Figure 34.4 **(a)** Radiograph showing sclerosis on the undersurface of the acromion and the greater tuberosity, with reduced subacromial space. **(b)** Radiograph showing an acromial spur and arthritis of the acromioclavicular joint.

Maurice Klippel, 1858–1942, neurologist, Hôpital Tenon, Paris, France.
André Feil, 1889–?, neurologist, Paris, France. **Klippel and Feil** described this condition in a joint paper in 1912.

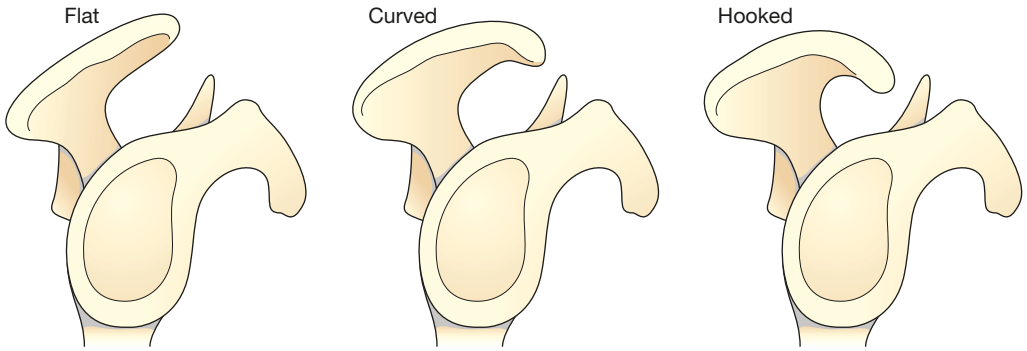

Figure 34.5 The three commonest acromial morphologies.

Rotator cuff tendonitis

The rotator cuff moves in a confined space between the humeral head, the acromion and the coracoacromial ligament (CAL). Even a trivial injury can start a progression of inflammation, swelling and pain, which in turn causes subacromial pain, termed impingement, felt to be attributable to abrasion of the cuff and bursa on the undersurface of the acromion. The impingement then causes further swelling and pain and a vicious circle is set up. The likelihood of tendonitis developing is increased in patients with a spur beneath the acromion, which is seen increasingly commonly with age (**Figure 34.5**) and may be an effect rather than a cause of painful subacromial degeneration, as described above. The result is a painful arc of movement for the patient, which corresponds to the position where the inflamed segment of the supraspinatus tendon jams under the anterior acromial spur. The examiner may find that, although the patient cannot lift their arm through this segment (because of the pain), passively lifting the arm for the patient enables them to continue with pain-free movement once the area of impingement is past (**Figure 34.7**).

TREATMENT

Injection of steroid into the inflamed area may break the cycle of inflammation and impingement (**Figure 34.8**), but arthroscopic removal of the subacromial spur, anteroinferior acromion and the CA ligament (if it is impinging) should give good relief of symptoms (**Figure 34.9**).

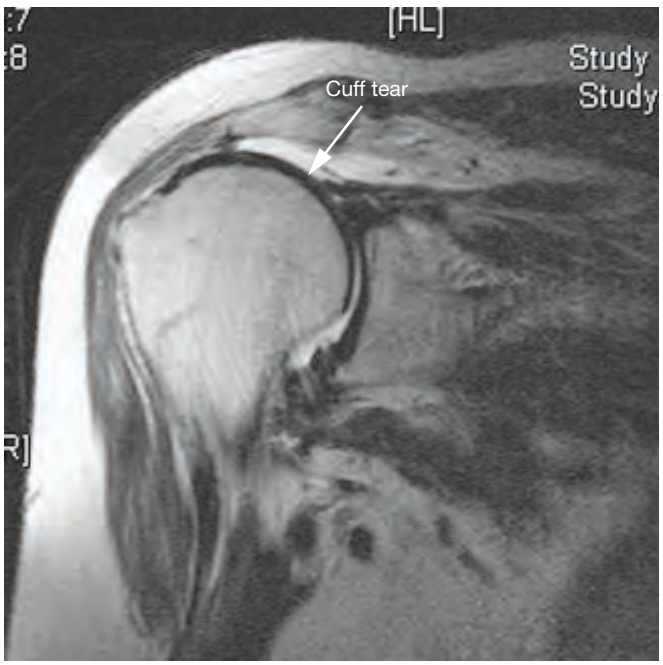

Figure 34.6 Magnetic resonance imaging scan showing a retracted cuff tear.

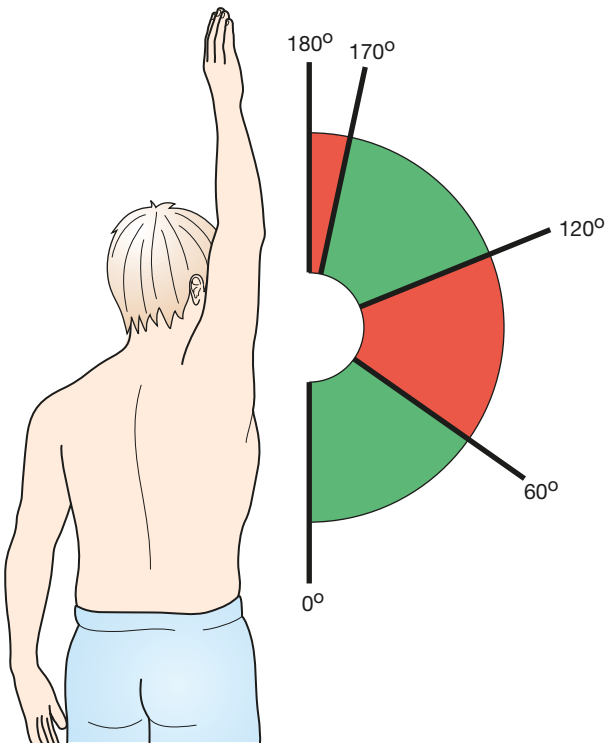

Figure 34.7 Arcs of shoulder girdle motion with subacromial impingement pain between 60° and 120° of abduction, and acromioclavicular joint pain between 170° and 180°.

Figure 34.8 Technique of administering an injection into the subacromial bursa.

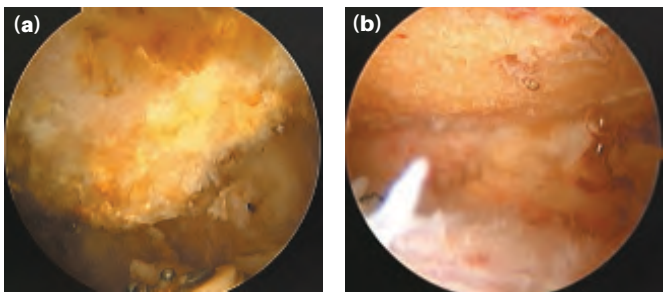

Figure 34.9 **(a)** Arthroscopic view of an acromial spur. **(b)** Arthroscopic view after the acromial spur has been removed and the cuff decompressed.

Summary box 34.1

Rotator cuff tendonitis

- Tendonitis produces weakness secondary to pain (often a painful arc)
- A tendon tear produces weakness which is only secondarily painful
- Injection of local anaesthetic and retesting can be diagnostic

Summary box 34.2

Treatment of subacromial impingement

- Non-operative treatment includes injections and rotator cuff rehabilitation
- Surgery indicated if symptoms persist beyond 3 to 6 months
- Surgery decompresses the rotator cuff

Rotator cuff tears

The rotator cuff has a poor blood supply in the segment that glides between the humeral head and acromion and is subject to degenerative changes, which weaken it with age. The cuff thins and eventually develops defects that are termed tears, whether or not there has been any trauma involved in their appearance. This means that tears are more common in the elderly, and at any age they do not heal spontaneously. Tears usually begin at the anterolateral edge of the supraspinatus, and progress posteriorly to involve the infraspinatus and teres minor tendons. This creates a bare area over the greater tuberosity, as the torn cuff retracts medially (Figure 34.10).

