinary tract accessible to endoscopic examination and manipulation. Ureteroscopes are classed as rigid, semi-rigid or flexible. Semi-rigid ureteroscopes are frequently used to directly visualise ureteric calculi (**Figure 76.12**).

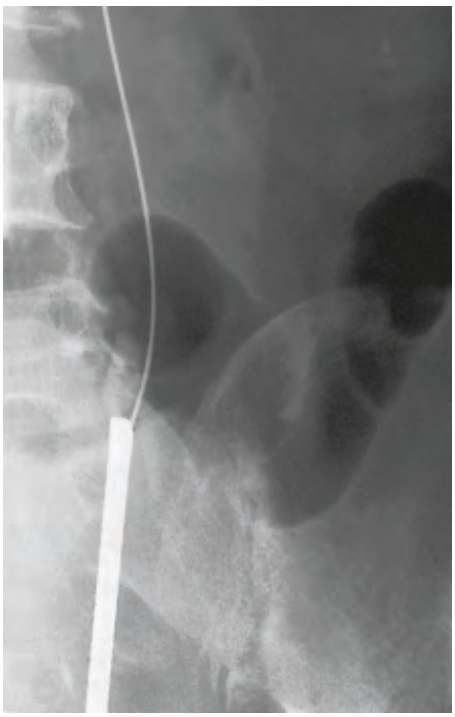

Figure 76.12 Ureteroscopy. X-ray showing a ureteroscope and guidewire in the ureter.

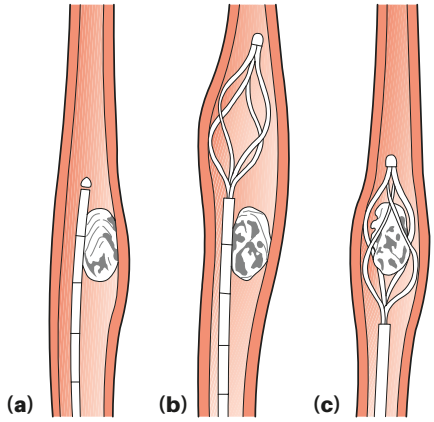

Figure 76.13 Dormia stone-catching basket in use. **(a)** Basket introduced past stone. **(b)** Opened. **(c)** Enclosing stone, ready for withdrawal.

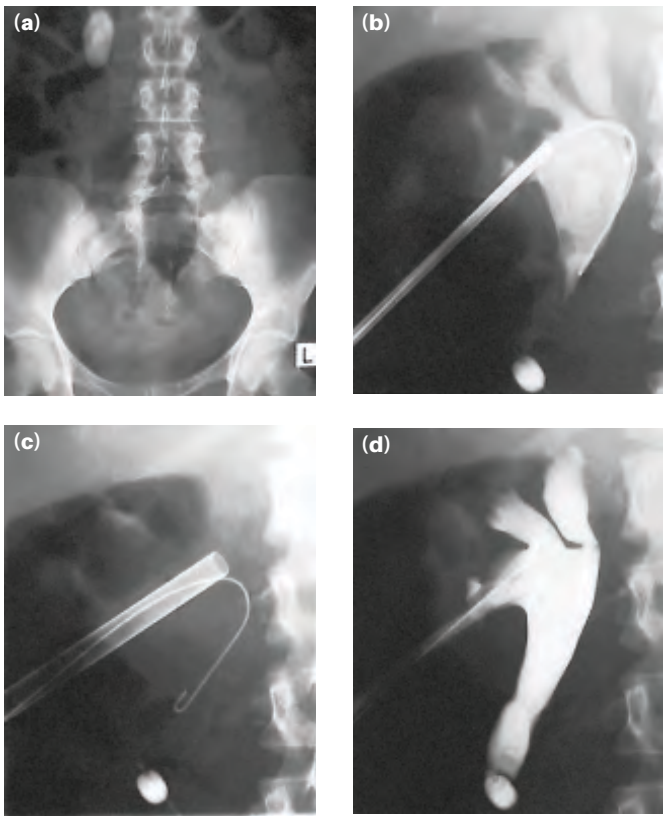
Thereafter, stones are retrieved by either using wire retrieval baskets (if <6 mm and in the distal ureter (**Figure 76.13**)) or, more commonly, using lithotripsy employing different energy sources (ultrasound, electrohydraulic – rarely used these days, laser, electrokinetic). Stones can also be fragmented using mechanical disintegration using the lithoclast. The most significant complications relate to injury to the ureteric mucosa or wall and include ureteric perforation and extravasation, avulsion of the ureter and ureteric stricture.



PERCUTANEOUS NEPHROLITHOTOMY (PCNL) (FIGURE 76.14)

Percutaneous nephrolithotomy was performed first in the mid-1970s. It is a technique used to treat larger stones in the renal pelvis or calyces but is sometimes also employed to deal with stones in the proximal ureter. During PCNL, a tract is established into the renal collecting system using ultrasound or fluoroscopic guidance. A series of dilators is used followed by placement of a working sheath into the collecting system through which the stone is visualised and fragmented (using ultrasound, laser or lithoclast). At the conclusion, a nephrostomy tube is left in the kidney for 24/48hrs. As well as for larger stones, PCNL is indicated for:

1. An obstruction: anatomic abnormalities such as PUJ obstruction, calyceal diverticula or ureteric obstruction might prevent the passage of stone fragments after ESWL.
2. Obese patients in whom ESWL is contraindicated.
3. Lower calyceal stones: these are less likely to pass after ESWL.
4. Stone composition: struvite stones need to be completely removed because of associated infection. As previously mentioned, some stones with a very hard composition are difficult to fragment using ESWL, including calcium oxalate monohydrate and cystine stones.

Complications relating to PCNL include:

1. Injury to the spleen, pleura and colon.
2. Haemorrhage from usually the renal parenchyma but also from major renal vessels. If the latter occurs, the treatment of choice is embolisation but, if this doesn't work, nephrectomy very occasionally has to be considered.
3. Sepsis.
4. Extravasation due to rupture of the collecting system.
5. Retained stone fragments.
6. Open surgery to the kidney is sometimes more complicated after PCNL.

OPEN STONE SURGERY

Open stone surgery other than total nephrectomy is incredibly infrequently undertaken in the modern era. In the past, pyelolithotomy, ureterolithotomy and nephrolithotomy with cooling of the kidney were sometimes indicated. A longstanding obstructing calculus can result in chronic inflammatory change in the kidney with substantial if not complete loss of function leading to XGP – see above). Nephrectomy for XGP can be one of the most challenging nephrectomies performed by a urological surgeon as the kidney is often adherent to

Figure 76.14 Percutaneous renal stone removal. **(a)** The stone is in the right renal pelvis. **(b)** Placement of a cannula under radiological control into the renal pelvis and through it a balloon catheter to stop fragments migrating into the upper ureter. **(c)** The stone is disrupted by contact lithotripsy and the fragments have been successfully removed by irrigation. **(d)** A nephrostogram confirms that the renal pelvis is intact.

Enrico Dormia, 1928–2009, Professor of Urology, University of Milan and Chief of the Department of Urology, S Carlo Hospital, Milan, Italy.

many of its surrounding structures. This resulted in the development of the subcapsular nephrectomy for this condition, where the renal capsule is left *in situ*.

Medical treatment of stones

The goal is to prevent further formation of new stones or the further growth of existing stones. Treatment may have to be lifelong. A high fluid intake is advised to prevent supersaturation of the urine, with the aim of producing at least 2.5 L of urine in 24 hours. Dietary excesses need to be eliminated.

Idiopathic calcium lithiasis

An increased fluid intake is advised and correction of dietary excesses of calcium and oxalate. Thiazide diuretics may reduce urinary calcium excretion by increasing fractional calcium reabsorption in the distal nephron. Orthophosphates may be used, which decrease urinary calcium excretion and increase inhibitor activity. Cellulose phosphate given enterally is useful in absorptive hypercalciuria. It is a calcium-binding resin and reduces calcium absorption when taken with meals. Citrate mixtures are useful to increase inhibitor activity in the urine.

Hypercalcaemic disorders

Increased fluid intake may prevent calculus formation, especially in immobilised patients. Oral orthophosphates may be used to decrease urinary calcium excretion. Corticosteroids in sarcoidosis reduce serum calcium. Thiazide diuretics have a role.

Renal tubular acidosis

Sodium or potassium bicarbonate or citrate is given, resulting in an increased renal citrate excretion.

Cystinuria

Potassium citrate is preferred to sodium bicarbonate for this condition. The aim is to increase the urinary pH to 7.5–7.8. D-penicillamine may be used which reacts with cysteine to form a soluble salt that reduces, through competition, the formation of cystine. It is a potentially toxic drug and should only be used if hydration and alkalinisation fail. Adverse effects include rashes, fever, agranulocytosis, arthralgia and lymphadenopathy. 6-mercaptopropionyl glycine (MPG) is an alternative and has fewer side effects. Captopril may be used to lower urinary cystine levels in homozygous cystinuric patients. Dietary methionine (precursor of cystine) restriction is rarely needed.

Uric acid lithiasis

Uric acid stones may be dissolved medically. Urinary pH is increased to 6.5 using sodium bicarbonate or potassium citrate. Allopurinol, a xanthine oxidase inhibitor, may reduce uric acid excretion; once calcium is dissolved this is discontinued and alkalinisation is maintained.

Primary hyperoxaluria

Large doses of pyridoxine reduce urinary oxalate excretion in 20–50% of patients. Neutral orthophosphates may be used to halt the growth of existing calculi.

Enteric hyperoxaluria

Fat restriction is necessary and oral calcium supplements are indicated. Cholestyramine may be used to bind acidic components in the gut lumen, including oxalate. Intestinal bypass may need to be reversed.

Summary box 76.11

Medical treatment of urinary stones

- Aim for urine output of 2.5 L in 24 hours
- Dietary excesses to be corrected
- Specific drugs are available for certain conditions

Stones associated with infection

After surgical removal, antimicrobial prophylaxis should be maintained for 3–12 months. Urinary acidification with ammonium chloride may be used in conjunction. Dissolution of stones with hemiacridrin or Suby G and M solutions is an option.

URINARY TRACT OBSTRUCTION

Obstructive uropathy refers to the structural or functional changes in the urinary tract that impede normal urine flow. **Obstructive nephropathy** refers to the renal disease caused by impaired flow of urine or tubular fluid. **Hydronephrosis** refers to the aseptic dilatation of the urinary tract. Urinary tract obstruction can be classified as either congenital or acquired.

Congenital urinary tract obstruction

Congenital urinary tract obstruction may affect either the upper or lower urinary tract and occurs most frequently in males, most commonly as a result of either posterior urethral valves or pelvi-ureteric junction obstruction. If it occurs early during development, the kidney fails to develop and becomes dysplastic. If obstruction occurs later in gestation and is low grade or unilateral, hydronephrosis and nephron loss will still occur, but renal function may be sufficient to allow survival.

Acquired urinary tract obstruction

Likewise, acquired urinary tract obstruction may affect either the upper or lower urinary tract and can result from either intrinsic or extrinsic causes. Intrinsic causes of obstruction may be intraluminal or intramural.

Causes of upper urinary tract obstruction are summarised in *Table 76.1* and causes of lower urinary tract obstruction are summarised in *Table 76.2*.

Clinical features

Unilateral hydronephrosis

Unilateral hydronephrosis (commonly caused by idiopathic PUJ obstruction or calculus) is more common in women and on the right side.

TABLE 76.1 Causes of upper urinary tract obstruction.

Intrinsic causes	Extrinsic causes
Intraluminal Intratubular deposition of crystals (uric acid, drugs) *Stones* Papillary tissue Blood clots Fungal ball	**Reproductive system** Cervix: *carcinoma* Uterus: *pregnancy*, *tumours*, prolapse, endometriosis, pelvic inflammatory disease Ovary: tumour, cysts Prostate: *carcinoma*
Intramural Functional: pelviureteral or vesicoureteral junction dysfunction Anatomic: tumours (benign or malignant) Infections, granulomas, strictures	**Vascular system** Aneurysms: aorta, iliac vessels Aberrant arteries: pelviureteral junction Venous: ovarian veins, retrocaval ureter
	Gastrointestinal tract Crohn's disease Pancreatitis Appendicitis Diverticulitis Tumours
	Retroperitoneal space Lymph nodes Fibrosis: idiopathic, drugs, inflammatory or IgG4-related disease Tumours: primary or metastatic Haematomas Radiation therapy Surgical disruption or ureteral ligation

The most common causes are in italics. (Adapted from Johnson JJ, Feehally J, Floege J. *Comprehensive clinical nephrology*, 5th edn, Philadelphia: Saunders, 2015, p. 704.)

TABLE 76.2 Causes of lower urinary tract obstruction.

Urethral anatomic causes Urethral strictures: trauma, *postinstrumentation*, infections such as gonococcal urethritis, nongonococcal urethritis, tuberculosis *Posterior urethral valves* Stones Blood clots Periurethral abscess Phimosis Paraphimosis Meatal stenosis
Urethral functional causes Anticholinergic drugs, antidepressants, levodopa
Prostate *Benign prostatic hypertrophy* *Prostatic carcinoma*
Bladder anatomic causes *Bladder cancer* *Schistosomiasis (Schistosoma haematobium infection)* Bladder calculi Bladder trauma, pelvic fracture
Bladder functional causes *Neurogenic bladder:* spinal cord defects or trauma, diabetes, multiple sclerosis, Parkinson's disease, cerebrovascular accidents

The most common causes are in italics. (Adapted from Johnson JJ, Feehally J, Floege J. *Comprehensive clinical nephrology*, 5th edn, Philadelphia: Saunders, 2015, p. 704.)

Presenting features include the following:

- Mild pain or dull aching in the loin, often a dragging heaviness worsened by excessive fluid intake. The kidney may be palpable.
- Intermittent hydronephrosis (Dietl's crisis). Loin swelling is associated with acute renal pain. The pain goes and the swelling disappears when a large volume of urine is passed.
- Antenatal detection in the fetus by USS. Many of these cases are benign, but postnatal investigation is required to detect those with significant PUJ obstruction.

Summary box 76.12

Idiopathic pelvi-ureteric obstruction

- May be asymptomatic
- Can present as intermittent loin pain often exacerbated by a fluid load

Bilateral hydronephrosis

- From lower urinary obstruction: symptoms of bladder outlet obstruction predominate.
- From bilateral upper urinary tract obstruction: idiopathic retroperitoneal fibrosis affects both ureters and idiopathic PUJ obstruction can be bilateral. Symptoms may be referred to one side.
- Hydronephrosis from pregnancy.

Dilatation of the ureters and renal pelves occurs early in pregnancy up to the 20th week. It results from the effects on the ureteric smooth muscle of high levels of circulating progesterone and is part of normal pregnancy. The ureters return to their normal size within 12 weeks of delivery. This physiological condition is associated with an increased liability to infection and there is a possibility that abdominal pain during pregnancy may be erroneously ascribed to ureteric obstruction.

Summary box 76.13

Ureteric dilatation in pregnancy

- Physiological dilatation of the ureter is common in pregnancy

Imaging

Ultrasound scanning (**Figure 76.15**) is the least invasive means of detecting hydronephrosis and is regularly used to diagnose PUJ obstruction *in utero*.

IVU helps only if there is significant function in the obstructed kidney. The extrarenal pelvis is dilated and the minor calyces lose their normal cupping and become 'clubbed'. If the level of obstruction is in doubt, it can help to take follow-up films 36 hours after the contrast has been injected. Contrast slowly diffuses to fill the obstructed system down to the blockage.

Joseph Dietl, 1804–1878, Professor of Pathology and Therapeutics, Krakau, Poland.

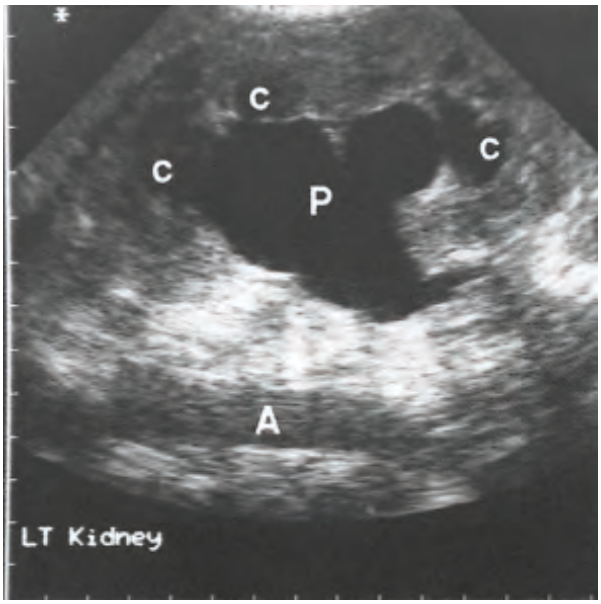


Figure 76.15 Ultrasound of a hydronephrotic kidney. A, artery; C, calyces; P, pelvis.

Figure 76.16 Retrograde ureteropyelogram showing hydronephrosis with greatly enlarged pelvis and dilated 'clubbed' calyces.

Isotope renography is the best test to confirm obstructive dilatation of the collecting system. A substance (usually diethylenetriaminepentaacetic acid (DTPA) or MAG-3) is injected intravenously. The DTPA is labelled with technetium-99m, a gamma-ray emitter, so that the passage of 99mTc-labelled DTPA through the kidneys can be tracked using a gamma camera. 99mTc-DTPA is cleared from a normal kidney but stays in the renal pelvis on the obstructed side and is retained even if urine flow is increased by administering frusemide **(Figure 76.17)**.

Very occasionally, a Whitaker test is indicated. A percutaneous puncture of the kidney is made and fluid is infused at a constant rate with monitoring of intrapelvic pressure. An abnormal rise in pressure confirms obstruction. Retrograde pyelography **(Figure 76.16)** is rarely indicated but will confirm the site of obstruction immediately before corrective surgery.

Summary box 76.14

Imaging

- Obstruction of the ureter is diagnosed by a combination of ultrasound scanning and isotope renography
- An obstructed kidney is worth preserving if it is contributing >20% of total renal function

Treatment

The indications for operation are bouts of renal pain, increasing hydronephrosis, evidence of parenchymal damage and infection. Nephrectomy should be considered only when the kidney has largely lost most of its function (<10% split function). Mild cases should be followed by serial ultrasound scans and operated upon if dilatation is increasing.

Pyeloplasty

In the original Anderson–Hynes open pyeloplasty, the upper third of the ureter and the renal pelvis are mobilised,

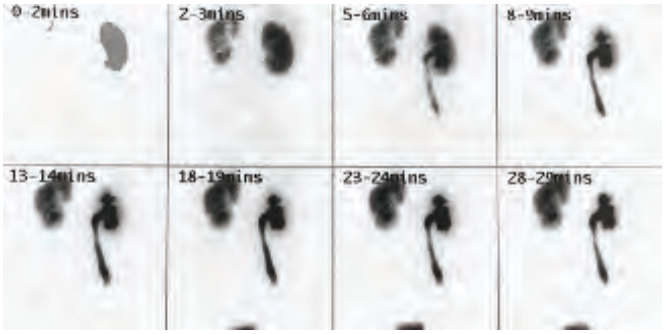

Figure 76.17 Isotope renogram series showing a late accumulation and persistence of radioactivity in the left kidney (the image is a posterior view).

James Christie Anderson, 1899–1984, urologist, The Royal Hallamshire Hospital, Sheffield, UK.
Wilfred Hynes, 1903–1991, plastic surgeon, The Plastic and Jaw Department, The Royal Sheffield Hospital, Sheffield, UK. Anderson and Hynes devised the operation in 1949. It is nowadays done laparoscopically, particularly in children. Robotically assisted laparoscopic dismembered pyeloplasty has also been carried out.

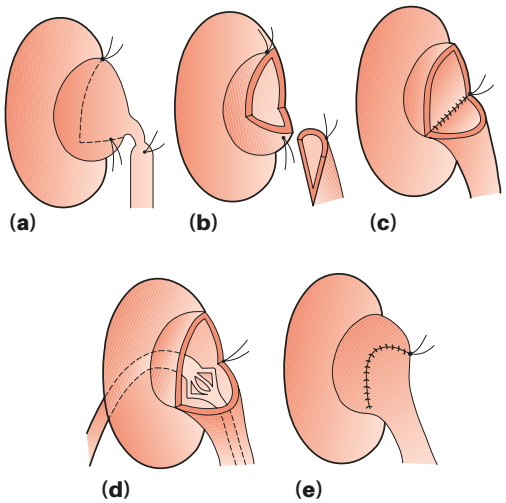

Figure 76.18 (a-e) Anderson–Hynes pyeloplasty.

the ureter is dismembered from the renal pelvis, redundant renal pelvis is excised and a new PUJ is reconfigured (**Figure 76.18**). A renal vein overlying the distended pelvis can be divided, but an artery in this situation should be preserved to avoid infarction of the renal parenchyma it supplies. The anastomosis is made in front of such an artery if it exists. A ureteric stent is inserted to splint the anastomosis. This type of surgery is now almost universally performed using laparoscopic techniques and in some centres is being performed with robotic assistance. Other surgical procedures have been described to widen the PUJ without dismembering the ureter from the renal pelvis.

Endoscopic pyelolysis

Other endoscopic treatments have been tried to surgically remedy PUJ obstruction including retrograde balloon dilatation, incision of the PUJ using a hot wire over a balloon, laser incision, and percutaneous pyelolysis from above but, in general, these do not produce results equivalent to pyeloplasty.

RETROPERITONEAL PATHOLOGY

Retroperitoneal pathology may result in extrinsic obstruction of the ureters, as can metastases or extension of tumours from the cervix, prostate, bladder, colon, ovary and uterus. Primary tumours of the retroperitoneum, such as lymphomas and sarcomas, can commonly cause obstruction. Obstruction can also result from inflammatory conditions affecting the retroperitoneum such as Crohn's disease and colonic diverticulitis. Less common pathological processes include retroperitoneal fibrosis (RPF), in which thick fibrous tissue 'plaques' extend out from the aorta to encase the ureters and draw them medially. RPF can be idiopathic but can result from inflammatory aortic aneurysms, certain drugs (β-blockers, bromocriptine, methysergide), previous irradiation, trauma or surgery and granulomatous disease (tuberculosis and sarcoidosis).

RPF can be treated medically or surgically. There are reports of favourable outcomes after immunosuppression with high doses of corticosteroids or azathioprine, usually used in combination with bilateral ureteric stents. Alternatively, surgery consisting of ureterolysis (freeing the ureters from the fibrotic plaques) and omentoplasty (transposition of the ureters into the peritoneal cavity in omental wraps) has been shown to have good long-term results. Increasingly, this surgery is being performed laparoscopically with or without robotic assistance rather than as an open surgical procedure.

RENAL TRAUMA

Ten percent of all trauma cases involve the genitourinary tract. This is usually as a result of blunt trauma and the injury is usually self-limiting. Five to 10% of blunt trauma and up to 70% of penetrating trauma are major injuries. Common blunt injuries result often from road traffic accidents, falls, assaults and sporting injuries. Common penetrating injuries are knife or gunshot wounds.

Major renal injury should be suspected with gross haematuria, shock in combination with microscopic haematuria, paediatric renal trauma and penetrating renal injuries. Haematuria may be absent in up to 40% of renal injuries and 24% of pedicle injuries. Renal injuries (**Figure 76.19**) are classified as follows:

- **Grade I:** contusion or non-enlarging subcapsular perirenal haematoma, and no laceration.
- **Grade II:** superficial laceration <1 cm depth and does not involve the collecting system (no evidence of urine extravasation), non-expanding perirenal haematoma confined to retroperitoneum.
- **Grade III:** laceration >1 cm without extension into the renal pelvis or collecting system (no evidence of urine extravasation).
- **Grade IV:**
  - Laceration extends to renal pelvis or urinary extravasation.
  - Vascular: injury to main renal artery or vein with contained haemorrhage.
  - Segmental infarctions without associated lacerations.
  - Expanding subcapsular haematomas compressing the kidney.
- **Grade V:**
  - Shattered kidney.
  - Avulsion of renal hilum: devascularisation of a kidney due to hilar injury.
  - Ureteropelvic avulsions.
  - Complete laceration or thrombus of the main renal artery or vein.

The indications for radiological assessment are:

- Penetrating injuries.
- Gross haematuria.

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described Crohn's disease in 1932.

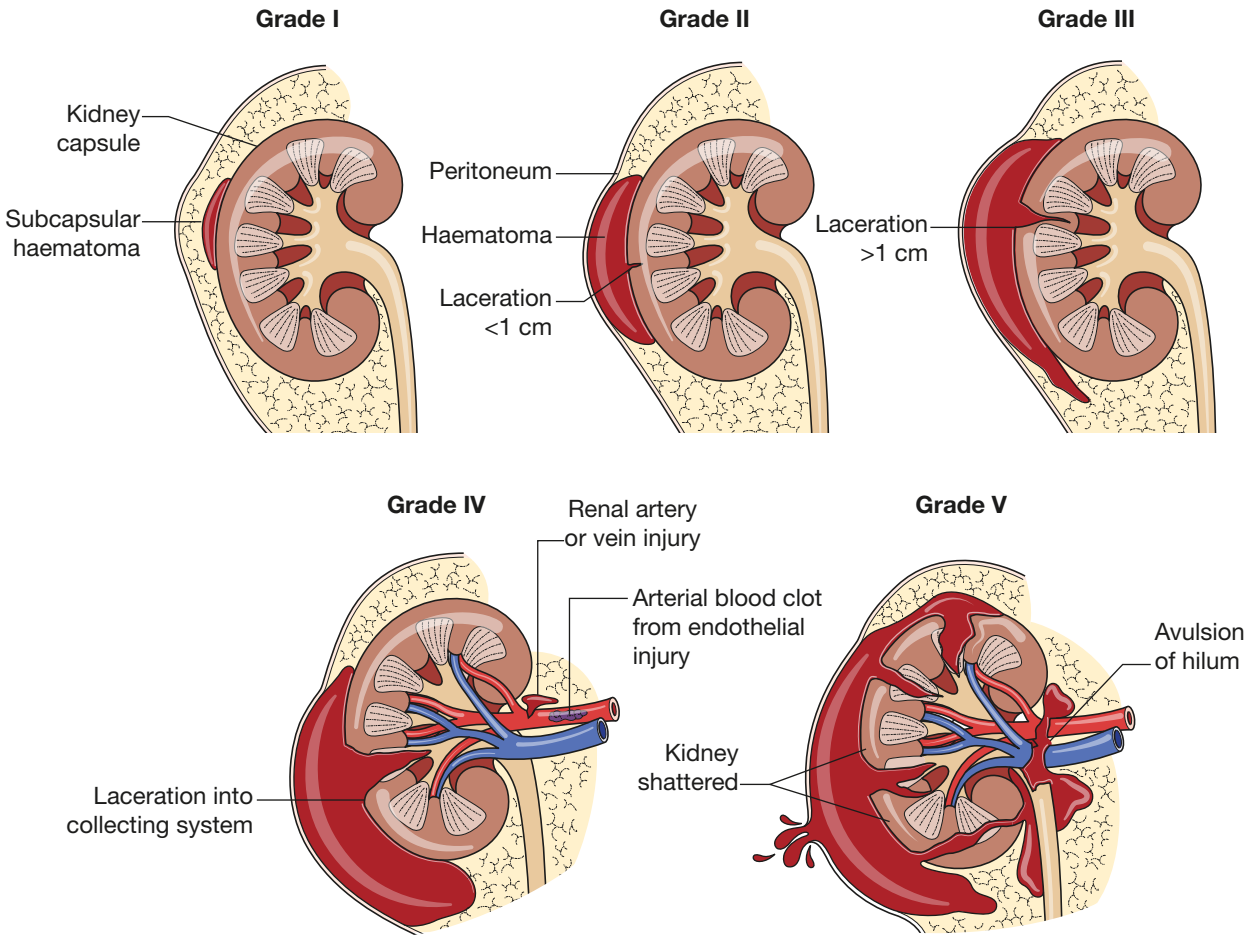

Figure 76.19 Classification of renal trauma.

- Shock in combination with microscopic haematuria.
- Children: in whom the kidneys are much lower and less well protected.

CT scan with contrast is the investigation of choice. It will accurately assess the extent of the injury, showing laceration, extravasation, surrounding haemorrhage and vessel injury. It also shows non-renal injuries and effectively stages renal pedicle injuries. Arterial occlusion is manifest as rim enhancement of the normal renal contour.

The vast majority of cases of blunt renal trauma can be treated conservatively and in one major series only 2.5% of such cases required surgical exploration. Most penetrating injuries from knife or gunshot wounds require renal exploration.

In general, minor and limited major injuries are treated conservatively. Unstable major injuries are best treated with prompt surgical exploration as this lessens the risk of continued bleeding, sepsis and renal loss.

Some patients who have not undergone prior radiological assessment will require an immediate laparotomy and in some patients renal trauma will be encountered unexpectedly during laparotomy. If this occurs, then an on-table intravenous urogram is required. If significant extravasation, non-function, poor opacification or caliceal distortion is found then renal exploration is indicated. An expanding or pulsatile retroperitoneal haematoma should be explored but only after vascular control has been achieved.

Summary box 76.15

Renal trauma

- 10% of trauma cases involve the genitourinary tract
- Blunt trauma is much more common than penetrating trauma
- Most cases of blunt trauma are treated conservatively
- Most penetrating injuries require renal exploration

INJURY TO THE URETER

Rupture of the ureter

This is an uncommon result of a hyperextension injury of the spine. The diagnosis is rarely made until there is swelling in the loin or iliac fossa associated with a reduced urine output. An IVU or contrast-enhanced CT shows extravasation of contrast.

Injury to one or both ureters during pelvic surgery

This occurs most often during vaginal or abdominal hysterectomy when the ureter is mistakenly divided, ligated, crushed or excised. Pre-emptive ureteric catheterisation makes it easier to identify the ureters.

Injury recognised at the time of operation

Ureterovesical continuity should be restored by one of the methods described below unless the patient's condition is poor. Deliberate ligation of the proximal ureter and temporary percutaneous nephrostomy is then the best course until the patient is well enough for a repair.

Summary box 76.16

Ureteric injury during operation

- Surgical trauma during pelvic surgery is the most common cause of ureteric trauma
- Preoperative catheterisation of the ureters makes them easier to protect
- Injuries discovered during surgery should be repaired immediately

Injury not recognised at the time of operation

UNILATERAL INJURIES

There are three possible outcomes:

1. No symptoms. Ligation of a ureter may lead to silent atrophy of the kidney. The injury may be unsuspected until the patient undergoes urological imaging.
2. Loin pain and fever, possibly with pyonephrosis, occur with infection of the obstructed system. Loss of function will be permanent unless obstruction is relieved by promptly inserting a percutaneous nephrostomy.
3. A urinary fistula develops through the abdominal or vaginal wound. The IVU or contrast-enhanced CT shows extravasation with or without obstruction of one or both ureters. Nephrostomies may be inserted and repair postponed until oedema and inflammation have subsided. Early repair is safe if the patient is fit for surgery.

BILATERAL INJURY

Ligation of both ureters leads to anuria. Ureteric catheters will not pass and urgent nephrostomy or immediate surgery is essential.

Repair of the injured ureter

An open repair may be avoidable if a stent will pass the obstruction (*Table 76.3*). If the cut ends of the ureter can be apposed without tension, they should be joined by a spatulated anastomosis over a double pigtail catheter.

TABLE 76.3 Methods for repairing a damaged ureter.

If there is no loss of length	Spatulation and end-to-end anastomosis without tension
If there is little loss of length	Mobilise kidney
	Psoas hitch of bladder
	Boari operation
If there is marked loss of length	Transureteroureterostomy
	Interposition of isolated bowel loop or mobilised appendix
	Nephrectomy

If the division is low, the bladder may be hitched and the ureter can be re-implanted. Extra length may be obtained by mobilising the kidney.

In the Boari operation (**Figure 76.20**), a flap of bladder wall is fashioned into a tube to replace the lower ureter. The disadvantage of implanting the ureter end-to-side into the contralateral ureter (a transureteroureterostomy) is that it risks converting a unilateral injury into a bilateral one.

Nephrectomy may be best when the patient's outlook is poor and the other kidney is normal. When conservation of all renal tissue is vital, replacement of the damaged ureter by a segment of ileum is necessary.

Summary box 76.17

Repair of ureteric injury

When surgical damage to a ureter is discovered postoperatively:

- Repair need not be delayed
- Ideally surgical repair should be performed by a urologist

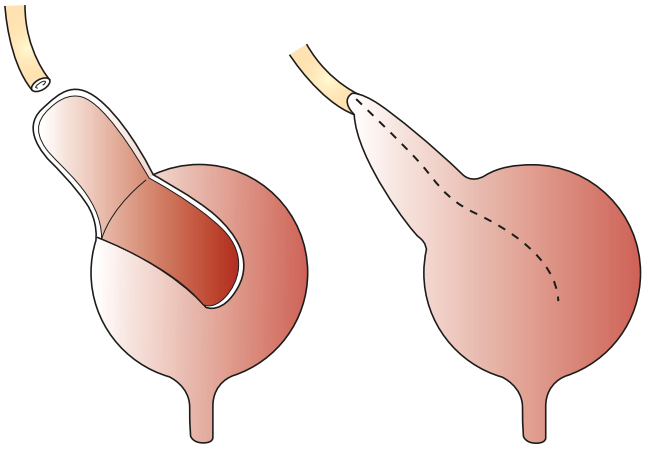

Figure 76.20 Boari operation: a strip of bladder wall is fashioned into a tube to bridge the gap between the cut ureter and the bladder.

Achille Boari, 19th century Italian, urological surgeon from Ferrara, described the technique of a bladder flap in dogs in 1894; it was first performed in a patient in 1936.

VASCULAR PATHOLOGY

Renal artery occlusion/renal infarction

Renal infarction may involve the whole kidney or small areas of the cortex and medulla. The most common presenting symptoms of renal infarction are loin, flank or abdominal pain with nausea and vomiting. Urinalysis often demonstrates microscopic haematuria and proteinuria. Transient or accelerated hypertension may occur secondary to the abrupt release of renin from the infarcted segment. Approximately 25% of cases are asymptomatic. Transient elevation in serum creatinine is not uncommon. When bilateral occlusion of both kidneys or infarction of a single functioning kidney occurs, the patient presents with oliguric or anuric acute kidney injury (AKI). Systemic signs of renal infarction include pyrexia and leucocytosis. CT scan with IV contrast is the best imaging modality for demonstrating areas of renal cortex that are not perfused. The most common causes of renal infarction are trauma, renal artery embolism from cardiac thrombus, and iatrogenic complications of endovascular procedures. Spontaneous renal artery thrombosis or dissection is most often associated with atherosclerotic disease of the aorta or renal arteries, but other vascular causes include fibromuscular hyperplasia, Takayasu's arteritis, polyarteritis nodosa, Marfan's syndrome and Ehlers–Danlos syndrome with associated dissection or aneurysms. Less common causes include hypercoagulable states and inflammatory diseases of the retroperitoneum.

In the setting of renal infarction, a search for the cause of the renal vascular compromise should be undertaken to determine whether it is embolic or thrombotic. Treatment of the infarction itself is usually conservative. If renal artery occlusion is caused by a hypercoagulable state or an embolism from a central source, systemic anticoagulation is indicated. Common sources include atrial fibrillation, atrial or mural thrombi, intracardiac mass and valvular lesions; therefore, echocardiography is indicated.

Renal vein thrombosis

Renal vein thrombosis is rare and primarily observed in children with severe dehydration or in adults with nephrotic syndrome, renal tumours, or hypercoagulable states and after surgery or trauma to the renal vessels. Thrombosis of the longer left renal vein may also involve ureteric, gonadal, adrenal and phrenic branches that drain into the left renal vein. Most patients are treated with systemic anticoagulation.

TUMOURS OF THE KIDNEY

Benign tumours

Adenoma

Pea-like cortical adenomas are occasionally discovered. They are asymptomatic and are benign.

Angioma

Angioma may cause profuse haematuria, often in young adults. The bleeding source may be difficult to diagnose without renal angiography.

Angiomyolipoma

Angiomyolipoma is an unusual tumour of the kidney, often but not always associated with tuberous sclerosis. Its high fat content has a typical appearance on CT. Malignant elements are present in about one-quarter and may metastasise.

Renal cell carcinoma

Renal cell carcinoma (RCC) encompasses a heterogeneous group of cancers derived from renal tubular epithelial cells and is among the 10 most common cancers worldwide, accounting for about 2% of all cancer diagnoses and deaths. The male:female ratio is approximately 2:1. Key advances in histopathological and molecular characteristics of RCC over the past two decades have led to major revisions in its classification. Major subtypes with >5% incidence are clear-cell RCC (ccRCC), papillary RCC (pRCC) and chromophobe RCC (chRCC). ccRCC is the most common subtype and accounts for the majority of deaths from kidney cancer. Indeed, owing to the predominance of clear-cell histology in metastatic disease (83–88%), tumours with non-clear-cell histology have been grouped as 'nccRCC' (*Table 76.4*). Kidney cancer accounts for approximately 84 000 new cases and approximately 35 000 deaths in Europe annually. The median age at presentation is 64 years and when RCC is diagnosed at younger ages (<46 years) the possibility of an underlying hereditary kidney cancer syndrome – which accounts for 3–5% of all RCCs – should be considered (*Table 76.5*). Although overall the incidence rates of RCC are increasing, the mortality rates have levelled off, probably accounted for by increasing incidental detection – from increased use of abdominal imaging – of small renal masses (<4 cm) that are unlikely to have metastasised. The global increase in the prevalence of obesity, an established risk factor, might also play a part in increasing incidence.

Mikito Takayasu, 1860–1938, Japanese ophthalmologist, described Takayasu's arteritis in 1908.
Antoine Bernard-Jean Marfan, 1858–1942, French pediatrician, described Marfan's syndrome in 1886.
Edvard Laurits Ehlers, 1863–1937, Danish dermatologist.
Henri-Alexandre Danlos, 1844–1912, French physician and dermatologist.

TABLE 76.4 Non-clear-cell renal cell carcinomas.

Tumour type	Subtype	Cytogenetic alterations	Genes mutated	Gross appearance	Histological features*
Papillary	Type 1	• Gains of 7, 8q, 12q, 16p, 17 and 20 • Loss of 9p	*MET*	• Mixed cystic or solid consistency • Often whitish in colour and may show haemorrhage and necrosis • Frequently with a well-demarcated pseudocapsule	• Single layer of cuboid tumour cells • Thin, basophilic papillae with scant pale cytoplasm and low nuclear grade • Concentric lamellated calcifications (psamomma bodies) • Foamy macrophage infiltration
	Type 2	• Gains of 8q • Loss of 1p and 9p	• *CDKN2A* • *SETD2* • *NRF2*		• Heterogeneous, thick papillae and eosinophilic cytoplasm, high nuclear grade and pseudostratification • Concentric lamellated calcifications • Foamy macrophage infiltration
Chromophobe	Classic	Loss of chromosomes 1, 2, 6, 10, 13, 17 and 21	• *TP53* • *PTEN*	• Large, well-circumscribed grey to tan-brown coloured tumour • Occasional central scar	• Tumour cells with prominent membrane and pale cytoplasm • Voluminous cytoplasm (cytoplasmic accumulation of acid mucopolysaccharides)
	Eosinophilic				• Large tumour cells with fine eosinophilic granules • Distinct cell borders • Voluminous cytoplasm
MiT family translocation	NA	Recurrent translocations involving Xp11.23 *(TFE3)* or 6p21 (TFEB)	• *TFE3* • *TFEB*	• Yellowish tissue • Often studded by haemorrhage and necrosis	• Papillary or nested architecture • Abundant clear or eosinophilic cytoplasm
Collecting duct	NA	• Losses at 8p, 16p, 1p and 9p • Gains at 13q	Unknown	• Partially cystic • White-grey appearance • Often exhibit invasion into the renal sinus	• Tubulopapillary pattern • Often with cells taking columnar pattern with hobnail appearance • Presence of mucinous material • Desmoplastic stroma
Medullary	NA	Poorly described, but thought to be normal karyotype	*SMARCB1*	• Tan or white appearance • Poorly defined capsule • Extensive haemorrhage and necrosis	• Poorly differentiated, eosinophilic cells • Inflammatory infiltrative cells • Sheet-like or reticular pattern is common
Oncocytoma	NA	• Loss of chromosome 1 and Y chromosome • *CCND1* rearrangement	Mitochondrial genes *(COX1, COX2, MTND4* and *MTCYB)*	• Mahogany colour • Circumscribed • Occasional central scar • Rarely with necrosis	• Polygonal cells with abundant eosinophilic cytoplasm • Uniform, round nuclei

NA, not applicable. *No consensus is currently available that describes the immune infiltration of non-clear-cell renal cell carcinomas. (Adapted from Hsieh JJ, Purdue MP, Signoretti S *et al*. Renal cell carcinoma. *Nat Rev Dis Primers*. 2017; **9**(3): 1–19.)

Risk factors for RCC include:

- age;
- sex;
- obesity;
- hypertension;
- cigarette smoking.

Other medical conditions have been associated with RCC including chronic kidney disease, haemodialysis, kidney transplantation and acquired cystic disease of the kidney (ACDK). Genetic factors also contribute to RCC risk, as evidenced by individuals with a family history of renal cancer having an approximate twofold increased risk. Investigations into familial RCC have uncovered mutations in at least 11 genes (*BAP1*, *FLCN*, *FH*, *MET*, *PTEN*, *SDHB*, *SDHC*, *SDHD*, *TSC1*, *TSC2* and *VHL*), some of which have been implicated in sporadic RCC. A notable example is *VHL*, the mutated gene underlying von Hippel–Lindau disease, which is characterised by a high risk of developing ccRCC.

The classic triad of loin pain, loin mass and haematuria is seen in <10% of patients with a renal tumour. Nowadays, the majority of diagnoses result from incidental findings. This shift is a consequence of the widespread use of USS and CT imaging, performed for other reasons. That said, paraneoplastic

TABLE 76.5 Hereditary syndromes associated with renal cell carcinoma.

Syndrome (phenotype OMIM reference)	Gene (position)	Protein	Incidence of developing a kidney tumour (%)	Median age at diagnosis (years)	Other phenotypic features

(Adapted from Hsieh JJ, Purdue MP, Signoretti S *et al*. Renal cell carcinoma. *Nat Rev Dis Primers*. 2017; **9**(3): 1–19.)

syndromes – symptoms caused by hormones or cytokines excreted by the tumour cells or by an immune response against the tumour – are not uncommon in RCC and symptoms include hypercalcaemia, fever and erythrocytosis.

Summary box 76.18

Renal cell carcinoma (RCC)

- Arises from epithelium of the proximal convoluted tubule
- Frequently detected coincidentally
- Has a male preponderance
- Major subtypes are clear-cell, papillary and chromophobe RCC
- Surgery is the mainstay of treatment for organ-confined disease
- Metastatic disease is treated with tyrosine kinase inhibitors (TKIs) or mTOR inhibitors

Staging (Figure 76.21).

CT imaging with contrast enhancement of the chest, abdomen and pelvis is required for optimal staging. Such imaging enables the assessment of the primary tumour (such as the size and whether the tumour is organ-confined or extends to perinephric fat or the renal hilum), regional spread (lymph node involvement) and distant metastases (including lung, bone and distant lymph nodes). MRI can also provide additional information, especially to determine whether the tumour extends into the vasculature. Bone scan and 18F-FDG PET scan are not recommended for initial staging.

Pathology

In 2016, the World Health Organisation (WHO) classification of RCC was updated from previous (2004) WHO and International Society of Urological Pathology (ISUP) Consensus Conference (2013) systems. At macroscopic level, the cut surface of ccRCC tumours is golden-yellow in colour with frequent haemorrhagic, necrotic and cystic areas (Figure 76.22). Microscopically, ccRCC usually consists of tumour cells with clear cytoplasm arranged in nests or tubules surrounded by a rich vascular network. The clear appearance of the cytoplasm is due to the accumulation of glycogen and lipids. The most widely used grading system for ccRCC is the Fuhrman grading system, which defines 4 nuclear grades (1–4) in order of increasing nuclear size, irregularity and nucleolar prominence. The pathologist also often assigns a Leibovich score following nephrectomy – the Leibovich prognostic score runs from 0 to 11 and is based on the tumour's stage, grade, size, involvement of lymph nodes and the presence of tumour necrosis histologically. It should be noted that all RCC types may contain foci of high-grade malignant spindle cells (i.e. sarcomatoid differentiation).

Surgery

Surgical treatment of RCC is related to the clinical stage of the disease and to the general condition of the patient. Although typically reserved for localised disease, nephrectomy can also be used with cytoreductive intent in patients with metastatic

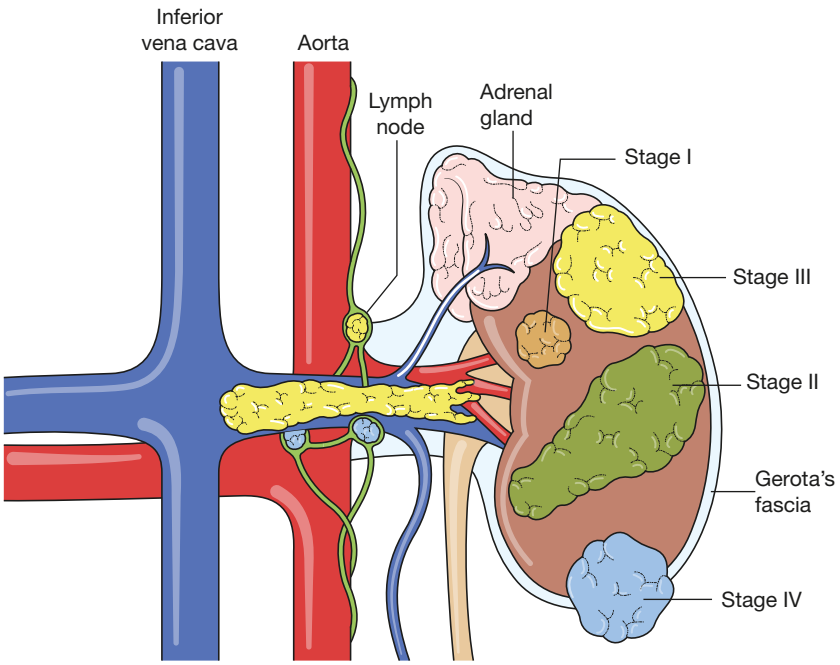

Figure 76.21 Staging renal cell carcinoma is based on size, position and lymph node involvement:
Stage I: tumour <7 cm in the largest dimension, limited to the kidney
Stage II: tumour >7 cm in the largest dimension, limited to the kidney
Stage III: tumour in the major veins or adrenal gland with intact Gerota's fascia, or regional lymph nodes involved
Stage IV: tumour beyond Gerota's fascia

Susan A Fuhrman, American pathologist, described the Fuhrman grading system in 1982.
Bradley C Leibovich, contemproary, Professor of Urology, Rochester, MN, USA.

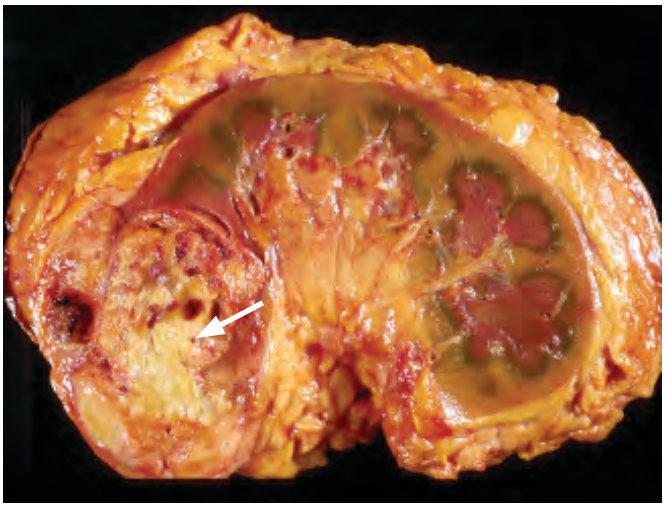

Figure 76.22 A radical nephrectomy specimen containing a renal cell carcinoma (arrow) (courtesy of Dharam M Ramani, MD).

disease, especially if there is substantial disease volume at the primary site but only a low burden of metastatic disease.

PARTIAL NEPHRECTOMY

The goal of partial nephrectomy is to completely remove the primary tumour while preserving the largest possible amount of healthy renal parenchyma. Partial nephrectomy is indicated for patients with a T1 tumour (according to the UICC TNM staging system) and a normal contralateral kidney. Moreover, partial nephrectomy is strongly recommended (imperative absolute indications) in patients with RCC who have only one kidney (anatomically or functionally), in those with bilateral synchronous RCC and in those with von Hippel–Lindau syndrome. Similarly, relative indications include conditions that can impair renal function (e.g. kidney stones, hypertension, diabetes and pyelonephritis). Indeed, partial nephrectomy offers lower renal function impairment and equivalent oncological survival outcomes compared with radical nephrectomy in those with T1 tumours. In the past decade, nephrometry scoring systems (such as the R.E.N.A.L. and PADUA systems) have been proposed to predict the complexity of the partial nephrectomy procedure. Laparoscopic partial nephrectomy (LPN) and robot-assisted partial nephrectomy (RAPN) are the main alternatives to classic open partial nephrectomy (OPN). In the past, cooling of the kidney using crushed ice was frequently employed during partial nephrectomy but this is being used in a more selective fashion in the modern era. Haematuria, perirenal haematoma and urinary fistulas are the most common complications of partial nephrectomy. Less frequent postoperative complications are acute renal impairment and infection.

RADICAL NEPHRECTOMY

Classic radical nephrectomy consists of removal of the kidney, perirenal fat, adrenal gland and regional lymph nodes. However, in patients with a tumour <5 cm in size, located at the inferior pole, the adrenal gland can be spared. Similarly, regional lymph node dissection can be reserved for patients with clinically positive nodes detected by CT or during the surgical procedure. It is performed if possible as a laparoscopic procedure (most stage I and stage II tumours) but if this is not feasible then as an open procedure. Data recently taken from the US National Cancer database support the use of cytoreductive nephrectomy in those with metastatic disease, even while they receive systemic targeted therapies. Indeed, the median overall survival was 17.1 months in cytoreductive nephrectomy patients compared with 7.7. months in the non-cytoreductive nephrectomy group. Patients with renal vein or IVC involvement by tumour but without evidence of metastatic disease remain surgical candidates. Occasionally, nephrectomy and removal of IVC tumour thrombus need to be done in conjunction with cardiothoracic surgeons, using cardiopulmonary bypass techniques for those tumours extending above the diaphragm. Bench surgery and autotransplantation is performed in highly specialised centres for larger tumours in a solitary kidney.

Summary box 76.19

Surgery for renal tumours

- Surgery is the mainstay treatment for organ-confined renal cancer
- Partial nephrectomy is increasingly used for renal tumours <7 cm
- Partial nephrectomy is increasingly performed using robotic assistance
- Cytoreductive nephrectomy (removal of the kidney in the presence of metastatic disease) has a role in patients with a good performance status

Active surveillance and ablative therapies

Active surveillance and ablative therapies, such as radiofrequency ablation (RFA) and cryotherapy, are alternative strategies for elderly patients and/or those with competing health risks and limited life expectancy that render them unsuitable for surgery. Intervention should be considered for growth to >3–4 cm or by >0.5 cm per year.

Ablative technology must be able to completely destroy all viable tumour tissue with no viable tumour left. Both cryotherapy and RFA can be performed using a laparoscopic or percutaneous approach under CT or ultrasound guidance. Available low-quality studies suggest a higher local recurrence rate for ablative therapies than for partial nephrectomy.

Medical management using targeted therapies

The past 10 years have seen the approval of several targeted therapeutic agents for the treatment of metastatic RCC. Given the highly vascular nature of RCCs, it is unsurprising that several therapies are available to exploit this feature. Indeed, tyrosine kinase inhibitors targeting the VEGF (vascular endothelial growth factor) signalling axis that are approved in the first-line and second-line settings for the treatment of metastatic RCC are sorafenib, sunitinib, pazopanib, axitinib, lenvatinib and cabozantinib. In addition, the anti-VEGF monoclonal antibody, bevacizumab, is approved for use with interferon-α. The mTOR inhibitors,

everolimus and temsirolimus, are approved as single agents in the second-line setting and in the first-line setting in patients with poor risk status. The average duration of disease control with these drugs is 8–9 months in the first-line setting and 5–6 months in the second-line setting. Most of the phase III RCTs leading to approval of these agents have excluded patients with nccRCC. Many studies are currently investigating combinations of anti-VEGF therapy with a new generation of immunotherapy agents in the form of T cell-immune checkpoint inhibitors such as antibodies against programmed cell death protein 1 ligand 1 (PDL1), which include avelumab and atezolizumab, and antibodies against programmed cell death protein 1 (PD1) which include nivolumab and pembrolizumab.

Summary box 76.20

Targeted therapies for renal cancer

- These include tyrosine kinase inhibitors (TKIs), anti-VEGF monoclonal antibodies and mTOR inhibitors
- The average duration of disease control with these agents is 8–9 months

Upper tract transitional cell carcinoma (UTTCC)

Transitional cell carcinomas of the renal pelves or ureters account for 5–10% of transitional cell tumours of the urinary tract. The risk factors for these tumours are the same as for bladder cancer. Tumours, especially high-grade ones, in the upper urinary tract are often multifocal and associated with carcinoma in situ (CIS). Approximately 5% of patients who have been diagnosed with bladder cancer will, during follow-up, develop a metachronous UTTCC – usually patients with high-grade tumours or CIS of the bladder. Approximately 40% of patients who present with a UTTCC will, at some point, develop a metachronous bladder cancer, hence the need for endoscopic follow-up after the diagnosis of a UTTCC. The incidence of subsequent bladder tumours in these patients has been shown to be reduced by 25% with a single intravesical dose of mitomycin-C around the time of treatment of the UTTCC. UTTCC often presents late with the disease already invading the muscle of the ureter or renal pelvis, involving lymph nodes or already metastatic.

The standard treatment of UTTCC is nephroureterectomy. In most cases, the surgery to mobilise (a) the kidney and (b) the distal ureter is accomplished using different surgical approaches depending on whether the tumour is high up in the renal pelvis or involves the distal ureter. If the tumour is in the renal pelvis, laparoscopic mobilisation of the kidney and ureter can be combined with endoscopic resection of the ipsilateral intramural ureter to allow nephroureterectomy. If the tumour involves the distal ureter, the distal ureter is usually dissected out using a lower midline incision and opening the bladder – with again laparoscopic mobilisation of the kidney which is then delivered through the open incision. A catheter is needed for around 10 days after nephroureterectomy to allow the bladder to heal satisfactorily. Robotic assistance for this operation is likely to continue to develop.

Summary box 76.21

Upper tract transitional cell carcinoma

- Accounts for 5–10% of urothelial carcinomas
- Often presents late with advanced disease
- In the absence of metastatic disease, standard treatment is nephroureterectomy
- Surgical technique is tailored depending on whether the UTTCC is in the upper ureter/renal pelvis or lower ureter

Wilms' tumour (nephroblastoma)

This mixed tumour contains elements from embryonic nephrogenic tissue (**Figure 76.23**). Nephroblastoma is usually discovered during the first five years of life, usually in one pole of one kidney. Bilateral tumours pose a difficult problem.

Pathology

A rapidly growing tumour is likely to be friable in consistency.

Clinical features

An abdominal tumour grows rapidly in a poorly child. The mass may be very large. Some patients are hypertensive.

Figure 76.23 Wilms' tumour.

Carl Max Wilhelm Wilms, 1867–1918, German surgeon, described Wilms' tumour in 1899.

Haematuria is an unfavourable symptom denoting extension of the tumour into the renal pelvis.

Imaging confirms a solid space-occupying lesion in the kidney, with or without venous invasion, contralateral disease and distant spread.

Metastasis to the lungs occurs early. Liver, bone and brain metastases are rare. Lymphatic spread is uncommon.

Treatment

These children are best treated in specialist paediatric oncology units. Most unilateral tumours are treated by chemotherapy followed by nephrectomy. Partial nephrectomy may be possible in patients with bilateral disease.

Prognosis

Eighty per cent survive long term with modern chemotherapy and surgery. The prognosis is worse in those with metastases and in older children.

Summary box 76.22

Nephroblastoma (Wilms' tumour)

- Usually presents in the first five years of life
- Typically presents with an abdominal mass
- May cause haematuria, abdominal pain or fever
- Metastasises to the lung
- Is best treated in a specialist paediatric oncology unit

Chapter 77

The urinary bladder

Learning objectives

To understand:

- The anatomy, vascular supply and innervation of the bladder in relation to function and disease
- The principles of management of bladder trauma, incontinence and fistulae
- The common causes of acute and chronic urinary retention and management
- The different types of bladder cancer and the principles of management

SURGICAL ANATOMY OF THE BLADDER

- It is lined by transitional epithelium covering the connective tissue lamina propria, which contains a rich plexus of vessels and lymphatics.
- When the detrusor muscle hypertrophies, the inner layer, covered by urothelium, stands out, resulting in the appearance of trabeculation.
- Over the trigone is a thin layer of smooth muscle to which the epithelium is closely adherent and which extends as a sheath around the lower ureters and into the proximal urethra.
- Around the male bladder neck is the smooth muscle internal sphincter innervated by adrenergic fibres, which prevents retrograde ejaculation.
- The distal urethral sphincter is a horseshoe-shaped mass of striated muscle that lies anterior and distal to the prostate, or in the proximal two-thirds of the female urethra. It is distinct from the pelvic floor and is supplied by S2–4 fibres via the pudendal nerve and by somatic fibres passing through the inferior hypogastric plexus.

Fascial and ligamentous supports of the bladder

At the posterolateral bladder neck, condensations of fascia pass forward medially and laterally to the ureter to join with the prostatic fascia; this fascia needs to be divided during cystectomy. The puboprostatic ligaments are well-defined condensations of the anterior endopelvic fascia; they stretch from the front of the prostate to the periosteum of the pubis and lie lateral to the dorsal vein complex. The urachus and obliterated hypogastric arteries, together with the folds of peritoneum overlying them, are called the median and lateral umbilical ligaments. Condensations of fascia also occur around the superior and inferior vascular pedicles.

Arteries

The superior and inferior vesical arteries are derived from the anterior trunk of the internal iliac artery. Branches from the obturator and inferior gluteal arteries (and from the uterine and vaginal arteries in females) also help to supply the bladder.

Veins

The veins form a plexus on the lateral and inferior surfaces of the bladder. In males the prostatic plexus is continuous with the vesical plexus, which drains into the internal iliac vein. In females similar large veins are continuous with the vaginal plexus.

Lymphatics

These accompany the veins and drain to nodes along the internal iliac vessels, and then to the obturator and external iliac chains. Some lymphatics pass to nodes that are situated posteriorly to the internal iliac artery (hypogastric nodes).

INNERVATION

The parasympathetic input

The parasympathetic input (**Figure 77.1**) is derived from the anterior primary divisions of the second, third and fourth

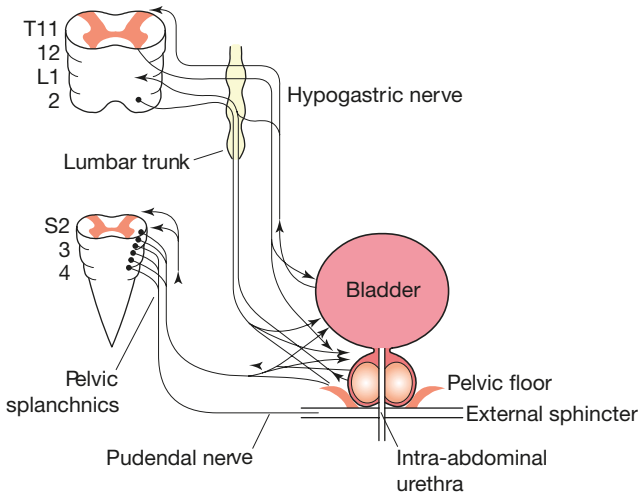

Figure 77.1 The nervous control of the bladder. Micturition is partly a reflex and partly a voluntary act.

sacral segments (mainly S2 and S3). Fibres pass through the pelvic splanchnic nerves to the inferior hypogastric plexus, from where they are distributed to the bladder. The pelvic plexus can be damaged during deep pelvic operations.

The sympathetic input

This arises in the eleventh thoracic to the second lumbar segments; fibres pass via the presacral hypogastric nerve (rather than via the sympathetic chains) to the inferior hypogastric plexus.

Somatic innervation

A somatic innervation passes to the distal sphincter mechanism via the pudendal nerves and also via fibres that pass through the inferior hypogastric plexus.

Figure 77.2 Ectopia vesicae in a man. A drop of urine (arrow) is seen at the left ureteric orifice, the corona glandis being retracted by threads (courtesy of GD Adhia, Bombay, India).

Functional aspects

Sympathetic nerves convey afferents from the fundus. Afferents arise from the mucosa, where they respond to touch, temperature and pain, and from the detrusor and lamina propria, where they convey stretch information. Afferents pass via the inferior hypogastric plexus to the posterior roots of S2–4. Some aspects of micturition are centred in the pons, where detrusor contraction is coordinated with inhibition of the distal sphincter. Interruption of this pathway below the pons, with preservation of the sacral cord. is likely to result in a contractile detrusor and tonically active distal sphincter that will not relax during voiding (detrusor–sphincter dyssynergia).

CONGENITAL DEFECTS OF THE BLADDER

Bladder exstrophy

Clinical features

Bladder exstrophy occurs in 1:50 000 births (male:female ratio 4:1) (**Figure 77.2**). In males, the penis is broad and short, and bilateral inguinal herniae may be present. There is separation of the pubic bones (**Figure 77.3**). In epispadias alone, the pubes are united and external genitalia are almost normal, although in females the clitoris is bifid (**Figure 77.4**).

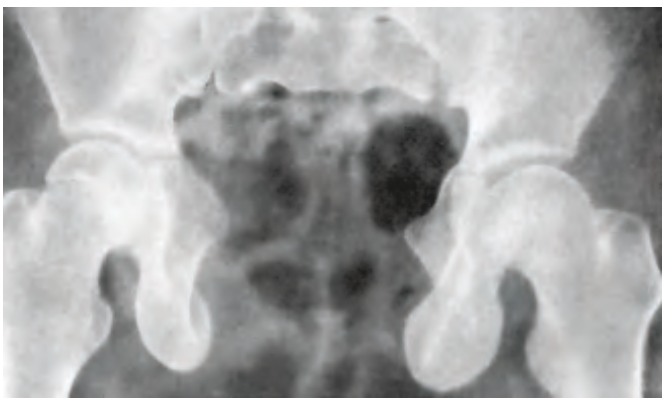

Figure 77.3 Separation of the pubes in a case of ectopia vesicae (courtesy of the late Professor Grey Turner, London, UK).

Figure 77.4 Female epispadias showing deficient sphincter and bifid clitoris.

Treatment

The bladder is closed in the first year of life, usually after osteotomy of both iliac bones just lateral to the sacroiliac joints. Later, reconstruction of the bladder neck and sphincters is required. In some patients the reconstructed bladder remains small and requires augmentation. One-stage reconstruction is being practised in some major centres.

Less satisfactorily, urinary diversion can be carried out by means of ureterosigmoid anastomosis, an ileal or colonic conduit, or continent urinary diversion. Long-term complications include: (1) stricture at the site of anastomosis with bilateral hydronephrosis and infection; (2) hyperchloraemic acidosis; and (3) an increased (20-fold) risk of tumour formation (adenoma and adenocarcinoma) at the site of a ureterocolic anastomosis.

BLADDER TRAUMA

Bladder rupture

This can be intraperitoneal (20%) or extraperitoneal (80%) (**Figures 77.5 and 77.6**). Intraperitoneal rupture is usually secondary to a blow or fall on a distended bladder, and more rarely to surgical damage. Extraperitoneal rupture is caused by blunt trauma or surgical damage. Gross haematuria can be absent. It may be difficult to distinguish extraperitoneal rupture from rupture of the membranous urethra (see Chapter 79). Intraperitoneal rupture is associated with sudden severe pain in the hypogastrium, often accompanied by syncope. The shock subsides and the abdomen distends and there is no desire to micturate. Peritonitis does not follow immediately if the urine is sterile; varying degrees of rigidity are present on examination.

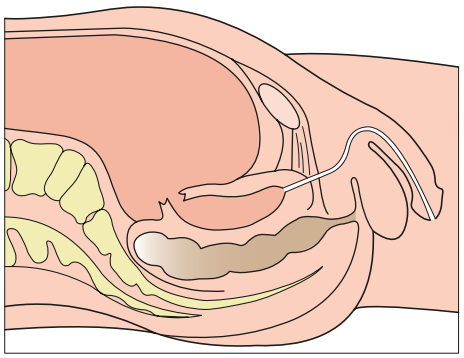

Figure 77.5 Intraperitoneal extravasation of urine.

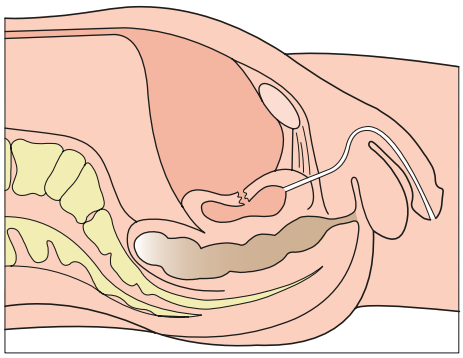

Figure 77.6 Extraperitoneal extravasation of urine.

Investigation

Computed tomography (CT) is ideal. Plain erect radiographs may show a ground-glass appearance (fluid). Intravenous urography (IVU) may confirm a leak. Retrograde cystography will confirm the diagnosis (**Figure 77.7**). It is important to image the patient after drainage of contrast because the full bladder may mask extravasation.

Treatment of intraperitoneal rupture

A lower midline laparotomy should be performed; the edges of the rent are trimmed and sutured with a single-layer 2/0 absorbable suture. A suprapubic and a urethral catheter are placed. Very rarely, the rupture will be through an unsuspected tumour; a biopsy can be taken before suturing the defect. Laparoscopic approaches are also now being used.

Injury to the bladder during operation

The bladder may be injured in (1) inguinal or femoral herniotomy, (2) hysterectomy and (3) excision of the rectum. If the injury is recognised, the bladder must be repaired and catheter

Figure 77.7 Cystogram of a patient who has fallen over and developed severe abdominal pain. Leakage of contrast into the peritoneal cavity is seen.

Summary box 77.1

Bladder trauma

- Intraperitoneal or extraperitoneal
- Suspected if there is trauma and damage to the pelvis
- May be diagnosed by retrograde cystography

drainage maintained for 7 days. If it is not recognised, the treatment is similar to that of rupture of the bladder.

When accidental extraperitoneal perforation of the bladder occurs during endoscopic resection, drainage of the bladder with a urethral catheter and the administration of antibiotics usually suffice. If a mass of extravasated fluid is present it is best to place a small drain through a stab incision. A laparotomy will usually be required if an intraperitoneal perforation is caused by transurethral resection.

Summary box 77.2

Management of bladder trauma

- Extravesical injury – catheter drainage for 10 days
- Intraperitoneal injury – laparotomy, repair and bladder drainage

RETENTION OF URINE (SEE ALSO CHAPTER 78)

Acute retention

There are many possible causes of acute retention of urine.

Summary box 77.3

The most frequent causes of acute retention

Male

- Bladder outlet obstruction (the most common cause)
- Urethral stricture
- Acute urethritis or prostatitis
- Phimosis

Female

- Retroverted gravid uterus
- Bladder neck obstruction (rare)

Both

- Blood clot
- Urethral calculus
- Rupture of the urethra
- Neurogenic (injury or disease of the spinal cord)
- Smooth muscle cell dysfunction associated with ageing
- Faecal impaction
- Anal pain (haemorrhoidectomy)
- Intensive postoperative analgesic treatment
- Some drugs
- Spinal anaesthesia

Clinical features

- No urine is passed for several hours.
- Pain is present.
- The bladder is visible, palpable, tender (Figure 77.8) and dull to percussion.
- Potential neurological causes should be excluded by checking reflexes in the lower limbs and perianal sensation.

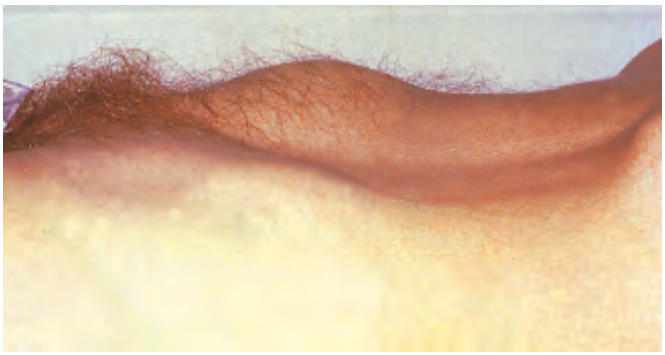

Figure 77.8 Distended bladder in a man who presented with retention of urine.

Treatment

Treatment is to pass a fine urethral catheter (14F – French gauge is defined as the circumference in millimetres) and arrange urological management. Occasionally, in postoperative retention a warm bath can help (Figures 77.9–77.12).

URETHRAL CATHETERISATION

After a thorough hand wash, sterile gloves are donned. The genitalia are cleaned using soapy antiseptic. Lidocaine gel is inserted into the urethra, warning the patient that this may create stinging. The jelly should be massaged posteriorly in an attempt to anaesthetise the sphincter region, and it is of advantage to place a penile clamp for several minutes. A small Foley catheter should be passed while the penis is held

Figure 77.9 Cleaning of the penis before catheterisation.

Figure 77.10 Insertion of local anaesthetic before insertion of a catheter.

Figure 77.11 The use of a penile clamp to ensure that sufficient time is given to allow the anaesthetic to work before the catheter is inserted.

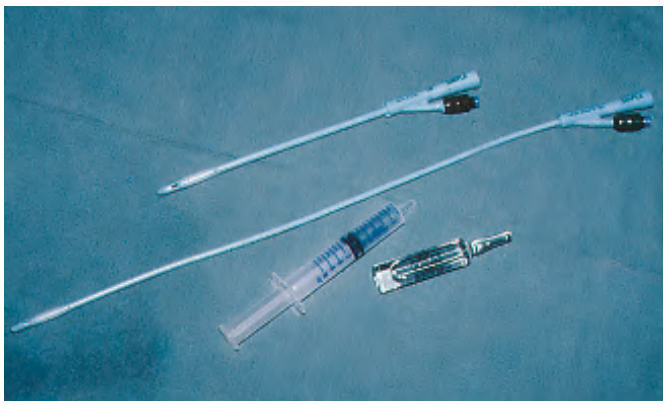

Figure 77.12 A selection of silicone catheters.

taut. In a female patient, the labia should be parted using the middle and index fingers of the left hand, which should not be moved once cleaning has been performed. Provided that a stricture is not the cause, the catheter should pass freely. Once urine begins to drain it is wise to pass a few more centimetres of catheter into the bladder before the balloon is inflated to avoid inflation in the prostate. Force must not be used.

Summary box 77.4

Catheterisation for acute retention of urine

After catheterisation:

- Record the volume of urine drained
- Examine the abdomen to exclude other pathology (rupture of an aortic aneurysm, ureteric colic or diverticulitis can cause confusion)

If the catheter will not pass, it is usually due to poor technique, lack of anaesthesia, traumatisation of the urethra or a urethral stricture. Occasionally, a large prostatic middle lobe may prevent the catheter entering the bladder; sometimes a coudé catheter will pass. If a catheter cannot be passed the following plan should be pursued.

Suprapubic puncture

Suprapubic puncture with commercially available catheters such as Cystofix or Lawrence Add-a-Cath catheters is straightforward provided that the bladder is palpable. The skin, fascia and retropubic space are anaesthetised with 0.5% lidocaine. Correct placement is confirmed by aspiration. A large-bore needle is then placed into the bladder, down which a fine catheter is passed (Cystofix) and then secured in position. The other option is to place a plastic suprapubic trocar and cannula, which has a removable plastic strip on the side. A standard 12F Foley catheter can be passed down the cannula, the balloon is inflated, the cannula is extracted and the strip pulled away from the catheter (Add-a-Cath). If urine cannot be aspirated through the fine-bore needle, passing a suprapubic trocar should not be attempted.

If these devices are not available, a catheter can be placed in the bladder under direct vision through a small incision under local anaesthetic.

Urethral instrumentation

In a patient with a known stricture, an experienced urologist may elect to dilate the stricture or to take the patient to theatre to carry out an optical urethrotomy (see Chapter 79).

Chronic retention

In chronic retention there is no pain. These patients are at risk of upper tract dilatation because of high intravesical tension – they require urgent urological referral. Men with impaired renal function may develop postobstructive diuresis after catheterisation. Such men need careful monitoring, with replacement of inappropriate urinary losses by intravenous saline; they are also at risk of haematuria as the distended urinary tract empties. Often it is several days before full renal recovery occurs.

Retention with overflow

The patient is incontinent with small amounts of urine passing involuntarily from the distended bladder. It usually follows a neglected retention.

Indwelling catheters and closed systems of catheter drainage

The risk of ascending infection is decreased by connecting the catheter to sterile tubing connected to a collecting bag. Irrigations should be avoided unless clot retention occurs. When a catheter has been *in situ* for a few days, some degree

Frederic Eugene Basil Foley, 1891–1966, urologist, Anker Hospital, St Paul, MN, USA.

of urethritis and bacteriuria is likely; changing a catheter then entails risks of severe infection if prophylactic antibiotics are not used (Figure 77.13).

Acute retention due to drugs

A number of drugs can induce retention, including antihistamines, antihypertensives, anticholinergics and tricyclic antidepressants.

The acute neuropathic bladder

1 Immediately after spinal cord injury, 'spinal shock' occurs (see Chapter 25), which may last for days or months. The detrusor cannot contract, the bladder distends and overflow incontinence occurs. Neglected bladder distension will lead to damage to the detrusor, infection and ultimately renal failure. Management is as follows.
2 The bladder must be emptied by aseptic intermittent catheterisation performed two or three times daily or the use of an indwelling urethral catheter on continuous drainage, making sure that the patient has a high urinary output (3 litres per day) to combat infection. Currently, intermittent catheterisation is preferred as soon as the patient's spinal injury is stable.
3 Neurological examination must be performed to assess the level of sensory and motor loss. Ischaemic necrosis of the cord may extend below the upper level of cord injury. When sensory loss below the upper level is total, recovery is unlikely. Incomplete lesions may recover somatic and bladder function.
4 Demonstration of intact bulbocavernosus and anal reflexes indicates that the sacral cord and nerves are intact and that reflex bladder contractions are likely to develop, although they may be insufficient to empty the bladder. If there is persistent total loss of reflexes and perineal sensation then either the sacral cord or the cauda equina is damaged. In such circumstances an acontractile bladder is likely. In cauda equina lesions there may be sensory, motor or mixed loss.
5 Full urodynamic assessment of bladder function should be undertaken when the injury is stable. This allows an accurate assessment of bladder and sphincter activity and will enable decisions to be made about further management; the prime aim is to prevent upper tract damage by promoting good bladder emptying.

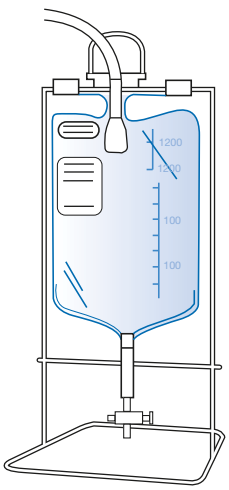

Figure 77.13 Modern Simpla bag used for continuous bladder drainage. (The nurse who is emptying the bag should be wearing disposable gloves to avoid contaminating the hands with organisms.)

Summary box 77.5

Clinical management of spinal injury

- The bladder should be emptied during spinal shock by catheterisation
- Encourage high fluid intake
- Commence intermittent catheterisation
- When the patient is stable undertake full urodynamic evaluation

The following situations represent the typical patterns of bladder function seen after spinal cord injury.

Lesions above T10

Usually leads to an 'upper motor neuron' bladder with reflexes intact but isolated from higher control mechanisms. Such patients are at risk of autonomic dysreflexia.

As a result of detrusor–sphincter dyssynergia, bladder contractions are high pressure and ineffective in producing bladder emptying; the bladder neck is normally open. If left untreated, upper tract dilatation and renal failure may result. Bladder capacity is usually decreased with the development of trabeculation and a typical 'fir-tree' appearance. Patients are incontinent during high-pressure phasic contractions because the sphincter resistance suddenly diminishes.

Some patients with low-pressure bladders that empty may be managed by means of condom drainage. Others will require clean, intermittent, self-catheterisation (CISC), popularised by Lapides. Patients with poor emptying, low bladder capacity and upper tract dilatation require treatment with endoscopic sphincterotomy and condom drainage. Some carefully selected patients may require bladder reconstruction.

Lesions involving the sympathetic outflow (T11, T12, L1, L2)

These patients are usually similar to the group with lesions above T10.

Damage to the sacral centre S2, S3, S4 and cauda equina lesions

Usually leads to a 'lower motor neuron' bladder, also found in spina bifida (myelodysplasia); the detrusor is acontractile. Abdominal straining can produce reasonable emptying but the mainstay is CISC. Some patients may have sensation of filling through the hypogastric nerves if T11 and T12 are intact. The bladder capacity may be good, but some patients have high resting pressures and high increases during bladder filling, which

means that there is a risk to the upper urinary tract. The bladder neck is usually open and the distal sphincter mechanisms may be paralysed but of fixed resistance. Vesicoureteric reflux is common and upper tract damage is frequent in neglected cases. Patients who can achieve satisfactory bladder emptying by means of CISC usually have reasonable continence.

Bladder dysfunction after excision of the rectum or radical hysterectomy

Between 10% and 15% of patients undergoing radical rectal excision for cancer sustain damage to the inferior hypogastric plexus, leading to impotence in males and neurogenic bladder dysfunction. This type of bladder dysfunction is similar to the cauda equina lesion. Postoperative retention in other patients may also be caused by simple bladder outlet obstruction. The best plan is to catheterise the patient to allow postoperative recovery and then carry out urodynamic investigation to determine the appropriate treatment.

INCONTINENCE OF URINE

Overall, urinary incontinence occurs in 5% of men and 20% of women. Up to 40% of women over the age of 60 years and 50% of institutionalised elderly patients experience regular episodes of urinary incontinence. Health problems include skin breakdown and depression, and loss of esteem and sexual activity. Continence is dependent on normal mobility and brain function allowing a perception of when it is socially acceptable to void, normal bladder sensation, normal voluntary detrusor contraction producing good bladder emptying, a normally competent sphincter mechanism, which relaxes appropriately during a voluntary detrusor contraction allowing good bladder emptying, and good bladder capacity with normally low pressures during filling. This is clearly a fine balance and several factors can cause incontinence. In children, non-neurogenic incontinence is often associated with other dysfunctional conditions such as infections, constipation, psychological factors, increased fluid intake, intentional misconduct or an overactive bladder. Several investigations are required for diagnosis of urinary incontinence.

Summary box 77.6

Diagnosis of urinary incontinence

The following investigations are required:

- A careful history and physical examination and completion of frequency voiding charts
- Urodynamic testing in most patients and in all patients in whom surgical intervention is proposed
- Urine culture to exclude infection and measurement of serum creatinine

In selected cases IVU is carried out if a ureteric fistula is suspected, although ultrasound examination will often provide adequate details

Urodynamic testing

The key to the practical management of lower urinary tract dysfunction, and particularly incontinence, lies with urodynamic investigation. The principle is to artificially simulate bladder filling and emptying while obtaining pressure measurements (**Figure 77.14**).

The patient attends with a full bladder and is allowed to void in private to measure the maximum urinary flow rate. After voiding, the residual urine is measured by ultrasound. A pair of catheters or a twin-lumen catheter is passed into the bladder, which allows the bladder to be filled at a rate of 50 mL/min while a continuous recording of intravesical pressure is made. To obtain 'true' detrusor pressure, a second channel is required to assess intra-abdominal pressure, measured by means of a small intrarectal or intravaginal balloon. The bladder is filled until the patient states that the bladder is full. Radiographic screening may be carried out to assess bladder neck closure and urinary leakage during movement or coughing (stress incontinence) or during bouts of phasic detrusor pressure (detrusor instability). The patient is then asked to void at the end of bladder filling after the filling catheter has been removed (**Figure 77.15**).

The normal bladder will accept approximately 400–550 mL when filled at room temperature at a rate of <50 mL/min. The pressure increase in the bladder should be less than 15 cmH_2O. In addition, phasic pressure increases should not be seen. The normal voiding pressure should not exceed 60 cmH_2O in men and about 40 cmH_2O in women, with a flow rate of between 20 mL/s and 25 mL/s.

Common abnormalities identified during urodynamic testing in incontinence

THE OVERACTIVE BLADDER

Phasic increases in pressure give rise to urgency and urge incontinence (detrusor overactivity; **Figure 77.16**). This abnormality is found in patients with neurogenic bladder

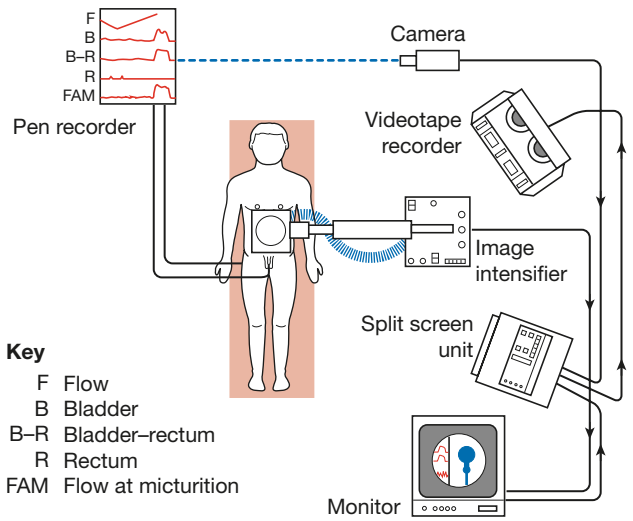

Figure 77.14 Urodynamic study.