HISTORY

In the younger patient with a healthier cuff the onset often requires relatively major trauma, e.g. avoiding a fall by hanging onto the rung of a ladder, but in the elderly the onset may

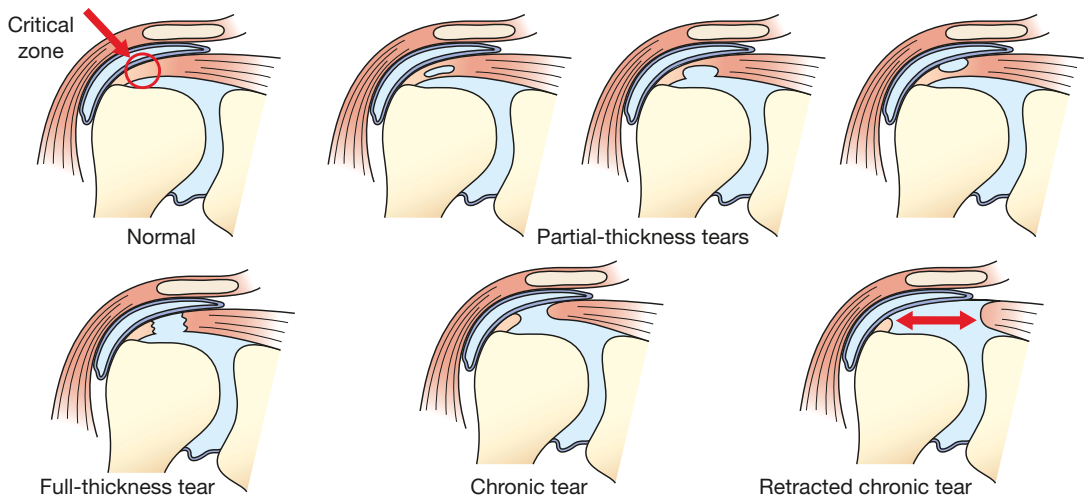

Figure 34.10 Various stages of rotator cuff tear. Initial partial-thickness tears have the potential to progress to full-thickness and retracted tears.

follow a painful period of tendonitis or the condition may apparently occur spontaneously.

EXAMINATION

The patient may have a mixed picture of tendonitis and a tear, but if the pain is removed by injection of local anaesthetic the weakness will persist. Symptomatic tears are associated with pain, weakness, limited active abduction, cuff muscle wasting and hunching of the shoulder when attempting abduction (**Figure 34.11**).

Figure 34.11 A 75-year-old man with a >5 cm retracted cuff tear attempting to abduct his shoulder, which is limited, by lack of balanced motor power, below 60°.

INVESTIGATION

Tears are classified as small (less than 1 cm), intermediate (2–4 cm) and large (more than 5 cm).

TREATMENT

Treatment depends on the patient's age, lifestyle and severity of symptoms. Arthroscopic or open repair with subacromial decompression can be considered for all tears, but is likely to give a better outcome in the young (see characteristics above) than in the old. It may not be possible to suture large tears owing to their size, or the attempt at repair may be fruitless because of fatty atrophy of the rotator cuff and loss of muscle contractility, in which case complex surgery e.g. tendon transfers, patch grafts or reverse joint replacement (**Figure 34.12**) will need to be considered.

Figure 34.12 Reverse geometry total shoulder replacement.

Summary box 34.3

Rotator cuff tears

- Occur more commonly in older age groups
- 4–20% of 40–50 year olds have asymptomatic rotator cuff tears
- Up to 50% of 70 year olds have an asymptomatic tear
- Subacromial decompression is carried out to facilitate pain relief at cuff repair
- Acute tears may present with little pain but profound weakness
- Earlier repair after traumatic onset gives better results

Frozen shoulder (adhesive capsulitis, contracted shoulder)

This is an idiopathic painful and stiff condition most commonly affecting females in their 50s. It is also associated with diabetes, heart or thyroid disease.

HISTORY AND EXAMINATION

Frozen shoulder is characterised by the onset of severe pain and may follow minor trauma. The differential diagnosis includes infection, fractures and rotator cuff tears. Initially there is severe pain but this improves with time. However, there is global loss of active and passive movement, limited by pain. The pathognomonic sign is loss of external rotation active. Radiographs are normal and distinguish it from the other condition that can globally and painfully affect shoulder movement: osteoarthritis.

TREATMENT

The clinical course can run over 1–2 years, often considerably longer in diabetic individuals, and is divided into painful, stiffening and thawing phases. If untreated, frozen shoulder will resolve, and the majority of patients are left with no functional problems. In the first phase of the condition, treatment is pain relief. Corticosteroids can also be injected locally. Despite the pain, the patient should be encouraged to perform as much active and passive movement as they can. Non-operative treatment can include distension injection of the glenohumeral joint with local anaesthetic and steroid. Operative options include manipulation under anaesthesia or arthroscopic release of the tight capsule, which usually produce pain relief and are indicated for prolonged stiffness.

Summary box 34.4

Frozen shoulder (adhesive capsulitis)

- Most commonly occurs in females in their 50s
- Spontaneous onset
- Produces severe pain followed by reduced shoulder motion
- Spontaneous resolution can occur over 1–2 years
- Differential diagnoses: calcific tendonitis and rotator cuff tear
- Injections, distension with saline, manipulation and surgical release may all help

Calcific tendinitis

Calcium deposition within the supraspinatus tendon is believed to be part of a degenerative process, or the consequence of a partial degenerative tear of the tendon.

HISTORY AND EXAMINATION

There is severe, rapid onset shoulder pain with painful, restricted motion. However, in contrast to adhesive capsulitis, external rotation is possible. Subacromial calcific deposits can be seen on plain radiographs (Figure 34.13).

Figure 34.13 Radiograph demonstrating calcific tendonitis.

TREATMENT

Subacromial corticosteroid injections may help and can be accompanied by needling, aspiration or flushing of the deposits (barbotage). The condition is often self-limiting, with resorption of the calcium deposits. Surgery for resistant cases includes arthroscopic or open subacromial decompression and excision of the calcific deposits if they are prominent.

Arthritis of the shoulder

Rheumatoid arthritis

The glenohumeral joint is commonly involved in rheumatoid arthritis (Figure 34.14). As is typical of this condition, there is osteoporosis, destruction of the articular cartilage and synovial proliferation with pannus formation. The rotator cuff is weakened and frequently tears. Arthroscopic synovectomy may slow the progress of the joint destruction and lead to a reduction in pain and improvement in range of movement, though it is needed much less frequently since the introduction of biological therapies for rheumatoid disease. Intra-articular steroid injections may also be helpful. Shoulder replacement is complicated by poor bone stock and damage to the stabilising structures around the shoulder, especially the rotator cuff. The patient should only expect a reduction in pain. Any increase in range of movement is a bonus.

Figure 34.14 Rheumatoid arthritis of the shoulder.

Summary box 34.5

Shoulder problems in rheumatoid arthritis

- Arthroscopic synovectomy may be effective
- Rotator cuff tears are common
- Glenohumeral joint replacement improves pain but motion depends on rotator cuff involvement

Osteoarthritis of the shoulder

Glenohumeral joint osteoarthritis is either primary (Figure 34.15), secondary to trauma (Figure 34.16) or end-stage rotator cuff disease i.e. cuff arthropathy (Figure 34.17).

TREATMENT

If medical treatment has failed, the surgical options are arthroscopic debridement or joint arthroplasty. Debridement is not predictable, but both total shoulder replacement (Figure 34.18) and hemiarthroplasty (Figure 34.19) have good results in appropriate patients. A standard total shoulder arthroplasty can be performed if the rotator cuff is intact. However, in most rheumatoid patients and all patients with cuff tear arthropathy, the cuff is deficient and either a hemiarthroplasty or a reverse polarity total shoulder arthroplasty (see Figure 34.12) should be used. Shoulder arthroplasty is an effective pain-relieving procedure, but less predictable in restoring motion, especially above shoulder level.

Figure 34.15 Osteoarthritis of the glenohumeral joint.

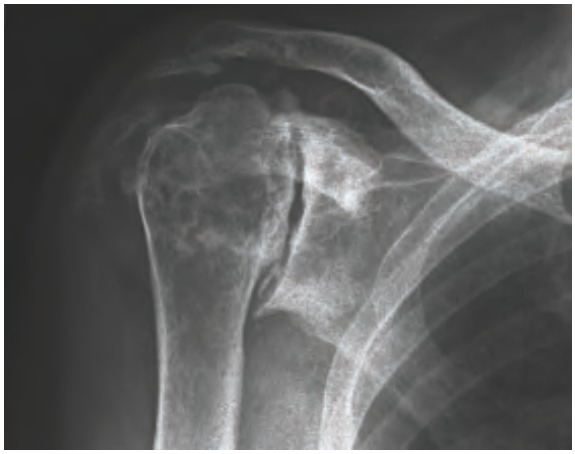

Figure 34.16 Post-traumatic arthritis with malunion of the proximal humerus, collapse of the humeral head, subchondral sclerosis and osteophytes.

Figure 34.17 A massive cuff tear that has led to superior migration of the humeral head and secondary osteoarthritis of the glenohumeral joint.

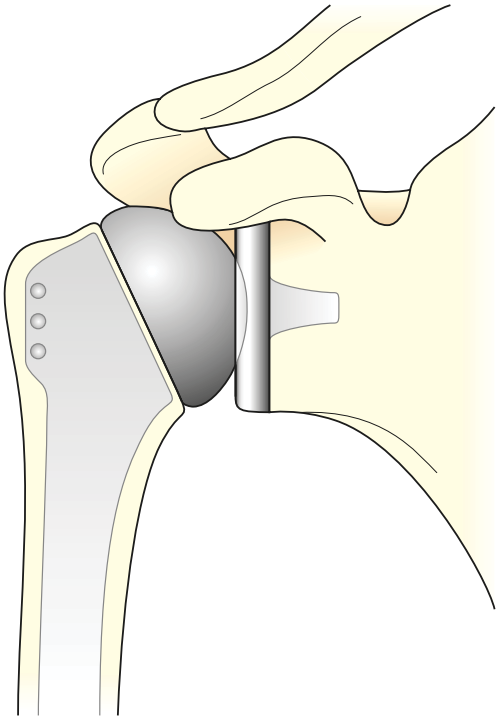

Figure 34.18 Total shoulder replacement performed for osteoarthritis. An intact rotator cuff is essential.

Figure 34.19 Shoulder hemiarthroplasty is performed for arthritis if there is a deficient rotator cuff.

Arthrodesis of the joint is an alternative in younger patients with a history of sepsis or neurological problems (Figure 34.20). It is also used after brachial plexus injury, when nerve repairs restore hand and elbow function but the shoulder remains flail because of loss of the C5 supply. Good scapulothoracic control, tested by the ability to shrug the shoulder powerfully, is a prerequisite to successful arthrodesis. Patients retain a moderate range of movement at the shoulder girdle, as a result of scapulothoracic motion, which normally makes up one-third of apparent shoulder elevation, the remaining two-thirds being glenohumeral movement, which is lost in arthrodesis.

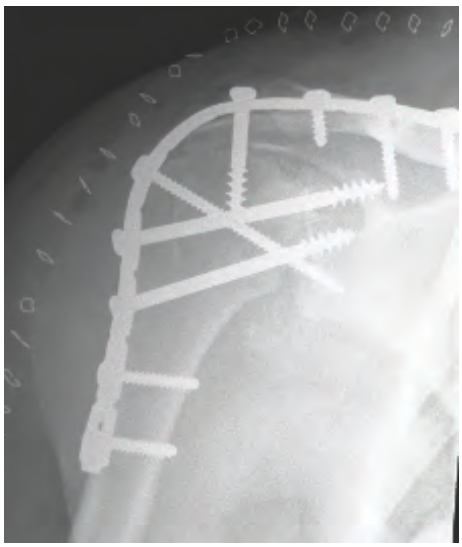

Figure 34.20 Arthrodesis of the shoulder.

Summary box 34.6

Arthritis of the shoulder

- Severe cases are treated with hemiarthroplasty or total shoulder arthroplasty
- Total shoulder replacements should not be performed if the rotator cuff is deficient
- Pain relief is good following arthroplasty, though improvement in range of motion is less predictable
- Glenohumeral arthrodesis is an option in the young or those with a history of sepsis
- Post arthrodesis, motion is fair but is entirely scapulothoracic

Acromioclavicular joint arthritis

Acromioclavicular joint (ACJ) arthritis is common and is often asymptomatic, noted as an incidental finding on radiographs (see Figure 34.4b). Symptoms typically arise in males aged 20–50 years. Inferior osteophytes can impinge on the underlying rotator cuff.

HISTORY AND EXAMINATION

There may be a history of trauma to the ACJ. Pain is activity related. There is prominence of the lateral end of the clavicle. The joint line is tender. Flexing and adducting the arm to place the hand behind the opposite shoulder reproduces pain. If symptoms are related to inferior osteophytes, impingement symptoms and signs are also present.

TREATMENT

An intra-articular corticosteroid injection will usually help, and even if the effect is short lived it localises the problem accurately. Surgery involves arthroscopic or open excision of the lateral 0.5–1 cm of the clavicle (Figure 34.21). This gives good pain relief. In patients with symptoms that are predominantly those of impingement, arthroscopic removal of the inferior osteophytes with subacromial decompression should be performed.

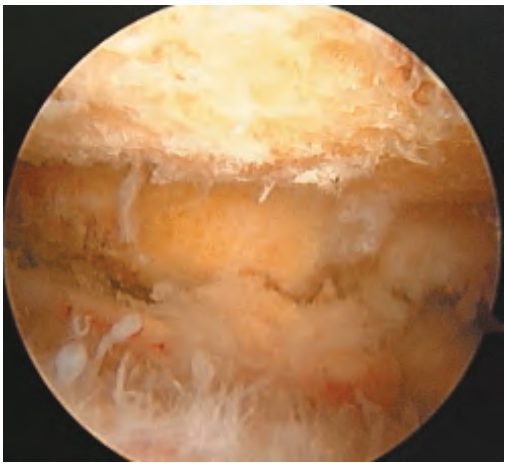

Figure 34.21 Arthroscopic end-on view of the clavicle after excision of its distal end.

Summary box 34.7

Acromioclavicular joint problems

- AC joint arthritis is common and may be asymptomatic
- It may become symptomatic secondary to trauma or repetitive overload
- Inferior clavicular osteophytes can impinge on the cuff
- Intra-articular steroid and local anaesthetic injection may relieve symptoms
- Excision of the lateral end of the clavicle gives good results

Long head of biceps tendon rupture

Rupture of the long head of biceps usually occurs in the elderly and is due to abrasion of the tendon in the bicipital groove, especially at the superior end, beneath the anterior acromion. It is associated with rotator cuff tears. Most patients present with few symptoms, although they often seek advice because of the bulge they notice in their arm.