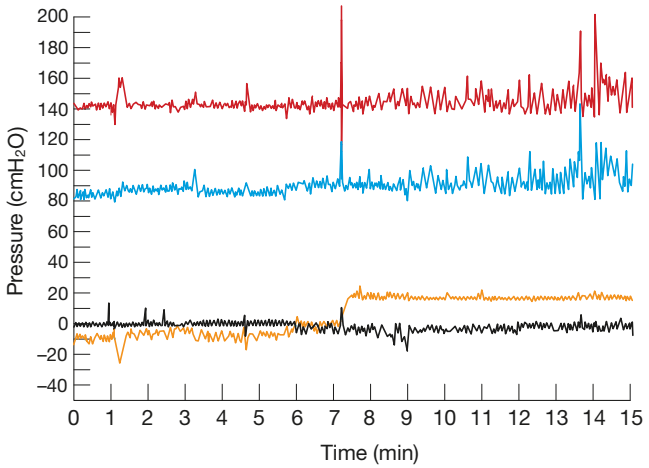

Figure 77.15 A section of an ambulatory, natural-fill urodynamic trace. The rectal pressure is in red, the bladder pressure in blue and the subtracted detrusor trace in black. The orange trace is the output of an electronic nappy, which records urinary leakage. A cough is shown, which results in genuine stress incontinence.

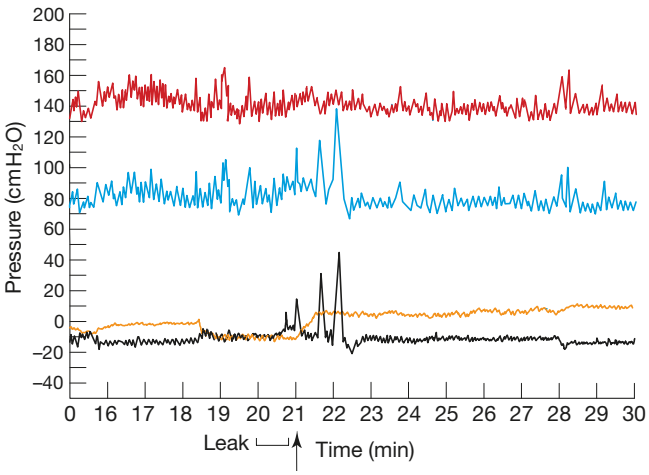

Figure 77.16 A section of an ambulatory, natural-fill urodynamic trace. The rectal pressure is in red, the bladder pressure in blue and the subtracted detrusor trace in black. The orange trace is the output of an electronic nappy, which records urinary leakage. Phasic activity is shown, which is detrusor instability resulting in urge incontinence.

dysfunction, such as in multiple sclerosis (MS) or Parkinson's disease, or after a stroke or spinal injury, when it is known as detrusor hyperreflexia. About 50% of men with bladder outflow obstruction have detrusor instability, and in about half of them the instability resolves after prostatectomy. Idiopathic detrusor overactivity is common and must be distinguished from genuine stress incontinence (GSI) in women before performing bladder neck suspension procedures. In children, overactive bladder symptoms must be carefully investigated and treated with conservative measures before initiating antimuscarinic therapy.

GENUINE STRESS INCONTINENCE

This is defined as urinary leakage occurring during increased bladder pressure when this is solely due to increased abdominal pressure and not to increased true detrusor pressure (see **Figure 77.15**). It is caused by sphincter weakness.

CHRONIC URINARY RETENTION

Chronic urinary retention with overflow incontinence is recognised by a large residual volume of urine **(Figure 77.17)** and is usually associated with high pressures during bladder filling.

BLADDER OUTFLOW OBSTRUCTION

Bladder outflow obstruction is associated with increased voiding pressures, often in excess of 90 cmH_2O **(Figure 77.18)**, coupled with low urinary flow rates.

NEUROGENIC DYSFUNCTION

Neurogenic bladder dysfunction may also be identified.

Causes of incontinence

There are various ways of classifying the causes of incontinence.

- **Problems of social control.** Patients with dementia often have incontinence because of uninhibited detrusor hyperreflexia and impaired social perception.
- **Storage problems.** Patients with a small bladder capacity owing to fibrosis (tuberculosis, radiotherapy or interstitial cystitis) can develop incontinence. Patients with a small functional capacity owing to severe detrusor instability, neurogenic dysfunction or infection can develop incontinence.
- **Impairment of emptying.** Patients with chronic retention or neurogenic bladder dysfunction have small functional bladder capacities with detrusor overactivity causing incontinence, despite having large residual volumes of urine.
- **Weak sphincter.** This leads to GSI and can follow surgical procedures such as radical prostatectomy in men.

Figure 77.17 An ultrasound scan showing a large postvoid residual urine.

James Parkinson, 1755–1824, general practitioner of Shoreditch, London, UK, published *An essay on the shaking palsy* in 1817.

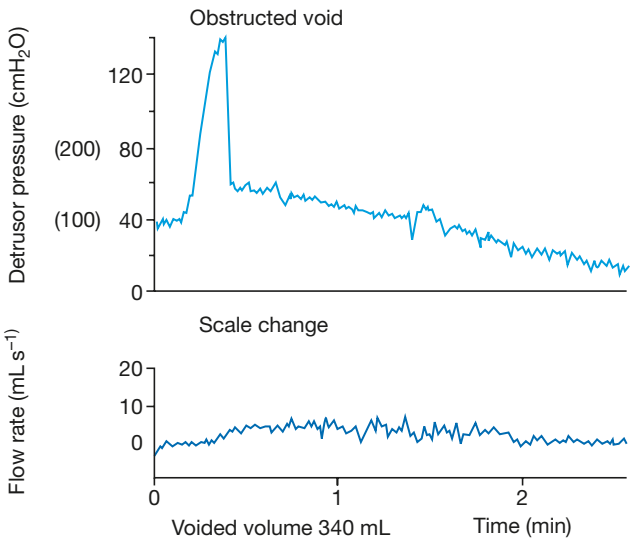

Figure 77.18 A conventional urodynamic trace showing detrusor pressure during voiding. There has been a change of scale because the pressure was so high; voiding pressures are increased with a low flow rate, which is diagnostic of bladder outflow obstruction.

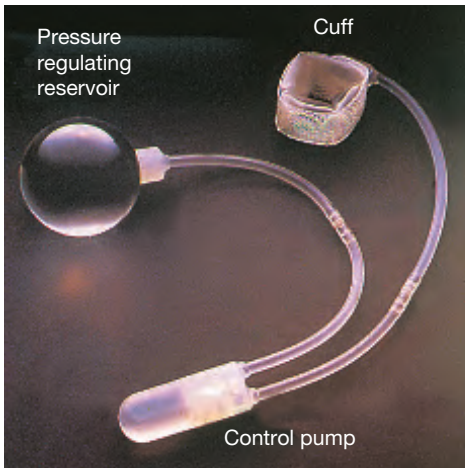

Figure 77.19 The artificial urinary sphincter made by American Medical Systems.

- **Fistulae.** Leakage from fistulae or upper tract duplication with an ectopic ureter.
- **In children**, the causes must be carefully investigated and treated with conservative measures before initiating anti-muscarinic therapy.

The common causes may be classified into male, female or mixed-sex groups.

Summary box 77.7

Uses of urodynamic testing

- To distinguish genuine stress incontinence (due to sphincter weakness) from detrusor instability in women (see **Figure 77.15**)
- For the classification of neurogenic bladder dysfunction
- To distinguish bladder outflow obstruction from idiopathic detrusor instability in men
- To investigate incontinence or other lower urinary tract symptoms

Male incontinence

CHRONIC URINARY RETENTION WITH OVERFLOW

This may be due to benign prostatic hypertrophy, carcinoma of the prostate, urethral stricture and, in younger men, hypertrophy of the bladder neck. Examination may reveal that the bladder is distended, and it can be confirmed by ultrasonography. The treatment is discussed in Chapter 78.

POST-PROSTATECTOMY

Post-prostatectomy incontinence may result from injury to the external sphincter mechanism. Treatment should be conservative initially with pelvic floor exercises, and an anastomotic stricture must be excluded. The condition may necessitate insertion of an artificial urethral sphincter (**Figure 77.19**).

Female incontinence

STRESS INCONTINENCE

The most common cause is GSI although, in some parts of the world, vesicourethral fistulae as a result of neglected labour are common. It is usually found in multiparous women with a history of difficult labour. It can be found in normal young women who indulge in competitive trampolining and in patients with epispadias. The classic symptom is urine loss during coughing, laughing, sneezing or a sudden change of posture. The symptoms may change with the menstrual cycle. The volume of urine loss can be measured during an exercise test, which is performed by putting the patient through a standard set of tests with 300 mL of fluid in the bladder; in GSI the fluid losses usually range from 10 mL to 50 mL. Urinary frequency and urgency are often found in such patients because they try to avoid incontinence by frequent voiding.

Idiopathic detrusor instability can mimic GSI and coexist with it. It is important to make a correct preoperative diagnosis by urodynamic measurements, because the outcome of surgery is suboptimal in women with idiopathic detrusor instability.

Minor-to-moderate stress urinary incontinence can be controlled by pelvic floor exercises. However, if this fails, surgery is indicated. Standard operations include open colposuspension or the use of a minimally invasive approach involving the insertion of a transvaginal tape (TVT procedure).

OPEN COLPOSUSPENSION

This operation is carried out through a Pfannenstiel incision with the patient in the Lloyd-Davies position. The vaginal fascia is identified by sweeping the bladder off the vagina, and three sutures are placed on each side between the vaginal fascia and the iliopubic ligament. A suprapubic catheter is

Hermann Johann Pfannenstiel, 1862–1909, gynaecologist, Breslau, Germany (now Wroclaw, Poland), described this incision in 1900.
Oswald Lloyd-Davies, 1905–1987, surgeon, St Mark's Hospital and the Middlesex Hospital, London, UK.

placed. Voiding difficulties are frequent but usually temporary. It is best to warn women with large bladder capacities and low voiding pressures that this complication may occur and that they may be required to carry out CISC for a period. The operation is very successful for the treatment of GSI, with good results at 1 year in 90% of patients, which are maintained in about 80% of patients at 5 years.

Modifications of bladder neck suspension can also be achieved by minimally invasive approaches such as the transvaginal sling. This technique does reduce both hospital stay and postoperative morbidity.

Incontinence common to both sexes

IDIOPATHIC DETRUSOR OVERACTIVITY

Phasic increases in bladder pressure may occur during filling in otherwise normal patients (idiopathic) or it may be found in neurogenic bladder dysfunction (when it is known as detrusor hyperreflexia) and bladder outflow obstruction. Idiopathic detrusor overactivity may be asymptomatic but usually results in symptoms of frequency, urgency, urge incontinence, nocturia or nocturnal incontinence (enuresis), depending on the severity of the instability. It must be distinguished from GSI and from bladder outflow obstruction before surgical treatment. Infection, tuberculosis or carcinoma *in situ* (CIS) should be excluded. The mainstay of treatment is the use of various anticholinergic medications (oxybutynin and tolterodine). Severe symptoms resistant to conventional conservative treatment, resulting in major impairment of quality of life, may need more aggressive treatment such as enterocystoplasty or the injection of small doses of botulinum toxin (the toxin from *Clostridium botulinum*), known as BoTox, which blocks cholinergic neuromuscular transmission, at least for a time.

AGEING

Ageing can result in smooth muscle cell dysfunction, which can cause combinations of small functional capacity, detrusor overactivity, impaired bladder emptying and symptoms of lower urinary tract dysfunction.

CONGENITAL

Congenital causes include ectopic vesicae and severe epispadias. The abnormal entry of an ectopic ureter distal to the sphincter complex or into the vagina in a female patient should theoretically result in total urinary incontinence. This is discussed in Chapters 9 and 76.

TRAUMA

Trauma, whether from pelvic surgery or associated with pelvic fracture, may result in disruption of the nerve supply to the bladder or urethra, or in fistula formation.

INFECTION

Lower urinary tract infection (UTI) may be sufficient to induce urinary incontinence. A history of frequency, burning and a fever should prompt the diagnosis. Symptoms will usually settle with a course of antibiotics, but in the case of recurrent infection further investigation of the urinary tract will clearly be indicated.

NEOPLASIA

Locally advanced cancers in the pelvis, particularly carcinoma of the cervix in a woman and carcinoma of the prostate in a man, may result in direct invasion of the sphincter mechanism causing incontinence; occasionally, fistula formation may occur in women.

Other causes

CONSTANT DRIBBLING OF URINE COUPLED WITH NORMAL MICTURITION

This occurs when there is a ureteric fistula or an ectopic ureter associated with a duplex system opening into the urethra beyond the urethral sphincter in females or into the vagina. The history is diagnostic, and IVU or ultrasonography may reveal the upper pole segment, which is often poorly functioning. Treatment is by excision of the aberrant ureter and portion of kidney. A ureteric fistula can be difficult to diagnose and its demonstration may require retrograde ureterography and a high degree of suspicion.

NOCTURNAL ENURESIS

This is a condition of young children and young adults. Of course, the time at which children become dry at night varies and, in some, nocturnal enuresis is merely a delayed onset of continence. In others, it persists until late adolescence and is classified into primary and secondary nocturnal enuresis. In children, once neurogenic dysfunction has been excluded, the condition can be associated with other symptoms such as intentional misconduct, infections, constipation and increased fluid intake. These causes must be ruled out before medication is considered.

Primary nocturnal enuresis occurs in patients with nocturnal symptoms alone, which are absent during the day. Often, they have been dry for a period, and the vast majority of patients will eventually become dry. In the meantime, a sympathetic approach to these children is essential. They often respond to a system of rewards using a 'star' chart. In addition, the use of DDAVP (a vasopressin analogue) can produce increased urinary concentration at night with a decrease in nocturnal incontinence. Other treatments include the use of an alarm that wakes the child (or at least the child's parents) when incontinence occurs and medication in the form of an anticholinergic drug such as oxybutynin.

Treatments for incontinence

Treatments are listed below. Management is dependent on making a correct diagnosis.

Management and treatment

After careful assessment and investigation, many cases of incontinence can improve with simple measures such as lifestyle interventions, pelvic floor exercises with biofeedback, bladder training and incontinence devices where necessary. In mixed urge and stress incontinence, the major component has to be treated first.

PROBLEMS OF SOCIAL FUNCTIONING

Patients with dementia may respond to regular toileting. Anticholinergic agents can cause increased confusion in these patients and often, in severe cases, an indwelling catheter is needed.

STORAGE PROBLEMS

Patients with a small bladder capacity because of fibrosis may require augmentation cystoplasty. Detrusor overactivity will require treatment with anticholinergic medication but, in severe cases, particularly in neuropathic patients at high risk of upper tract dilatation, bladder substitution (near-total supratrigonal cystectomy followed by the need for detubularised ileocaecal segment bladder substitution) or augmentation (enterocystoplasty) may be needed. These procedures should be carried out only after careful assessment in units used to dealing with such problems. Patients with very impaired mobility and MS may require ileal conduit diversion. The use of intravesical injections of BoTox has provided good improvements, and it may avoid or delay the need for major surgery.

IMPAIRED BLADDER EMPTYING

Patients with overflow incontinence because of bladder outflow obstruction will usually respond well to prostatectomy. Patients with impaired bladder emptying because of neurogenic bladder dysfunction should be treated in the first place by means of CISC.

WEAK SPHINCTER

Patients with GSI should be treated by means of pelvic floor exercises initially. Duloxetine can be used as medical treatment for GSI. Bulking agents, such as macroplastique, can be used and can provide good temporary solutions. Surgical treatment by means of colposuspension or TVT may be needed. Those with post-prostatectomy incontinence or neurogenic bladder dysfunction may need to be fitted with an artificial urinary sphincter (see **Figure 77.19**), if they are well motivated and mobile, but careful assessment is required.

Use of appliances

An indwelling catheter drained constantly into a leg urinal may be a satisfactory solution although, in some instances, diversion via an ileal conduit is necessary. In men, a condom urinary appliance may be satisfactory and can avoid an indwelling catheter.

More major surgical treatments

VARIOUS TYPES OF URINARY DIVERSION

Urinary diversion may be required for the treatment of end-stage incontinence that is not otherwise treatable (see later in this chapter).

BLADDER SUBSTITUTION PROCEDURES

The principle behind these operations is the creation of a low-pressure, large-capacity reservoir, which can be made using any segment of bowel isolated on its vascular pedicle (**Figures 77.20–77.22**). This is then detubularised by dividing its anti-mesenteric border and suturing this into a plate,

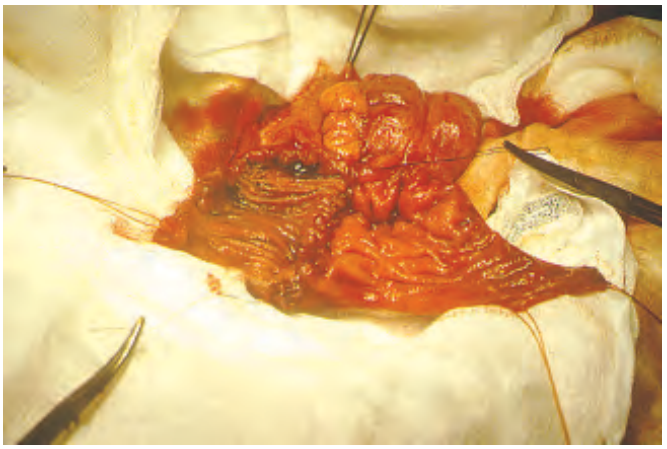

Figure 77.20 A vascularised ileocaecal segment being detubularised.

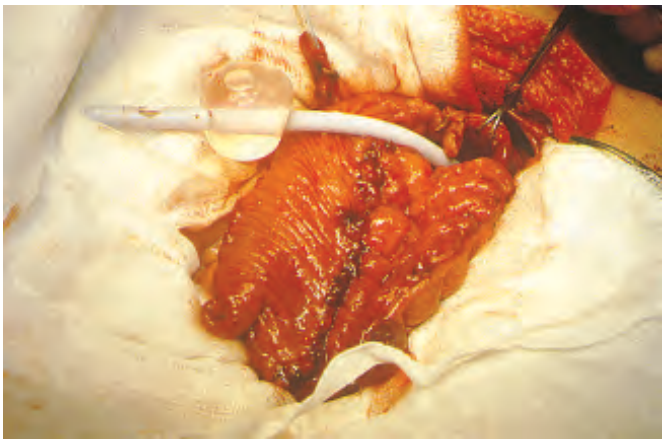

Figure 77.21 An ileocaecal segment being anastomosed to the trigone after near-total cystectomy; the left ureter is about to be implanted by means of a Camay–Le Duc anastomosis.

Figure 77.22 A capacious ileocaecal reservoir to be used in a patient requiring bladder substitution. These segments may be used for total bladder replacement, bladder substitution and the construction of continent diversion with a Mitrofanoff-type anti-incontinence mechanism (see later in the chapter).

which is then reconfigured into a spherical structure. This reservoir can then be anastomosed to the bladder remnant after excision of the fundus above the trigone. If necessary, the ureters can be reimplanted into the bowel segment. This new bladder will need to be emptied by means of CISC in up to 30% of cases.

'CLAM' ENTEROCYSTOPLASTY

This procedure was originally described by Bramble for the treatment of nocturnal enuresis. It has been used in the treatment of idiopathic detrusor instability (**Figure 77.23**). This procedure can also be used as an augmentation procedure in patients with neurogenic bladder dysfunction and a reasonable bladder capacity (approximately 300 mL).

FITMENT OF ARTIFICIAL URINARY SPHINCTER

See **Figure 77.19**.

Summary

Treatments for incontinence can be summarised as follows:

1 **Conservative** measures such as lifestyle interventions, pelvic floor muscle and bladder training.
2 **Devices for collection**: external penile condom or an indwelling urethral or suprapubic catheter.
3 **Drugs**: to decrease the strength of the bladder neck (e.g. adrenergic blockers); with mixed action on the bladder neck and central nervous system (e.g. tricyclic drugs); to inhibit bladder activity (e.g. anticholinergic drugs). Botulinum toxin A is used in selected patients. Duloxetine can be used as medical treatment for GSI – it is a serotonin–noradrenaline reuptake inhibitor.
4 **Intermittent self-catheterisation**: to improve emptying.
5 **Increasing outlet**: pelvic floor physiotherapy; resistance colposuspension or TVT tapes or slings; periurethral injections of 'bulking agents' such as cross-linked collagen or other particles; use of the artificial urinary sphincter.
6 **Denervation of bladder**: S3 sacral nerve blockade, neurectomy or surgical transection of the bladder to inhibit bladder activity and improve functional capacity. These are rarely used nowadays because of the use of botulinum toxin and the clam cystoplasty or S3 nerve stimulation (see point 7).
7 **Sacral nerve stimulation devices** can improve incontinence. They involve percutaneous insertion of electrodes through the sacral foramina under radiological control and implantation of an electronic stimulator.
8 **Augmentation of bladder**: 'clam' enterocystoplasty, bladder capacity substitution with detubularised bowel segment.
9 **Urinary diversion**: ileal conduit, continent urinary diversion.

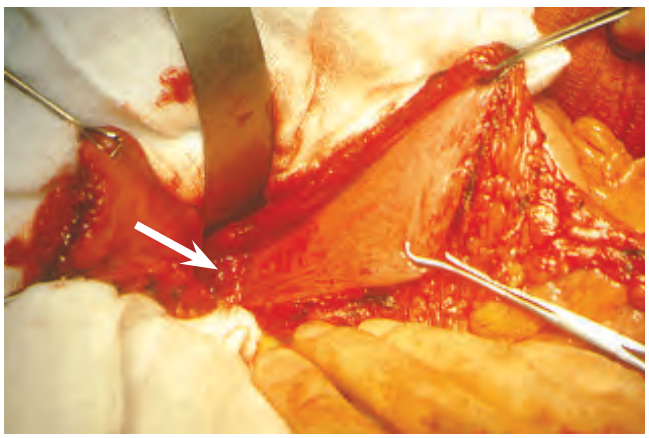

Figure 77.23 A 'clam' cystoplasty being performed. One of the ureteric orifices can be seen with the interureteric bar (arrow); the defect will be filled by a segment of detubularised ileum, performing a bladder augmentation.

BLADDER STONES

Definition

A primary bladder stone is one that develops in sterile urine; it often originates in the kidney. A secondary stone occurs in the presence of infection, outflow obstruction, impaired bladder emptying or a foreign body.

Incidence

Until the twentieth century, bladder stone was a prevalent disorder among poor children and adolescents. As a result of improved diet, especially an increased protein:carbohydrate ratio, primary vesical calculus is rare.

Composition and cystoscopic appearance

Most vesical calculi are mixed. An oxalate calculus is a primary calculus that grows slowly; usually, it is of moderate size and solitary, and its surface is uneven (**Figure 77.24**). Although calcium oxalate is white, the stone is usually dark brown or black because of the incorporation of blood pigment. Uric acid calculi are round or oval and smooth, and vary in colour from yellow to brown (**Figure 77.25**). They occur in patients with gout but are also found in patients with ileostomies or bladder outflow obstruction. A cystine calculus occurs only in the presence of cystinuria and is radio-opaque because of its high sulfur content. A triple phosphate calculus is composed of ammonium, magnesium and calcium phosphates and occurs in urine infected with urea-splitting organisms. It tends to grow rapidly. In some instances it occurs on a nucleus of one of the other types of calculus; more rarely it occurs on a foreign body (**Figures 77.26 and 77.27**). It is dirty white in colour and of chalky consistency.

A bladder stone is usually free to move in the bladder and it gravitates to the lowest part of the bladder. Less commonly, the stone is wholly or partially in a diverticulum, where it may be hidden from view.

Clinical features

Men are affected eight times more frequently than women. Stones may be asymptomatic and found incidentally.

Frank James Bramble, formerly urologist, the Royal Victoria Hospital, Bournemouth, UK.

Figure 77.24 A rough bladder stone.

Figure 77.25 Smooth uric acid-type stones.

Figure 77.26 Stone on a vaginal sling that had eroded into the bladder.

Symptoms

Frequency is the earliest symptom and there may be a sensation of incomplete bladder emptying. Pain (strangury) is most often found in patients with a spiculated oxalate calculus. It occurs at the end of micturition and is referred to the tip of the penis or the labia majora; more rarely it is referred to the perineum or suprapubic region. The pain is worsened by movement. In young boys, screaming and pulling at the penis with the hand at the end of micturition are indicative of a bladder stone. Haematuria is characterised by the passage of a few drops of bright-red blood at the end of micturition, and is due to the stone abrading the vascular trigone. Interruption of the urinary stream is due to the stone blocking the internal meatus. Urinary infection is a common presenting symptom.

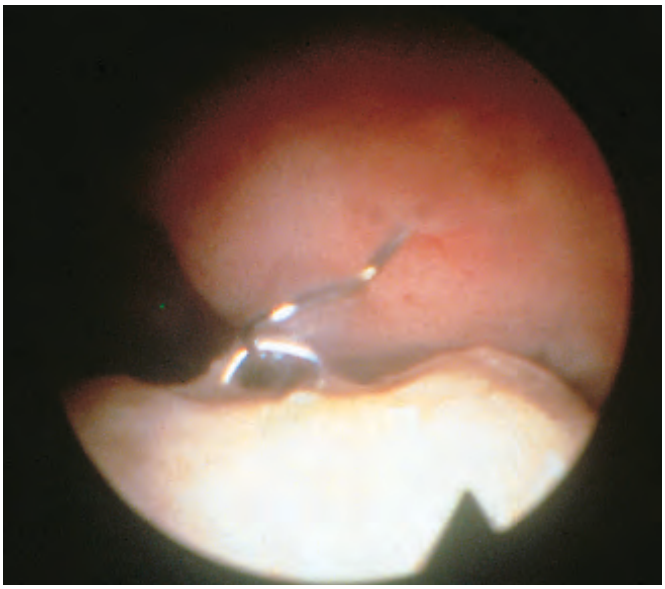

Figure 77.27 Uric acid stones that had formed on metal staples used to construct a colonic bladder augmentation.

Examination

Rectal or vaginal examination is normal; occasionally, a large calculus is palpable in females. Examination of the urine reveals microscopic haematuria, pus or crystals that are typical of the calculus, e.g. envelope like in the case of an oxalate stone or hexagonal plates in the case of cystine calculi. In most patients the stone is visible on an ultrasound scan or a plain radiograph (Figure 77.28). Imaging of the whole of the urinary tract should be undertaken to exclude an upper tract stone. Nearly all stones can be dealt with endoscopically. In men with bladder outflow obstruction, endoscopic resection of the prostate should be performed at the same time as the stone is dealt with.

Treatment

The cause of the stone should be sought and treated; this may include bladder outflow obstruction or incomplete bladder emptying in patients with neurogenic bladder dysfunction.

Litholapaxy

The blind lithotrite (Figure 77.29) was an early type of minimally invasive technique. Standard management now includes the optical lithotrite, electrohydraulic lithotrite, holmium laser or ultrasound probe (Figure 77.30). Other devices include the stone punch, which is useful for crushing small fragments further so that they can be evacuated with an

Figure 77.28 Radiograph showing a vesical calculus (no contrast has been used).

Figure 77.29 'Blind' lithotrite used to crush bladder stones.

Figure 77.30 An endoscopic ultrasound probe, which is used to fragment bladder or kidney stones.

Ellik evacuator. Contraindications to perurethral litholapaxy are extremely rare and include the following:

- **Urethral**: a urethral stricture that cannot be dilated sufficiently; when a patient is aged below 10 years
- **Bladder**: a contracted bladder
- **Stone characteristics**: a very large stone.

Ultrasound lithotripsy is extremely safe but appropriate only for small stones. Laser lithotripsy with the holmium laser can deal with most large stones. Once small fragments are produced, the optical lithotrite can be used to finish the job. For evacuation of the fragments, fluid (200 mL) is introduced into the bladder. The evacuator, filled with solution, is fitted on to the sheath. The bulb is compressed slowly and then permitted to expand; the returning solution carries with it fragments of stone.

Percutaneous suprapubic litholapaxy

It is possible to insert a needle into the bladder and then pass a guidewire. As in percutaneous nephrolithotomy, Alken metal dilators can be passed over the guidewire to dilate the track and an Amplatz sheath inserted, followed by a large-bore nephroscope. This is the best method to use if it is not possible to carry out litholapaxy per urethram because of a narrow urethra.

Removal of a retained Foley catheter

A retained Foley catheter is usually caused by the channel that connects the balloon to the side arm becoming blocked, usually at the end near the balloon. The best way of dealing with this problem is to further inflate the balloon with 20 mL of water and then burst the balloon percutaneously using a needle under ultrasound screening. If the balloon bursts, it is important subsequently to cystoscope the patient to ensure that any fragments are removed before they can form a foreign body calculus. Cutting off the side arm and attempting to clear the channel with a wire is only occasionally successful.

FOREIGN BODIES IN THE BLADDER

The most common foreign body in the bladder is a fragment of catheter balloon (see above). Occasionally, a foreign body enters through the wall of the bladder, e.g. non-absorbable sutures used in an extravesical pelvic operation. Complications include:

- lower UTI;
- perforation of the bladder wall;
- bladder stone.

Treatment

A small foreign body can usually be removed per urethram by means of an operating cystoscope. Occasionally, a suprapubic approach using the percutaneous insertion of a cystoscope is needed.

DIVERTICULA OF THE BLADDER

Definition

The normal intravesical pressure during voiding is about 35–50 cmH_2O; however, pressures as great as 150 cmH_2O may be reached by a hypertrophied bladder endeavouring to force urine past an obstruction. This pressure causes the lining between the inner layer of hypertrophied muscle to protrude, forming multiple saccules. If one or more, but usually one,

Milo Ellik, b.1905, American urologist.

P Alken, urologist, the University of Heidelberg, Germany.

saccule is forced through the bladder wall, it becomes a diverticulum (Figure 77.31). Congenital diverticula are the result of a developmental defect.

Aetiology of diverticula

Congenital diverticula

These are situated in the midline anterosuperiorly and represent the unobliterated vesical end of the urachus.

Pulsion diverticula

The usual cause is bladder outflow obstruction.

Pathology

The mouth of the diverticulum is situated above and to the outer side of one ureteric orifice. Exceptionally, it is near the midline behind the interureteric ridge. The size varies from 2 cm to 5 cm, but they may be larger. Diverticula are lined by bladder mucosa and the wall is composed of fibrous tissue only (compare with a traction diverticulum). A large diverticulum enlarges in a downward direction and sometimes may obstruct a ureter – probably because of peridiverticular inflammation.

Complications

Recurrent urinary infection

As the pouch cannot empty itself efficiently, there remains a stagnant pool of urine within it. Peridiverticulitis can cause dense adhesions between the diverticulum and surrounding structures. Squamous cell metaplasia and leukoplakia are infrequent complications.

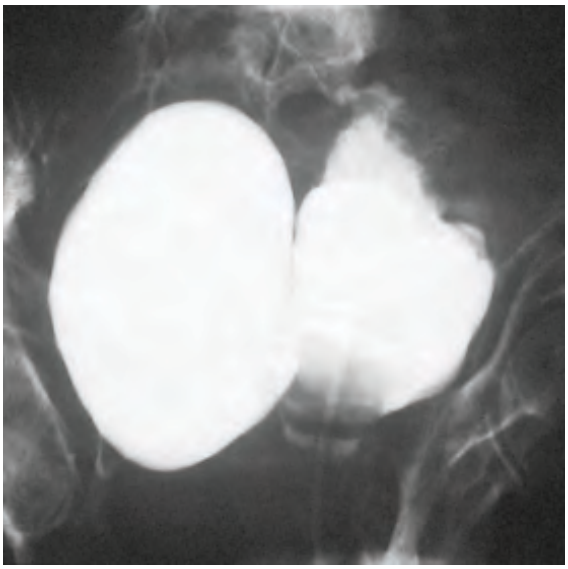

Figure 77.31 Cystogram showing a large diverticulum of the bladder.

Bladder stone

This develops as a result of stagnation and infection. The stone often protrudes into the bladder.

Hydronephrosis and hydroureter

This is extremely rare and is a consequence of peridiverticular inflammation and fibrosis.

Neoplasm

Neoplasm arising in a diverticulum is an uncommon complication (<5%). The prognosis is dependent on the stage of the tumour (see below).

Clinical features

An uninfected diverticulum of the bladder usually causes no symptoms. The patient is nearly always male (95%) and aged over 50 years. Symptoms are those of associated urinary tract obstruction, recurrent infection and pyelonephritis. Haematuria (due to infection, stone or tumour) is a symptom in about 30%. In a few patients micturition occurs twice in rapid succession (the second act may follow a change of posture).

Diagnosis

Diverticula are usually discovered incidentally on cystoscopy or ultrasonography (Figures 77.32–77.34).

Figure 77.32 Cystoscopic appearance of the orifice of a diverticulum and trabeculation of the bladder.

Figure 77.33 Occasional appearance of a diverticulum with inadequate distension of the bladder.

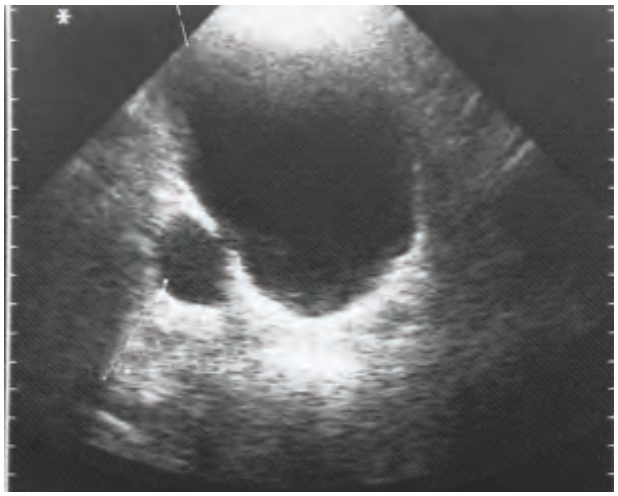

Figure 77.34 Bladder diverticulum demonstrated by ultrasound.

Indications for surgery

Surgery is necessary only for the treatment of complications. Provided that the diverticulum is small and associated outflow obstruction has been dealt with by prostate resection, there is no reason to resect the diverticulum. Even a large diverticulum may not require treatment in the absence of infection or other complications.

Combined intravesical and extravesical diverticulectomy

A ureteric stent is passed up the ureter on the affected side and the anterior bladder wall is exposed through a suprapubic incision. The bladder is incised in the midline and the diverticulum is packed with a strip of gauze. The neck of the diverticulum is separated from the ureter and, when the pouch is free, it is severed from the bladder. The resulting defect is closed in a single layer with 2/0 absorbable sutures. A suprapubic catheter is left in place and an extravesical drain is inserted. An alternative method, if the sac is densely adherent, is to carry the incision in the bladder down to the rim of the diverticular orifice, then to detach the diverticulum together with its fibrous rim. The incision in the bladder is closed and the diverticulum left in position with a corrugated drain placed into it for 2–3 days. The track fibroses rapidly after removal of the drain. If bladder outlet obstruction is present, prostatectomy should be carried out at the same time as the diverticulectomy, using any appropriate method (transurethral resection of the prostate [TURP], laser or open).

Summary box 77.8

Bladder diverticula

- Bladder diverticula are most frequently diagnosed incidentally by cystoscopy or urinary tract imaging
- The presence of a diverticulum – even quite a large one – is not an indication for diverticulectomy unless symptoms or cancer is present

Traction diverticulum (synonym: hernia of the bladder)

A portion of the bladder protruding through the inguinal or femoral hernial orifice occurs in 1.5% of such herniae treated by surgery (**Figure 77.35**).

URINARY FISTULAE

Congenital urinary fistulae

The causes of congenital urinary fistulae include:

- ectopia vesicae;
- a patent urachus – the presence of a urinary leak from the umbilicus, present at birth or commencing soon after, suggests this diagnosis. In adult life, infection in a urachal cyst may produce a fistula and adenocarcinoma may occur (**Figures 77.36 and 77.37**). Treatment is by means of excision of the urachal tract and closure of the bladder once distal obstruction has been excluded;
- in association with imperforate anus (see Chapters 9 and 73).

Traumatic urinary fistulae

Perforating wounds, damage not recognised during surgery or poor healing and avascular necrosis after radiotherapy and surgery may lead to fistula formation. Also, clot retention occurring after an open bladder operation may lead to dehiscence of

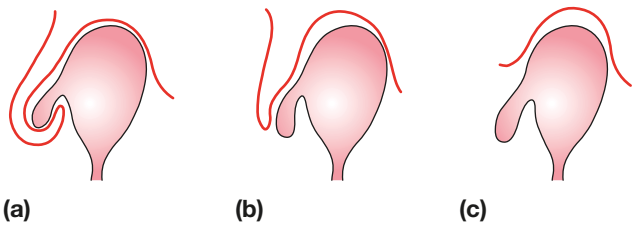

Figure 77.35 **(a)** Intraperitoneal, **(b)** paraperitoneal and **(c)** extraperitoneal hernia of the bladder, in relation to a hernial sac.

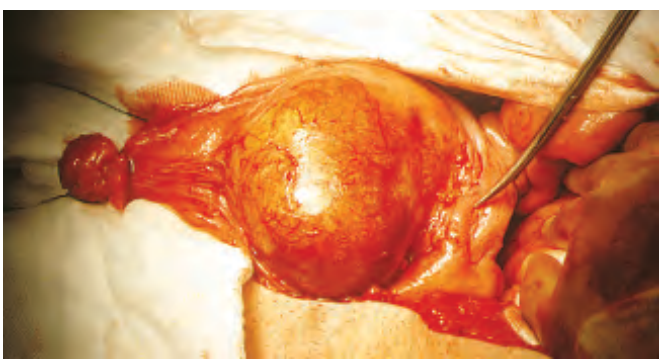

Figure 77.36 An operative photograph showing a large urachal cyst in which adenocarcinoma formation has occurred. A partial cystectomy with total removal of the urachal remnant is about to be carried out.

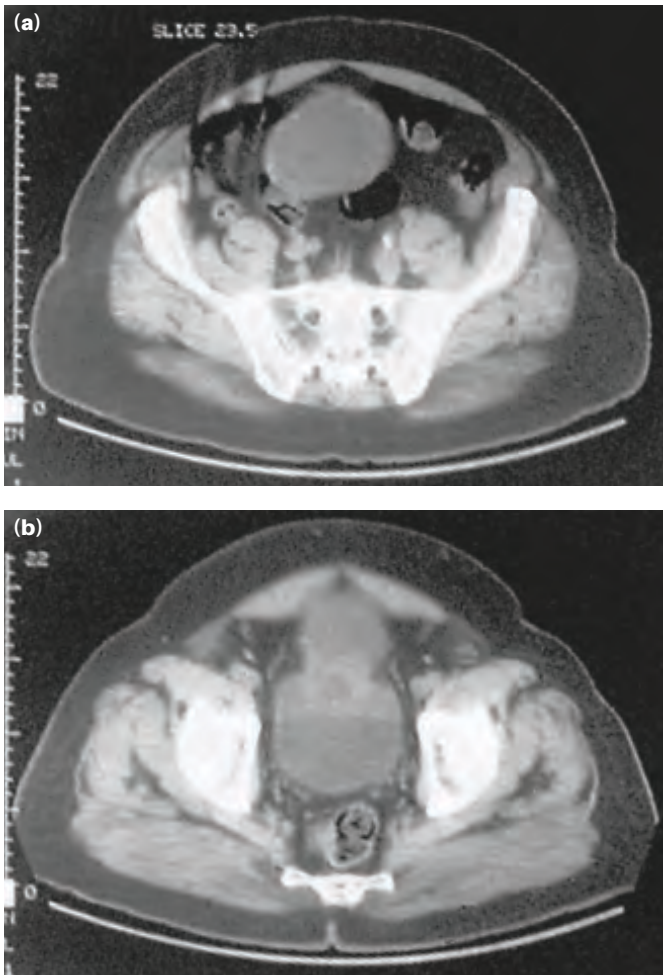

Figure 77.37 (a, b) Computed tomography scans of the same patient as in Figure 77.36, showing a large urachal cyst closely approximated to the dome of the bladder.

the wound and a fistula, which will heal quickly provided that the bladder is kept empty with an indwelling catheter.

Vesicovaginal fistulae

Aetiology

- **Obstetric**. The usual cause is protracted or neglected labour.
- **Gynaecological**. The operations chiefly causing this complication are total hysterectomy and anterior colporrhaphy.
- **Radiotherapy**.
- **Direct neoplastic infiltration**. Exceptionally, carcinoma of the cervix ulcerates through the anterior fornix to implicate the bladder.

When an injury to the bladder is recognised and repaired, leakage is uncommon, but escape of urine will quickly follow if such damage passes unnoticed. However, most vesicovaginal fistulae are the result of ischaemic necrosis of the bladder because of prolonged pressure of the fetal head in obstetric cases. In gynaecological cases, the ischaemia is brought about by grasping the bladder wall in an artery forceps, including the bladder wall in a suture or perhaps even by local oedema or haematoma. Leakage because of tissue necrosis seldom manifests itself before 7 days after the operation. An intractable fistula after radiotherapy for carcinoma of the cervix uteri may arise from avascular necrosis years after the apparent cure of the original lesion.

Clinical features

There is leakage of urine from the vagina and excoriation of the vulva. Vaginal examination may reveal a localised thickening on its anterior wall or in the vault. On inserting a vaginal speculum, urine will be seen escaping from an opening in the anterior vaginal wall.

The 'three-swab test'

The differential diagnosis between a ureterovaginal and vesicovaginal fistula can be made by placing a swab in the vagina and injecting a solution of methylene blue through the urethra; the vaginal swab becomes coloured blue if a vesicovaginal fistula is present. Cystoscopy and bilateral retrograde ureterography provide a more reliable demonstration. IVU should be performed to exclude a coincidental ureterovaginal fistula (ureterovaginal fistula occurs with vesicovaginal fistula in about 10% of cases). Usually, IVU shows some upper tract dilatation resulting from partial obstruction.

Treatment

Just occasionally, conservative management of a vesicovaginal fistula after a hysterectomy, by urethral bladder drainage, is successful; however, most fistulae will require definitive surgical repair. A low fistula (subtrigonal) is best repaired per vaginam. The fistula is exposed, the bladder is closed using absorbable sutures and the vagina subsequently closed with a separate layer. A urethral catheter should be left *in situ* for at least 10 days. For higher (supratrigonal) fistulae a transvaginal approach can be difficult. These patients should always undergo cystoscopy before the repair procedure and bilateral ureterograms performed. For high fistulae a suprapubic approach is the best method in most hands; however, some experts will aim to carry out vaginal closure in most cases that have not involved complex surgery or radiotherapy.

To repair a ureterovaginal fistula, an extraperitoneal approach to the ureter via the previous Pfannenstiel incision is made. Considerable adhesions will be encountered, but the ureter can usually be found above the level of the injury and followed down. Reimplantation into the bladder is often required. Depending on the amount of ureter lost, it may be possible to achieve reimplantation with a psoas hitch procedure. If the gap is too large a Boari flap of anterior bladder wall should be cut and brought over to meet the ureter and a reimplant performed. The most important principle of ureteric reimplantation is that there should be no tension on the repair.

Achille Boari, nineteenth century Italian surgeon.

Fistulae from renal pelvis to skin or gut

Tuberculosis of a kidney may result in a fistula to the duodenum, colon or skin. Similarly, a pyonephrosis may discharge into the gut or on to the skin. Duodenal ulcer involving the pelvis of the right kidney, Crohn's disease involving the renal pelvis or ureter or cases of xanthogranulomatous pyelonephritis may cause fistulae. A longstanding urinoma will occasionally fistulate into the gut.

Fistulae arising from infection

The most common cause is diverticulitis of the colon. Fistulae may also follow Crohn's disease, appendix abscess or pelvis sepsis after acute salpingitis, or pelvic surgery.

The onset of a fistula from diverticular disease may well be treated as a simple urinary infection. The diagnosis can be difficult to make, but on cystoscopy a patch of oedema on the left side of the vault is suggestive and bubbles of gas may be seen (**Figure 77.38**). A cystogram may reveal the fistula. The passage of gas per urethram in a patient is most suggestive (provided that diabetes resulting in urinary infection with a gas-forming organism is excluded).

Treatment of fistulae caused by diverticular disease

In most patients a single-stage operation is indicated provided that the surgeon is experienced in colonic surgery. At laparotomy, the communication is separated, the hole in the bladder being closed and patched with omentum, and the segment of diseased bowel resected; it is most important to ensure that the left colon and, if necessary, the splenic flexure are fully mobilised to facilitate a tension-free, well-vascularised anastomosis. The bladder is drained by a urethral catheter.

Figure 77.38 Cystoscopic view of a vesicointestinal fistula. Bubbles of gas can be seen issuing from the orifice of the fistula.

Fistulae caused by carcinoma

By the time that a fistula between the bowel and the bladder has developed, the tumour is usually locally advanced but may be operable.

Urethral fistulae in males

These occur as the result of infection above a stricture producing a paraurethral abscess that ruptures into the urethra, allowing extravasation to occur suddenly into the scrotum and perineum. Urine and infection extend into the upper 2.5 cm of the thigh and lower abdominal wall. Widespread cellulitis and tissue necrosis (which may lead to Fournier's gangrene) may occur unless drainage of urine is achieved by suprapubic cystotomy and the tissue planes are freely drained by inguinal and scrotal incisions.

Neoplastic fistulae

Primary bladder tumours very rarely produce fistulae. Involvement of the bladder by tumours of the cervix, uterus, colon and rectum can produce fistulae, as may sarcoma of the small gut. Carcinoma of the prostate rarely produces a rectal fistula. Treatment is difficult and in most cases only palliative relief can be given. It is rarely in the patient's interest to carry out urinary diversion, although minimally invasive techniques such as placement of ureteric stents can be helpful in palliating symptoms.

Summary box 77.9

Fistulae

- A fistula is a communication between two epithelium-lined surfaces
- Most urinary fistulae are vesicovaginal and result from obstetric trauma; an associated ureterovaginal fistulae occurs in about 10% of cases
- A 'three-swab test' is used to aid the diagnosis. An examination under anaesthesia, vaginoscopy, and cystoscopy and intravenous urography should be performed and, if necessary, retrograde ureterography
- Conservative management is rarely successful
- The principles of repair include good exposure, excision of diseased tissue and tension-free vascularised repair in anatomical layers
- Fistulae caused by radiation, cancer and sepsis can be complex with multiple tracts
- The persistence of a fistula on the skin implies the presence of distal obstruction, chronic infection, such as tuberculosis, or a foreign body, such as a stone or non-absorbable ligature

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.
Jean Alfred Fournier, 1832–1915, French syphilologist and founder of the Venereal and Dermatological Clinic, Hôpital St Louis, Paris, France.

LOWER URINARY TRACT INFECTION AND CYSTITIS

Infection of the bladder gives rise to symptoms of frequency, urgency, suprapubic discomfort, dysuria and cloudy offensive urine. These symptoms are often known as 'cystitis'. Lower UTIs are much more common in women than in men, particularly in those aged under 50. It should be remembered that a lower UTI is often associated with upper tract colonisation and the presence of associated loin pain, pyrexia, rigors and malaise (these symptoms represent complicated infection and should be taken seriously because serious sepsis can ensue).

Isolated infection

A single episode of lower tract infection occurs frequently in women and is rarely complicated.

Recurrent infection

Recurrent infection may be associated with an underlying predisposing cause or may be a result of bacterial resistance. In healthy women, infection after intercourse can occur without any demonstrable abnormality of the urinary tract. Repeated attacks of UTIs in women, or a single attack in a man or a child of either sex, should always be followed by investigation to discover and treat the cause; sometimes, however, no cause can be found. Asymptomatic bacteriuria is common and investigation may fail to demonstrate any underlying cause.

Infection in men

Although more common in women, the incidence of infection is higher in male infants because underlying urinary tract abnormalities are more frequent. Complicated or recurrent infection in men warrants prompt antibiotic therapy and investigation to exclude an underlying cause.

Infection in pregnancy

The incidence of asymptomatic bacteriuria in pregnant women is twice as high as in non-pregnant women. Simple uncomplicated infection can be treated after urine culture with an appropriate antibiotic that is not contraindicated in pregnancy, such as cephalosporin or ampicillin. Non-responsive infection may require intravenous therapy and an ultrasound scan.

Predisposing causes of urinary tract infection

- Incomplete emptying of the bladder, secondary to bladder outflow obstruction, a bladder diverticulum, neurogenic bladder dysfunction or decompensation of the detrusor muscle.
- A calculus, foreign body or neoplasm.
- Incomplete emptying of the upper tract, dilatation of the ureters associated with pregnancy, or vesicoureteric reflux. In childhood, the mainstay of treatment of vesicoureteric reflux is antibiotic therapy; surgery is reserved for those with recurrent infection despite antibiotics or with severe upper tract dilatation.
- Oestrogen deficiency, which may give rise to lowered local resistance.
- Colonisation of the perineal skin by strains of *Escherichia coli* expressing molecules that facilitate adherence to mucosa.
- Diabetes.
- Immunosuppression.

Avenues of infection

Ascending infection from the urethra is the most common route (see Chapter 79). The organisms originate in the bowel, contaminate the vulva and reach the bladder. The passage of urethral instruments may cause infection in either sex, especially when the bladder contains residual urine (**Figure 77.39**). Other routes are less common and include descending infection from the kidney (tuberculosis), haematogenous spread, lymphogenous spread and spread from adjoining structures (Fallopian tube, vagina or gut).

Bacteriology

Bacterial virulence factors affect the ability of a pathogen to infect the host. The possession of pili (rod-shaped structures) that project from the outer membrane increases adhesiveness.

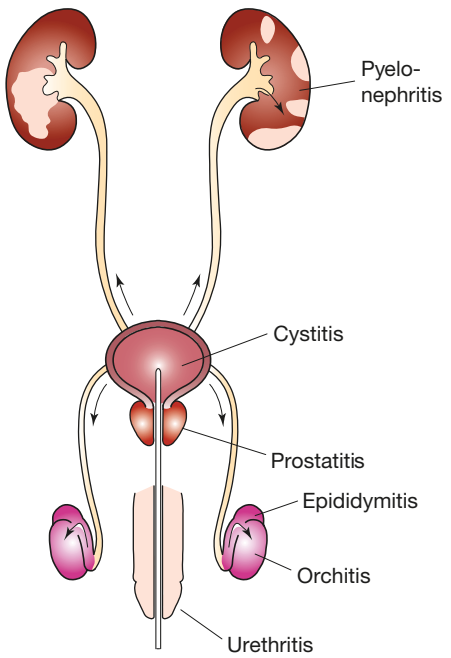

Figure 77.39 Complications liable to follow the changing of a urethral catheter in the presence of urethritis (courtesy of CG Scorer, FRCS, London, UK).

Gabriele Falloppio (Fallopius), 1523–1563, Professor of Anatomy, Surgery and Botany, Padua, Italy.

The type of pilus can be used to classify the pathogen involved. *E. coli* is the most common organism followed by *Proteus mirabilis*, *Staphylococcus epidermidis* and *Streptococcus faecalis*. Infection with other organisms or infection with mixed organisms is found in patients with neurogenic bladder dysfunction or those with a longstanding indwelling urethral catheter. These organisms include *Pseudomonas* and *Klebsiella* spp., *Staphylococcus aureus* and various streptococci. Tuberculous infection is considered below. The presence of pus cells without organisms calls for examination for *Mycobacterium tuberculosis* and *Neisseria gonorrhoeae*. Having eliminated these possibilities, the underlying condition may be abacterial cystitis, CIS, renal papillary necrosis, stones or incomplete treatment of a urinary infection.

Clinical features

These include frequency, pain, haematuria and pyuria. Pyrexia and rigors are not associated with a simple UTI but are a sign of upper tract infection or septicaemia.

Examination

On examination there is tenderness over the bladder. Initial and midstream urine specimens should be collected in males as acute prostatitis may be present (see below), which will lead to threads in the initial specimen. The midstream specimen must be subjected to microscopy and culture, and the sensitivity of any organisms assessed.

Treatment

Treatment should be started immediately and modified if necessary when the bacteriological report is to hand. The patient is urged to drink. Appropriate first-line antibiotics depend on local likely sensitivities but would include trimethoprim or one of the quinolones. Failure to respond indicates the need for further investigation to exclude predisposing factors. It is important to check for associated allergies or other drugs or conditions that might preclude the use of some antibiotics (e.g. concomitant administration of methotrexate and trimethoprim [both inhibit tetrahydrofolate reductase]).

Summary box 77.10

Urinary tract infections (UTIs) in adults

- Isolated UTIs in adults are not infrequent and are more common in women
- Recurrent or complicated infection (haematuria, rigors) warrants appropriate antimicrobial therapy and investigation
- Investigation to exclude a predisposing cause includes urinalysis, microscopy and culture, upper tract imaging and cystoscopy
- *Mycobacterium tuberculosis*, *Neisseria gonorrhoeae* or *Mycoplasma genitalium* should be suspected if pus cells are present but urine culture is negative
- Cancer, especially CIS, masquerading as infection may be diagnosed as abacterial cystitis

Investigation

Investigation may be needed in the male or when recurrent infection occurs. This includes measurement of urinary flow rates and post-void residual urine. IVU, ultrasound scan or CT scanning will usually be carried out together with cystoscopy. Difficult cases may require urodynamic investigation.

SPECIAL FORMS OF LOWER URINARY TRACT INFECTIONS

Acute abacterial cystitis (acute haemorrhagic cystitis)

The patient presents with a severe UTI. Pus is present in the urine but no organism can be cultured. It is commonly sexually acquired but tuberculous infection and CIS must be ruled out. The underlying causative organism may be *Mycoplasma* sp. or herpes simplex virus. Cyclophosphamide can also cause this problem.

Frequency–dysuria syndrome (urethral syndrome)

This consists of symptoms of a lower tract infection but with negative urine cultures. CIS, tuberculosis and interstitial cystitis should be excluded. Most urologists advise patients to adopt general measures such as wearing cotton underwear, using simple soaps, adopting general perineal hygiene measures and voiding after intercourse. Other treatments include cystoscopy and urethral dilatation, although the benefits remain doubtful.

Tuberculous urinary infection

Tuberculous urinary infection is secondary to renal tuberculosis. Early tuberculosis of the bladder starts around the ureteric orifice or trigone, the earliest evidence being pallor of the mucosa due to submucous oedema. Subsequently, tubercles may be seen and, in longstanding cases, there is marked fibrosis and the capacity of the bladder is greatly reduced (**Figure 77.40**).

Treatment

Tuberculous infection usually responds rapidly to antituberculous drugs but occasionally the involved kidney and ureter have to be removed. If the bladder remains of low capacity, patients will have severe symptoms and the upper tracts are at

Albert Ludwig Siegmund Neisser, 1855–1916, Director of the Dermatological Institute, Breslau, Germany (now Wroclaw, Poland).

Figure 77.40 Retrograde cystograph showing an exceedingly contracted ('thimble') bladder in a case of tuberculous cystitis.

risk because of high filling pressures and vesicoureteric reflux. Such patients, after appropriate chemotherapy, respond well to bladder augmentation. The ureters may need reimplantation.

BLADDER AUGMENTATION BY ILEOCYSTOPLASTY OR CAECOCYSTOPLASTY

The fibrosed supratrigonal bladder is removed and the bladder augmented with a segment of bowel. This may consist of intact caecum, a detubularised segment of ileum or a detubularised ileocaecal segment (see **Figures 77.20–77.22**).

Interstitial cystitis (Hunner's ulcer)

For practical purposes, this is confined to women. The first symptom is increased frequency; pain, relieved by micturition and aggravated by jarring and overdistension of the bladder, is another characteristic symptom. In most patients pyuria and urinary infection are absent. Haematuria also occurs. The aetiology remains as obscure as it was when Guy Hunner described the condition in 1914. It consists of a chronic pancystitis, often with marked infiltration with lymphocytes and macrophages. Fibrosis of the vesical musculature and areas of avascular atrophy of the epithelium occur. Ulceration of the mucosa occurs in the fundus of the bladder. In severe cases the bladder capacity is reduced to 30–60 mL. The characteristic linear bleeding ulcer is caused by splitting of the mucosa when the bladder is distended under anaesthesia. Inflammation of all coats of the bladder is present with granulation tissue in the submucosa underlying the ulcer. The muscularis is hypertrophied and the peritoneum in proximity to the area of maximum disease is thickened. The inflammation may involve the trigone, the urethra and, in severe cases, the peritoneum. Pronounced mast cell infiltration is seen but is not specific. It is important to check urinary cytology and to biopsy the mucosa to exclude underlying neoplastic disease.

On cystoscopy the characteristic ulcer is found in the fundus, but it may be absent. This area bleeds readily as the bladder is decompressed. Treatment is difficult and unsatisfactory. Hydrostatic dilatation under anaesthesia may give relief for some months. Instillation of dimethylsulfoxide results in improvement in some patients. Other drugs that have been tried include intravesical heparin, oral ranitidine and steroid therapy. Patients with severe symptoms may well require cystectomy and orthotopic bladder substitution. In patients with severe inflammation involving the trigone and urethra, this operation may not result in complete relief and some type of urinary diversion may be needed.

Alkaline encrusting cystitis

Alkaline encrusting cystitis is rare and is due to urea-splitting organisms causing phosphatic encrustations on the bladder mucosa of elderly women. There are symptoms of a chronic UTI and a plain radiograph shows the bladder outline. The encrustations may be removed by bladder irrigation and the infection treated with appropriate antibiotics.

Cystitis cystica

Under the influence of chronic inflammation the surface epithelium sends down buds, resulting in minute cysts filled with clear fluid, most abundant on the trigone. This is frequently found in patients with recurrent frequency and dysuria.

SCHISTOSOMIASIS OF THE BLADDER (SEE CHAPTER 6)

Geographical distribution

The disease is endemic in Egypt, parts of Africa, Israel, Syria, Saudi Arabia, Iran, Iraq and the shores of China's great lakes. Dwellers of the Nile valley have suffered for centuries. Marshes or slow-running fresh water provide the habitat for the freshwater snail (*Bulinus truncatus*) that is the intermediate host.

Mode of infestation

The disease is acquired through exposure of the skin to infected water, which usually occurs while bathing. The free-swimming, bifid-tailed embryos (cercariae) of the trematode *Schistosoma haematobium* penetrate the skin. Shedding their tails, they enter blood vessels and are swept to all parts of the body but they flourish in the liver where they live on

Guy Leroy Hunner, 1868–1951, gynaecologist, Johns Hopkins Hospital, Baltimore, MD, USA.

erythrocytes and develop into male and female worms. Once sexual maturity has been attained, the nematodes leave the liver and enter the portal vein. The male worm bends into the shape of a gutter (the gynaecophoric canal) into which a female worm nestles, and the pair makes its way towards the inferior mesenteric vein. *Schistosoma haematobium* has an affinity for the vesical venous plexus, which it reaches through the portosystemic anastomotic channels.

Having reached the bladder the female worm eventually enters a submucous venule which is so small that it completely blocks it. It now proceeds to lay about 20 ova in a chain; each ovum is provided with a terminal spine that penetrates the vessel wall. A heavily infected individual passes hundreds of ova a day. If the ova reach fresh water, the low osmotic pressure causes rupture and the ciliated miracidium emerges. To survive, it must reach and penetrate the intermediate snail host within 36 hours. Within the snail's liver, the miracidium enlarges and gives rise to myriads of daughter cysts, which are set free on the death of the snail. A single miracidium begets thousands of cercariae to complete the life cycle.

Clinical features

After penetration of the skin, urticaria lasting about 5 days can occur (swimmer's itch). After an incubation period of 4–12 weeks, a high evening temperature, sweating and asthma, together with leukocytosis and eosinophilia, occur. Usually, an asymptomatic period of several months supervenes before the ova are released, causing the typical early signs and symptoms of intermittent, painless, terminal haematuria. Men are affected three times more frequently than women.

Examination of the urine

The last few millilitres of an early morning urine specimen are collected and centrifuged. Examination on several consecutive days may be required, but a negative result does not exclude bilharziasis, especially in patients no longer resident in bilharzial districts. Antibody detection by enzyme-linked immunosorbent assay (ELISA) using *Schistosoma mansoni* adult microsomal antigen (MAMA) can be performed. The test is positive 1 month after infection and is specific for *Schistosoma mansoni* and *Schistosoma haematobium*.

Cystoscopy

Depending on the length of time for which the disease has remained untreated, cystoscopy will reveal one or more of the following:

1 **Bilharzial pseudotubercles** are the earliest specific appearance of the disease **(Figure 77.41)**.
2 **Bilharzial nodules** **(Figure 77.42)** are caused by the fusion of tubercles.

Figure 77.41 Bilharzial tubercles (courtesy of N Makar).

Figure 77.42 Bilharzial nodules (courtesy of N Makar).

Figure 77.43 'Sandy patches' (courtesy of N Makar).

3 **'Sandy patches'** are the result of calcified dead ova with degeneration of the overlying epithelium **(Figure 77.43)**.
4 **Ulceration** is the result of sloughing of the mucous membrane containing dead ova **(Figure 77.44)**.
5 **Fibrosis** is mainly the result of secondary infection.
6 **Granulomas**. Bilharzial masses are caused by the aggregation of nodules.
7 **Papillomas** are more pedunculated **(Figure 77.45)**.
8 **Carcinoma** is a common end-result in grossly infected bilharziasis of the bladder that has been neglected for years.

Theodor Maximilian Bilharz, 1825–1862, Professor of Zoology, Cairo, Egypt.
Sir Patrick Manson, 1844–1922, practised in Formosa (now Taiwan), and Hong Kong before becoming physician to the Dreadnought Hospital, Greenwich, London, UK. He is regarded as the founder of Tropical Medicine.

Figure 77.44 Bilharzial ulcer (courtesy of N Makar).

Figure 77.45 Bilharzial papilloma (courtesy of N Makar).

Treatment

Safe and effective drugs are available for the treatment of schistosomiasis, including praziquantel taken in three doses of 20 mg/kg (total 60 mg/kg) 4 hours apart. It takes many months for dead ova to be expelled and, even after repeated courses and healing of the bladder lesion, living bilharzial worms have been found at necropsy in the portal system.

Other complications, requiring specific treatment, include the following:

- urinary calculi;
- stricture of the ureters;
- prostatoseminal vesiculitis;
- fibrosis of the bladder and bladder neck (**Figure 77.46**);
- bilharzial urethral strictures;
- squamous bladder cancer.

NEOPLASMS OF THE BLADDER

In total, 95% of primary bladder tumours originate in transitional epithelium; the remainder arise from connective tissue (angioma, myoma, fibroma and sarcoma) or are extra-adrenal phaeochromocytomas.

Secondary tumours of the bladder are common and most frequently arise from the sigmoid and rectum, the prostate, the uterus or the ovaries, although bronchial neoplasms may also spread to the bladder.

Figure 77.46 Bilharzial contracture of the bladder, with ureteric reflux (courtesy of H Talib, Baghdad, Iraq).

Pathology

Benign papillary tumours

The papilloma consists of a single frond with a central vascular core with villi; it looks like a red sea anemone (**Figures 77.47 and 77.48**). Inverted papilloma is a condition in which the proliferative cells penetrate under normal mucosa so that the lesion is covered with smooth urothelium. It is benign.

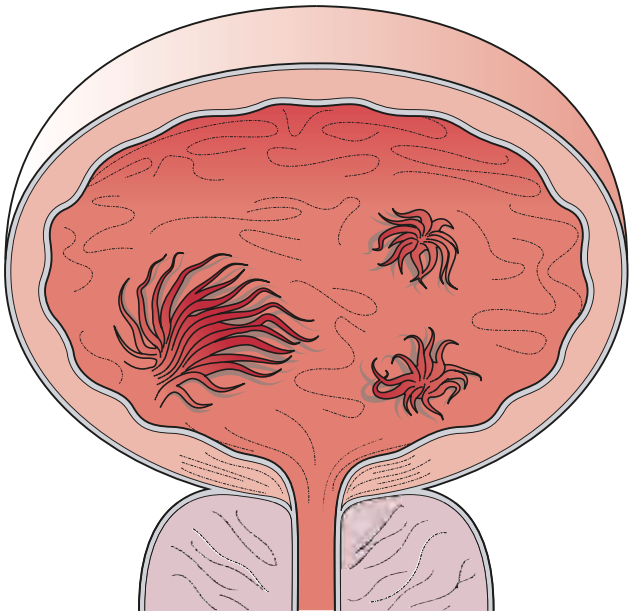

Figure 77.47 Papillary tumour with daughter implantation ('kiss' cancer).

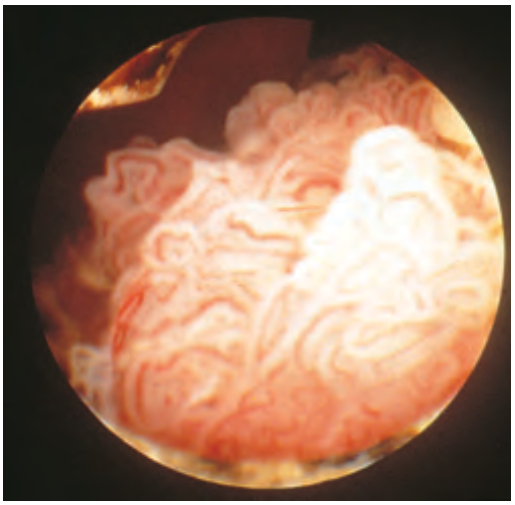

Figure 77.48 Endoscopic photograph of a pTa bladder tumour about to be resected.

CARCINOMA OF THE BLADDER

Histological types of bladder cancer include urothelial, squamous and adenocarcinoma (or mixed, as a result of metaplasia in a transitional cell carcinoma [TCC]). Over 90% are urothelial in origin. Pure squamous carcinoma is uncommon (approximately 5%), except in areas where bilharzia is endemic. Primary adenocarcinoma, which arises from either the urachal remnant or areas of glandular metaplasia, accounts for 1–2% of cases.

Urothelial cell carcinoma

Aetiology

Cigarette smoking is the main aetiological factor (40% of cancers). Occupational exposure to urothelial carcinogens remains common. The first suspicion of a chemical cause for bladder cancer was raised by Rehn in 1895 when he recorded a series of tumours in workers in aniline dye factories. Hueper showed that 2-naphthylamine was carcinogenic in dogs. Subsequent investigation demonstrated that the following compounds may be carcinogenic:

- 2-naphthylamine;
- 4-aminobiphenyl;
- benzidine;
- chlornaphazine;
- 4-chloro-*o*-toluidine;
- *o*-toluidine;
- 4,4′-methylene bis(2-choloroaniline);
- methylene dianiline;
- benzidine-derived azo dyes.

Occupations associated with an increased risk of bladder cancer are:

- textile workers;
- dye workers;
- tyre rubber and cable workers;
- petrol workers;
- leather workers;
- shoe manufacturers and cleaners;
- painters;
- hairdressers;
- lorry drivers;
- drill press operators;
- chemical workers;
- rodent exterminators and sewage workers.

Bladder cancer became a prescribed industrial disease (No. 39) in 1953, and previously exposed workers may be entitled to compensation. Balkan nephropathy is associated with an increased incidence of upper tract urothelial tumours (see Chapter 76).

A series of genetic events has been clearly implicated in cancer formation but is outside the remit of this chapter. Activation of dominantly acting oncogenes such as *ras* and c-*erbB*-1 and -2, and transcription factors such as E2F3, have been reported in bladder cancer, as has the inactivation of tumour-suppressor genes such as *p53*, *p21*, *p16* and the retinoblastoma gene. Activation of many other genes occurs including: those coding for enzymes that dissolve the basement membrane, such as the metalloproteinases (stromelysin, collagenases and elastase), lysosomal enzymes such as the cathepsins and others including urinary plasminogen activators; angiogenic factors (e.g. vascular endothelial growth factor (VEGF]) and other peptide growth factors such as the epidermal growth factor (EGF) and its receptor (EGFR) also have a role to play, as well as the fibroblast growth factor (FGF) and its receptor-3 (FGFR-3) which was found to be altered mostly in non-muscle invasive disease. These changes are common to several tumour types, including prostate cancer. More recently, new approaches through genome-wide association studies allowed the investigation of genetic susceptibility for urothelial cancer. Sev-

Summary box 77.11

Urothelial cell carcinoma of the bladder

- The fourth most common non-dermatological malignancy in men (male:female ratio 3:1)
- Strongly associated with smoking and chemical exposure in western societies
- Strongly associated with *Schistosoma haematobium* infection (bilharzial bladder cancer) in regions where the parasite is endemic
- Reducing in incidence in countries where smoking is decreasing

Ludwig Rehn, 1849–1930, surgeon, Frankfurt am Main, Germany.
The Balkans are the countries that occupy an area in the south-east of Europe. They are south of the Danube and the Sava rivers, and form a peninsula bounded on the east by the Aegean and Black seas, on the west by the Adriatic and Ionian seas, and on the south by the Mediterranean sea.

eral new loci were identified, but, to date, only two, *NAT2* (*N*-acetyltransferase 2) and *GSTM1* (glutathione *S*-transferase Mu 1) have been demonstrated to be consistent germline susceptibility markers. These genetic markers do not yet have sufficient discriminatory ability to be used for clinical decision-making.

Tumour staging and grading

Study of the biological behaviour of TCC of the bladder shows that cancers fall into the three following groups shown in the list. Depth of invasion (T) from the tumour–node–metastasis (TNM) classification and grade (World Health Organization I, II or III) are important factors in planning treatment and determining prognosis in bladder cancer.

- Non-muscle-invasive pTa (see **Figure 77.48**) and pT1 tumours account for 70% of all new cases; the previous terminology of 'superficial' bladder cancer in this category has now been abandoned; it is important, however, to distinguish 'low-risk' uothelial cancers, which are unlikely to progress, such as well-differentiated (G1) pTa tumours (not invading lamina propria), from 'high-risk' cancers, such as poorly differentiated (G3) pT1 cancers (invading lamina propria), which should be followed up carefully and treated aggressively as necessary. This can be determined by careful histological examination. Single papillary pTa tumours account for a significant proportion of bladder cancers and carry an excellent prognosis.
- Muscle-invasive disease (pT2) accounts for 25% of new cases. Such tumours carry a much worse prognosis because they are subject to local invasion and distant metastasis.
- Flat, non-invasive CIS (primary CIS) accounts for 5% of new cases. Unless diagnosed and treated promptly it carries a poor prognosis. The highest-risk non-muscle invasive cancer is found with multifocal poorly differentiated tumours invading lamina propria (pT1G3) in the presence of CIS.

Summary box 77.12

Bladder cancer staging

- Cystoscopy and resection of tumour with separate resection of the tumour base are essential for accurate analysis of invasion into detrusor muscle
- Bimanual examination should be performed after resection of the tumour
- Complete urinary tract imaging is required using contrast computed tomography (CT) or magnetic resonance (MR) urography. Cross-sectional imaging by CT or MR is essential in high-risk and muscle-invasive disease to stage the tumour, further including lymph node status for metastasis.

Non-muscle invasive bladder cancer

These are usually papillary tumours that grow in an exophytic fashion into the bladder lumen (see **Figures 77.47 and 77.48**). They may be single or multiple and may appear pedunculated, arising on a stalk with a narrow base, but if the tumours are less well differentiated they are more solid with a wider base. The mucosa around the tumour is often rather oedematous, with angry-looking, dilated blood vessels. These areas may contain *in situ* changes (concomitant CIS).

The urothelium elsewhere in the bladder may appear rather oedematous and velvety; this suggests a generalised 'field change' with the presence of widespread CIS. The most common sites for superficial tumours are the trigone and lateral walls of the bladder.

After initial complete treatment by endoscopic transurethral resection (TURT), patients with pTa or pT1 disease may develop two problems:

1. About 50–70% develop recurrent tumours that may be single or multiple, and the recurrences may occur on one or on many occasions. The recurrent tumours are usually of the same stage or grade as the primary tumour. High-grade multiple tumours with concomitant CIS are most likely to develop recurrent disease.
2. About 15% will develop a recurrent tumour that invades the bladder muscle. The risk of such progression increases with high-grade disease, pT1 disease, multiple primary disease and concomitant CIS. Many urologists now regard the presence of pT1 grade 3 tumours as an indication for offering the patient immediate cystectomy because of the excellent outcome.

This behaviour provides the rationale for performing check cystoscopies. The factors that result in an increased recurrence and progression rate are:

- high grade;
- pT1 disease;
- concomitant CIS;
- multiple primary tumours;
- recurrent disease at the first check cystoscopy 3 months after diagnosis.

Patients presenting with a solitary grade 1 or grade 2 pTa tumour without concomitant CIS, which does not recur within the first 6 months, have an excellent outcome. Patients with recurrent low-grade disease can be treated with intravesical instillations of a chemotherapeutic agent such as mitomycin C or epirubicin, with regular cystoscopic check-ups and repeat biopsies, or immunotherapy

Summary box 77.13

Non-muscle-invasive bladder cancer (NMIBC)

- Does not invade the detrusor muscle but can extend to the lamina propria
- Extension to the lamina propria (pT1) is a significant risk factor for progression to invasive disease, especially if associated with high-grade disease and carcinoma *in situ*
- The incidence of recurrence of this disease can be reduced by intravesical chemotherapy and immunotherapy
- High-risk superficial disease (any grade 3 disease) is best managed by bacille Calmette–Guérin immunotherapy followed by radical treatment if disease persists

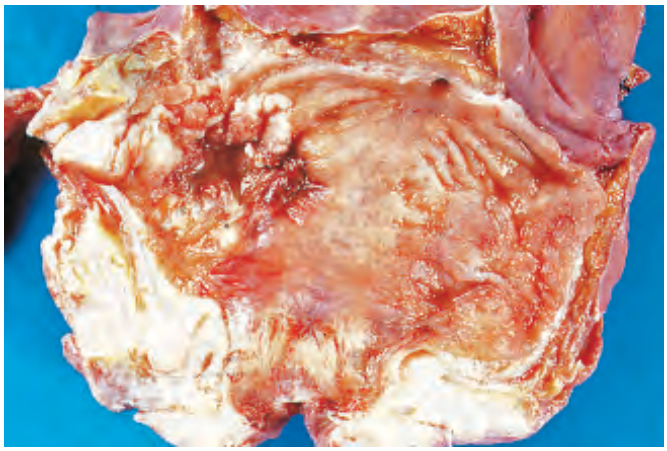

Figure 77.49 Radical cystectomy specimen showing a large solid bladder cancer with total removal of the bladder and prostate.

using regular intravesical instillations of bacille Calmette–Guérin, (BCG) an attenuated form of the anti-tuberculosis vaccine. Patients with high-grade pTa or pT1 disease are at high risk and should be counselled very carefully. The options include immediate cystectomy or a more conservative approach with a course of BCG), followed by careful cystosopic assessment and maintenance instillations. The presence of persistent disease after BCG therapy is a reason for offering cystectomy.

Muscle-invasive bladder cancer

Muscle-invasive tumours are nearly always solid (**Figure 77.49**), although there may be a low tufted surface. These tumours are often large and broad based, having an irregular, ulcerated appearance within the bladder. The incidence of metastases, whether from lymphatic invasion in the pelvis or blood borne to the lung, liver or bones, is much more common and will cause the death of 30–50% of patients.

Summary box 77.14

Muscle-invasive bladder cancer

- Muscle-invasive bladder cancer (MIBC) should be staged by an accurate bimanual examination performed under anaesthesia before and after resection of the tumour
- Complete urinary tract assessment should be performed, including CT, MR and IV urography, as well as cross-sectional imaging to identify lymph node involvement and distant spread
- Radical primary treatment options include radical cystectomy, urinary diversion and thorough lymph node dissection, which tends to be offered as first line, or radical external beam radiotherapy
- Neoadjuvant chemotherapy improves survival rates as well as adjuvant chemotherapy in some cases, particularly in the presence of nodal and distant disease
- Locally advanced disease may be downstaged by radiotherapy or chemotherapy to enable salvage cystectomy

In situ carcinoma

The histological appearance of irregularly arranged cells, with large nuclei and a high mitotic index replacing the normally well-ordered urothelium, is known as CIS. It may occur alone (primary CIS) or in association with a new tumour (concomitant CIS), or it may occur later in a patient who has previously had a tumour (secondary CIS). It can be diagnosed only when a biopsy is examined under the microscope. It may cause severe symptoms of dysuria, suprapubic pain and frequency (hence its old name of malignant cystitis). It carries a risk for the patient of developing a malignant muscle-invasive cancer. Without treatment, 50% will die of invasive bladder cancer. It can be treated initially with intravesical BCG, but failure of response is an indication for cystectomy. CIS cannot be treated with external beam radiotherapy

Pure squamous cell carcinoma of the bladder

Squamous cell tumours tend to be solid and are nearly always associated with muscle invasion. This is the most prevalent form of bladder cancer in areas where bilharzia is endemic. Squamous cell tumours may be associated with chronic irritation caused by stone disease in the bladder as a result of metaplasia.

Pure adenocarcinoma

Adenocarcinoma accounts for approximately 1–2% of all bladder cancers. It usually arises in the fundus of the bladder at the site of the urachal remnant. Occasionally, primary adenocarcinomas arise at other sites and probably originate from areas of glandular metaplasia. Such tumours need to be distinguished from secondary cancer, and can be treated with partial cystectomy

CLINICAL FEATURES OF BLADDER CARCINOMA

Painless gross haematuria is the most common symptom and is indicative of a bladder carcinoma until proven otherwise. Often, however, the patient fails to declare the symptom to their GP. The bleeding may give rise to clot formation and clot urinary retention.

Constant pain in the pelvis usually heralds extravesical spread. There is often frequency and discomfort associated with urination. Pain in the loin or pyelonephritis may indicate ureteric obstruction and hydronephrosis. A late manifestation is nerve involvement causing pain that is referred to the suprapubic region, groins, perineum, anus and into the thighs.

Albert Leon Charles Calmette, 1863–1933, and **Jean-Marie Camille Guérin**, 1872–1961, microbiologists at the Institute Pasteur, at Lille in France, introduced the bacille Calmette–Guérin in 1908.

It is also important to assess the patient as a whole. Many are elderly men who have been lifelong smokers and who have chronic obstructive pulmonary disease or cardiovascular disease. Their suitability for major surgery must be borne in mind.

INVESTIGATION OF BLADDER CARCINOMA

Urine

Urine should be cultured and examined cytologically for malignant cells. This is not a good screening test but a positive result is highly specific, and it is mostly helpful with high-grade disease and CIS. New tests are being developed based on the presence of antigens such as nuclear matrix proteins (NMP22) or mini-chromosome maintenance (MCM) proteins, which may be able to detect new or recurrent tumours, and epigenetic events such as methylated panels of markers or micro-RNA fragments. These tests continue to be under evaluation and are not used routinely.

Blood

Estimation of haemoglobin and the level of serum electrolytes and urea should be carried out.

CT, MR, IV urography or ultrasonography

This should be performed on all patients with painless haematuria. Occasionally, the preliminary film shows a faint shadow of an encrusted neoplasm of the bladder. The most common radiological sign is a filling defect **(Figure 77.50)**. Occasionally, irregularity of the bladder wall may herald the presence of an invasive tumour. Hydronephrosis may occur if a superficial tumour grows up the intramural ureter or direct invasion of the ureteric wall occurs. Ultrasonography should be carried out if the kidney is non-functioning to determine its presence and the possibility of an obstructed system.

Figure 77.50 Intravenous urography showing a filling defect in the region of the right ureteric orifice.

Cross-sectional imaging

Non-contrast CT and MRI and ultrasonography are now replacing IVU in most centres for the immediate management of patients with gross painless haematuria. For staging when a MIBC is suspected, contrast-enhanced CT is used, ideally before TURT. False-positive pT3 disease can be diagnosed if cross-sectional imaging is carried out soon after TURT. MRI is being used more frequently **(Figure 77.51)** and can demonstrate lymph node metastasis or muscle invasion.

Cystourethroscopy

Cystourethroscopy is the mainstay of diagnosis and should always be performed on patients with haematuria. It can be carried out with a rigid instrument under general anaesthesia or with a flexible instrument under local anaesthesia. The urethra is inspected at the initial insertion of the instrument (urethroscopy) and the bladder is then examined in a systematic fashion (cystoscopy). Conventional 'white' light cystoscopy has been improved recently by the introduction of photodynamic 'blue' light cystoscopy, which relies on the photosensitiser hexaminolaevulinate. It is now recommended in patients with high suspicion of the disease and negative initial findings and in follow-up of patients with CIS.

Bimanual examination

A bimanual examination with the patient fully relaxed under general anaesthesia should be performed both before and after endoscopic surgical treatment of these tumours. The bladder should be empty. Once there is muscle invasion the differentiation between pT2 and pT3 disease depends on whether a mass is palpable bimanually at the end of the procedure (pT3). When invasion has spread into the prostate in a man or the vagina in a woman it is classified as pT4a. If the tumour is fixed to the lateral pelvic side wall it is staged as pT4b.