HISTORY AND EXAMINATION

Patients feel a sense of 'something giving way' in front of the shoulder, sometimes with relief of pain if there was any

present beforehand due to biceps tendinitis. The upper arm is bruised and elbow flexion produces a swelling in the front and middle of the arm (Figure 34.22). The lump will be permanent and is initially tender. Power is slightly diminished in the early stages, when there may also be cramping pains on use of the arm.

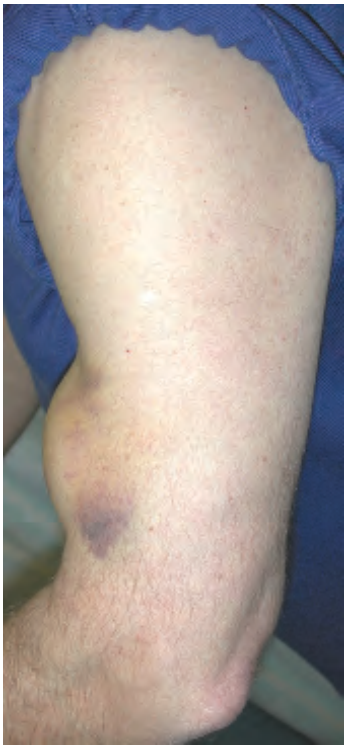

Figure 34.22 Bruising and change in the upper arm shape due to rupture of the long head of biceps.

TREATMENT

Reassurance that pain and bruising will resolve is sufficient. Power improves over several months and surgery (biceps tenodesis) is not needed for function, though it may help the cosmetic appearance.

Dislocation of the shoulder and instability of the glenohumeral joint

Three broad groups of shoulder instability exist.

Classification of glenohumeral instability

- **Traumatic**: unidirectional; involuntary; surgery is usually successful.
- **Atraumatic**: multidirectional, painful; involuntary; responds to surgery.
- **Habitual**: voluntary, with ligament laxity, painless; surgery usually contraindicated.

Recurrent traumatic instability

HISTORY

Traumatic shoulder dislocation is the commonest of all dislocations, usually first presenting in patients under 25. Usually the shoulder dislocates anteroinferiorly. Initially there is a notable traumatic event. Subsequent dislocations require less force. The shoulder may subluxate or actually dislocate (complete separation of the joint surfaces).

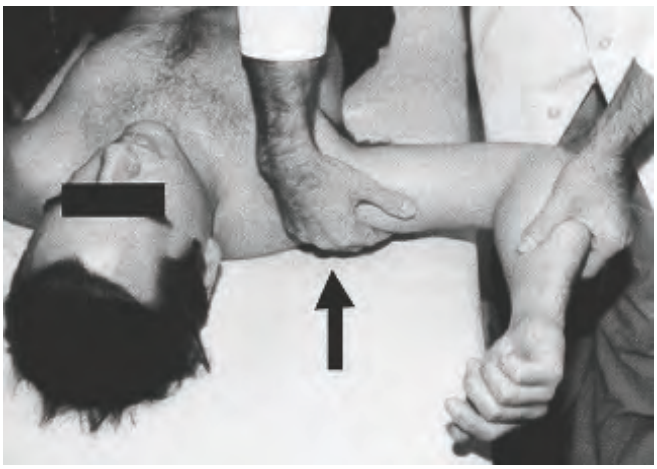

Figure 34.23 Apprehension test for anterior instability.

EXAMINATION

On examination the shoulder has a full range of motion, but with forced abduction and external rotation the patient experiences apprehension (a sense of impending doom!) (Figure 34.23).

INVESTIGATIONS

On computed tomography (CT) or MR arthrography (Figure 34.24), detachment of the anteroinferior labrum (Bankart's lesion) (Figures 34.25 and 34.26) and damage to the humeral head (Hill–Sach's lesion) can often be seen.

TREATMENT

The relative indications for surgery are repeated dislocations, or symptoms of instability that persist after reduction of the first dislocation, that are interfering with the patient's quality of life. Anterior instability can be treated with arthroscopic or open repair of the Bankart defect with tightening of the capsule, which prevents further dislocations in up to 90–95% of patients. Bony defects of the glenoid, and occasionally large Hill–Sachs lesions, may have to be grafted. For the less common recurrent posterior instability, repair of the damaged labrum and tightening of the posterior capsule is needed.

Arthur Sydney Blundell Bankart, 1879–1951, orthopaedic surgeon, The Middlesex Hospital, London, UK.

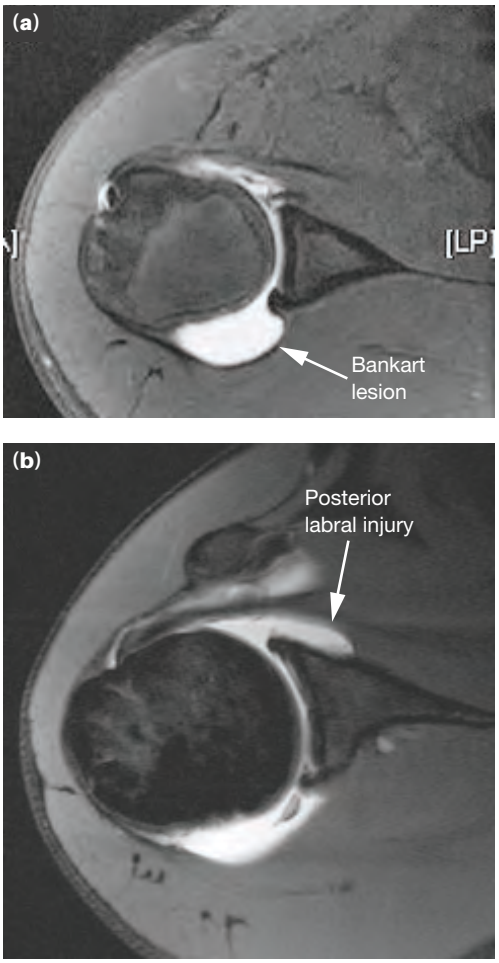

Figure 34.24 **(a)** Magnetic resonance (MR) arthrogram showing anterior Bankart lesion. **(b)** MR arthrogram showing posterior labral injury.

Summary box 34.8

Recurrent traumatic shoulder instability

- An appreciable force leads to the first dislocation or subluxation
- Subsequent dislocations/subluxations require less force
- The commonest direction of dislocation is anteroinferior
- There is a positive apprehension sign
- Surgical treatment repairs the labral lesion and tightens the capsule

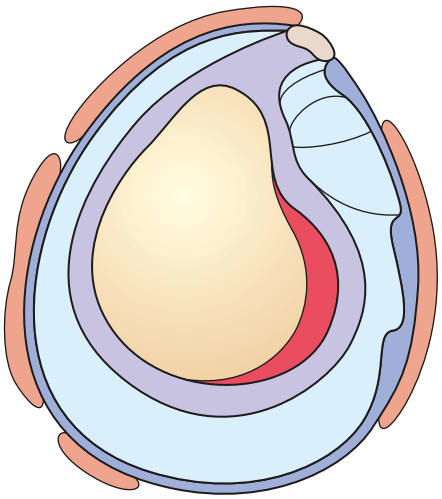

Figure 34.26 An end-on view of the glenoid labrum, demonstrating anteroinferior labral detachment (red) with the rotator cuff muscles (brown), long head of biceps tendon and labrum (grey).

Posterior dislocation of the shoulder

This is a rare event but is easy to miss. The clue is often in the history, as the patient will have either had an electric shock, had an epileptic fit, or have been subject to severe restraint when their arm has been forced up their back (a half-Nelson) – all mechanisms producing forced internal rotation of the glenohumeral joint.

The patient will be in severe pain and can be difficult to examine e.g. if they are psychotic and if this is why they are being restrained. For the same reason, the radiographer may only be able to get an anteroposterior (AP) view of the shoulder and, on this view, the shoulder may look normal to the unwary (**Figure 34.27**). It is the high 'index of suspicion' from the history which gives the best chance of making the diagnosis.

TREATMENT

This dislocation may be difficult to reduce if the posterior margin of the glenoid is embedded in the humeral head (a 'locked' posterior dislocation), so that open reduction is needed.

Atraumatic instability

HISTORY

There is usually no history of an initial injury. Instability may be multidirectional and the shoulder is usually associated with

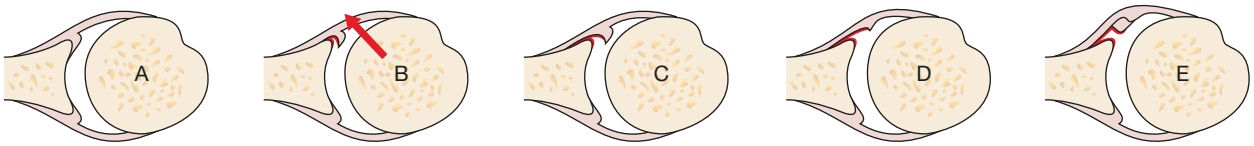

Figure 34.25 Schematic representation of Bankart's lesion, which forms a spectrum of pathology from minor labral detachment (B) to large detachments with glenoid rim fractures (bony Bankart; E).

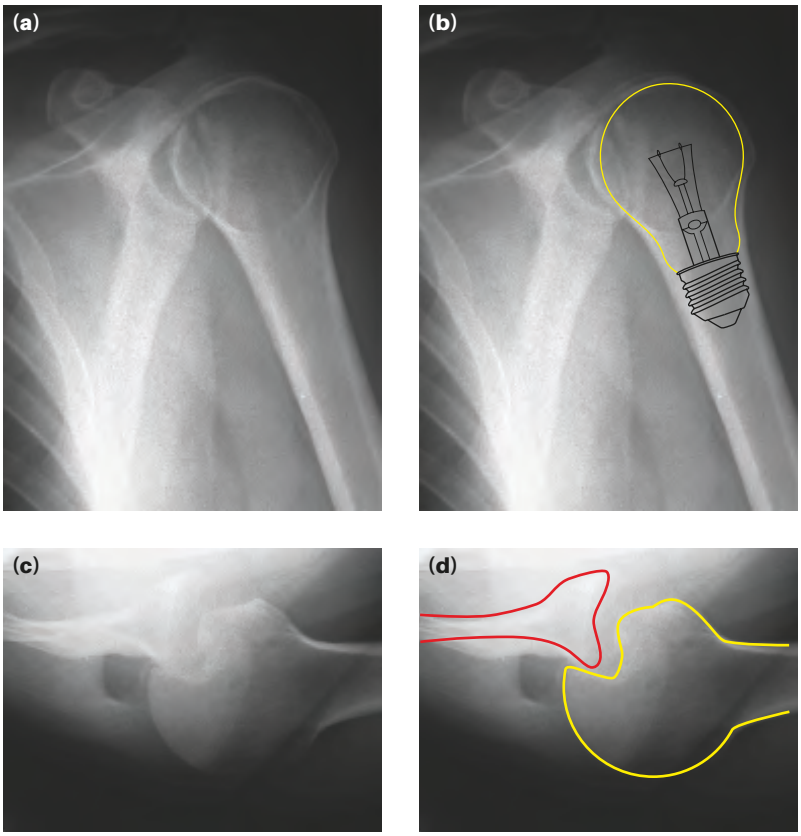

Figure 34.27 Posterior dislocation of the shoulder. **(a)** Anteroposterior view; **(b)** origin of the light bulb sign; **(c)** axial projection demonstrating how much easier it is to visualise the injury on this view; **(d)** axial projection highlighting this joint and further demonstrating the impacted fracture in the humeral head, or Hill–Sachs lesion.

subluxation rather than dislocation. The patient is often able to reduce the shoulder without assistance.

EXAMINATION

Generalised ligament laxity is common. Apprehension tests are positive, but often in more than one direction. Anterior and posterior drawing of the humeral head allows laxity to be tested (**Figure 34.28**). Overactivity of muscle groups such as pectoralis major should be sought, as this gives an avenue of treatment through rehabilitation.

TREATMENT

Specialist physiotherapy should be tried first in these patients, aiming to improve both the proprioception and firing patterns of the muscles around the shoulder (for instance biofeedback to control an overactive pectoralis major, or strengthening of underactive muscle groups). If this fails then surgery may be considered, by way of capsular tightening.

Habitual dislocation

Habitual dislocators are patients who can sublux the shoulder at will, usually either anteroinferiorly or posteriorly. The manoeuvre is painless. Patients have generalised joint laxity and may subluxate the shoulder as a 'party trick'.

Patients should be advised to stop subluxating the shoulder, which may then allow the capsule to tighten naturally with age. They may benefit from assessment and advice from a specialist physiotherapist. Surgery is associated with a high failure rate and should be avoided.

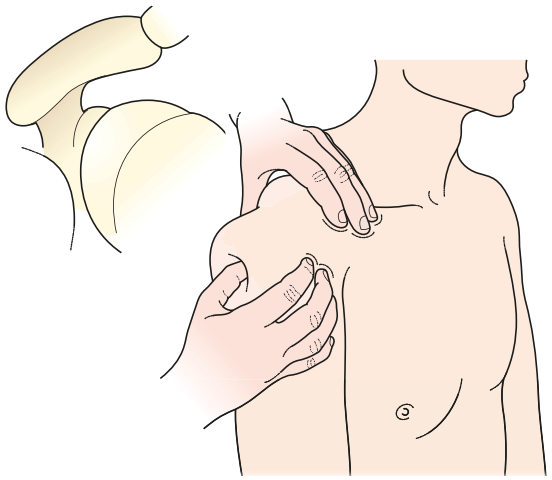

Figure 34.28 Generalised laxity can be appreciated by drawing the humeral head in anterior and posterior directions and feeling it slide up to, and possible even over, the glenoid rim. A sulcus will be produced under the acromion if the humerus is drawn inferiorly (sulcus sign).

DISORDERS OF THE ELBOW

Anatomy and function

The elbow joint allows flexion and extension as well as making up the proximal part of the radioulnar joint, which permits pronation and supination of the forearm. The brachial

artery passes immediately in front of the joint, while the ulnar nerve passes lateral to the medial epicondyle, immediately behind it.

Tennis elbow (lateral epicondylitis) and golfer's elbow (medial epicondylitis)

These are discussed in Chapters 31 and 32.

Arthritis of the elbow

Rheumatoid arthritis

Surgery may be required, especially in end-stage disease (**Figure 34.29**). Arthroscopic or open radial head excision and synovectomy is effective for painful, restricted pronation and supination. Elbow arthroplasty is effective in the earliest stages for pain relief and functional restoration.

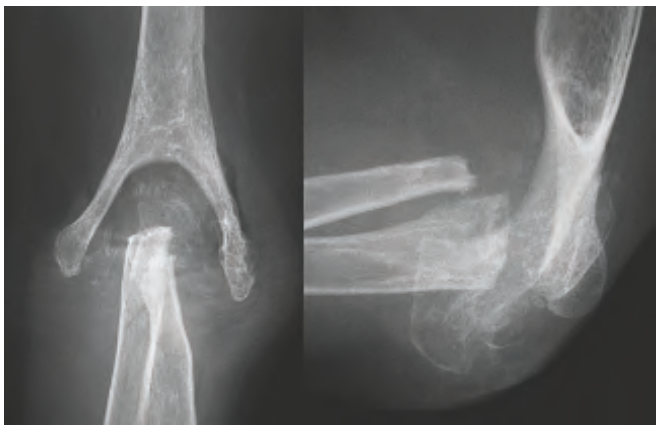

Figure 34.29 Typical end-stage unstable and destroyed rheumatoid elbow.