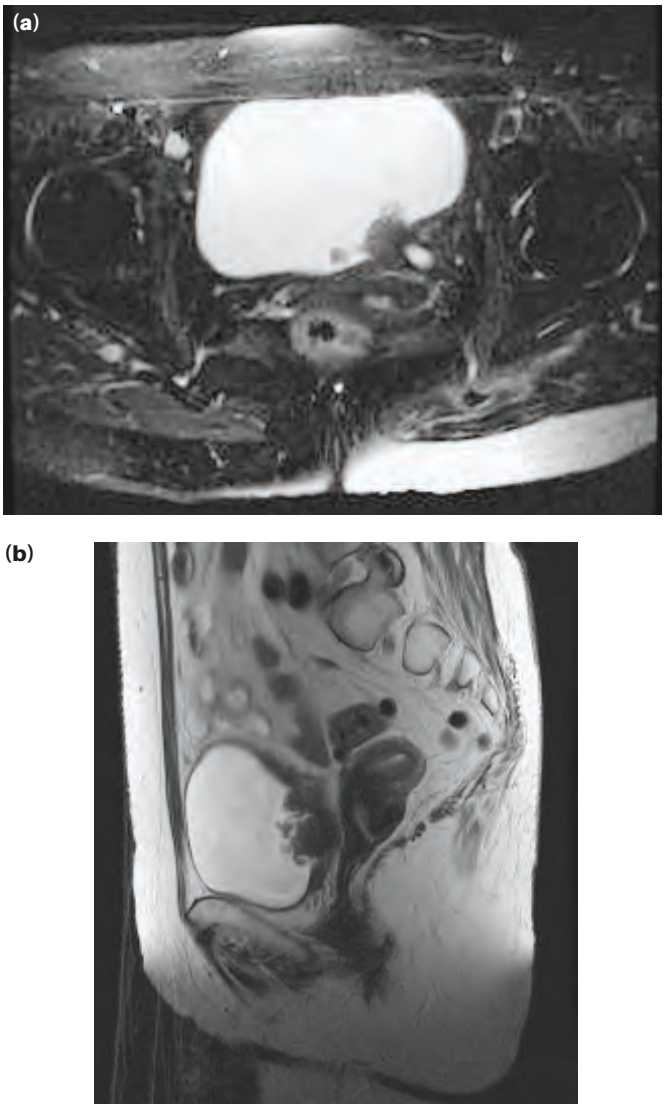

Figure 77.51 **(a)** Cross-sectional magnetic resonance imaging (MRI) showing a 'cystogram' and a bladder cancer. **(b)** Cross-sectional MRI showing invasive bladder cancer.

TREATMENT FOR CARCINOMA OF THE BLADDER

Non-muscle invasive tumours

Endoscopic surgery

The tumour should be carefully resected in layers using a resectoscope. The base of the tumour is sent separately for histological examination. Small pinch biopsies are taken near to and distant from the primary lesion when CIS is suspected (inflamed or velvety appearance). After removal of the tumour, two or three further loops of tissue from the base should be sent separately so that the pathologist can accurately determine whether there is lamina propria or muscle invasion. The base of the tumour is then coagulated, so achieving haemostasis. The appearance of pale-yellow glistening fat will indicate a perforation of the bladder. Should this occur before the resection is complete, it may be prudent to stop the resection and leave a catheter in the bladder for a few days. In this instance the procedure could be completed some 2 weeks later. The bimanual examination is repeated at the end of the endoscopic procedure. After these procedures, an irrigating catheter is left *in situ* for 48 hours to prevent clot retention of urine. There is good evidence that a single dose of mitomycin (mitomycin C, 40 mg in 60 mL of fluid) instilled into the bladder before catheter removal decreases the risks of recurrence in patients with pTa and pT1 grade 1 and 2 disease.

Patients with larger solid tumours should have adequate material resected for histological staging and grading. If it is possible and straightforward, the mass of the tumour should be resected as completely as possible – even when pT2 or pT3 disease is suspected.

FOLLOW-UP

Most urologists agree that patients with a single low- or medium-grade pTa tumour can safely be treated by resection alone plus a single instillation of mitomycin, followed up with regular cystoscopies.

The treatment of patients with multiple low- or medium-grade pTa tumours can be by either resection alone or resection followed by a 6-week course of intravesical chemotherapy with mitomycin, doxorubicin or epirubicin.

The treatment of pT1 disease is difficult. Approximately 30% of tumours are understaged at first resection. For this reason, a repeat cystoscopy and resection of the tumour base are advocated within 6 weeks. Some urologists would offer immediate cystectomy to a patient with a high-grade pT1 tumour, particularly if it were multiple or accompanied by CIS, because of the 30–50% risk of progression to muscle invasion. Others will treat such patients by endoscopy followed by immunotherapy with intravesical BCG. The most effective treatment of solitary medium-grade pT1 disease remains uncertain, but a reasonable approach would be endoscopic resection followed by re-resection of the area after 6 weeks, followed by intravesical BCG.

Follow-up cystoscopies are essential; they may be carried out under local anaesthesia with a flexible cystoscope or under general anaesthesia if the urologist feels that the patient is at high risk of recurrence. They should be performed at 3-monthly intervals over the first year; after this the time interval between cystoscopies can be determined according to the presence or absence of further disease. In total, 30% of patients will never develop another tumour so that, if the bladder has remained clear after 2 years, annual inspection may be adequate. For patients who go on to develop multiple recurrences within the bladder at each examination, the cystoscopies need to be maintained at frequent intervals so that the growths can be resected. These patients are at a greater risk of their disease progressing; although intravesical chemotherapy can decrease the recurrence rate, no reduction in progression rates has been found.

Open surgical excision

This should be totally avoided. If by some error a bladder containing a tumour is entered, then the tumour may be removed with a diathermy needle, the base coagulated and the bladder closed. Postoperative radiotherapy to the wound will diminish the chance of tumour implantation.

Muscle-invasive tumours

The treatment of cancer with proven muscle invasion remains a subject for debate. Whatever the modality of treatment employed, few centres have 5-year survival rates of more than 50%. There is a move towards primary surgical treatment in most centres. The use of systemic chemotherapy with a combination of agents – cisplatin, methotrexate, doxorubicin and vinblastine (M-VAC) or cisplatin plus gemcitabine given before (neoadjuvant) radical cystectomy – has been shown to be of benefit. The current evidence is that neoadjuvant chemotherapy improves survival by about 5–7%. There is no good evidence for the use of adjuvant chemotherapy in these patients. Survival from MIBC has not improved over the past two decades, and newer immunotherapy approaches are being evaluated, in particular immune-checkpoint inhibitors with antibodies targeting the programmed cell death 1 ligand 1 (PDL1) pathway with promising results.

Radiotherapy

EXTERNAL BEAM RADIOTHERAPY

External beam radiotherapy is usually given at 60 Gy over a 4- to 6-week period. There is a complete response rate of 40–50%. Unfortunately, some patients do not respond and others exhibit only a partial response, with pTa or pT1 tumour remaining in the bladder, giving rise to a risk of recurrence, and predictive biomarkers of radiosensitivity are emerging to guide therapy, such as the DNA damage-signalling protein MRE11. Patients with residual disease after radiotherapy should be offered 'salvage cystectomy' if they are fit. Proponents of radiotherapy claim that it avoids the need to remove the bladder in some patients and allows men to retain potency. Radiotherapy is not without complications, and during the course of treatment will cause urinary frequency and also diarrhoea. Late complications can leave the bladder contracted and fibrosed, in which case it may need to be removed for palliative reasons. Late complications affecting the rectum should be uncommon, especially if lateral fields of irradiation are employed.

Surgery

PARTIAL CYSTECTOMY

This should be limited to the treatment of small adenocarcinomas of the bladder.

RADICAL CYSTECTOMY AND PELVIC LYMPHADENECTOMY

This is now standard treatment for localised pT2–pT3 disease without evidence of secondary spread or of CIS that has not responded to BCG. However, bladder cancer tends to occur in elderly people, with a median age at diagnosis of 73 years, and radical surgery carries morbidity in this age group; thus patients must be carefully assessed preoperatively. Before contemplating radical surgery to remove the bladder, it is important to have evidence that surgical cure is attainable. Cross-sectional imaging of the pelvis may locally overstage the bladder if a recent resection has been carried out, although the finding of grossly enlarged pelvic, iliac or para-aortic nodes or liver metastases will alter the decision for cystectomy. A bone scan (using technetium-99m [^{99m}Tc]), or bone marrow MRI will help to show whether there is spread to bone, and a chest plain radiograph should be performed to exclude pulmonary metastases, although many centres now perform routine CT imaging of the chest preoperatively and it tends to be more sensitive than plain radiography in detecting small lung lesions.

SURGERY

Alternative drainage for urine is necessary after removal of the bladder. The standard procedure is to perform an ileal conduit diversion. Male patients should be counselled about the onset of erectile impotence and absent ejaculation after the operation, although in some cases the nerve supply for erectile function can be preserved through careful dissection; they should also be told about alternative forms of urinary diversion, which include continent urinary diversions and orthotopic bladder replacement.

Patients should be seen by a stoma care therapist, who will help to advise the patient and will try different ileostomy bags to ensure that the correct site is chosen, avoiding skin creases so that one does not end up with the disaster of a leaking urinary ileostomy. A decision is made about whether the male urethra is to be removed (depending on the estimated risk of recurrence within the urethra); a urethrectomy is usually indicated in patients with primary CIS or those with tumour invading the prostate stroma. Many surgeons are now offering total replacement of the bladder after cystectomy.

The patient should receive prophylactic antibiotics including metronidazole, cefuroxime and amoxicillin, and low-dose heparin or equivalent thromboembolic prophylaxis, including physical means such as stockings and inflatable devices applied to the legs peroperatively to promote venous circulation.

The abdomen is opened through a midline incision extending down to the symphysis pubis. The liver and the retroperitoneum are checked for evidence of metastases, and the operability of the bladder is assessed. A bilateral pelvic lymphadenectomy is performed, removing external iliac nodes, internal iliac nodes and the nodes in the obturator fossae. Some surgeons will remove lymph nodes up to the aortic bifurcation or higher with some evidence of improved long-term oncological outcomes. The vessels passing to the bladder from the side wall of the pelvis are ligated and divided; these include the obliterated hypogastric vessels, the superior vesical artery, the middle vesical veins, and the inferior vesical arteries and veins. The ureters are then divided. The posterior ligaments extending from the pararectal area to the back of the bladder are ligated and divided, and the layer posterior to Denonvilliers' fascia is opened up. The endopelvic fascia is then divided on each side and the puboprostatic ligaments are divided. A ligature is passed between the dorsal vein complex and the urethra, and the former is ligated and divided. The urethra is then mobilised and divided. The ligaments lateral to the prostate are divided and the bladder is removed. In women, the uterus

Charles Pierre Denonvilliers, 1808–1872, Professor of Anatomy, and later of Surgery, Paris, France.

and anterior vaginal wall need to be included. Women must be counselled about the loss of ovarian and uterine function.

An isolated loop of ileum is then prepared on its own mesentery, and continuity of the small bowel restored. The ureters are then implanted into the bowel and the ileostomy is created. Meticulous care must be taken to close all mesenteric windows, thus avoiding internal hernias. If the bladder is to be replaced orthotopically, a reservoir made from detubularised bowel (usually a segment of well-vascularised ileum) is created and anastomosed to the urethra after implantation of the ureters.

More recently, the technique of cystectomy and urinary diversion has evolved using minimally invasive approaches such as robot-assisted surgery, which is being evaluated in some centres, because it may in theory carry advantages including reduced blood loss, improved precision surgery and speedier patient recovery.

The surgical mortality rate associated with cystectomy used to be considerable but is now less than 2%. Late complications include urethral recurrence (about 5–8%), which is increased in the presence of multifocal tumours, CIS and, particularly, invasion of prostatic stroma **(Figure 77.52)**.

Leukoplakia

This condition is simply squamous metaplasia of the bladder. Profuse production of keratin may result in the passing of white particles in the urine. It cannot be treated easily. Localised areas may be resected endoscopically. Diffuse leukoplakia of the bladder is pre-malignant and results in squamous cancer of the bladder. Careful cystoscopic assessment is required and the condition may require cystectomy.

Endometriosis

Endometriosis within the bladder wall is rare but can have the appearance of a vascular bladder tumour or a tumour that contains chocolate-coloured or bluish cysts. The swelling enlarges and bleeds during menstruation. If medical management fails, by means of danazol or luteinising hormone-releasing hormone (LHRH) agonists, further treatment is usually by means of partial cystectomy or full-thickness endoscopic resection, depending on its site. The condition may be part of more widespread disease. Endometriosis is also a cause of ureteric stricture.

Figure 77.52 Urethrectomy specimen from a patient who has previously undergone a radical cystectomy showing new transitional cell tumour formation in the urethra.

INTERNAL AND EXTERNAL URINARY DIVERSION

Indications

Diversion of the urine may be either a temporary expedient to relieve distal obstruction or a permanent procedure when the bladder has been removed or lost normal neurological control, and in cases of incurable fistula or irremovable obstruction.

Methods of urinary diversion

Temporary methods use prosthetic materials, the most common being a urinary catheter. In elderly patients unfit for prostatectomy, and in some patients with terminal carcinoma of the prostate, an indwelling, silicone, urethral Foley catheter changed every 3 months is a satisfactory method of drainage. A suprapubic placement is an alternative to urethral placement. The major drawback of long-term catheterisation is infection secondary to the associated bacteriuria that invariably develops. Ureteric obstruction can be relieved by placement of internal 'double-J' pigtail ureteric stents, which can remain for 4–5 months but are usually changed every 3 months. As an alternative, a nephrostomy tube, inserted percutaneously by ultrasound and fluoroscopic imaging, is effective when internal stent placement is not feasible.

Permanent urinary diversion

External diversion

ILEAL CONDUIT

Permanent urinary tract diversion is most commonly performed by conduit diversion. The ureters are implanted into a short, isolated segment of ileum **(Figure 77.53a)** or, less commonly, colon. The conduit diverts the urine onwards to a cutaneous stoma for collection in an ileostomy bag. This form of diversion is well established and associated with a low complication rate of less than 10%. The main complication is ureteroileal stricture, which can be limited by spatulation of the distal ureters and an end-to-end anastomosis as described by Wallace **(Figure 77.53a)**. Stenosis at the ileocutaneous site is less frequent, and a short isoperistaltic conduit limits the formation of a residual urine volume, reducing infection and avoiding the problems of reabsorption of urine. In some cases, when the pelvic area has been subjected to radiation, the lower ureters may be unhealthy; a high division with insertion of the ureters into an ileal loop above the root of the mesentery may then be wiser **(Figure 77.54)**.

The site for the stoma must be chosen before the operation, in consultation with a stoma care therapist; the site is marked indelibly on the skin.

Operative details

A coil of ileum, approximately 15–20 cm long and 30 cm from the ileocaecal valve, with its blood supply intact, is isolated. The left ureter is brought behind the mesorectum. The

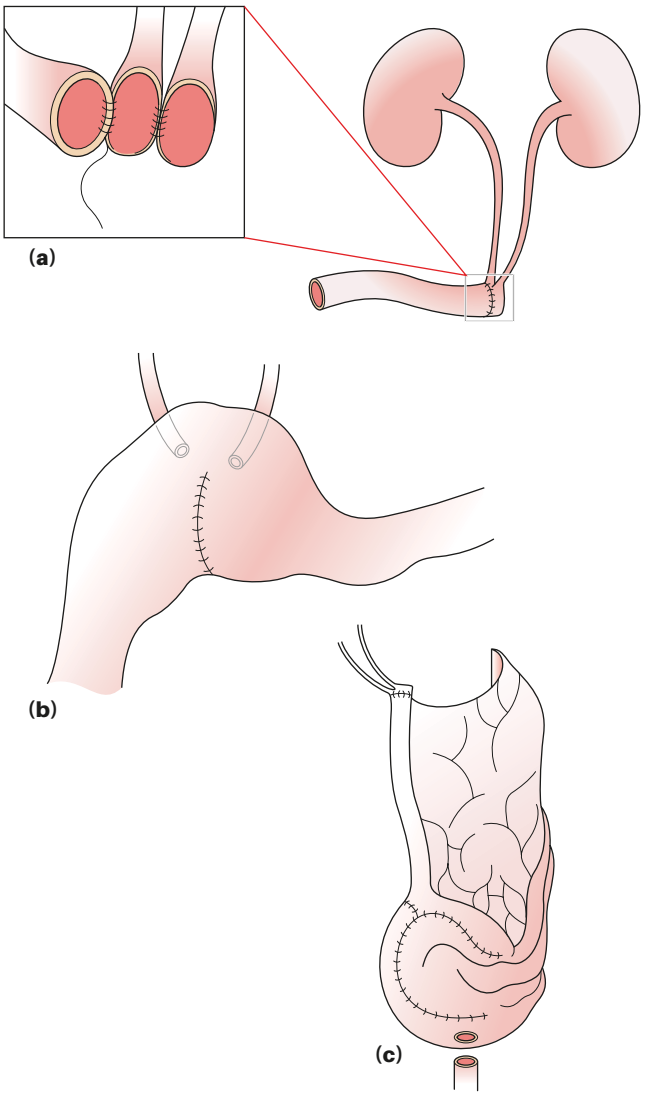

Figure 77.53 Diversion of urine. Favoured methods: **(a)** ileal conduit; the ureters are spatulated and anastomosed to ileum end to side (insert); **(b)** ureterosigmoidostomy; **(c)** ileal neobladder with antireflux long afferent limb.

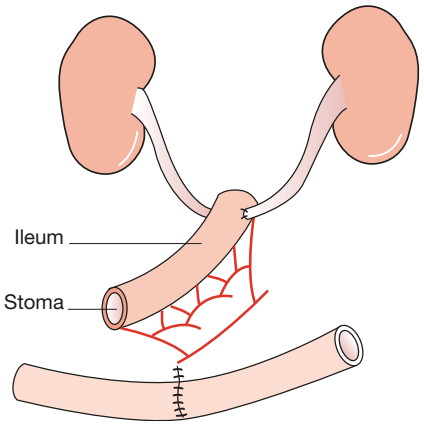

Figure 77.54 Ureteroileostomy (after DM Wallace, FRCS).

ureters may be joined to the ileum either end to side or end to end after anastomosing the distal spatulated ureters to form a plate (Wallace). The distal end of the coil is brought out through an incision made at the site identified before operation; a disc of skin and fat is removed, a cruciate incision is made in the fascia and the muscle is split. The stoma is made about 2–3 cm long. It is evaginated initially by means of four sutures passing through the skin, the ileal loop as it passes through the opening and the cut edge of the ileum.

Internal urinary diversion

COLON AND RECTUM

The advantage of diverting urine into the colon is that no collecting apparatus is necessary. Clearly, however, the anal sphincter must be competent. Before ureterosigmoidostomy is undertaken, the patient must prove that he or she can control at least 200 mL of fluid in the rectum. The disadvantage of the operation is that the renal tract is exposed continuously to infection from the faeces; this can be minimised by constructing an anti-reflux procedure. Various diversions are described; the Mainz II ureterosigmoidostomy creates a cul-de-sac-type, low-pressure reservoir in the sigmoid into which the ureters are placed (see **Figure 77.53b**). This reduces reflux, and bowel content, although in contact with urine, takes a direct route to the rectum. In the long term, cancer can develop at longstanding ureterocolic junctions **(Figure 77.55)**.

BLADDER RECONSTRUCTION

Over the past decade, several techniques have been developed to allow a near-spherical urinary reservoir to be formed out of various lengths of bowel that are detubularised. These may consist of ileum, ileum and caecum, or sigmoid colon (see **Figure 77.53c**). The ureters can then be reimplanted in these reservoirs in an anti-reflux manner and the reservoir anastomosed to the membranous urethra in males (see **Figures 77.20–77.22**). This is indicated only when the urethra can be preserved, with no evidence of tumour at the junction

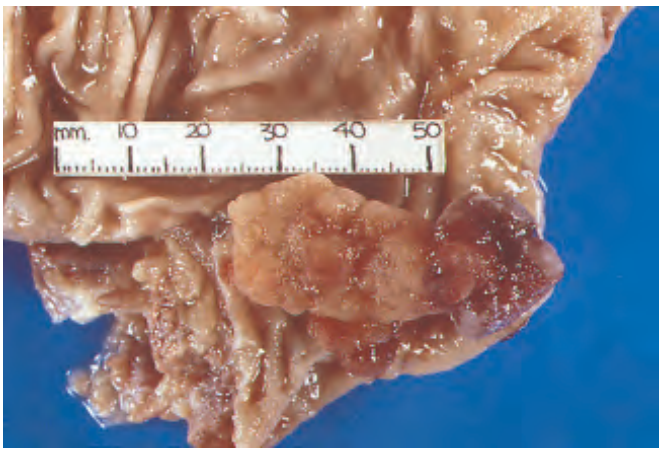

Figure 77.55 An anterior resection of the rectum specimen containing a rectal cancer in a patient aged 18 years who has previously undergone ureterosigmoidostomy for the treatment of bladder exstrophy.

between the urethra and the prostate in males, and bladder neck in females. About 15–30% of patients cannot empty the neobladder completely and will need to perform intermittent self-catheterisation. The results are good after radical cystectomy, particularly in younger well-motivated patients.

CONTINENT URINARY DIVERSION

A similar concept is used in the construction of continent diversions. A urinary reservoir is made as described above and the ureters are attached to the reservoir. A continence mechanism is then made to connect the reservoir to the skin. This is the complication-prone part of the operation. The continence mechanism may be made of an invaginated loop of ileum supported by three rows of staples (Kock pouch) or from the appendix, buried in an anti-reflux manner in a submucosal tube (Mitrofanoff; **Figure 77.56**). Alternatively, a length of ileum can be made into a tube (of a similar size to the appendix) after excision of the anti-mesenteric ileum, and buried in a submucosal tunnel in an anti-reflux way. Clearly, these operations are complex, with the potential for increased postoperative complications.

BLADDER SUBSTITUTION AND AUGMENTATION

In patients with contraction of the bladder because of tuberculosis or with neuropathic dysfunction and a small bladder capacity, the bladder may need to be augmented. Similar techniques to those used to perform a bladder replacement can be utilised to make a near-spherical pouch from detubularised bowel, which can then be attached to the trigone or bladder neck after a near-total cystectomy (see **Figures 77.20–77.22**). The ureters are then reimplanted. The facility to provide a continence mechanism must be available if needed in the neuropathic patient. This may comprise an artificial urinary sphincter or a colposuspension in females.

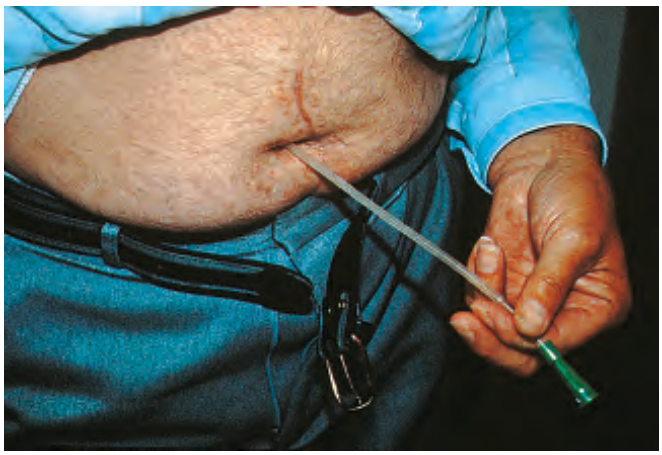

Figure 77.56 A patient with a pT3a bladder cancer who has previously undergone cystoprostatectomy and urethrectomy. A detubularised ileocaecal reservoir has been made with the ureters implanted in submucosal tunnels. The appendix has been implanted within the reservoir in a submucosal tunnel to provide the continence mechanism. The appendix has been brought to the umbilicus and is catheterised 4- to 6-hourly to empty the reservoir.

Complications of internal diversion

Stricture

Ureterosigmoidostomy was first used by Chaput in 1894. Subsequent modifications included those made by Coffey and Grey Turner. In these methods the ureters were cut obliquely and pulled into the gut by a stitch – the ends were not stitched to the gut wall – and stenosis was common. Nesbit, Cordonnier and Leadbetter all recognised that these strictures could be prevented by anastomosing mucosa to mucosa.

Reflux of urine

High-pressure activity within a segment of gut can cause reflux of potentially infected urine at high pressure to the kidneys. In the long term, this can cause renal impairment. The principle of a low-pressure reservoir for both neobladder and ureterosigmoidostomy (Mainz II) reduces this. In addition, an anti-reflux mechanism, used in neobladder construction, is created by anastomosing the ureters to a non-detubularised 20-cm segment of small bowel, which is in continuity with the neobladder (see **Figure 77.53c**).

Metabolic consequences of internal diversion

Resorption of solutes

This depends upon the following factors: (1) the area of bowel that is exposed to urine, and (2) the length of time that the urine is in contact with the bowel epithelium.

The biochemical changes associated with urinary diversion are due to a combination of reabsorption of chloride and urea and progressively diminishing tubular function as a result of pyelonephritis. Diarrhoea with loss of potassium-containing mucus may exacerbate the loss of potassium. The typical changes of a hyperchloraemic acidosis with potassium depletion occur more frequently with ureterosigmoid diversion than with a colonic and ileal neobladder. When severe, the patient develops loss of appetite, weakness, thirst and diarrhoea. Coma may ensue. Mild acidosis, unrecognised over a long period, produces osteomalacia. Bone pain and even pathological fracture can occur. Renal impairment from pyelonephritis and reabsorption from the mucosa are seen less frequently after ileal or colonic conduit formation, continent urinary diversion or orthotopic bladder substitution. In fact, they are seen very infrequently except in patients with

pre-existing renal impairment and unsatisfactory emptying of the urinary reservoir. Malabsorption can occur with the loss of terminal ileum and small bowel. The loss of terminal ileum can result in vitamin B_{12} deficiency and so monitoring of vitamin B_{12} and folate is recommended after the first year.

TREATMENT

Patients should be instructed to empty the rectum or continent reservoir or neobladder 3-hourly by day. In patients who have undergone ureterosigmoidostomy and in whom acidosis is present, a rectal tube should be inserted at night to drain the urine continuously. The patient should take a mixture of potassium citrate and sodium bicarbonate three times a day (2 g of each, as either crystals or tablets). Regular serum biochemical analyses, including calcium, are required.

Established hyperchloraemic acidosis is usually associated with marked dehydration and the mainstay of treatment is administration of intravenous saline. The patient may be given small doses of sodium bicarbonate to half-correct the pH deficit if it is severe and additional intravenous potassium. This should be coupled with appropriate systemic antibiotic treatment.

Risk of malignancy

There is a risk of cancer developing in bowel used to reconstruct the urinary tract. When the urine is not mixed with faeces, the incidence is small, becoming significant after 15–18 years. The major risk of malignancy was discovered when ureterosigmoidostomy construction enabled free mixing of urine and faeces. The development of sigmoid reservoirs into which the ureters are inserted has reduced this risk.

Chapter 78

The prostate and seminal vesicles

Learning objectives

To understand:

- The relationship of anatomical structure and biochemical function to the development and treatment of benign and malignant disease of the prostate
- The terminology used to describe lower urinary tract symptoms and to know their causes as well as the treatment options available
- Which investigations are appropriate for carcinoma of the prostate
- Clinical staging of carcinoma of the prostate and how staging contributes to the complex decision

EMBRYOLOGY

From the primitive urethra, a series of solid epithelial buds develop and become canalised in a matter of weeks. The surrounding mesenchyme forms the muscular and connective tissue of the gland and has a major role in differentiation (stromal epithelium interactions). Skene's tubules, which open on either side of the female urethra, are the homologue of the prostate.

SURGICAL ANATOMY

The contemporary classification of the prostate into different zones was based on the work of McNeal (Figure 78.1). He showed that it is divided into the peripheral zone (PZ), which lies mainly posteriorly and from which most carcinomas arise, and a central zone (CZ), which lies posterior to the urethral lumen and above the ejaculatory ducts as they pass through the prostate; the two zones are rather like an egg in an eggcup. There is also a periurethral transitional zone (TZ), from which most benign prostatic hyperplasia (BPH) arises. Smooth muscle cells are found throughout the prostate but, in the upper part of the prostate and bladder neck, there is a separate sphincter muscle that subserves a sexual function, closing during ejaculation. Resection of this tissue during prostatectomy is responsible for retrograde ejaculation. The distal striated urethral sphincter muscle is found at the junction of the prostate and the membranous urethra; it is horseshoe shaped with the bulk lying anteriorly and is quite distinct from the muscle of the pelvic floor (Figure 78.1).

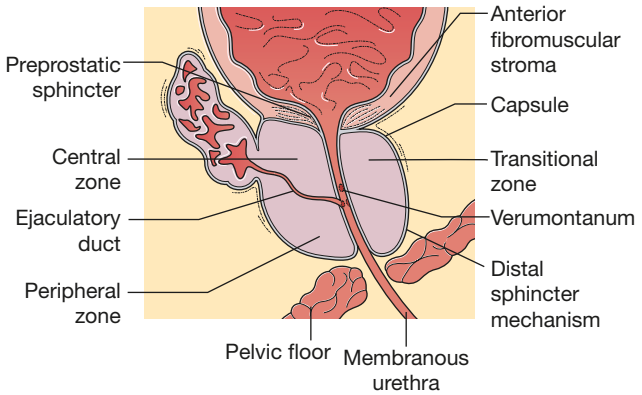

Figure 78.1 Sagittal diagram of the prostate just lateral to the urethra showing the division into the different zones described by McNeal. The transitional zone is the area from which most benign prostatic hyperplasia arises.

The glands of the peripheral zone (Figure 78.2), lined by columnar epithelium, lie in the fibromuscular stroma and their ducts, which are long and branched, open into posterolateral grooves on either side of the verumontanum. The glands of the CZ and TZ are shorter and unbranched. All these ducts, the common ejaculatory ducts and the prostatic utricle open into the prostatic urethra. BPH starts in the periurethral transitional zone and, as it increases in size, it compresses the outer PZ of the prostate, which becomes the false capsule. There is also the outer true fibrous anatomical capsule and external to this lie condensations of endopelvic fascia known

Alexander Johnston Chalmers Skene, 1828–1900, Professor of Gynecology, Long Island Hospital, Brooklyn, New York, NY, USA.

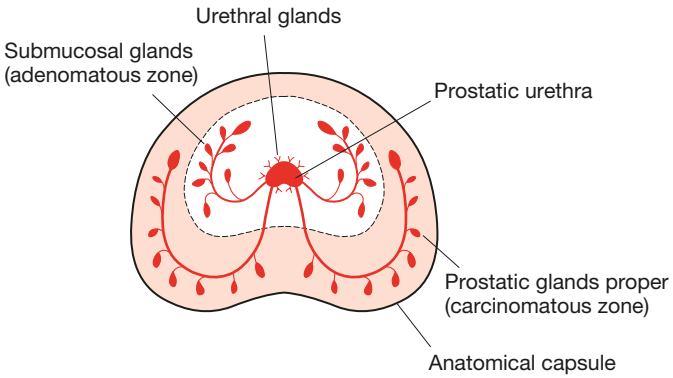

Figure 78.2 A transverse section of the prostate. The peripheral zone is the area from which most prostate cancers arise. The 'adenomatous' zone comprises the central and transitional zones.

as the periprostatic sheath of endopelvic fascia. Between the anatomical capsule and the prostatic sheath lies the abundant prostatic venous plexus. The neurovascular bundles supplying autonomic innervation to the corpora of the penis are in very close relationship to the posterolateral aspect of the prostatic capsule and are at risk of damage during radical cystoprostatectomy or radical prostatectomy; inadvertent diathermy in the region of these nerves may be the cause of uncommon erectile impotence after transurethral prostatectomy.

PHYSIOLOGY

The prostate has a sexual function, but it is unclear how important its secretions are to human fertility. That the normal adult prostate undergoes atrophy after castration was known to John Hunter.

Systemic hormonal influences (endocrine) and local growth factors (paracrine and autocrine)

The growth of the prostate is governed by many local and systemic hormones whose exact functions are not yet known. The main hormone acting on the prostate is testosterone, which is secreted by the Leydig cells of the testes under the control of luteinising hormone (LH), itself secreted from the anterior pituitary under the control of hypothalamic luteinising hormone-releasing hormone (LHRH). LHRH has a short half-life and is released in a pulsatile manner. This pulsatile release is important, as receptors for LHRH will become desensitised if permanently occupied. The administration of LHRH analogues in a continuous, non-pulsatile manner exploits the concept of receptor desensitisation and forms the basis for androgen deprivation therapy in prostate cancer. Testosterone is converted to 1,5-dihydrotestosterone (DHT) by the enzyme 5α-reductase, which is found in high concentration in the prostate and the perigenital skin (type II). Other androgens are secreted by the adrenal cortex, but their effects are minimal in the normal male. Oestrogenic steroids are also secreted by the adrenal cortex and, in the ageing male, may play a part in disrupting the delicate balance between DHT and local peptide growth factors, and hence increase the risk of BPH. Increased levels of serum oestrogens, by acting on the hypothalamus, decrease the secretion of LHRH (and hence LH) and thereby decrease serum testosterone levels. Thus, pharmacological levels of oestrogens cause atrophy of the testes and prostate by means of reductions in testosterone. Other locally acting peptides are secreted by the prostatic epithelium and mesenchymal stromal cells in response to steroid hormones. These include epidermal growth factor, insulin-like growth factors, basic fibroblast growth factor and transforming growth factors alpha and beta. These undoubtedly play a part in normal and abnormal prostatic growth, but as yet their functions are unclear.

Summary box 78.1

Androgenic hormones

- Androgenic hormones, which drive prostate growth, are derived from several sources
- The majority of testosterone (90%) is secreted by the Leydig cells of the testes under the control of luteinising hormone, secreted from the anterior pituitary
- Metabolised adrenal androgen accounts for the remaining 5–10% of testosterone
- Testosterone is converted to 1,5-dihydrotestosterone (DHT) by the enzyme 5a-reductase type II, which is found in high concentration in the prostate and the perigenital skin
- DHT has five times the potency of testosterone

Elaboration and secretion of prostate-specific antigen

Prostate-specific antigen (PSA) is a glycoprotein that is a serine protease. Its function may be to facilitate liquefaction of semen, but it is a marker for prostatic disease. It is measured by an immunoassay and the normal range can differ a little from laboratory to laboratory. There is no real normal upper limit. The levels increase with age, with prostate cancer and with BPH. There are age-related values but, in general, in men aged 50–69 years, a level of about 3–4 ng/mL would prompt a discussion about the need for prostate biopsy. Its level in men with metastatic prostate cancer is usually increased to >30 ng/mL and falls to low levels after successful androgen ablation. Men with locally confined prostate cancer usually have serum PSA levels <10–15 ng/mL. Although PSA is a reliable marker for the progression of advanced disease, it is neither specific nor sensitive in the differential diagnosis of early prostate cancer and BPH, as both diseases are compatible with PSA in the range of 3–15 ng/mL. In summary, about 25% of men with a PSA of 4–10 ng/mL have prostate cancer (i.e. it is not very specific) and about 15–20% of men with a PSA of 1–4 ng/mL have prostate cancer. In general, one would advise men aged

Franz von Leydig, 1821–1908, Professor of Histology successively at Wurzburg, Tubingen and Bonn, Germany.

50–69 years to undergo prostate biopsy if the PSA was more than ~3 ng/mL. The threshold would be lower in younger men with a strong family history. PSA is a useful tumour marker in the postsurgery setting, where a supersensitive assay, with sensitivity to 0.02 ng/mL, facilitates early detection of biochemical recurrence.

BENIGN PROSTATIC HYPERPLASIA

Aetiology

Hormones

Serum testosterone levels slowly but significantly decrease with advancing age; however, levels of oestrogenic steroids are not decreased equally. According to this theory, the prostate enlarges because of increased oestrogenic effects. It is likely that the secretion of intermediate peptide growth factors plays a part in the development of BPH.

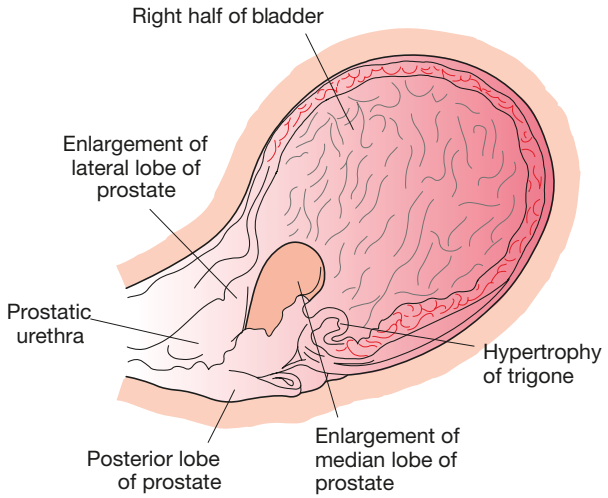

Figure 78.3 Diagram of late-stage bladder outflow obstruction showing enlargement of the prostate from benign prostatic hyperplasia, trabeculation of the bladder with smooth muscle hypertrophy and fibrosis.

Summary box 78.2

Benign prostatic hyperplasia (BPH)

- Occurs in men over 50 years of age; by the age of 60 years, 50% of men have histological evidence of BPH
- Is a common cause of significant lower urinary tract symptoms in men and is the most common cause of bladder outflow obstruction in men >70 years of age

Pathology

BPH affects both glandular epithelium and connective tissue stroma to variable degrees. These changes are similar to those occurring in breast dysplasia (see Chapter 53), in which adenosis, epitheliosis and stromal proliferation are seen in differing proportions. BPH typically affects the submucous group of glands in the transitional zone, forming a nodular enlargement. Eventually, this overgrowth compresses the PZ glands into a false capsule and causes the appearance of the typical 'lateral' lobes.

When BPH affects the subcervical CZ glands, a 'middle' lobe develops that projects up into the bladder within the internal sphincter (**Figure 78.3**). Sometimes, both lateral lobes also project into the bladder, so that when viewed from within, the sides and back of the internal urinary meatus are surrounded by an intravesical prostatic collar.

Effects of benign prostatic hyperplasia

It is important to realise that the relationship between anatomical prostatic enlargement, lower urinary tract symptoms (LUTS) and urodynamic evidence of bladder outflow obstruction (BOO) is complex (**Figure 78.4**). Pathophysiologically, BOO may be caused in part by increased smooth muscle tone, which is under the control of α-adrenergic agonists.

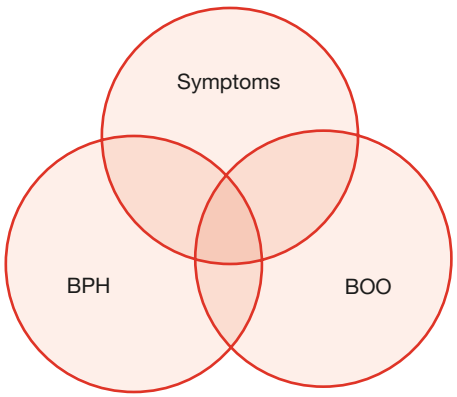

Figure 78.4 Diagrammatic representation of the relation between symptoms of prostatism, benign prostate hyperplasia (BPH) and urodynamically proven bladder outflow obstruction (BOO).

Summary box 78.3

Consequences of benign prostatic hyperplasia

- No symptoms, no bladder outflow obstruction (BOO)
- No symptoms, but urodynamic evidence of BOO
- Lower urinary tract symptoms, no evidence of BOO
- Lower urinary tract symptoms and BOO
- Others (acute/chronic retention, haematuria, urinary infection and stone formation)

Anatomically, the effects are as follows:

- **Urethra**. The prostatic urethra is lengthened, sometimes to twice its normal length, but it is not narrowed anatomically. The normal posterior curve may be so exaggerated that it requires a curved catheter to negotiate it. When only one lateral lobe is enlarged, distortion of the prostatic urethra occurs.
- **Bladder**. If BPH causes BOO, the musculature of the bladder hypertrophies to overcome the obstruction and appears

trabeculated (Figure 78.5). Significant BPH is associated with increased blood flow, and the resultant veins at the base of the bladder are apt to cause haematuria.

Lower urinary tract symptoms

In both sexes, non-specific symptoms of bladder dysfunction become more common with age, probably owing to impairment of smooth muscle function and neurovesical coordination. Not all symptoms of disturbed voiding in ageing men should therefore be attributed to BPH causing BOO. Urologists prefer the term LUTS and discourage the use of the descriptive term 'prostatism'.

The following conditions can coexist with BOO, leading to difficulty in diagnosis and in predicting the outcome of treatment:

- idiopathic detrusor overactivity (see Chapter 77);
- neuropathic bladder dysfunction as a result of diabetes, strokes, Alzheimer's disease or Parkinson's disease (see Chapter 77); degeneration of bladder smooth muscle giving rise to impaired voiding and detrusor instability;
- BOO due to BPH.

Figure 78.5 Pathological specimen of bladder and kidneys in a case of bladder outflow obstruction caused by benign prostatic hyperplasia. Bladder trabeculation, bilateral hydroureter and hydronephrosis can be seen.

Lower urinary tract symptoms can be described as:

- Voiding:
  - hesitancy (worsened if the bladder is very full);
  - poor flow (unimproved by straining);
  - intermittent stream – stops and starts;
  - dribbling (including after micturition);
  - sensation of poor bladder emptying;
  - episodes of near retention.
- Storage:
  - frequency;
  - nocturia;
  - urgency;
  - urge incontinence;
  - nocturnal incontinence (enuresis).

LUTS are usually assessed by means of scoring systems, which give a semiobjective measure of severity. However, some symptoms do not give an accurate picture of the underlying pathophysiological problem. For instance, a man with severe detrusor instability may void only small volumes and hence he will have a sensation of poor flow because low voided volumes (<100 mL) are associated with low flow rates.

Severe irritative symptoms are usually associated with detrusor instability. Postmicturition dribbling is now known not to be a consequence of BOO and is not usually improved by prostatectomy.

Bladder outflow obstruction

This is a urodynamic concept based on the combination of low flow rates in the presence of high voiding pressures. It can be diagnosed definitively only by pressure–flow studies. This is because symptoms are relatively non-specific and can result from detrusor instability, neurological dysfunction and weak bladder contraction. Even low measured peak flow rates (<10–12 mL/s) are not absolutely diagnostic because, in addition to BOO, weak detrusor contractions or low voided volumes (owing to instability) can be the cause. Nonetheless, flow rates provide a useful guide for everyday clinical management.

Urodynamically proven BOO may result from:

- BPH;
- bladder neck stenosis;
- bladder neck hypertrophy;
- prostate cancer;
- urethral strictures;
- functional obstruction due to neuropathic conditions.

The primary effects of BOO on the bladder are as follows:

- **Urinary flow rates decrease** (for a voided volume >200 mL, a peak flow rate of >15 mL/s is normal (Figure 78.6), one of 10–15 mL/s is equivocal and one <10 mL/s is low (Figure 78.7).

Alois Alzheimer, 1864–1915, neurologist, worked at Heidelberg and Munich before being appointed Professor of Psychiatry at Breslau, Germany (now Wroclaw, Poland).

- **Voiding pressures increase** (pressures >80 cmH_2O are high (**Figure 78.8**), pressures between 60 and 80 cmH_2O are equivocal and pressures <60 cmH_2O are normal).

The long-term effects of bladder outflow obstruction are as follows:

- The bladder may decompensate so that detrusor contraction becomes progressively less efficient and a residual urine develops.

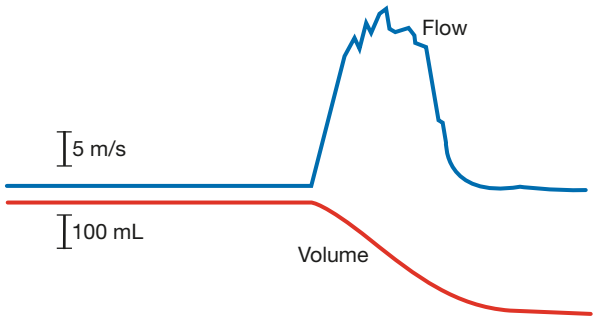

Figure 78.6 Normal flow rate. The voided volume is well in excess of 350 mL, and the maximum flow rate is in excess of 25 mL/s.

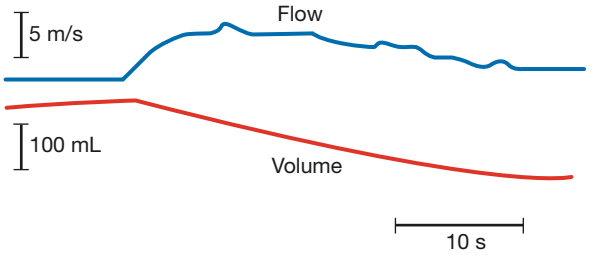

Figure 78.7 Diagram of a low flow rate showing a rather low voided volume of about 200 mL, but with markedly decreased flow rate. Such a flow rate could be caused by a urethral stricture, bladder outflow obstruction or a weak detrusor.

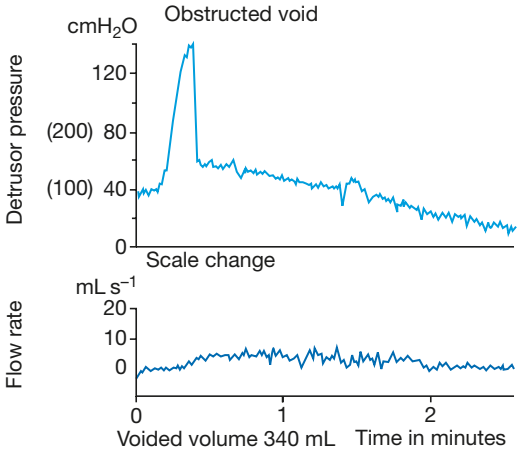

Figure 78.8 Conventional urodynamic trace showing detrusor pressure during voiding. There has been a change in scale because the pressure was so high; voiding pressures are increased with a low flow rate. This is diagnostic of bladder outflow obstruction.

- The bladder may become more irritable during filling with a decrease in functional capacity partly caused by detrusor overactivity (see Chapter 77), which may also be caused by neurological dysfunction or ageing, or may be idiopathic.

Aside from symptoms, the complications of BOO are as follows:

- Acute retention of urine is sometimes the first symptom of BOO. Postponement of micturition is a common precipitating cause; overindulgence in beer and confinement to bed on account of intercurrent illness or operation are other causes.
- Chronic retention. In patients in whom the residual volume is >250 mL or so (**Figure 78.9**), the tension in the bladder wall increases owing to the combination of a large volume of residual urine and increased resting and filling bladder pressures (a condition known as high-pressure chronic retention). The increased intramural tension results in functional obstruction of the upper urinary tract with the development of bilateral hydronephrosis (**Figure 78.10–78.12**). As a result, upper tract infection and renal impairment may develop. Such men may present with overflow incontinence, enuresis and renal insufficiency. These symptoms should alert the doctor to the presence of this condition.
- Impaired bladder emptying. If the bladder decompensates with the development of a large volume of residual urine, urinary infection and calculi are prone to develop.
- Haematuria. This may be a complication of BPH. Other causes must be excluded by carrying out an intravenous urography (IVU), cystoscopy, urine culture and urine cytological examination.
- Other than pain from retention, pain is not a symptom of BOO, and its presence should prompt the exclusion of acute retention, urinary infection, stones, carcinoma of the prostate and carcinoma in situ of the bladder.

ASSESSMENT OF THE PATIENT WITH LOWER URINARY TRACT SYMPTOMS

History

Symptom score sheets such as the International Prostate Symptom Score (IPSS) assign a score that gives information regarding the severity of symptoms at the outset and changes over time and following intervention. The IPSS assessment should include an assessment of quality of life, which is a reflection of the degree of 'bother' caused by a patient's symptoms. In addition to the IPSS, a frequency–volume diary completed by the patient before attending the clinic is invaluable in revealing fluid intake habits, diurnal variation in outputs and low-volume, frequent voiding. These assessments are routinely performed at lower urinary tract clinics but can be elicited by a thorough clinical history.

Summary box 78.4

Investigations of men with lower urinary tract symptoms

Essential investigations

- Urine analysis by dipstick for blood, glucose and protein
- Urine culture for infection
- Serum creatinine
- Urinary flow rate and residual volume measurement

Additional investigations

- Prostate-specific antigen if indicated
- Pressure-flow studies

Abdominal examination

Abdominal distension is usually normal. In patients with chronic retention, a distended bladder will be found on palpation, on percussion and sometimes on inspection with loss of the transverse suprapubic skin crease. General physical examination may demonstrate signs of chronic renal impairment with anaemia and dehydration. The external urinary meatus should be examined to exclude stenosis and the epididymides are palpated for signs of inflammation.

Rectal examination

In benign enlargement, the posterior surface of the prostate is smooth, convex and typically elastic, but the fibrous element may give the prostate a firm consistency. The rectal mucosa can be made to move over the prostate. Residual urine may be felt as a fluctuating swelling above the prostate. It should be noted that, if there is a considerable amount of residual urine present, it pushes the prostate downwards, making it appear larger than it is. It is not always possible to examine the cranial extreme of the very large prostate per rectum. An inability to get to the prostate base implies a volume of at least 50 mL.

The nervous system

The nervous system is examined to eliminate a neurological lesion. Diabetes mellitus, tabes dorsalis, disseminated sclerosis, cervical spondylosis, Parkinson's disease and other neurological states may mimic prostatic obstruction. If these are suspected, then a pressure–flow urodynamic study should be carried out to diagnose BOO. Examination of perianal sensation and anal tone is useful in detection of an S2 to S4 cauda equina lesion.

Serum prostate-specific antigen

The difficulty here is the uncertain benefit of early detection and radical treatment of prostate cancer – this is dealt with in the section on prostate cancer. Certainly, men should be informed about the test, the risks of the prostate biopsy that might be required and the risks of the detection of a cancer that we are not certain how best to treat, as well as the positive aspects of the early discovery of a small prostate cancer. After suitable counselling, measurement of serum PSA may be helpful. Men in whom a diagnosis of early prostate cancer might influence treatment option (such as those under 70 years or those with a positive family history who might be offered radical treatment) should be offered a PSA measurement. If this is in excess of 2.5–4 ng/mL, then transrectal ultrasound scanning (TRUS) plus transrectal biopsies (12 biopsies taken from six areas) should be considered.

If rectal examination is quite normal with no suspicion of cancer, and if no change in treatment policy would in any case result from the diagnosis of early prostate cancer, then there is little point in the routine measurement of PSA in men with uncomplicated BOO. However, because of the fear of future litigation, many find it easier to offer a PSA test. A variety of online calculators using PSA data from thousands of men involved in clinical trials are available and can be used to calculate the risk of a man having a positive biopsy at a given PSA level.

Flow rate measurement

For this to be meaningful, two or three voids should be recorded using a special flow meter, usually found in urology outpatient clinics and the voided volume should be in excess of 150–200 mL. A typical history and a flow rate <10 mL/s (for a voided volume of >200 mL; see **Figure 78.7**) will be sufficient for most urologists to recommend treatment. Usually, a flow rate measurement will be coupled with ultrasound measurement of postvoid residual urine.

There are pitfalls in the measurement of flow rates. The machine must be accurately calibrated. The patient must void volumes in excess of 150 mL and two or three recordings are needed to obtain a representative measurement. Decreased flow rates and LUTS may be seen in:

- BOO;
- low voided volumes (characteristically in men with detrusor instability);
- men with weak bladder contractions (low pressure–flow voiding).

Pressure–flow urodynamic studies

Details of these studies are outlined in Chapter 77 (see **Figure 77.14**). They should be performed on the following patients:

- men with suspected neuropathy (Parkinson's disease, dementia, longstanding diabetes, previous strokes, multiple sclerosis);
- men with a dominant history of irritative symptoms and men with lifelong urgency and frequency;
- men with a doubtful history and those with flow rates in the near normal range (~ or >15 mL/s);
- men with invalid flow rate measurements (because of low voided volumes).

Blood tests

Serum creatinine, electrolytes and haemoglobin should be measured.

Examination of urine

The urine is examined for glucose and blood; a midstream specimen should be sent for bacteriological examination and cytological examination may be carried out if carcinoma in situ is thought possible.

Upper tract imaging

Most urologists no longer carry out imaging of the upper tract in men with straightforward symptoms. Obviously, if infection or haematuria is present, then the upper tract should be imaged by means of intravenous urogram or ultrasound scan.

Cystourethroscopy

Inspection of the urethra, the prostate and the urothelium of the bladder should always be done immediately prior to prostatectomy, whether it is being done transurethrally or by the open route to exclude a urethral stricture, a bladder carcinoma and the occasional non-opaque vesical calculus. The decision of whether to perform prostatectomy must be made before cystoscopy. This should be based on the patient's symptoms, signs and investigations. Direct inspection of the prostate is a poor indicator of BOO and the need for surgery.

Transrectal ultrasound scanning

There is no need to carry this out routinely. Accurate estimation of prostatic size is possible by means of transrectal or transabdominal ultrasound scanning when a very large prostate is suspected.

MANAGEMENT OF MEN WITH BENIGN PROSTATIC HYPERPLASIA OR BLADDER OUTFLOW OBSTRUCTION

Strong indications for treatment (usually prostatectomy) include:

- **Acute retention** (see Chapter 77) in fit men with no other cause for retention (drugs, constipation, recent operation, etc.) (accounts for 25% of prostatectomies).
- **Chronic retention and renal impairment**: a residual urine of 200 mL or more, a raised blood urea, hydroureter or hydronephrosis demonstrated on urography and uraemic manifestations (accounts for 15% of prostatectomies).
- **Complications of bladder outflow obstruction**: stone, infection and diverticulum formation.
- **Haemorrhage**: occasionally, venous bleeding from a ruptured vein overlying the prostate will require prostatectomy to be performed.
- **Elective prostatectomy for severe symptoms**: this accounts for about 60% of prostatectomies. Increasing difficulty in micturition, with considerable frequency day and night, delay in starting and a poor stream are the usual symptoms for which prostatectomy is advised. Frequency alone is not a strong indication for prostatectomy. The natural progression of outflow obstruction is variable and rarely gets worse after 10 years. Severe symptoms, a low maximum flow rate (<10 mL/s) and an increased residual volume of urine (100–250 mL) are relatively strong indications for operative treatment. The exact cut-off for operative or non-operative treatment will depend on careful discussion between the patient and the urologist. Holmium laser enucleation of the prostate (HOLEP) or open prostatectomy should be considered for very large prostates.

Summary box 78.5

Options for treatment of LUTS secondary to BPH

- Conservative measures include watchful waiting in conjunction with fluid restriction and reduction in caffeine intake
- Drug therapy is with a-blockers or, in men with a large prostate, a 5a-reductase inhibitor, or both
- Interventional measures include transurethral resection of the prostate, which remains the 'gold standard'; consider open prostatectomy for large glands

Acute retention

The management of retention is discussed in detail in Chapter 77. Once the bladder has been drained by means of a catheter, the patient's fitness for treatment is determined. If retention was not caused by drugs or constipation, then prostatectomy would usually be the correct management. Unfit men or those with dementia may be treated by means of indwelling prostatic stents or a catheter. Similar comments apply to men with chronic retention once renal function has been stabilised by catheterisation. The role of α-adrenergic drugs followed by a trial of catheter has been tested and found to be successful in certain groups with a short history and a low residual volume of urine, but the recurrence rate becomes cumulatively high. 5alpha-reductase is given to prevent progression of symptoms in men with large (>35 mL) prostates.

Special problems in the management of chronic retention

Men with chronic retention who have relatively low volumes of residual urine and who do not have symptoms suggestive of coexisting infection and with good renal function do not necessarily require catheterisation before proceeding to prostatectomy on the next available list. For those who are uraemic, urgent catheterisation is mandatory to allow renal function to recover and stabilise. Haematuria often occurs following catheterisation owing to collapse of the distended bladder and upper tract, but settles within a couple of days.

Uraemic patients with chronic retention are often dehydrated at the time of admission. Owing to the chronic back pressure on the distal tubules within the kidney, there is loss of the ability to reabsorb salts and water. The result, following release of this pressure, may be an enormous outflow of salts and water, which is known as postobstructive diuresis. It is for this reason that a careful fluid chart, daily measurements of the patient's weight and serial estimations of creatinine and electrolytes are essential. Intravenous fluid replacement is required if the patient is unable to keep up with this fluid loss. These patients are often anaemic and may require a blood transfusion once fluid balance is stabilised (if haemoglobin is <9 g/l).

The general management of retention is discussed in Chapter 77.

Indications for elective treatment in men with LUTS secondary to BPH

Following careful assessment (see section on the assessment of men with LUTS), the following questions should be answered:

- Have they failed a preliminary trial of medical therapy? Commonly, men will have been treated with α-blockers or 5α- reductase inhibitors and will have failed treatment. They are then referred by their general practitioner to the urologist.
- Is BOO present? In many cases, the findings of significant symptoms (assessed by symptom scoring), a benign prostate supplemented by the finding of a low maximum flow rate (<10–12 mL/s for a good voided volume [>200 mL]) will suffice to make a reasonable working diagnosis of BOO. In some men, particularly those with irritative symptoms, suspected neurological disease or those with technically imperfect flow rate measurements, pressure–flow studies will need to be performed.

- How severe are the symptoms and what are the risks of doing nothing? Severe symptoms and a large residual volume of urine will usually require treatment. Men with mild symptoms, good flow rates (>15 ml/s) and good bladder emptying (residual urine <100 mL) may be safely managed by reassurance and review: such patients rarely develop severe complications such as retention in the long term.
- Is the man fit for operative treatment?
- What treatments are available, what are the outcomes and do the side-effects justify treatment?

Treatment

Men with symptoms attending for elective treatment (excluding acute and chronic retention)

CONSERVATIVE TREATMENT

It is in men with relatively mild symptoms, reasonable flow rates (>10 mL/s) and good bladder emptying (residual urine <100 mL) that careful discussion over the merits and side-effects of operative treatment is warranted. Waiting for a period of 6 months after careful discussion of the diagnosis is indicated. After this, a repeat assessment of symptoms, flow rates and ultrasound scan is helpful; many men with stable symptoms will elect to leave matters be. Advice over limiting fluid intake in the evening and careful use of propantheline to help with irritative symptoms is also useful.

DRUGS

In men who are very concerned about the development of sexual dysfunction after transurethral resection of the prostate (TURP), the use of drugs may be helpful. Two classes of drug have been used in the treatment of men with BOO. Alpha-adrenergic blocking agents inhibit the contraction of smooth muscle that is found in the prostate. The other class of drug is the 5α-reductase inhibitors, which inhibit the conversion of testosterone to DHT, the most active form of androgen. These drugs, when taken for a year, result in a 25% shrinkage of the prostate gland. Both groups of drugs are effective; however, α-blockers work more quickly and, although the 5α-reductase inhibitors have fewer side effects, they need to be taken for at least 6 months, and their effect is greatest in patients with large (>50 g) glands. Drug therapy results in improvements in maximum flow rates by about 2 mL/s more than placebo and results in a mild (20%) improvement in symptom scores. TURP, however, results in improvements in maximum flow rates from 9–18 mL/s and a 75% improvement in symptom scores. These drugs are expensive in comparison with their effectiveness, and a significant proportion of men who try these drugs will subsequently undergo TURP. They may be best targeted at men who have failed an initial trial of watchful waiting and who wish to avoid surgery for a period.

OPERATIVE TREATMENT

Apart from the strong indications for operative treatment mentioned above, the most common reason for TURP is a combination of severe symptoms and a low flow rate <12 mL/s. The key is to assess the symptoms carefully and to counsel men about side effects and likely outcome before advising operative treatment.

Counselling men undergoing prostatectomy

Men undergoing prostatectomy need to be advised about the following:

- **Retrograde ejaculation**. This occurs in about 65% of men after prostatectomy.
- **Erectile impotence**. This occurs in about 5% of men, usually those whose potency is waning.
- **Success rate**. On the whole, men with acute and chronic retention do well from the symptomatic point of view. Ninety per cent of men undergoing elective operation for severe symptoms and urodynamically proven BOO do well in terms of symptoms and flow rates. Only about 65% of those with mild symptoms or those with weak bladder contraction as the cause of their symptoms do well. Men with unobstructed detrusor instability do not respond well to TURP. This is the reason for carefully documenting the severity of symptoms and flow rates (supplemented when necessary by pressure–flow studies) before deciding on treatment.
- **Risk of reoperation**. After TURP, this is about 15% after 8–10 years.
- **Morbidity rate**. Death after TURP is infrequent (<0.5%), severe sepsis is found in about 6% and severe haematuria requiring transfusion of more than 2 units of blood occurs in about 3%. After discharge, about 15–20% of men subsequently require antibiotic treatment for symptoms of urinary infection. Risk factors for complications include admission with retention, prostate cancer, renal impairment and advanced age.

Methods of performing prostatectomy

The prostate can be approached (1) transurethrally (TURP), (2) retropubically (RPP), (3) through the bladder (transvesical; TVP) or (4) from the perineum (**Figure 78.13**).

Transurethral prostate surgery

TURP remains the most commonly performed procedure for the surgical correction of BOO. Perhaps the greatest advance in the history of transurethral surgery was marked by the development of the rigid lens system of Professor Harold Hopkins. His lenses, illuminated by a fibreoptic light source, permit unparalleled visualisation of the working field. Men with indwelling catheters, those with recent urinary infection, those with chronic retention or those with prosthetic material or heart valves benefit from prophylactic antibiotics in addition to the standard for clean surgery at induction of anaesthesia.

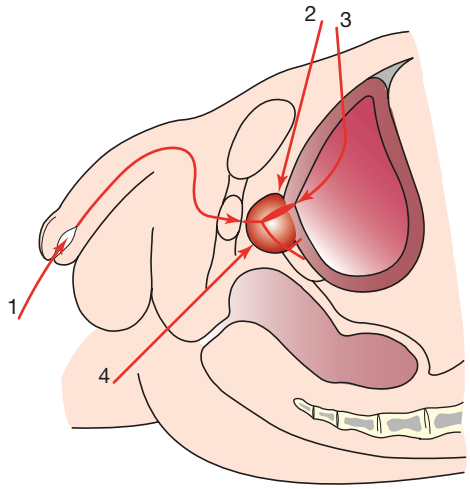

Figure 78.13 The surgical approaches to the prostate. (For key see text.)

Strips of tissue are cut from the bladder neck down to the level of the verumontanum **(Figure 78.14)**. Cutting is performed by a high-frequency diathermy current, which is applied across a loop mounted on the hand-held trigger of the resectoscope. Coagulation of bleeding points can be accurately achieved. The 'chips' of prostate are then removed from the bladder using an Ellik evacuator. Resection proceeds at 1 g/minute in experienced hands. The duration of resection for monopolar TURP is limited to 1 hour due to the risk of resorption of water if 1% glycine is used as an irrigant. The advent of bipolar TURP where normal saline is used as an irrigant permits resection of larger prostates. Following TURP, careful haemostasis is performed, and a three-way, self-retaining catheter irrigated with isotonic saline is introduced into the bladder to prevent any further bleeding from forming blood clots. Irrigation is continued until the outflow is pale pink, and the catheter is usually removed on the second or third postoperative day. In men with small prostates or bladder neck dyssynergia or stenosis, it is better to divide the bladder neck and prostatic urethra with a Collings knife.

Laser can be used to evaporate (e.g. Green light laser) or enucleate the prostate (e.g. HOLEP). The advantage of green light laser is that vaporisation is haemostatic and this procedure can be performed even while patients are anticoagulated. HOLEP involves the use of a laser to coagulate any of the small vessels crossing the relatively avascular plane between the peripheral and transitional zones of the prostate while the tip of the cystoscope is used, much like the surgeons finger at Millin's prostatectomy, to enucleate the transition zone adenoma. The enucleated adenoma is pushed into the bladder, where it is morcellated and extracted via the cystoscope. Damage to the external sphincter is avoided provided one uses the verumontanum as a guide to the most distal point of the resection/vaporisation/enucleation.

Retropubic prostatectomy (Millin)

This procedure is rarely performed nowadays as it has been largely superceded by HOLEP. However, where HOLEP is not available or where diverticulectomy or the removal of large stones are required, this open operation may be performed. Using a low, curved transverse suprapubic Pfannenstiel incision, which includes the rectus sheath, the recti are split in the midline and retracted to expose the bladder. With the patient in the Trendelenburg position, the surgeon separates the bladder and the prostate from the posterior aspect of the pubis. In the space thus obtained, the anterior capsule of the prostate is incised with diathermy below the bladder neck, care being taken to obtain complete control of bleeding from divided prostatic veins by suture ligation. The prostatic adenoma is exposed and a finger used to dissect along the avascular plane between the transition and peripheral zones. A wedge is taken out of the posterior lip of the bladder neck to prevent secondary stricture in this region. The exposure of the inside of the prostatic cavity is good, and control of haemorrhage is achieved with diathermy and suture ligation of bleeding points before closure of the capsule over a Foley catheter (inserted per urethram) draining the bladder.

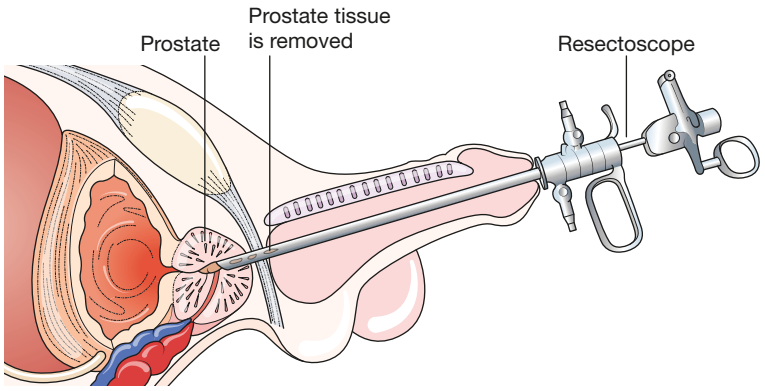

Figure 78.14 For transurethral resection of the prostate the resectoscope is inserted transurethrally. Electric current is passed through a diathermy loop at the end of the instrument. The surgeon moves this back and forth to create a cavity using diathermy to cauterise as they go. The resultant chips are washed out of the bladder intermittently throughout the procedure. A visual image of the operative field is transmitted through lenses running in the middle of the resectoscope. Around this lens, irrigating fluid is instilled and flows out, washing blood away from the operative field. The procedure is complete when an adequate channel has been created through the prostate.

Terence John Millin, 1903–1980, surgeon, The Westminster Hospital, London, UK and Honorary surgeon, All Saints' Hospital for Genitourinary Diseases, London, UK, described the operation of retropubic prostatectomy in 1945. He was regarded as 'the greatest of Irish urologists' and 'the pioneer of the retropubic space'. To facilitate his operation, he devised a self-retaining retractor that goes by his name and the 'boomerang' needle to close the prostatic capsule. He used to be invited all over the world to operate on VIPs. He was a former President of the Royal College of Surgeons in Ireland. He gave up operating at the age of 57 to enjoy his farm in County Wicklow where he died of laryngeal carcinoma. He played international rugby for Ireland.

Transvesical prostatectomy

This operation is very rarely performed nowadays but provides an alternative means by which to enucleate the prostate when BOO is combined with a large bladder stone. The bladder is opened and the prostate enucleated by putting a finger into the urethra, pushing forwards towards the pubes to separate the lateral lobes, and then working the finger between the adenoma and the false capsule (compressed peripheral zone). In Freyer's operation (1901), the bladder was left open widely and drained by a suprapubic tube with a 16-mm lumen in order to allow free drainage of blood and urine. Harris (1934) advocated control of the prostatic arteries by lateral stitches inserted with his boomerang needle. The bladder wall was then closed and the wound drained.

After treatment

Most urologists irrigate the bladder with sterile saline by means of a three-way Foley catheter for 24 hours or so.

Complications

Local

Haemorrhage is a major risk following prostatectomy whatever the surgical approach. Care should be taken in diathermising arterial bleeding points after TURP; they are often better seen when the rate of inflow of fluid is decreased. In the recovery room, one should check that the bladder is draining adequately; if it is not, this may indicate that a clot is blocking the eye of the catheter. The bladder should be promptly washed out using strict aseptic technique. The catheter should be changed by the surgeon. Only rarely is it necessary to return the patient to the operating room.

Secondary haemorrhage tends to occur after the patient has been discharged. All men should be warned about this possibility and given appropriate advice to rest and to have a high fluid intake. It is usually minor in degree but if clot retention occurs, the patient will need to be readmitted, a catheter passed and the bladder washed out.

Perforation of the bladder or the prostatic capsule can occur at the time of transurethral surgery. This usually occurs from a combination of inexperience in association with a large prostate or heavy blood loss. If the field of vision becomes obscured by heavy blood loss, it is often prudent to achieve adequate haemostasis and abandon the operation, swallowing one's pride on the understanding that a second attempt may be necessary. A large perforation with marked extravasation may require the insertion of a small suprapubic drain. Rectal perforation should be extremely rare.

Sepsis

Bacteraemia is common even in men with sterile urine and occurs in over 50% of men with infected urine, prolonged catheterisation or chronic retention. Septicaemia can occur in these patients shortly after operation or when the catheter is removed. Routine use of prophylactic antibiotics is recommended based on local antimicrobial sensitivity profiles. Wound infection following open prostatectomy is common if a urethral catheter has been *in situ* for a number of days before the operation. The most worrying aspect of infection is the early rigor following surgery. If left undetected and untreated, this may progress to frank septicaemia with profound hypotension. A blood culture should be taken and antibiotics given parenterally (e.g. amoxicillin plus cefuroxime, or gentamicin).

Incontinence

Incontinence is inevitable if the external sphincter mechanism is damaged. The bladder neck is rendered incompetent by any prostatectomy and, therefore, an intact distal sphincter mechanism is essential for continence. The verumontanum marks the proximal margin of the external sphincter. If physiotherapy is ineffective, then the only satisfactory treatment is the fitting of an artificial urinary sphincter or a sling to increase the resistance of the urethra. In some patients, detrusor instability contributes to the incontinence. The use of the anticholinergic agents imipramine or duloxetine may help.

Retrograde ejaculation and impotence

Impotence in men with good sexual function before surgery is uncommon, but retrograde ejaculation occurs commonly (>50%) because of disruption to the bladder neck mechanism.

Urethral stricture

This may be secondary to prolonged catheterisation, the use of an unnecessarily large catheter, clumsy instrumentation or the presence of the resectoscope in the urethra for too long a period. These strictures arise either just inside the meatus or in the bulbar urethra. An early stricture can usually be managed by simple bouginage but, later on, it may be necessary to cut the densely fibrotic stricture with the optical urethrotome. The routine use of an Otis urethrotomy prior to TURP reduces the incidence of postoperative stricture.

Bladder neck contracture

Occasionally, a dense fibrotic stenosis of the bladder neck occurs following overaggressive resection of a small prostate. It may be due to the overuse of coagulating diathermy. Transurethral incision of the scar tissue is necessary using laser or diathermy.

Reoperation

It is now well known that, after 8 years, 15–18% of men with BPH will require repeat TURP (the rate after open prostatectomy is about 5%). The reasons include a technically imperfect

Sir Peter Johnston Freyer, 1852–1921, Irish born surgeon, performed the first successful prostatectomy in 1900 at St Peter's Hospital for Stone, London, UK. He used to give a running commentary to his visiting surgeons in French and Hidustani.
Samuel Harry Harris, 1881–1937, urologist, Lewisham Hospital, Sydney, NSW, Australia.
Fessenden Nott Otis, 1825–1900, nineteenth century American urologist.

primary procedure and a speculative repeat operation in men with symptoms who are cystoscoped after operation.

General complications

Death occurs in about 0.2–0.3% of men undergoing elective prostatectomy. In very elderly men, in men with prostate cancer admitted as an emergency with acute or chronic retention or in those with very large prostates, the 30-day death rate may be in the order of 1%.

Cardiovascular

Pulmonary atelectasis, pneumonia, myocardial infarction, congestive cardiac failure and deep venous thrombosis are all potentially life-threatening conditions that can affect this elderly and often frail group of men.

Water intoxication

Absorption of water into the circulation at the time of transurethral resection can give rise to congestive cardiac failure, hyponatraemia and haemolysis. Accompanying this, there is frequently confusion and other cerebral events often mimicking a stroke. The incidence of this condition has been reduced since the introduction of isotonic glycine for irrigating during resection, and further still with the development of bipolar TURP where saline is used as an irrigant. The treatment consists of fluid restriction.

Laser treatment of bladder outflow obstruction

A wide range of tissue ablative techniques using hyperthermia and laser energy have been developed and evaluated. These could often be performed as outpatient procedures with little morbidity. However, as experience has grown and high level data has accumulated, several of these techniques have been excluded and others ensconced within the surgical armamentarium in the treatment of BOO. Most successful transurethral alternatives to TURP involve the use of medical lasers.

The different penetrative and haemostatic characteristics render each type of laser most useful for a particular application. The holmium laser does not penetrate deep but is haemostatic, making it useful in sealing the small vessels that are opened on blunt dissection of the Millin's plane using the beak of the cystoscope during HOLEP. This approach involves excision of parts of the prostate using a cutting laser and then morcellating the excised prostate fragments, which fall back into the bladder so that they can be removed. Morbidity with this procedure is low and long-term results suggest that the benefit will be sustained.

The KTP (green light) laser vaporises tissue and has a deeper penetration than holmium, making it suitable for vaporisation of prostate tissue. This has not yet been shown to be as durable as holmium laser treatment or TURP, because the amount of tissue removed is usually less. Vaporisation of the tissue causes minimal bleeding and green light laser has been used to vaporise the prostate of men in whom stopping anticoagulants is dangerous.

Intraurethral stents

These devices **(Figure 78.15)** are possibly helpful in the management of men with retention who are grossly unfit (classified by the American Society of Anesthesiologists as ASA grade IV). These men are rare cases.

BLADDER OUTFLOW OBSTRUCTION CAUSED BY THE BLADDER NECK

Aetiology

This condition usually occurs in men, but can rarely affect children of both sexes and women. It may be due to muscular hypertrophy or fibrosis of the tissues at the bladder neck following TURP.

Clinical syndromes

Owing to muscle hypertrophy or dyssynergia

Marion described a series of cases in which muscular hypertrophy of the internal sphincter in a young person had resulted in the development of a vesical diverticulum or hydronephrosis (Marion's disease or 'prostatism sans prostate'). It is thought that dyssynergic contraction of the smooth muscle of the bladder neck (bladder neck dyssynergia) may account for some cases of BOO.

Owing to fibrosis

The symptoms are similar to those of prostatic enlargement but are a consequence of scarring after TURP or radical prostatectomy (usually compounded by external beam radiotherapy)

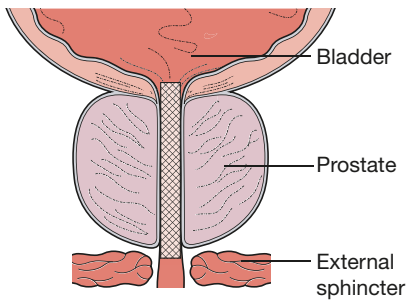

Figure 78.15 Diagram showing one type of prostatic stent *in situ*.

Jean Baptiste Camile Marion, 1869–1932, Professor of Urology, The Faculty of Medicine, Paris, France.

Treatment

The management of these patients depends on achieving an accurate diagnosis. For this, urodynamic investigation is often necessary, which should demonstrate raised voiding pressures and diminished flow rate.

Drugs

The presence of α-adrenergic receptors in the region of the bladder neck and prostatic urethra allows pharmacological manipulation of the outflow to the bladder.

ALPHA-BLOCKING DRUGS

Alfuzosin (2.5 mg b.d. to t.d.s., to a total maximum of 10 mg/day), doxazosin (1 mg nocte, up to a maximum of 8 mg/day), indoramin (20 mg b.d., increased to a total maximum of 100 mg/day in divided doses), prazosin (500 mg b.d., maintenance up to 2 mg/day) and terazosin (1 mg nocte, to a total maximum of 10 mg/day), can be very useful, causing relaxation of the bladder neck. These drugs are not target specific, and patients must be warned of the possibility of postural hypotension, which is usually limited to the first few doses. They can be safely used in combination with anticholinergics to minimise the symptoms of bladder overactivity associated with BOO.

Transurethral incision

Transurethral incision of the bladder neck is the operation of choice. Sometimes symptoms recur, but this is usually due to inadequate division of the fibres of the bladder neck.

Congenital valves of the prostatic urethra

See Chapter 79.

PROSTATIC CALCULI

Prostatic calculi are of two varieties: endogenous, which are common, and exogenous, which are comparatively rare. An exogenous prostatic calculus is a urinary (commonly ureteric) calculus that becomes arrested in the prostatic urethra. Endogenous prostatic calculi are usually composed of calcium phosphate combined with about 20% organic material.

Clinical features

Prostatic calculi are usually symptomless, being discovered on TRUS, on radiography of the pelvis, during prostatectomy or associated with carcinoma of the prostate or chronic prostatitis. In cases associated with severe chronic prostatic infection, the associated fibrosis and nodularity are difficult to differentiate from carcinoma. On radiographs or ultrasound scans, these stones are often seen to form a horseshoe (**Figure 78.16**) or a circle.

Treatment of prostatic calculi

Prostatic calculi usually require no treatment.

Figure 78.16 Endogenous prostatic calculi.

Conservative measures

Associated chronic prostatic infection may be treated by means of ciprofloxacin or trimethoprim.

Transurethral resection

Transurethral resection will often release small calculi as the strips of prostatic tissue are excised. Others are passed per urethram at a later date.

Corpora amylaceae

Corpora amylaceae are tiny calcified lamellated bodies found in the glandular alveoli of the prostates of elderly men and apes, but not in the prostates of animals lower in the phylogenetic scale than anthropoids. Corpora amylaceae are probably the forerunners of endogenous prostatic calculi.

CARCINOMA OF THE PROSTATE

Carcinoma of the prostate is the most common malignant tumour in men over the age of 65 years. In England and Wales in 2004, 30 000 men were registered and 10 000 died from prostate carcinoma; the corresponding figures in the USA were 260 000 and 35 000, respectively. If histological section of prostates at autopsy is performed, increasingly frequent foci of microscopic prostate cancers are found with increasing age. These foci of prostate cancer have variable potential for progressing clinically to metastatic disease. About 10–15% of younger men who develop prostate cancer have a positive family history of the disease, but the aetiology is unclear.

Throughout the world, rates of microscopic foci of prostate cancer are constant, but rates of clinically evident disease are low in men in Japan and China. Carcinoma of the prostate usually originates in the PZ of the prostate (see **Figure 78.2**), so 'prostatectomy' for benign enlargement of the gland confers no protection from subsequent carcinoma.

Pathology

Serial sections of prostates obtained at routine necropsy demonstrate prostate carcinoma in 25% of men between 50 and 65 years of age. The incidence in men over 80 years is in the region of 70% (Franks). Most of these neoplasms are tiny and (if life had continued) might have remained latent for years.

The following types of prostate cancer occur:

- microscopic latent cancer found on autopsy or at cystoprostatectomy;
- tumours found incidentally during TURP (T1a and T1b) or following screening by PSA measurement (T1c);
- early, localised prostate cancer (T2);
- advanced local prostate cancer (T3 and T4);
- metastatic disease, which may arise from a clinically evident tumour (T2, T3 or T4) or from an apparently benign gland (T0, T1) (i.e. occult prostate cancer).

It should be noted that only the last two groups cause symptoms, and such tumours are not curable. Only screening or the treatment of incidentally found tumours can result in cure of the disease. The problem is that many such tumours would never progress during the patient's lifetime; herein lies the problem with prostate cancer.

Screening for prostate cancer

The cancer detection rate using measurement of PSA is between 2% and 4%, and approximately 30% of men with an elevated PSA will have prostate cancer confirmed by biopsy. Unfortunately, 20% of men with clinically significant prostate cancer will have PSA values within the normal range. There is therefore controversy over the usefulness of PSA alone as a screening procedure. Currently, a number of prospective trials aimed at determining whether or not PSA testing reduces the disease-specific mortality of prostate cancer are under way. At present, in Europe, population-based screening is performed only within the confines of clinical trials.

Summary box 78.6

- The results of several large scale randomised clinical trials evaluating the role of prostate-specific antigen (PSA) screening for prostate cancer suggest that at present screening the entire population with serum PSA is not cost effective as a large number of men must be screened, biopsied and treated in order to prevent each death from prostate cancer.

Histological appearances

The prostate is a glandular structure consisting of ducts and acini; thus, the histological pattern is one of an adenocarcinoma. The prostatic glands are surrounded by a layer of myoepithelial cells. The first change associated with carcinoma is the loss of the basement membrane, with glands appearing to be in confluence. As the cell type becomes less differentiated, more solid sheets of carcinoma cells are seen. A classification of the histological pattern based on the degree of glandular de-differentiation and its relation to stroma has been devised by Gleason. Prostate cancers exhibit heterogeneity within tissue, and so two histological areas of prostate are each scored between 1 and 5. The scores are added to give an overall Gleason score of between 2 and 10; this (and the volume of the cancer) appears to correlate well with the likelihood of spread and the prognosis.

Local spread

Locally advanced tumours tend to grow upwards to involve the seminal vesicles, the bladder neck and trigone and, later, the tumours tend to spread distally to involve the distal sphincter mechanism. Further upward extension obstructs the lower end of one or both ureters, obstruction of both resulting in anuria. The rectum may become stenosed by tumour infiltrating around it, but direct involvement is rare.

Spread by the bloodstream

Spread by the bloodstream occurs particularly to bone; indeed, the prostate is the most common site of origin for skeletal metastases, followed in turn by the breast, the kidney, the bronchus and the thyroid gland. The bones involved most frequently by carcinoma of the prostate are the pelvic bones and the lower lumbar vertebrae. The femoral head, rib cage and skull are other common sites.

Lymphatic spread

Lymphatic spread may occur (1) via lymphatic vessels passing to the obturator fossa or along the sides of the rectum to the lymph nodes beside the internal iliac vein and in the hollow of the sacrum and (2) via lymphatics that pass over the seminal vesicles and follow the vas deferens for a short distance to drain into the external iliac lymph nodes. From retroperitoneal lymph nodes, the mediastinal nodes and occasionally the supraclavicular nodes may become implicated.

Staging using the tumour, node, metastasis (TNM) system (**Figure 78.17**)

- **T1a, T1b and T1c**. These are incidentally found tumours in a clinically benign gland after histological examination of a prostatectomy specimen. T1a is a tumour involving less than 5% of the resected specimen; these tumours are usually well or moderately well differentiated. T1b is

Donald F Gleason, 1920–2008, pathologist, University of Minnesota, Minneapolis, MN, USA, published The Gleason System in 1966. He spent his last 20 years sailing, baking bread and playing bridge.

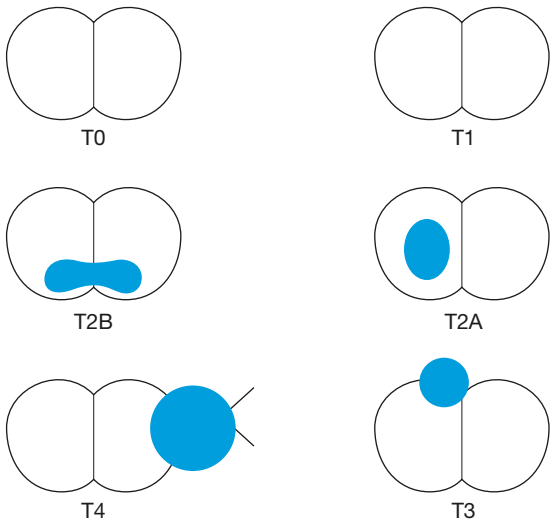

Figure 78.17 Tumour, node, metastasis staging system for prostate cancer.

a tumour involving >5% of the resected specimen. T1c tumours are impalpable tumours found following investigation of a raised PSA.

- **T2a** disease presents as a suspicious nodule (Figure 78.18) on rectal examination confined within the prostate capsule and involving one lobe. T2b disease involves both lobes.
- **T3** tumour extends through the capsule (T3a, uni- or bilateral extension; T3b, seminal vesical extension).
- **T4** is a tumour that is fixed or invading adjacent structures other than seminal vesicles – rectum or pelvic side wall.

Summary box 78.7

The natural history of prostate cancer

This depends on the stage and grade of disease:

- T1 and T2
  - The progression rate of well-differentiated T1a prostate cancer is very low: 10–14% after eight years. For moderately differentiated tumours, the rate is about 20%
  - For T1b and T2 tumours, the rate is in excess of 35%
- T3 and T4 (MO)
  - About 50% progress to bony metastases after 3–5 years
- M1
  - The median survival of men with metastatic disease is about 3 years

Clinical features

Only advanced disease gives rise to symptoms, but even advanced disease may be asymptomatic. Symptoms of advanced disease include:

- BOO;
- pelvic pain and haematuria;
- bone pain, malaise, 'arthritis', anaemia or pancytopenia;
- renal failure;

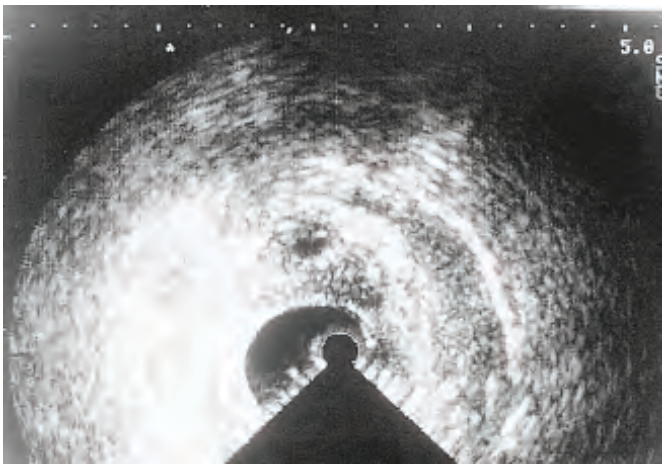

Figure 78.18 Transrectal ultrasound scan of a T2 nodule in the prostate.

- locally advanced disease or even asymptomatic metastases, which may be found incidentally on investigation of other symptoms.

Early prostate cancer is asymptomatic and may be found:

- incidentally following TURP for clinically benign disease (T1);
- as a nodule (T2) on rectal examination.

Summary box 78.8

The presentation of men with prostate cancer

- Often men are asymptomatic, and detection is by opportunistic PSA testing
- Cancer is detected in men describing lower urinary tract symptoms or may present with symptoms of metastatic disease

Rectal examination

Rectal examination can detect nodules within the prostate and advanced disease. Irregular induration, characteristically stony hard in part or in the whole of the gland (with obliteration of the median sulcus), suggests carcinoma. Extension beyond the capsule up into the bladder base and vesicles (Figure 78.19) is diagnostic, as is local extension through the capsule (Figure 78.20).

Prostatic biopsy

If there is suspicion of prostate cancer, because of local findings, a raised PSA or metastatic disease, then a prostate biopsy using an automated gun is recommended (Figure 78.21). This is usually performed transrectally, although increasingly the transperineal approach is being used. In a standard transrectal biopsy about 12 systematic biopsy cores are obtained as well as biopsy of any suspicious areas. Broad-spectrum antibiotic cover is given to all patients to reduce the incidence of sepsis,

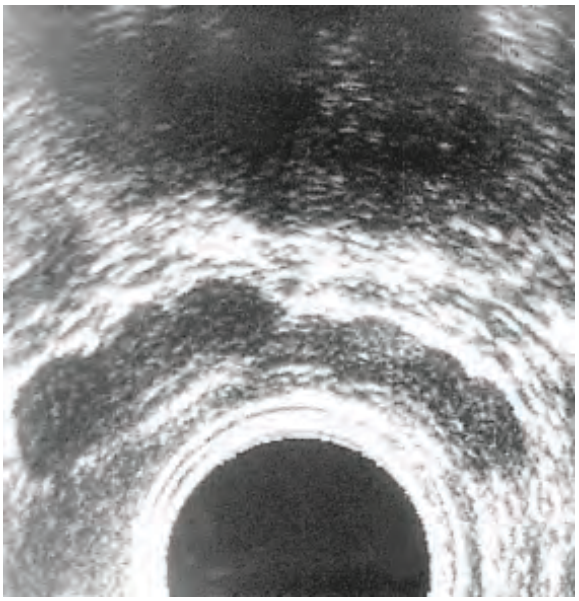

Figure 78.19 Transrectal ultrasound scan showing normal seminal vesicles.

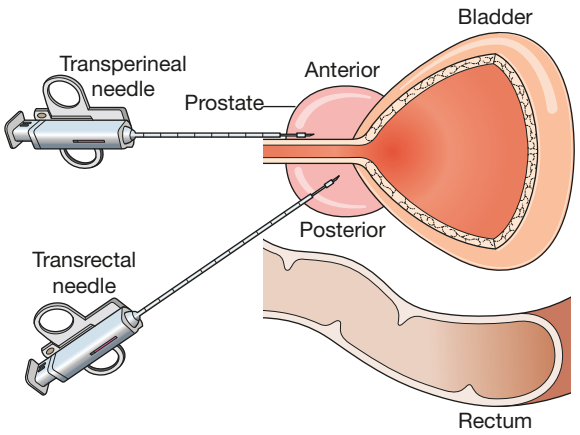

Figure 78.21 The prostate is commonly biopsied by two routes. The biopsy needle can be inserted through skin between the scrotum and anus (perineum) or the rectum. In both cases the passage of the needle is usually guided to the correct place with transrectal ultrasound. Transrectal ultrasound is not good for sampling the anterior prostate, particularly when the prostate is large. Transperineal biopsy is gaining popularity as an alternative to conventional transrectal biopsy.

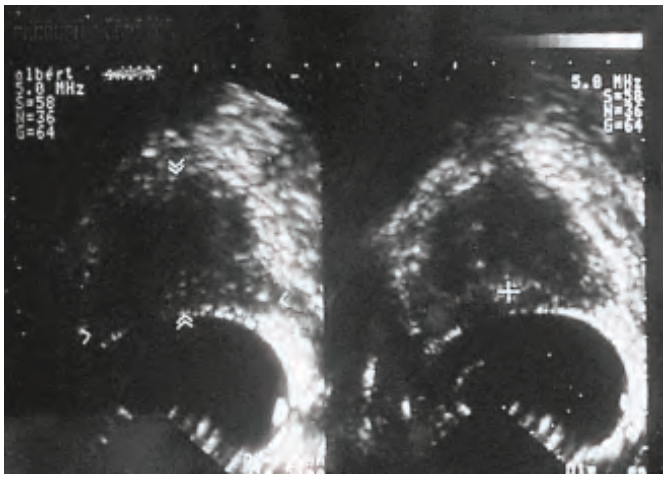

Figure 78.20 Transrectal ultrasound scan showing local extension of a T3 prostate cancer.

which is greater with transrectal than transperineal biopsy. Transperineal biopsy usually involves sedation or general anaesthetic while transrectal biopsy can be performed under local anaesthetic. Increasingly, areas appearing suspicious for prostate cancer on multiparametric magnetic resonance imaging (mp-MRI) can be targeted for biopsy to increase the diagnostic yield.

If there are associated symptoms of BOO, then either:

- a TURP can be performed, which will provide diagnostic material and symptomatic relief; or
- a transrectal biopsy can be carried out. If the diagnosis is positive and there is locally advanced disease, then hormone ablation can provide good symptomatic relief without the need for operation.

General blood tests

These are normal in early disease but, in metastatic disease, there may be leucoerythroblastic anaemia secondary to extensive marrow invasion, or anaemia may be secondary to renal failure. There may be thrombocytopenia and evidence of disseminated intravascular coagulopathy with increased fibrinogen degradation products.

Liver function tests

These will be abnormal if there is extensive metastatic invasion of the liver. Alkaline phosphatase may be raised from either hepatic involvement or secondaries in the bone. These can be distinguished by measurement of isoenzymes or gammaglutamyltransferase.

Prostate-specific antigen

This is discussed earlier in this chapter. It is good at following the course of advanced disease; however, it is lacking in sensitivity and specificity in the diagnosis of early localised prostate cancer. Nevertheless, the finding of a PSA >10 ng/mL is suggestive of cancer and >35 ng/ml is almost diagnostic of advanced prostate cancer. A decrease in PSA to the normal range following hormonal ablation is a good prognostic sign. Following radical prostatectomy the serum PSA should fall to undetectable levels (the limit for detection for modern supersensitive assays is 0.02 ng/mL)

Radiological examination

Radiographs of the chest may reveal metastases in either the lung fields or the ribs. An abdominal radiograph may show the characteristic sclerotic metastases in lumbar vertebrae

and pelvic bones (Figure 78.22). The bone appears dense and coarse, and it is sometimes difficult to distinguish the change from that in Paget's disease of bone. Nevertheless, osteolytic metastases are very common in prostate cancer and may coexist with sclerotic ones. Information about the upper urinary tracts can be obtained by excretion urography or ultrasound.

Cross-sectional imaging with magnetic resonance imaging and TRUS

MRI with a high tesla magnet (1.5–3 T) is the most accurate method of staging local disease In order to characterise prostate cancer a combination of imaging sequences must be interpreted (mp-MRI). mp-MRI consists of T2-weighted imaging combined with several functional sequences including diffusion-weighted imaging, perfusion or dynamic contrast-enhanced imaging and spectroscopic imaging. The accuracy of mp-MRI in localising and staging prostate cancer shows a high degree of variation between reporting radiologists. mp-MRI is used preoperatively to assess pelvic lymph nodes as well as local stage, although the sensitivity of mp-MRI to detect small areas of capsular spread is limited, even in the best hands. As well as preoperative staging, mp-MRI plays an important role in active surveillance and localisation of recurrent prostate cancer after surgery. Low-grade tumours are frequently not seen on MRI, which is useful as these low-grade tumours are often clinically insignificant.

Transrectal ultrasound scanning can also be used to stage prostate cancer. Locally extensive disease (T2) can be diagnosed with increased sensitivity by TRUS (see Figure 78.18) compared with rectal examination, but many tumours will still be missed. This problem remains a real one in screening for early prostate cancer; in comparison with breast cancer, with mammography detecting 70–80% of tumours, TRUS plus rectal examination and measurement of PSA will detect only 30–50% of cancers that are known to be present on autopsy studies (although it may detect the larger, more significant cancers).

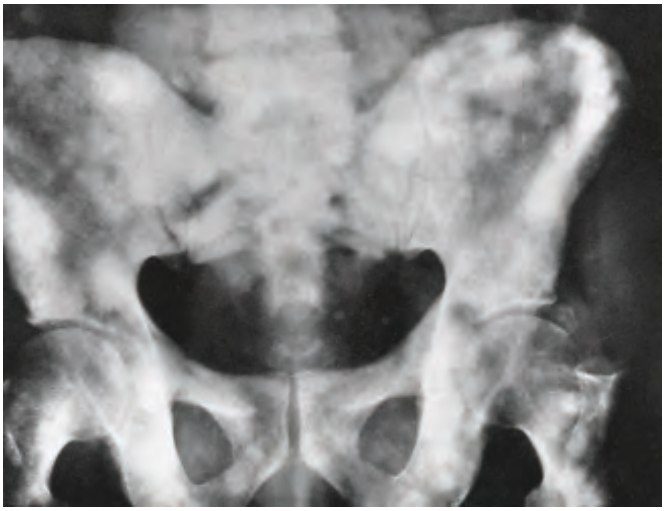

Figure 78.22 Osseous metastases of the pelvic bones in carcinoma of the prostate (courtesy of LN Pyrah, Leeds, UK).

Bone scan

Once the diagnosis has been established, if metastatic spread is suspected (on the basis of a high PSA [>10 ng/mL], locally advanced disease or presence of Gleason 7 or higher) a bone scan should be carried out. If however the PSA is <10 ng/mL, then a bone scan would be performed only on clinical indications. The bone scan is performed by the injection of technetium-99m, which is then monitored using a gamma camera. It is more sensitive in the diagnosis of metastases (Figure 78.23) than a skeletal survey, but false positives occur in areas of arthritis, osteomyelitis or a healing fracture.

Treatment

Patients are counselled on their treatment options based on an estimated risk of a localised cancer spreading and causing death. The strongest risk factors for metastasis are PSA level, Gleason grade and clinical stage.

Early disease

Curative treatment can only be offered to patients with early disease. Low risk prostate cancer (low PSA, small foci of Gleason 6 disease) can be managed by active surveillance. Here, with 3- to 6-monthly digital rectal examination (DRE) and PSA measurement and repeated prostate biopsy, a proportion can safely avoid the toxicity of radical treatment. However, one-third of patients embarking on this approach will require radical treatment within a few years. The options available for T1, T2 or some T3 disease need to take into account patient

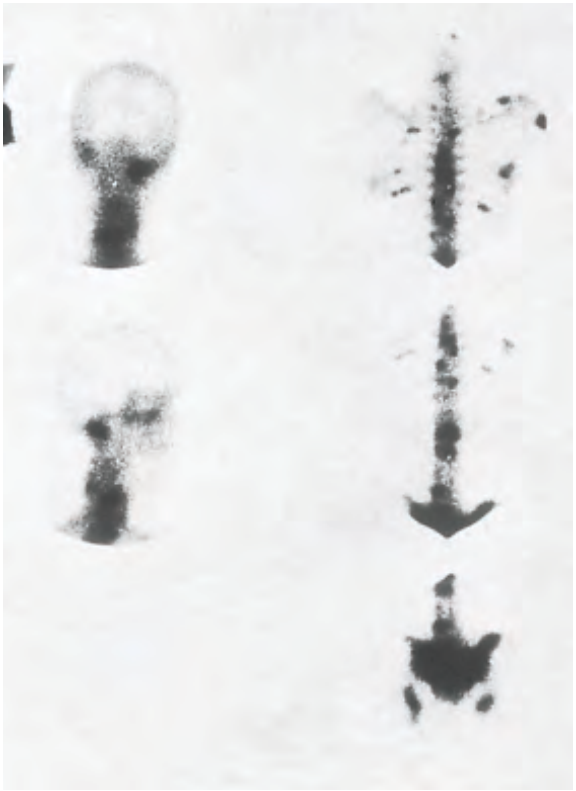

Figure 78.23 Bone scan showing multiple hot-spots suggestive of metastatic disease in a man with prostate cancer.

age, performance status and lifestyle preferences. The treatment of patients with advanced disease (T4 or any nodal or distant metastases) is only palliative.

Summary box 78.9

Treatment and stage

- Treatment options for prostate cancer depend on stage of disease, life expectancy of the patient and patient preference
- Prostate-specific antigen, digital rectal examination and biopsy Gleason grade are used to predict pathological stage
- Localised cancer can be treated by radical prostatectomy, radiation therapy and active monitoring
- Treatment of advanced disease is palliative, and hormone ablation remains the first-line therapy

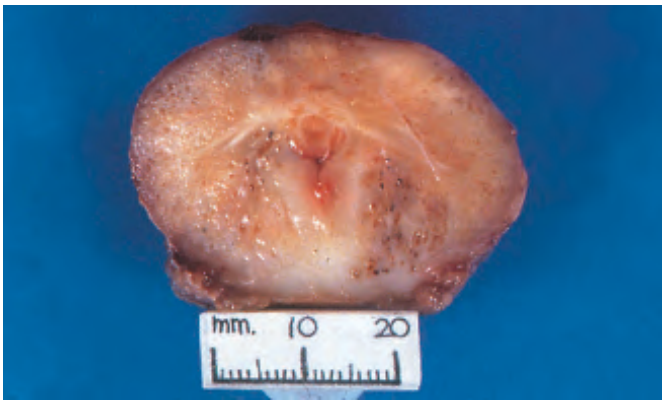

Figure 78.24 Radical prostatectomy specimen for a T2a prostate cancer. Preoperative prostate-specific antigen was 6 ng/mL; postoperative levels remained undetectable at 8 years. The patient is fully continent.

Radical prostatectomy

Radical prostatectomy is suitable for localised disease and should be carried out only in men with a life expectancy of >10 years. A wide excision approach can give clear surgical margins in T3a disease. Exclusion of metastases would require a negative bone scan and MRI of the pelvis. It is a procedure that should be performed only by experienced surgeons when there is a high chance of cure. It results in a high incidence of impotence, but a low incidence of severe stress incontinence (<2%), which may require the fitting of an artificial urinary sphincter or urethral sling. It involves removal of the prostate down to the distal sphincter mechanism in addition to the seminal vesicles (Figure 78.24). The bladder neck is reconstituted and anastomosed to the urethra. Modifications to this operation by Walsh can lead to preservation of the neurovascular bundles that lie behind the prostate. This modification has led to the preservation of erectile function in about 60–70% of cases. Laparoscopic approaches to radical prostatectomy, often with robotic assistance, generate similar oncological results to the open approach with a more rapid recovery.

Radical radiotherapy for early prostate cancer

External beam radiotherapy (EBRT) can be administered in fields that conform to the contours of the prostate, thereby limiting exposure of adjacent tissues. Survival rates following the treatment of T1 and low-volume T2 disease are not greatly different from those following radical prostatectomy, although histological evidence of persistent tumour is found within the prostate in about 30% of treated patients. Patients with locally advanced disease (T3) may be treated by radiotherapy. The treatment requires the patient to attend hospital on a daily basis for between 4 and 6 weeks. Some local complications are inevitable, namely irritation of the bladder with urinary frequency, urgency and sometimes urge incontinence and similar problems affecting the rectum with diarrhoea and, occasionally, late radiation proctitis. Development of erectile dysfunction occurs less frequently than following radical prostatectomy, but is present in up to 30% of cases. EBRT is rendered more effective with a period of neoadjuvant and adjuvant androgen ablation, with its inherent effects on libido.

Brachytherapy

Under transrectal ultrasound guidance, radioactive seeds are permanently implanted into the prostate. A computer program converts accurate ultrasound measurements of the prostate gland to construct a plan of the gland. Under anaesthesia, the patient is placed in the lithotomy position and, according to the template plan, seeds are placed through transperineal needles. The radioisotopes commonly used are iodine-125 and palladium-103. These isotopes deliver an intense, confined radiation dose, which falls off rapidly to spare the surrounding structures. Brachytherapy is gaining widespread acceptance for the treatment of lower grade low-volume T1 disease. A major factor is the reduced peroperative complications and generally low morbidity. Long-term cancer survival results from institutions specialising in the procedure are encouraging.

Advanced disease

There is still debate about the timing of androgen ablation treatment in patients with locally advanced or metastatic disease without symptoms. The options are androgen deprivation at diagnosis or careful review, reserving active treatment for the later development of symptoms. Patients with poorly differentiated disease are at risk of a catastrophic event such as spinal cord compression; in these patients, early androgen ablation can prolong the time to complications. Also, patients with local or general symptoms should be offered androgen deprivation.

Patrick C Walsh, Professor of Urology, Johns Hopkins Hospital, Baltimore, MD, USA, recipient of 2007 National Physician of the Year Clinical Excellence Award.

Orchidectomy

Orchidectomy is performed in advanced disease. In 1941, prostate cancer was shown to be responsive to such treatment by Charles Huggins, the only urologist to win a Nobel Prize. Bilateral orchidectomy, whether total or subcapsular, will eliminate the major source of testosterone production.

Medical castration

Medical forms of androgen ablation have been available since the discovery of stilbestrol. The other commonly available treatments to reduce testosterone levels to the castrate range are LHRH agonists. These agents initially stimulate hypothalamic LHRH receptors but, because of their constant presence (rather than the normal diurnal rhythm), they then downregulate them, resulting in cessation of pituitary LH production and, hence, a decrease in testosterone production. In the first 10 days or so, serum testosterone levels may increase, and it is wise to give flutamide, bicalutamide or cyproterone acetate for this period. LHRH agonists may be given by monthly, 3-monthly or 6-monthly depot injection. Other treatments that block the androgen receptor have become available recently. Cyproterone acetate also has some progestogenic effect, while flutamide and bicalutamide are pure antiandrogen. In general, oral antiandrogen monotherapy has not been shown to be as good as LHRH agonists or orchidectomy. Androgen ablation can be administered in an intermittent fashion governed by serum PSA levels.

Recently agents such as enzalutamide (a second generation androgen receptor blocker), degarelix (an LHRH antagonist), abiraterone (a drug that blocks the production of testosterone from its precursors) and taxane chemotherapy have all been shown to promote survival in metastatic prostate cancer. Many clinical trials are underway to ascertain which drugs should be used in which patients and the therapeutic landscape is changing rapidly.

General radiotherapy

Radiotherapy for symptomatic metastases is an excellent form of palliative treatment, often producing dramatic pain relief in men with hormone-relapsed prostate cancer that can last up to 6 months. When multiple sites are involved, intravenous radiopharmaceuticals such as strontium-89 can be employed. Strontium is a bone-seeking isotope that delivers effective radiotherapy to metastatic areas. It appears to be as effective as hemibody irradiation in the treatment of men with metastatic hormone-relapsed disease; however, the duration of response has been disappointing.

Chemotherapy

Cytotoxic agents in the treatment of these men have proved disappointing, but whether this is because the tumour is inherently insensitive or because these elderly men will not tolerate effective doses is uncertain. Trials of docetaxel and carbitaxel have shown improvements in survival, but only by a few months in end-stage castrate-resistant prostate cancer. Recent data suggest better results when used earlier in the natural history of advanced prostate cancer.

Summary of treatment for carcinoma of the prostate

- **Low risk disease**. For men in their 70s, conservative treatment would usually be the correct approach. Radical surgical treatment might be considered in the younger (<70 years) man with this form of the disease, although even in this group, some men will elect to pursue a conservative course when counselled about risks versus benefits.
- **Intermediate risk disease**. In younger, fitter men (<70 years), this may be treated by radical prostatectomy or radical radiotherapy. Active monitoring remains an option, particularly for more elderly patients towards the lower end of the risk spectrum. In the elderly patient with outflow obstruction, transurethral resection with or without hormone therapy is indicated. The benefit of radical treatment over a conservative approach is likely to be about 25%, given that progression to metastatic disease is of this order of magnitude after 10 years.
- **High risk disease**. These patients are at significant risk of disease progression. Early androgen ablation is favoured if close follow-up is not possible. For the sexually active, a careful conservative approach with the adoption of androgen ablation when symptoms arise is reasonable. Androgen ablation coupled with radiotherapy, perhaps with surgery as part of a multimodal approach, is standard treatment for younger men with T3 disease.
- **Metastatic disease**. Once metastases have developed, the outlook is poor. For patients with symptoms, there is no dilemma; androgen ablation will provide symptomatic relief in over two-thirds of patients. For patients with asymptomatic metastases, the timing of treatment is less clear. Systemic chemotherapy with docetaxel should be considered in younger, fitter men.

PROSTATITIS

In both acute and chronic prostatitis, the seminal vesicles and posterior urethra are usually also involved.

Acute prostatitis

Aetiology

Acute prostatitis is common, but underdiagnosed. The usual organism responsible is *Escherichia coli*, but *Staphylococcus aureus*, *Staphylococcus albus*, *Streptococcus faecalis*, *Neisseria gonorrhoeae* or *Chlamydia* may be responsible. The infection may be haematogenous from a distant focus or it may be secondary to acute urinary infection.

Charles Brenton Huggins, 1901–1997, Canadian born, Professor of Surgery, The University of Chicago, IL, USA, shared the 1966 Nobel Prize for Physiology or Medicine for his discoveries concerning hormonal treatment of prostate cancer.

Clinical features

General manifestations overshadow the local: the patient feels ill, shivers, may have a rigor, has 'aches' all over, especially in the back, and may easily be diagnosed as having influenza. The temperature may be up to 39°C. Pain on micturition is usual, but not invariable. The urine contains threads in the initial voided sample, which should be cultured. Perineal heaviness, rectal irritation and pain on defaecation can occur; a urethral discharge is rare. Frequency occurs when the infection involves the bladder. Rectal examination reveals a tender prostate; one lobe may be swollen more than the other, and the seminal vesicles may be involved. A frankly fluctuant abscess is uncommon.

Treatment

Treatment must be rigorous and prolonged or the infection will not be eradicated and recurrent attacks may ensue. Spread of infection to the epididymides and testes may occur. Prolonged treatment with an antibiotic that penetrates the prostate well is indicated (trimethoprim or ciprofloxacin).

Prostatic abscess

In addition to the foregoing symptoms and signs, the advent of a prostatic abscess is heralded by the temperature rising steeply with rigors. Antibiotics disguise these features. Severe, unremitting perineal and rectal pain with occasional tenesmus often cause the condition to be confused with an anorectal abscess. Nevertheless, if a rectal examination is performed, the prostate will be felt to be enlarged, hot, extremely tender and perhaps fluctuant. TRUS or MRI may aid diagnosis. Retention of urine is likely to occur and, in such men, suprapubic catheterisation is best.

Treatment

The abscess should be drained without delay by perurethral resection (unroofing the whole cavity) or using a needle via the transrectal or perineal route.

Chronic prostatitis

Many urologists find the diagnosis of chronic prostatitis and 'prostatodynia' very difficult, for many men present with perigenital pain, testicular pain, prostatic pain exacerbated by sexual intercourse or pain that apparently renders sexual intercourse out of the question. Psychosexual dysfunction in such patients may be the underlying problem. The diagnosis of chronic prostatitis has to be based on:

- persistent threads in voided urine;
- prostatic massage showing pus cells with or without bacteria in the absence of urinary infection.

Aetiology

This is thought to be the sequela of inadequately treated acute prostatitis. While pus is present in the prostatic secretion, the responsible organism is often difficult to find. Other organisms such as *Chlamydia* species may be responsible for chronic abacterial prostatitis.

Clinical features

The clinical features are extremely varied. Only men with symptoms of posterior urethritis, prostatic pain and perigenital pain accompanied by intermittent fever and pus cells or bacteria in the post-prostatic massage specimen should be diagnosed as having chronic prostatitis.

Diagnosis

The three-glass urine test is valuable. If the first glass with the initial voided sample shows urine containing prostatic threads, prostatitis is present.

Rectal examination of the prostate may be normal or may show a soft, boggy and tender prostate.

Examination of the prostatic fluid obtained by prostatic massage should show pus cells and bacteria.

Urethroscopy may reveal inflammation of the prostatic urethra, and pus may be seen exuding from the prostatic ducts. The verumontanum is likely to be enlarged and oedematous. In many men with the symptoms described above, all investigations are normal.

Treatment

Antibiotic therapy should be administered only in accordance with bacteriological sensitivity tests. Trimethoprim or ciprofloxacin penetrate well into the prostate. If *Trichomonas* or anaerobes are the responsible agent, a rapid response is obtained from administration of metronidazole (200 mg t.d.s. for 7 days to both partners). If *Chlamydia* is suspected, doxycycline is the antibiotic treatment of choice. There is little evidence that prostatic massage helps in eradicating the infection.

Prostatodynia

This diagnosis is made by the presence of perigenital pain in the absence of any objective evidence of prostatic inflammation. Whether the syndrome has any relationship with the prostate is unclear. The syndrome is part of the chronic pelvic pain syndrome spectrum.

TUBERCULOSIS OF THE PROSTATE AND SEMINAL VESICLES

Tuberculosis of the prostate and seminal vesicles is rare and associated with renal tuberculosis. In 30% of cases, there is a history of pulmonary tuberculosis within 5 years of the onset of genital tuberculosis.

Tuberculosis of one or both seminal vesicles may be found when examining a patient with chronic tuberculous epididymitis, no symptoms being referable to the internal genitalia. On rectal examination, the affected vesicle is found to be nodular.

When the prostate is involved, rectal examination reveals nodules in one or both lateral lobes. Patients with tuberculous prostatitis usually present with the following:

- urethral discharge;
- painful, sometimes blood-stained, ejaculation;

- mild ache in the perineum;
- infertility;
- dysuria;
- abscess formation.

Special forms of investigation

Radiography sometimes displays areas of calcification in the prostate and/or the seminal vesicles. Bacteriological examination of the seminal fluid yields positive cultures for tubercle bacilli.

Treatment

The general treatment is that for tuberculosis. If a prostatic abscess forms, it should be drained transurethrally.

SEMINAL VESICLES

Acute seminal vesiculitis

Acute seminal vesiculitis occurs in association with prostatitis. Prior to the antibiotic treatment of gonorrhoea, gonococcal vesiculitis was common.

Chronic seminal vesiculitis

Chronic seminal vesiculitis usually presents with haematospermia and pain on intercourse. TRUS demonstrates the features of distension and thickening and the presence of turbid fluid. The treatment is the same as for chronic prostatitis.

Tuberculous seminal vesiculitis

The clinical features and treatment have been discussed above.

Diverticulum of the seminal vesicle

Diverticulum of the seminal vesicle occurs occasionally. In such cases, the kidney of that side is absent and the diverticulum represents an abortive ureteric bud. It is a cause of persistent infection.

Cyst of the seminal vesicle

A cyst of the seminal vesicle is uncommon and rarely requires treatment. It may be removed by dissection through an incision similar to that for perineal prostatectomy if it is large or giving rise to symptoms.

Chapter 79

Urethra and penis

Learning objectives

To recognise and understand:

- The common congenital abnormalities of the urethra
- The diagnosis and management of urethral trauma
- The diagnosis and management of urethral stricture
- The diagnosis and management of phimosis
- The principles of management of a man with erectile dysfunction
- The common diseases of the penis and urethra and the principles of their surgical management

THE MALE URETHRA

Anatomy

The male urethra is a tubular structure extending from the bladder neck to the external urinary meatus at the tip of the glans penis. It has four components, which are named (from proximal to distal) the prostatic, membranous, bulbar and penile urethra. The prostatic urethra extends from the bladder neck to the verumontanum and is compressed on either side by the lateral lobes of the prostate, giving it a slit-like configuration. The verumontanum is a small hillock of tissue indented at its crown by a pit called the utriculus masculinus, which marks the proximal extent of the external urethral sphincter and is an important landmark for urologists performing transurethral resection of the prostate. The membranous urethra lies just distal to the verumontanum and is located where the urethra penetrates the pelvic floor and it is the usual site of urethral rupture at the time of a pelvic fracture. It is the primary location of continence as a consequence of the surrounding pelvic floor musculature and external urethral sphincter. The bulbar urethra extends from the membranous urethra to the penoscrotal junction and is anteriorly located within the corpus spongiosum. The penile urethra is normally flattened anteroposteriorly but distends when filled with fluid. The urethral lining changes from transitional cell epithelium proximally to stratified squamous cell epithelium distally.

The external urethral sphincter is composed of circular striated muscle within the urethral wall. It is innervated by the pudendal nerve, originating from spinal segments S2, 3 and 4. The bladder neck contributes to maintenance of continence in the man, although its main role is as a genital sphincter that closes at the time of ejaculation. Its innervation originates in the spinal segments T10–12 with sympathetic innervation mediated by release of noradrenaline via alpha adrenoceptors.

Congenital abnormalities

Posterior urethral valves

Posterior urethral valves occur in around 1 in 5000–8000 live male births. The valves are membranes that have a small posterior slit within them, which typically lie just distal to the verumontanum and cause obstruction to the urethra of boys. They function as flap valves and so although they are obstructive to antegrade urinary flow, a urethral catheter can be passed retrogradely without any difficulty.

DIAGNOSIS

Posterior urethral valves need to be detected and treated as early as possible to minimise the degree of renal failure. The presentation varies according to the severity of the obstruction. The more severe the obstruction, the earlier the presentation. Diagnosis is most commonly made antenatally with ultrasound, which demonstrates bilateral hydronephrosis above a distended bladder.

If the diagnosis is not made antenatally, then babies typically present with urinary infection in the neonatal period or with uraemia and renal failure.

Rarely the valves are incomplete and the patient is symptom free until adolescence or adulthood, when again urinary infection or renal impairment can supervene.

Investigation will involve a voiding cystogram, with the dilatation of the urethra above the valves demonstrable on a voiding cystogram (**Figure 79.1**). The bladder is hypertrophied and often shows diverticula. Typically, there is vesicoureteric reflux into dilated upper tracts. The valves themselves can be difficult to see on urethroscopy because the flow of

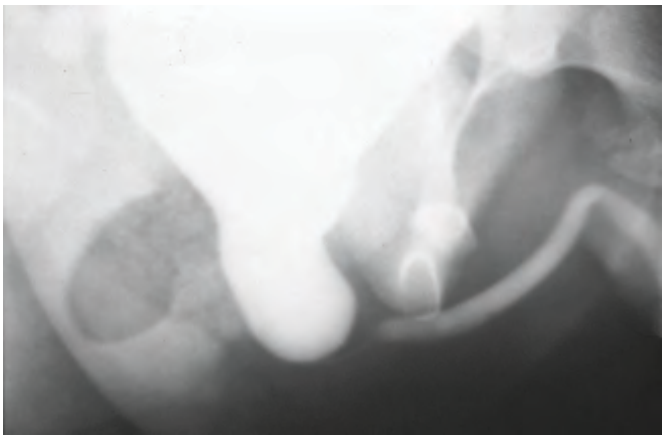

Figure 79.1 A voiding cystogram showing a dilated bladder with a dilated prostatic urethra above an obstruction at the level of the posterior urethral valve.

irrigant sweeps them into the open position. Renal function is usually impaired, albeit to a varying degree, and the extent is further assessed by measurement of ultrasound scanning, which will assess the renal cortical thickness, and renography to assess differential renal function.

TREATMENT

Initial treatment is by catheterisation to relieve the obstruction and to allow the effects of renal failure to improve. Definitive treatment is by endoscopic destruction of the valves with continuing lifelong supportive treatment of the dilated urinary tract, the recurrent urinary infections and the uraemia.

Summary box 79.1

Posterior urethral valves

- Posterior urethral valves are congenital membranes that cause obstruction to the urinary tract in baby boys
- Antenatal ultrasound typically shows urinary tract dilatation
- If not recognised antenatally, they may cause recurrent urinary infection, urinary retention and uraemia
- Treatment is valve destruction accompanied by treatment of urinary infection and renal impairment

Hypospadias (see also Chapter 9)

Hypospadias occurs in around 1 in 200–300 male live births and is the most common congenital abnormality of the urethra. There are three characteristic features. The external meatus opens on the underside of the penis anywhere from just short of the normal site as far back as the perineum, while the ventral aspect of the prepuce is poorly developed (the 'hooded prepuce') and there is usually a ventral deformity of the erect penis (chordee).

Hypospadias is classified according to the position of the meatus (Figure 79.2):

- Glanular hypospadias. The ectopic meatus is placed on the glans penis, but proximal to the normal site of the external meatus, which is marked by a blind pit. Occasionally the two are connected by a channel.

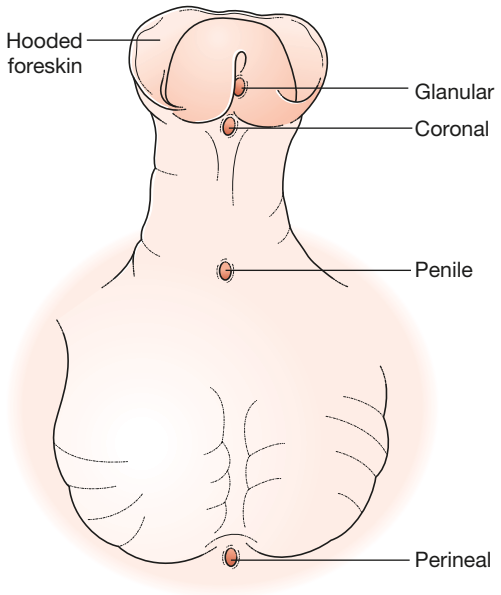

Figure 79.2 Hypospadias classification.

- Coronal hypospadias. The meatus is placed at the junction of the underside of the glans and the body of the penis.
- Penile and penoscrotal hypospadias. The meatus is on the underside of the penile shaft.
- Perineal hypospadias. This is the rarest and most severe abnormality. The scrotum is bifid and the urethra opens between its two halves. In children with severe hypospadias it is important to consider disorders of sexual development, which are usually associated with testicular maldescent and micropenis.

The more severe varieties of hypospadias represent an absence of the urethra and corpus spongiosum distal to the ectopic opening. The absent structures are represented by a fibrous cord, which deforms the erect penis in a downward direction (chordee).

TREATMENT

Hypospadias does not cause either obstruction or urinary tract infection. Surgery is indicated to improve sexual function, to correct problems with the urinary stream and for cosmetic reasons. A variety of plastic surgical procedures have been described to correct the chordee and to re-site the urethral opening. The commonest procedure for distal hypospadias is the 'tubularised incised plate' urethroplasty, while techniques that utilise the foreskin are commonly used for more proximal hypospadias. Circumcision should be avoided, therefore, before the hypospadias has been repaired. Operations for hypospadias are best performed by a paediatric urologist and are typically undertaken before the age of 18 months.

Epispadias

Epispadias is very rare. In penile epispadias, the urethral opening is on the dorsum of the penis and is associated with an upward curvature of the erect penis (Figure 79.3). Epispadias often coexists with bladder exstrophy and other severe developmental defects.

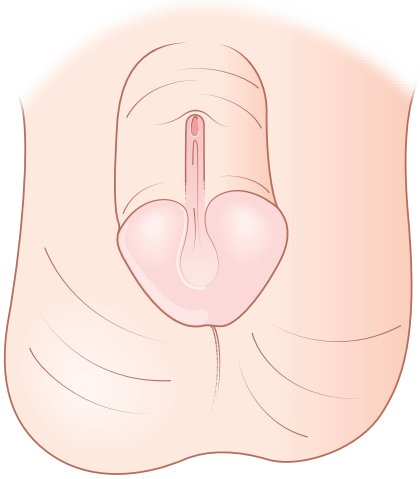

Figure 79.3 Epispadias.

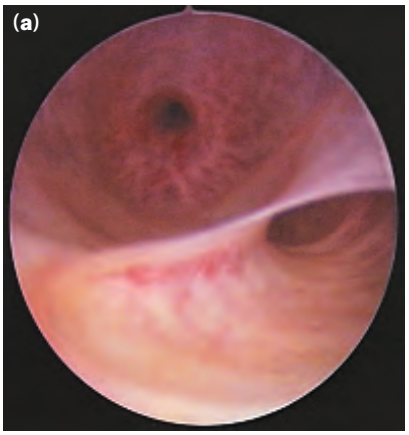

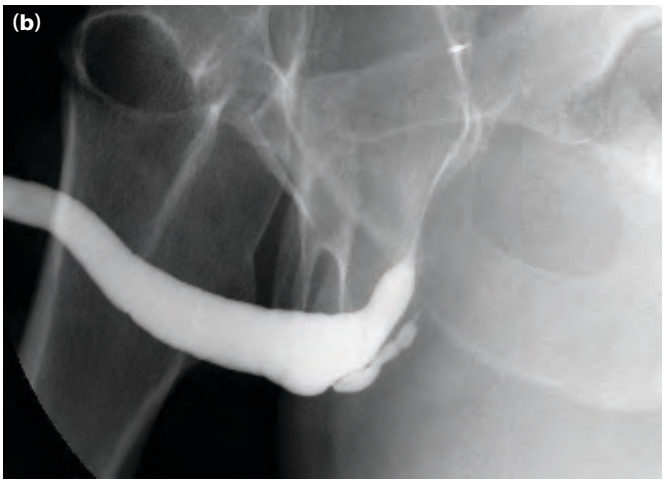

Figure 79.4 Urethral diverticulum. **(a)** Cystoscopic appearance of a urethral diverticulum. The normal urethra can be seen to extend superiorly to the urethral sphincter, while the blind ending diverticulum is seen inferiorly. **(b)** Urethrogram showing a urethral diverticulum.

Summary box 79.2

Hypospadias

- Hypospadias is characterised by the combination of a ventrally placed urethral meatus, a hooded foreskin and chordee
- In severe cases with coexisting testicular maldescent and micropenis, consider disorders of sexual development (intersex) as a diagnosis
- Avoid circumcision as the prepuce may be used in procedures to correct the abnormality
- Surgical treatment should be undertaken by a paediatric urologist

Urethral diverticulum

This is usually congenital and represents a partial duplication of the urethra. Acquired cases are uncommon but are sometimes seen as a result of increased intraurethral pressure behind a stricture. Others are caused by the longstanding presence of a foreign body such as a stone or calculus in the urethra. Typically, patients present in adult life with a history of postmicturition dribbling and diagnosis is made at cystoscopy (**Figure 79.4a**) or via a urethrogram (**Figure 79.4b**). Treatment is often unnecessary, but they can be treated endoscopically by incising the flap of urethral mucosa between the two lumens or, in severe cases, by excision of the diverticulum.

Injuries to the male urethra

The commonest cause of urethral trauma is that which occurs at the time of instrumentation, either with a catheter or with a cystoscope. Prevention is therefore the most important issue here, with the need for careful urethral instrumentation being paramount. Typically, when such an injury does occur it tends to happen either where the urethra bends or where it narrows. Such injuries initially result in bleeding and typically heal by scarring, which then results in a urethral stricture. The commonest sites of such strictures are the submeatal area, the bulbar urethra or the region of the membranous urethra.

Injuries following external trauma are much less common, but require appropriate and prompt management. The most common sites for such injury are the bulbar urethra and the membranous urethra.

Rupture of the bulbar urethra

There is a history of a blow to the perineum, usually due to a fall astride injury. The bulbar urethra is crushed upwards onto the pubic bone, typically with significant bruising. In the days of sailing ships, the common cause was falling astride a spar and the modern equivalent is seen among workers losing their footing on scaffolding. Cycling accidents, loose manhole covers and gymnasium accidents astride the beam account for a number of cases. Almost certainly King William I of England died in 1087 following a ruptured bulbar urethra. It was written that 'his horse reared in fright at a blazing timber and threw its ponderous rider against the iron of his saddle', suggesting that he ruptured the urethra on the saddle's pommel. He subsequently developed urinary retention and sepsis secondary to infection of the haematoma and he died some days after the accident.

Extravasation of urine is common if the urine is not diverted and the extravasated urine is confined in front of the mid-perineal point by the attachment of Colles' fascia to the triangular ligament and by the attachment of Scarpa's fascia just below the inguinal ligament. The external spermatic fascia stops it getting into the inguinal canals. Extravasated urine collects in the scrotum and penis and beneath the deep layer of superficial fascia in the abdominal wall.

CLINICAL FEATURES

The signs of a ruptured bulbar urethra are perineal bruising and haematoma, typically with a butterfly distribution. There is usually bleeding from the urethral meatus and retention of urine is also typically present.

MANAGEMENT

If the diagnosis is suspected, the patient should be treated with appropriate analgesia and antibiotics should be administered. He should be discouraged from passing urine. A full bladder should be drained with a catheter placed by percutaneous suprapubic puncture using a Seldinger technique (Figure 79.5). This reduces urinary extravasation and allows investigations to establish the extent of the urethral injury. Diagnosis is made by urethrography using water-soluble contrast.

If there is significant extravasation, then the perineal collection should be drained. The suprapubic catheter should remain *in situ* while the bruising and extravasation settle down and a stricture will typically develop at the site of the injury. The optimal treatment is delayed anastomotic urethroplasty after the swelling and bruising have settled down (typically 8–12 weeks later), with excision of the traumatised section and spatulated end-to-end reanastomosis of the urethra.

Summary box 79.3

Bulbar urethral injury

- Suspect urethral injury after blunt perineal trauma when the man cannot void, when there is perineal bruising and when there is blood at the urethral meatus
- Diagnosis is made by urethrography using water-soluble contrast
- The safest initial management is to insert a suprapubic catheter
- Beware of urinary extravasation and sepsis in the perineal haematoma
- Delayed urethroplasty is the preferred definitive management of complete disruptions

Rupture of the membranous urethra

Rupture of the membranous urethra typically occurs in association with a fractured pelvis and may be associated with an extraperitoneal rupture of the bladder. When the pelvis fractures, the membranous urethra is ruptured as it passes through the bony ring of the pelvis. The urethra is elastic at this point, and if the fracture results in only a minor displacement, then the tear may only be partial, but more typically the rupture is complete, such that the two ends are completely displaced,

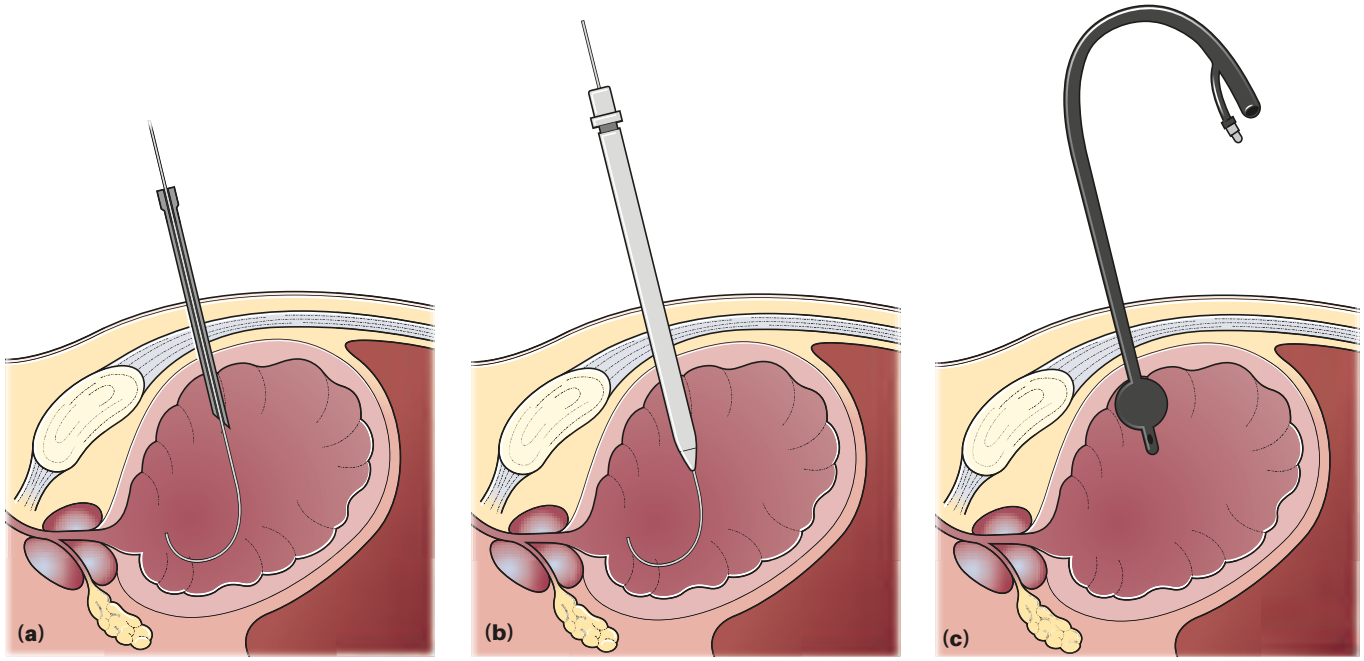

Figure 79.5 **(a)** Percutaneous puncture of the bladder with passage of a guidewire into the bladder followed by dilatation of the track over the guidewire **(b)**, thereby allowing placement of a catheter into the bladder **(c)**.

Abraham Colles, 1773–1843, Professor of Surgery, The Royal College of Surgeons in Ireland, and surgeon, Dr. Stevens' Hospital, Dublin, Ireland.
Antonio Scarpa, 1747–1832, Professor of Anatomy, Pavia, Italy.
Sven Ivar Seldinger, 1921–1998, Swedish radiologist, introduced the Seldinger technique to obtain safe access to blood vessels and other hollow organs.

with the development of a significant interposing haematoma. About 1–2% of cases of fractured pelvis have an associated urethral injury and such injuries are almost universally seen in men.

CLINICAL FEATURES

The most common causes of pelvic fracture are road traffic accidents, severe crush injuries and falls. Typically there are multiple associated injuries that may be immediately life threatening and the overriding priority is to keep the patient alive by appropriate resuscitation. Under these circumstances the management of the other injuries takes precedence.

The clinical features include urinary retention, blood at the urethral meatus and a high riding prostate on digital rectal examination. There is typically marked bruising of the pubic area, scrotum and penis. If the diagnosis is suspected, a urethrogram performed with water-soluble contrast media is confirmatory **(Figure 79.6)**.

A suprapubic catheter should be inserted as soon as practicable using the Seldinger technique. The distended bladder may be palpable, making suprapubic catheterisation straightforward, but often the bruising and swelling associated with the fracture makes this difficult and ultrasound guidance is required. When suprapubic urinary diversion has been achieved then no further urological management is required until the patient has stabilised.

In the presence of a coexisting extraperitoneal bladder injury, no bladder will be apparent on ultrasound examination, and surgical exploration, bladder repair, suprapubic catheter placement and drainage of the retropubic space is needed.

In a patient with a pelvic fracture who does not have blood at the urethral meatus but who has not yet passed urine (such that there is uncertainty as to whether there is a urethral injury), a single, gentle attempt at catheterization, by an experienced doctor, is permissible. In adults a 16F soft, silicone catheter should be used. If the catheter will not pass or passes and drains only blood, the balloon should not be inflated, but the catheter should be withdrawn and a retrograde urethrogram should be performed.

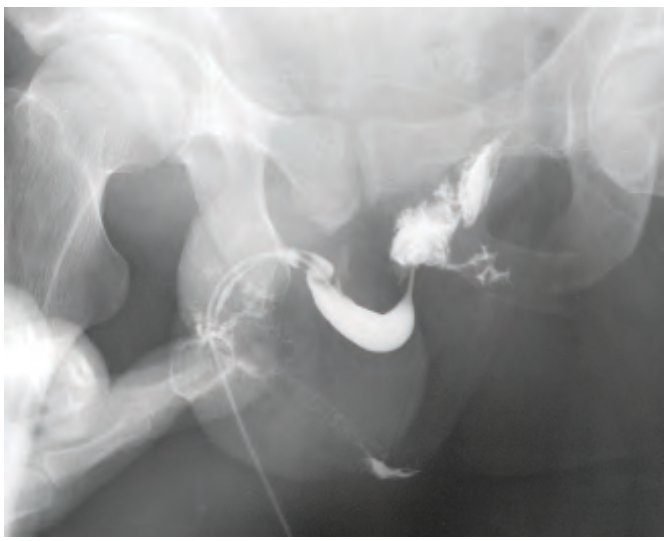

Figure 79.6 An ascending urethrogram demonstrating extravasation of contrast from the membranous urethra at the site of a urethral injury. Note the associated pelvic fracture with disruption of the inferior pubic rami.

COMPLICATIONS

Urethral disruption injury The two ends of the urethra, having been torn apart, become separated by a haematoma. With time, this haematoma resolves and is replaced by fibrosis. This pelvic fracture urethral disruption injury is technically not a stricture of the urethra but is often, erroneously, described as being one. The conventional management of such an injury is delayed surgical reconstruction with excision of the scar tissue and end-to-end anastomosis. This surgery should be delayed until the patient has recovered from any other injuries and is usually undertaken 3–6 months later. It is a highly challenging technical procedure and should be undertaken only in specialist centres. Some surgeons continue to undertake early attempts to realign the urethral ends endoscopically, and while there are some successful reports, most experts feel that there is an increased risk of sepsis, (true) stricture, incontinence and erectile dysfunction (ED).

Urinary incontinence The site of the urethral rupture is at or close to the striated urethral sphincter. If the external urethral sphincter is damaged or destroyed, continence of urine will depend on the bladder neck mechanism. While this is usually adequate to maintain complete continence (only 5–10% of men suffer stress urinary incontinence after urethroplasty), subsequent surgical manoeuvres that destroy the bladder neck (such as transurethral prostatectomy) may cause incontinence.

Erectile dysfunction ED is common after pelvic fracture with urethral injury and is due to damage of either the cavernosal nerves, which innervate the penis, or the penile arteries, which also lie close to the site of the urethral disruption. Indeed, surgical treatment of the urethral disruption can itself cause ED by similar mechanisms. If this does occur, treatment is with an orally active agent such as sildenafil or if that fails, with intracavernosal prostaglandin injections, a vacuum device or a penile implant.

Orthopaedic For management of a fractured pelvis see Chapter 27.

Extravasation of urine This can occur with extraperitoneal rupture of the bladder, pelvic fracture urethral disruption or in the rare cases where the level of the disruption is the prostatic urethra. Urine extravasates in the layers of the pelvic fascia and the retroperitoneal tissues. Treatment is by suprapubic cystostomy. In rare cases where the extravasation persists despite the suprapubic tube, drainage of the retropubic space and definitive repair of the urethral, prostatic or bladder rupture is required.

Summary box 79.4

Pelvic fracture urethral disruption injury

- Suspect the diagnosis in cases of pelvic fracture, when the patient has not voided and when there is blood at the urethral meatus
- If the diagnosis is suspected, a water-soluble urethrogram is needed to confirm the diagnosis
- Initial management is insertion of a suprapubic catheter
- Immediate surgical exploration is needed if there is coexisting rupture of the bladder
- Delayed anastomotic urethroplasty is the preferred definitive management

Urethral stricture

CAUSES

The common causes of urethral stricture are:

- Inflammatory
  - Secondary to urethritis
  - Secondary to balanitis xerotica obliterans (BXO)
- Traumatic
  - Bulbar urethral injury
  - Pelvic fracture urethral disruption injury
- Iatrogenic
  - Secondary to urethral instrumentation including catheterisation and transurethral prostatectomy
  - Secondary to radical prostatectomy
  - Secondary to radiotherapy for prostate cancer
- Idiopathic

PATHOPHYSIOLOGY

Postinflammatory strictures are less common since the introduction of effective antibiotic treatment of gonorrhoea. The stricture is most commonly seen in the bulbar urethra but submeatal strictures also occur. There is infection in the periurethral glands, which persists after inadequately treated gonorrhoea. The infection spreads to cause a periurethritis, which heals by fibrosis. Most strictures appear within 1 year of infection but may not cause difficulty in micturition for some time later.

BXO is a rare condition characterised by fibrosis of the foreskin resulting in phimosis. In around 10% of cases the glans penis is also affected, causing meatal stenosis, and in a proportion of these cases there is also fibrosis and stricturing of the penile urethra. The cause of the condition is unknown, but the strictures produced are typically long and difficult to treat.

Post-traumatic strictures have been discussed previously.

Postinstrumentation strictures follow endoscopy or catheterisation and may affect any part of the urethra. Typically, when such an injury does occur it tends to happen either where the urethra bends or where it narrows. Such injuries initially result in bleeding and typically heal by scarring, which then results in a urethral stricture. The commonest sites of such strictures are the submeatal area, the bulbar urethra or the region of the membranous urethra. Some surgeons recommend prophylactic dilatation or urethrotomy before transurethral prostatectomy in order to try to avoid this complication. Some cases of stricture seem to be due to sensitivity to chemicals from a catheter, but most are the result of a combination of trauma, infection and pressure necrosis.

Bladder neck stenosis can occur following TURP and following radical prostatectomy for the treatment of prostate cancer. If it cannot be managed by dilatation, bladder neck stenosis should be treated by transurethral incision and resection of the stricture, although in the man who has undergone radical prostatectomy, this will result in urinary incontinence.

CLINICAL FEATURES

Symptoms are usually hesitancy of micturition, straining to void and a poor urinary stream. The relative youthfulness of the patient often rules out prostatic enlargement, which characteristically occurs after the age of 50. As the stream becomes narrower, micturition is prolonged and is followed by postmicturition dribbling as a result of urine trickling from the dilated urethra proximal to the stricture. Urinary frequency by day and night is common and is due to incomplete bladder emptying, coexisting detrusor overactivity or urinary infection.

If the stricture is tight enough, the patient will go into acute retention, although this is rare. If this happens, there is a danger that clumsy attempts to pass a urethral catheter will result in a false passage. If a patient has gone into retention because of a urethral stricture, its lumen will be too narrow to pass even a tiny catheter and suprapubic catheterisation is required.

Investigation involves uroflowmetry, urethroscopy, urethrography and ultrasound scanning to assess bladder emptying and to detect any upper tract dilatation. The urinary flow rate is typically prolonged and plateau shaped (**Figure 79.7**) while urethroscopy allows the stricture to be viewed

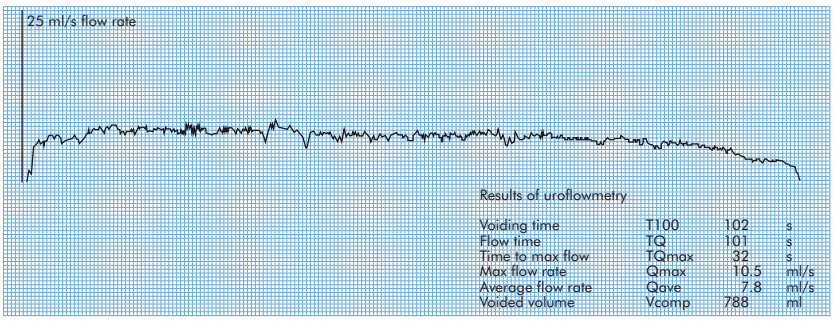

Figure 79.7 Urinary flow rate trace from a patient with a urethral stricture. Note the prolonged flow with the typical plateau shape of the curve.

as a circumferential scar (Figure 79.8). Openings of false passages commemorate previous misguided attempts to pass a urethral catheter. Urethrography using a water-soluble contrast medium will show the extent and severity of the stricture (Figures 79.9 and 79.10).

COMPLICATIONS

The commonest complication of a urethral stricture is urinary tract infections, which usually respond to antibiotic treatment, although there is a tendency for them to recur as a consequence of the increased residual urine within the bladder. Any of the complications of bladder outflow obstruction can occur, including bladder calculi and upper tract dilatation with renal impairment, although the latter is rare. Similarly, retention of urine is also rare and should be treated by suprapubic catheterisation. Rare complications include urethral diverticulum and paraurethral abscess.

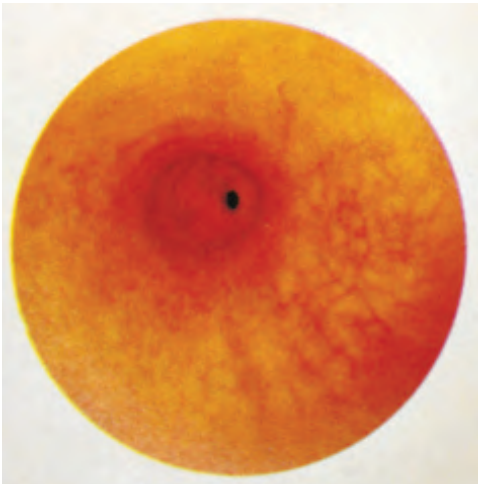

Figure 79.8 Urethroscopic appearance of a urethral stricture.

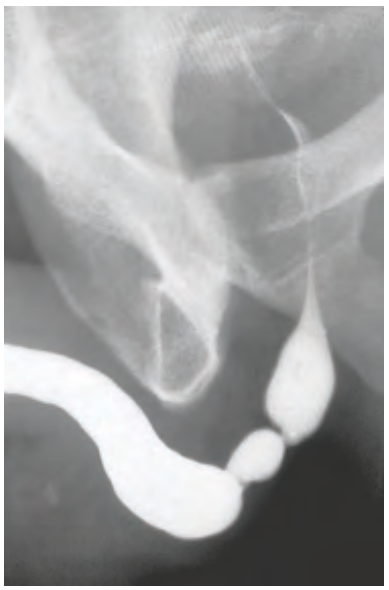

Figure 79.9 Ascending urethrogram showing urethral stricture of the bulbar urethra.

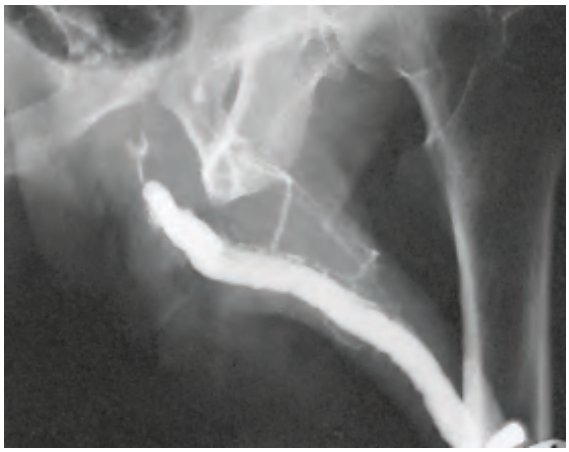

Figure 79.10 Gonorrhoeal stricture of the bulbar urethra. Note that some of the contrast has entered the penile veins.

Summary box 79.5

Diagnosis of urethral stricture

- Suspect the diagnosis of urethral stricture in a young man with poor urinary stream
- Diagnosis is made either by visualisation (urethroscopy) or radiologically (by urethrography)
- Urinary infection should be excluded

TREATMENT

The management of urethral strictures has changed considerably over the past 20 years. The old treatments of urethral dilatation have largely been superceded by endoscopic incision (internal urethrotomy) or by formal reconstruction (urethroplasty). Urethral dilatation still has a place in elderly men with short strictures that recur infrequently and when the stricture is intimately related to the continence mechanism (such as the bladder neck stricture that follows radical prostatectomy). In these patients, occasional dilatation may be preferable to more complex procedures.

In patients with recurrent strictures who are unable or unwilling to undergo urethroplasty, then intermittent self-dilatation with soft hydrophilic catheters on a regular (daily) basis can prevent stricture recurrence, although such self dilatation is needed lifelong.

Short strictures with a clear traumatic history should be treated by urethroplasty since cure rates in excess of 90% can be achieved by excision of the stricture with end-to-end anastamosis.

A conventional therapeutic algorithm, therefore, is to offer an internal urethrotomy to all newly diagnosed strictures (excluding post-traumatic strictures) and to reserve the more major urethroplasty procedures for recurrent strictures.

Urethral dilatation This is the old treatment for stricture. Under aseptic conditions, the urethra is stretched using graduated dilators. With care and gentleness the procedure can be performed under local urethral anaesthesia with lidocaine gel. It is performed 'blind', so there is always a danger of causing a false passage. This is most likely with an inexperienced operator unfamiliar with the complexities of an individual patient's urethra.

Endoscopic (internal) urethrotomy Internal urethrotomy is performed using the optical urethrotome. The stricture is cut under visual control using a knife passed through the sheath of a rigid urethroscope. The stricture is usually cut at the 12 o'clock position, taking care not to cut too deeply into the vascular spaces of the corpus spongiosum that surrounds the urethra. It is possible to get lost when trying to cut a way through a very tight stricture, and this is especially true when there are false passages because of previous dilatation attempts. Accordingly, a guidewire should be passed through to the bladder prior to incision of the stricture in order to establish the true lumen of the urethra. Following urethrotomy a catheter should be left *in situ* for 1–3 days afterwards.

A single urethrotomy seems to give a permanent cure of an uncomplicated stricture in about 50% of patients. Success rates are highest when the stricture is short and when it is present within the bulbar urethra. In contrast, failure rates are highest in long strictures, strictures within the penile urethra and in recurrent strictures. The main complications are infection and bleeding.

Urethroplasty The simplest urethroplasty involves excision of the stenosed length of urethra and reanastomosis of the spatulated cut ends. This operation is possible only if the stricture is relatively short, because there must be no tension at the suture line and it can only be performed where the urethra can be stretched, so it is not possible within the penile urethra. If an end-to-end anastomosis is not feasible, a large number of different surgical procedures can be used to reconstruct the fibrosed urethra. The operations typically utilise free grafts, usually of buccal mucosa, but also occasionally of penile skin, lingual mucosa and bladder mucosa. Buccal mucosa is in plentiful supply (approximately 6–7 cm can be obtained from each cheek), is tough with an excellent vascular plexus, is used to being wet and is associated with minimal donor site morbidity.

Urethroplasty should be considered when the stricture has arisen following trauma and when a stricture has recurred following endoscopic treatment. The actual technique used should depend on the site of the stricture, the length of the stricture and the cause of the stricture. Careful preoperative assessment with ascending and descending urethrography is vital.

Summary box 79.6

Treatment of urethral strictures

- Newly diagnosed strictures are best treated initially by internal urethrotomy, with a high short-term success rate and a 50% long-term success rate
- Intermittent self-dilatation increases the success rate of internal urethrotomy alone
- Urethroplasty should be considered in traumatic strictures and in recurrent strictures
- Urethral dilatation should be considered in strictures closely related to the external sphincter mechanism

Anastomotic urethroplasty has a success rate of around 90% while substitution urethroplasty has a success rate at 10 years of around 80%.

Other conditions of the urethra

Urethral fistula

The most frequent cause of urethral fistula is bursting or incision of a periurethral abscess. If the fistula arises behind a tight stricture, there may be multiple openings (watering-can perineum). A fistula can also follow urethroplasty if there is necrosis of part of the graft or flap. The stricture should be treated, after which case some fistulae heal themselves. Occasionally, formal urethroplasty is indicated.

Urethral calculi

Urethral calculi can arise primarily behind a stricture or in an infected urethral diverticulum. More commonly, the stone is a renal calculus that has migrated to the urethra via the bladder.

CLINICAL FEATURES

Migratory calculi cause sudden pain in the urethra soon after an attack of ureteric colic. There is blockage to the flow of urine and, if the stone is small, the force of the jet will usually expel it from the urethral meatus. Larger stones get stuck and must be removed endoscopically. It is sometimes possible to feel the calculus as a hard lump in the urethra, but if there is doubt the diagnosis is confirmed by urethroscopy.

TREATMENT

A stone lodged within the prostatic urethra should be displaced back into the bladder and treated by lithopaxy or suprapubic cystotomy as if it were a bladder stone. Calculi in more distal parts of the urethra are removed by basketing under vision or fragmented *in situ* using the electrohydraulic or ultrasonic lithotripter. It may be necessary to perform a meatotomy to deliver the stone. Open removal by external urethrotomy is rarely necessary.

Neoplasms

Polyps are a relatively common finding in the prostatic urethra, where they may result from chronic infection. Genital warts acquired by sexually transmitted infection are sometimes found in the anterior urethra as an extension of warts on the skin of the glans penis. Angioma of the urethra is a very rare cause of urethral bleeding.

Bloody urethral discharge without infection should raise the suspicion that the patient has a urethral tumour, although such tumours are rare. Multifocal transitional cell cancers of the bladder are sometimes associated with tumours in the prostatic urethra and occasionally more distally. Although superficial and susceptible to local ablation by diathermy or laser, they are associated with a tendency to distant spread. Squamous carcinoma can develop in an area of squamous metaplasia sometimes seen with a urethral stricture. It carries a poor prognosis even if the patient is treated by radical surgery.

THE FEMALE URETHRA

Anatomy

The female urethra is around 2–3 cm long, extending from the bladder neck to the external urethral meatus. Continence is maintained by the external striated urethral sphincter, which in women extends for almost the whole length of the urethra. There is extra support from the surrounding pelvic floor musculature. In contrast to men, the female bladder neck has little role in the maintenance of continence.

Abnormalities of the female urethra include:

- prolapse;
- stricture;
- Fowler's syndrome (dysfunction of the striated urethral sphincter);
- diverticulum;
- caruncle;
- papillomata acuminata;
- carcinoma.

Prolapse (syn: urethrocele)

Urethroceles reflect weakening of the tissues that hold the urethra in place, causing it to move and to put pressure on the vagina, leading to the prolapse of the anterior distal wall of the vagina. They typically occur in conjunction with prolapse of the bladder into the vagina (cystocele). Prolapse occurs in later life and is usually, in part, due to the trauma of childbirth. Prolapse of the urethral lining also occurs as a congenital abnormality, when it causes discomfort proportional to the degree of prolapse.

Stricture

Urethral strictures are uncommon in women but may follow urethritis or, more commonly, the trauma of a difficult labour. Urinary retention is an occasional consequence and is usually chronic. True strictures in women respond well to urethral dilatation.

Fowler's syndrome

This idiopathic condition, which was described by Fowler and Kirby, is associated with an abnormal myotonic discharge in the striated urethral sphincter that can be detected by sphincter electromyography. It is often associated with polycystic ovaries and causes urinary retention in women and should not be confused with a urethral stricture. Urethral dilatation is ineffective and the retention is best treated by intermittent self-catheterisation. There is some evidence that sacral neuromodulation can be effective.

Diverticulum

Urethral diverticula are more commonly seen in women than in men, but they are still rare. Some seem to be congenital while others are acquired by rupture of a distended urethral gland or injury of the urethra during childbirth. Urine within the diverticulum becomes infected, causing local pain and repeated bouts of cystitis. Purulent urine is discharged if the urethra is compressed with a finger placed in the vagina. Diagnosis is by magnetic resonace imaging (MRI) or by transvaginal ultrasound (**Figure 79.11**). Excision of the diverticulum through the anterior vaginal wall is effective, but care must be taken not to damage the urethral sphincter.

Caruncle

This is common in elderly women. It presents as a soft, raspberry-like, pedunculated granulomatous mass about the size of a pea, attached to the posterior urethral wall near the external meatus (**Figure 79.12**). It is composed of highly vascular

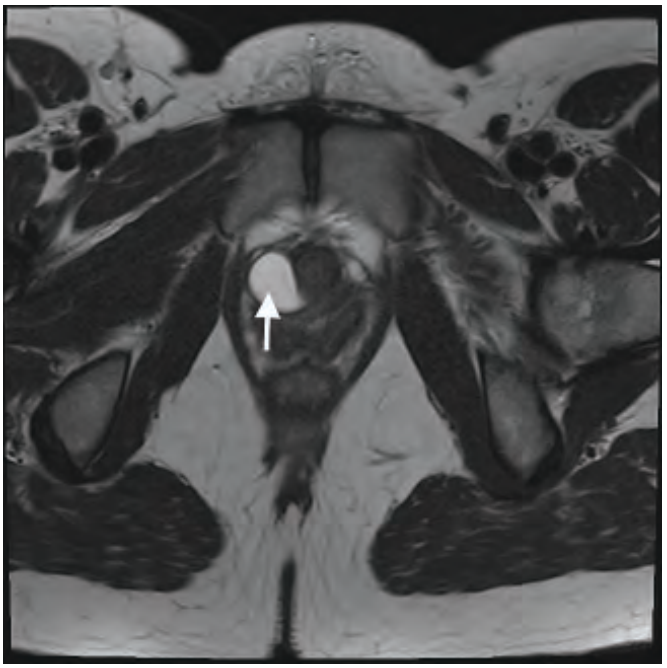

Figure 79.11 A magnetic resonance imaging scan of a urethral diverticulum in a female. The arrow identifies the fluid-filled diverticulum adjacent to the urethra.

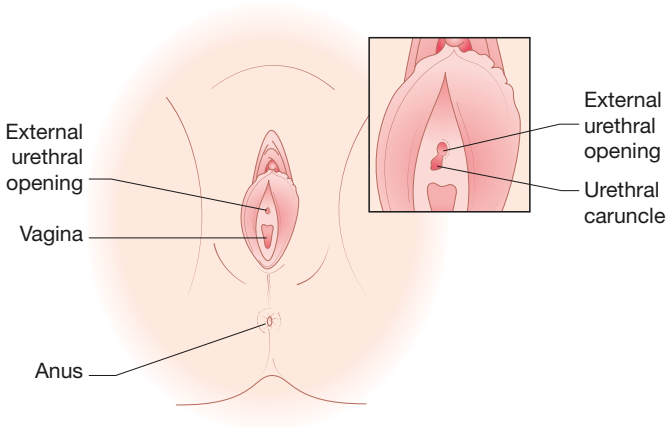

Figure 79.12 A urethral caruncle.

Clare Juliet Fowler, contemporary, Professor of Uroneurology, The National Hospital for Nervous Diseases, Queen Square, London, UK.
Roger Sinclair Kirby, contemporary, Professor of Urology, St George's Hospital, London, UK.

connective tissue stroma infiltrated with pus cells. There may be frequency of micturition and urethral pain afterwards. Occasionally, there is bleeding. A urethral prolapse is less tender and is not pedunculated. Treatment is by excision and diathermy coagulation of the base of the stalk. The patient should be given antibiotics to treat the underlying chronic urethritis.

Papillomata acuminata

Papillomata acuminata are the same as the sexually transmitted warts that occur on the penis. They are treated in the same way. In African women, papillomata acuminata are common and may grow to such a large size during pregnancy that they obstruct labour and necessitate a caesarean section.

Carcinoma of the urethra

This occurs twice as often in women as in men. Whether a caruncle can become malignant is disputed, but caruncles and tumours often occur close together. Malignant swellings of the urethra feel harder than benign ones. Treatment by radiotherapy or radical surgery is often ineffective. The overall prognosis is poor.

THE PENIS

Anatomy

The penis is composed of three tubular structures. The upper two structures, the corpora cavernosa, provide erectile function and are apposed to each other, being anchored posteriorly onto the pubic rami. The third tubular structure is the corpus spongiosum, which contains the urethra and which expands distally to form the glans penis.

The corpora cavernosa have an outer covering of tunica albuginea, which is relatively inelastic and which also forms the septum between them. The tunica albuginea encloses the erectile tissue itself, which has a trabecular structure with a network of sinusoidal spaces lined by endothelium within which the blood pools during erection. The central arterial blood supply (the central penile artery) is a branch of the internal pudendal artery. Erection occurs when the sacral parasympathetic nerves that innervate the penis cause smooth muscle relaxation with increased arterial inflow and dilatation of the sinusoids such that blood accumulates within the trabecular spaces.

DISEASES OF THE FORESKIN

Phimosis (see also Chapter 9)

At birth, the foreskin is normally adherent to the glans penis. These physiological adhesions between the foreskin and the glans penis begin to disappear around the age of 2 years and may persist until 6 years of age or later, giving the false impression that the prepuce will not retract. This condition (sometimes known as physiological phimosis) should not be confused with true phimosis in young boys.

Phimosis in boys

True phimosis is where there is scarring of the prepuce such that it will not retract without fissuring of the foreskin (**Figure 79.13**). This may result in ballooning of the foreskin during micturition and may also result in infection (balanoposthitis). Rarely, the aperture in the prepuce may be so tight as to cause urinary obstruction.

Phimosis in adults

Scarring in adults occurs as a result of balanitis (inflammation of the glans penis), posthitis (inflammation of the foreskin), or lichen sclerosus et atrophicus (syn: balanitis xerotica obliterans). BXO is an uncommon condition in which the normally pliant foreskin becomes thickened, typically whitish in appearance and forms a constricting band (cicatrix) that prevents retraction (**Figure 79.14**). BXO may also affect the glans penis (causing meatal stenosis) (**Figure 79.15**) and the penile urethra (causing urethral stricture). As a consequence it is difficult to keep the penis clean, there may be recurrent attacks of balanitis and there is both a problem with hygiene and, in later life, an increased susceptibility to carcinoma.

Treatment

In a young child with a non-retractile foreskin, no treatment is necessary or appropriate. When the foreskin is mildly scarred, then preputioplasty is possible. For all other cases, circumcision is the appropriate treatment. In cases of BXO, circumcision is often curative, although when the condition affects the glans penis, topical steroid cream may be helpful. In resistant cases, formal meatotomy is necessary. In emergency situations, such as when catheterisation is required, but is impossible, then it is possible to divide the foreskin dorsally under local anaesthetic (a so called dorsal slit).

Figure 79.13 Non-retractile foreskin. The patient presented with a recent history of symptoms. Examination reveals thickening and scarring with a true phimosis (picture courtesy of Kim Hutton).

Figure 79.14 Phimosis secondary to balanitis xerotica obliterans. Note the white and thickened appearance of the preputial skin **(a)** with a constriction such that the foreskin cannot be retracted **(b)**.

PREPUTIOPLASTY

This is an application of the Heineke-Mikulicz principle whereby the tight ring of the foreskin is divided longitudinally and sewn transversely, thereby allowing retraction of the preserved foreskin. There is a recurrence rate and it is only indicated in mild cases with minimal scarring. If it fails, then circumcision is indicated.

Figure 79.15 Severe balanitis xerotica obliterans causing meatal stenosis, thickened and scarred preputial and penile skin. There was also a severe penile urethral stricture.

CIRCUMCISION

Apparently, circumcision did not originate among the Jewish people; they took the practice either from the Babylonians or from African tribes, probably the latter. It had been practiced in West Africa for over 5000 years.

Indications In infants and young boys, circumcision is most usually performed at the request of the parents for social or religious reasons. Medical indications for circumcision in boys include true phimosis, BXO (rare under the age of 5 years), recurrent attacks of balanoposthitis and recurrent urinary tract infections with an abnormal upper urinary tract.

In adults, circumcision is indicated because of an inability to retract the foreskin for intercourse, for splitting of an abnormally tight frenulum or for recurrent balanitis.

Recently, evidence has emerged that circumcision protects against the spread of human immunodeficiency virus (HIV), and a large scale programme of adult circumcision under the auspices of the World Health Organisation is ongoing in some African countries where HIV is a major health problem.

Technique in an infant Applying a clamp or bone forceps across the prepuce distal to the glans with blind division of the foreskin is to be condemned. To see one boy with partial or total amputation of the glans is enough to realise the folly of this technique. It is far better to perform a proper circumcision under direct vision as in an adult. The Plastibel device can be used in infants (Hollister) and its use is shown in Figure 79.16; the ring separates between 5 and 8 days postoperatively.

Technique in adolescents and adults In adolescents and adults the following method is preferable. The prepuce is held in artery forceps and put on a gentle stretch. Marking the skin with a pen at the level of the corona is essential prior to incision to ensure that excess skin is not removed. A

Walter Hermann von Heineke, 1834–1901, German surgeon and Professor of Surgery in Erlangen.
Jan Mikulicz-Radecki, 1850–1905, Polish surgeon and Director of Surgery in Krakow and Wroklaw.

Figure 79.16 The Plastibel (Hollister) device for circumcision in infants. **(a)** The foreskin is freed and retracted. **(b)** After the Plastibel device has been slipped into place over the glans penis, the foreskin is ligated over the groove of the bell and redundant foreskin is cut away. **(c)** This shows the completed operation (courtesy of Professor Asal Y Izzidien Al-Samarrai, King Saud University, Riyadh, Saudi Arabia).

circumferential incision in the penile skin is made at the level of the corona using a knife. The prepuce is then slit dorsally in the midline to within 1 cm of the corona. This converts the foreskin into two flaps connected at the midline anteriorly.

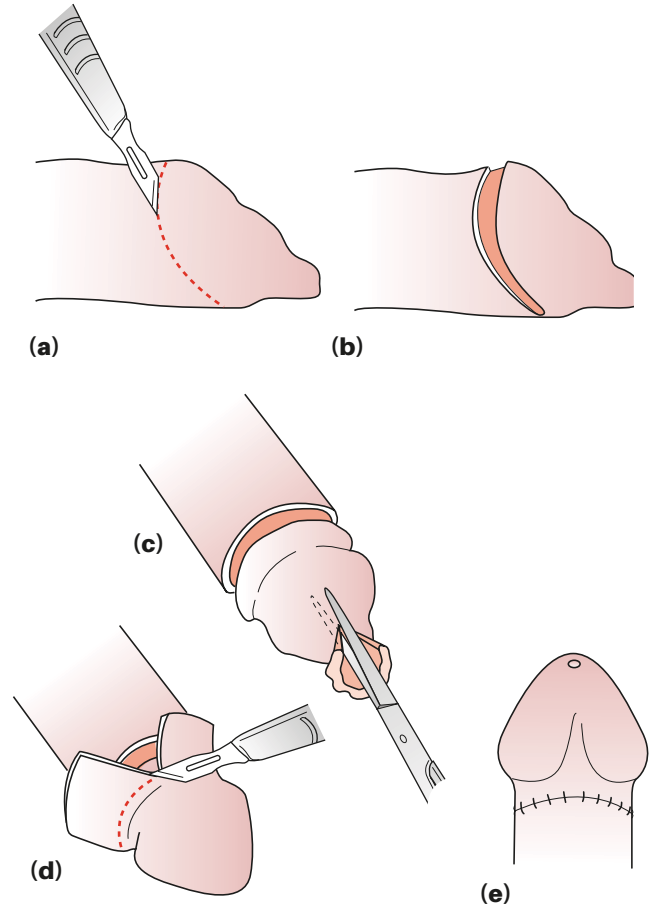

Figure 79.17 (a-e) Stages in circumcision.