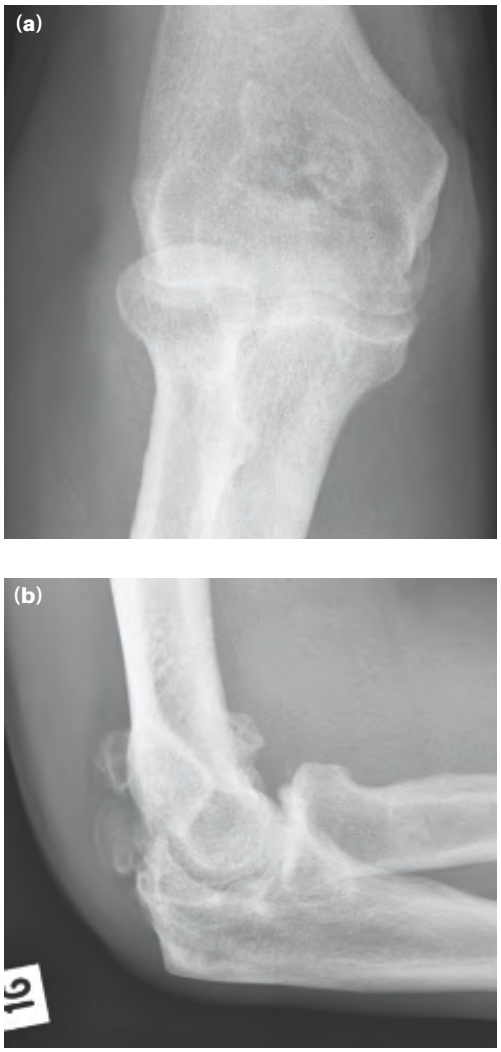

Figure 34.30 **(a, b)** Radiographs showing osteoarthritis of the elbow joint.

Osteoarthritis

Osteoarthritis of the elbow is usually primary (**Figure 34.30**) or secondary to trauma.

HISTORY

Typical patients are middle-aged males in manual occupations. Symptoms are pain, locking, crepitus and painful motion with loss of extension. Ulnar nerve entrapment symptoms may be present.

EXAMINATION

There is usually loss of extension and restriction of flexion. Pronation and supination tend to be spared in comparison with rheumatoid arthritis.

TREATMENT

Surgery should be considered only if medical treatment fails. Arthrodesis may be offered for those performing heavy manual work (**Figure 34.31**), but is associated with significant residual functional loss, as a joint replacement will not survive long under heavy loading. Surgical debridement alleviates pain and increases range of motion in earlier stages. Interposition arthroplasty (for example Achilles tendon allograft) may be considered in younger patients though it can be associated

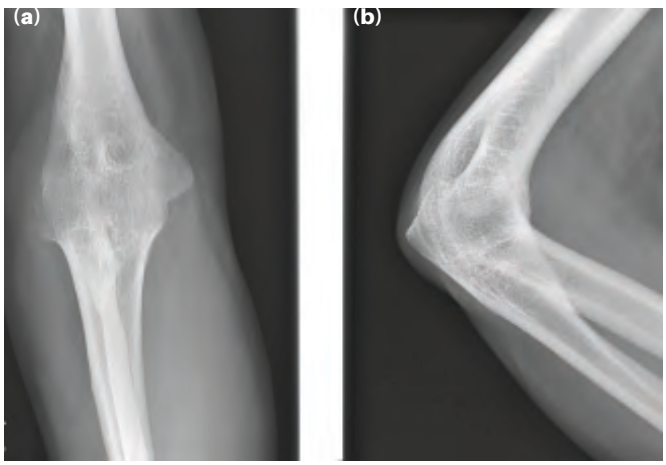

Figure 34.31 **(a, b)** Ankylosed elbow after tuberculosis. Arthrodesis is a surgical procedure to achieve the same end result, by excising the articular surfaces and compression plating across the joint.

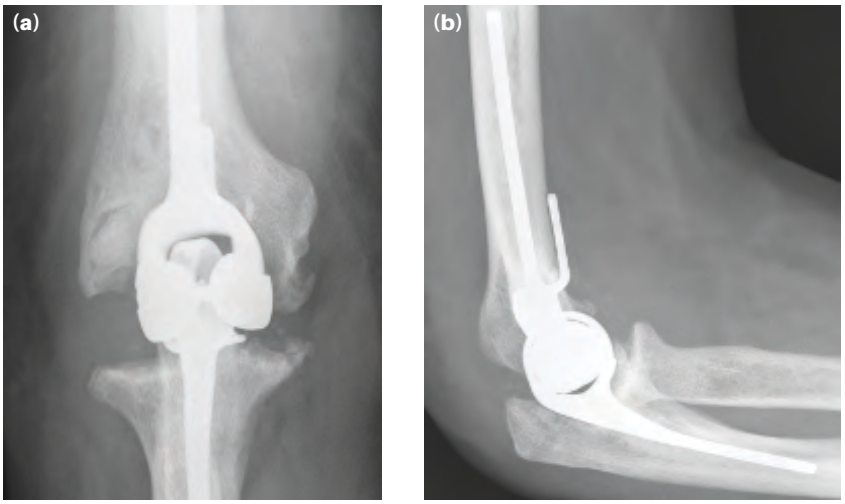

Figure 34.32 **(a, b)** Linked total elbow replacement.

with significant bone loss with time, possibly restricting future treatments). Prosthetic joint arthroplasty provides more predictable symptomatic relief (**Figure 34.32**) but high activity levels are associated with early loosening.

Summary box 34.9

Arthritis of the elbow

- Excision of the radial head improves pain and pronation–supination in rheumatoid arthritis
- Total elbow replacement gives good results in rheumatoid and low demand patients
- Arthrodesis may be the only surgical option in a high demand manual labourer

Figure 34.33 Osteochondritis dessicans of the capitellum (Panner's disease).

Loose bodies in the elbow

The common causes are osteoarthritis, osteochondritis dissecans in the young (**Figure 34.33**) and synovial chondromatosis (**Figure 34.34**). Patients describe sudden pain and locking, and the need to manipulate the elbow for relief. Plain radiographs will usually confirm the diagnosis (**Figure 34.35**). Arthroscopic clearance of the joint produces good results (**Figure 34.36**).

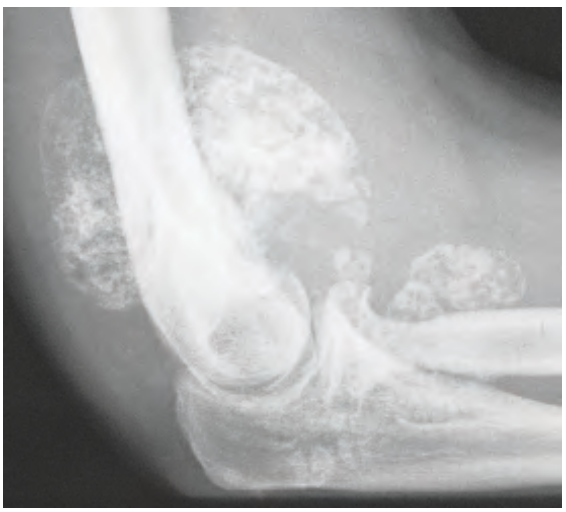

Figure 34.34 Synovial chondromatosis.

Olecranon bursitis

This is a relatively common disorder in which the elbow becomes red, warm, swollen and painful. Initially, septic arthritis may be suspected. However, on examination signs and symptoms are confined to the back of the elbow (**Figure 34.37**) and movement within an arc of 30–130° is possible. Most cases settle with anti-inflammatories. If the patient is pyrexial antibiotics should be given. Formal drainage of the bursa is indicated if purulent material is present.

Figure 34.35 Radiographs showing loose bodies in the elbow (arrow).

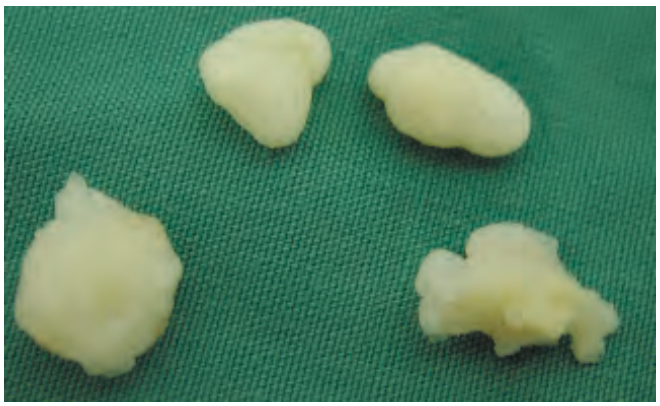

Figure 34.36 Loose bodies removed arthroscopically from the patient in Figure 34.35.

Figure 34.37 Olecranon bursitis.

Chronic bursitis may be associated with calcific nodules of the bursal lining (**Figure 34.38**). These can be excised if they prove troublesome.

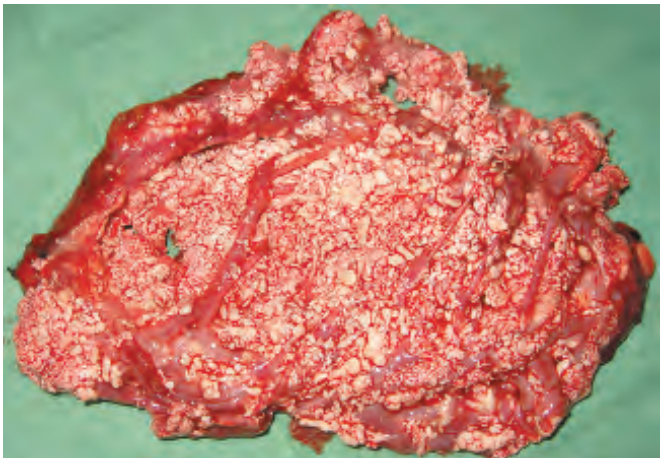

Figure 34.38 Large chronic olecranon bursa with dense calcific deposit.

Ulnar nerve compression

Compression of the ulnar nerve occurs in the cubital tunnel (behind the medial epicondyle), at the junction of the arcade of Struthers, and also at the medial intermuscular septum, as the nerve passes into the posterior compartment of the distal humerus. It can also occur as the nerve passes between the heads of the flexor carpi ulnaris (**Figure 34.39**).

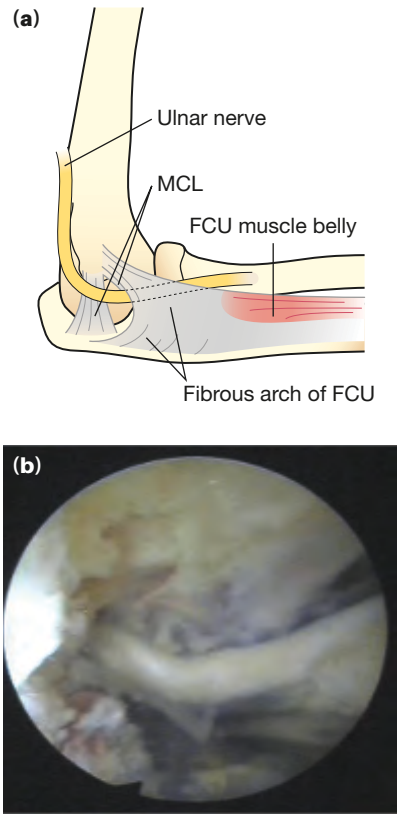

Figure 34.39 **(a)** Anatomy of the cubital tunnel site for ulnar nerve compression, with **(b)** a view of arthroscopic ulnar nerve decompression (inset). FCU, flexor carpi ulnaris; MCL, medial collateral ligament.

Sir John Struthers, 1823–1899, Professor of Anatomy, University of Aberdeen, Aberdeen, UK.

HISTORY AND EXAMINATION

Patients describe tingling/numbness in the little and ring fingers. A positive Tinel's sign is usually present at the compression site, with wasting and weakness of the intrinsic muscles of the hand (**Figure 34.40**). Froment's sign will be positive, due to weakness of the adductor pollicis (**Figure 34.41**). Nerve conduction studies have an unpredictable diagnostic value in the early stages. Radiographs may confirm medial osteophytes if compression is secondary to arthritis.

Figure 34.40 Intrinsic muscle wasting on the left due to ulnar neuropathy.

Figure 34.41 Froment's sign tests the adductor pollicis. The patient is asked to hold a piece of paper in a side pinch between the thumb and the index finger. The examiner attempts to pull the paper out. Owing to weakness of the adductor pollicus, the patient will compensate by flexing the flexor pollicis longus, which is supplied by the anterior interosseous nerve.

TREATMENT

Splints preventing elbow flexion at night may be useful. If symptoms persist, surgery can be performed, including simple nerve decompression (most cases), partial medial epicondylectomy and/or anterior transposition of the nerve. Transposition is necessary in cases of valgus deformity or if the nerve is unstable after decompression.

Summary box 34.10

Other common elbow problems

- Loose bodies cause locking and can be removed arthroscopically
- If the ulnar nerve is compressed, weakness and wasting will be seen in the hands
- Simple decompression is usually successful

TUMOURS OF THE UPPER LIMB

Tumours are discussed in Chapter 37.

HAND

The index finger works against the thumb for fine pinch grip; the thumb can press against the side of the flexed index finger for a key grip; the tips of the thumb, index and middle fingers provide a tripod pinch; all fingers curl for hook grip while the little and ring fingers provide the most power when making a fist. A stable wrist is required to allow good hand function.

Clinical history and physical examination

History

The occupation, sport and recreational activities (especially music) and hand dominance are all important items of information needed when treating a hand problem.

Examination

The examination of the hand should assess perfusion, sensation, movement, power and coordination. A check should also be made for rotational malalignment of the digits (**Figure 34.42**). There are also a number of special tests (which are beyond the scope of this chapter) relevant to different conditions.

Figure 34.42 Rotational deformity of the little finger.

Investigations

Radiographs can be used to assess for arthritis or tumours. Electrophysiological studies may be required to assess nerve function. MRI is useful for diagnosing avascular necrosis, ligament injuries or soft tissue tumours.

Hand swelling and stiffness

Swelling followed by stiffness is the arch enemy of hand rehabilitation. The hand will swell after injury, surgery or infection. In response, the wrist flexes and then there is compensatory metacarpophalangeal joint (MCPJ) extension and interphalangeal joint (IPJ) flexion. If action is not taken this position will become permanent, as collateral ligaments shrink and tissues fibrose. Hand elevation to reduce swelling, splintage in the position of safety to prevent collateral shortening (Edinburgh position: wrist extension, MCPJ flexion, IPJ extension) and early mobilisation prevent permanent stiffness.

Summary box 34.11

General principles of treatment

Avoid swelling and stiffness by:

- Elevation – reduce swelling
- Splintage – avoid contractures
- Movement – pump away swelling and encourage suppleness

Thumb ulnar collateral ligament injury

Chronic thumb overuse leads to stretching of the ulnar collateral ligament and instability (gamekeeper's thumb). The ligament can also rupture acutely if the thumb is forcibly abducted (skier's thumb). If valgus stress causes significant opening of the joint on the ulnar side then the ligament needs to be repaired surgically, as the adductor aponeurosis interposes between the torn end of the ligament and its insertion (**Figure 34.43**), preventing healing and causing chronic instability.