When the undersurface of the prepuce has been separated from the glans, the inner layer of each flap is again marked with a pen and then incised with a second circumferential incision, leaving about 0.5 cm of the inner layer of the preputial skin. Cutting the remaining connective tissue completes the excision (Figure 79.17). Monopolar diathermy must be avoided in operations on the penis because there is a danger that the current path will cause coagulation at the base of the penis. Haemostasis is important in circumcision, however, and vessels should be secured with bipolar diathermy or with absorbable ligatures. The cut edges of the skin are approximated using interrupted sutures, making certain that the frenular vessels are ligated.

Summary box 79.7

Circumcision

- Is most commonly performed for cultural reasons
- Is not indicated for failure of retraction caused by congenital adhesions between the glans penis and the prepuce
- Is indicated when there is true phimosis
- Never use monopolar diathermy when performing circumcision

Frenulum breve

Phimosis should not be confused with this condition, where the frenulum is short, such that it causes pain when the foreskin is retracted. Another possible presentation is tearing of the frenulum during sexual activity. Treatment is by frenuloplasty, which utilises the Heineke–Mikulicz principle to 'lengthen' the frenulum.

Paraphimosis

A tight foreskin once retracted may be difficult to return and a paraphimosis results. In this condition, the venous and lymphatic return from the glans and distal foreskin is obstructed and these structures swell, causing even more pressure within the obstructing ring of prepuce. Icebags, gentle manual compression and injection of a solution of hyaluronidase in normal saline may help to reduce the swelling. Such patients can be treated by circumcision if careful manipulation fails. A dorsal slit of the prepuce under local anaesthetic may be enough in an emergency.

Balanoposthitis

Inflammation of the prepuce is known as posthitis; inflammation of the glans is balanitis. The opposing surfaces of the two structures are often involved, hence the term balanoposthitis. In mild cases, the only symptoms are itching and some discharge. In more severe inflammation, the glans and foreskin are red-raw and pus exudes. Treatment is by broad-spectrum antibiotics and local hygiene measures. If there is associated phimosis, then a circumcision is required.

Preputial calculi

Later in life, chronic posthitis may lead to adhesions between the prepuce and the glans and closure of the orifice of the preputial sac. Preputial calculi result from the accumulation beneath a non-retractable foreskin of inspissated smegma, urinary salts or both.

INJURIES OF THE PENIS

Avulsion of the skin of the penis

Entanglement of clothing in rotating machinery is the usual cause. Repair can be effected by burying the shaft of the penis in the scrotum, with subsequent release at the time of a definitive plastic surgical repair. An alternative approach is initial debridement with delayed, but early, skin grafting.

Fracture of the penis

Fracture of the penis is an uncommon accident, usually occurring when the erect penis is bent violently during intercourse. The forced deformity results in a rupture of the tunica albuginea with immediate extravasation of blood from within the penis. There is typically a loud cracking sound with immediate loss of the erection, and the rapid development of a large bruise around the penis and extending onto the scrotum (**Figure 79.18**). There may occasionally be an associated urethral injury. Optimal management involves early exploration of the penis with surgical repair of the ruptured tunica albuginea.

Strangulation of the penis

Strangulation of the penis by rings placed on the penis, usually for sexual reasons, can cause venous engorgement, which prevents their removal. It may help to aspirate the corpora cavernosa but often the ring must be cut off with a ring cutter or hacksaw.

Other abnormalities of the penis

Erectile dysfunction

ED is failure to attain or maintain an erection. It is a symptom, rather than a condition in itself. It can arise as a consequence of psychological issues, but the commonest cause is vascular disease, and as such ED is associated with diabetes, hypertension, dyslipidaemia and smoking. Other rarer causes include endocrine disease (hypogonadism and prolactin secreting pituitary tumours), neurological disease (multiple sclerosis, spinal cord injury and prolapsed intervertebral disc), iatrogenic damage to the cavernosal nerves due to radical pelvic surgery (e.g. radical prostatectomy, abdominoperineal excision of the rectum and radical cystectomy), neuropathy secondary to pelvic radiotherapy and drug-induced cases (including antihypertensive agents, antidepressants and antipsychotics).

Figure 79.18 Penile fracture. Note the extensive bruising of the penis and scrotum.

Assessment involves confirmation of the diagnosis by taking a careful history, assessing the patient for underlying risk factors and trying to identify the rare case that can be cured as opposed to being treated. Physical examination of the genitalia, measurement of the blood pressure and assessment of the secondary sexual characteristics is required and biochemical assessment of the blood sugar, the serum lipid profile and the serum testosterone is necessary in all cases.

Treatment for most patients involves the use of the phosphodiesterase type 5 inhibitors (such as sildenafil) with intracavernosal injection of alprostadil, vacuum erection devices and penile implants reserved for resistant cases.

Summary box 79.8

Erectile dysfunction

- The commonest cause of erectile dysfunction is atherosclerosis
- Appropriate investigation involves identification of vascular risk factors
- Phosphodiesterase inhibitors are the first line treatment for most men

Peyronie's disease

Peyronie's disease is characterized by penile deformity (**Figure 79.19**), palpable penile plaques within the penis, ED and pain on erection. The cause is unknown, but probably involves minor injury to the erect penis with secondary microhaemorrhage beneath the tunica albuginea and secondary fibrosis. The latter results in the palpable plaques that can be identified on examination. The plaques may rarely be calcified (**Figure 79.20**). The presence of these relatively inelastic plaques causes the erect penis to bend, often dramatically, towards the side of the plaque. The commonest direction of deformity is dorsally (towards the abdomen) and the deformity may be so great as to prevent penetrative sexual intercourse.

While the aetiology is uncertain, there is an association with Dupuytren's contracture. The natural history of the condition is that it typically progresses for 18–24 months before stabilising. During this acute (or active) phase of the disease, surgery is not indicated, and a variety of medical treatments have been tried, although none with any good evidence of benefit.

When the disease has stabilised (the chronic or stable phase), the crucial issue is whether the patient is still able to have sexual intercourse. If he can, then no treatment is indicated, while if the deformity prevents penetration, or makes it difficult, then corrective treatment is indicated. Using this criterion, only around a quarter of men require treatment. While injections of collagenase have been recently licensed for this condition, the commonest treatment is surgery with the Nesbitt procedure being the most common procedure. This operation corrects the deformity by plicating the convex side of the deformity, thereby straightening the penis, albeit with some accompanying loss of length.

Summary box 79.9

Peyronie's disease

- Medical treatments during the active phase have little evidence of efficacy
- The disease has two phases: an initial acute phase lasting 12–24 months and a later chronic phase
- There is no effective treatment in the acute phase
- Surgery may be indicated in the chronic phase to correct deformity that interferes with sexual activity
- Surgical treatment will shorten the erect penile length

Figure 79.19 An artificial erection obtained perioperatively, demonstrating the dorsal deformity of the erect penis that is typical of Peyronie's disease.

Baron Guillaume Dupuytren, 1777–1835, surgeon, Hôtel Dieu, Paris, France, described this condition in 1831.
Reed Nesbitt, urological surgeon, Nashville, TN, USA.

Congenital curvature of the penis

A penile deformity that is similar and analagous to Peyronie's disease is occasionally seen in young men. Called congential curvature of the penis, the urethral length is normal and it typically results in a ventral deformity of the erect penis. If the deformity interferes with sexual activity, then surgery, usually a Nesbit procedure, will straighten the erect penis.

Chordee

Chordee (French = corded) is a fixed bowing of the penis caused by hypospadias or, more rarely, chronic urethritis. Erection is deformed and sexual intercourse may be impossible. Treatment is usually surgical.

Priapism

Priapism means a persistent erection lasting longer than 4 hours and it is a surgical emergency. There are two main types of priapism.

ISCHAEMIC PRIAPISM

Ischaemic or venogenic priapism is the commoner and is due to venous congestion, with consequent thrombosis and ischaemia. The penis remains erect and becomes painful. This is a pathological erection and the glans penis and corpus spongiosum are not involved. The condition is most commonly seen as a side effect of medication, most notably antipsychotic medication and intracavernosal injections, but it can also arise as complication of a hypercoagulable blood disorders such as sickle cell disease or leukaemia. A tiny proportion of cases are caused by malignant disease in the corpora cavernosa or the pelvis.

The clinical features are of a painful erection not involving the glans penis. Blood taken from the penis shows hypoxia, hyercapnoea and acidosis, while Doppler scanning shows an absence of blood flow within the penis.

An underlying cause should be excluded and the patient should be referred for specialist urological care. Treatment is an emergency, since delay beyond 6 hours results in progressive, irreversible damage to the corpus cavernosal tissue with subsequent fibrosis and ED. Aspiration of the sludged blood in the corpora cavernosa is the first-line therapy but if this fails, then intracavernosal injection of phenylephrine (an alpha adrenoceptor agonist) is the next line of therapy. If that proves ineffective, it may be necessary to decompress the penis by creating a shunt between the corpus cavernosum and either the glans penis or the corpus spongiosum. Treatment initiated after 24–36 hours rarely restores normal erectile function.

Summary box 79.10

Ischaemic priapism

- The characteristic clinical features are a painful erection not involving the glans penis
- Blood gas analysis from the penis shows hypoxia, hypercapnoea and acidosis
- Detumescence should be ideally achieved within 6-12 hours to avoid long-term erectile dysfunction

NON-ISCHAEMIC PRIAPISM

This rarer form of priapism arises as a consequence of traumatic damage to the central penile artery, usually as a consequence of blunt perineal trauma. A fistula develops between the artery and the sinusoidal space, which results in a persistent erection that is painless, in contrast to the ischaemic priapism. Blood gas analysis shows the characteristics of arterial blood and Doppler scanning and selective arteriography will demonstrate the fistula (**Figure 79.21**). Treatment is not an emergency, since there is no ischaemia, and is most appropriate achieved by selective arterial embolisation.

CARCINOMA OF THE PENIS

Penile cancer is rare in the UK, with only around 600 cases being recorded annually. It is much commoner in other parts of the world, most notably South America, where it is one of the commonest cancers.

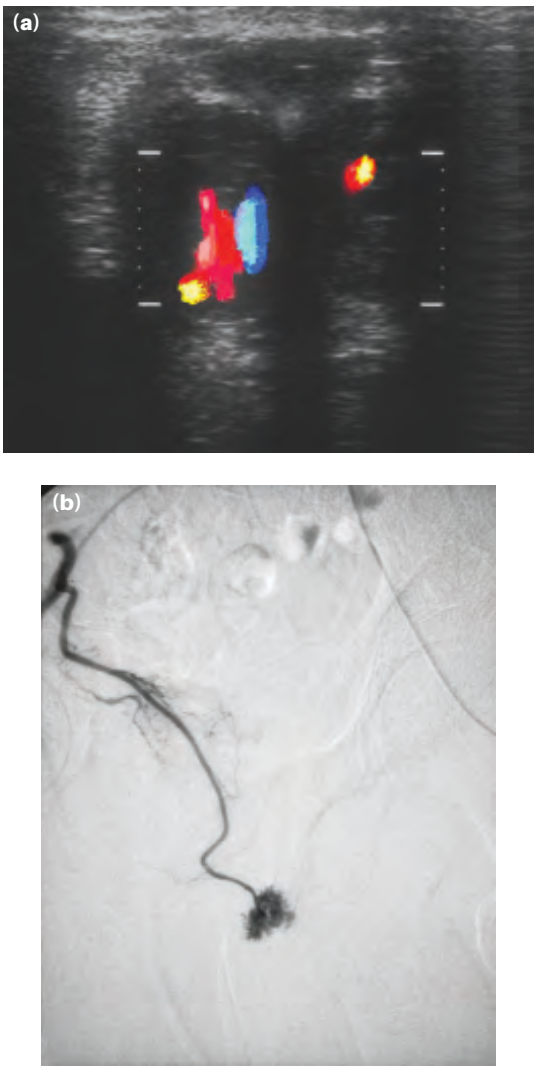

Figure 79.21 **(a)** Colour Doppler scan of a high flow (non-ischaemic) priapism showing turbulence at the site of the arterial injury. Compare the high unilateral signal (turbulence) with normal contralateral flow. **(b)** Selective pudendal arteriogram showing the site of the fistula (the arterial blush) between the central penile artery and the corpus cavernosum.

Aetiology

Circumcision soon after birth confers immunity against carcinoma of the penis. Later circumcision does not seem to have the same benefit, with the assumption that smegma is in some way carcinogenic. Human papillomavirus infection (HPV types 16 and 18) is a risk factor, as are BXO and smoking. Phimosis and chronic balanoposthitis are known to be contributory factors, and there are definite precarcinomatous states including leucoplakia of the glans, which is similar to the condition seen on the tongue, and penile intraepithelial neoplasia (PeIN).

Penile intraepithelial neoplasia (carcinoma in situ of the penis, Bowen's disease, erythroplasia of Queyrat)

PeIN is typically seen as a red cutaneous patch on the penis **(Figure 79.22)**. When it occurs on the glans penis, it is known as erythroplasia of Queyrat and when it occurs on the shaft of the penis it is called Bowen's disease. There are several other benign causes of red patches on the penis, and when there is clinical doubt as to the underlying diagnosis a biopsy is indicated. When the diagnosis of carcinoma in situ is confirmed, treatment is by means of topical 5-FU cream, CO_2 laser ablation or surgical excision.

Pathology

Carcinoma of the penis is most typically a squamous cell carcinoma arising in the skin of the glans penis or the prepuce. It may be flat and infiltrating or warty in appearance **(Figure 79.23)**. The former often starts as leucoplakia or PeIN and the latter results from an existing papilloma. Local growth continues for months or years. T1 tumours are confined to the skin, with T2 tumours invading the corpus spongiosum or the corpus cavernosum. T3 tumours invade the urethra and T4 tumours invade adjacent structures. The earliest lymphatic spread is to the inguinal (N1 and N2 disease) and then to the iliac nodes (N3 disease) **(Figure 79.24)**. Distant metastatic deposits are infrequent.

Clinical features

Many patients present late **(Figure 79.25)**, either because of embarrassment or because of misdiagnosis. About 10% of patients are under 40 years of age. By the time the patient presents, the growth is often large and secondary infection causes a foul, bloody discharge. There is typically little or no pain.

Around 50% have inguinal lymph node enlargement at presentation but the nodal enlargement often reflects infection. In many, the prepuce is non-retractile and must be split to view the lesion. A biopsy should be performed to make the diagnosis. Untreated, the whole glans may be replaced by a fungating offensive mass. Later, the inguinal nodes can erode the skin **(Figure 79.24)** of the groin and in rare cases,

Figure 79.22 Penile intraepithelial neoplasia affecting the glans penis.

Figure 79.23 A squamous cell cancer arising from the inner aspect of the prepuce.

John Templeton Bowen, 1857–1940, American dermatologist, described this condition in 1912.
Auguste Queyrat, b.1872, dermatologist, Paris, France, described this condition in 1911.

Figure 79.24 A late presenting squamous cell cancer of the penis.

Figure 79.25 A squamous cell cancer of the penis with an ulcerating groin node.

death of the patient can result from erosion of the femoral or external iliac vessels.

Treatment

Management is divided into treatment of the primary tumour and treatment of the inguinal nodes. For the primary tumour surgical excision is the mainstay of treatment, with the traditional view that a 2 cm margin of normal tissue be removed being superceded by a more recent, more conservative view, such that penile preserving surgery with excision of much lower margins of normal tissue are now accepted. Tumours affecting the glans penis require glansectomy, with more advanced tumours requiring partial penectomy. In advanced cases, total penectomy is required with formation of a perineal urethrostomy. Such surgery is indicated even in advanced metastatic disease for reasons of local control.

Treatment of any associated enlarged inguinal lymph nodes should be delayed until at least 3 weeks after local treatment of the primary lesion. Enlargement caused by infection will usually show signs of subsiding with antibiotic treatment. For palpable nodes, ultrasound-guided fine needle aspiration will confirm the diagnosis and a block dissection of both groins should be undertaken. The management of patients where the nodes are not palpable disease involves the use of sentinel lymph node biopsy (SLNB) followed by inguinal node dissection if the SLNB is positive .

Management of the pelvic nodes is controversial. When they are involved on CT scanning, surgery probably has little role, but when the iliac nodes are not enlarged in the presence of N2 disease, the options are observation, pelvic lympadenectomy or radiotherapy. Chemotherapy is relatively ineffective and currently is reserved for palliation in those with metastatic disease. The prognosis for tumours confined to the penis is good with 5-year survival rates in excess of 80%. With nodal involvement the 5-year survival rate falls to around 40%.

Summary box 79.11

Carcinoma of the penis

- A relatively uncommon tumour
- Enlargement of superficial inguinal lymph nodes may be caused by infection or metastatic spread
- Surgery is the mainstay of treatment
- Nodal involvement indicates a poor prognosis

Buschke–Löwenstein tumour

The Buschke–Löwenstein tumour is uncommon. It has the histological pattern of a verrucous carcinoma. It is locally destructive and invasive but appears not to spread to lymph nodes or to metastasise. Treatment is by surgical excision.

Malignant melanoma of the penis

This is an uncommon tumour, with the principles of management being the same as for squamous cell carcinoma. Blood borne metastatic disease is, however, more common.

Abraham Buschke, 1868–1943, dermatologist, Berlin, Germany.
Ludwig Löwenstein, 1885–1959, dermatologist, Berlin, Germany

INFLAMMATION OF THE PENIS AND URETHRA

Urethral discharge

The commonest cause of urethral discharge in men is urethritis and the two commonest causes of urethritis are non-specific urethritis (NSU) and gonococcal urethritis. Other related symptoms include dysuria and urethral pruritis while epididymitis can also be present. A sexual history should be sought, particularly a history of unprotected intercourse, oral sex and anal intercourse. A routine investigative screen includes Gram stain of the discharge, dipstick testing of a urine specimen, culture of a urine specimen and nucleic acid amplification testing (NAAT) of either a urine specimen or a urethral swab. If relevant, the same techniques can be used for vaginal, endocervical, anal and pharyngeal swabs. NAAT is a sensitive way of identifying both gonococcal and chlamydial urethritis. As with all sexually transmitted infections (STIs) the possibility of other infections (such as HIV) should always be borne in mind and, where appropriate, tested for.

Non-specific urethritis (syn: non-gonococcal urethritis)

NSU is a STI that is the commonest cause of urethritis in the Western world. In around 40% of cases it is due to *Chlamydia trachomatis* with other cases being caused by *Ureaplasma urealyticum*, *Trichomonas vaginalis* or *Mycoplasma genitalium*. The causative agent in up to 50% of cases is unknown.

NSU can affect both men and women and asymptomatic infection is common in both. In men, dysuria and a white mucopurulent urethral discharge appear up to 6 weeks after sexual intercourse. Dysuria is usual. The urine appears to be clear but may contain 'threads' or pus cells. Epididymitis is common and urethral stricture is a potential late complication. In women, the condition is usually asymptomatic, although it can present as vaginal discharge or as a form of urethrotrigonitis. It may result in cervicitis or pelvic inflammatory disease.

Exclusion of gonorrheal infection is important. The diagnostic test of choice is NAAT and in men either a urine specimen or a urethral swab can be used, while in women urine, endocervical or vaginal swabs can be used. If testing is positive, then partners should be screened.

The standard treatment regimes are azithromycin as a single dose or doxycycline orally for 7 days. Treatment is usually effective, although relapse is common, especially in men, in whom the prostate may act as a reservoir of infection. It is important to treat both partners as reinfection is probable if this is not done, and re-testing of both partners at 3 months is recommended.

Gonorrhoeal urethritis

Gonorrhoea is a sexually transmitted disease caused by *Neisseria gonorrhoeae* (gonococcus), a gram-negative kidney-shaped diplococcus that infects the anterior urethra in men, the urethra and cervix in women and the oropharynx, rectum and anal canal in both sexes, but especially men. It is transmitted by unprotected sexual intercourse and is the second commonest cause of urethritis in western countries.

Most men have symptoms of urethral discomfort and urethral discharge within a few days of infection. There is often scalding dysuria. In women it is often asymptomatic. There can be mild dysuria or slight urethral discharge, which can go unnoticed by the patient. Cervicitis can occur with about 10% suffering from pelvic inflammatory disease (salpingitis), which, if bilateral, may lead to infertility. A mother may transmit gonorrhea to her newborn during childbirth with the risk that blindness of the child can result. In addition, in both men and women exposed orally or anally, gonococcal infections can cause a predominantly asymptomatic pharyngitis or proctitis.

Traditionally, the diagnosis was made by identification of pus and gonococci in a gram-stained urethral smear with subsequent culture. However, more recently, NAAT, which is more sensitive, has become the norm.

Complications are prevented by effective early treatment. In men complications include posterior urethritis, prostatitis (acute or chronic), acute epididymo-orchitis, periurethral abscess and urethral stricture. Gonococcal arthritis, iridocyclitis, septicaemia and endocarditis are unusual.

Treatment is with antibiotics, with ceftriaxone currently the treatment of choice as a consequence of the increasing prevalence of antibiotic resistance to more traditional antibiotics such as ciprofloxacin or penicillin. Contact tracing is important in controlling the spread of the disease and management is usually by a genitourinary physician. Failure to respond to first-line treatment should raise the possibility of antibiotic resistance or co-infection with chlamydia.

Reiter's disease (syn: sexually acquired reactive arthritis)

Reiter's disease is an autoimmune disease characterised by the triad of urethritis or diarrhoea, conjunctivitis and polyarthritis. Common triggers include chlamydial urethritis, less commonly gonococcal urethritis and diarrhoea secondary to *Salmonella*, *Shigella* or *Campylobacter*. It is an HLA-B27-associated condition. The conjunctivitis (present in around 50%) and arthritis typically occur 1–3 weeks after the primary infection. Diagnosis is made on clinical grounds and treatment is largely symptomatic, although antibiotic treatment of the precipitating infection is important. The urethritis and

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900) and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.
Albert Ludwig Siegmund Neisser, 1855–1916, Director of the Dermatological Institue, Breslau, Germany (now Wroclaw, Poland).
Hans Conrad Julius Reiter, 1881–1969, President of the Health Service and Honorary Professor of Hygiene, Berlin, Germany, described this condition in 1916. He was subsequently convicted of war crimes as a consequence of his involvement in the death of hundreds of inmates in Buchenwald.

conjunctivitis frequently subside after a few weeks but the arthritis may persist for months. Severe anterior uveitis and frequently recurrent attacks suggest a poor outlook.

Periurethral abscess

Periurethral abscesses were once common with high morbidity, but are now rare. Clinical presentation is varied but may include fever, dysuria, urethral discharge and swelling of the penis or scrotum. In untreated cases urethral fistulation can occur and occasionally extensive cellulitis or necrotising fasciitis can occur.

A penile periurethral abscess arises following a gonococcal or chlamydial infection of one of the glands of Littre. There may be delay in diagnosis or a coexisting urethral stricture. There is usually penile swelling with tender induration felt on the underside of the penis, which if left untreated, may discharge externally, often leaving a fistula. Diagnosis can be helped by ultrasound of the urethra. Treatment should include both antibiotic treatment, as for urethritis, combined with surgical drainage into the urethra .

A periurethral abscess in relation to the bulbar urethra is even more uncommon. It may be associated with a urethral stricture, urethral trauma or, rarely, a urethral cancer. The infecting organisms are varied and can include both streptococci and anaerobic organisms. Extravasation of urine is not unusual. There is perineal pain with pyrexia, rigors and tachycardia. Tenderness and swelling rapidly spread from the perineum to the penis and the anterior abdominal wall. Ultrasound scanning and MRI are useful diagnostic aids and treatment with antibiotics are essential. Collections of pus should be drained and the urethra should be defunctioned by a suprapubic urinary catheter.

A chronic periurethral abscess sometimes results from a longstanding urethral stricture **(Figure 79.26)**. The multiple loculi of pus should be drained and the stricture treated. Urethral fistula occurs either spontaneously or as a result of incision of the abscess.

Figure 79.26 Chronic periurethral abscess.

Genital ulcers

The commonest cause of a genital ulcer is genital herpes. Other less common causes include syphilis and chancroid. As with all STIs, the possibilitiy of other infections (such as HIV) should always be borne in mind and, where appropriate, tested for.

Genital herpes

Genital herpes is caused by sexual transmission of the herpes simplex virus (usually HSV-2, occasionally HSV-1). Infection is lifelong with recurrent symptomatic attacks occuring in 50% or more of cases. Pain along the distribution of the sensory nerve, usually the genitofemoral nerve, precedes the eruption by 2 days and may be particularly severe around the anus. A group of tiny vesicles rapidly erodes to form shallow ulcers, which are painful. The first attack occurs around 4 days after exposure and is typically accompanied by fever, myalgia and inguinal lymphadenopathy. In female patients, the ulcers often spread on to the thighs during the attack. Involvement of the urethra may cause retention of urine, which may persist for up to 14 days if there is radiculitis of the S2 and S3 nerve roots.

Diagnosis is made clinically or, when there is doubt, by either cell culture or by polymerase chain reaction (PCR)-based techniques. All primary infections should be treated by oral antiviral agents such as acyclovir or valacyclovir, which have been shown to be effective in treating genital herpes, although they do prevent recurrences.

A child born to a mother with active infection is susceptible to a fatal generalised herpes infection in the neonatal period. Caesarean section should be considered in these circumstances. There is an increased risk of carcinoma of the cervix and annual cytology for life is recommended.

Syphilis

Syphilitic ulcers are typically painless, rubbery and indurated. Caused by the spirochaete *Treponema pallidum*, diagnosis was traditionally achieved by dark-field microscopy, but modern serological techniques are nowadays more appropriate. The incidence of syphilis is increasing since the advent of the retrovirals used to treat HIV in the mid 1990s. Treatment is with long-acting penicillin.

Tropical sexually transmitted infections

Lymphogranuloma veneruem, lymphogranuloma inguinale and chancroid are rare conditions in the Western world. However, they are still relatively common in some resource-poor countries. As with all STIs, the possibilitiy of other infections (such as HIV) should always be borne in mind and, where appropriate, tested for.

Lymphogranuloma venereum

Lymphogranuloma venereum is a sexually transmitted disease caused by *Chlamydia trachomatis* (chlamydia A) types L1–L3

Alexis Littre, 1658–1726, surgeon and lecturer in Anatomy, Paris, France.

and is primarily an infection of the lymphatics and lymph nodes. It can affect both sexes. While it was considered rare in resource-rich countries, some recent outbreaks in Europe have occurred, usually in conjunction with HIV.

The primary lesion is a fleeting, painless, genital papule or ulcer that develops 1–4 weeks after infection and is often unnoticed by the patient. The inguinal glands become enlarged and painful around 2–6 weeks after the primary lesion. The masses of nodes mat together above and below the inguinal ligament to give the 'sign of the groove'. The overlying skin reddens, there may be fluctuance and the mass occasionally ruptures. There may be a proctitis, which can go on to produce a rectal stricture if untreated. Lymphatic obstruction leads to lymphoedema in the perineum and, occasionally, the lower limbs. Urethritis and urethral stricture occur in men.

Diagnosis is confirmed clinically and by the detection of antibodies against the organism. Treatment is by a combination of antibiotics, which may include doxyclycine, azithromycin, erythromycin and ciprofloxacin. The multilocular lymphatic masses should not be incised, although aspiration is permissible to reduce discomfort.

Lymphogranuloma inguinale

This is a chronic and slowly progressive ulcerative tropical disease affecting the genitals and surrounding tissue, but occasionally occurring elsewhere in the body. It is usually sexually transmitted and is caused by *Klebsiella granulomatis* and is most commonly seen among socially deprived people. The incubation period varies greatly but is typically between 7–30 days.

A painless vesicle or indurated papule, usually on the external genitals but occasionally elsewhere on the skin, gradually erodes into a slowly extending ulcer with a beefy-red, granulomatous base. More chronic lesions may become greyish, especially at the edges, where, after months or years, malignant change may develop. The ulcerated area may bleed if touched but is usually surprisingly painless. Without treatment healing is only partial and keloid is common.

Diagnosis is by microscopy of material from the edges of the ulcer, which shows the presence of short gram-negative rods within the cytoplasm of the large mononuclear cells. Treatment is with azithromycin, although doxycycline, erythromycin, trimethoprim/sulfamethoxazole and gentamicin are alternatives.

Chancroid

Chancoid is a sexually transmitted, acute, ulcerative disease caused by *Haemophilus ducreyi*, a gram-negative facultative anaerobe. Following an incubation period of 3–10 days, a soft painful penile ulcer appears and is commonly followed by the development of inguinal lymphadenopathy. Diagnosis is by bacterial culture or by PCR techniques. Antibiotic treatment with ceftriaxone or azithromycin is usually effective therapy.

Condylomata acuminata (syn: genital warts)

Genital warts are caused by infection with HPV and are sexually transmitted. Infection is very common, with only a small proportion of infected patients actually having visible warts.

Figure 79.27 Genital warts affecting the outer prepuce. These were treated by radical circumcision.

Most commonly due to HPV types 6 and 11, these viruses do not cause cervical cancer. Ordinary skin warts can occur on the genitals by direct contact with a finger lesion, but they are less moist and soft and less often pedunculated than the genital variety. The lesions most commonly occur under the prepuce in the coronal sulcus but may be found elsewhere, including inside the urinary meatus and on the outer prepuce (**Figure 79.27**). In women, genital warts are most commonly found on the vulva but they may line the vagina and occur on the cervix. Perianal warts are common.

Other associated sexually transmitted diseases should be excluded: in women mainly candidiasis and *Trichomonas* infection and in men syphilis or gonorrhoea. Genital warts may complicate HIV infection.

Treatment is by chemical or physical means. Podophyllin is often effective as a topical application. It is applied to the wart, taking great care to avoid the surrounding skin and washed off after 6 hours or so. An alternative agent is Imidaquod. If chemical methods fail, the warts can be excised or they can be ablated with cryosurgery, electrosurgery or laser. Circumcision is sometimes advised if there are florid lesions under the foreskin.

Chapter 80

Testis and scrotum

Learning objectives

- To recognise testicular maldescent and to appreciate the reasons for intervention
- To recognise and manage testicular torsion
- To be able to recognise and understand the management of the common scrotal swellings (varicocoele, hydrocoele and epididymal cysts)
- To recognise and understand the management of testicular tumours
- To understand the treatment options for infertile men

EMBRYOLOGY AND ANATOMY OF THE TESTIS

The testes develop in the retroperitoneum below the kidneys at around the 10th thoracic level. During the 7th week of fetal development, the gubernaculum forms within the folds of the peritoneum. The upper end is attached to the developing testis and the lower end is attached to the fascia between the developing abdominal wall muscles. At the same time an evagination of the peritoneum itself, the **processus vaginalis**, develops adjacent to the gubernaculum and over the subsequent weeks evaginates through the abdominal wall to create the inguinal canal. The processus vaginalis initially picks up fibres of the internal oblique (which become the cremasteric muscle) and then fibres of the external oblique (which become the external spermatic fascia). As it elongates the processus carries with it the gubernaculum, which contains muscle fibres although it is not fully clear what part it plays in testicular descent. What is clear is that the testes lie at the internal inguinal ring at 3 months' gestation and descend to the scrotum between 7 and 9 months. This latter descent into the scrotum is accompanied by shortening of the gubernaculum. Final descent from the external ring to the base of the scrotum takes 4–6 weeks and is usually complete by birth.

The mechanisms that result in testicular descent are poorly understood but probably involve Müllerian inhibiting substance. Maternal chorionic gonadotrophin stimulates growth of the testis and may stimulate its migration. Imperfectly developed testes tend to descend incompletely.

The anatomy of the adult testis reflects its embryonic development. The testicular arteries originate high up in the retroperitoneum from the abdominal aorta just below the renal arteries. The testicular veins drain into the renal vein on the left and the inferior vena cava on the right. For much of their course the testicular artery and vein run parallel to the ipsilateral ureter, for which they may be mistaken during retroperitoneal surgery. Lymphatic drainage also follows this route, such that it is the para-aortic nodes that are the draining lymph nodes, which is important in the assessment and staging of men with testicular cancer.

The epididymis lies on the posterior aspect of the testis and is palpable as a separate structure, with a head, a body and a tail. The seminiferous tubules enter the epididymis at the upper end of the epididymis (the head). From the head, sperm travel through the body and tail of the epididymis to enter the vas deferens at the lower pole of the testis. The vas curves up behind the testis and can be felt above the testis as a firm tubular structure entering the external inguinal ring. In the inguinal canal, the vas deferens is invested by the cremasteric muscle along with the other components of the spermatic cord.

INCOMPLETELY DESCENDED TESTIS (SEE ALSO CHAPTER 9)

Definitions

Incomplete descent of the testis occurs when the testis is arrested in some part of its normal path to the scrotum. An ectopic testis is a testis that is abnormally placed outside this path.

Johannes Peter Müller,1801–1858, German physiologist and comparative anatomist, first described the paramesonephric (Müllerian) duct.

Incidence

About 4% of boys are born with one or both testes incompletely descended. About two-thirds of these reach the scrotum during the first 3 months of life, but full descent after that is uncommon. The incidence of testicular maldescent at the age of 1 year is around 1%. The condition is sometimes missed in the neonatal period and only discovered later in life. In a few cases, the presence of a hernia, testicular pain or acute torsion directs attention to the abnormality. In 10% of unilateral cases there is a family history.

Pathology

The condition is more common on the right and is bilateral in 20% of cases. In adults, secondary sexual characteristics are typically normal.

The testis may be:

- intra-abdominal; usually lying extraperitoneally just inside the internal inguinal ring;
- intracanalicular; it may or may not be palpable (**Figure 80.1**);
- extracanalicular; usually at the scrotal neck;
- ectopic; an ectopic testis has taken a non-standard path through the body and has ended up in an unusual location, the commonest site being the superficial inguinal pouch, which lies just inferior and medial to the superficial inguinal ring. Other rarer ectopic sites include the femoral triangle, the root of the penis and perineum.

Incompletely descended testes are often macroscopically normal in early childhood, but by puberty the testis is typically smaller compared with its intrascrotal counterpart. Microscopic changes are apparent from 1–2 years including loss of Leydig cells, degeneration of Sertoli cells and decreased spermatogenesis. The higher the testis, the greater the degree of histological change.

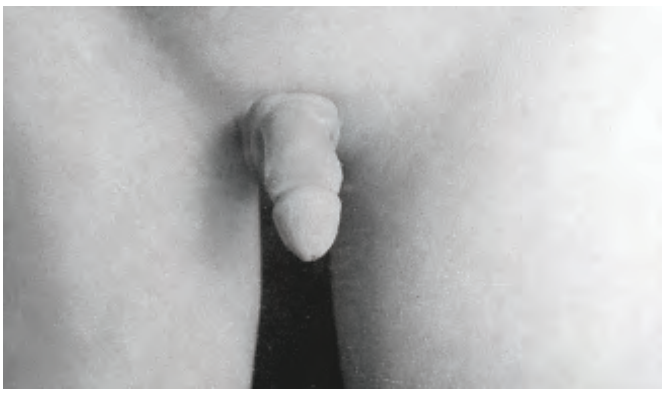

Figure 80.1 Undescended testes in a boy aged 12 years. Note the bilateral undescended testes with the underdeveloped scrotum. In cases of retractile testis, the scrotum is relatively well developed.

Consequences

Infertility

Impaired fertility is a well-recognised consequence of testicular maldescent, with paternity rates around two-thirds of normal for unilateral undescended testes and one-third of normal for bilateral undescended testes. Although there has been a recent tendency to undertake surgical orchidopexy earlier in life, evidence to show that this benefits fertility is currently lacking.

Malignancy

The cancer risk for adults after cryptorchidism in childhood is 5–10 times greater than normal. The commonest cancer is a seminoma, and as with fertility, it is unclear whether early orchidopexy reduces the risk of malignancy. However, if a testicular tumour does develop, it is undoubtedly easier to identify in a testis that is within the scrotum.

Hernia

Around 90% of boys with an undescended testis have a patent processus vaginalis although the incidence of a clinically apparent hernia is much lower.

Testicular torsion

The undescended testis is more prone to testicular torsion, largely as a consequence of a developmental abnormality between the testis and its mesentery.

Summary box 80.1

Undescended testis

- Testes that are absent from the scrotum after 3 months of age are unlikely to descend
- Histological changes in the testis can be seen from 1 year of age
- An incompletely descended testis tends to atrophy as puberty approaches
- Boys with undescended testes are at greater risk of infertility, testicular malignancy, hernia and testicular torsion

Clinical features

When assessing a child with suspected testicular maldesecent, it is helpful to have the boy as relaxed as possible and for him to be examined in a warm room, usually in a supine position. The important differential diagnosis is the so called 'retractile testis'. During childhood the testes are mobile and the cremasteric reflex is active so that in some boys, any stimulation of the skin of the scrotum or thigh causes the testis to ascend and to temporarily disappear into the inguinal canal. When the cremaster relaxes, the testis reappears only to vanish when the scrotal skin is touched again.

In comparison to a true undescended testis, the scrotum of a boy with such a retractile testis is normal as opposed to

Franz von Leydig, 1821–1908, German zoologist and comparative anatomist, discovered the Leydig cells.
Enrico Sertoli, 1842–1910, Italian physiologist, discovered the Sertoli cells of the testis.

underdeveloped, while a retractile testis can be gently milked from its position in the inguinal region to the bottom of the scrotum. A diagnosis of true incomplete descent should be made only if this is not possible.

When the testis is impalpable, ultrasound may be helpful in identifying the intracanalicular testis, while laparoscopy may be needed to differentiate between the abdominal testis and a truly absent testis.

Summary box 80.2

Retractile testis

- Retractile testes should be differentiated from true undescended testes
- This is most easily done with the child relaxed in a warm room
- Retractile testes are more common than true undescended testes
- Retractile testes require no treatment

Surgical treatment

Orchidopexy

Orchidopexy is usually performed before the boy reaches 12 months of age in an attempt to prevent the consequences described earlier. The testis and spermatic cord are mobilised and the testis is repositioned in the scrotum. The operation is performed through a short incision over the deep inguinal ring. The inguinal canal is exposed by division of the external oblique aponeurosis in the direction of its fibres.

Three manoeuvres help to gain the length required to bring the testis down into the bottom of the scrotum. First, the patent processus vaginalis should be indentified, separated and ligated. Second, the coverings of the spermatic cord (including the cremasteric muscle) should be divided and third, lateral fibrous bands just inside the internal inguinal ring should be divided. Although these techniques are usually effective, the tiny vas and testicular vessels are vulnerable to injury. The empty hemiscrotum is stretched with a finger passed into it through the inguinal incision to give enough room for the testis, which is placed in a pouch constructed between the dartos muscle and the skin (Figure 80.2).

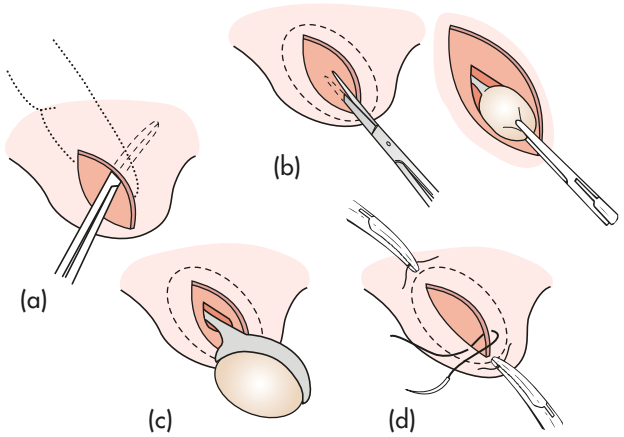

Figure 80.2 The testis is mobilised and retained in a pouch constructed between the dartos muscle and skin.

Failure to bring the testis down

Sometimes for a high undescended testis a two-stage surgical procedure is necessary. The testis is mobilised as far as possible and anchored with a suture and the mobilisation is completed 6 months later. An alternative approach involves initial division of the gonadal artery (which is usually 'tighter' than the vas deferens) such that the testis becomes dependent for its blood supply upon the cremasteric artery. The second stage procedure involves conventional orchidopexy. Orchidectomy should be considered if the incompletely descended testis is atrophic, particularly in the postpubertal boy if the other testis is normal.

INJURIES TO THE TESTIS

The testis can be damaged either by blunt or by penetrating trauma. Injuries can range from simple bruising, through significant intratesticular haematomas to rupture of the tunica albuginea, with very significant collections of blood within the tunica vaginalis (haematocoele) (Figure 80.3). If the tunica ruptures, the blood can track into the groin and perineum.

Careful clinical assessment, together with the use of ultrasound examination, is central to the management of men with a scrotal injury. Ultrasound has excellent sensitivity and specificity in the diagnosis of testicular rupture. If there is testicular rupture, there is good evidence that early surgical exploration, with debridement and repair of the tunica albuginea, is more likely to preserve useful testicular function. Scrotal wall haematomas and injuries without rupture can usually be treated conservatively.

Summary box 80.3

Scrotal trauma

- In cases of scrotal trauma, surgical exploration is indicated when there is testicular rupture or when there is a rapidly expanding scrotal haematoma
- Ultrasound is invaluable in the assessment of the injury

Figure 80.3 Longitudinal scan of a testicle with a haematocoele (H) at the lower pole.

ABSENT TESTIS

'Vanishing' testis describes a condition in which a testis develops but disappears before birth. The most likely cause for this is prenatal torsion. True agenesis of the testis is rarer. Laparoscopy is useful in distinguishing these causes of clinically absent testis from intra-abdominal maldescent.

TORSION OF THE TESTIS

Pathophysiology

Testicular torsion is a condition whereby the testicle twists in such a way that its blood supply becomes compromised. If left untreated the blood flow to the testicle ceases and the testicle dies. Testicular torsion is therefore a surgical emergency and the earlier the surgery to untwist the testis can be undertaken the better the outcome.

Torsion of the testis is uncommon because the normal testis is anchored and cannot rotate. For torsion to occur one of several abnormalities must be present:

- High investment of the tunica vaginalis causes the testis to hang within the tunica like a clapper in a bell (Figure 80.4). This is the most common cause in adolescents and is typically a bilateral abnormality.
- Inversion of the testis. The testis is rotated so that it lies transversely or upside down.
- Separation of the epididymis from the body of the testis permits torsion of the testis on the pedicle that connects the testis with the epididymis (Figure 80.5).

Normally, when there is a contraction of the abdominal muscles, the cremaster contracts as well. In the presence of one of the abnormalities described above, the spiral attachment of the cremaster favours rotation of the testis around the vertical axis. Sudden contraction of the cremasteric muscle, which may be a response to mechanical, sexual or thermic stimulation, may cause a rotational effect on the testis as it is pulled upward. Accordingly, straining on stool, lifting of a heavy weight, sexual activity and sport can all precipitate an episode.

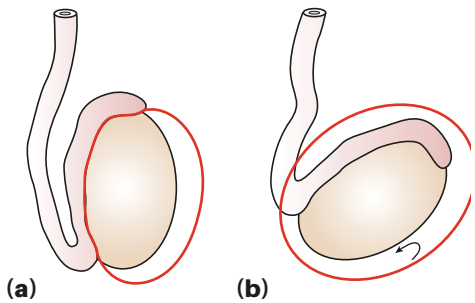

Figure 80.4 Testicular torsion: **(a)** normal attachment; **(b)** an abnormally high attachment of the tunica vaginalis predisposes to torsion – the 'bell-clapper'.

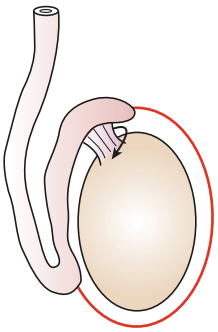

Figure 80.5 Testicular torsion. Separation of the testis from the epididymis – torsion about the pedicle between them.

The two main factors that determine the damage to the testis are the extent of the twist and the duration of the episode. Twists of 720° cause more rapid ischaemia than twists of 360° or less, while if the testis can be untwisted within 6 hours of the torsion taking place there is nearly a 100% chance of testicular salvage compared with a 20% salvage rate if the surgery is delayed for 24 hours.

Occasionally the testis untwists spontaneously without the need for surgical treatment and such episodes of intermittent testicular torsion should be considered as a cause of intermittent testicular pain in adolescents.

Clinical features

Testicular torsion is most common between 10 and 25 years of age, although a few cases occur outside this age range. Typically there is sudden agonising pain in the groin and the lower abdomen and the patient feels nauseated and may vomit. Torsion of a fully descended testis is usually easily recognised. The scrotum is swollen and tender, while the skin is usually not erythematous initially (although it may become so with a prolonged history) and the patient is apyrexial. The testis itself is swollen and tender and seems high within the scrotum, while the tender twisted cord can often be palpated above it. The cremasteric reflex is lost.

Differential diagnosis

Redness of the skin and a mild pyrexia may result in the condition being confused with epididymo-orchitis in the older patient; however, in epididymo-orchitis there will usually be dysuria associated with the accompanying urinary infection. Elevation of the testis reduces the pain in epididymo-orchitis while it makes it worse in torsion.

Torsion of a testicular appendage cannot always be distinguished with certainty from testicular torsion. The most common structure to twist is the appendix of the testis (the pedunculated hydatid of Morgagni). The twisted testicular appendages can sometimes be visible through the scrotal wall as a small dark spot. If the diagnosis is made clinically, then conservative management is possible, but if in doubt then

Giovanni Battista Morgagni, 1682–1771, Professor of Anatomy at the University of Padua, is associated with a number of eponymous structures including the aortic sinus, the appendix testis, the anal columns and the sternocostal triangles. He is regarded as the 'Father of Morbid Anatomy'.

surgical exploration should be undertaken with ligation and amputation of the twisted appendage.

In mumps orchitis, the cord is not particularly thickened and the condition is often bilateral.

Idiopathic scrotal oedema is an oddity that occurs between the age of 4 and 12 years and must be differentiated from torsion. The scrotum is very swollen but there is little pain or tenderness. The swelling is usually bilateral and may extend into the perineum, groin and penis. It is thought to be an allergic phenomenon and occasionally there is eosinophilia. The swelling subsides after a day or so but may recur (**Figure 80.6**).

Very occasionally, torsion can be convincingly mimicked by a small tense strangulated inguinal hernia compressing the cord and causing compression of the pampiniform plexus.

Management

The management of the case should be determined primarily on clinical grounds. While Doppler ultrasound scanning can confirm the absence of the blood supply to the affected testis, false-positive results can be seen so it is not routinely recommended. If there is any doubt as to the diagnosis, then urgent scrotal exploration is indicated.

Exploration for torsion should be performed through a transverse scrotal incision. If the testis is viable when the cord is untwisted, it should be prevented from twisting again by fixation with three non-absorbable sutures between the tunica albuginea of the testis and the scrotal raphe. The use of absorbable sutures risks the possibility of recurrent torsion at some time in the future. The other testis should also be fixed because the anatomical predisposition is likely to be bilateral. If there is clinical doubt as to testicular viability after detorsion of the testis, then it should be wrapped in a warm swab and observed over a few minutes. If a small incision in the tunica albuginea demonstrates bright red arterial bleeding then the testis may survive. An infarcted testis should be removed – the patient can be counselled later about a prosthetic replacement.

In cases where there is a history of pain for several days, the affected testis will be dead. It is not possible to recover such a testis and although little is gained (other than pain relief) by immediate exploration, it is necessary to fix the contralateral testis.

Figure 80.6 Idiopathic oedema of the scrotum.

Summary box 80.4

Testicular torsion

- If the diagnosis of testicular torsion is possible, then surgical exploration is indicated
- Prompt exploration, untwisting and fixation is the only way to save the torted testis
- The patient should be counselled and consented for orchidectomy before exploration
- The anatomical abnormality is bilateral and the contralateral testis should also be fixed
- Three non-absorbable sutures should be used for the fixation of each testis

VARICOCOELE

A varicocoele is a varicose dilatation of the veins draining the testis.

Surgical anatomy

The veins draining the testis and the epididymis form the pampiniform plexus. The veins gradually join each other as they traverse the inguinal canal and at, or near, the inguinal ring, there are only one or two testicular veins, which pass upwards within the retroperitoneum. The left testicular vein empties into the left renal vein while the right empties into the inferior vena cava below the right renal vein. The testicular veins usually have valves near their terminations, but these are sometimes absent. There is an alternative (collateral) venous return from the testes through the cremasteric veins, which drain mainly into the inferior epigastric veins.

Aetiology

Varicocoeles are common, affecting perhaps 15–20% of adult males and 90% are left sided, reflecting the proximal venous anatomy. They are unusual in boys and typically develop during late childhood and adolescence. In some cases, the dilated vessels are cremasteric veins and not part of the pampiniform plexus. The usual cause is absence or incompetence of valves in the proximal testicular vein. While most varicocoeles are idiopathic, obstruction of the left testicular vein by a renal tumour or nephrectomy is a cause of varicocoele in later life; characteristically, in such cases the varicocoele does not decompress in the supine position.

Clinical features

While most varicocoeles are asymptomatic, those that are symptomatic tend to present in adolescence or early

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler Principle' in 1842.

adulthood, when there may be an annoying dragging discomfort that is worse on standing at the end of the day. This presumably reflects distension of the testicular veins. When examined in the erect position, the scrotum on the affected side hangs lower than normal (Figure 80.7); on palpation, with the patient standing, the varicose plexus feels like a bag of worms. There may be a cough impulse. If the patient lies down the veins empty by gravity and this provides an opportunity to ensure that the underlying testis is normal to palpation. In long-standing cases the affected testis is smaller and softer than its fellow, owing to a minor degree of atrophy.

Ultrasonography can be helpful in the diagnosis of small varicocoeles (Figure 80.8), and in older men with an apparently recent onset of varicocoele, ultrasonography of the kidneys is important in excluding a left renal tumour.

Grading of the varicocoele is possible, with a Grade I varicocoele being impalpable (i.e. observed only on ultrasound), Grade II being palpable and Grade III being visible.

Varicocoele and spermatogenesis

Of all the possible causes of primary infertility, oligozoospermia (reduced numbers of sperm in the ejaculate) is one of the most difficult to treat. Because varicocoeles are relatively common, some men with oligozoospermia will have a varicocoele, and it is tempting to blame this for the infertility. Certainly the varicocoele will tend to 'warm' the testis, which is usually around 2.5°C below rectal temperature, and there is conflicting evidence regarding the effect of this temperature difference upon spermatogenesis. Unfortunately, there is little evidence that varicocoelectomy improves semen quality or the rate of conception.

Figure 80.7 Large varicocoele in a pendulous scrotum. Note the left inguinal hernia.

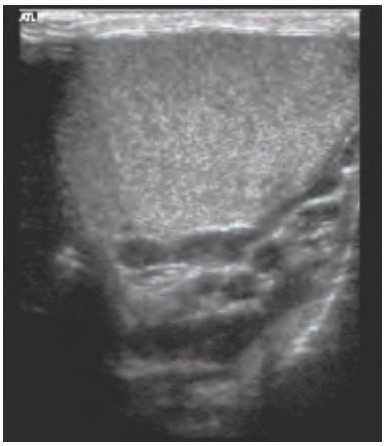

Figure 80.8 Ultrasound of a varicocoele. Note the dilated veins at the lower pole of the testis.

Treatment

Operation is not indicated for an asymptomatic varicocoele. When the discomfort is significant, then percutaneous embolisation of the gonadal veins is the usual first-line intervention. If this is not possible, or if the varicocoele recurs (as it does in around 20% after embolisation), then surgical ligation of the testicular veins is the appropriate treatment, although recurrence can occur even after such surgery.

Summary box 80.5

Varicocoele

- Varicocoele is a common condition and 90% are left sided
- Development of a left-sided varicocoele in later life may indicate the presence of a renal tumour
- They are usually asymptomatic and as such rarely need treatment
- First-line treatment is embolisation in symptomatic cases
- Varicocoeles often recur, even after surgical treatment
- The association of varicocoeles with subfertility is controversial

HYDROCOELE

A hydrocoele is an abnormal collection of serous fluid in a part of the processus vaginalis, usually the tunica vaginalis. Acquired hydrocoeles are primary or idiopathic, or secondary to epididymal or testicular disease.

Aetiology

A hydrocoele can be produced in four different ways (Figure 80.9):

1. By connection with the peritoneal cavity via a patent processus vaginalis (congenital).
2. By excessive production of fluid within the sac, e.g. a secondary hydrocoele.

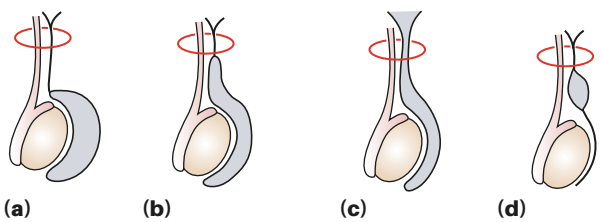

Figure 80.9 **(a)** Vaginal hydrocoele (very common); **(b)** 'infantile' hydrocoele; **(c)** congenital hydrocoele; **(d)** hydrocoele of the cord.

3 By defective absorption of fluid; this appears to be the explanation for most primary hydrocoeles, although the reason why the fluid is not absorbed is obscure. They are sometimes called vaginal hydrocoeles.
4 By interference with the lymphatic drainage of scrotal structures.

A secondary hydrocoele is most frequently associated with acute or chronic epididymo-orchitis. It is also seen with torsion of the testis and with some testicular tumours. A secondary hydrocoele is usually lax and is typically small: the underlying testis is usually palpable. If a tumour is suspected, the hydrocoele should not be punctured for fear of needle-track implantation of malignant cells. A secondary hydrocoele subsides when the primary lesion resolves.

Clinical features

Examination of a scrotal swelling should be undertaken in both the upright and supine position. The examiner should ask themselves a series of questions. First, is it possible to get above the swelling to palpate a normal cord? For instance, if it is not possible to achieve this, the swelling may represent an inguinal hernia that has entered the scrotum. Second, is the swelling primarily testicular or epididymal or is it enclosing both of those structures? Thirdly, does the swelling transilluminate? In almost all cases of scrotal swelling an ultrasound is a useful adjunct, both in clarifying the nature of the swelling and in determining whether the testis itself is diseased.

A hydrocoele is a swelling that encloses the testis and epididymis such that they may be impalpable, and it is possible to get 'above' it to palpate a normal spermatic cord (**Figure 80.10**). They are typically translucent.

A primary hydrocoele is seen most commonly in middle and later life, but can also occur in older children. The condition is particularly common in hot countries. Because the swelling is usually painless it may reach a prodigious size before the patient presents for treatment. Be wary of an acute hydrocoele in a young man since there may be a testicular tumour.

In congenital hydrocoele, the processus vaginalis is patent and connects with the peritoneal cavity. The communication is usually too small to allow herniation of intra-abdominal contents. Pressure on the hydrocoele does not always empty it but the hydrocoele fluid may drain into the peritoneal cavity when the child is lying down; thus, the hydrocoele may be intermittent. Ascites should be checked for if the swellings are bilateral.

An encysted hydrocoele of the cord is a smooth oval swelling that lies above the testis near the spermatic cord, which is liable to be mistaken for an inguinal hernia. The swelling moves downwards and becomes less mobile if the testis is pulled gently downwards.

Hydrocoele of the canal of Nuck is a similar condition in females. The cyst lies in relation to the round ligament and is always at least partially within the inguinal canal.

Figure 80.10 A right-sided hydrocoele.

Treatment

Congenital hydrocoeles are treated by herniotomy if they do not resolve spontaneously (see Chapter 9).

Small acquired hydrocoeles do not need treatment. If they are sizeable and bothersome for the patient, then surgical treatment is indicated. Established acquired hydrocoeles often have thick walls. There are three main surgical techniques for hydrocoeles;

- **Plication**. Lord's operation is suitable when the sac is reasonably thin-walled (**Figure 80.11**). There is minimal dissection and the risk of haematoma is reduced.
- **Eversion.** The sac is opened and everted behind the testis, with placement of the testis in a pouch prepared by dissection in the fascial planes of the scrotum (Jaboulay's procedure) (**Figure 80.12**).

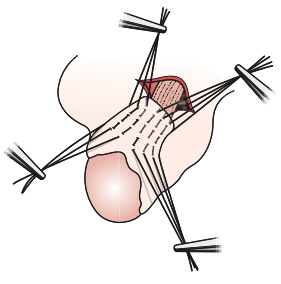

Figure 80.11 Lord's operation. A series of interrupted absorbable sutures is used to plicate the redundant tunica vaginalis. When these are tied, the tunica bunches at its attachment to the testis.

Anton Nuck, 1650–1692, Professor of Anatomy and Medicine, Leiden, The Netherlands.
Peter Herent Lord, contemporary, formerly surgeon, Wycombe General Hospital, High Wycombe, Buckinghamshire, UK.

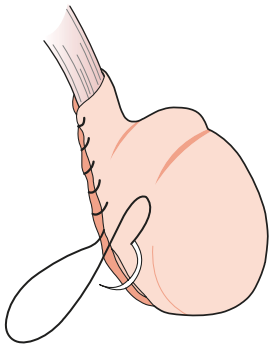

Figure 80.12 Jaboulay's procedure. The hydrocoele sac is everted and anchored with sutures.

- **Excision**. Unless great care is taken to stop bleeding after excision of the wall, haemorrhage from the cut edge is liable to cause a large scrotal haematoma. This approach is not recommended.

Aspiration of the hydrocoele fluid is simple, but the fluid always reaccumulates within a week or so. It may be suitable for men who are unfit for scrotal surgery, although hydrocoele surgery can be undertaken under local anaesthetic. Aspiration can result in bleeding into the hydrocoele sac and haematocoele formation. Injection of a sclerosant, such as tetracycline, is effective but painful.

Summary box 80.6

Hydrocoele

- A hydrocoele is a collection of fluid within the tunica vaginalis
- Primary hydrocoeles surround the testis and transilluminate brightly
- Ultrasound examination is valuable, especially when the testis and epididymis are impalpable
- Hydrocoeles can be treated conservatively unless they are large and symptomatic
- Surgery is the mainstay of treatment
- Testicular malignancy is an uncommon cause of hydrocoele that can be excluded by ultrasound examination

Filarial hydrocoeles and chylocoeles

Filarial hydrocoeles and chylocoeles account for up to 80% of hydrocoeles in tropical countries, where the parasite *Wuchereria bancrofti* is endemic. Filarial hydrocoeles follow repeated attacks of filarial epididymo-orchitis. They vary in size and may develop slowly or very rapidly. Occasionally, the fluid contains liquid fat, which is rich in cholesterol. This is caused by rupture of a lymphatic varix with discharge of chyle into the hydrocoele. In long-standing chylocoeles, there are dense adhesions between the scrotum and its contents. Filarial elephantiasis supervenes in a small number of cases. Treatment is by rest and aspiration. The more usual chronic cases are treated by excision of the sac.

CYSTS ASSOCIATED WITH THE EPIDIDYMIS

There are several types of cyst associated with the epididymis, including epididymal cysts and spermatocoeles.

Epididymal cysts

These are filled with a crystal-clear fluid. They are very common, usually multiple and vary in size at presentation. They represent cystic degeneration of the epididymis. Cysts of the epididymis are usually found in middle age and are often bilateral. The clusters of tense cysts feel like a tiny bunches of grapes that lie posterior to, and quite separate from, the testis. They should transilluminate brilliantly. The diagnosis can by confirmed by ultrasound (**Figure 80.13**).

Aspiration is useless because the cysts are usually multilocular. If they are causing discomfort they should be excised. While single large cysts can be excised separately, recurrent or multilocular cysts usually require partial or total epididymectomy. Excision should be expected to interfere with the transportation of sperm from the testis on that side and young men should be counselled regarding this.

Spermatocoele

This is a unilocular retention cyst derived from some portion of the sperm-conducting mechanism of the epididymis. A spermatocoele typically lies in the epididymal head above

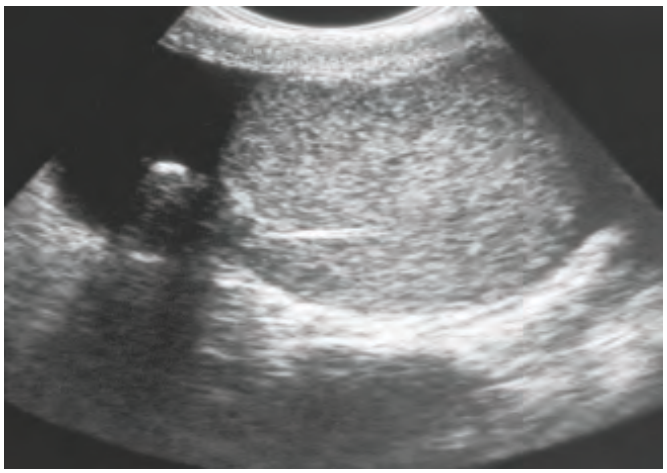

Figure 80.13 Ultrasound of an epididymal cyst.

Mathieu Jaboulay, 1860–1913, Professor of Surgery, Lyons, France.
Edward Gibbon, 1737–1794, the author of '*The decline and fall of the Roman empire*', was greatly embarrassed by a large hydrocoele. The second time that it was tapped it became infected, and Gibbon died a few days later. The hydrocoele was associated with a large scrotal hernia, which had probably been punctured.
Otto Eduard Heinrich Wucherer, 1820–1873, German physician who practised in Brazil.
Joseph Bancroft, 1836–1894, English physician working in Australia.

and behind the upper pole of the testis. It is usually softer and laxer than other cystic lesions in the scrotum but, like them, it transilluminates. The fluid contains spermatozoa and resembles barley water in appearance. Spermatocoeles are usually small and unobtrusive. Small spermatocoeles can be ignored. Larger ones should be excised.

Summary box 80.7

Cysts associated with the epididymis

- Lie posterior to and separate from the testis and they transilluminate
- Diagnosis can be confirmed by ultrasound examination
- Can be treated conservatively unless they are large or uncomfortable

EPIDIDYMO-ORCHITIS

Inflammation confined to the epididymis is epididymitis; infection spreading to the testis is epididymo-orchitis.

Pathophysiology

Infection reaches the epididymis via the vas from a primary infection of the urethra, prostate or seminal vesicles. A general rule is that epididymitis arises in sexually active young men from a sexually transmitted genital infection, while in older men it more usually arises from a urinary infection or may be secondary to an indwelling urethral catheter.

In young sexually active men, the most common cause of epididymitis is now *Chlamydia trachomatis*, but gonococcal epididymitis is still occasionally seen. In older men with bladder outflow obstruction, epididymitis may result from a urinary infection – it is proposed that a high pressure in the prostatic urethra might cause reflux of infected urine up the vasa. Blood-borne infections of the epididymis are less common but may be suspected when there is epididymal infection without evidence of urinary infection; it is presumably the only possible mechanism in men who have previously undergone a vasectomy. Acute epididymo-orchitis can follow any form of urethral instrumentation and it is particularly common when an indwelling catheter is associated with infection of the prostate.

Infection usually starts in the tail of the epididymis and spreads to the rest of the epididymis and occasionally to the testis. Complications include abscess formation, testicular infarction, testicular atrophy, chronic induration and inflammation and infertility.

Clinical features

While there may be initial symptoms of a urinary or a genital infection, such symptoms are not always seen. The development of an ache in the groin and a fever can herald the onset of epididymitis. The epididymis and testis swell and become painful. The scrotal wall, at first red, oedematous and shiny, may become adherent to the epididymis.

Investigation should include a urethral swab, a urine specimen for culture, nucleic acid amplification testing (NAAT) of either a urine specimen or a urethral swab and scrotal ultrasound. Urinalysis will usually show leukocytes and may show a formal urinary tract infection. NAAT is a sensitive way of identifying both gonoccal and chlamydial urethritis. Ultrasound is useful in the initial assessment of epididymitis and will identify abscess formation.

In adolescents, the differential diagnosis is testicular torsion and if there is any clinical doubt as to the diagnosis then testicular exploration should always be performed.

Treatment

Either doxycycline (100–200 mg daily) or a quinolone should be the initial treatment in young men. There should be contact tracing of the partner and treatment if necessary. Antibiotic treatment should continue for at least 2 weeks.

In older men, quinolones are the usual initial treatment, but if there is evidence of systemic sepsis, then intravenous antibiotics directed at urinary pathogens may be valuable. If an organism is isolated from the urine, this simplifies the choice of antibiotic.

All patients should drink plenty of fluid. Local measures including scrotal support and analgesia are helpful. Antibiotic treatment should continue for at least 2 weeks or until the inflammation has subsided. If suppuration occurs, drainage is necessary.

Chronic disease

Chronic non-tuberculous epididymitis usually follows the failure of resolution of an acute episode of epididymitis. Patients typically complain of intermittent episodes of discomfort and the epididymis feels thickened and tender. Treatment involves use of antibiotics (usually quinolones or doxycycline) and anti-inflammatory agents for 4–6 weeks. Epididymectomy or orchidectomy can be considered if there is no resolution, although some patients continue to suffer from pain despite such surgery.

Summary box 80.8

Acute epididymo-orchitis

- In young men usually arises secondary to a sexually transmitted genital infection
- In older men usually arises secondary to urinary infection
- May be a complication of catheterisation or instrumentation of the urinary tract
- May need aggressive treatment with parenteral antibiotics

Tuberculous epididymo-orchitis

Chronic tuberculous epididymo-orchitis usually begins insidiously. The frequency with which the lower pole of the epididymis is involved first indicates that the infection is usually retrograde from a tuberculous focus in the seminal vesicles.

Clinical features

Typically, there is a firm, uncomfortable discrete swelling of the lower pole of the epididymis. The disease progresses until the whole epididymis is firm and craggy behind a normal-feeling testis. There is a lax secondary hydrocoele in 30% of cases, and a characteristic beading of the vas may be apparent as a result of subepithelial tubercles. The seminal vesicles feel indurated and swollen. In neglected cases, a tuberculous 'cold' abscess forms, which may discharge. The body of the testis may be uninvolved for years but the contralateral epididymis often becomes diseased. In two-thirds of cases there is evidence of renal tuberculosis or previous disease. Otherwise, patients typically appear healthy.

The urine and semen should be examined repeatedly for tubercle bacilli in all patients with chronic epididymo-orchitis. A chest radiograph should be performed, as should imaging of the upper urinary tract. Ultrasound will demonstrate a thickened epididymis.

Treatment

Secondary tuberculous epididymitis may resolve when the primary focus is treated. Treatment with antituberculous drugs is less effective in genital tuberculosis than in urinary tuberculosis. If resolution does not occur within 2 months, epididymectomy or orchidectomy is advisable. A course of antituberculous chemotherapy should be completed even if there is no evidence of disease elsewhere.

ORCHITIS

Mumps orchitis, which is the most common form of orchitis, develops in 20–30% of postpubertal patients with a mumps virus infection and it usually develops as the parotid swelling is waning. Evidence of IgM antibodies in the serum supports the diagnosis. The main complication is testicular atrophy, which may cause infertility if the condition is bilateral. Partial testicular atrophy is associated with persistent testicular pain.

Syphilitic orchitis is now uncommon. It can cause bilateral orchitis (which is a feature of congenital syphilis), interstitial fibrosis, which causes painless destruction of the testis, or, rarely, it may lead to a gumma of the testis, which presents as a unilateral slowly growing painless swelling. The latter presentation may be difficult to distinguish from a neoplasm without surgical exploration. Diagnosis is confirmed by serology.

TUMOURS OF THE TESTES

Testicular cancer represents around 1–1.5% of male neoplasms and there is clear evidence of an increased incidence of these tumours in the past 30 years. The vast majority are germ cell tumours and the peak incidence of seminomas is in the 4th decade of life, with the non-seminomatous germ cell tumours (NSGCT) being more common in the 3rd decade of life. They are the commonest form of tumour in young men. Risk factors include a history of testicular maldescent, a history of a contralateral testicular tumour and Klinefelter's syndrome.

Classification and pathology

Tumours of the testis are classified according to their predominant cellular type:

- **germ cell tumours** (90–95%) (these include seminoma, embryonal cell carcinoma, yolk sac tumour, teratoma, and choriocarcinoma);
- **interstitial tumours** (1–2%) (these include Leydig cell tumours);
- **lymphoma** (3–7%);
- **other tumours** (1–2%).

Seminoma

A seminoma typically has a cut surface that is homogeneous and pinkish cream in colour. It appears to compress neighbouring testicular tissue (**Figure 80.14**). It consists of oval cells with clear cytoplasm and large, rounded nuclei with prominent acidophilic nucleoli. Sheets of cells resembling spermatocytes are separated by a fine fibrous stroma. Active lymphocytic infiltration of the tumour suggests a good host response and a better prognosis. There are two histological variants, one with a more anaplastic appearance and another that is characterised by cells that closely resemble different phases of maturing spermatogonia (spermatocytic seminoma).

Seminomas metastasise mainly via the lymphatics (**Figure 80.15**) and haematogenous spread is uncommon. The lymphatic drainage of the testes is to the para-aortic lymph nodes near the origin of the gonadal vessels. The contralateral para-aortic lymph nodes are sometimes involved by tumour spread, but the inguinal lymph nodes are affected only if the scrotal skin is involved.

Non-seminomatous germ cell tumours

These tumours may be tiny but can reach the size of a coconut. The smaller tumours may not even distort the tunica albuginea (**Figure 80.16**). The usual type of teratoma is yellowish in colour with cystic spaces containing gelatinous fluid (**Figure 80.17**). There are a number of histological types of NSGCT, which may coexist within a single tumour:

- **embryonal carcinoma**: highly malignant tumours that occasionally invade cord structures;
- **yolk sac tumour**: tumours with this component secrete alpha fetoprotein (AFP);

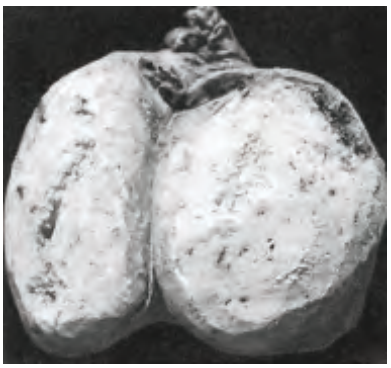

Figure 80.14 Seminoma of the testis.

Harry Fitch Klinefelter, Jr., 1912–1990, American rheumatologist and endocrinologist.

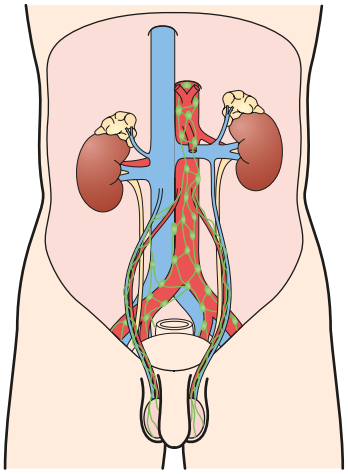

Figure 80.15 Lymphatic drainage of the testes to para-aortic lymph nodes.

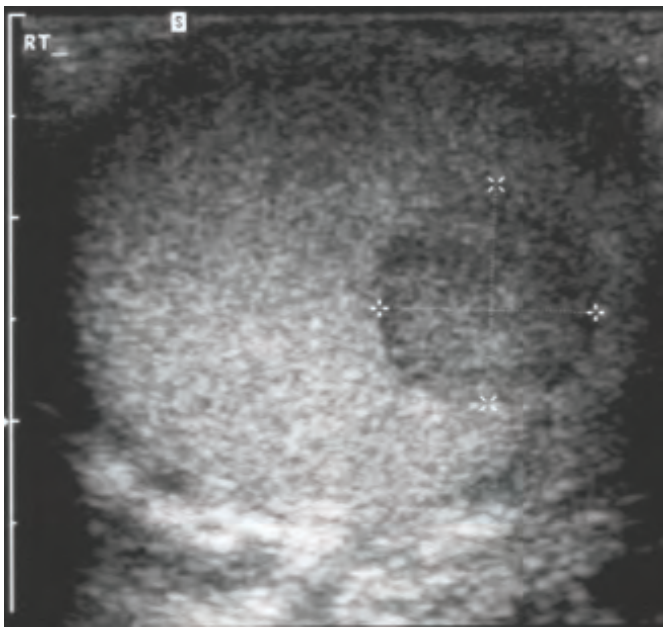

Figure 80.16 Ultrasound of a small intratesticular tumour with minimal distortion of the tunica albuginea.

- **choriocarcinoma**: often produces human chorionic gonadotrophin (hCG). This is a highly malignant tumour that metastasises early via both the lymphatics and the bloodstream;
- **teratoma**: these tumours contain more than one cell type, with components derived from ectoderm, endoderm and mesoderm. Tumours may range from 'mature' with well-differentiated tissue elements, to 'immature' with undifferentiated primitive tissues. All can metastasise.

Interstitial cell tumours

Interstitial cell tumours arise from Leydig or Sertoli cells. A Leydig cell tumour masculinises; a Sertoli cell tumour feminises. They are typically small well-circumscribed tumours with a yellow cut surface. Microscopically, the cells are usually uniform and closely packed. Approximately 10% are malignant.

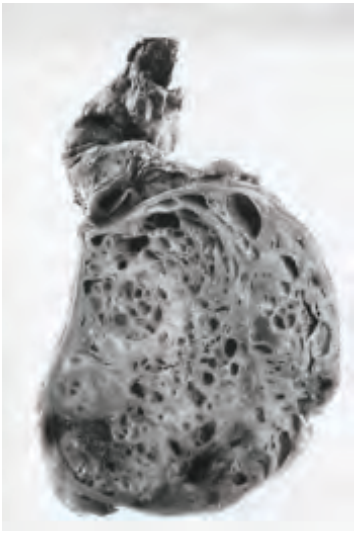

Figure 80.17 Teratoma of the testis – note the solid and cystic areas (courtesy of Dr Keith Simpson, London, UK).

Most prepubertal interstitial cell tumours (which account for around 25% of cases) produce androgens, which cause sexual precocity including prominent external genitalia, suprapubic hair growth and a deep masculinised voice. Regression of the symptoms after orchidectomy may be incomplete. Most postpubertal interstitial cell tumours produce feminising hormones, leading to gynaecomastia, erectile dysfunction, loss of libido and azoospermia.

Clinical features

Usually the patient presents with a painless testicular lump. A sensation of heaviness can occur if the testis is two or three times its normal size, but only a minority of patients experience pain. In a few cases, an episode of trauma calls attention to the swelling. Some cases may simulate epididymo-orchitis and, rarely, some patients present with severe pain and acute enlargement of the testis because of haemorrhage into the tumour. Such cases can occasionally mimic testicular torsion.

Rarely, the predominant symptoms are those of metastatic disease. Intra-abdominal disease may cause abdominal or lumbar pain and the mass may be discovered in the epigastrium. Lung metastases are usually silent, but they can cause chest pain, dyspnoea and haemoptysis in the later stages of the disease. The primary tumour may not have been noticed by the patient, and indeed may be so tiny that it can be detected only by ultrasonography (**Figure 80.16**).

On examination there is an intratesticular solid mass. If present, a lax secondary hydrocoele does not usually obscure the underlying tumour. The epididymis becomes more difficult to feel when it is flattened or incorporated in the growth. The vas is never thickened and rectal examination is normal. Around 5% of cases have gynaecomastia (mainly the NSGCT). Metastatic disease is rarely apparent clinically and is more usually identified by formal staging investigations. In 1–2% of cases the tumour is bilateral at the time of diagnosis.

Investigation and staging

The diagnosis is confirmed by ultrasound scanning of the testis (Figure 80.18), which is also able to assess the contralateral testis. It is a mandatory test in all suspected cases of testicular tumour.

In confirmed cases, staging is an essential step in planning treatment. Blood is taken prior to orchidectomy to measure the levels of tumour markers, which are raised in around 50% of cases. A rise in AFP is seen in around 50–70% of NSGCTs and a rise in hCG is seen in 40–60% of NSGCTs and around 30% of seminomas. When raised, these markers are used to monitor the response to treatment. The mean serum half-lives of AFP and hCG are 5–7 days and 2–3 days respectively, and reassessment of the markers following orchidectomy can indicate whether all the tumour tissue has been removed.

While a chest x-ray will occasionally demonstrate the 'classical' cannon ball metastases (Figure 80.19) computed tomography (CT) of chest, abdomen and pelvis has taken over as the most useful means of detecting metastatic disease and for monitoring the response to therapy. Such imaging is usually undertaken after the affected testis has been removed.

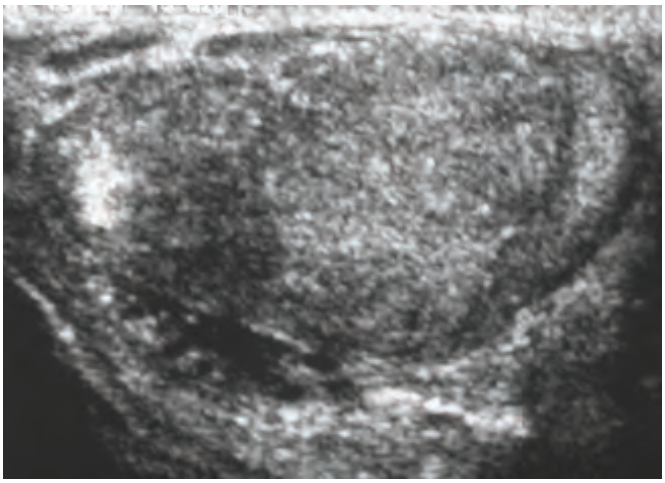

Figure 80.18 Testicular ultrasound: the homogeneous tissue of the testicular teratoma on the left of the image produces multiple ultrasound reflections.

Figure 80.19 Cannon ball metastases from carcinoma of the testis.

Staging of testicular tumours

While TNM staging is the most widely used system for the staging of testicular cancer, the older staging system of Stages I-IV is still considered valuable in determining the treatment options.

The stages are:

Stage I: Tumour is confined to the testis and epididymis.
Stage II: Nodal disease is present but is confined to nodes below the diaphragm.
Stage III: Nodes are present above the diaphragm.
Stage IV: Non lymphatic metastatic disease (most typically within the lungs).

Summary box 80.9

Testicular tumours

- A solid testicular lump that cannot be felt separately from the testis may be a malignant tumour
- Lymphatic spread is to the para-aortic lymph nodes
- Ultrasound is a mandatory investigation in all cases of suspected testicular tumour
- Tumour markers (AFP and hCG) should be measured prior to orchidectomy

Treatment

Scrotal exploration and orchidectomy for suspected testicular tumour

The orchidectomy is undertaken via an inguinal incision. The spermatic cord is displayed by dividing the external oblique aponeurosis and a soft clamp is placed across the cord to stop dissemination of malignant cells as the testis is mobilised into the wound. Rarely, if there is doubt about the diagnosis, the testis should be bisected along its anterior convexity to examine its internal structure. If there is a tumour the cord should be double transfixed and divided at the level of the internal inguinal ring and the testis removed.

Management by staging and histological diagnosis (after orchidectomy)

The treatment of patients with germ cell tumours of the testis is usually successful, even in cases that are advanced at presentation. This largely reflects the excellent response of these tumours to platinum-based chemotherapy and (for seminomatous tumours) to radiotherapy. Indeed in recent years the emphasis of clinical trials has been focused upon the identification of those patients who do **not** need chemotherapy, and who therefore will escape the side effects of treatment.

STAGE I TUMOURS

Seminomas are radiosensitive and for many years adjuvant radiotherapy to the para-aortic nodes was the mainstay of treatment for stage I disease. However, there is also an

excellent response to platinum-based chemotherapy, which led to chemotherapy being introduced as the primary treatment for stage I seminoma. However, given that only around 15–20% of men with stage I seminoma have subclinical metastatic disease, current protocols use CT and tumour marker-based surveillance protocols, with chemotherapy being reserved for men who demonstrate relapse.

NSGCTs are not radiosensitive, but they are highly sensitive to combination chemotherapy with bleomycin, etoposide and cis-platinum (so called BEP chemotherapy). Up to 30% of NSGCT patients with stage I disease have subclinical metastases and will relapse if surveillance alone is applied after orchidectomy. Accordingly, some NSGCTs with good prognoses can be managed by surveillance protocols (using regular CT scanning and tumour marker measurement), with the more high-risk cases receiving chemotherapy.

STAGE II–IV TUMOURS

Combination BEP chemotherapy is the mainstay of treatment for stages II–IV seminoma and NSGCT. Retroperitoneal lymph node dissection is sometimes needed in cases of NSGCT when retroperitoneal masses remain after chemotherapy (**Figure 80.20**). The tissue removed may contain only necrotic tissue, but some patients have foci of mature teratoma or active malignancy. The operation can be formidable if the tumour mass is large, and retrograde ejaculation is likely unless steps are taken to preserve the sympathetic outflow to the bladder neck.

INTERSTITIAL TUMOURS

Most of these tumours are benign (around 80%), so conservative treatment of small lesions with organ-sparing surgery is feasible, if the diagnosis is considered. For larger tumours, orchidectomy is necessary with multimodality treatment for those with the rare malignant forms of these tumours.

Prognosis

The prognosis of testicular tumours depends on several factors, including the histological type and the stage at presentation. For seminoma, if there are no metastases, 90–95% of patients will be alive 5 years after diagnosis. If there are poor prognostic features, the survival rate drops to around 70%. For NSGCTs a 5-year survival rate of more than 90% is achievable in patients with good prognosis tumours, while for more advanced tumours, the 5-year survival rate is about 60%.