Triangular fibrocartilage complex (TFCC)

The triangular fibrocartilage is a complex consisting of the ulnocarpal ligaments, extensor carpi ulnaris tendon sheath and a meniscus-like structure between the distal ulna and the carpus. It is continuous with the dorsal and volar wrist capsules and stabilises the distal radioulnar joint. It can undergo traumatic or degenerative tears, presenting with ulna-sided wrist pain and distal radioulnar instability. An MR arthrogram or wrist arthroscopy aids diagnosis (**Figure 34.44**). Peripheral tears of the TFCC can be repaired (open or arthroscopically), while central degenerative tears can be arthroscopically debrided.

Figure 34.43 Magnetic resonance imaging showing rupture of the ulnar collateral ligament of the thumb (skier's thumb).

Figure 34.44 Magnetic resonance arthrogram showing peripheral detachment of the triangular fibrocartilage complex.

Infections

Paronychia

Nail bed infection is the commonest hand infection (**Figure 34.45**). After initial inflammation, pus accumulates beside the nail. It is best treated with incision, drainage and appropriate antibiotic therapy. This is sometimes, but not always, facilitated by partial nail removal to allow full drainage of the collection.

Felon

A felon is an abscess between the specialised fibrous septae in the fingertip pulp. It causes intense pain and may lead

Figure 34.45 Acute paronychia.

to terminal phalangeal osteomyelitis. Incision and drainage through the midline of the pulp of the finger in the location of maximal swelling, followed by intravenous antibiotics, are recommended.

Flexor tendon sheath infection

Flexor tendon sheath infections present with Kanavel's cardinal signs: the affected finger is held in flexion; there is uniform swelling over the tendon and digit; it is tender to touch; and the patient experiences pain on passive extension of the finger. Treatment is by tendon sheath irrigation using catheters inserted through small wounds at the proximal and distal ends of the affected sheath or by an open approach if the viability of the digit is threatened. This is followed by what is often an extended course of intravenous antibiotics. If infection is untreated tendon adhesions and necrosis occur. Infection can spread proximally, damaging the whole hand.

Summary box 34.12

Treatment of hand infections

- Elevate, splint and give intravenous antibiotics
- Surgical drainage should include tendon sheath irrigation
- Early mobilisation

Mycobacterial infections

Tuberculosis may involve the tenosynovium, joints or bone. The most dramatic form is a compound palmar ganglion, with synovial swelling proximal and distal to the transverse carpal ligament, occasionally causing symptoms of carpal tunnel syndrome. The diagnosis is made by taking a biopsy. Synovectomy should be performed and the patient treated with the appropriate antibiotics.

Deep fascial space infections

These infections occur in the palm but may be limited to a web space. The whole hand becomes swollen and tender as pus collects on either side of the septum. Treatment is incision and drainage with thorough washout of the wound. It is important that all deep spaces are opened: incision on both dorsal and volar sides of the hand may be needed. If in doubt an ultrasound scan or MRI can delineate the extent of the collections within the deep palmar spaces.

Arthritis

Rheumatoid arthritis

Rheumatoid arthritis presents with classic symptoms: morning stiffness, symmetrical arthritis, hand deformities and rheumatoid nodules. Diagnostic criteria include seropositive rheumatoid factor and radiographic changes (*Table 34.1*). The inflamed rheumatoid synovium (pannus) destroys ligaments, tendons and joints, producing pain, deformity and loss of function. Typical rheumatoid deformities in the hand include boutonnière (**Figure 34.46**), swan neck (**Figure 34.47**) and radial drift of the wrist (due to supination of the

TABLE 34.1 Radiographic differences between rheumatoid and osteoarthritis.

Rheumatoid arthritis	Osteoarthritis
Periarticular osteoporosis/ subchondral erosions	Subchondral sclerosis and cysts
Periarticular soft-tissue swelling	Less pronounced swelling
Joint space narrowing	Joint space narrowing
Marginal erosions	Marginal osteophytes
Joint deformity/malalignment	Less pronounced deformities
Ankylosis	Less common ankylosis

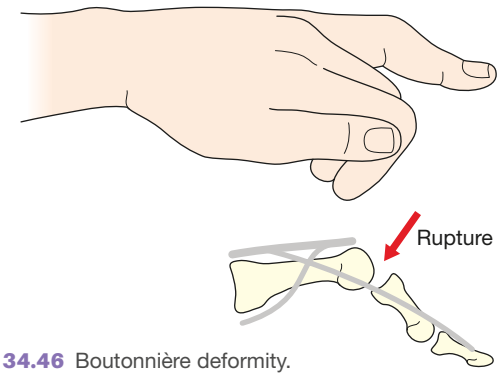

Figure 34.46 Boutonnière deformity.

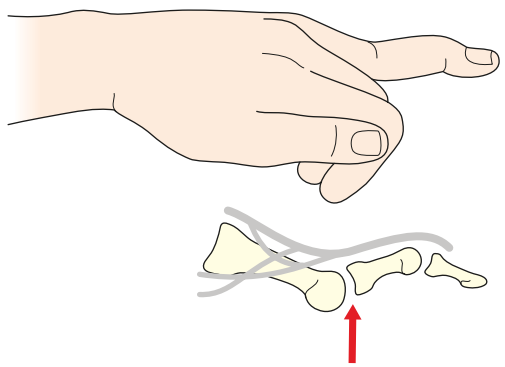

Figure 34.47 Swan neck deformity.

carpus), with compensatory ulnar deviation of the metacarpophalangeal joints (Figure 34.48). Pannus can cause extensor tendon ruptures, classically starting with the little finger and progressing stepwise in a radial direction (Vaughan Jackson syndrome). With progressive deformity and instability of the wrist and hand, activities such as key pinch and the opening of jars become impossible to perform. The treatment should be dictated by the patient's levels of pain and disability, not purely on the basis of deformity.

Figure 34.48 Rheumatoid hand showing ulnar drift at the metacarpophalangeal joints.

Summary box 34.13

Manifestations of rheumatoid arthritis in the hand

- Swan neck, Boutonnière finger deformities
- Extensor tendon ruptures (Vaughan–Jackson syndrome)
- Flexor tendon synovitis or rupture
- Metacarpophalangeal joints: flexion, ulnar deviation, subluxation, dislocation
- Wrist: radial deviation, carpal supination, prominent ulnar head (caput ulnae), extensor tenosynovitis

MANAGEMENT

The primary indications for surgery are: (1) pain relief; (2) functional improvement; (3) to prevent disease progression; (4) cosmesis. Patients may require many surgical procedures over time and a helpful axiom is to start proximally and work distally, alternating between motion-sacrificing and -sparing procedures. The various procedures which can be considered are:

1 Synovectomy: improves pain, increases function and prevents tendon rupture.
2 Trigger finger releases and nerve decompression surgery (carpal tunnel syndrome).
3 Distal ulna excision: reduces pain, prevents extensor tendon rupture or protects repaired extensor tendons. Distal ulna excision leads to instability and so, in the young patient, a constrained ulnar head arthroplasty is preferred.
4 Arthrodesis of the wrist, thumb and some of the smaller joints: gives good pain relief and creates a stable axis against which other parts can function.
5 Metacarpophalangeal and interphalangeal joint replacements: provide pain relief and functional improvement. Total wrist arthroplasty will also provide good pain relief and some motion (Figure 34.49).
6 Tendon reconstructions: some ruptured tendons can cause significant morbidity (Figure 34.50) and are often treated either by a tendon transfer or a local joint fusion

Figure 34.49 Total wrist replacement.

Figure 34.50 