Summary box 80.10

Testis tumour staging and treatment

- Tumour markers (AFP and hCG) help to make the diagnosis and to follow the response to treatment
- Computed tomography scanning of chest, abdomen and pelvis is central to the staging of testicular tumours
- Testicular tumours are extremely sensitive to platinum-based chemotherapy
- Prognosis is excellent when the patient is treated with combination chemotherapy in a cancer centre

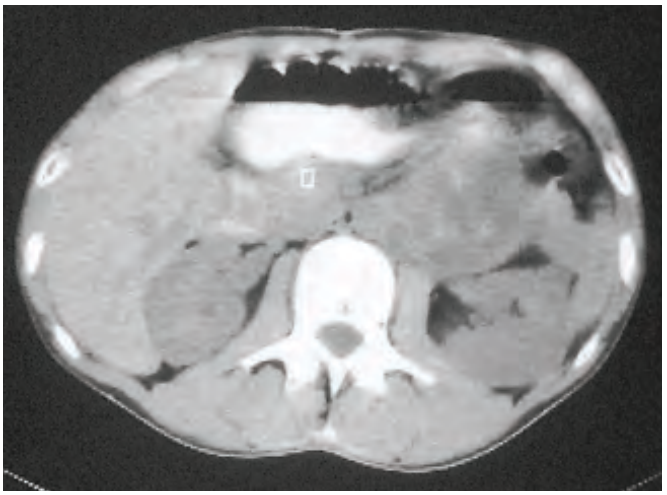

Figure 80.20 Computed tomography scan showing a large residual retroperitoneal mass after chemotherapy.

Testicular tumours in children

These are usually anaplastic teratomas. They occur before the age of 3 years and are often rapidly fatal.

TUMOURS OF THE EPIDIDYMIS

These may be benign mesothelioma or malignant sarcoma or secondary carcinoma. They are extremely rare but should not be forgotten when the patient presents with a non-cystic lump in the epididymis.

THE SCROTUM

Fournier's gangrene

Fournier's gangrene is an uncommon and nasty condition (**Figure 80.21**) characterised by a polymicrobial infection of the soft tissues of the perineum, external genitalia and perianal region. It is a form of necrotising fasciitis. There is rapid onset of gangrene leading to exposure of the scrotal contents. Although it can occur in conjunction with sepsis of the testis, epididymis or perianal region, an obvious cause is absent in over half the cases. It can arise following minor injuries or procedures in the perineal area, such as a bruise, scratch, urethral dilatation, injection of haemorrhoids or opening of a periurethral abscess. Many patients have concurrent illnesses that diminish their defences, most notably diabetes mellitus and alcoholism.

There is a mixed infection of aerobic and anaerobic bacteria in a fulminating inflammation of the subcutaneous tissues, which results in an obliterative arteritis of the arterioles to the scrotal skin that in turn results in gangrene. The condition can spread rapidly to involve the fascia and skin of the penis, perineum and abdominal wall.

Jean Alfred Fournier, 1832–1915, syphilologist, founder of the Venereal and Dermatological Clinic, Hôpital St Louis, Paris, France.

Figure 80.21 Fournier's gangrene with an area of necrotic skin overlying an area of scrotal inflammation.

Clinical features

There is sudden pain in the scrotum associated with prostration, pallor and pyrexia. Cellulitis spreads rapidly (within hours) with small necrotic areas of skin which, if untreated, coalesce to involve the entire scrotal and penile coverings, which may then slough, leaving the testes exposed but healthy. There may be crepitus and a foul-smelling exudate. The patient typically becomes septic and severely unwell in a short period of time

Treatment

Treatment of a case of Fournier's gangrene is a surgical emergency. Initial management involves intravenous fluid resuscitation and early use of broad spectrum intravenous antibiotics. Urgent wide surgical excision of the dead and infected tissue is essential and the extent of the internal necrosis is typically much greater than the external appearances suggest, such that extensive debridement is often necessary. Urinary and faecal diversion may be necessary. Supportive care is essential, because the patients often become severely septic.

Early review of the wounds is helpful to confirm that all dead tissue has been removed, and when the infection has been controlled, vacuum-assisted dressing is helpful, if it is available. If the patient survives the acute episode, skin grafting is often necessary. Despite best therapy, mortality rates as high as 50% are often reported.

Filarial elephantiasis of the scrotum

Filarial elephantiasis of the scrotum is caused by obstruction of the pelvic lymphatics by worms, of which *Wuchereria bancrofti* accounts for 90% of cases. The condition is common in the tropics and is transmitted by mosquitoes. It is often accompanied by superadded infection and lymphangitis, resulting in swelling of the genital skin and skin of the lower limbs. In long-standing cases, the enormously swollen scrotum may bury the penis (**Figure 80.22**). Associated symptoms and signs include fever, epididymitis, hydrocoele and chyluria. The diagnosis is usually made clinically although immunological testing can be helpful.

Medical treatment involves the use of diethylcarbamazine (DEC), ivermectin and albendazole, with the exact regime depending upon geographical location. Surgical treatment is rarely helpful, although a range of procedures have been devised to remove redundant skin and to reconstruct the enlarged scrotum.

Summary box 80.11

Fournier's gangrene

- Fournier's gangrene requires early and aggressive treatment if the patient is to survive
- Treatment involves urgent surgical debridement of necrotic tissue in combination with early use of intravenous broad spectrum antibiotics

Non-filarial elephantiasis

Elephantiasis can occur in the absence of filariasis, most notably in sub-Saharan Africa. Non-filarial elephantiasis can result from fibrosis of the lymphatics caused by lymphogranuloma venereum, but in many cases it is thought to arise as a consequence of persistent contact with irritant soils.

Sebaceous cysts

Sebaceous cysts are common in the scrotal skin. They are usually small and multiple (**Figure 80.23**). If troublesome, then surgical excision is necessary.

Figure 80.22 Elephantiasis of the scrotum burying the penis (courtesy of Mr S Bhattacharjee, Lucknow, India).

Figure 80.23 Sebaceous cysts of the scrotum (courtesy of Dr R Kaje MS, Jipmer, India).

Figure 80.24 Scrotal cancer.

Carcinoma of the scrotum

'Chimney sweeps' cancer' was the first reported occupational cancer (described by Percival Pott in 1775). It is a rare cancer that has also been seen in other workers who come into contact with oil and coal products. Animal studies suggest that aromatic cyclic hydrocarbons are the aetiological factor. Nowadays, this tumour is rarely associated with any obvious aetiological factor. Unlike carcinoma of the penis, carcinoma of the scrotum is almost unknown in India and Asiatic countries.

The growth starts as a wart or ulcer (**Figure 80.24**) and as it grows it may involve the testis. The tumour should be excised with a margin of healthy skin. The management of the inguinal nodes parallels the management of penile cancer, and if nodal enlargement does not settle with antibiotics following treatment of the primary, then a bilateral groin dissection is indicated.

MALE FACTOR INFERTILITY

For couples of unknown fertility status, approximately 15% are unable to achieve a pregnancy within 1 year. The inability to conceive may be due to female factor infertility, male factor infertility or a combination of these two factors and approximately 20% of cases of infertility are caused entirely by the male factor.

Aetiology

The two main causes of male factor infertility are either primary testicular causes or obstruction at the level of either the vas or the epididymis. A few cases reflect endocrinological abnormalities such as hypogonadism or hyperprolactinaemia. Testicular causes include chromosomal problems (e.g. Klinefelter's syndrome), microdeletions of the Y chromosome, cryptorchidism, mumps orchitis, drugs and radiation damage. In most cases however, the cause is unclear. In these cases, there may be reduced numbers of sperm in the ejaculate (oligozoospermia) or a complete absence of sperm in the ejaculate (azoospermia).

Obstructive causes include congenital absence of the vasa (often in association with cystic fibrosis), surgical damage to the vasa and epididymitis. Azoospermia is inevitable in these cases.

Assessment and investigation

Given the interplay between male and female factors, the man should not be investigated in isolation from his female partner. A careful history is the mainstay of the assessment with a careful search for aetiological factors. Physical examination is usually normal, but occasionally the testes may feel small (suggestive of a testicular cause), the vasa may be absent, there may be evidence of endocrine abnormalities

Percival Pott, 1714–1788, surgeon, St Bartholomew's Hospital, London, UK, described chimney sweeps' cancer of the scrotum in 1775. In those days the chimney sweep's apprentice climbed up inside the chimney.

(gynaecomastia or abnormal hair distribution) or there may be a varicocoele. The relation of any varicocoele to the infertility is controversial and treatment is not usually indicated.

The woman should be also be assessed. It is important to remember that female fertility declines from the age of 35 years in a way that is not true of men. The age of the woman is therefore important and the regularity of menstruation should be confirmed either by temperature testing or by endocrinological testing.

The assessment of the man includes semen analysis, which should be tested within 2 hours of the semen being produced. Two or three samples should be tested. The volume of the ejaculate, the numbers of sperm, their motility and the percentage of abnormal or damaged sperm are all predictive of male fertility. An endocrine screen should be performed including serum testosterone, prolactin, follicle-stimulating hormone (FSH) and luteinising hormone (LH).

Treatment

Sperm counts of less than 15 million sperm per millilitre are defined as oligozoospermia. If there is a reversible cause, it should be treated. However, in many cases, some form of assisted conception is required.

Azoospermia (the complete absence of sperm from the ejaculate) is either due to obstruction of the pathway of spermatozoa from the testis to the ejaculatory ducts or due to severe testicular failure. In the latter the serum FSH is typically raised, while in obstructive cases, the FSH is typically normal. If there is doubt as to the cause, then testicular biopsy is mandated to check for the presence of spermatogenesis, combined with vasography to assess the presence and location of any obstructive lesion. If the site of the obstruction can be identified it may be possible to perform a bypass operation. Unfortunately, even in the best hands, the results of epididymovasostomy are poor.

Assisted conception including *in vitro* fertilisation (IVF) and intracytoplasmic sperm injection (ICSI) has revolutionised the management of male factor infertility regardless of the cause of the problem. In ICSI, spermatozoa harvested from the ejaculate, by aspiration of the epididymis or even from testicular biopsy, can be injected *in vitro* into ova obtained from the mother. Embryos are then transferred into the mother's uterus at the four- to six-cell stage.

Summary box 80.12

Male infertility

- Atrophy of the testis is associated with raised levels of follicle-stimulating hormone in the blood
- Testicular biopsy will show whether azoospermia is a result of obstruction or failure of sperm production
- If spermatozoa can be harvested they can be used in intracytoplasmic sperm injection with a fertility rate of around 30%

Vasectomy for sterilisation

Vasectomy for sterilisation is a common and effective contraceptive procedure. It should be undertaken only after the couple has been carefully counselled. Both partners need to know that the operation is performed to make the man permanently sterile. They should be warned that normal contraceptive precautions should continue until the success of the operation is confirmed by semen analysis performed 12–16 weeks after surgery. They should also be warned of the possibility of spontaneous recanalisation, which may restore fertility unexpectedly and of the possibility of chronic testicular pain that may occur in up to 5% of men.

Vasectomy is easily and painlessly performed under local anaesthetic. The vasa are delivered through tiny bilateral scrotal incisions or through a single midline scrotal incision. For medico-legal reasons it is wise to remove a segment of each vas to prove that it has been successfully divided. Burying the cut ends, fascial interposition or turning them back on themselves helps to prevent them rejoining.

Reversal of vasectomy may not restore fertility even if the surgery is technically successful because of damage to the testis secondary to the vasectomy. Although patency rates of 80% or more are commonly reported, successful fertility rates are much lower, and diminish with increasing delay from the time of vasectomy.

Summary box 80.13

Vasectomy

Counselling before vasectomy should include mention that:

- The operation is not immediately effective and that contraceptive precautions should be continued until there have been two negative semen analyses
- The procedure should be considered irreversible
- Spontaneous recanalisation is rare, but can occur
- There is a risk of chronic scrotal pain postoperatively

Chapter 81

Gynaecology

Learning objectives

To understand:

- The pelvic anatomy and reproductive physiology
- The common causes of vaginal bleeding and acute pain in early pregnancy
- The surgical management of acute pelvic inflammatory disease, endometriosis, uterovaginal prolapse, uterine fibroids and ovarian tumours.

ANATOMY

The reproductive structures of the dividing embryo differentiate after the seventh week of development. The gonads, internal and external genitalia consititute the sex organs. In the female, the Müllerian ducts develop into the uterus, Fallopian tubes, cervix and upper third portion of the vagina. The urogenital sinus in turn forms the lower two-thirds of the vagina.

The female external genitalia are described as the vulva, which is bordered by the mons veneris anteriorly and the labiocrural folds posterolaterally. The opposing skin that covers the introitus is known as the labia majora. The labia minora are folds of skin that fuse anteriorly around the clitoris, which contains erectile tissue similar to the penis in the male. The posterior part of the introitus is referred to as the fourcette, and this stretches considerably during childbirth to allow delivery of the baby.

The vagina is an elastic, distensible tube, approximately 6–7 cm in length, passing upwards and backwards from the introitus. The cervix protrudes into the vault of the vagina, dividing it into the anterior, posterior and lateral fornices. Pelvic structures can be felt in the posterior and lateral fornices on bimanual examination, as the vaginal vault sits just below the pouch of Douglas (the area at the bottom of the pelvic cavity bordered by the uterus anteriorly and rectum posteriorly). The urethra and bladder neck sit above the anterior wall of the vagina; the perineal body and rectum behind the posterior wall (**Figure 81.1**).

The uterus consists of a body and a cervix (neck of the uterus), and is an upside-down pear-shaped structure that is flattened anteroposteriorly, giving its cavity a flat, triangular shape. The uterus is supported partly by ligaments attached to the cervix (transverse cervical, pubocervical and uterosacral) consisting of condensed connective tissue. The cervix is a canal, approximately 2–3 cm in length in the nonpregnant woman, connecting the external os, which can be seen on speculum examination, to the internal os, where the cervix enters the uterine cavity. The uterine cavity to cervical length ratio varies through hormonal influences and the developmental phases, with the uterine body increasing in size as puberty progresses.

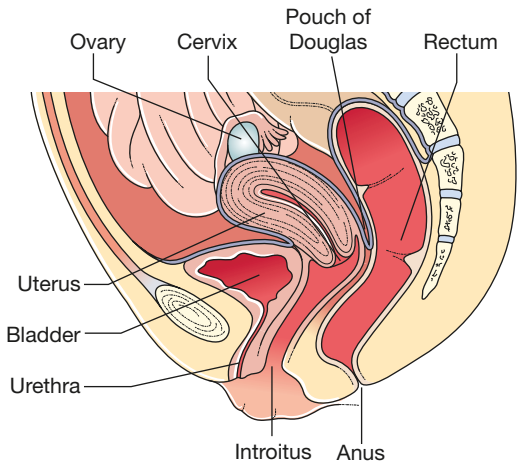

Figure 81.1 Female anatomy.

Johannes Peter Müller, 1801–1858, Professor of Anatomy and Physiology, Berlin, Germany, described the paramesonephric duct in 1825.
Gabriele Falloppio (Falloppius), 1523–1563, Professor of Anatomy, Surgery and Botany, Padua, Italy. He carried out what may have been the first clinical trial in over 1,000 men of the use of condoms to prevent transmission of syphilis.
James Douglas, 1675–1742, anatomist, midwife and physician to Queen Caroline, London, UK, helped expose the fraudulent claims of Mary Toft who, in 1726, famously tricked a number of doctors into believing that she had given birth to rabbits.

The uterine walls are 1–2 cm thick and composed of smooth muscular tissue (myometrium). The uterine cavity is lined with endometrium, a tissue that undergoes cyclical changes in response to ovarian hormones (refer to Reproductive physiology below). The endometrium has both a basal and functional layer. The basal layer lies adjacent to the myometrium and from it develops the functional layer. The basal layer is not shed during menstruation, unlike the functional layer. The functional layer is influenced by oestrogen and progesterone, which thicken it, preparing the lining for implantation. This layer is completely shed during menstruation should conception not occur.

At the uterine fundus, on either side, are the cornua, connecting the uterus to the Fallopian tubes. These are thin, muscular tubes, approximately 10 cm in length. They are divided into four parts: intramural, isthmus, ampulla and the fimbriated opening, which picks up the oocyte following its release at the time of ovulation. The tubes are very narrow in the isthmic and intramural parts but they widen at the ampullary region. Each tube is contained within the upper part of the broad ligament, a fold of peritoneum on either side of the uterus, which also contains blood vessels as well as the round and ovarian ligaments. The fimbriated opening and part of the ampulla, however, are free and closely associated with the ovary on either side. The ovaries are flattened, ovoid structures, approximately 3–4 cm in dimension, suspended from the back of the broad ligament on either side of the pelvic side wall by the ovarian ligament, which originates from the uterine body. The ovarian blood vessels are contained within the infundibulopelvic ligaments, which are continuations of the broad ligament to the pelvic brim on either side.

The cervical canal is located within the centre of the bony cavity of the pelvis, with the uterus pivoted around this point. It is more commonly angled forwards (anteverted), relative to the vagina. It is usually freely mobile, with filling of the bladder or changes in position rotating it backwards. In others, the uterus can be retroverted, as a variation of normal, secondary to either weak ligaments or because the uterus becomes adherent as the result of a disease process such as endometriosis. The uterus may also be angled forwards (anteflexed) relative to the cervix, or backwards (retroflexed), which can be determined through bimanual examination.

In the lean patient the uterine size can also be estimated on palpation. This is usually a subjective assessment outside of imaging modalities. The most common cause of an enlarged uterus, outside of pregnancy, is fibroids (benign tumours of the myometrium) growing inside or outside of the uterus. In the presence of fibroids, the overall size of the uterus is often described in terms of weeks of pregnancy if it expands forwards and upwards into the abdominal cavity, similar to increasing gestational age.

REPRODUCTIVE PHYSIOLOGY

The menstrual cycle is under the control of circulating hormones produced within the hypothalamic-pituitary-ovarian axis and works as part of a negative feedback pathway (**Figure 81.2**). Gonadotrophin-releasing hormone (GnRH) is produced by the hypothalamus and, in turn, stimulates the pituitary to produce and secrete follicle-stimulating hormone (FSH) and luteinising hormone (LH). FSH and LH act on the ovary (theca and granulosa cells), controlling folliculogenesis (oocyte development) and ovulation. The ovary is responsible for production of the hormones oestrogen, progesterone and androgen. These hormones have an effect on a number of structures within the body, principally the endometrium, which prepares itself to receive a fertilised egg (embryo) during the course of the menstrual cycle. In the first half (proliferative or follicular phase) of the cycle, following menstruation the endometrium starts to regrow or proliferate in response to oestrogen produced by the growing ovarian follicle(s). The endometrium becomes thick and spongy during this phase of the cycle, and is associated with considerable angiogenesis.

Ovulation occurs midcycle, i.e. 14 days prior to the onset of the next menstrual cycle, which is equivalent to day 14 of a 28-day cycle (day 1 defined as the first day of menstruation). After ovulation the remnant follicle is transformed into a corpus luteum, which is responsible for the immediate production of progesterone. During the second half (secretory or luteal phase) of the cycle, the endometrium thickens further under the influence of progesterone in preparation to receive a fertilised ovum.

Fertilisation takes place within the ampullary region of the Fallopian tube, usually within 24 hours after ovulation. The fertilised egg is then transported along the Fallopian tube into the uterine cavity through movement of ciliae and tubal musculature, ideally implanting into the endometrium approximately 5–6 days after ovulation. Through the secretion of human chorionic gonadotrophin (hCG), the corpus luteum is signalled to maintain progesterone production. If fertilisation does not occur, or if the fertilised egg fails to implant, the endometrium is shed as the hCG signal is missing or lost, leading to a fall in progesterone (and oestrogen) levels. Menstruation, (a 'period') lasts on average for 4 days, but can range between 2 and 7 days. Typically, 40 mL of blood is lost during each period; heavy menstruation is described when more than 80 mL of blood loss occurs, which is difficult to assess and can be subjective. The whole process then starts again in the next menstrual cycle.

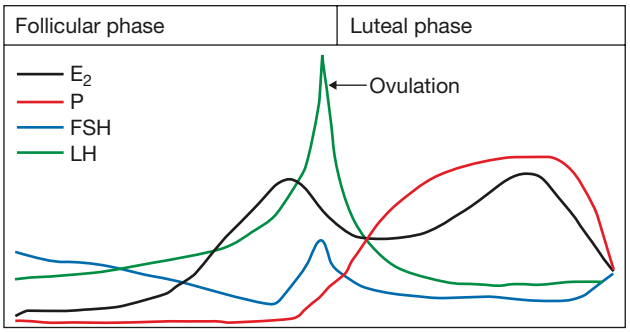

Figure 81.2 Endocrine cycle. E2, oestrogen; FSH, follicle-stimulating hormone; LH, luteinising hormone; P, progesterone.

If fertilisation does occur, the duration of the pregnancy (gestational age) is traditionally calculated from the first day of the last menstrual period (LMP); however, ovulation may occur earlier or considerably later than day 14 and is dependent on the woman's cycle length, or the woman's recollection of the date of the LMP may be incorrect, potentially making calculation of the gestational age on the basis of the LMP alone inaccurate. This explains the alternative practice of calculating gestational age using ultrasound measurements of fetal size, ideally during the first trimester.

VAGINAL BLEEDING IN EARLY PREGNANCY

A miscarriage is defined as the loss of an intrauterine pregnancy at less than 24 weeks' gestation. An early miscarriage refers to pregnancy loss before 12 weeks' gestation ('first trimester'). A late miscarriage refers to pregnancy loss between 12 and 24 weeks' gestation ('second trimester'). Approximately 20% of pregnancies will miscarry. However, this number is highly influenced by maternal age and can reach approximately 50% in a 45-year-old woman.

A miscarriage can be diagnosed on transvaginal ultrasound scan in the absence of a visible fetal heartbeat with a crown–rump length of 7.0 mm or more, or, in the absence of a fetal pole in the presence of a mean gestational sac diameter of 25.0 mm or more.

A miscarriage often begins with painless vaginal bleeding, at which point it is defined as a threatened miscarriage. The bleeding may then become heavier with associated uterine cramps and an opening of the cervical os, at which point it is defined as an inevitable miscarriage. Blood clots and products of conception (i.e. fetal and placental tissue) are passed through the cervical os until the uterus is emptied (defined as a complete miscarriage). If some of the products of conception are retained within the uterus, this is referred to as an incomplete miscarriage. A missed miscarriage occurs when no fetal heart beat can be detected on ultrasound scan, but no clinical signs of a miscarriage as described above are present.

Management of a miscarriage ranges from expectant management to medical or surgical intervention. For medical management, medications such as prostaglandins can be given that support uterine contractions and cervical softening. Surgical management of a miscarriage (SMOM) can be conducted using manual vacuum aspiration under local anaesthesia, or surgically under general anaesthesia. The operation involves passing a plastic suction curette through the cervical opening and into the uterine cavity. A SMOM should be considered in the presence of persistent excessive bleeding, haemodynamic instability, evidence of infected retained tissue or suspected gestational trophoblastic disease. Serious operative complications, which are fortunately rare, include uterine perforation (up to 5 in 1000 women) with the possibility of intra-abdominal trauma (e.g. bowel damage), cervical tears, haemorrhage (risk of needing a blood transfusion is 1–2 in 1000 women) and infection (3 in 100 women). Approximately 5 in 100 women may require a repeat surgical evacuation. In view of the potential risk of organ damage, women should concomitantly be consented for a laparoscopy and laparotomy. Furthermore, anti-D immunoglobulin should be prescribed to all non-sensitised rhesus (Rh)-negative women undergoing surgical treatment for a miscarriage or in cases with excessive bleeding in conservative or medical management of miscarriage.

Vaginal bleeding in early pregnancy may also result from a local cause such as a cervical lesion (which may first manifest itself as bleeding after intercourse) or, rarely, trauma.

VAGINAL BLEEDING IN THE NON-PREGNANT STATE

Bleeding in the non-pregnant state may occur at the time of an expected menstrual period, between periods (intermenstrual bleeding; IMB), after intercourse (postcoital bleeding; PCB) or following the menopause (postmenopausal bleeding; PMB). It may also occur after surgical instrumentation of the uterus and/or cervix, including insertion of an intrauterine contraceptive device (IUCD). The principal causes of uterine or vaginal bleeding in the non-pregnant state can be divided into structural and non-structural (*Table 81.1*) and relationship to menses or coitus (*Table 81.2*).

TABLE 81.1 Structural and non-structural causes of uterine and vaginal bleeding.

Structural	Polyp
	Fibroids (leiomyoma)
	Endometrial hyperplasia
	Malignancy of the genital tract
Non-structural	Coagulopathy, e.g. thrombocytopaenia, von Willebrand's disease
	Ovulatory dysfunction, e.g. polycystic ovary syndrome
	Endometrial, e.g. endometritis
	Iatrogenic, e.g. exogenous sex steroid adminstration, IUCD
	Other, e.g. arteriovenous malformations, chronic renal/hepatic disease

IUCD, intrauterine contraceptive device.

TABLE 81.2 Causes of uterine and vaginal bleeding in the non-pregnant state.

Menstrual	Endometrial polyp/malignancy[a]
	Fibroids
Intermenstrual	Vaginal trauma/malignancy[a]
	Cervical polyp/malignancy
	Endometrial polyp/malignancy[a]
Postcoital	Vaginal malignancy[a]
	Cervical ectropion/polyp/malignancy

[a] These cancers occur principally in postmenopausal women.

Erik Adolf von Willebrand, 1870–1949, physician, Helsinki, Finland.

The mainstay of management is to identify and treat the associated pathology (except in women <40 years of age with heavy menstrual periods in whom malignancy is very rarely found; these women are best managed symptomatically). Investigations include a pregnancy test and ultrasound assessment of the pelvic anatomy (2D/3D ultrasonogram or saline sonogram) as well as an endometrial biopsy of the uterine cavity, either performed under direct vision at hysteroscopy or blindly with a Pipelle® biopsy. Hysteroscopy combined with endometrial biopsy improves the sensitivity and specificity for detection of endometrial pathology compared with either performed alone. A colonoscopy may also be indicated to exclude colorectal pathology as a potential cause for the bleeding. The indications for undertaking an endometrial biopsy are shown in *Summary box 81.1*.

Summary box 81.1

Indications for endometrial biopsy

Endometrial biopsy should be considered in the following women:

- Suspected endometrial pathology
- All women >45 years of age in whom medical treatment has been unsuccessful
- Persistent intermenstrual bleeding
- Endometrial thickness of >4 mm in postmenopausal women or >16 mm in premenopausal women and >7 mm in women with known polycystic ovarian syndrome
- Irregular or unscheduled bleeding while on hormone replacement therapy after the initial 3 months
- Younger women with major risk factors for endometrial hyperplasia/ cancer:
  - Polycystic ovarian syndrome
  - Obesity
  - Treatment with tamoxifen
- Irregular bleeding while on unopposed oestrogen therapy
- Irregular bleeding in high-risk populations, such as family history of endometrial/colon cancer, especially hereditary non-polyposis colorectal cancer

Women taking tamoxifen, a selective oestrogen receptor modulator used in the treatment of breast cancer, represent a special group, as the drug can induce uterine abnormalities in 10–40% of women, such as the development of endometrial polyps, hyperplasia, cancer and, rarely, uterine sarcomas, which are much more aggressive. Tamoxifen treatment results in a doubling of the risk of endometrial cancer after 1–2 years and a quadrupling after 5 years of usage. The relationship is time dependent but dose independent. The risk does not decrease on cessation of treatment. There is no consensus regarding the need for screening and which method to use; the alternative, more common approach, is to investigate only those women who develop abnormal uterine bleeding with tamoxifen use. Aromatase inhibitors such as anastrozole, letrozole and exemestane, also used in the treatment of breast cancer, but whose effects are not mediated via the oestrogen receptor, have been associated with less endometrial pathology than tamoxifen. They may also reverse abnormalities induced by tamoxifen use.

Women known to have Lynch syndrome (hereditary non-polyposis colorectal cancer) and those considered at risk of inheriting a mismatch repair gene abnormality are another special group, as their lifetime risk of developing endometrial cancer is as high as 60%. Unlike sporadic cases of endometrial cancer, which are usually diagnosed during the sixth and seventh decades, the mean age at diagnosis in Lynch syndrome is the fifth decade. However, it appears that the 5-year survival rate in patients with Lynch syndrome associated endometrial cancer is similar to that in women with sporadic disease. International guidelines suggest that these women should be screened annually from the age of 35 years with transvaginal ultrasound to measure the endometrial thickness and with an endometrial biopsy.

Abnormal bleeding can also be caused by invasive carcinoma of the cervix, the incidence of which has been reduced by screening programmes that aim to detect the precancerous state – cervical intraepithelial neoplasia (CIN) – using cervical cytology. In the UK, this is carried out every 3 years in women aged 25–49 years of age, and 5-yearly in women aged 50–64 years. Infection with certain human papillomavirus (HPV) serotypes (16, 18, 31 and 33) is associated with an increased risk of invasive disease. Current vaccination programmes against HPV serotypes are aimed at reducing the incidence of cervical carcinoma. The vaccination is offered to girls aged 12–13 years. Abnormalities in cervical cytology are followed up by microscopic examination of the cervix (colposcopy). CIN may be treated with local ablation (cryocautery, cold coagulation, electrodiathermy or laser) or excision (large loop excision of the transformation zone (LLETZ)).

Menstrual bleeding may be excessively heavy, irregular or frequent in the absence of pathology; this is known as dysfunctional uterine bleeding. The UK's National Institute for Health and Care Excellence (NICE) has suggested a three-step hierarchal treatment approach to the management of heavy menstrual bleeding: (1) medical therapy; (2) minimally invasive uterus-conserving surgey; (3) major surgical procedures. The management plans are individualised for the patient, taking into account the concomitant symptoms and fertility requirements. Medical treatments used to reduce the amount of menstrual blood loss include tranexamic acid, mefenamic acid and the combined or progestin-only oral contraceptive pill (COCP or POP, respectively). It may be necessary to stop the bleeding completely using high-dose progestagens, the COCP taken continuously or a gonadotrophin-releasing hormone (GnRH) analogue with or without add-back hormone replacement therapy (HRT), which induces a menopause-like state. Increasingly, an intrauterine system (IUS) similar to a conventional coil, which releases levonorgestrel, is offered to patients as an alternative; it has the added advantage of being a reliable long-acting reversible contraceptive (up to 5 years). After 1 year of usage, there is a 71–95% reduction in menstrual blood loss with approximately 50% of women becoming amenorrhoeic.

The surgical treatments for excessive bleeding and their principal operative complications are described in *Table 81.3*.

Henry T Lynch, b.1928, Professor of Preventative Medicine, Creighton University, Omaha, NE, USA.

TABLE 81.3 Surgical treatments for excessive vaginal bleeding.

Treatment	Route	Major operative risks
Uterus-conserving surgery:		
• Hysteroscopic polypectomy	Vaginal	Uterine perforation; damage to surrounding organs
• Endometrial ablation	Vaginal	
• Transcervical resection of the endometrium	Vaginal	Fluid overload; thermal injury to surrounding organs
• Focal fibroid destruction (MRI-guided focused ultrasound, radiofrequency ablation)	Transcutaneous	
• Uterine fibroid embolisation	Transcutaneous	
• Uterine artery occlusion	Vaginal/abdominal	Fluid overload; thermal injury to surrounding organs
• Transcervical resection of fibroids	Vaginal	
• Laparoscopic myomectomy	Abdominal	Injury to surrounding organs
• Open myomectomy	Abdominal	Injury to surrounding organs
Non-uterus conserving surgery:		
• Hysterectomy (subtotal or total)	Vaginal/abdominal	Damage to internal organs; fistula formation

MRI, magnetic resonance imaging.

The aim of ablative methods is to reduce the menstrual bleeding by ablating the endometrium down to the basalis layer using electrical, thermal or laser energy. More than 90% of women report a reduction in menstrual blood loss without the need for further treatment at 2 years of follow-up, with 25–35% experiencing amenorrhoea. The criteria for endometrial ablation are described in *Table 81.4*.

TABLE 81.4 Criteria for suitability for endometrial ablation.

Uterus is <10 cm in length (and 14 cm in length for microwave ablation)
Absence of major intrauterine pathology that would distort the uterine cavity
No history of previous endometrial ablation procedures
No evidence of endometritis
Family is complete

A hysterectomy can be carried out by three different routes: vaginally, abdominally or laparoscopically. The route of entry is dependent on a number of factors, including: uterine size; presence of other pathology; mobility and descent of the uterus; history of previous surgery; and skill of the operating surgeon. A total or subtotal (conservation of the cervix) hysterectomy can be performed. No difference in prolapse symptoms, sexual satisfaction or pelvic pain has been reported between the two techniques. Furthermore, it is now recommended that the Fallopian tubes are removed in conjunction with the uterine body, whether the ovaries are conserved or not. The Fallopian tubes have no continued functionality following a hysterectomy, but can be a potential source of malignancy if retained. Conservation or removal of the ovaries is dependent on the woman's age, presence of coexisting pathology and/or risk factors for malignancy.

ACUTE PELVIC PAIN IN EARLY PREGNANCY

Ectopic pregnancy

An ectopic pregnancy refers to a pregnancy that grows outside of the uterine cavity, most commonly within the Fallopian tube, with rarer sites including the ovary, cervix, broad ligament and abdominal cavity. As the ectopic pregnancy grows, the placental tissue can infiltrate the blood vessels surrounding the Fallopian tube, leading to bleeding within the tube and into the peritoneal cavity. Further growth of the ectopic pregnancy can rupture the Fallopian tube, causing significant intraperitoneal blood loss. This constitutes a gynaecological emergency. An ectopic pregnancy occurs in 11 per 1000 pregnancies, and a maternal mortality rate of 0.2 per 1000 estimated ectopic pregnancies. The major risk factors for an ectopic pregnancy are shown in *Summary box 81.2*.

Summary box 81.2

Risk factors for an ectopic pregnancy

- Previous pelvic inflammatory disease
- Smoking
- History of infertility
- Use of an intrauterine contraceptive device
- Previous ectopic pregnancy
- Previous abdominal/pelvic surgery
- Previous tubal surgery, e.g. sterilisation, salpingostomy, tuboplasty
- Endometriosis

An ectopic pregnancy may be suspected on clinical grounds but making the diagnosis can be difficult (*Table 81.5*).

TABLE 81.5 Symptoms and signs of an ectopic pregnancy.

Symptoms	Signs
Abdominal or pelvic pain	Pelvic, abdominal and/or adnexal tenderness or fullness
Vaginal bleeding	Signs of peritonism
Gastrointestinal symptoms	Cervical motion tenderness (pain on moving the cervix)
Dizziness, fainting, syncope	Tachycardia, hypotension
Shoulder tip pain	
Asymptomatic	

The presentation of an ectopic pregnancy is very variable and the differential diagnoses include:

- ectopic pregnancy;
- miscarriage;
- urinary tract infection;
- ovarian cyst accident;
- appendicitis.

A transvaginal ultrasound scan should be performed if the diagnosis is suspected. The complete absence of an intrauterine gestational sac with a positive pregnancy test increases the probability of an ectopic pregnancy, unless the pregnancy is not sufficiently advanced for the sac to be seen on ultrasound scan. An ectopic pregnancy is more likely if free fluid is seen in the pouch of Douglas, or an adnexal mass is seen on ultrasound scan.

In equivocal cases, serial measurements of serum beta-human chorionic gonadotrophin (β-hCG) levels, 48 hours apart, can help to establish the diagnosis. A rise in β-hCG levels by at least 63% is more indicative of a viable intrauterine pregnancy. Levels that halve when taken 48 hours apart are more suggestive of a failing pregnancy. Levels that remain static, or show a suboptimal increase or decrease over a 48-hour period, are more likely to be representative of an ectopic pregnancy. Furthermore, a single level above approximately 1500 IU/L, in association with an empty uterus on ultrasound scan, is highly suggestive of an ectopic pregnancy. Laparoscopy can also be used as a diagnostic tool (**Figure 81.3**); occasionally however, a false-negative diagnosis is obtained, when the pregnancy is not sufficiently advanced and is therefore too small to be seen within the Fallopian tube.

Management of an ectopic pregnancy can be divided into expectant, medical (methotrexate) or surgical treatment. The choice of treatment is dependent on: the haemodynamic stability of the patient; ultrasonographic features of the ectopic pregnancy (presence of free fluid, presence or absence of a fetal heartbeat); serum β-hCG level; and the patient's understanding of the diagnosis, commitment to follow-up and choice.

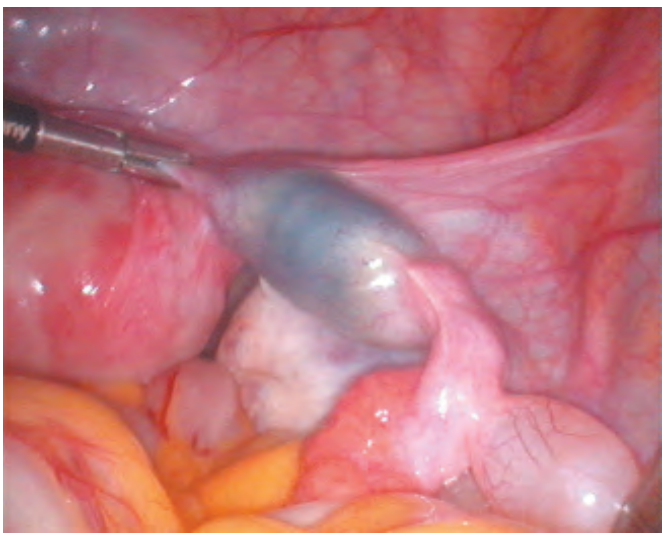

Figure 81.3 Laparoscopy showing an ectopic pregnancy.

Methotrexate is a folic acid anatagonist that interferes with deoxyribonucleic acid (DNA) synthesis. Significant side effects include hepatotoxicity. Further pregnancies should be avoided for a minimum of 3 months following treatment with methotrexate. Careful patient selection is vital. Furthermore, some patients fail to respond to this medication and will require surgical management.

Surgical management occurs in the form of a salpingectomy (removal of the Fallopian tube) or salpingostomy (opening of the Fallopian tube and extraction of the pregnancy tissue). This is ideally performed laparoscopically in the stable patient, as it is associated with shorter operative times, less intraoperative blood loss, shorter hospital stays and similar subsequent intrauterine pregnancy rates. A laparotomy may be required if the woman is haemodynamically unstable. A salpingectomy is the preferential technique in the presence of a contralateral healthy Fallopian tube. A salpingostomy is associated with an 8% risk of persistent trophoblastic tissue, intra-abdominal bleeding and an increased risk of a repeat ectopic pregnancy. These patients are subsequently followed up with monitoring of serum β-hCG levels until a negative result is obtained, to exclude the presence of residual trophoblastic tissue. If a further ectopic pregnancy occurs within the same Fallopian tube, then a salpingectomy is recommended regardless of the condition of the contralateral tube.

The management of non-tubal ectopic pregnancies (e.g. interstitial ectopics, caesarean section scar ectopics) can be complex and associated with more significant complications, such as bleeding and the risk of needing a hysterectomy. These cases are best managed in tertiary centres. The management plan will be guided by the haemodynamic stability of the patient and the location of the ectopic pregnancy, including the expertise of the clinician managing the case.

These patients should be counselled regarding their increased risk of further ectopic pregnancies in subsequent conceptions. In view of this, they are encouraged to present as early as possible in any subsequent pregnancy to establish its location.

INFECTION

The overwhelming majority of cases of pelvic inflammatory disease (PID) are caused by ascending infection, most commonly sexually transmitted, leading to endometritis, salpingitis, tubo-ovarian abscess formation and/or pelvic peritonitis. Rarer causes include spread from other pelvic organs, e.g. the appendix. *Chlamydia trachomatis* is the most common organism responsible for PID; the prevalence of *Neisseria gonorrhoeae* varies depending upon the locality. Other organisms commonly found in the vagina may also be implicated. Risk factors include young age at first sexual activity, a high number of sexual partners and current use of an IUCD; infection may also follow a surgical procedure, e.g. termination of pregnancy.

There are no definitive criteria for making a diagnosis of PID. Most clinicians rely instead upon the presence of one

Albert Ludwig Siegmund Neisser, 1855–1916, Director of the Dermatological Institute, Breslau, Germany, (now Wroclaw, Poland).

or more of the following features, which are suggestive of the diagnosis:

- lower abdominal pain and tenderness, more commonly bilateral;
- deep dyspareunia (pain on intercourse);
- abnormal vaginal bleeding;
- abnormal cervical discharge, commonly purulent;
- cervical excitation and adnexal tenderness;
- fever ≥38°C;
- elevated white blood cells (neutrophils) and platelets.

It should be noted that some patients are asymptomatic or may present with non-specific symptoms, and a high degree of clinical suspicion is needed to avoid a delay in making the diagnosis.

The differential diagnoses include:

- endometriosis;
- urinary tract infection;
- appendicitis;
- gastrointestinal dysfunction;
- ectopic pregnancy;
- ovarian cyst accident.

Raised inflammatory markers (white cell count, neutrophil count and C-reactive protein (CRP)) support the diagnosis. Ultrasound scan assessment of the pelvis can detect the presence of hydrosalpinges and/or a tubo-ovarian abscess. All women with suspected PID should be screened for *N. gonorrhoeae* and *C. trachomatis*; however, an absence of infection does not exclude a diagnosis of PID. *Chlamydia trachomatis* is an intracellular organism; therefore, samples obtained for diagnostic purposes should contain cellular material. If an endocervical swab is to be used to obtain a specimen, then it is important to clean the cervix of excessive discharge before inserting the swab inside the cervical os.

Summary box 81.3

Chlamydia and gonorrhoea testing

There is a need to test women (especially those sexually active under the age of 25 years) who present with:

- purulent vaginal discharge
- postcoital/intermenstrual bleeding
- change in vaginal bleeding pattern
- mucopurulent cervicitis
- inflamed/friable cervix (which may bleed on contact)
- urethritis
- suspected pelvic inflammatory disease
- reactive arthritis

Current guidelines recommend a low threshold for empirical treatment because the consequences of failing to treat acute PID effectively are extremely significant: chronic pelvic pain; infertility; increased risk of an ectopic pregnancy (6%; approximately 10 times higher than the background population); and Fitz-Hugh–Curtis syndrome (an extrapelvic manifestation of PID associated with right upper quadrant pain, most probably resulting from the inflammation of the liver capsule and diaphragm). Approximately 20% of women treated for PID will become infertile, secondary to tubal damage; >50% of tubal factor infertility cases arise from infection secondary to *Chlamydia*; however, interestingly, many of these women do not report a history of PID.

Treatment should be commenced as soon as samples have been obtained for culture, without the need to wait for the results, but changing the antibiotics once the sensitivities become available; it should include a broad-spectrum antibiotic against coliforms and anaerobic species, which are responsible for secondary infection. Contact tracing (a minimum of 6 months within the onset of symptoms) and treatment are essential.

The majority of suspected cases are treated within the community, with a review advised after 72 hours. Hospital admission is advisable if there is doubt about the diagnosis, or if the symptoms/signs are severe. If an IUCD is *in situ*, this is better removed under antibiotic coverage, with adequate counselling regarding pregnancy risk, and emergency contraception prescribed in appropriate circumstances. Counselling should also cover future contraception.

A tubo-ovarian abscess can develop in severe cases of PID; this is where the Fallopian tube and ovary become blended into a single, pus-filled, inflammatory mass, which is usually adherent to the uterus and surrounding bowel. The infection may have progressed from a milder form of PID or, increasingly, it may result from the introduction of infection or bowel damage at transvaginal oocyte aspiration in a patient undergoing *in vitro* fertilisation (IVF). Modern medical practice is to manage the tubo-ovarian abscesses **(Figure 81.4)** conservatively, unless the patient fails to respond to intravenous antibiotics and systemic support. The response is judged to be inadequate if the woman remains systemically unwell, her symptoms do not improve, fever is not reduced, the white blood cell count does not fall and there is no radiological evidence of the abscess becoming smaller. In such circumstances, surgical treatment is necessary, i.e. adhesiolysis and drainage of the abscess, at laparotomy or laparoscopy. As most women with a tubo-ovarian abscess are in the reproductive years, the intention is always to be as conservative as possible at surgery. Rarely, however, if the abscess has ruptured **(Figure 81.5)** and the patient is extremely ill, then a hysterectomy and bilateral salpingo-oophorectomy may become necessary.

Abscess drainage under radiological guidance, e.g. a transgluteal approach via the greater sciatic foramen under computed tomography (CT), is sometimes performed. Transvaginal ultrasound-guided aspiration has also been advocated.

Thomas Fitz-Hugh Jr., 1894–1963, physician, Chief of the Hematological Section, The University Hospital, The University of Pennsylvania, Philadelphia, PA, USA.
Arthur H Curtis, 1881–1955, Professor of Obstetrics and Gynecology, The Northwestern Medical School, Chicago, IL, USA. Fitz-Hugh and Curtis were not the first to describe the syndrome: it was described in 1920 by Stajano, a Uruguyan Professor of Surgery, but the paper was written in Spanish.

Summary box 81.4

Treatment of pelvic inflammatory disease (PID)

- A low threshold for the initiation of empirical treatment for PID is recommended, because of the lack of definitive clinical diagnostic criteria
- Women with suspected PID should be screened for *N. gonorrhoeae* and *C. trachomatis*
- Testing for gonorrhoea should be undertaken with an endocervical specimen, via culture (direct inoculation onto a culture plate or transport of the swab to the laboratory within 24 hours) or using a nucleic acid amplification test (NAAT). Screening for chlamydia should also be from the endocervix, preferably using a NAAT. Taking an additional sample from the urethra increases the diagnostic yield for gonorrhoea and chlamydia. A first-catch urine sample provides an alternative source
- A pregnancy test should be undertaken and screening for other sexually-transmitted infections, such as human immunodeficiency virus and hepatitis
- Out-patient antibiotic treatment should be commenced as soon as the diagnosis is suspected. Treatment should be based on one of the following regimens:
  - Ofloxacin 400 mg orally twice a day + metronidazole 400 mg orally twice a day for 14 days (ofloxacin should be avoided in cases at high risk of gonococcal PID due to increasing resistance against quinolone antibiotics in the UK); or,
  - Ceftriaxone 500 mg intramuscular as a single dose, followed by doxycycline 100 mg orally twice a day + metronidazole 400 mg twice a day for 14 days
- Admission to hospital is appropriate in the following circumstances:
  - Surgical emergency cannot be excluded
  - Clinically severe disease
  - Tubo-ovarian abscess
  - PID in pregnancy
  - Lack of response to oral therapy
  - Intolerance to oral therapy
- In more severe cases, in-patient antibiotic treatment should be based on intravenous therapy, which should be continued until 24 hours after clinical improvement and followed by oral therapy. Recommended regimens are:
  - Ceftriaxone 2 g intravenously daily + doxycycline 100 mg intravenously twice a day (oral doxycycline may be used if tolerated), followed by doxycycline 100 mg orally twice a day + metronidazole 400 mg orally twice a day for a total of 14 days; or
  - Clindamycin 900 mg intravenously three times a day + gentamicin 2 mg/kg loading dose followed by 1.5 mg/kg intravenously three times a day (a single daily dose of 7 mg/kg may be substituted), followed by clindamycin 450 mg orally four times a day to complete 14 days, or doxycycline 100 mg orally twice a day + metronidazole 400 mg orally twice a day to complete 14 days
- Abstinence or the use of barrier contraception is advised until resolution of the condition on repeat testing
- Treatment in the presence of pregnancy should take account of local policies and guidelines with consideration to the treatment's teratogenic potential, but parental therapy is advised secondary to the increased risk of maternal and fetal morbidity
- Surgical drainage of a pelvic abscess may be indicated in the absence of clinical improvement with medical therapy

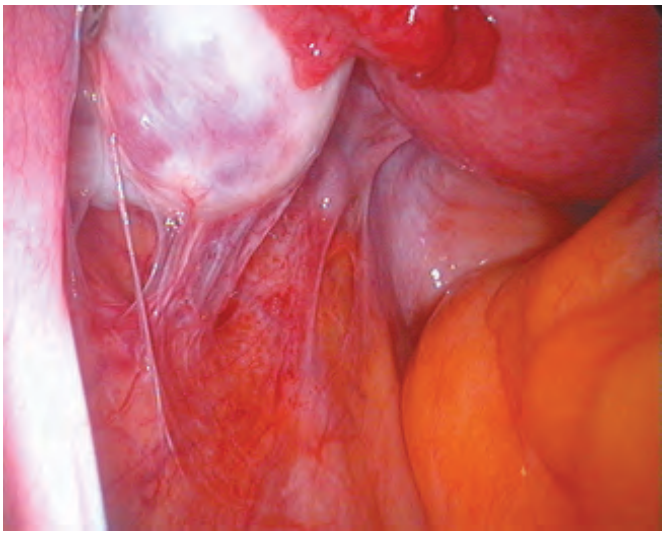

Figure 81.4 Pelvic inflammatory disease.

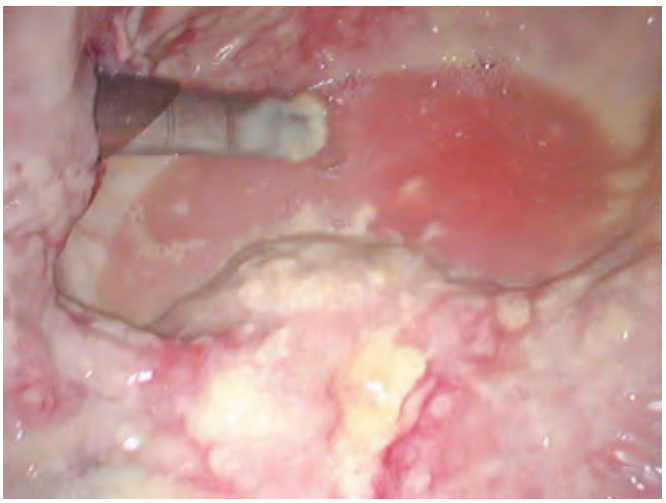

Figure 81.5 Pelvic inflammatory disease with rupture of a pelvic abscess.

It is clearly less invasive and there are claims that the method is as effective as surgery; however, it carries additional risks such as bowel damage and tracking of the infection along the root of entry of the needle.

ENDOMETRIOSIS

Endometriosis is defined as the presence of endometrial-like tissue in extrauterine sites. The most commonly affected sites are the pelvic organs and peritoneum, although distant sites such as the lungs are occasionally affected (resulting in symptoms such as recurrent haemoptysis at the time of menstruation or recurrent pneumothoraxes) (Figure 81.6). The exact pathogonomic mechanism remains elusive, but it is widely believed that most endometriotic lesions develop from retrograde menstruation. It is estimated to affect 5–10% of women mainly of reproductive age, with the incidence reported to be higher in certain subgroups, e.g. women with a history of infertility. Endometriosis may be associated with a number of

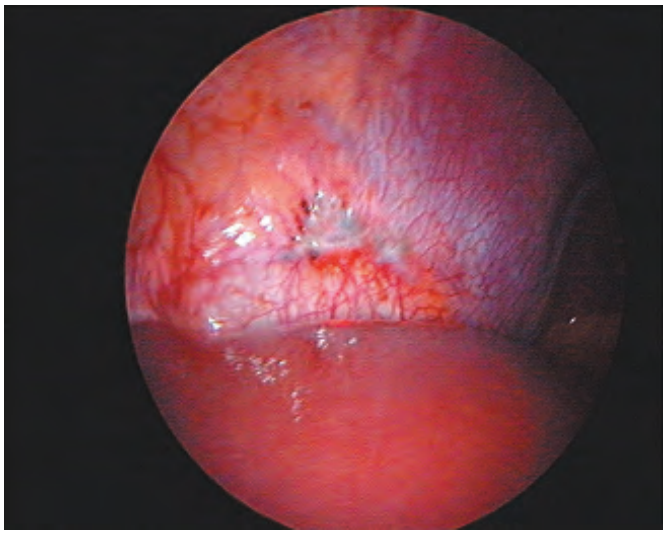

Figure 81.6 Endometriosis seen on the peritoneal surface of the diaphragm.

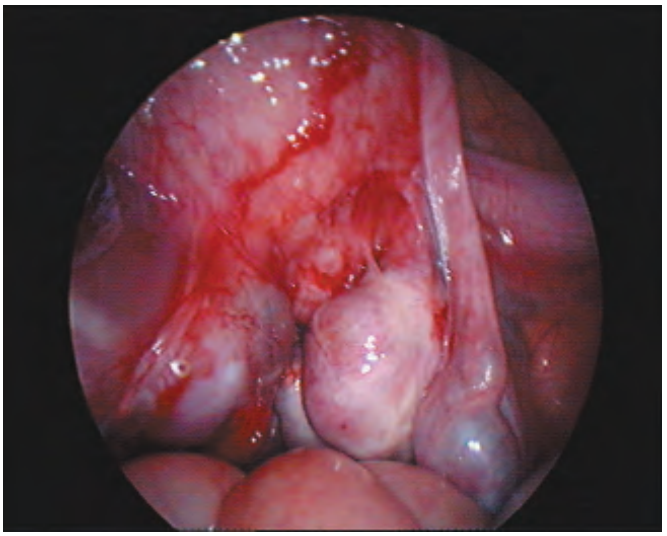

Figure 81.8 Bilateral ovarian endometriosis with pelvic adhesions.

symptoms, but the predictive value of any one symptom or set of symptoms remains uncertain as each can have other causes (e.g. irritable bowel syndrome or interstitial cystitis), with a significant proportion of affected women remaining asymptomatic. The most common symptom is pain. Other symptoms include: cyclical and non-cyclical pain; deep dyspareunia (pain during intercourse); dyschezia (pain on opening the bowels); and dysuria. Many women also suffer from fatigue, haematuria, chronic pelvic pain, infertility and rectal bleeding.

The extent of the disease varies from a few small lesions on otherwise normal pelvic organs to large ovarian endometriotic cysts (endometriomas). There can be extensive fibrosis in structures such as the uterosacral ligaments (**Figure 81.7**), and adhesion formation causing marked distortion of the pelvic anatomy (**Figure 81.8**). Disease severity can be assessed by describing the operative findings, or quantitatively using various classification systems, but there is little correlation between such systems and the type or severity of symptoms experienced.

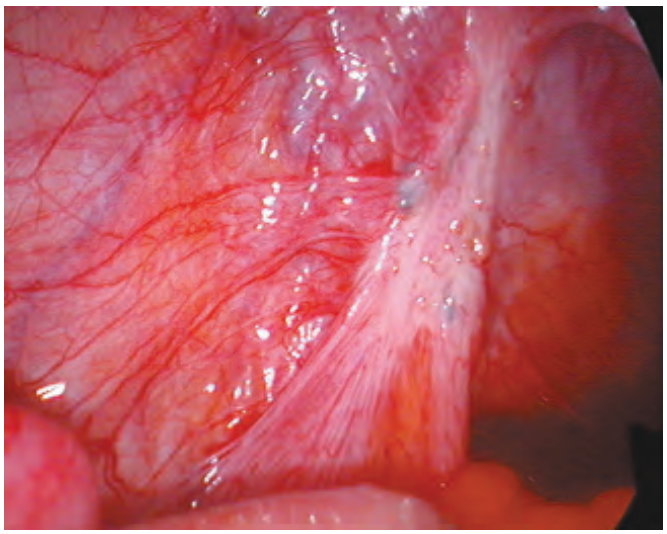

Figure 81.7 Endometriosis seen on the uterosacral ligament.

Endometriosis typically appears as superficial 'powder-burn' or 'gunshot' lesions on the ovaries, serosal surfaces and peritoneum – black, dark-brown or bluish puckered lesions, nodules or small cysts containing old haemorrhage surrounded by a variable extent of fibrosis. Atypical or 'subtle' lesions are also common, including red implants (petechial, vesicular, polypoid, haemorrhagic, red flame-like) and serous or clear vesicles. Other appearances include white plaques or scarring and yellow-brown peritoneal discolouration of the peritoneum. Ovarian endometriomas usually contain thick fluid-like tar. They are distinguishable from simple haemorrhagic ovarian cysts because typically they are densely adherent to the peritoneum of the ovarian fossa. The surrounding fibrosis may involve the bowel. Deeply infiltrating endometriotic nodules represent another disease type. They can extend more than 5 mm beneath the peritoneum and may grow into the uterosacral ligaments, vagina, bowel, bladder or ureters; when such lesions grow into the vagina they may be visible on speculum examination as 'blue-domed' cystic lesions in the posterior fornix. Lesions infiltrating the bowel may mimic cancer in their presentation.

The gold standard for making a diagnosis of endometriosis is through laparoscopy, ideally with histological confirmation; non-invasive diagnostic tools, such as ultrasound scanning, can reliably detect only severe forms of the disease, i.e. endometriomas. Magnetic resonance imaging (MRI) can detect haemosiderin deposits in deeply infiltrating disease.

The treatment options are limited because the cause is uncertain. These include: conservative management; medical management (simple analgesia or hormonal drugs to suppress ovarian function (progestins, the levonorgestrel-IUS)); and surgical management (ablation or excision of endometriotic lesions). Women may require multiple admissions for surgery and/or prolonged treatment with costly drugs that can have problematic side effects. Lastly, endometriosis is associated with an increased risk of ovarian cancer (especially

endometrioid and clear-cell types) and non-Hodgkin's lymphoma, which adds to the burden of the disease.

Finding pelvic tenderness, a fixed retroverted uterus, tender uterosacral ligaments or enlarged ovaries on examination is suggestive of endometriosis. The diagnosis is more certain if deeply infiltrating nodules are found on the uterosacral ligaments or in the pouch of Douglas and/or visible lesions are seen in the vagina or on the cervix. The findings may, however, be normal.

For a woman who has completed her family, hysterectomy plus bilateral salpingo-oophorectomy and removal of all of the endometriosis present offers a good chance of cure. However, surgical treatment in a woman who wishes to conceive in the future aims to be as conservative as possible, ensuring in particular that ovarian function is preserved. The aim is to remove all of the endometriotic tissue and restore anatomy to normal by lysing adhesions. The standard (preferably laparoscopic) methods used are ovarian cystectomy and tissue excision or ablation with electrodiathermy, thermal coagulation or laser. The surgical risks include those for any laparoscopic procedure, as well as damage to the ureters and bowel; the risks are increased if deeply infiltrating disease is present, particularly if there is bowel wall involvement. Rarely, infection in an endometrioma will result in the formation of a tubo-ovarian abscess.

UROGYNAECOLOGY

Uterovaginal prolapse

Pelvic organ prolapse refers to the protrusion or displacement of the pelvic organs from their normal anatomical position into or through the vagina to varying degrees (Figure 81.9). It is said to affect up to 40% of women at some time in their

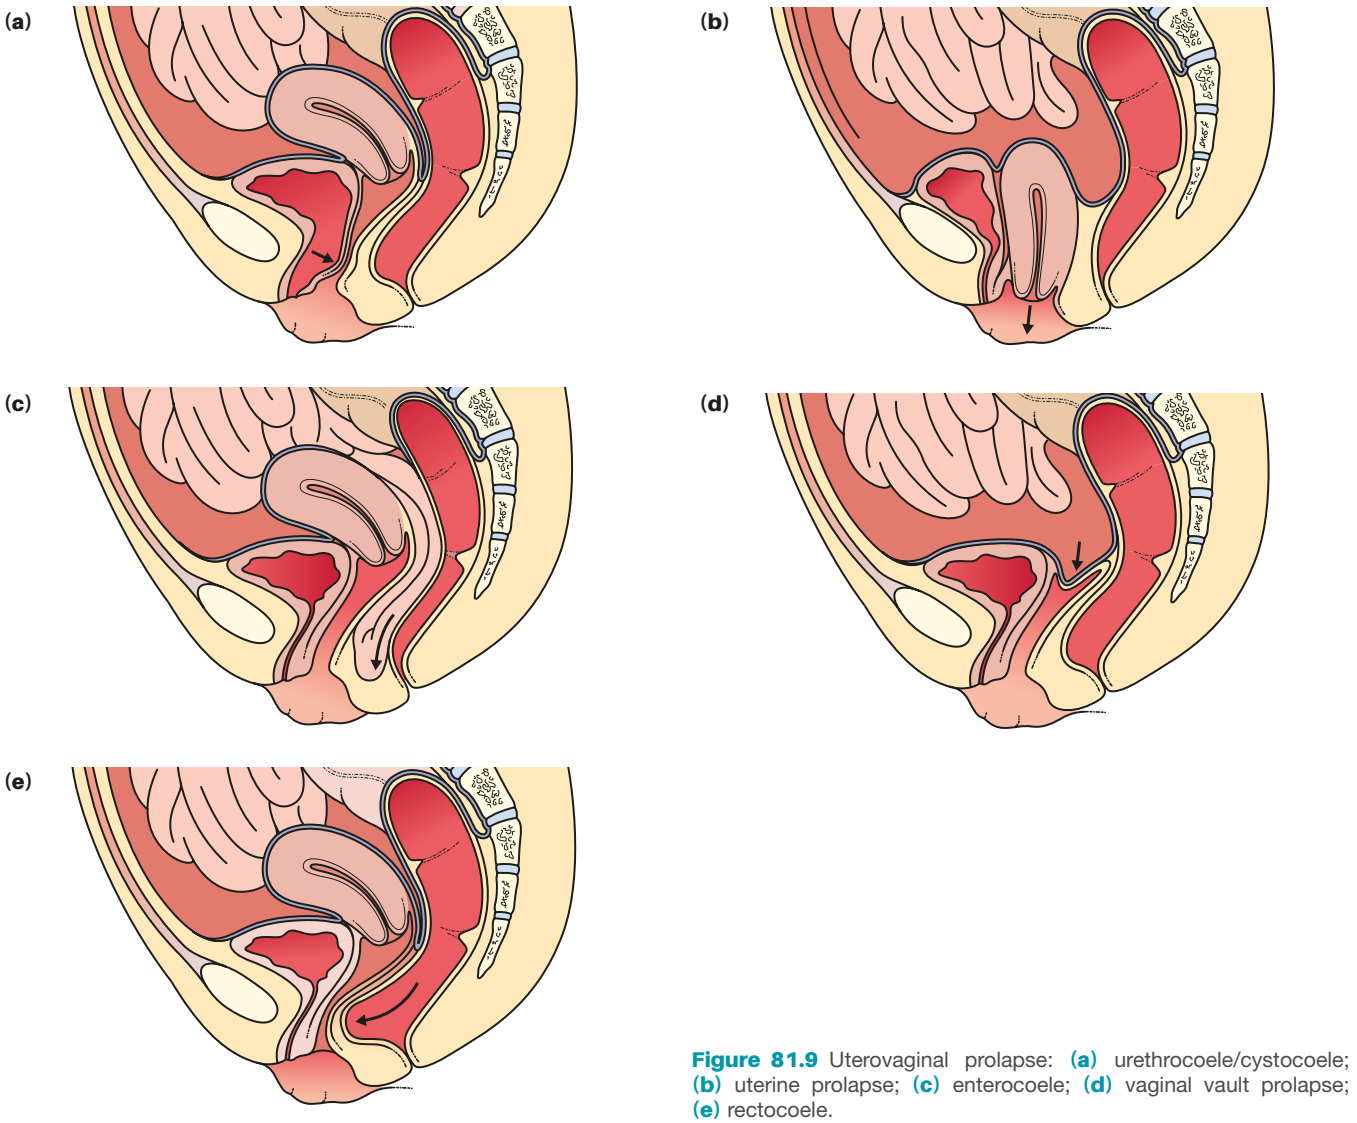

Figure 81.9 Uterovaginal prolapse: **(a)** urethrocoele/cystocoele; **(b)** uterine prolapse; **(c)** enterocoele; **(d)** vaginal vault prolapse; **(e)** rectocoele.

Thomas Hodgkin, 1798–1866, curator of the Museum and demonstrator of Morbid Anatomy, Guy's Hospital, London, UK.

lifetime. A prolapse can have a detrimental impact on normal organ performance, including anorectal, urinary and sexual function.

Prolapse is more common in certain groups, including:

- older women;
- parous women, increased parity, prolonged labours, vaginal deliveries;
- obese women;
- sufferers of chronic constipation;
- occupations that involve heavy lifting;
- oestrogen-deficient women;
- women with a family history or genetic risk;
- connective tissue disorders, e.g. Ehlers–Danlos syndrome, Marfan's.

Women with a minor degree of prolapse may be asymptomatic, but with more significant degrees the patient usually complains of a sensation of 'something coming down'. A cystocoele (bladder prolapse) and a cystourethrocoele (prolapse of the bladder and urethra) lead to the sensation of a lump in the vagina, and may be associated with urinary urgency (overactive bladder symptoms) and recurrent urinary tract infections. Uterine descent can lead to a lump in the vagina or a dragging sensation; with complete prolapse of the uterus (procidentia) there may be vaginal discharge, ulceration of the vaginal skin and bleeding. A rectocoele (prolapse of the rectum into the vagina) may cause difficulties with defaecation or a sensation of incomplete emptying, which can be relieved by digital reduction of the prolapse.

The degree of prolapse is graded in terms of descent. Currently, the commonly used grading systems is the Pelvic Organ Prolapse Quantification System (POP-Q).

Non-surgical management of uterovaginal prolapse includes: lifestyle changes (avoidance of constipation); physiotherapy to help strengthen the pelvic floor muscles; HRT for oestrogen deficiency and to help increase tissue strength and elasticity; and vaginal pessaries. There are a number of different pessaries available and they are replaced every 3–6 months, with the ring pessary being the most frequently used. It is inserted between the posterior fornix and the pubic bone. The main complications are vaginal ulceration and infection leading to discharge and bleeding; it is advisable, therefore, to replace the ring frequently.

Surgical management aims to correct the prolapse. The surgical procedures are intended to restore the uterovaginal anatomy and position. They may be carried out using a vaginal or abdominal approach or, increasingly, by a laparoscopic or minimal access approach, with the use of polypropylene mesh to augment weak connective tissue (*Table 81.6*).

TABLE 81.6. Surgical treatments for uterovaginal prolapse.

Condition	Treatment	Complications
Urethrocoele/cystocoele (**Figure 81.9a**)	Traditionally, an anterior vaginal wall repair (anterior colporrhaphy) was performed vaginally. The use of mesh has been utilised but is falling out of favour with the current controversies	Bleeding, infection, fistula formation, voiding dysfunction, unmasking of occult stress urinary incontinence, failure, recurrence
Uterine prolapse (**Figure 81.9b**)	If the patient's family is complete, a vaginal hysterectomy with an anterior vaginal wall repair if necessary can be performed. Uterus-preserving surgery includes: amputation of the cervix with suturing of the transverse cervical ligaments vaginally (Manchester repair); laparoscopic plication of the uterosacral ligaments (McCall suture); or hysteropexy, which may be vaginal (attaching the cervix to the sacrospinous ligaments using non-absorbable sutures) or laparoscopically (using a polypropylene mesh to suspend the uterus to the sacral promontory)	Bleeding, infection, injury to the bladder, bowel or ureters, voiding dysfunction, dyspareunia, failure, recurrence, conversion to a laparotomy. A Manchester repair can specifically be associated with infertility, miscarriage and dystocia
Enterocoele (**Figure 81.9c**)	A similar technique to repair of a hernia is used. The vaginal skin is opened and the hernial sac repaired	Bleeding, infection, rectal or small bowel injury (fistula formation), dyspareunia, failure, recurrence
Vaginal vault prolapse (**Figure 81.9d**)	Sacrospinous fixation performed vaginally: the vault is attached to the right sacrospinous ligament using a non-absorbable suture/mesh, avoiding the rectosigmoid colon on the left. Sacrocolpopexy perfomed abdominally or laparoscopically: the vaginal vault is attached to the sacral promontory using a mesh	Bleeding, infection, injury to the bowel or ureter, unmasking of occult urinary stress incontinence, right buttock pain, sexual dysfunction
Rectocoele (**Figure 81.9e**)	Posterior colperineorrhaphy: the posterior vaginal wall is opened, the rectum returned to its normal position and redundant vaginal skin excised	Bleeding, infection, rectal or small bowel injury (fistula formation), dyspareunia, failure, recurrence

Approximately 30% of women in their lifetime report a recurrence of their symptoms following surgical treatment. This figure increases with subsequent procedures.
The **Manchester repair** was introduced at St Mary's Hospital for Women and Children, Manchester, UK.

Edvard Laurits Ehlers, 1863–1937, dermatologist, Copenhagen, Denmark.
Henri-Alexandre Danlos, 1844–1912, dermatologist, Paris, France.
Antoine Bernard-Jean Marfan, 1858–1942, paediatrician, Paris, France.
Milton Lawrence McCall, 1911–1963, obstetrician, Magee-Womens' Hospital, Pittsburg, PA, USA.

Urinary incontinence

Urinary incontinence is defined as the involuntary leakage of urine. It is said to affect approximately 30% of women, with a higher prevalence seen in older age groups. It can have a significant impact on their quality of life.

Incontinence can be classified into:

- stress urinary incontinence (involuntary leakage of urine secondary to increased intra-abdominal pressure, e.g. coughing, sneezing);
- overactive bladder;
- mixed urinary incontinence (combination of both urge and stress incontinence).

It can result from both functional and anatomical causes, including:

- multiparity;
- vaginal delivery;
- menopause;
- fistulae;
- urethral diverticulum/congenital anomalies, e.g. ectopic ureters;
- immobility, constipation or urinary tract infection;
- neurological disorders, e.g. multiple sclerosis;
- secondary to pelvic masses.

Common symptoms and complaints include:

- frequency (increased frequency of more than 8 times during the day);
- nocturia (increased frequency of voiding more than once a night);
- urgency;
- urinary incontinence with increased coughing;
- altered stream, e.g. slow/intermittent stream or hesitancy;
- incomplete bladder emptying;
- postmicturition dribbling;
- nocturnal enuresis;
- haematuria (in women >40 years of age, additional investigations should be performed to rule out malignancy).

Investigations include:

- urine analysis and mid-stream urine sample for microscopy, culture and sensitivity;
- urodynamics if conservative measures have failed;
- ultrasound kidney, ureters and bladder in cases with recurrent urinary tract infections/haematuria;
- cystoscopy if pathology is suspected.

Management can be divided into conservative methods, medical therapy or surgical intervention (*Table 81.7*). The treatment of choice is dependent on the underlying cause.

Treatments can be combined and are individualised for the patient. Should initial therapy be unsuccessful or repeat procedures be required, then the patients should be discussed within a multidisciplinary team setting.

TUMOURS

Uterine fibroids (leiomyoma)

Fibroids are usually benign, well-circumscribed, smooth muscle tumours of the uterus. Less than 1% of fibroids undergo malignant transformation (leiomyosarcoma). They are more common in certain populations (African-Caribbean women) and vary in size and number. They are typically found in the following locations (**Figure 81.10**):

- **subserosal** – may cause pressure-type symptoms; if pedunculated, they can be difficult to distinguish from an ovarian tumour;

TABLE 81.7. Management options for urinary incontinence.

Method	Techniques	Complications
Conservative	Lifestyle changes (i.e. limit fluid intake, avoid diuretics such as tea/coffee, weight loss) Behavioural modification (i.e. bladder drills) Review of coexistent medications (i.e. diuretics) Pelvic floor exercises (physiotherapy) Bladder catheterisation	Infection
Medical	Antibiotics for a urinary tract infection Topical oestrogen therapy in postmenopausal women with urogenital atrophy Antimuscarinic drug therapy (e.g. oxybutynin (avoid in elderly frail women), tolterodine) Selective β_3 adrenoreceptor agonist (e.g. mirabegron) Serotonin and noradrenaline reuptake inhibitor (e.g. duloxetine) (can be used in stress urinary incontinence when conservative measures have failed and surgical treatment is contraindicated or declined) Desmopressin Intravesical botulinum toxin A/urethral bulking agents (e.g. silicone) Neuromodulation	Dry mouth Repeated procedures
Surgical	Management of pelvic masses Bladder reconstruction (augmentation cystoplasty) Urinary diversion Sling procedures (e.g. transvaginal tapes/transobturator tapes) Burch colposuspension Bladder neck suspension Artificial sphincter Fistulae/ectopic ureter surgical correction	 Dependent on the material used for augmentation Bladder voiding difficulties, organ perforation, de novo incontinence, bleeding, erosion, dyspareunia, suprapubic pain

John C Burch, 1900–1977, gynaecologist, Vanderbilt University, Nashville, TN, USA.

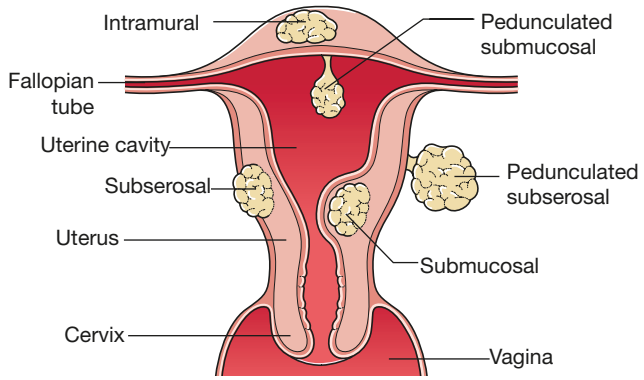

Figure 81.10 Uterine fibroids.

- **intramural** – may similarly cause pressure-type symptoms; associated with infertility and heavy periods;
- **submucosal** – associated with infertility, recurrent pregnancy loss and heavy periods; if pedunculated, may occasionally extrude through the cervical os;
- **rare** – sites include the broad ligament and cervix.

Women with uterine fibroids may present with heavy and/or irregular menstrual bleeding, anaemia, pressure-type symptoms or infertility, especially if the fibroid is distorting the uterine cavity. The pressure-type symptoms include pelvic discomfort, urinary incontinence, frequency and retention, constipation and backache. When large fibroids are present, back pressure may cause or exacerbate varicosities. Although these symptoms are common, it is important to note that some women with fibroids are asymptomatic. Rarely, women may present acutely with pain arising from torsion of a pedunculated fibroid or red degeneration, especially in pregnancy.

A diagnosis can usually be made on bimanual and/or abdominal examination, in the presence of an enlarged uterus with attached swellings. The principal differential diagnosis is an ovarian tumour; in general, if an ovarian tunour is present, the uterus is felt separately on vaginal examination, although not if the structures are adherent to each other. A pelvic ultrasound scan is a good first-line investigation; if not, MRI can be clinically useful (**Figure 81.11**) but, sometimes, it may be necessary to perform a laparoscopy to distinguish between the two pathologies (**Figure 81.12**).

Treatment can be divided into: conservative if the woman is asymptomatic; medical to control menstrual bleeding in the form of hormonal manipulation, or newer treatment to shrink the fibroids; or surgical (uterus conserving or non-conserving). The choice of treatment depends upon the woman's age and fertility intentions, the size and number of fibroids as well as their location. Emergency surgical treatment is only required if there is substantial menstrual bleeding or uncontrollable pain; these are rare events.

GnRH agonists aim to shrink the fibroids by inducing a hypo-oestrogenic state. However, this class of drug has the disadvantage that treatment cannot be continued indefinitely because of the associated loss in bone mineral density; in addition, the fibroids tend to regrow to their original size when treatment is discontinued. Ulipristal acetate (Esmya®), a selective progesterone receptor modulator (SPRM), can be used preoperatively to shrink the size of the fibroids through inhibition of cell proliferation. However, these drugs should not be used in conjunction with POP, a progesterone-releasing intrauterine device or the COCP. Uterine artery embolisation (UAE) is becoming increasingly popular as an alternative to surgery. It involves blocking the blood supply to the fibroids using a technique in which particles are embolised into each uterine artery via an angiographic catheter in a similar manner to the well-established technique for treating massive postpartum haemorrhage (**Figure 81.13**). The aim is to shrink the fibroids, bringing symptomatic relief, i.e. decreased menstrual bleeding and fewer pressure symptoms. This technique has shown more value in the presence of a single large fibroid than in a multifibroid uterus. Complications include arterial injury at the site of catheter insertion, severe pain as a result of uterine ischaemia, infection, ovarian damage

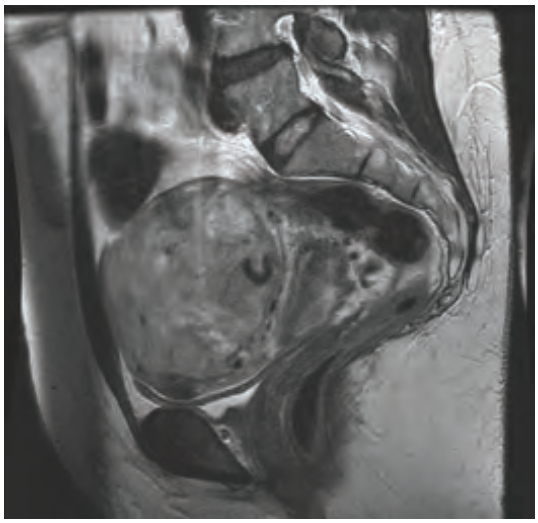

Figure 81.11 Magnetic resonance imaging of uterine fibroids.

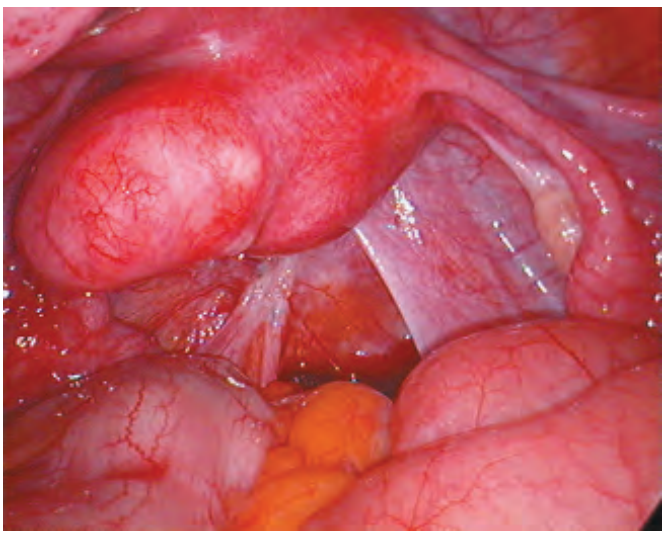

Figure 81.12 Laparoscopic view of a fibroid of the uterine fundus.

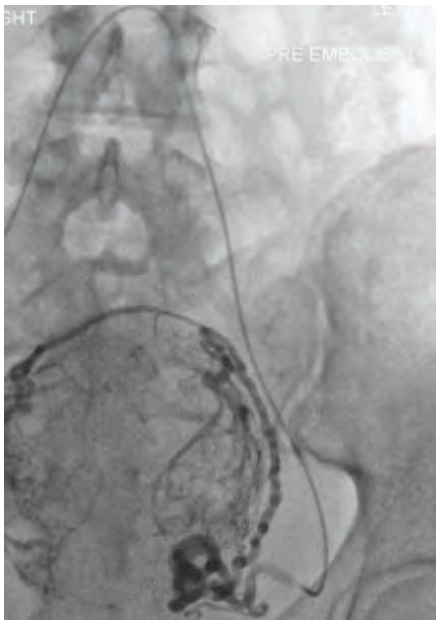

Figure 81.13 Pre-embolisation angiogram showing catheterisation of left uterine artery and blood supply to large fundal fibroid (courtesy of Dr Mark Bratby, Consultant Vascular and Interventional Radiologist, John Radcliffe Hospital, Oxford, UK).

and thromboembolism (a small number of deaths have been reported from uterine infection and pulmonary embolism). There is no consensus regarding the suitability of the technique for women who wish to conceive. Numerous pregnancies have been reported in women who have undergone UAE, but concern still exists regarding the possible adverse effects on the endometrium, myometrial strength and ovarian function, which might affect a woman's chances of conceiving, carrying the pregnancy and delivering normally. Other newer focal fibroid treatments include MR-guided focused ultrasonography, laparoscopic uterine artery occlusion with/without utero-ovarian occlusion, transvaginal Doppler-guided uterine artery occlusion and bipolar radiofrequency ablation (intrauterine ultrasound guided or laparoscopic guided).

A myomectomy (performed through a laparotomy, or increasingly at laparoscopy) involves the removal of pedunculated, subserosal and/or (rarely) intramural fibroids, with closure of the defects left in the uterine wall. Surgical complications include bleeding and damage to surrounding structures, with the risk of conversion to a hysterectomy <1% secondary to uncontrollable blood loss. Fibroids within the uterine cavity can be removed hysteroscopically (transcervical resection of a fibroid (TCRF)); complications include hyponatraemic fluid overload and thermal injury to surrounding structures. This occasionally needs to be performed as a two-stage procedure to avoid the risk of fluid overload and manage the roof of the fibroid, which can protude into the cavity following excision of its base.

Benign ovarian tumour and cysts

Overall, 90% of ovarian tumours are benign, with an increased risk of malignancy in older women: the malignant potential of an ovarian cyst in a premenopausal woman is 1:1000, increasing to 3:1000 at the age of 50 years. Ovarian tumours are subdivided into five main categories according to the World Health Organisation's classification system (*Table 81.8*).

TABLE 81.8 Classification of ovarian tumours.

Epithelial tumours	Represent approximately 75% of all ovarian tumours and 90–95% of ovarian malignancies Further classified by cell type (serous, mucinous, endometrioid, clear cell, transitional cell, epithelial stromal)
Germ cell tumours	Represent approximately 15–20% of all ovarian neoplasms
Sex cord–stromal tumours	Represent approximately 5–10% of all ovarian neoplasms
Metastatic tumours	Represent approximately 5% of ovarian malignancies; usually arise from the breast, colon, endometrium, stomach and cervical cancers
Other/miscellaneous	A small number of other types of neoplasms, which develop from ovarian soft tissue or non-neoplastic processes

The most common solid tumours in young women are cystic teratomas (known more commonly as dermoid cysts), which typically contain a variety of tissues including hair, teeth and bone. Benign ovarian tumours are often asymptomatic and may present incidentally, for example when an abdominal radiograph reveals the appearance of a tooth in the abdomen or pelvis. Conversely, they may present with pain, abdominal swelling and pressure-type symptoms. The pain may result from torsion or bleeding into the cysts. Management will depend on the age of the woman and the characteristics of the cyst. In older women, a conservative approach is reasonable only if the risk of malignancy is low (refer to Ovarian cancer below). In perimenopausal women, the cyst can be followed by serial ultrasound scanning as many will regress. If there is uncontrollable pain, haemodynamic compromise, suspicion of torsion or the cyst does not regress, then surgical management is advised. In most cases this would involve a laparoscopic ovarian cystectomy with conservation of ovarian tissue as the treatment of choice. As the vast majority of oocytes lie within 5 mm of the surface of the ovary, a carefully carried out cystectomy can leave a normally functioning ovary (**Figure 81.14**).

Ovarian cancer

Ovarian cancer is the sixth most common malignancy in women, behind breast, lung, bowel, uterine cancer and malignant melanoma. In the UK, over 7000 women are diagnosed with ovarian cancer each year. Over 90% of cancers

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler Principle' in 1842.

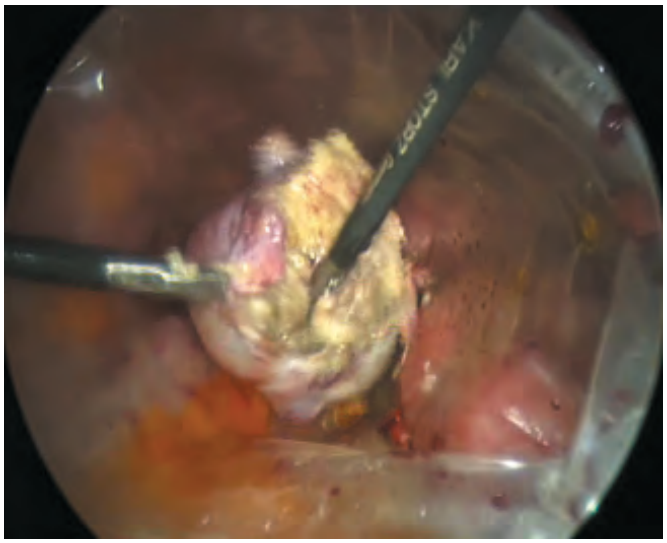

Figure 81.14 Ovarian cystectomy.

Summary box 81.5

Management of benign ovarian cysts

- Commonly, an incidental finding, but may be suggested by symptoms and signs
- A pregnancy test is done to exclude an ectopic pregnancy (however, it is important to note that hCG can also be positive in dysgerminomas and choriocarcinoma)
- Transvaginal ultrasonography (mainstay diagnostic tool) can usually confirm the diagnosis. If the results are indeterminate, MRI or CT imaging may help (MRI is more useful than CT for the assessment of complex cysts/endometriosis). Masses with radiographic characteristics of cancer (e.g. cystic and solid components, surface excrescences, multilocular appearance, irregular shape) require removal
- Tumour markers may help in the diagnosis of specific masses (refer to Ovarian cancer)
- In women of reproductive age, simple, thin-walled cystic adnexal masses of a maximum diameter of 50 mm without characteristics of cancer do not require further investigation unless they persist for more than 3 months. A follow-up scan can be arranged for 4 months to check for resolution. In postmenopausal women, this is conducted every 4 months with cancer antigen 125 (CA-125) levels for 1 year, and if no change is detected, then the women can be discharged
- Perimenopausal women with simple cysts 50–70 mm should undergo annual ultrasound follow-up
- Women with larger cysts (>70 mm) or persistent cysts may benefit from an MRI scan or surgical intervention
- Cyst removal (ovarian cystectomy) is preferrably performed laparoscopically. Cyst aspiration is not recommended as it is associated with a high risk of recurrence. Bilateral salpingo-oophorectomy is preferable for postmenopausal women, if surgery is indicated
- An oophorectomy may become necessary if the cyst cannot be surgically removed from the ovary

arise from the surface epithelium of the ovary (which has the same embryological origins as the peritoneum); the majority arise sporadically rather than secondary to inheritance. The peak incidence is in the age range of 65–69 years. The overall 5-year survival rate is less than 50% because approximately two-thirds of women present with advanced disease.

The common presenting symptoms are:

- abdominal distension and/or pain;
- change in appetite;
- weight gain and increased girth (ascites);
- urinary obstruction.

However, over half of all women present initially to a speciality other than gynaecology, with often vague symptoms caused by metastatic disease, e.g. shortness of breath, gastrointestinal disturbance or a change in bowel habit. Consequently, it is important to include ovarian cancer in the differential diagnosis of any woman presenting with a recent onset of persistent, non-specific, abdominal symptoms (including those whose abdomen and pelvis appear normal on clinical examination).

Ultrasound, more specifically a transvaginal ultrasound scan, is the first-line investigation if an ovarian mass is suspected on clinical grounds. The features suggestive of malignancy on ultrasound include the presence of:

- cyst complexity (number of locules, wall structure, thickness of septae, fluid echogenicity, irregularity, size ≥10 cm);
- solid papillary projections into the cyst (at least four);
- bilateral lesions;
- ascites;
- intra-abdominal metastases;
- strong blood flow.

Serum tumour markers can also be performed to aid diagnosis. CA-125 is a glycoprotein expressed on tissue derived from coelomic and Müllerian epithelia; the normal cut-off value is 35 U/mL. Elevated levels are found in 50% of patients with stage I disease and >90% of those with advanced disease. It primarily detects epithelial ovarian cancers. However, CA-125 is a non-specific marker with raised levels also seen in other cancers, e.g. pancreatic, breast, lung and colon. Levels may also be increased during menstruation; in benign conditions such as endometriosis, PID and liver disease; if ascites or other effusions are present; and after a recent laparotomy. Combining menopausal status, ultrasonographic features and CA-125 measurements using the Risk of Malignancy Index (RMI) algorithm, guides management and helps to identify those patients who require referral to a gynaecological oncologist in a cancer centre. *Summary boxes 81.6 and 81.7* address the basic tests that can be conducted to diagnose ovarian malignancy.

Summary box 81.6

Risk of malignancy index (RMI)

- RMI = U × M × CA-125

  U, ultrasonographic features scoring 1 for each malignant feature (multilocular, solid components, metastases, ascites, bilateral lesions); M, menopausal status with 1 for premenopausal and 3 for postmenopausal; CA-125, CA-125 level in U/mL
- Other tumour markers include lactate dehydrogenase, α-fetoprotein (α-FP), inhibin and β-hCG. They are particularly recommended in women <40 years of age, with a suspected complex ovarian mass, to exclude germ cell tumours

Summary box 81.7

Basic tests on suspicion of ovarian malignancy

- Ultrasonography: findings that suggest cancer include a solid component, surface excrescences, size >5 cm, irregular shape and low vascular resistance on transvaginal Doppler flow studies
- A pelvic mass plus ascites usually indicates ovarian cancer but sometimes indicates Meigs' syndrome (a benign fibroma with ascites and the presence of a pleural effusion)
- CT or MRI is usually carried out before surgery to determine the extent of the cancer
- Tumour markers, including β-hCG, lactate dehydrogenase, α-FP, inhibin and CA-125, CA 19-9, CEA (carcinoembryonic antigen) are measured
- CA-125 is elevated in 80% of advanced epithelial ovarian cancers but may also be mildly elevated in endometriosis, PID, pregnancy, fibroids, peritoneal inflammation and non-ovarian peritoneal cancer

Unfortunately, there are still no effective screening methods for ovarian cancer for the general population. Hence, the preliminary results of the UK Collaborative Trial of Ovarian Cancer Screening are of great interest. The study recruited over 200 000 women, aged 50–74 years, who were randomised to a control arm or one of two screening strategies: primary screening using measurement of serum CA-125 levels followed by transvaginal ultrasound as a second-line test, or transvaginal ultrasound alone. The two screening procedures were similar in terms of sensitivity for all primary ovarian and Fallopian tube cancers, but specificity was higher with combined screening.

There is also no consensus regarding how to screen women who are at high risk for ovarian cancer secondary to a family history, i.e. those with a first-degree relative affected by cancer within a family that meets one of the following criteria:

- two or more individuals with ovarian cancer, who are first-degree relatives of each other;
- one individual with ovarian cancer at any age and one with breast cancer diagnosed at <50 years, who are first-degree relatives of each other (or second-degree relatives if the transmission is paternal);
- one relative with ovarian cancer at any age and two with breast cancer diagnosed at <60 years, who are connected by first-degree relationships (or second-degree relationships if the transmission is paternal);
- a known carrier of relevant cancer gene mutations (e.g. *BRCA1* or *BRCA2*);
- an untested first-degree relative of a predisposing gene carrier;
- three or more family members with colon cancer or two with colon cancer and one with stomach, ovarian, endometrial, urinary tract or small bowel cancer in two generations. One of these cancers must be diagnosed at <50 years (Lynch syndrome);
- an individual with both breast and ovarian cancer.

Some genetic mutations are known to predispose women to ovarian cancer, e.g. *BRCA1* and *BRCA2* and the mismatch repair genes associated with Lynch syndrome families. *BRCA1* mutations confer a 39% lifetime risk of ovarian cancer up to the age of 70 years; the figure for *BRCA2* mutations is 11–17% up to the age of 70 years. The mismatch repair genes confer an increased lifetime risk of ovarian cancer of 9–12%, in addition to the increased risk of endometrial cancer (refer to Vaginal bleeding in the non-pregnant state). Referral to a specialist cancer genetics service is advisable. Women at high risk of ovarian cancer may be offered prophylactic bilateral salpingo-oophorectomy, especially as they may also be at increased risk of breast cancer and there is some evidence to suggest that oophorectomy reduces breast cancer risk in these women. Unfortunately, there is currently no proven role for screening in women at high risk.

Staging (*Table 81.9*) is performed at laparotomy via a midline incision if disease is suspected preoperatively, by:

- careful evaluation of all peritoneal surfaces;
- four washings of the peritoneal cavity: diaphragm, right and left abdomen, pelvis;
- infracolic omentectomy;
- selected lymphadenectomy of the pelvic and para-aortic lymph nodes;
- biopsy and/or resection of suspicious lesions, masses and adhesions;
- random blind biopsies of normal peritoneal surfaces, including that from the undersurface of the right hemidiaphragm, bladder reflection, cul-de-sac, right and left paracolic recesses and both pelvic side walls;
- total abdominal hysterectomy and bilateral salpingo-oophorectomy;
- appendicectomy for mucinous tumours; if a routine appendicectomy results in an intraoperative suspicion of a mucinous tumour, the surgeon should take washings and a biopsy from suspicious area(s).

TABLE 81.9 Staging of ovarian cancer.

Stage I	Growth limited to the ovaries
Stage II	Growth involving one or both ovaries with pelvic extension
Stage III	Tumour involving one or both ovaries with histologically confirmed peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes. Superficial liver metastases are considered stage III. Tumour is limited to the true pelvis but with histologically proven extension to the small bowel or omentum
Stage IV	Growth involving one or both ovaries with distant metastases. If pleural effusion is present there must be positive cytology to classify a case as stage IV. Parenchymal liver metastasis equals stage IV

Joe Vincent Meigs, 1892–1964, gynaecological surgeon, Massachusetts General Hospital, Boston, MA, USA.

Ovarian cancer is chemosensitive; however, a staging laparotomy and histological findings provide accurate information about prognosis and postoperative therapy. The general principle is cytoreductive surgery followed by combination chemotherapy; only a minority of patients with ovarian cancer need bowel resected during the primary procedure or surgery for recurrent disease. The only exception to this rule is a young woman with stage I disease or a borderline tumour who requests unilateral oophorectomy to conserve her fertility.

Stage IA or IB/grade 1 epithelial adenocarcinoma requires no postoperative therapy. Stage IA or IB/grade 2 or 3 cancers and stage II cancers require six courses of chemotherapy (typically, paclitaxel and carboplatin). Stage III or IV cancer requires six courses of similar chemotherapy. Intraperitoneal chemotherapy or high-dose chemotherapy with bone marrow transplantation is under study. Radiotherapy is used infrequently. Even if chemotherapy results in a complete clinical response (i.e. normal physical examination, normal serum CA-125 and negative CT scan of the abdomen and pelvis), approximately 50% of such patients with stage III or IV cancer will have residual disease. Of patients with persistent elevation of the CA-125, 90–95% will have residual tumour.

Ovarian stimulation with oocyte or embryo cryopreservation has been reported in patients with low-grade tumours (grade IA/B) who wish to preserve their fertility, but the effect of this on the underlying disease is as yet unknown and it must therefore be carried out with caution. Newer techniques include ovarian tissue cryopreservation with the potential risk of cancer reoccurence following autologous transplantation.

PART 13

Transplantation

Chapter 82

Transplantation

Learning objectives

- To appreciate the immunological basis of allograft rejection
- To know the principles of immunosuppressive therapy
- To be aware of the side effects of non-specific immunosuppression
- To be familiar with the major issues concerning organ donation
- To appreciate the main indications for organ transplantation
- To know the surgical principles of organ implantation
- To be able to give an account of the causes of graft dysfunction
- To know the likely outcomes after transplantation
- To be aware of potential future developments in transplantation

HISTORICAL PERSPECTIVE

Since early times, the idea of tissue and organ transplantation has captured the imagination of successive generations and, over the centuries, numerous fanciful descriptions of successful transplants have been recorded.

The modern era of transplantation began in the 1950s (*Table 82.1*) and relied on surgical techniques for anastomosing blood vessels that had been developed at the start of the twentieth century by Mathieu Jaboulay and Alexis Carrel. The first successful kidney transplant was a living-donor transplant performed between identical twins in 1954 at the Brigham Hospital in Boston by Joseph Murray and colleagues. This, and other kidney transplants between identical twins, demonstrated the technical feasibility of kidney transplantation, but attempts to perform renal transplantation when the donor and recipient were not genetically identical failed because no effective immunosuppressive therapy was available (**Figure 82.1**). Then, in 1959, Schwartz and Dameshek discovered that 6-mercaptopurine had immunosuppressive properties, and Calne showed that azathioprine, a derivative of 6-mercaptopurine, prevented rejection of canine kidney transplants. From the early 1960s, a combination of azathioprine and corticosteroids was used with moderate success in the clinic to prevent graft rejection after kidney transplantation. These chemical agents were sometimes supplemented with a polyclonal anti-lymphocyte antibody.

Figure 82.1 One of the early Boston recipients of a kidney transplant from an identical twin, shown here with her twin sister and their children.

Mathieu Jaboulay, 1860–1913, Professor of Surgery, Lyons, France.
Alexis Carrel, 1873–1944, surgeon, Lyons, France, who worked at the Rockefellar Institute for Medical Research in New York, NY, USA. He received the Nobel Prize for Physiology or Medicine in 1912 'In recognition of his works on vascular suture and the transplantation of blood vessels and organs'.
Joseph E Murray, 1919–2012, Professor of Plastic Surgery, Harvard University Medical School, Boston, MA, USA, shared the 1990 Nobel Prize for Physiology or Medicine with E Donnall Thomas for his work on organ and cell transplantation.
Robert S Schwartz, Professor of Medicine, the Tufts University School of Medicine, Boston, MA, USA.
William Dameshek, 1900–1969, American physician and haematologist.

TABLE 82.1 Milestones in organ transplantation.

1954	Joe Murray performed successful kidney transplantations between identical twins (Boston, MA, USA)
1962	Roy Calne demonstrated the efficacy of azathioprine in preventing rejection of kidney allografts (Boston, MA, USA)
1963	Tom Starzl performed the first human liver transplantation (Denver, CO, USA)
1966	Tom Starzl and colleagues used anti-lymphocyte globulin immunosuppression (Denver, CO, USA)
1966	Richard Lillehei and William Kelly performed first human whole organ pancreas transplantation (along with a kidney transplantation) (Minneapolis, MN, USA)
1967	Christiaan Barnard performed the first human heart transplantation (Cape Town, South Africa)
1968	Fritz Derom performed the first human lung transplantation (Ghent, Belgium)
1969	Geoff Collins developed Collins solution – a new kidney preservation solution
1974	David Sutherland and John Najarin performed the first human pancreatic islet transplantation (Minneapolis, MN, USA)
1978	Roy Calne introduced ciclosporin into clinical practice (Cambridge, UK)
1981	Bruce Reitz and Norman Shumway performed the first successful human heart–lung transplantation (Stanford, CA, USA)
1987	Fokert Belzer and colleagues developed University of Wisconsin (UW) solution – a new liver and pancreas preservation solution (Wisconsin, USA)
1988	Rudolf Pichlmayr performed the first splitting of a donor liver for use in two recipients (Hannover, Germany)
1989	Tom Starzl demonstrated clinical efficacy of FK506 (tacrolimus) (Pittsburgh, PA, USA)
1991	Kil Park performed the first living-donor kidney paired exchange to overcome antibody incompatibility (Seoul, South Korea)
1995	Lloyd Ratner and colleagues first described laparoscopic living-donor nephrectomy (Johns Hopkins University, Baltimore, MD, USA)

The ciclosporin era began in the late 1970s after its discovery by Borel at the Sandoz laboratories in Basle and the demonstration, by Calne in Cambridge, UK, of its potent immunosuppressive properties in clinical transplantation. The introduction of ciclosporin was a major advance and ciclosporin (usually given together with azathioprine and steroids) not only improved the results of renal transplantation, but also allowed transplantation of the heart and liver to be undertaken with acceptable results. Organ transplantation is now well established as an effective treatment for selected patients with end-stage organ failure. Kidney, liver, pancreas, heart and lung transplantation are all routine procedures with good outcome, and transplantation of the small intestine is becoming more widely practised. Transplant activity is limited only by the shortage of donor organs.

Summary box 82.1

Definitions

- Allograft: an organ or tissue transplanted from one individual to another
- Alloantigen: transplant antigen
- Alloantibody: transplant antibodies
- HLA: human leukocyte antigen, the main trigger to graft rejection
- Xenograft: a graft performed between different species
- Orthotopic graft: a graft placed in its normal anatomical site
- Heterotopic graft: a graft placed in a site different from that where the organ is normally located

GRAFT REJECTION

Allografts provoke a powerful immune response that results in rapid graft rejection unless immunosuppressive therapy is given. The pioneering studies of Medawar in the 1940s and 1950s firmly established that allograft rejection was due to an immune response and not a non-specific inflammatory response and subsequent studies demonstrated that T lymphocytes play an essential role in mediating rejection.

Allografts trigger a graft rejection response because of allelic differences at polymorphic genes that give rise to histocompatibility antigens (transplant antigens) of which ABO blood group antigens and human leukocyte antigens (HLAs) are the most important.

ABO blood group antigens

The ABO blood group antigens are expressed not only by red blood cells, but also by most other cell types. It is vitally important, for all types of organ allograft, to ensure that recipients do not unintentionally receive a graft that is ABO blood group incompatible otherwise naturally occurring anti-A or anti-B antibodies will likely cause hyperacute graft rejection.

Permissible transplants are from:

- group O donor to group O, A, B or AB recipient;
- group A donor to group A or AB recipient;
- group B donor to group B or AB recipient;
- group AB donor to group AB recipient.

There is no need to take account of rhesus antigen compatibility in organ transplantation.

Jean-Francois Borel, b.1933, research scientist working in Switzerland.

Sir Roy York Calne, Emeritus Professor of Surgery, the University of Cambridge, Cambridge, UK. In 1968 he performed Europe's first liver transplantation. He was associated with the world's first liver, heart and lung transplantation in 1987. He was elected Fellow of the Royal Society in 1974. He is an accomplished painter who has painted many of his transplant recipients and has had exhibitions worldwide.

Sir Peter Brian Medawar, 1915–1987, zoologist and immunologist, Director of the National Institute of Medical Research, London, UK. He shared the 1968 Nobel Prize for Physiology or Medicine with Sir Frank Macfarlane Burnet, for his research into immunological tolerance.

HLA

Allograft rejection (in blood group-compatible grafts) is directed predominantly against HLA – a group of highly polymorphic cell-surface molecules. HLA are strong transplant antigens by virtue of their special physiological role as antigen recognition units for display of antigens from foreign pathogens for recognition by T lymphocytes. Their existence was first demonstrated by Dausset in 1958, through their role in stimulating graft rejection responses, and hence their description as major histocompatibility antigens (MHA).

Summary box 82.2

Human leukocyte antigen (HLA)

- Are the most common cause of graft rejection
- Their physiological function is to act as antigen recognition units
- Are highly polymorphic (amino acid sequence differs widely between individuals)
- HLA-A, -B, -C (class I), and -DR, -DP and -DQ (class II) are most important in organ transplantation

There are two types of HLA molecule: HLA class I and HLA class II (*Table 82.2*). They are broadly similar in structure (**Figure 82.2**) but have different cell expression profiles. HLA class I antigens are present on all nucleated cells, whereas HLA class II antigens have a more restricted distribution and are expressed most strongly on antigen-presenting cells, such as dendritic cells, macrophages and B lymphocytes. T cells recognize HLA molecules via their T-cell receptor, but full T-cell activation also requires the delivery of an additional or second signal by the interaction of co-stimulatory molecules on the surface of the antigen-presenting cell and T cell (**Figure 82.3**).

TABLE 82.2 Human leukocyte antigen (HLA) class I and HLA class II molecules.

	Class I	Class II
HLA loci	HLA-A, -B and -C	HLA-DR, -DP and -DQ
Structure	Heavy chain and β_2-microglobulin	α- and β-chain
Distribution	All nucleated cells	B cells, dendritic cells, macrophages

Effector mechanisms of rejection

HLA expressed by graft cells activate T cells and stimulate them to proliferate in response to interleukin-2 (IL-2) and other T-cell growth factors. Activated CD4 T cells, through release of cytokines, play a central role in orchestrating the various effector mechanisms responsible for graft rejection (**Figure 82.4**). The cellular effectors of graft rejection include cytotoxic CD8 T cells, which recognise donor HLA class I antigens expressed by the graft and cause target cell death through the release of lytic molecules such as perforin and granzyme. Graft-infiltrating CD4 T cells, which recognise donor HLA class II antigens, mediate direct target cell damage and are also able, by releasing proinflammatory cytokines such as interferon-γ, to recruit and activate macrophages that act as non-specific effector cells. Finally, CD4 T cells provide essential T-cell help for B lymphocytes which differentiate into plasma cells and produce alloantibodies that bind to graft antigen and induce target cell injury directly or through antibody-dependent, cell-mediated cytotoxicity.

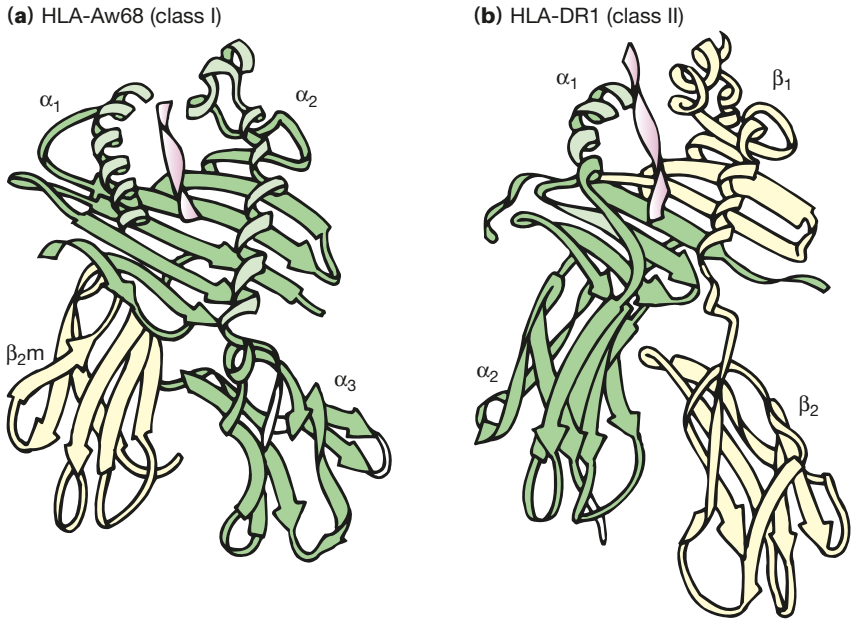

Figure 82.2 The three-dimensional structure of the extracellular domains of human leukocyte antigen (HLA) class I and class II. The α_1 and α_2 domains of class I and the α_1 and β_1 domains of class II form a cleft that is floored by a β-pleated sheet and walled by two α-helices. The cleft binds an antigenic peptide and displays it on the cell surface for recognition by a T lymphocyte. (Redrawn with permission from Stern and Wiley (1994) *Structure* **2**: 245–52.)

Jean Dausset, 1916–2009, French immunologist, Professor of Experimental Medicine at the College of France, Paris, France, shared the 1980 Nobel Prize for Physiology or Medicine with George Snell and Baruj Benacerraf for his discovery of the HLA antigens.

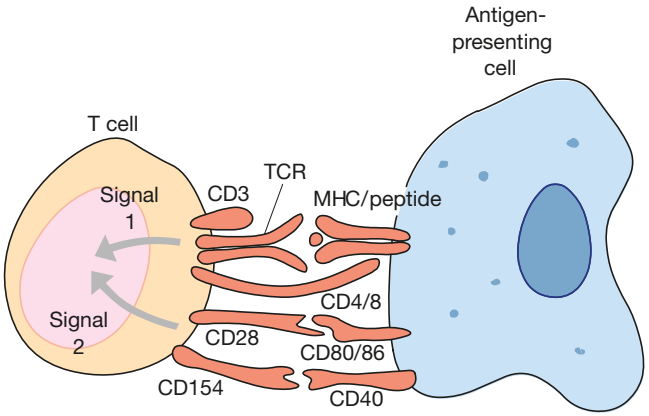

Figure 82.3 Molecular events involved in T-cell activation by an antigen-presenting cell. T-cell activation requires the delivery of two distinct signals to the T cell. The first signal is delivered by ligation of the TCR/CD3 complex with the human leukocyte antigen (HLA)/peptide complex. The second signal is delivered after the interaction between pairs of co-stimulatory molecules such as CD28 with CD80/86 and CD154 with CD40.

Summary box 82.3

Types of graft rejection

- Hyperacute rejection
  - Immediate graft destruction due to ABO or preformed anti-HLA antibodies
  - Characterised by intravascular thrombosis and interstitial haemorrhage
- Acute rejection
  - Usually occurs during first 6 months
  - T-cell dependent
  - May be cell mediated, antibody mediated or both
  - Usually reversible
- Chronic rejection
  - Occurs after first 6 months
  - Most common cause of graft failure
  - Antibodies play an important role
  - Non-immune factors contribute to pathogenesis
  - Characterised by myointimal proliferation in graft arteries leading to ischaemia and fibrosis

Types of allograft rejection

Allograft rejection can be divided into three distinct types:

1 hyperacute rejection (occurs immediately);
2 acute rejection (usually occurs in the first 6 months);
3 chronic rejection (occurs months and years after transplantation).

Allograft rejection manifests itself as functional failure of the transplant and is confirmed by histological examination. Biopsy material is obtained from renal and pancreas grafts by needle biopsy, and from hepatic grafts by percutaneous or transjugular liver biopsy. Cardiac grafts are biopsied by transjugular endomyocardial biopsy and lung grafts by transbronchial biopsy. After small intestinal transplantation, mucosal biopsies are obtained from the graft stoma or more proximally by endoscopy. A standardised histological grading system, termed the Banff classification (named after the Canadian town where the initial scientific workshop was held), defines the presence and severity of allograft rejection after organ transplantation.

Hyperacute rejection

This is due to the presence in the recipient of preformed antibodies against HLA class I antigens expressed by the donor. These arise from a previous blood transfusion, a failed transplant and pregnancy. This type of rejection also occurs if an ABO blood group-incompatible organ graft is performed inadvertently. After revascularisation of the graft, antibodies bind immediately to the vasculature, activate the complement system, and cause extensive intravascular thrombosis, interstitial haemorrhage and graft destruction within minutes and hours. Kidney transplants are particularly vulnerable to hyperacute graft rejection, whereas heart and liver transplants are relatively resistant. It is not clear why the liver is resistant to hyperacute rejection. One factor may be that it is less susceptible to ischaemia than the kidney by virtue of its dual

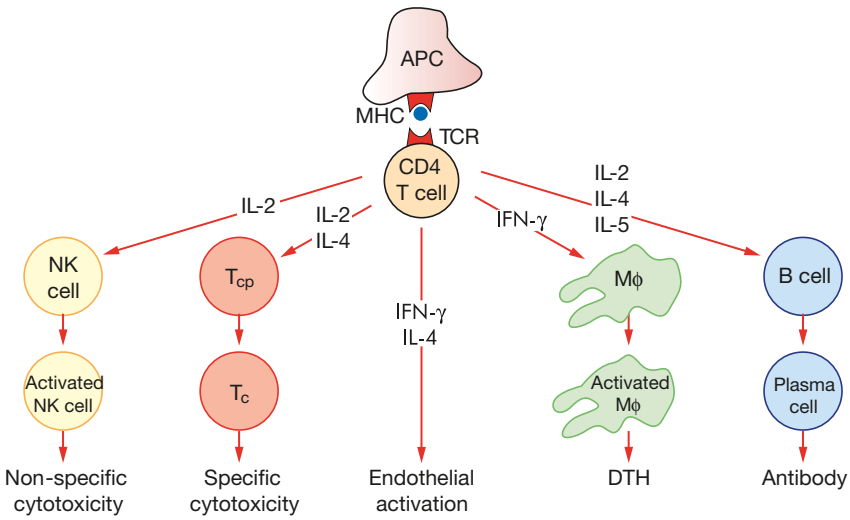

Figure 82.4 The central role of the CD4 T cell in orchestrating the various effector mechanisms responsible for allograft rejection. APC, antigen-presenting cell; DTH, delayed-type hypersensitivity; IFN-γ, interferon-gamma; IL, interleukin; MΦ, macrophage; MHC, major histocompatibility complex; NK, natural killer; Tc, T-cytotoxic cell; Tcp, T-cytotoxic precursor cell; TCR, T-cell receptor.

blood supply: 60% of the hepatic blood supply is derived from the portal vein and 40% from the hepatic artery.

Hyperacute rejection can be avoided by ensuring ABO blood group compatibility and performing a cross-match test on recipient serum to ensure that there are no clinically relevant antibodies directed against HLAs expressed by a prospective kidney donor.

Acute rejection

This usually occurs during the first 6 months after transplantation but may occur later. It is mediated predominantly by T lymphocytes, but alloantibodies may also play an important role. Acute rejection is characterised by mononuclear cell infiltration of the graft (**Figure 82.5**). The mononuclear cell infiltrate is heterogeneous and includes cytotoxic T cells, B cells, natural killer (NK) cells and activated macrophages. Antibody-mediated damage may also be present, as evidenced by the deposition of the complement component C4d within the graft microvasculature (**Figure 82.6**). All types of organ allograft are susceptible to acute rejection (typically occurring in around 20–30% of grafts). Most episodes of acute cellular rejection can be reversed by additional immunosuppressive therapy. Acute antibody-mediated rejection is more difficult to treat effectively and may require plasmaphoresis or immunoadsorption.

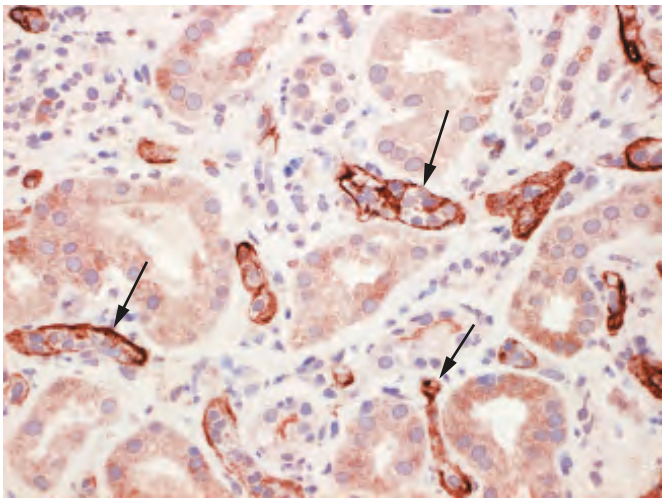

Figure 82.6 Acute antibody-mediated renal allograft rejection. There is widespread staining for the complement component C4d within the peritubular capillaries (arrows), which indicates alloantibody binding to the graft vasculature.

Chronic rejection

This usually occurs after the first 6 months. All types of transplants are susceptible to chronic rejection, and it is the major cause of allograft failure. Interestingly, the liver is more resistant than other organs to the destructive effects of chronic rejection. The pathophysiology of chronic rejection is not well understood, although the underlying mechanisms are immunological, and alloantibodies are thought to be a major cause and cellular effector mechanisms may also contribute. Alloantigen-independent factors also contribute. The risk factors for chronic rejection of a kidney transplant are:

- previous episodes of acute rejection;
- poor HLA match;
- long cold ischaemia time;
- cytomegalovirus (CMV) infection;
- raised blood lipids;
- inadequate immunosuppression (including poor compliance).

The single most important risk factor for chronic rejection after kidney transplantation is acute rejection (with vascular inflammation) and recurrent episodes of acute rejection. As non-immune factors often contribute significantly to the long-term failure of a kidney transplant, the term 'chronic allograft nephropathy' is sometimes used.

The histological picture of chronic rejection after organ transplantation is dominated by vascular changes, with the development of myointimal proliferation in arteries, which results in ischaemia and fibrosis (**Figure 82.7**). In addition to

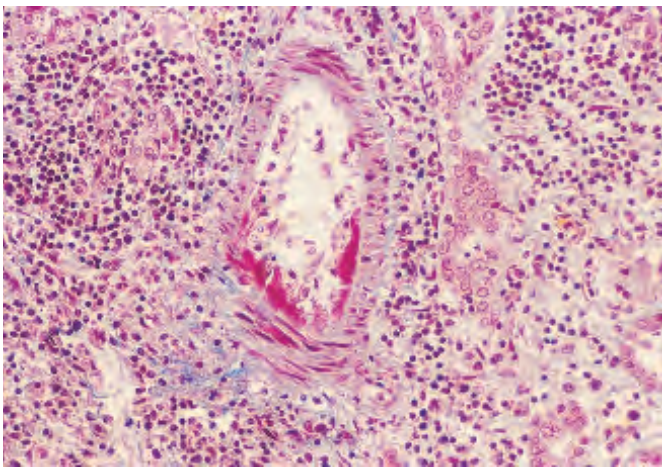

Figure 82.5 Severe acute renal allograft rejection with a heavy mononuclear cell infiltrate and intimal arteritis.

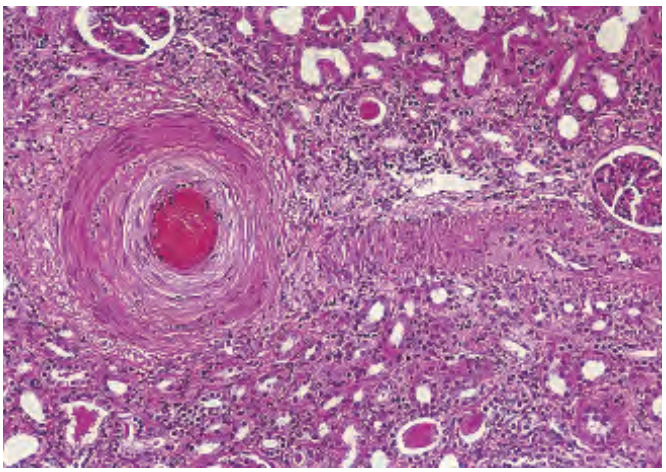

Figure 82.7 Chronic renal allograft rejection. The arteriole shows severe myointimal proliferation and luminal narrowing, resulting in ischaemic fibrosis.

vasculopathy, there are organ-specific features of chronic graft rejection. These are:

- kidney: glomerular sclerosis and tubular atrophy;
- pancreas: acinar loss and islet destruction;
- heart: accelerated coronary artery disease (cardiac allograft vasculopathy);
- liver: vanishing bile duct syndrome;
- lungs: obliterative bronchiolitis.

Chronic rejection causes functional deterioration in the graft, resulting after months or years in complete graft failure. Unfortunately, currently available immunosuppressive therapy has had little effect in preventing chronic rejection.

Graft-versus-host disease

Although the main immunological problem after transplantation is graft rejection, the reciprocal problem of graft-versus-host reaction is occasionally seen after certain types of organ transplantation. Some donor organs (particularly liver and small bowel) contain large numbers of lymphocytes, and these may react against HLAs expressed by recipient tissues, leading to graft-versus-host disease (GVHD). GVHD frequently involves the skin, causing a characteristic rash on the palms and soles. It may also involve the liver (after small bowel transplantation) and the gastrointestinal tract (after liver transplantation). GVHD is a serious and sometimes fatal complication.

HLA MATCHING

HLA molecules are encoded by the major histocompatibility complex (MHC), a cluster of genes situated on the short arm of chromosome 6 (**Figure 82.8**). The HLA class I antigens comprise HLA-A, -B and -C, and the HLA class II antigens comprise HLA-DR, -DP and -DQ. Expression of MHC genes is co-dominant, i.e. the genes on both the maternally derived and the paternally derived chromosomes are expressed. Consequently, an individual may express between 6 and 12 different HLA antigens, depending on the degree of homozygosity (shared genes) at individual loci.

The HLA haplotype inherited from each parent is usually inherited as a complete haplotype, according to simple mendelian genetics (**Figure 82.9**). In deceased donor renal transplantation (but not other types of organ transplantation), attempts are usually made to match the donor and recipient for as many of the relevant HLAs as possible. In addition to reducing the risk of graft loss from rejection, a well-matched kidney allograft that subsequently fails is less likely to cause sensitisation to the HLAs that it expresses. It is particularly important in children and young adults to avoid, where possible, grafts that are mismatched for common HLAs because, if retransplantation is required subsequently, it may be difficult to find an organ donor who does not express the antigens to which the recipient has become sensitised. In terms of organ transplantation, HLA-A, -B and -DR are the most important antigens to take into account when matching donor and recipient in an attempt to reduce the risk of graft rejection (**Figure 82.10**).

HLA matching has a relatively small but definite beneficial effect on renal allograft survival (HLA-DR > HLA-B > HLA-A). Recipients who receive well-matched renal allografts may require less intensive immunosuppression and are also troubled less by rejection episodes. It is common practice to express the degree of HLA matching between the donor and recipient in terms of whether or not there are mismatches at each locus for HLA-A, -B and -DR. A '000 mismatch' is a 'full-house' or complete match, whereas a '012 mismatch' is matched at HLA-A loci, has one mismatched HLA-B antigen and is mismatched for both -DR antigens. Deceased donor kidneys are allocated in some countries, including the UK, by a points system that optimises HLA matching but also takes into account other factors, such as time on the waiting list, sensitisation to HLA antigens and the age relationship between the donor and the recipient. Allocation of organs for transplantation must also take into account the relative size of the donor and recipient. This is not an issue in renal transplantation, and adult kidneys can be readily used for children (and vice versa). However, in the case of heart, lung, liver and

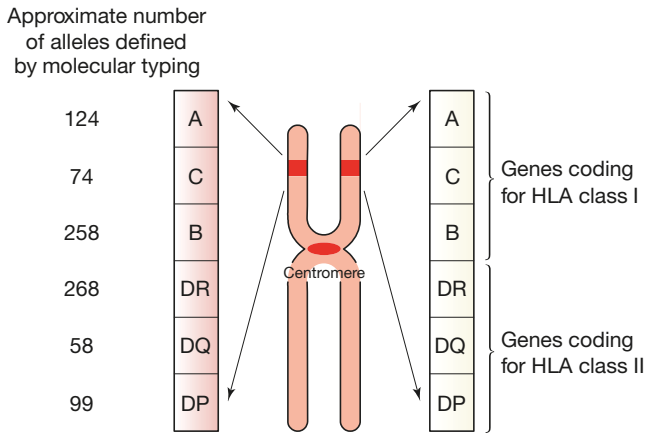

Figure 82.8 The human leukocyte antigen (HLA) system on the short arm of chromosome 6.

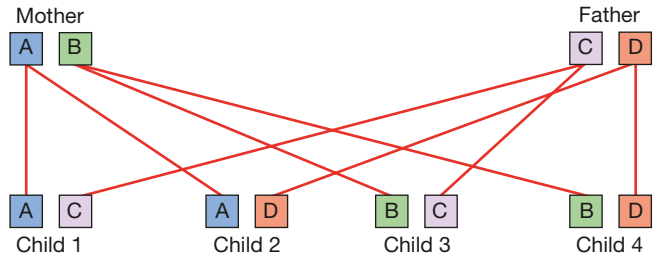

Figure 82.9 Human leukocyte antigen (HLA) inheritance. Children acquire one HLA haplotype (depicted as A–D) from each parent. As shown, child 1 shares one HLA haplotype (haploidentical) with child 2 and child 3, but does not share either haplotype with child 4. The chances that two siblings will share the same parental haplotypes, or that they will share neither HLA haplotype, is one in four. The chance that they will share one HLA haplotype is one in two.

Gregor Johann Mendel, 1822–1884, Austrian monk and naturalist, became Abbot of the Augustinian Monastery at Brunn, former Czechoslovakia and discovered the laws of inheritance by studying the edible pea. In 1865 he described 'dominant' and 'recessive' traits in hybrids. His work passed unnoticed for 35 years.

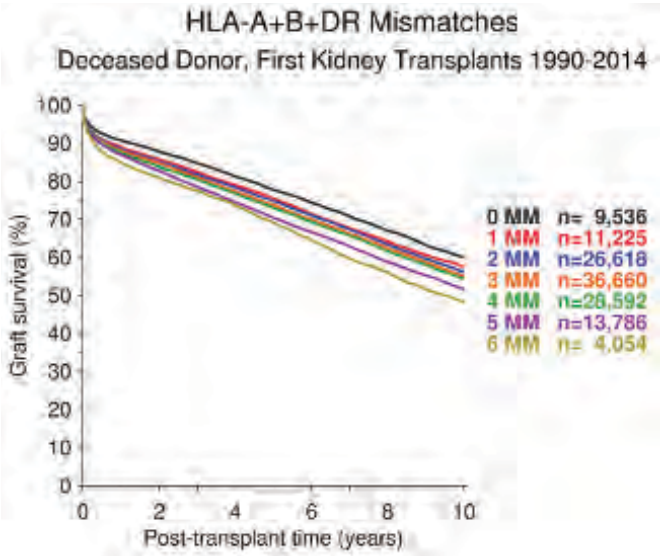

Figure 82.10 Beneficial effect of human leukocyte antigen (HLA) matching (HLA-A, -B and -DR) on first deceased donor renal allograft survival (courtesy of Collaborative Transplant Study, CTC-K-21101-0816). MM, antigen mismatch.

small bowel transplantation, it is important to consider size compatibility between the donor and the recipient. In the case of liver transplants, HLA matching does not confer an advantage and, although it is beneficial in cardiac transplantation, it is not practicable because of the relatively small size of the recipient pool and the short permissible cold ischaemic time.

THE TISSUE-TYPING LABORATORY

Successful organ transplantation requires a close working relationship between the tissue-typing laboratory and the clinical transplant team. The tissue-typing laboratory carries out three key tasks. First, they determine the HLA type ('tissue type') of all potential organ transplant recipients and organ donors. This is achieved by applying polymerase chain reaction (PCR)-based DNA-typing techniques to samples of peripheral blood. Second, they perform a cross-match test to exclude the presence in a recipient of clinically significant circulating antibodies to HLAs expressed by a potential organ donor that would result in rapid or hyperacute graft rejection. This involves incubating recipient sera with donor lymphocytes prepared from either blood or lymphoid tissue. The presence of anti-donor antibodies is detected in a conventional cytotoxic cross-match assay by adding rabbit complement, along with indicator dyes, and visualising target cell death. More often a flow cytometric cross-match is performed as well as, or instead of, a cytotoxic cross-match. Third, the tissue-typing laboratory determines the HLA specificity of circulating anti-HLA antibodies in recipients before and after organ transplantation to guide organ allocation and immunosuppressive therapy. This task has been revolutionised by the availability of solid phase assays, particularly Luminex technology, where patient sera are incubated with a panel of latex beads coated with purified HLA molecules and antibody binding detected by flow cytometric analysis.

Patients on the renal transplant waiting list should be screened for the development of HLA antibodies on a regular basis and especially after potential priming to HLA antigens by blood transfusion.

If, when considering renal transplantation, the cross-match test is strongly positive, transplantation should not proceed, or hyperacute rejection is likely. Antibodies directed against HLA class II antigens, unlike those to HLA class I, do not usually cause hyperacute rejection but are associated with acute rejection and a poor clinical outcome. Patients awaiting heart transplantation are also screened for the presence of HLA antibodies and those with preformed antibodies are subjected to a prospective cross-match test. Although heart allografts rarely undergo hyperacute rejection, transplantation in the presence of a positive cross-match is associated with graft loss from accelerated acute rejection. Even in the presence of a strongly positive cross-match test, liver transplants rarely undergo hyperacute rejection, although long-term survival is reduced.

IMMUNOSUPPRESSIVE THERAPY

A range of different agents are available that act at different sites during T-cell activation to prevent rejection (*Table 82.3* and **Figure 82.11**). They can be classified according to their principal mode of action.

Calcineurin inhibitors (ciclosporin and tacrolimus)

Ciclosporin and tacrolimus are the mainstay of most modern immunosuppressive protocols for organ transplantation. Although structurally distinct, they exert their principal immunosuppressive effect through the same intracellular pathway. Each of the two agents binds within the T cell to a cytoplasmic protein or immunophilin (ciclosporin binds

TABLE 82.3 Immunosuppressive agents.

Agent	Principal mode of action
Corticosteroids	Widespread anti-inflammatory effects
Azathioprine	Prevents lymphocyte proliferation
Mycophenolic acid preparations	Prevents lymphocyte proliferation
Calcineurin inhibitors (ciclosporin/tacrolimus)	Blocks IL-2 gene transcription
mTOR inhibitors	Blocks IL-2 receptor signal transduction
ALG	Depletion and blockade of lymphocytes
Anti-CD25 mAb	Targets activated T cells
Anti-CD52 mAb	Depletion of lymphocytes
Anti-CD20	Depletion of B lymphocytes
CTLA-4Ig	Blocks T-cell costimulation

IL-2, interleukin-2.

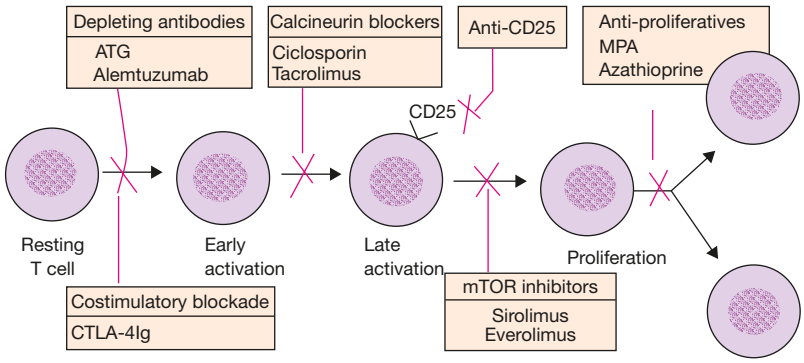

Figure 82.11 Site of action of immunosuppressive agents on T cell. ATG, anti-thymocyte globulin; MPA, mycophenolic acid derivatives; mTOR, mammalian target of rapamycin.

to cyclophilin and tacrolimus to FK-binding protein). The resulting immunophilin–drug complex then blocks the activity of calcineurin (a phosphatase) within the cytoplasm of the T cell. Calcineurin plays a critical role in facilitating the transcription of IL-2, the main T-cell growth factor, and other cytokines after T-cell activation. By blocking cytokine synthesis, ciclosporin and tacrolimus exert a potent immunosuppressive effect. The two agents share a number of side effects, the most notable of which is nephrotoxicity (*Table 82.4*). Ciclosporin sometimes causes cosmetic side effects (hirsutism and gingival hypertrophy) that may be distressing, particularly in younger female recipients. The calcineurin inhibitors (CNIs) have a relatively small therapeutic window. Their immunosuppressive action, as well as their side effects, is dependent on their blood concentration, and monitoring of whole-blood drug levels is an important guide to optimal therapy. Ciclosporin and tacrolimus are broadly equivalent in terms of long-term graft survival but increasing evidence suggests that tacrolimus is more effective in reducing acute rejection. The choice between the two agents depends on the preference of the transplant unit and on individual patient tolerance to the different side effects of the two agents.

TABLE 82.4 Agent-specific side effects of immunosuppressive agents used in organ transplantation (all immunosuppressive agents increase the risk of infection).

Agent	Side effects (not comprehensive)
Corticosteroids	Hypertension, dyslipidaemia, diabetes, osteoporosis, avascular necrosis, cushingoid appearance
Azathioprine	Leukopenia, thrombocytopenia, hepatotoxicity, gastrointestinal symptoms
Mycophenolic acid derivatives	Leukopenia, thrombocytopenia, gastrointestinal symptoms
Ciclosporin	Nephrotoxicity, hypertension, dyslipidaemia, hirsutism, gingival hyperplasia
Tacrolimus	Nephrotoxicity, hypertension, dyslipidaemia, neurotoxicity, diabetes
mTOR inhibitors	Thrombocytopenia, dyslipidaemia, pneumonitis, impaired wound healing
ALG	Infusion reactions, leukopenia and thrombocytopenia
Anti-CD25	Uncommon
CTLA-4Ig	? Increased risk of PTLD
Anti-CD52	Infusion reaction and autoimmune disease
Anti-CD20	Infusion reactions and pulmonary toxicity

ALG, anti-lymphocyte globulin; mTOR, mammalian target of rapamycin; PTLD, post-transplant lymphoproliferative disease.

Antiproliferative agents (azathioprine and mycophenolate)

Lymphocytes are among the most rapidly proliferating cells in the body, and lymphocyte proliferation and clonal expansion are an integral part of the immune response to an allograft. The antiproliferative agents available for immunoprophylaxis are azathioprine and mycophenolic acid preparations (mycophenolate mofetil [MMF] and mycophenolic acid sodium [MPAS]). Azathioprine is converted in the liver to its active metabolite, 6-mercaptopurine, which blocks purine metabolism and thereby inhibits cellular proliferation. Mycophenolic acid (MPA) preparations are more expensive than azathioprine but have largely replaced it as the agent of choice. After ingestion, MMF is converted to its active metabolite MPA. It inhibits the enzyme inosine monophosphate dehydrogenase, which is the rate-limiting enzyme in the de novo pathway of purine nucleotide synthesis. As lymphocytes do not have a salvage pathway for purine synthesis, their ability to proliferate is selectively impaired. The main side effects of azathioprine and MPA are bone marrow suppression and gastrointestinal symptoms.

Steroids

Steroids are an important component of many immunosuppressive regimens. Glucocorticoids are potent anti-inflammatory agents and have wide-ranging effects on the immune response. As a result of their numerous and well-known side effects, some centres attempt to gradually withdraw steroids from patients who have stable graft function after transplantation, but this sometimes precipitates a rejection episode and necessitates recommencement of steroids.

Antibody therapies

Monoclonal antibodies directed against the IL-2 receptor on T lymphocytes (CD25) are commonly given at the time of

transplantation to temporarily augment the effects of calcineurin blockade during the early post-transplant period. Their effect lasts for a few weeks only and they lack any significant agent-specific side effects. Polyclonal antibody (anti-thymocyte globulin [ATG]) and monoclonal antibody preparations (alemtuzumab [anti-CD52 expressed on T cells and dendritic cells]) are also quite widely used as more potent and alternative induction agents. They cause a temporary depletion of circulating lymphocytes that reduces rejection but may lead to an increase in infection and malignancy. In addition to their use as induction agents, antibody preparations may be used to treat acute rejection episodes that fail to respond to steroid therapy.

The monoclonal anti-CD20 antibody (rituximab) depletes B lymphocytes, and is widely used as a component of protocols to enable ABO and HLA antibody-incompatible renal transplantation. It may also be helpful for the treatment of antibody-mediated acute rejection, although its efficacy here is limited because it does not deplete antibody-producing plasma cells.

Mammalian target of rapamycin inhibitors (sirolimus and everolimus)

Sirolimus and its structural analogue everolimus are, similar to tacrolimus, macrolides that bind within T lymphocytes to FK-binding protein. However, their mode of action is completely different to that of both ciclosporin and tacrolimus. They act by inhibiting an intracellular kinase called mammalian target of rapamycin (mTOR) and interfere with intracellular signalling from the IL-2 receptor, arresting T-cell division in the G1 phase. In contrast to CNIs they are not nephrotoxic. However, their side-effect profile includes lymphocele formation, impaired wound healing, an adverse effect on the blood lipid profile, thrombocytopenia and very occasionally pneumonitis. The mTOR inhibitors may have anti-tumour activity and the potential value of this effect in transplant recipients is under investigation. Although the negative effect on wound healing and lymphocele formation limits the immediate use of mTOR inhibitors after transplantation, switching from CNIs to mTOR inhibitors is sometimes used as a strategy to minimise CNI-induced nephrotoxicity.

T-cell co-stimulatory blockers

CTLA-4Ig (belatocept, LEA29Y) is a fusion protein comprising the extracellular domain of CTLA-4 fused to human immunoglobulin (Ig) Fc. It binds to the co-stimulatory ligands CD80 and CD86 expressed on antigen-presenting cells and, as a result, prevents them from delivering the co-stimulatory signals to the T cells that are required for full T-cell activation. It has recently been shown in renal transplantation to provide an effective alternative to CNIs when given by regular intravenous injection, thereby avoiding the metabolic, cardiovascular and nephrotoxic effects of CNIs. Although its future looks very promising, a potential concern is that it may be associated with an increased risk of post-transplant lymphoproliferative disease (PTLD).

Immunosuppressive regimens

When selecting an immunosuppressive regimen, the challenge is to provide levels of immunosuppression that are sufficient to protect the graft from rejection without exposing the recipient to excessive risk from infection and malignancy as a result of non-specific immunosuppression. Immunosuppressive therapy is started at the time of transplantation and is continued indefinitely (as maintenance therapy), although the requirement for immunosuppression is highest in the first few weeks after transplantation when the risk of acute rejection is greatest. Immunosuppressive protocols vary, but all use a combination of immunosuppressive agents acting at different points in the pathway of lymphocyte activation. Most currently include a CNI (ciclosporin or tacrolimus) as the main agent, and this is often supplemented with anti-CD25 monoclonal antibody induction therapy. CNIs are usually combined with an anti-proliferative agent (most often MMF) and steroids, so-called triple therapy. Less often, a CNI is used with an anti-proliferative agent alone or with steroids alone (dual therapy). When there is particular concern about acute rejection, polyclonal or monoclonal antibody preparations are administered followed by a CNI, an anti-proliferative agent and steroids.

Summary box 82.4

Principles of immunosuppression

- Principles are the same for all types of organ transplantation
- Aim is to maximise graft protection with minimum of side effects
- Most regimens are based on calcineurin blockade and include steroids and an anti-proliferative agent
- Need for immunosuppression is highest in the first 3 months but indefinite treatment is needed
- Immunosuppression increases the risk of infection and malignancy

The principles of immunoprophylaxis are similar for all types of organ transplantation. Interestingly, liver grafts seem to be less susceptible to rejection for reasons that are still unclear. The mTOR inhibitors have been shown to be effective immunosuppressive agents for preventing acute rejection after kidney transplantation, and they provide a non-nephrotoxic alternative to CNIs for maintenance therapy. They have a similar safety profile to CNIs in terms of post-transplant infection, but some of their agent-specific side effects are of potential concern and their clinical niche has still to be fully determined. Similarly, the potential role that CTLA-4Ig will find as an alternative to CNIs remains to be seen.

Acute rejection occurs in up to around 30% of transplant recipients but usually responds to a short course of high-dose steroid therapy. If the response to steroids is inadequate or if acute rejection recurs, acute rejection can often be treated successfully by recourse to anti-lymphocyte globulin (ALG) therapy.

COMPLICATIONS OF IMMUNOSUPPRESSION

As well as the agent-specific side effects already mentioned, the immunosuppressive agents used in organ transplantation cause non-specific immunosuppression and increase the risk of both infection and malignancy.

Summary box 82.5

Side effects of non-specific immunosuppression

- Infection
  - Transplant recipients are at high risk of opportunistic infection, especially by viruses
  - Bacterial and fungal infections are also common
  - Risk of infection is greatest during the first 6 months
  - Chemoprophylaxis is important for high-risk patients
  - Viral infection may result from reactivation of latent virus or from primary infection
  - Cytomegalovirus is a major problem
  - Pre-transplant vaccination against community-acquired infection should be considered
- Malignancy
  - Most types of cancer are more common after transplantation (approximately twofold)
  - Recipients, especially children, are at risk of post-transplant lymphoproliferative disease
  - There is a very high risk of squamous cancer of the skin and recipients should have a regular skin review

Infection

Transplant recipients receiving immunosuppressive therapy are at high risk from opportunistic infection, especially by viruses. Opportunistic infection is a potential problem in all transplant recipients, but those receiving aggressive immunosuppressive therapy are most at risk. Chemoprophylaxis is important in high-risk recipients, and early recognition followed by prompt and aggressive treatment of infection is essential in all transplant recipients. Pre-transplant vaccination against community-acquired infections should be considered.

Bacterial infection

The risk of bacterial infection is highest during the first month after transplantation. Transplant recipients are, similar to any patient undergoing major surgery, at risk of bacterial infections in the wound, respiratory tract and urinary tract. It is standard practice to give a broad-spectrum antibiotic to cover the perioperative period as prophylaxis against wound infection and possible bacterial contamination of the donor organ. The risk of bacterial infection is greatest in transplant recipients who are critically ill before or after surgery, and are in the intensive care unit with indwelling catheters and lines. After recovery from surgery, the risk of bacterial infection is much reduced. Tuberculosis is a concern in patients who have previously had mycobacterial infection and in patients from the Indian subcontinent, and it is usual to give them chemoprophylaxis for a period of 6–12 months after transplantation.

Viral infection

The risk of viral infection is highest during the first 6 months after transplantation and the most common problem is CMV infection. CMV disease may arise because of either reactivation of latent infection or primary infection that can be transmitted by an organ from a CMV-positive donor. Recipients at most risk from CMV infection are those who are CMV seronegative (i.e. those who have not been infected previously with CMV) and receive an organ from a CMV-seropositive donor (about half of all UK donors are CMV seropositive). Unfortunately, matching seronegative donors with seronegative recipients is not practicable. Without prophylaxis, CMV disease typically presents at 4–8 weeks with a high swinging fever, lethargy and leukopenia. The severity of the disease is variable and the clinical picture depends on the organ system most affected. It may present as:

- pneumonia
- gastrointestinal disease
- hepatitis
- retinitis
- encephalitis.

Severe CMV disease is potentially fatal. Prophylaxis for CMV consists of administration of antiviral agents, most commonly valganciclovir; aciclovir and valaciclovir are cheaper but less effective alternatives. A diagnosis of active CMV infection is confirmed by PCR to detect viral DNA in whole blood, and by histological examination of biopsy material. Treatment is with antiviral agents (either oral valganciclovir or intravenous ganciclovir), and is more effective when given pre-emptively on the basis of increased viral load detected by quantitative PCR analysis of peripheral blood.

Herpes simplex virus (HSV) infection is common after transplantation and is usually due to reactivation of latent infection. It causes mucocutaneous lesions around the mouth and sometimes the genitalia. These usually respond to topical treatment with aciclovir, but in severe cases systemic antiviral therapy is needed. Disseminated HSV infection is rare.

BK virus is emerging as an important cause of graft dysfunction after renal transplantation. Infection with BK virus is almost universal during childhood, with latent infection in the epithelium of the urinary tract. Immunosuppression causes lytic BK virus replication with graft involvement in 1–5% of renal transplants. The only effective treatment is to reduce the level of immunosuppression to allow natural immune mechanisms to regain control of the virus.

Herpes zoster infection, as a result of reactivation of latent varicella-zoster virus, occurs more frequently in transplant recipients and should be treated with systemic antiviral therapy. Primary varicella-zoster virus infection (chickenpox) is potentially very serious in immunosuppressed patients but is relatively uncommon because most adults have acquired immunity.

Fungal infection

Pneumocystis jiroveci (previously designated *Pneumocystis carinii* and wrongly classified as a protozoa) is one of the more important fungal infections after transplantation. It occurs

during the first few months and presents with respiratory symptoms. The diagnosis is made by examination of bronchoalveolar lavage fluid or lung biopsy material for evidence of fungal infection (Figure 82.12). Chemoprophylaxis is highly effective and usually continued for up to 6 months after transplantation.

Other types of invasive fungal infections are uncommon in renal transplant recipients but infection with *Candida* or *Aspergillus* spp. is more common after other types of organ transplantation. Fungal infection usually occurs in the first 3 months after transplantation, and early diagnosis and aggressive treatment are essential to avoid fatal infection.

Malignancy

After transplantation, there is an increased risk of developing most types of malignant disease but the risk is particularly high for those types of tumour in which viral infection plays an aetiological role. The increased risk of malignancy is particularly high for skin cancer and PTLD. Most of the skin cancers seen are squamous cell carcinomas, but basal cell carcinoma and malignant melanoma are also more common than in the general population. The risk of skin cancer after transplantation rises with age and exposure to sunlight, and it has been predicted that 50% of transplant recipients will develop a skin malignancy within 20 years of transplantation. Patients must be warned of this risk before they undergo transplantation and be advised to take precautions to protect their skin from excessive sunlight. They should undergo regular review of their skin to detect early malignancy, and when malignant lesions occur they must be treated promptly and aggressively.

PTLD is an abnormal proliferation of B lymphocytes, usually in response to Epstein–Barr virus infection. The condition presents in a variety of ways including as an infectious mononucleosis-type illness or lymphadenopathy, or with involvement of extranodal sites such as the tonsils, gastrointestinal tract, lung, liver or the transplanted organ (Figure 82.13). PTLD occurs in around 1–3% of kidney and liver transplant recipients and the incidence is considerably higher in children. Those patients at most risk are those who have received aggressive immunosuppression. PTLD is a serious condition with an overall mortality rate of up to 50%. If it is identified at an early stage, reduction or cessation of immunosuppressive therapy may cause disease regression and result in a cure. Chemotherapy is often given and antiviral therapy, surgery and radiotherapy may also have a role in treating established disease. Disseminated PTLD and central nervous system (CNS) involvement have a very poor prognosis.

Transplant recipients also have a 300-fold increased risk of developing Kaposi's sarcoma, although this malignancy is still very uncommon after transplantation.

ORGAN DONATION

The number of organs required to satisfy the needs of transplantation far exceeds the number of donor organs available. In the case of renal transplantation in the UK there are approximately 6000 patients waiting for transplantation,

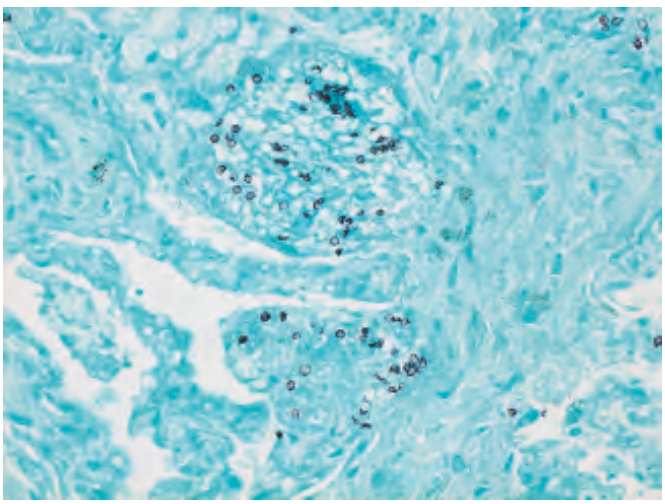

Figure 82.12 Transbronchial lung biopsy from a renal allograft recipient with *Pneumocystis jiroveci* pneumonia. The silver stain used reveals fungal cysts, each containing several intracystic bodies or spores, distributed widely within the biopsy material.

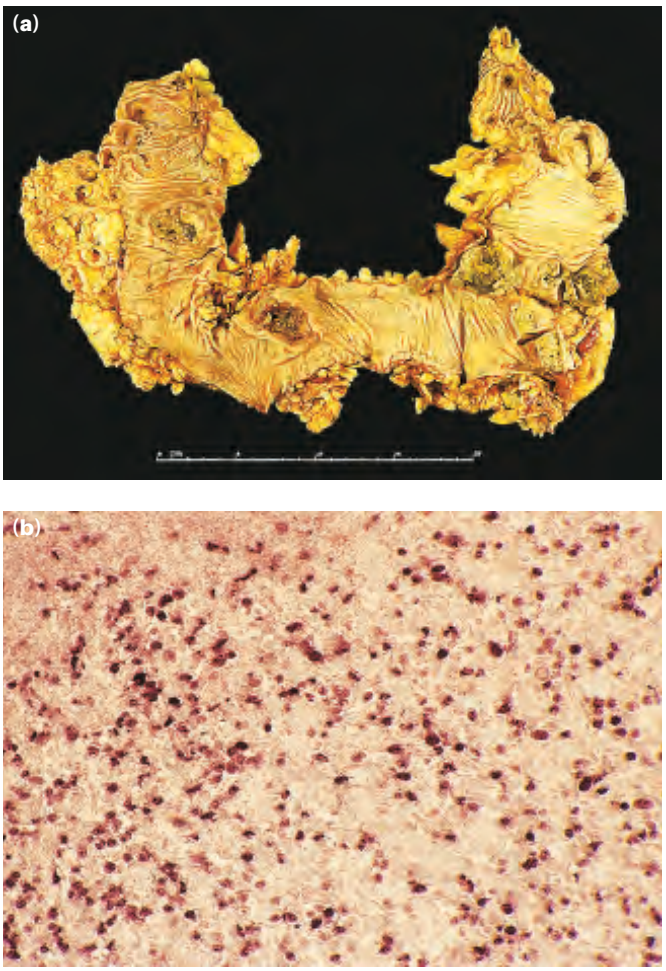

Figure 82.13 **(a)** Intestinal post-transplant lymphoproliferative disease (PTLD). Note multiple lesions in the terminal ileum and colon. **(b)** Atypical B lymphocytes stained positive with a probe for Epstein–Barr virus DNA (courtesy of C Watson, R Chavez-Cartaya and D Wight).

but only around 3000 transplantations performed annually, which has led to a median waiting time for transplantation of around 3 years. Similar shortages exist for liver and pancreas transplantation. For cardiothoracic organs the shortage is even worse and not all patients who might benefit from transplantation are listed.

Organs may be obtained from living donors or from deceased donors (DD) and DD may be either brain-stem-dead, heart-beating donors (donation after brain death or DBD donors) or donation after circulatory death (DCD) donors. Living donation is limited to donation of the kidney and, to a much lesser extent, liver or lung lobe. DBD donors provide most of the organs for transplantation for all organ types, although DCD donors provide an increasing number of kidneys, livers, pancreas glands and lungs for transplantation. The approach to referral and consent for organ donation varies between countries. Some have 'required request' or 'required referral' systems in place, where all patients dying in intensive care settings have to be referred for their potential suitability to be organ donors assessed. Some countries (e.g. Austria and Spain) have an 'opt-out' or 'presumed consent' system, where the assumption is made that individuals wished to donate their organs for transplantation unless they specifically registered their objection before death. There is debate about whether such a policy alone increases organ donation and a concern expressed by some that individuals who may not have wanted to become organ donors may fail to opt out before death, and that conflict may occur with relatives and next of kin who may oppose organ donation.

Summary box 82.6

Overcoming the shortage of organs for transplantation

- Maximising donation after brain-death (DBD) donation
- Use of marginal DBD deceased donors
- Use of donation after circulatory death (DCD) donor
- Increased use of split-liver transplantation
- Increased living donor kidney (and liver) transplantation

Donation after brain death donors

Most DD organs are obtained from patients in whom brain-stem death has been diagnosed. Such donors were previously called 'heart-beating deceased donors' and in most brain death results from stroke or traumatic head injury. Brain death occurs when severe brain injury causes irreversible loss of the capacity for consciousness combined with the irreversible loss of the capacity for breathing. In most countries, it is accepted that the condition of brain death equates in medical, legal and religious terms with death of the patient. The concept of brain death arose through necessity in the management of patients with irreversible brain damage on life support when there was no prospect for recovery. It was not in the interest of such patients, their relatives or the hospital in which they were being treated to delay their inevitable demise by continuing with futile life support. Acceptance of the concept of brain death had major implications for organ transplantation because it allowed the possibility for removal of viable organs from brain-dead patients before their circulation failed.

In the UK and many other countries, brain death is defined in terms of permanent functional death of the brain stem as neither consciousness nor spontaneous respiration is possible in the absence of a functional brain stem. A diagnosis of brain-stem death should be considered only when certain preconditions have been met. The patient must have suffered major brain damage of known aetiology, be deeply unconscious and require ventilatory support. Particular care must be taken to ensure that muscle relaxant agents and drugs with known CNS depressant effects are not contributing to the clinical picture. Hypothermia, profound hypotension, and metabolic or hormonal conditions that may contribute to CNS depression and confound the diagnosis of brain-stem death must also be excluded. When the necessary preconditions have been satisfied, formal clinical assessment of the brain-stem reflexes can be undertaken (*Table 82.5*). The UK guidelines state that the tests should be performed on two separate occasions by two clinicians experienced in this area. At least one of the two clinicians should be a consultant and neither should be connected with the transplant team. The time that must elapse between the two sets of brain-stem tests is not specified in the guidelines and is determined on the basis of clinical judgement. In the UK, there is no requirement to perform electrophysiological or brain perfusion studies to aid the diagnosis of brain-stem death. Particular care is required in the diagnosis of brain-stem death in neonates and infants.

Donation after circulatory death donors

The number of potential DBD donors has remained relatively static or even declined as a result of changes in neurosurgical practice and improved road safety. To address the rising demand for organ transplantation there has been a major trend towards increasing use of organs from DCD donors.

TABLE 82.5 Clinical testing for brain-stem death.

Absence of cranial nerve reflexes	Pupillary reflex
	Corneal reflex
	Pharyngeal (gag) and tracheal (cough) reflex
	Oculovestibular (caloric) reflex
Absence of motor response	The absence of a motor response to painful stimuli applied to the head/face and the absence of a motor response within the cranial nerve distribution to adequate stimulation of any somatic area is an indicator of brain-stem death. The presence of spinal reflexes does not preclude brainstem death
Absence of spontaneous respiration	After pre-ventilation with 100% O_2 for at least 5 minutes, the patient is disconnected from the ventilator for 10 minutes to confirm absence of respiratory effort, during which time the arterial Pco_2 level should be >8 kPa (60 mmHg) to ensure adequate respiratory stimulation. To prevent hypoxia during the apnoeic period, O_2 (6 L/min) is delivered via an endotracheal catheter

DCD donors can be grouped according to the Maastricht classification as follows:

- category 1: dead on arrival at hospital;
- category 2: resuscitation attempted without success;
- category 3: 'awaiting cardiac arrest' after withdrawal of support;
- category 4: cardiac arrest while brain dead;
- category 5: cardiac arrest and unsuccessful resuscitation in hospital.

Maastricht categories 1, 2 and 5 donors are sometimes referred to as uncontrolled DCD donors. The warm ischaemic time of organs from these three categories of donor is usually longer and less predictable than in the case of categories 3 and 4 (controlled) donors. Most DCD donor organs used for transplantation in the UK, USA and several other European countries are from controlled (category 3) donors who have died in intensive care after planned withdrawal of futile cardiorespiratory support.

Kidneys may be also be recovered from carefully selected patients who are dead on arrival at the hospital or who have died after unsuccessful resuscitation. In Spain and France most DCD kidneys are obtained from uncontrolled donors.

Evaluation of the deceased donor

After a deceased donor has been referred to the transplant team with a view to organ donation, the general suitability of the potential organ donor must be carefully assessed. Particular care must be taken to assess the donor from the point of view of transmissible infectious agents and malignancy. The medical history should be scrutinised and evidence sought of risk factors for human immunodeficiency virus (HIV) and hepatitis B and C virus infection, such as intravenous drug abuse. The presence of Creutzfeldt–Jakob disease is an absolute contraindication to organ donation. Organs from HIV-infected donors should not be used for transplantation, except sometimes in recipients who are already infected by HIV. Hepatitis B infection (in most countries) and active systemic sepsis, e.g. major abdominal infection, are contraindications to donation. The presence of malignancy within the past 5 years is usually an absolute contraindication to organ donation with the exceptions of primary tumours of the CNS, non-melanotic tumours of the skin and carcinoma *in situ* of the uterine cervix. If there are no general contradictions to organ donation, consideration is then given to organ-specific selection criteria.

As a result of the high demand for donor organs there has been a progressive relaxation in the organ-specific selection criteria. The chronological age of the donor is less important than the physiological function of the organs under consideration for transplantation.

The organs to be donated should generally be free from primary disease. Potential kidney donors should have a reasonable urine output and relatively normal serum urea and creatinine, although acute terminal elevations are acceptable. Liver donors should not have hepatic disease, although impaired liver function tests are common in deceased donors and do not necessarily preclude donation. Heart donors should have a normal electrocardiogram and, in doubtful cases, echocardiography may be necessary. For lung donors the chest radiograph and gas exchange should be satisfactory, and bronchial aspirates should be free from fungal and bacterial infection. Elevations of blood glucose and serum amylase are not uncommon in deceased donors and do not preclude pancreas donation. The use of organs from suboptimal or 'marginal' deceased donors has increased markedly in an attempt to address the demand for transplantation. The definition of a marginal donor depends on the organs being considered for transplantation and varies between countries. In the case of kidney transplantation an extended criteria donor is defined in the USA as a donor age >60 years or one between the ages of 50 and 60 years with two of the following: hypertension, death from stroke and a terminal creatinine >132 mmol/L. Organs from 'marginal donors' generally lead to less satisfactory transplant outcomes than those from standard donors.

Organ recovery from deceased donors

In DBD donors, once brain-stem death has been confirmed, management of the donor is aimed at preserving the functional integrity of the organs to be recovered. Brain-stem death produces profound metabolic and neuroendocrine disturbances, leading to cardiovascular instability. Careful monitoring and management of fluid balance is essential. Vasopressin is often given to allow reduction or cessation of catecholamine pressors and, along with DDAVP, to treat diabetes insipidus. Donors are also usually given methylprednisolone to aid fluid and metabolic management, together with triiodothyronine (T_3) to help cardiovascular stability.

Recovery of multiple organs from a DBD donor requires cooperation between the thoracic and abdominal surgical teams. A midline abdominal incision and median sternotomy are used to obtain access. After dissection of the organs to be recovered, they are perfused *in situ*. The heart is perfused with cold cardioplegia solution via a cannula in the ascending aorta and the lungs are perfused via a cannula in the pulmonary artery. The abdominal organs are perfused with chilled organ preservation solution via an aortic and portal cannula. Blood and perfusate are vented from the left atrial appendage and the inferior vena cavae. This produces rapid cooling of the organs, reduces their metabolic activity and preserves their viability. Additional surface cooling of the abdominal organs may be achieved by application of saline ice slush. The heart and lungs are excised simultaneously with the liver and pancreas, followed by the kidneys, either en bloc or separately. The extent to which the abdominal organs are dissected before cold flush depends on the preference of the surgical team. Some surgeons perform minimal dissection before cold perfusion and complete the dissection

Maastricht is a city in the province of Limburg, in The Netherlands.

of the abdominal organs *in situ* or on the back table after the organs have been removed en bloc. During recovery of the liver, care is taken to ensure that, if there is an aberrant hepatic artery arising from the superior mesenteric artery, it is included in the aortic patch. An adult donor liver cannot be transplanted into a child because of the size mismatch, and there are insufficient deceased paediatric donor livers available for transplantation. One solution is to undertake split-liver transplantation, which was first performed by Pichlmayr in 1988. The liver from a deceased donor is split and the left lobe or left lateral segments are used for a child and the right lobe for an adult recipient **(Figure 82.14)**.

When removing the donor kidneys care is taken to ensure that any polar renal arteries are included on an aortic patch with the renal artery **(Figure 82.15)**. In older kidney donors with atherosclerosis the aortic segment may be too diseased to use as an arterial patch, and the donor renal artery and any polar arteries are divided shortly after their origin and, if necessary, reconstructed before implantation **(Figure 82.16)**. In the case of the pancreas, a Y graft of donor iliac artery is excised and used to reconstruct the divided splenic and superior mesenteric arteries of the graft before implantation **(Figure 82.17)**.

In DCD donors there is an inevitable period of warm ischaemia (up to 45 minutes is acceptable) between the diagnosis of death (cardiorespiratory arrest) and cold perfusion of the organs. The aim during organ recovery is to minimise the period of warm ischaemia, although the approach used differs according to whether the donor is a controlled or uncontrolled DCD donor. It is important to note that only around 50% of all patients considered as potential controlled DCD donors have a cardiorespiratory arrest within the period of time (usually 3 hours) considered practicable for the surgical team to stand by for organ recovery. After cardiorespiratory arrest there is an obligatory 'hands off' period before certification of death of at least 5 minutes, before the surgical procedure for organ recovery can begin. If not already in the operating theatre, the DCD donor is transferred immediately to the operating room and the abdomen opened to allow rapid cannulation of the aorta and cold perfusion of the organs to be recovered. In the case of uncontrolled DCD donors the warm ischaemic time can be minimised by rapid insertion of a double balloon catheter introduced into the aorta via a femoral cut-down and used to cool the kidneys *in situ* by chilled perfusate preferably within 30 minutes of circulatory arrest **(Figure 82.18)**. This allows time to gain consent from relatives for organ donation to proceed if it is not already available and to assemble the surgical team for organ recovery.

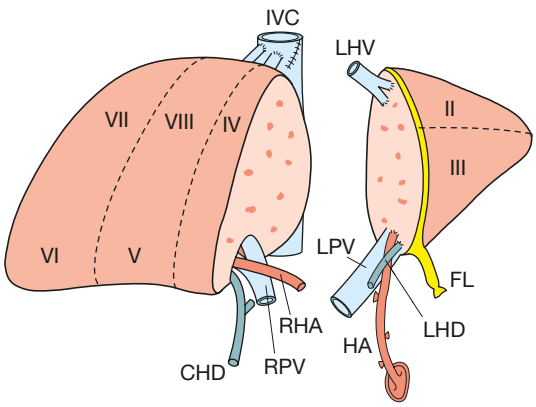

Figure 82.14 An adult liver may be split (according to Couinard's segments) so that the left lateral segment (segments II and III) can be transplanted into a child and the right lobe (together with segment IV) can be transplanted into an adult. CHD, common hepatic duct; FL, falciform ligament; HA, hepatic artery (on aortic patch); IVC, inferior vena cava; LHD, left hepatic duct; LHV, left hepatic vein; LPV, left portal vein; RHA, right hepatic artery; RPV, right portal vein.

Figure 82.15 Deceased donor kidney with multiple renal arteries on an aortic patch. The aortic patch has been shortened to limit the length of the anastomosis needed when joining the donor patch to the side of the recipient external iliac artery (Medical Photography, Addenbrooke's Hospital).

Figure 82.16 Deceased donor kidney from elderly (>70 years) donor illustrating the technical challenges of using kidneys from marginal donors. The aorta shows severe atherosclerosis with extensive plaque formation and ulceration, and is not suitable for use as an aortic patch. A lower polar artery has already been divided. The two arteries can be joined together before implantation or implanted separately.

Rudolph Pichlmayr, 1932–1997, surgeon, Hannover, Germany.

Figure 82.17 Donor pancreas viewed from the posterior aspect after preparatory bench surgery. The duodenal component of the graft has been sutured closed proximally and distally, and a Y graft of donor iliac artery used to reconstruct the divided splenic and superior mesenteric arteries. The bile duct (ligated) and portal vein are anterior and not seen in this view.

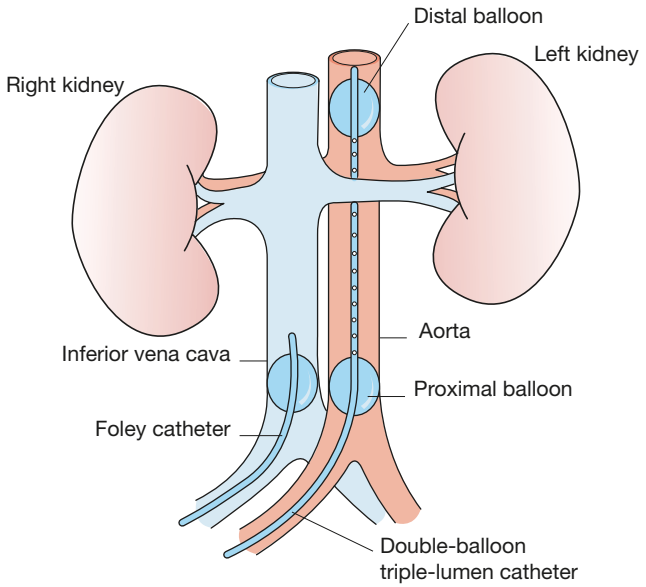

Figure 82.18 *In situ* perfusion of kidneys in a non-heart-beating donor (donation after cardiac death [DCD]). A double-balloon aortic catheter is introduced through a groin incision and 10–15 litres of chilled preservation solution is administered. The perfusate is vented through a Foley catheter introduced into the femoral vein.

After removal from the donor, the organs may undergo a further flush with chilled preservation solution before they are placed in double or triple sterile bags and stored at 4°C by immersion in ice, while they are transported to the recipient centre and await implantation. Once the donor organs have been excised, samples of donor spleen and mesenteric lymph nodes are obtained for confirmation of tissue type and use in the cross-match test.

Various organ preservation solutions are available for flushing organs before cold storage. They all contain impermeants to limit cell swelling, buffers to counter acidosis and electrolytes, the composition of which reflects that of intracellular rather than extracellular fluid. Commonly used preservation solutions include University of Wisconsin (UW) solution and Euro-Collins solution, but there are many others. The use of UW solution (*Table 82.6*) (developed by Belzer and colleagues in Wisconsin, USA) is particularly effective for liver grafts, and after perfusion with UW solution the liver can be stored safely for up to 24 hours. The length of time for which an organ can be stored before transplantation varies depending on the type of organ (*Table 82.7*). Although minimising the duration of organ storage is important for all organs, it is essential that organs from DCD donors be transplanted with the minimum possible cold storage time. Most organs for transplantation are stored by static cold storage in an icebox. However, there is a recent trend towards storing deceased donor kidneys by pulsatile machine perfusion,

where the kidneys are placed inside a purpose-designed perfusion machine that pumps cold preservation solution through the renal artery in an attempt to reduce ischaemic injury. Machine perfusion can be started immediately after kidney recovery or as soon as practicable thereafter, and is usually continued until the time of implantation. The benefit of machine perfusion over simple cold storage is currently the subject of considerable debate.

Living kidney donors

Living-donor renal transplants account for around 30% of the total renal transplant activity in the UK, but in some countries (notably the Scandinavian countries and the USA) this figure is much higher (>50%). The justification for living-donor renal transplantation is based on the shortage of deceased donor transplants and the superior results obtained. Traditionally, most living-donor transplants were between genetically related individuals. However, living-donor kidney transplantations performed between genetically unrelated individuals also fare better than even well-matched deceased donor grafts, and this observation gave rise to a steady increase in living-unrelated kidney transplantation activity, usually between spouses or partners. It is essential to ensure that, in all cases of living donation, the prospective donor is fully informed and free from coercion to donate, and that the risk to the donor is small. In the UK, all living-donor transplants (irrespective of whether they are or are not genetically related) require prior approval by the Human Tissue Authority (HTA). An independent person (one not associated with the transplant team) approved by the HTA must provide confirmation to the HTA that the donor and recipient understand the implications of the proposed operation and that there is no evidence of coercion or financial inducement.

Live donation should proceed only after prospective donors have undergone rigorous assessment to ensure that they are suitable. Before the donation, it is essential to perform imaging (usually magnetic resonance angiography or computed tomography-guided angiography), to delineate the anatomy of the arterial supply to the kidneys. If the left kidney has a single renal artery (10% of kidneys have two or more renal arteries), it is usually chosen for transplantation because the longer left renal vein simplifies the transplant operation. The presence of multiple renal arteries does not necessarily preclude donation, although implantation of living-donor kidneys with multiple renal arteries may increase the chances of vascular complications developing after implantation.

Live donor nephrectomy was historically undertaken either through a loin incision and retroperitoneal approach or through a midline abdominal incision and transperitoneal approach. In most transplant units, nephrectomy is now undertaken laparoscopically (totally laparoscopic or hand assisted). Laparoscopic nephrectomy is associated with less wound pain in the donor, allows more rapid mobilisation after surgery and reduces hospital stay. Initial concerns that kidneys removed by the laparoscopic technique may have more ureteric complications after implantation have proven unfounded. After removal from the donor the kidney is flushed immediately with chilled organ preservation solution (**Figure 82.19**). The mortality rate for live donation is less than 0.05%, and around half of reported deaths are due to pulmonary embolic disease, so it is essential to ensure prophylaxis to reduce deep-vein thrombosis (DVT). The major complication rate after live donor nephrectomy is <5%: potential complications include haemorrhage requiring blood transfusion or surgery, infection (chest, abdomen, renal tract and wound), damage to an intra-adominal viscus, adverse reaction to drugs and anaesthetic agents, and DVT and pulmonary embolus. In the long term, kidney donors may be at increased risk from hypertension and donors should have their blood pressure and urine checked annually.

Around 35% of potential living donor transplant recipients will be ABO blood group incompatible with their intended donor and until recently this precluded transplantation. However, there are now two potential solutions to this problem. The first is 'paired exchange' where incompatible donor/recipient pairs exchange kidneys between pairs to allow ABO-compatible transplantation (**Figure 82.20**).

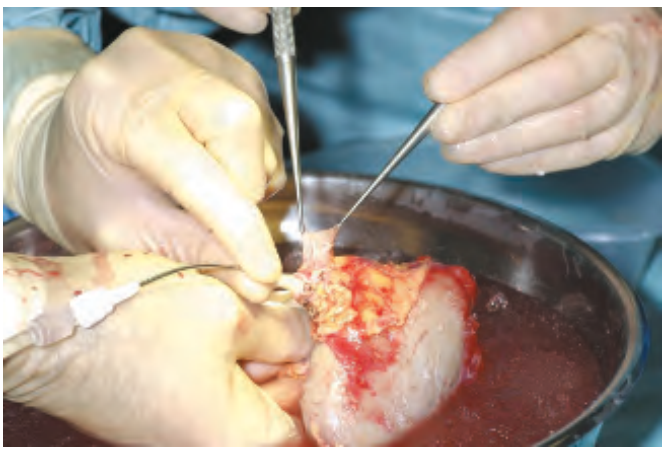

Figure 82.19 After removal from the donor, the kidney is flushed with chilled organ preservation solution and, if necessary, stored briefly on ice until transplanted into the recipient.

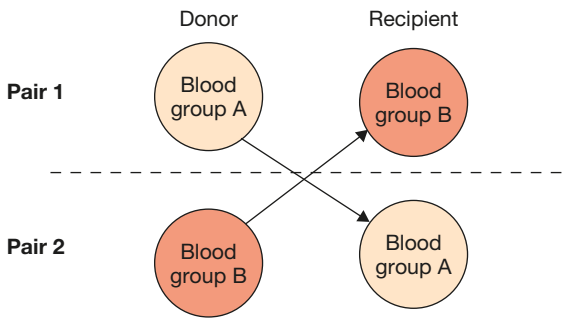

Figure 82.20 Paired living-donor kidney transplantation. Paired donation allows patients with willing but blood group-incompatible donors to be transplanted by pairing them with other incompatible donor–recipient pairs. In the example shown, the two willing donors are incompatible with their intended recipient (blood groups A to B and B to A) but by paired donation each recipient can receive an ABO-compatible kidney transplant (blood groups A to A and B to B).

Recruitment of more than two pairs to facilitate 'pooled donation' increases the likelihood of matching donors with compatible recipients and, although such schemes pose considerable logistical challenges, they are now operating successfully in several countries. An alternative approach is to transiently deplete ABO antibodies from potential recipients by passing their blood through special absorption columns or by performing plasmaphoresis along with administration of pre-transplant immunosuppressive agents (Figure 82.21). Perhaps surprisingly, graft outcome after desensitisation is similar to that after paired donation. Both paired donation and antibody depletion strategies are also potentially applicable to recipients in whom HLA antibodies preclude transplantation from an intended living donor, but graft survival after depletion of HLA antibodies is lower than when the recipient receives a kidney from an HLA antibody-compatible donor.

Living liver donors

Living donor liver transplantation is now undertaken in a number of transplant centres worldwide and is relatively common practice in some countries where deceased donation is not practised for cultural or religious reasons, notably Japan and Korea. The concept was first pioneered to allow children to receive the left lobe or left lateral segment from an adult donor and has been very successful. It has now been extended to adult-to-adult live liver transplantation (Figure 82.22). The majority of such transplants require a right liver lobe to provide adequate hepatic function. For adult-to-adult live liver donation, the donor procedure has a reported mortality rate of around 0.5% and a major complication rate of up to 15%. One of the more common donor complications is bile leak.

Living donors: other organs

Occasionally, living donors have provided segments of pancreas, small bowel and lung for transplantation, but this is more controversial. In the USA, living-donor, combined kidney and segmental pancreas transplantation has been undertaken to treat people with type 1 diabetes with end-stage renal disease. In occasional patients, living-donor small bowel transplantation has been performed using a small bowel graft, which comprises a length of around 1.5 m of ileum. Finally, a small number of living-donor segmental lung transplantations have been performed. To provide sufficient pulmonary tissue without compromising the donor, it is necessary to use segments from two different donors for each recipient. The ethical issues raised by living donation for extrarenal organs are understandably complex.

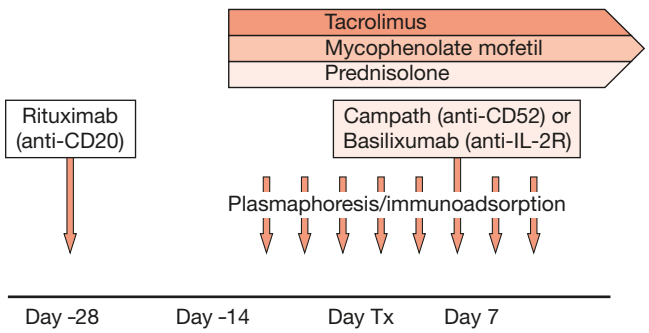

Figure 82.21 Typical desensitisation protocol for ABO or human leukocyte antigen (HLA) antibody-incompatible live-donor kidney transplant.

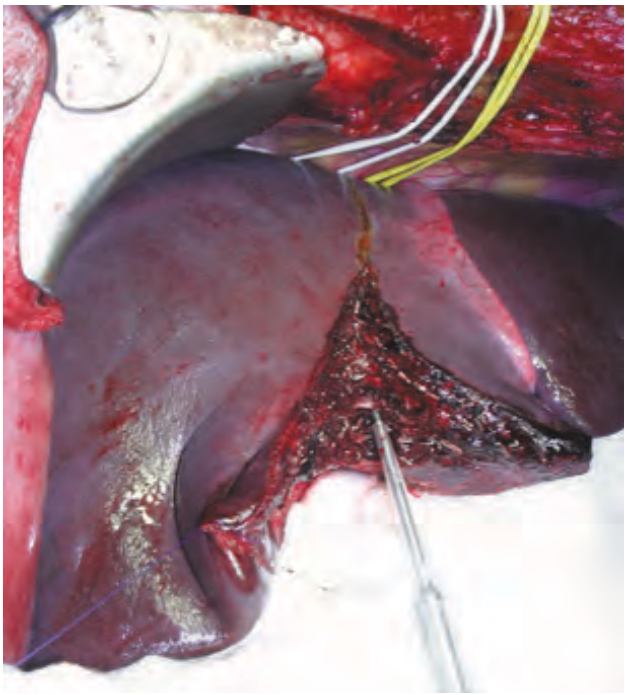

Figure 82.22 Living donor hepatectomy. A CUSA (cavitron ultrasonic aspirator) is being used to divide the right and left lobes of the liver so that the right lobe can be transplanted into an adult recipient.

Resumption of function after organ transplantation

It is crucial that, after a heart, lung or liver transplantation, the transplanted organ resumes satisfactory function immediately. If primary non-function occurs, the only option is rapid re-transplantation. After kidney, pancreas or small bowel transplantation, immediate graft function is desirable but not vital. Kidneys obtained from DCD donors invariably suffer a variable degree of ischaemic damage, and delayed graft function is more common (typically 50% for category 3 DCD donors) than for kidneys obtained from DBD deceased donors (typically 25%). Irreversible ischaemic necrosis occasionally occurs and the graft never functions adequately (primary non-function). However, graft survival results for kidneys from controlled DCD kidneys are similar to those obtained from DBD deceased donors. Livers obtained from DCD donors have an increased incidence of primary non-function and biliary complications, including biliary anastomotic strictures, bile leak and ischaemic cholangiopathy.

Summary box 82.7

Factors determining organ function after transplantation

- Donor characteristics
  - Extremes of age
  - Presence of pre-existing damage in transplanted organ
  - Haemodynamic and metabolic instability
- Procurement-related factors
  - Warm ischaemic time
  - Type of preservation solution
  - Cold ischaemic time
- Recipient-related factors
  - Technical factors relating to implantation
  - Haemodynamic and metabolic stability
  - Immunological factors
  - Presence of drugs that impair transplant function

KIDNEY TRANSPLANTATION

Patient selection

Renal transplantation is the preferred treatment for many patients with end-stage renal disease because it provides a better quality of life for them than dialysis. Transplantation releases patients from the dietary and fluid restrictions of dialysis and the physical constraints imposed by the need to dialyse. Transplantation is also more cost-effective than dialysis and improves patient survival.

In the UK, around 100 people per million of the population develop end-stage renal disease, and the incidence increases with age. The causes of end-stage renal disease are numerous and include the following:

- glomerulonephritis;
- diabetic nephropathy;
- hypertensive nephrosclerosis;
- renal vascular disease;
- polycystic kidney disease;
- pyelonephritis;
- obstructive uropathy;
- systemic lupus erythematosus;
- analgesic nephropathy;
- metabolic disease (oxalosis, amyloid).

Sometimes, the primary cause of end-stage renal disease is uncertain. For renal transplantation, as for other types of organ transplantation, careful patient selection is essential. Before acceptance as suitable candidates on the transplant waiting list, a transplant surgeon and nephrologist should formally assess all patients. A significant number of patients are likely to be considered unsuitable for renal transplantation because of major comorbid disease, especially cardiovascular disease. In the UK, around 30–40% of the dialysis population are on the waiting list for renal transplantation.

The nature of the primary renal disease does not generally affect the decision to proceed to transplantation. Many of the glomerulonephritides (especially IgA, focal segmental glomerulosclerosis, and mesangiocapillary glomerulonephritis types I and II) may recur in a kidney transplant, and sometimes can lead to early graft failure (especially focal segmental glomerulosclerosis). In the case of primary oxalosis, combined kidney and hepatic transplantation is usually undertaken to eliminate the metabolic defect and thereby prevent early graft failure from the formation of further oxalate stones.

The age of patients with end-stage renal failure accepted for dialysis has gradually risen over the last two decades, and in the UK the mean age of patients starting dialysis is around 70 years. There is no absolute upper age limit to renal transplantation, but inevitably older patients (aged >65 years) are less likely to be considered suitable candidates because of major cardiovascular and other comorbid diseases.

A careful assessment of comorbid disease that might significantly reduce the chances of successful outcome after transplantation is essential. Rigorous evaluation of the cardiovascular system is particularly important. Cardiovascular disease is very common in the dialysis population, especially those with diabetes, and is the major cause of death after transplantation. Before listing patients for transplantation, it is important to ensure that their urinary tract is functional and that there is no need for corrective urological surgery. Only when there is intractable renal sepsis or very large polycystic kidneys that intrude into both iliac fossae is native nephrectomy required before transplantation (**Figure 82.23**). Finally, the prospective transplant recipient must be deemed able to cope with the psychological consequences of transplantation and likely to comply with immunosuppressive therapy.

Summary box 82.8

Evaluation of potential recipients for organ transplantation

- Evaluation undertaken by appropriate multidisciplinary team including surgeon and physician
- Determine presence of comorbid disease
- Exclude malignancy and systemic sepsis
- Evaluate against organ-specific criteria for transplantation
- Determine probable ability to cope psychologically with transplant and comply with immunosuppression
- Evaluate need for any preparative surgery needed to facilitate transplantation
- Optimise recipient condition before transplantation

Immunosuppressive therapy impairs the protective response to both malignancy and infection. Consequently, pre-existing malignancy is an absolute contraindication and, even after curative treatment, transplantation should not usually be considered for at least 3 years. Similarly, the presence of active infection is a contraindication to transplantation.

Technique of renal transplantation

The transplant kidney is placed in the iliac fossa, in the retroperitoneal position, leaving the native kidneys *in situ*. After induction of general anaesthesia, a central venous line and

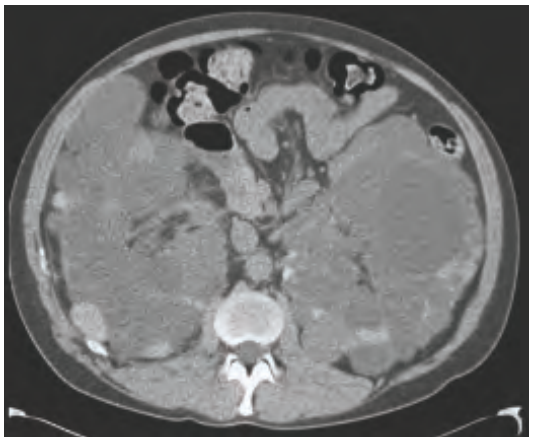

Figure 82.23 Computed tomography scan of a patient with very large polycystic kidneys that extend well into both iliac fossa. The patient requires removal of one of the polycystic kidneys to make room for a subsequent renal transplant. Nephrectomy should be performed several weeks before transplantation.

a urinary catheter are inserted. It is helpful to distend the bladder with saline containing methylene blue to allow it to be identified with certainty before ureteric implantation. A curved incision is made in the lower abdomen and, after dividing the muscles of the abdominal wall, the peritoneum is swept upwards and medially to expose the iliac vessels. These are dissected free so that they can be controlled with vascular clamps. The kidney is then removed from ice and the donor renal vein is anastomosed end to side to the external iliac vein. The donor renal artery on a Carrel patch of donor aorta is anastomosed end to side to the external iliac artery (**Figure 82.24a**). If the donor renal artery lacks an aortic patch, as in the case of a living-donor transplant, it may be preferable to anastomose the donor artery end to end to the recipient internal iliac artery (**Figure 82.24b**). While the vascular anastomoses are being undertaken, the kidney is kept cold by application of topical ice.

After completion of the venous and arterial anastomoses, the vascular clamps are removed and the kidney is allowed to reperfuse with blood. The ureter, which is kept reasonably short to avoid the risk of distal ischaemia, is then anastomosed to the bladder (**Figure 82.25**). This is achieved by direct implantation of the ureter into the dome of the bladder with a mucosa-to-mucosal anastomosis, followed by closure of the muscular wall of the bladder over the ureter to create a short tunnel, the Lich–Gregoir technique. A double-J ureteric stent should be left *in situ*, to reduce the risk of urine leak or early obstruction, and removed after several weeks by cystoscopy. If the donor ureter is too short to reach the bladder, the native ureter can be divided and the distal segment anastomosed to the ureter or renal pelvis of the donor kidney. The proximal segment of the native ureter can usually be ligated and the native kidney left *in situ* without causing a problem. Before closing the transplant wound, it is very important to ensure that the kidney is lying in a satisfactory position without

kinking or torsion of the renal vessels. In small children receiving an adult donor kidney, the abdomen is opened through a midline incision and the graft is placed intra-abdominally with anastomosis of the renal vessels to the aorta and vena cava.

Technical complications

Vascular complications

The incidence of vascular complications after renal transplantation is quite low. Renal artery thrombosis occurs in approximately 1% of cases. Renal vein thrombosis is more common

Robert Lich Jr, urologist, Louisville, KY, USA.
Willy Gregoir, Chef de Clinique Urologique, Brussels, Belgium 1962–1987.

(up to 5% of cases) and, although sometimes due to technical error, the aetiology is often uncertain. It presents during the first week after transplantation with sudden pain and swelling at the site of the graft. The diagnosis is confirmed by Doppler ultrasonography. Urgent surgical exploration is indicated, and in most cases transplant nephrectomy is required. The incidence of renal vein thrombosis can be minimised by giving low-dose heparin or aspirin prophylaxis. Renal artery stenosis usually presents late (often years) after transplantation with increasing hypertension and decreasing renal function. It may occur in up to 10% of grafts and is diagnosed by angiography. Renal artery stenosis is best treated by angioplasty, but if angioplasty fails or is not technically possible then the condition can be treated successfully by open surgery and vascular reconstruction.

Urological complications

Urological complications occur in around 5% of patients in the early post-transplantation period, but their incidence can be reduced markedly by leaving a temporary ureteric stent *in situ*. Urinary leaks result from technical errors at the ureteric anastomosis or because of ureteric ischaemia. They present with discomfort and leakage of urine from the wound and usually require surgical intervention and reimplantation of the ureter into the bladder or anastomosis of the transplant ureter to the ipsilateral native ureter. Obstruction of the transplant ureter may occur early or late. Causes of obstruction include technical error, external pressure from a haematoma or lymphocele and ischaemic stricture. Ureteric obstruction presents with painless deterioration in graft function and is confirmed by demonstrating hydronephrosis and ureteric dilatation on ultrasound examination. Initial treatment is by percutaneous anterograde nephrostomy and insertion of a stent. Some ureteric strictures may be amenable to treatment by balloon dilatation but most are best treated by surgical intervention, reimplanting the donor ureter into the bladder or anastomosing it to the native ureter.

Lymphocele

Peri-transplant lymphoceles are usually asymptomatic, but occasionally they become large enough to cause ureteric obstruction or oedema of the ipsilateral leg. Initial treatment is usually by ultrasound-guided percutaneous drainage. In the case of large or recurrent lymphoceles, surgical intervention may be needed to drain a persistent lymphocele into the peritoneal cavity, and this can often be achieved by an ultrasound-guided laparoscopic approach.

Investigation of graft dysfunction

Graft dysfunction during the early postoperative period is a common problem. Possible causes are:

- acute tubular necrosis;
- arterial/venous thrombosis;
- urinary leak/obstruction;
- CNI toxicity;
- hyperacute/accelerated acute rejection.

Summary box 82.9

Causes of allograft dysfunction

- Early
  - Primary non-function (irreversible ischaemic damage)
  - Delayed function (reversible ischaemic injury)
  - Hyperacute and acute rejection
  - Arterial or venous thrombosis of the graft vessels
  - Drug toxicity (e.g. calcineurin inhibitor toxicity)
  - Infection (e.g. cytomegalovirus disease in graft
  - Mechanical obstruction (ureter/common bile duct)
- Late
  - Chronic rejection
  - Arterial stenosis
  - Recurrence of original disease in graft (glomerulonephritis, hepatitis C)
  - Mechanical obstruction (ureter, common bile duct)

Delayed graft function (defined as the need for dialysis post-transplantation) as a result of acute tubular necrosis occurs in around 25% of kidneys from DBD and up to 50% of kidneys from DCD donors, but is uncommon (<5%) after living-donor transplantation. Often, recipients produce significant volumes of urine from their native kidneys, making the diagnosis of delayed graft function more difficult. The incidence of delayed function can be minimised by optimising donor management before kidney procurement and reducing the cold ischaemia time by avoiding unnecessary delay before implantation. As a first step in the management of early graft dysfunction, the urinary catheter should be irrigated in case it is occluded by a blood clot. Hypovolaemia, if present, should be corrected with the aid of central venous pressure (CVP) monitoring. A Doppler ultrasound examination of the graft is the single most important investigation because it allows exclusion of vascular thrombosis and urinary obstruction as causes of graft dysfunction. Renal radionuclide scanning provides information on renal perfusion and excretion and may be helpful but is used infrequently. If graft dysfunction is still present after several days, it is usual to perform an ultrasound-guided needle biopsy of the kidney to ensure that graft rejection is not present, and then to repeat the investigation every week or so until graft function occurs. CNI toxicity may cause graft dysfunction and it is important to monitor CNI blood levels to avoid nephrotoxicity. Acute tubular necrosis usually resolves within the first 4 weeks of transplantation, but a small number of grafts (<5%) suffer primary non-function (i.e. never function).

Allograft dysfunction developing late (>1 month after transplantation) may be due to:

- acute/chronic rejection;
- drug toxicity;
- ureteric obstruction (lymphocele/ureteric stricture);
- recurrent disease;
- urinary tract infection.

Blood levels of ciclosporin or tacrolimus are assessed to ensure that they are not unduly elevated, and ultrasound

examination of the graft is performed to determine whether ureteric obstruction is present. If obstruction is detected, it is further investigated by percutaneous anterograde urography and treated as outlined above. If there is uncertainty about the cause of graft dysfunction, a transplant biopsy should be performed to establish whether allograft rejection is present.

Outcome after transplantation

The results of organ transplantation are generally defined in terms of patient and graft survival. Patient survival after deceased donor renal transplantation is >95% at 1 year and >85% at 5 years. Graft survival is around 90% at 1 year and 80% at 5 years. Graft survival after a second transplant is only marginally worse than after a first graft. After living-related kidney transplantation, overall graft survival is around 95% at 1 year and 85% at 5 years. Graft survival after transplantation can also be expressed in terms of the half-life of the graft. The half-life of grafts obtained from living donors is substantially longer than that of DD grafts:

- deceased donor grafts, 13 years;
- living-unrelated grafts, 16 years;
- living-haploidentical grafts, 17 years;
- living-identical sibling grafts, 27 years.

Summary box 82.10

Outcome after transplantation

- Transplantation improves the quality and duration of life in most recipients
- Transplant outcome has improved progressively over the last two decades and continues to improve
- Improved outcome is due to better immunosuppression, organ preservation, chemoprophylaxis and technical advances
- Graft survival after kidney, liver and heart transplantation is >90% at 1 year and >80% at 5 years
- The results of lung and small bowel transplantation are less good
- Chronic rejection is the most common cause of graft failure after all types of solid-organ transplant
- Recurrence of the original disease necessitating transplantation may also lead to graft failure
- Death with a functioning transplant from cardiovascular disease is relatively common
- Up-to-date transplant outcomes for the different organs can be found at the online national and international transplant databases (see end of chapter for website addresses)

If a kidney transplant fails late after transplantation, the graft can often be left *in situ* and immunosuppression stopped, but transplant nephrectomy may be indicated if the graft is causing symptoms. The operation is undertaken via the original wound, but the kidney is dissected free from the renal capsule and delivered into the wound. The renal vessels are then ligated and divided, leaving behind the original vascular anastomosis.

In addition to graft survival, it is important to consider the extent to which transplantation improves the physical and mental wellbeing of the patient and allows them to lead a satisfactory social life. In the case of a kidney, as in other types of solid organ transplant, successful transplantation undoubtedly leads to a substantial improvement in quality of life. However, although some recipients return to a normal or near-normal life, others fare much less well and, for the group overall, the quality of life after transplantation falls short of that seen in normal healthy individuals. Renal transplantation is best regarded, therefore, as an effective form of therapy rather than a complete cure.

PANCREAS TRANSPLANTATION

Successful pancreas transplantation restores normal control of glucose metabolism and obviates the need for insulin therapy in patients with diabetes mellitus. Improved control of blood glucose levels in diabetes reduces the progression of secondary complications such as retinopathy, peripheral vascular disease and nephropathy. However, in considering the indications for pancreas transplantation, these advantages have to be weighed carefully against the risks posed by both the transplantation procedure itself and the immunosuppressive therapy required to prevent graft rejection. For most patients with diabetes, the additional risks associated with pancreas transplantation and immunosuppression are such that the operation can be justified only when kidney transplantation for diabetic nephropathy is also being undertaken. The additional risks of pancreas transplantation relate to the transplantation operation itself and the need for enhanced immunosuppressive therapy compared with kidney transplantation alone. In the USA, around a half of all patients with diabetes undergoing kidney transplantation also receive a pancreas transplant. In most cases, the kidney and pancreas are obtained from the same donor, so-called simultaneous pancreas and kidney (SPK) transplantation. Pancreas transplantation is sometimes performed in patients who have already undergone successful kidney transplantation, pancreas-after-kidney (PAK) transplantation. Occasionally, pancreas transplantation alone (PTA) can be justified to treat life-threatening diabetic complications such as hypoglycaemic unawareness.

Careful patient selection is essential to avoid excessive mortality and morbidity. The procedure is usually reserved for those patients with type 1 diabetes who are relatively young (aged <60 years) and do not have advanced coronary artery disease or advanced peripheral vascular disease. Investigation of the heart's response to stress, either using echocardiography or nuclear medicine imaging is usual.

Surgical technique

The whole pancreas gland together with a segment of duodenum is transplanted, essentially as pioneered by Lillehei in 1966. SPK transplantation is usually performed through a midline incision (**Figure 82.26**). The pancreas graft is placed intraperitoneally in the pelvis, usually on the right, and the

Richard Lillehei, surgeon, the University of Minnesota, Minneapolis, MI, USA.

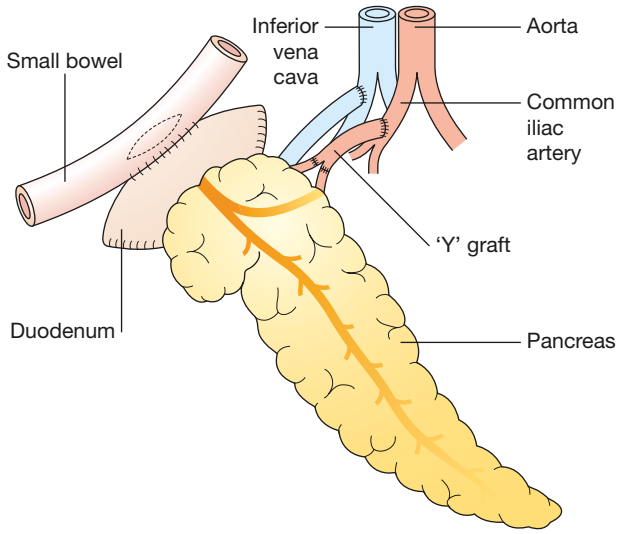

Figure 82.26 Pancreas transplantation operation with enteric drainage of the exocrine secretion via a duodenoenterostomy. A 'Y' graft using donor iliac artery is usually used to reconstruct the divided splenic and superior mesenteric arteries of the graft before implantation.

kidney graft is placed on the left side. The donor vessels of the pancreas graft are anastomosed to the recipient iliac vessels and the exocrine secretions are most commonly dealt with by anastomosing the graft duodenum to the small bowel (enteric drainage) often via a Roux-en-Y loop, although the duodenum may sometimes be anastomosed to the bladder (urinary drainage). The pancreas graft functions immediately after revascularisation, although supplementary insulin may be required for a few days. Technical complications usually occur early and include vascular thrombosis of the graft (5%) and duodenal anastomotic leaks. Graft pancreatitis is very common, but usually mild and unlikely to need intervention. Wound infection occurs in up to 10% of patients, and intra-abdominal infection is relatively common. The specific complications of enteric drainage include intra-abdominal sepsis and adhesive small intestinal obstruction. Bladder drainage of the exocrine pancreas may result in the following complications:

- bladder/duodenal anastomotic leaks;
- cystitis (owing to effect of pancreatic enzymes);
- urethritis/urethral stricture;
- reflux pancreatitis;
- urinary tract infection;
- haematuria;
- metabolic acidosis (due to loss of bicarbonate in the urine).

Urinary drainage of the pancreas has the advantage that urinary amylase levels can be used to monitor for graft rejection. However, after bladder drainage, urinary complications are common, and in around 20% of cases their severity necessitates conversion to enteric drainage. Most centres now prefer primary enteric drainage after SPK transplantation. Acute rejection after SPK transplantation is relatively common (10–20%) and if detected early responds to treatment with steroids. Biopsy confirmed that acute renal allograft rejection may be a surrogate for pancreas rejection, but acute rejection of the kidney or pancreas graft may occur in isolation. Serum lipase and amylase levels are useful indications of pancreas graft inflammation of which acute rejection is one cause. Elevation of blood glucose level is a late feature of acute rejection and often indicates the process is beyond reversal.

Results of pancreas transplantation

The principal aim of pancreas transplantation is to prolong life in patients with diabetes who otherwise have a high mortality at 10 years after receiving a kidney transplant alone. It also provides freedom from insulin treatment and improves quality of life.

The results of pancreas transplantation have improved significantly over the last decade. After SPK transplantation, the 1-year patient survival rate is greater than 95% and the 1-year graft survival rates for pancreas and kidney grafts are 85 and 95%, respectively. Most deaths are due to cardiovascular complications or overwhelming infection. Patient and kidney graft survival after SPK transplantation in patients with diabetic nephropathy is at least as good as after kidney transplantation alone in this group. The results of PTA are not as good as after SPK transplantation (1-year pancreas graft survival rate of 75%) because acute rejection is more difficult to monitor in the absence of a kidney allograft.

Transplantation of isolated pancreatic islets

Treatment of diabetes by transplantation of isolated islets of Langerhans is a more attractive concept than vascularised pancreas transplantation because major surgery and the potential complications of transplanting exocrine pancreas are avoided. Pancreatic islets for transplantation are obtained by mechanically disrupting the pancreas after injection of collagenase into the pancreatic duct. The islets are then purified from the dispersed tissue by density-gradient centrifugation and can be delivered into the recipient liver (the preferred site for transplantation) by injection into the portal vein. Until recently, human islet transplantation had been performed intermittently and with very disappointing results. However, in 2000, Shapiro and colleagues in Edmonton, Canada, reported success with islet transplantation in seven patients with type 1 diabetes. Sequential islet transplantation from two or three donor pancreas glands was required to produce insulin independence and, although the long-term success is less than initially hoped for, some patients remained free from exogenous insulin and other units are now undertaking islet transplantation with variable results.

As an alternative to preventing islet rejection through immunosuppressive therapy, attempts have been made to protect isolated islet cells from rejection by encapsulating them inside semipermeable membranes. The protective

Paul Langerhans, 1847–1888, Professor of Pathological Anatomy, Freiberg, Germany, described the islets in 1869.
Andrew Mark James Shapiro, Chairman of Clinical Research in Transplantation, CHRI/Wyeth Canada, Edmonton, Alberta, Canada.

membranes are designed with a pore size that allows insulin to pass through but prevents antibodies and leukocytes from reaching the islets, thereby avoiding the need for immunosuppressive therapy. A major attraction of this approach is that islets isolated from animals can be used and bioartificial pancreas grafts containing xenogeneic islets are currently under evaluation.

LIVER TRANSPLANTATION

Starzl first attempted liver transplantation in 1963 and, by 1967, had achieved prolonged survival. The first liver transplant performed outside the USA was performed in Cambridge, UK by Calne in 1968. Throughout the 1970s, liver transplantation remained a hazardous procedure that frequently failed. However, since then, the results have progressively improved as a result of better patient selection, improved immunosuppression and chemoprophylaxis, better organ preservation, refinements in the surgical technique, and advances in per- and postoperative management.

Indications and patient selection

The indications for liver transplantation fall into four groups:

1 cirrhosis;
2 acute fulminant liver failure;
3 metabolic liver disease;
4 primary hepatic malignancy.

The most common indication for transplantation is chronic liver failure. In adults the most common causes are alcoholic liver disease, viral liver disease (hepatitis C in Europe and the USA, and hepatitis B in some other countries), non-alcoholic steatohepatitis, primary biliary cirrhosis and sclerosing cholangitis. In children, who account for around 10–15% of all liver transplantations, biliary atresia is the most common indication for transplantation. Acute fulminant liver failure requiring transplantation on an urgent basis accounts for approximately 10% of liver transplant activity and is usually viral or drug induced (e.g. paracetamol overdose in the UK). There are a variety of metabolic diseases for which transplantation offers the prospect of cure, including Wilson's disease, oxalosis and familial amyloid polyneuropathy. Primary hepatic malignancy is more common in patients with cirrhosis, especially virally induced disease, and may be best treated by transplantation because the field changes in the cirrhotic liver predispose to further primary malignancies. Cholangiocarcinoma has a high recurrence rate and is seldom an indication for liver transplantation.

Technique of liver transplantation

A transverse abdominal incision with a midline extension is usually made and the diseased liver is mobilised (**Figure 82.27**). As a result of portal hypertension, the recipient hepatectomy is often the most difficult part of the operation, especially if there has been previous upper abdominal surgery. The common bile duct is divided, as is the hepatic artery. The inferior vena cava is clamped and divided above and below the liver, and the portal vein is clamped and divided, allowing the recipient liver to be removed. Occlusion of the vena cava and portal vein results in a reduction in cardiac output and may necessitate the use of venovenous bypass. The bypass circuit delivers blood from the inferior vena cava and/or portal vein and back to the heart via a cannula inserted into the internal jugular vein. After placing the donor liver in position, the supra- and infrahepatic caval anastomoses are performed. The portal vein and the hepatic arterial anastomoses are then completed and the graft is re-perfused. Finally, biliary drainage is re-established usually by a duct-to-duct anastomosis (without the use of a T-tube). It may be necessary, for example in recipients with biliary atresia or sclerosing cholangitis, to reconstruct the biliary drainage by a bile-duct-to-Roux-loop anastomosis. An alternative caval preservation technique of liver transplantation allows the recipient liver to be removed without cross-clamping the vena cava and the donor liver to be implanted using a 'piggy-back' technique on to the recipient hepatic veins, or using a side-to-side cavo-cavoplasty.

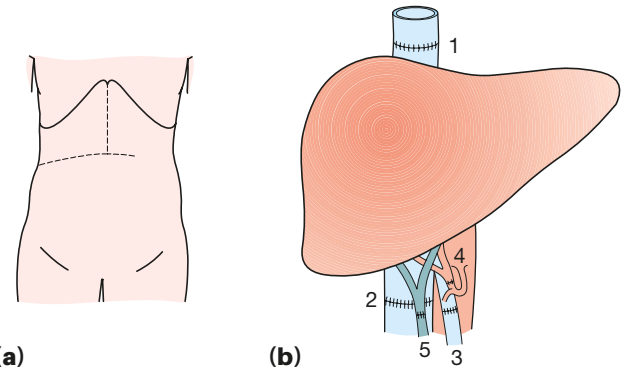

Figure 82.27 **(a)** Incision used for liver transplantation; **(b)** completed implantation. The anastomoses, in order of performance, are: (1) suprahepatic cava; (2) infrahepatic cava; (3) portal vein; (4) hepatic artery; (5) bile duct.

Many patients undergoing liver transplantation are extremely ill, and the surgery involved can be very technically demanding. Optimal perioperative management is crucial to a successful outcome and presents a major challenge. Blood loss during and after the transplantation procedure can be very considerable, and management of coagulopathy is particularly important. Coagulation is assessed repeatedly throughout the transplantation period and corrected with appropriate clotting factors if required. Many centres routinely use thromboelastography to perform dynamic assessment of coagulation.

Thomas Earl Starzl, Professor of Surgery, Pittsburgh, PA, USA.
Samuel Alexander Kinnier Wilson, 1878–1936, Professor of Neurology, King's College Hospital, London, UK, described this condition in 1912.

Technical complications

Haemorrhage

Meticulous haemostasis during the transplantation operation is important in order to minimise the risk of early haemorrhage. It may be necessary, occasionally, to pack the peri-transplant area for 2–3 days to achieve adequate haemostasis when there is diffuse oozing despite correction of coagulopathy. Evacuation of extensive peri-hepatic haematoma may be required to avoid secondary infection.

Vascular complications

Hepatic artery thrombosis may occur spontaneously or as a result of acute rejection and is more common in children and in adults with primary sclerosing cholangitis. It may present as a rise in serum transaminase levels, unexplained fever or bile leak. Doppler ultrasonography or angiography is used to confirm the diagnosis, and urgent re-transplantation is usually required. Portal vein thrombosis is rare and presents with the features of portal hypertension. Hepatic vascular occlusion often presents with increasing ascitic fluid losses over the postoperative period. A cavogram with hepatic vein pressure studies should be undertaken to confirm the diagnosis, and insertion of vascular stents, surgical correction or re-transplantation may be required to treat the problem.

Biliary complications

Biliary leaks are now relatively uncommon and biliary stenosis is the more common problem. It usually occurs within the first few months of transplantation and is managed by endoscopic dilatation and stenting or by surgical correction.

Outcome after liver transplantation

The outcome after liver transplantation depends on the underlying liver disease and the best results are seen in patients with chronic liver disease (**Figure 82.28**). Patients undergoing transplantation as a result of acute liver failure have a higher mortality in the early post-transplantation period because of multiorgan failure, but those who make a satisfactory recovery have very good long-term liver allograft survival. Conversely, patients transplanted for tumour have a very good early outcome but ultimately fare much less well because of recurrent malignancy. Patients receiving a liver transplantation after hepatitis B or hepatitis C infection may develop graft failure as a result of recurrent viral disease. However, the availability of improved antiviral therapy has largely eliminated this problem in recipients with hepatitis B infection and in the near future is expected to do so in those with hepatitis C infection.

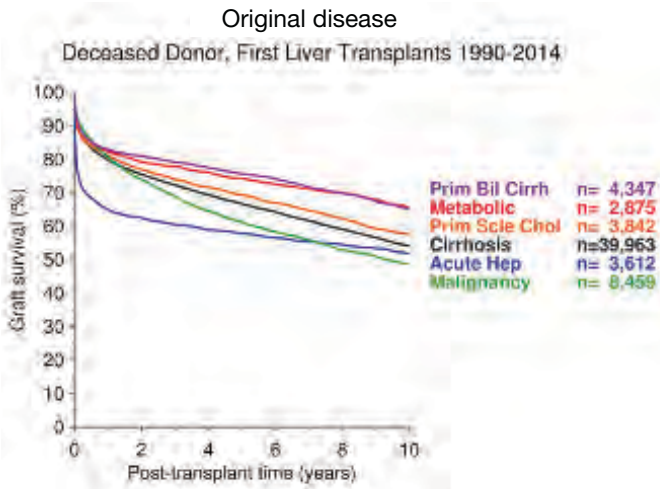

Figure 82.28 Outcome after liver transplantation according to the initial liver disease. Patients transplanted for acute liver disease have a higher early mortality but good long-term outcome. Patients transplanted because of liver tumour have a good initial outcome but survival continues to decline progressively (courtesy of Collaborative Transplant Study, L-75101-0816). Bil, biliary; Cirrh, cirrhosis; Chol, cholangitis; Hep, hepatitis; Scle, sclerosing.

SMALL BOWEL TRANSPLANTATION

Progress in small bowel transplantation has lagged behind that of other types of organ transplantation but it is now a well-established therapy for highly selected recipients. Intestinal transplants stimulate a particularly strong graft rejection response, probably because the small intestine contains very large amounts of lymphoid tissue. Moreover, ischaemia and rejection increase intestinal permeability and allow translocation of bacteria from the lumen of the bowel. Added to this, the operation is often complex and is made technically difficult because of repeated previous abdominal surgery. Consequently, graft rejection and infection remain major problems after small bowel transplantation and the results obtained are inferior to those seen after other types of organ transplantation. Small bowel transplantation is a treatment option for patients with intestinal failure requiring long-term parenteral nutrition. Intestinal failure may result from short bowel syndrome after resection of the intestine or from intestinal dysfunction. Conditions that may give rise to intestinal failure include the following:

- intestinal atresia;
- necrotising enterocolitis;
- volvulus;
- disorders of motility;
- mesenteric infarction;
- Crohn's disease;
- trauma;
- desmoids tumours.

As a result of the substantial risks associated with small bowel transplantation, the procedure is considered only for those patients in whom long-term total parenteral nutrition (TPN) has failed, usually because venous access has become impracticable or because of frequent life-threatening line sepsis. The need for small bowel transplantation is estimated at around 0.5–1.0 patients per million of the population. Previously 50% of cases were children but improvements in parenteral nutrition have reduced the role of small bowel transplantation in children.

Small bowel transplantation may be carried out as an isolated procedure, performed together with a liver trans-

plantation or undertaken as a component of a multivisceral transplantation. When possible, isolated small bowel transplantation is undertaken because patient survival is higher.

A small bowel transplant from a deceased donor comprises the entire small bowel, and may include the ascending colon in the graft. The superior mesenteric artery of the graft (with an aortic patch) is anastomosed to the recipient aorta, and the superior mesenteric vein is anastomosed to the inferior vena cava or to the side of the portal vein. The proximal end of the small bowel graft is anastomosed to the recipient jejunum or duodenum. The distal end of the graft is anastomosed to the side of the colon (with a loop ileostomy) or is fashioned as an end-ileostomy. A gastrostomy tube (to overcome delayed gastric emptying) and a feeding jejunostomy tube are inserted.

About 10–20% of all patients who require small bowel transplantation have cholestatic liver disease secondary to TPN and require combined liver and small bowel transplantation. When combined liver and small bowel transplantation is carried out, the two grafts are transplanted en bloc. The donor aorta is fashioned into a conduit including the superior mesenteric and coeliac arteries and anastomosed to the recipient aorta. There is no requirement for a portal vein anastomosis and venous drainage is exclusively by the inferior vena cava **(Figure 82.29)**.

Multivisceral or 'cluster' transplants may be necessary in the case of large desmoid tumours when excision of both the small bowel and adjacent organs is required, when there has been extensive thrombosis of the splanchnic vessels and for generalised disorders of gastrointestinal motility.

The 1-year graft survival rate after small bowel transplantation is about 80% for both isolated small bowel transplantation and combined liver and small bowel transplantation. After 3 years, the graft survival rate is around 70% after isolated small bowel transplantation and 50% after multivisceral transplantation. Most of the mortality after small bowel transplantation is due to sepsis and multiorgan failure. The risk of infection after small bowel transplantation is heightened by the additional requirements for immunosuppression in order to control graft rejection. This accounts for the relatively high incidence of lymphoproliferative disease (around 10%) observed in patients who have undergone small bowel transplantation. As a result of the large amount of donor lymphoid tissue transplanted, GVHD may be an added complication. Despite the hazards, small bowel transplantation offers patients with intestinal failure a chance to lead an active life free from the constraints of long-term nutritional support.

Figure 82.29 Combined liver and small bowel transplant in an adult shortly after reperfusion of the grafts. The small bowel is well perfused via the superior mesenteric artery anastomosed to the aorta on a patch along with the coeliac axis, and the venous blood drains into the portal vein via the superior mesenteric vein.

THORACIC ORGAN TRANSPLANTATION

Heart transplantation

Dr Christiaan Barnard performed the first human heart transplantation in Cape Town, South Africa, in 1967. The operation was based on the experimental work of Lower and Shumway in Stanford, and Shumway subsequently went on to pioneer successful cardiac transplantation in the clinic. Heart transplantation is now considered an effective treatment for selected patients with end-stage cardiac failure. The most common indications for heart transplantation are ischaemic heart disease and idiopathic cardiomyopathy, but other indications include valvular heart disease, myocarditis and congenital heart disease.

Transplantation is considered only in patients with end-stage heart disease that has failed to respond to all other conventional therapy and when predicted survival without transplantation is only 6–12 months. Transplantation is usually limited to patients under the age of 65 years who do not have irreversible damage to other organ systems. The preoperative assessment is rigorous, and measurement of pulmonary vascular resistance is mandatory because when it is raised the perioperative mortality is high.

Technique of heart transplantation

A median sternotomy is performed and the patient is given systemic heparin, placed on cardiopulmonary bypass and cooled to 29°C. After cross-clamping the aorta, the recipient heart is excised at the mid-atrial level. The donor heart is then prepared and the left atrium is opened by making incisions **(Figure 82.30)** in the posterior wall, between the orifices of the pulmonary veins, to create an atrial cuff. The left and then right atrial anastomoses are performed and the pulmonary and aortic arterial anastomoses are then completed **(Figure 82.31)**. The patient is then rewarmed and weaned from cardiopulmonary bypass. Occasionally, heterotopic cardiac transplantation is undertaken, when the donor heart is placed adjacent to and augments the recipient's own heart.

Christian Neethling Barnard, 1922–2001, Professor of Cardiac Surgery, the University of Cape Town, Cape Town, the Republic of South Africa.
Richard Rowland Lower, contemporary, thoracic surgeon, Richmond, VA, USA.
Norman Edward Shumway, 1923–2006, cardiothoracic surgeon, Stanford University School of Medicine, Palo Alto, CA, USA.

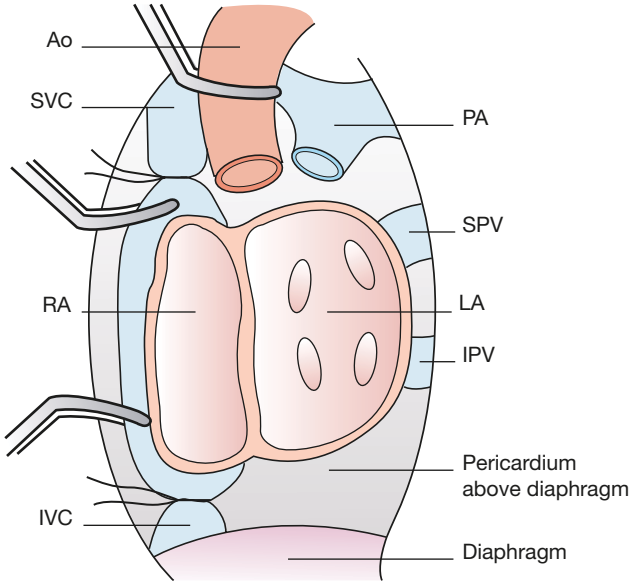

Figure 82.30 Recipient cardiectomy. After median sternotomy, the recipient is placed on cardiopulmonary bypass. Venous cannulae for bypass are sited in the superior vena cava (SVC) and inferior vena cava (IVC) via punctures in the right atrium (RA), and oxygenated blood is returned via a cannula in the ascending aorta (Ao). The diseased recipient heart is excised, leaving behind cuffs of right and left atria (courtesy of J Dunning). PA, pulmonary artery; IPV/SPV, inferior/superior pulmonary veins; LA, left atrium.

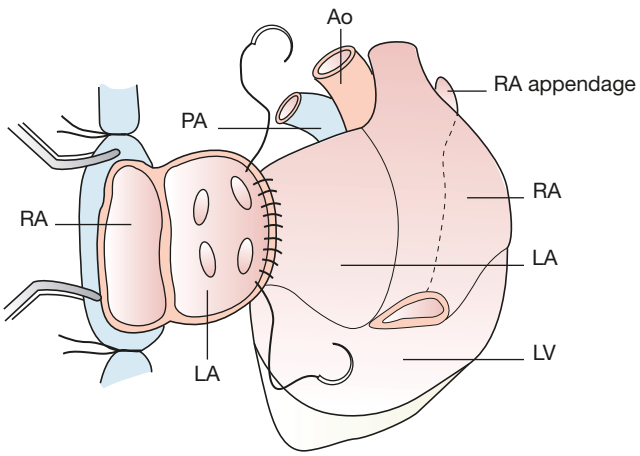

Figure 82.31 Implantation of the donor heart. The donor left atrium is opened by an incision connecting the four pulmonary veins, excising the central portion. The left atrial anastomosis is performed, starting at the lateral wall of the donor and continuing inferiorly and superiorly, concluding with the interatrial septum. The right atrial anastomosis is performed matching the recipient atrium by an incision towards the donor right atrial appendage (dotted line), which avoids the sinus node at the cavoatrial junction. Finally, the pulmonary artery and aortic anastomosis are completed. Abbreviations as for Figure 82.30; LV, left ventricle.

Heart–lung, single-lung and double-lung transplantations

Pulmonary transplantation became a clinical reality when Dr Bruce Reitz performed the first successful combined heart–lung transplantation in 1981. Combined heart–lung transplantation is still sometimes performed, usually in patients with pulmonary vascular disease in whom there is cardiac dysfunction due to congenital (e.g. Eisenmenger's syndrome, in which the left-to-right shunt is reversed owing to pulmonary hypertension) or acquired cardiac dysfunction. For most patients with end-stage pulmonary disease, however, single- or double-lung transplantation has now replaced heart–lung transplantation. Lung transplantation is more economical in terms of organ use, although, if heart–lung transplantation is undertaken for isolated respiratory disease, the healthy native heart can be used for transplantation, the so-called 'domino procedure'. Heart–lung transplantation is performed through a median sternotomy, taking particular care to avoid injury to the phrenic, vagus and recurrent laryngeal nerves during excision of the recipient heart and lungs. The recipient right atrium and aorta are divided as for orthotopic cardiac transplantation and the donor heart–lung block readied for implantation, incising the right atrium from the divided inferior vena cava. An end-to-end tracheal anastomosis is performed and the right atrial and aortic anastomoses are performed as for cardiac transplantation.

Single- and double-lung transplantation are effective therapies for selected patients with end-stage chronic lung disease, in whom declining lung function limits life expectancy despite optimal medical therapy. Common indications are pulmonary fibrosis, pulmonary hypertension, emphysema and cystic fibrosis. Single-lung transplantation can be performed for pulmonary fibrosis. Single-lung transplantation is performed through a posterolateral thoracotomy and double-lung transplantation through a bilateral thoracotomy or median sternotomy. During lung transplantation, the donor pulmonary veins on a left atrial cuff are anastomosed to the recipient left atrium. Next, the bronchial anastomosis and the pulmonary arterial anastomosis are completed. Cardiopulmonary bypass is usually required if pulmonary hypertension is present. Dehiscence of the airway anastomosis used to be common after heart–lung and lung transplantation, but improvements in organ preservation and surgical technique have dramatically reduced the incidence of this often fatal complication to <5%. Late airway stenosis at the bronchial anastomosis due to ischaemia occurs in around 10% of bronchial anastomoses and is treated by dilatation.

Outcome after thoracic organ transplantation

The 1- and 5-year graft survival rates after heart transplantation are around 85% and 70%, respectively. The results after

Bruce Arnold Reitz, thoracic surgeon, Stanford University School of Medicine, Palo Alto, CA, USA.
Victor Eisenmenger, 1864–1932, German physician.

heart–lung and lung transplantation are less good, with 1-year graft survival rates of around 75% and 5-year survival rates of around 50%.

FUTURE PROSPECTS

The two major problems in organ transplantation are:

1 chronic graft rejection and the side effects of non-specific immunosuppression;
2 the shortage of organs for transplantation.

New immunosuppressive agents that have fewer or different agent-specific side effects than existing therapy are likely to enter clinical practice and there is continuing research into the development of non-invasive biomarkers (in urine or blood) that will allow early diagnosis of graft rejection. A long-standing goal in organ transplantation has been the development of strategies for inducing specific immunological tolerance. Transplantation tolerance would eliminate the need for long-term, non-specific, immunosuppressive agents, leaving the immune system intact for defence against infection. It has long been possible to induce transplant tolerance in experimental animals with a variety of preconditioning regimens that often involve pre-treatment schedules using donor bone marrow cells or donor antigen. So far, however, there is no clinically applicable strategy for inducing transplant tolerance.

Summary box 82.11

Future developments in transplantation

- Novel immunosuppressive agents
- Non-invasive biomarkers for early diagnosis of graft rejection
- Donor-specific immunological tolerance
- Xenotransplantation
- Stem cell medicine and tissue engineering

The demand for human organs for transplantation is so great that deceased donors can never satisfy it. Many consider that the solution is to perfect xenotransplantation, and there is general agreement that the pig is the most suitable source of xenogeneic organs. However, all humans have preformed antibodies directed against carbohydrate antigens expressed by pig organs, and these cause hyperacute rejection. The dominant carbohydrate antigen responsible is gal-1, 3α-gal. Progress has been made towards circumventing hyperacute xenograft rejection and pigs that have been genetically engineered not to express the gal-1, 3α-gal antigen have been produced. However, organs from genetically modified pigs are still rejected within a few weeks by primates, despite the use of potent immunosuppressive agents. In addition to the complex immunological problems posed by xenotransplantation, there is a risk that pig organs may transmit infectious agents, and there is particular concern about the risks posed by the porcine endogenous retrovirus (PERV). Last, there are unanswered questions about the extent to which pig organs are able to fulfil the physiological demands required of them after transplantation into a human.

Finally, looking to the future, there is optimism that human pluripotent stem cells may ultimately provide a source of tissue transplants for treating a wide range of diseases. Attempts are now under way to define the cell signals needed to guide human embryonic and adult-induced pluripotent stem cells to differentiate *in vitro* into functional tissue of the desired cell type. These include insulin-producing cells, cardiac myocytes and neuronal tissue. Although cell transplantation is the initial goal, by combining the developments in stem cell medicine with those taking place in tissue engineering and biomaterials it may one day be possible to engineer more complex vascularised grafts for transplantation.

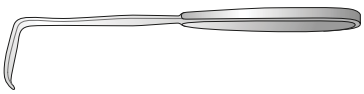
Appendices

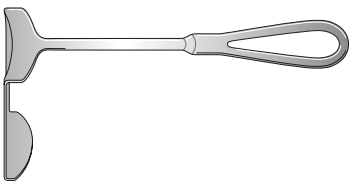
Appendix 1

Common instruments used in general surgery

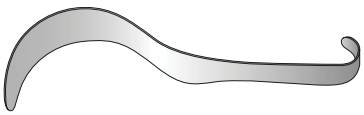
This is a list of some of the instruments used in open (as opposed to minimal access surgery) 'general surgery' with information on how they are used and about the people associated with them. It is hoped that this information will help the general surgical trainee answer questions on operative surgery in postgraduate examinations.



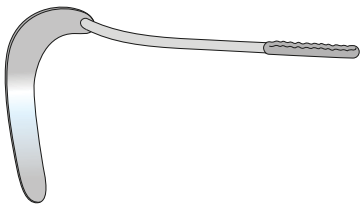
Langenbeck retractor. This small general purpose retractor is useful for holding open wounds, as in an open appendicectomy. They are often used in pairs (one in each of the assistant's hands). They stay in position best if the handles are lifted slightly so that the tips lock in under the fascia. The width of the lip of the retractors varies. Bernhard Rudolf Konrad von Langenbeck (1810–1887) was Professor of Surgery successively at Kiel and Berlin, Germany. He performed the first internal fixation of a femoral neck fracture in 1850.



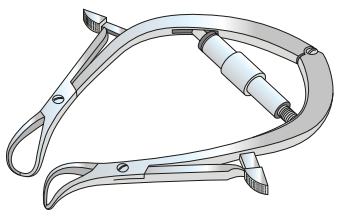
Morris retractor. This is a big retractor which is useful for giving maximum exposure in large incisions such as those used in the abdomen. It can be used to improve visibility on one side of an incision (by pulling firmly in that direction); so is valuable during the initial phase of a laparotomy. Sir Henry Morris (1844–1926) was a surgeon at the Middlesex Hospital, London, UK.



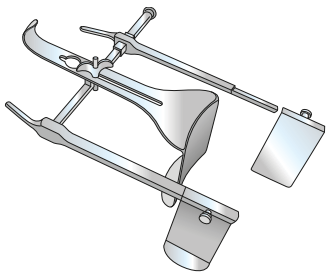
Deaver retractor. This retractor is specifically designed for holding the liver up out of the way during a cholecystectomy. It needs to be used carefully to avoid damaging the liver. Some surgeons protect the liver with an abdominal pack before placing the blade on top. John Blair Deaver (1855–1931) was Professor of Surgery at the University of Pennsylvania Medical School, Philadelphia, PA, USA. He also described a paramedian incision for appendicectomy.



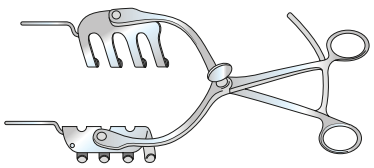
Dyball retractor. Used in major abdominal surgery to retract deeper parts of the abdominal wall or the bladder or the uterus while operating on the rectum and entering the rectovesical or rectouterine pouch. It has a lip at the bottom of the blade to prevent slippage. Care should be taken if it is used to retract the liver in operations in the region of the right upper quadrant as it may damage the liver parenchyma. Brennan Dyball was a distinguished West Country surgeon from Exeter. He also excelled as a carpenter and motor mechanic. He died in 1934 at the age of 62 leaving a great professional legacy to the Royal Devon and Exeter Hospital.



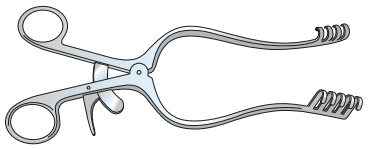
Joll retractor. This is a self-retaining retractor used in thyroid surgery. After making the collar incision and raising the lower and upper flaps fully, this retractor is then inserted. The two clips on the upper and lower edges are attached to the skin preferably with a swab over the skin edge. The central segment is then unscrewed to separate the two edges to obtain full exposure. Cecil Augustus Joll was a surgeon in London who first qualified as a dentist. He was regarded as 'a brilliant technician and an extraordinarily versatile surgeon' who operated on conditions 'from knees to necks and stomach to perineum'. A keen ornithologist, he was a connoisseur of all things good – furniture, pottery, food, wines and cigars. He died in 1945 at the age of 59.



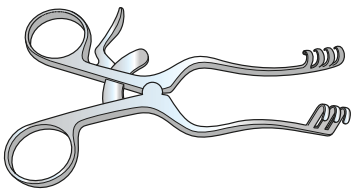
Goligher retractor. This is a self-retaining retractor used in operations on the sigmoid colon and rectum, such as anterior resection and upper end of abdominoperineal resection. Once the abdomen has been opened and laparotomy performed, the patient is placed head down and all the small bowel is packed to the upper end of the abdomen. The retractor is then inserted with the side blades to separate the edges of the abdominal wall. The central blade is then inserted to keep the small bowel well tucked away from the operation site. All three blades come in different widths to fit in with the patient's build. John Cedric Goligher (1912–1998), Ulsterman by birth, Professor of Surgery at Leeds, his contributions to colorectal surgery in the world have been legendary. His operating theatres at Leeds General Infirmary 'have been the Mecca for surgeons from all over the world'. His book, *Surgery of the Anus, Rectum and Colon*, was regarded as the ultimate authority on the subject and had five editions.



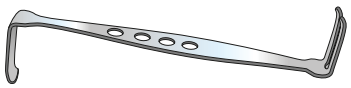
St Mark's perineal retractor. This is used for the perineal part of an abdominoperineal resection. After making the perineal incision and adequate dissection of the perineal wound, the retractor is inserted. As the dissection proceeds, the retractor has to be repositioned. The pointed ends are directed towards the front. St Mark's Hospital, Harrow, UK, is recognised as a national and international referral centre for intestinal and colorectal disorders. It was founded in a small room in No. 11 Aldersgate Street. Established in 1854 on City Road in Hackney as St Mark's Hospital for Fistula and other Diseases of the Rectum. It was so named as it was opened on St Mark's Day, 25 April. In 1994, it moved to its present site in Harrow.



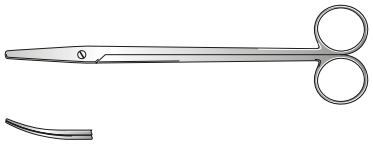
Travers retractor. This is a self-retaining retractor used for intermediate-type operations, such as heriorrhaphy, groin dissection for varicose veins and femoral embolectomy. It retracts skin and subcutaneous tissues; as the incision is deepened, the retractor has to be repositioned. If used incorrectly, it can traumatise the skin. For longer incisions, two such retractors may be used, one at each end of the incision for good exposure. Benjamin Travers (1783–1858) was a surgeon to the London Infirmary for Disease of the Eye (now Moorfields Ophthalmic Hospital). He is regarded as the first general hospital surgeon in England to devote himself specially to disease of the eye. He later became surgeon to St Thomas's Hospital and Vice-President and President of Royal College of Surgeons of England and a Fellow of the Royal Society. As an operator, he was regarded as clumsy and nervous. He had 'exquisite polish of manners, took off his hat and acknowledged salutes more elegantly than any contemporary dandy'.



West retractor. Used in a similar manner to the Travers retractor, this is ideal for minor procedures under local anaesthetic where the surgeon is operating without an assistant, e.g. lymph node biopsy, temporal artery biopsy. After making the incision and undermining the edges, the retractor is then inserted and the jaws are prised open gently. Charles Ernest West (1873–1951) 'aural surgeon' of St Bartholomew's Hospital is credited with devising this retractor. It is possible that he got the idea from Franz Weitlaner, an Austrian physician who published the first description of his retractor in the *Vienna Clinical Review* in 1905. He became known as 'the great spreader of surgery'. It would be safe to presume that the present retractor is West's modification of Weitlaner's spreader.



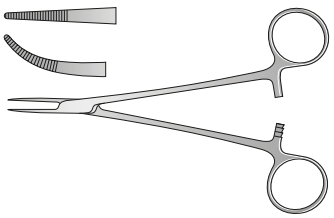
Czerny retractor. This is a double-ended retractor used to retract wound edges for intermediate-type procedures. One end has a blade with a lip which helps to retract without the edge slipping. The other end has two prongs and helps to retract the ends of an incision. When using it, a slight upward tilt gives a better exposure. It is used where a Langenbeck retractor can also be used, but the lip here is broader making it more versatile. Vincenz Czerny (1842–1915) was Professor of Surgery at Freiberg and Heidelberg in Germany. He was a disciple of Theodor Billroth. He was the originator of the concept of multidisciplinary management in cancer.



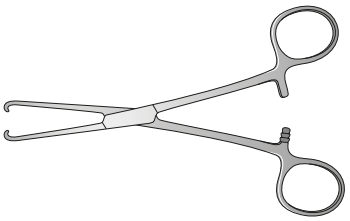
McIndoe scissors are used by surgeons to perform dissection respecting anatomical planes. The closed blades are inserted into a fascial plane, and then gently opened. The tissue to be divided can then be seen clearly and divided without risk of damage to vital structures. Sir Archibald Hector McIndoe (1900–1960) was a plastic surgeon at St Bartholomew's Hospital, London, and the Queen Victoria Hospital, East Grinstead, UK. He was born in New Zealand (cousin of Harold Gillies) and became a consultant plastic surgeon to the RAF during the Second World War. He supervised the rehabilitation of badly disfigured airmen who later formed the Guinea Pig Club.

DeBakey forceps allow the surgeon to grasp tissues firmly while minimising damage to the tissue held in the jaws of the forceps. They are useful for holding vessel walls in vascular surgery. Michael Ellis DeBakey (1908–2008) was Professor of Surgery at Baylor University College of Medicine, Houston, TX, USA. He was the first to successfully implant an artificial heart; he also performed the first successful carotid endarterectomy.

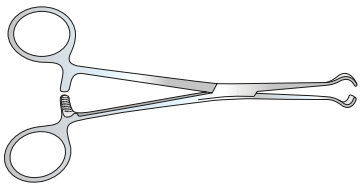
Gillies forceps have teeth and are ideal for holding tough tissues, such as skin. Sir Harold Gillies (1882–1960) was a plastic surgeon at St Bartholomew's Hospital, London, UK. He was born in New Zealand (cousin of Archibald McIndoe) and became one of the founders of British plastic surgery. He originated the tubed pedicle flap.



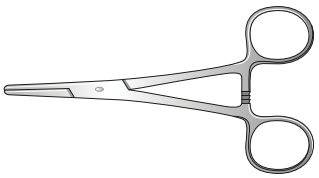
Adson forceps are non-toothed, and so are ideal for holding delicate tissues, such as bowel. Alfred Washington Adson (1887–1951) was Professor of Neurosurgery at the Mayo Clinic, Rochester, MN, USA. He was one of the first to use sympathectomy for the treatment of hypertension, and cervical sympathectomy for Raynaud's syndrome.



Allis forceps are used to hold soft tissues for a long period while minimising tissue damage. Using the ratchet they can be locked on to tissue, such as bowel, and can be used to provide gentle traction. Oscar Huntington Allis (1836–1921) was a surgeon at the Presbyterian Hospital, Philadelphia, PA, USA.



Babcock forceps. This is used to grasp any part of the bowel. The jaws are atraumatic and cause minimal tissue damage. Used commonly in appendicectomy to grasp the appendix and deliver it out of the wound. Care is taken when using it not to perforate the inflamed appendix. William Wayne Babcock (1872–1963), Professor and Head of the Department of Surgery at the Temple University School of Medicine, Philadelphia for 40 years. 'He was the inventor of the acorn-shaped vein stripper, introduced the alloy steel wire sutures, wire mesh in hernia repairs, and zinc chloride in the treatment of osteomyelitic sinus'.



Spencer Wells forceps. These were one of the first ratchet forceps ever designed and are still very useful. They are often used in pairs for clamping an artery before dividing it. The cut ends of the artery are then tied off, and the forceps removed (carefully!). Sir Thomas Spencer Wells (1818–1897) was a surgeon at the Samaritan Free Hospital for Women and Children, London, UK. He was one of the earliest surgeons to make use of anaesthetics in operation.

Kocher dissector. This is used during a thyroidectomy to dissect the upper pole of the thyroid. The instrument is blunt and therefore the surgeon is highly unlikely to inadvertently damage the superior thyroid artery or the external laryngeal nerve. It is used to dissect the superior pedicle, the superior thyroid artery. Once it has been isolated, the dissector is pushed under the pedicle. A tie is then put through the eye of the dissector which at this stage doubles up as an aneurysm needle. The pedicle is thus tied three times as close to the gland as possible. With the dissector under the tied pedicle, a fine knife is now used to cut leaving two ties in the patient. The presence of the dissector under the pedicle prevents any damage to the underlying structures. Emil Theodor Kocher (1841–1917), Professor of Surgery at Berne, Switzerland, was awarded the Nobel Prize for Physiology or Medicine in 1909 for his work on the thyroid. The first surgeon to be a Nobel Laureate.

Appendix 2

Fundamental principles in the operating theatre and the importance of global health

INTRODUCTION

Historically, operating theatres were designed to encourage large audiences of observers. Surgeons often wore their outdoor clothes and no consideration was given to sterility. The outcomes of surgery were less than satisfactory.

The modern operating theatre, safety checks, accepted theatre etiquette and theatre instrument sterilisation process have made a significant positive impact on outcomes after surgery.

A basic knowledge of the principles of theatre design, theatre etiquette and sterilisation are important for surgeons, aiding them to work with the 'flow' in theatres, preserve the sterile field, and communicate effectively with other members of the theatre and sterilisation team. This fundamental knowledge is applicable in a global setting.

PRINCIPLES OF THEATRE DESIGN

Optimisation of location and spaces

When building new operating theatres, both the principle of locating the operating theatre away from passing traffic (at a terminal location) and the concept of maintaining optimum 'patient flow' should be considered. Operating theatres are often co-located near wards and the intensive care unit to minimise transfer time, thereby increasing efficiency and productivity in the theatre.

Operating theatres should have both easy access to sterile services and sufficient space for all necessary equipment to be stored. The concept of good 'flow' should be extended to staff (in the location of their changing, rest and office areas) and surgical equipment (to and from sterile services).

A reception area for patient safety checks, an area for the patient to be anaesthetised (this may be done in a separate anaesthetic room or in the operating theatre itself) and a recovery area must be included in the theatre design.

The importance of the sterile surgical field

The principle of maintaining the sterile surgical field is at the heart of theatre design. To maintain this field, clean and contaminated areas of the theatre complex are separated into 'zones'. Although there are different individual designs, the principle of minimising the risk of cross-contamination between the 'clean' and 'dirty' zones remains.

Materials used to construct operating theatres should be smooth and easy to clean. Doors disrupt airflow and should be kept closed whenever possible. Sliding doors (electrically operated) cause less airflow disruption than swinging doors. Doors (when closed) and windows should be sealed.

Operating theatres should be large enough for the purpose for which they are used. There should be sufficient space to allow those 'circulating' to move freely without risk of contaminating the sterile surgical field. Modern operating theatres often have a 'modular' design where commonly used equipment is stacked together and mounted on movable gantries to improve cleaning and reduce clutter.

After surgery, contaminated instruments and equipment are physically isolated and removed from the clean to the contaminated zone, where the waste is disposed of and instruments decontaminated and reprocessed for sterilisation. This is often through the use of a 'dirty' corridor.

Theatre air and ventilation

Specialised ventilation in the operating theatre aids in the maintenance of clean and dirty zones because airborne bacteria are prevalent. Between 5000 and 55 000 skin particles laden with bacteria are shed each minute by each individual in the operating room.

Positive pressure ventilation forces airflow from clean to contaminated areas with 15–25 theatre air exchanges taking place per hour using conventional ventilation systems. These systems deliver atmospheric filtered air with positive pressure (15–25 N/m^2) through a downward displacement over the operating table. This ventilation allows for clearance of airborne particles, bacteria and waste anaesthetic gases. Ventilation ducts allow contaminated air to be expelled from the operating theatre.

Ultra-clean ventilation systems use high-efficiency particulate air (HEPA) filters that remove 99.9% of particulate matter >0.3 μm in diameter (bacteria are 0.5 μm). They also use vertical laminar airflow over the operating table to minimise turbulence, reduce contamination at the surgical site (horizontal laminar air flow is less effective (Salvati *et al.* 1982)). Laminar airflow theatres have an air exchange every 2–3 minutes.

The operating lights disturb the laminar airflow and are optimally placed to either side of the operative wound with 0.6 m between the lights to minimise obstruction to the vertical airflow (Refaie *et al.* 2015). Temperature in the operating theatre should be between 18 and 25°C.

STERILISATION

Preoperative checks

When equipment is taken from storage for use, careful checking of the instrument packaging must be carried out. Care must be taken to ensure that the instrument set is complete, without torn packaging, and has undergone sterilisation within the recommended time.

Postoperative checks

After the instruments have been used, they must go through decontamination. This process is standardised and includes cleaning the instruments thoroughly with water immediately after use. Staff involved in this decontamination should wear personal protection. In addition to using water, mechanical agitation aided by chemical cleansing and heat are all needed. Instruments can be decontaminated by hand (for delicate instruments) or in industrial washers.

After decontamination, instruments are checked for damage, sharpened and otherwise maintained. Broken or damaged instruments are replaced. This process is helped by the surgeon during the final step of the surgical safety checklist, when all instrument issues are noted. After maintenance, the instruments are packaged into sets and double wrapped before sterilisation.

Sterilisation for most instruments is carried out in a steam autoclave. For some equipment gas sterilisation is used. Accurate documentation of the sterilisation procedure, expiry dates, the contents of packaged sterile instruments, and missing or damaged instruments on labels before storage is imperative.

THEATRE ETIQUETTE AND INFECTION CONTROL

Personnel factors

At the start of an operating list, it is important, as part of the team brief, for each member of the team to introduce him- or herself. For members of staff arriving after the start, it is important to introduce themselves to the theatre practitioner in charge of the operating theatre at the outset. Behaviour and discipline of staff are a key aspect in the maintenance of patient safety and adequate infection control.

Scrub staff will wear a hat, mask with visor or protective glasses. They will then don a sterile gown and use a closed-glove technique to don their sterile gloves. It is also important that other members of the circulating team take account of universal precautions, including the use of non-sterile gloves when handling or transferring a patient and consideration of the use of masks and protective glasses. Careful handling of sharps is paramount.

Staff clothing is also important. It acts as an effective barrier against the spread of infection. Each operating theatre suite will have specific policies that should be adhered to. The principles are that within the clean zone of the operating theatre all staff must wear scrubs. These scrubs should not be worn in dirty zones if the member of staff is to walk back into the clean zone. If scrubs are soiled, these should be changed for a fresh pair. Hair should be covered by an appropriate hat.

Many policies state that masks should be worn when sterile instruments are opened or in the presence of an open wound. In contaminated surgery, some policies allow for surgeons to dispense with the mask, but consideration must be given for personal protection from fluids on to the face. Both mask visors and/or protective goggles protect the eyes from potential cross-contamination from the patient.

Shoes used in the operating theatre should have a solid covering over the dorsum of the foot, enclosing the toes, and not have multiple holes. This is protection in case sharp instruments fall to the floor, resulting in foot injuries. Shoes should be cleaned after every case to ensure that there is no cross-contamination.

Environmental factors

A number of different skin disinfectant surgical preparation fluids have been described in either an aqueous or an alcoholic base. The antiseptic is normally iodine based (e.g. Betadine) or chlorhexidine based. Chlorhexidine comes in two concentrations – 0.5% or 2% weight:volume (w/v) – and a number of different trials have shown the latter to be the most effective.

Surgical drapes that are used to isolate the surgical wound will be resistant to mechanical stress, impenetrable to liquids and ideally absorbent. Depending on the hospital situation, disposable or reusable drapes can be used if they fit these criteria. The use of incision drapes has some advantages, but recent evidence has shown that those incision drapes that are impregnated with iodine are more effective at reducing the skin bacterial load than non-iodine-impregnated drapes.

The number of people in the operating theatre also increases the risk of contamination of the sterile field. The number should be kept to the minimum. At least 1 metre must be kept between non-scrubbed staff and any sterile instrument tray or the operating table. Non-scrubbed staff should never pass between the sterile instrument tray and the operating table with the patient on it. When the doors are opened to the operating theatre a disturbance is made to the ventilation system. The number of times the doors are opened during the operation should be kept to the minimum. This often requires a high level of advance planning to ensure that all the necessary equipment is available at hand in the operating theatre.

GLOBAL HEALTH AND SURGERY

The previous sections identify fundamental principles relating to surgery wherever it is practised around the world. By way of contrast, in Chapter 33 the differing surgical options for spinal surgery in different global settings were highlighted.

In the last two decades, the interest in global health has notably increased. There are many reasons for this. First, there is better global communication, such that what happens in one part of the world is known almost instantaneously in the rest of the world. Second, there is an increased understanding that the world is a small place, and that the health needs of the poorest in the planet should be the concern of the whole planet. Global health as a concept started with the treatment of medical and infectious diseases such as malaria and tuberculosis (TB), but in the last few years there has been an increasing interest in global surgery. In 2013 the *Lancet* journal commissioned a group of surgeons, health planners, health economists and politicians to prepare a report on the state of surgery in the world. It was published in 2015 (Meara *et al.* 2015) and has been a major influence in world surgery, with five key messages that clarify the levels of disparity in surgical services globally; however, it ends with a strong economic argument for the surgeons of the world to engage with the global need.

The five key messages from the *Lancet* Commission

5 billion people cannot access safe, affordable surgery when needed

The World Health Organization (WHO) has previously stated that 2 billion people had no access to surgery. This is true, but when one adds a quality measure to the surgery available, and also an affordability measure, the number of people who cannot access surgery for themselves or their family within a reasonable time period is increased to 5 billion, which is most of the people on the planet.

143 million more surgical procedures are needed each year

This is the number of operations needed to bring the world up to a reasonable standard of surgery.

33 million individuals and families face catastrophic expenditure each year paying for surgery and anaesthesia

This figure is in fact higher if one adds the incidental expenses associated with having surgery, such as transport and accommodation for family members during the operation. The annual total then rises to US$81 million.

Investing in surgery is affordable, saves lives and promotes economic growth

The cost of improving surgical services across the world to a satisfactory level over the next 15 years is enormous, and has been estimated at US$350 billion, or just over US$20 billion per year. However, the cost of not investing in surgery is many times higher at US$12.3 trillion over 15 years, or US$820 billion a year because of lost economic growth resulting from untreated surgical conditions. **Figure 1** shows the estimated economic loss due to untreated surgical conditions. The graph clearly shows that untreated cancer and trauma are the two big causes of such economic loss.

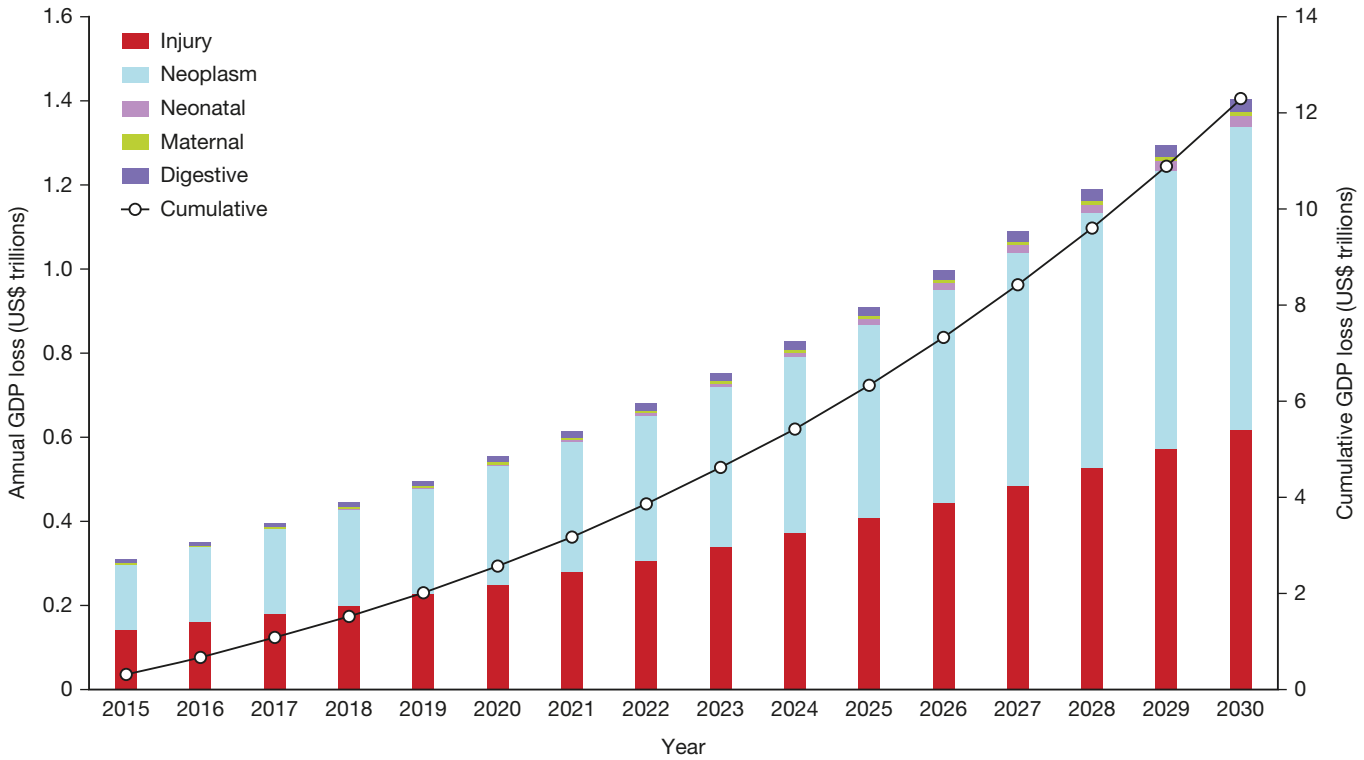

Figure 1 The graph illustrates the estimated economic loss due to untreated surgical conditions; untreated cancer and trauma represent the two largest causes of such economic loss (with permission of Meara *et al*. 2015).

Surgery is an indivisible, indispensable part of health care

This is a message that is directed more to health planners and public health teams. Surgery has in the past been seen as a minor and expensive part of a country's health plan. Most public health interventions are measured in terms of disability-adjusted life-years (DALYs) averted. The methodology involves calculating how much it costs to avert 1 year of suffering due to a disability. When measured in these terms, surgery competes well with the treatment of malaria and TB. The fact that surgery saves lives, surgery changes lives and surgery is a boost to the economy should encourage health planners to put surgery in the essential group of services in any national health strategy.
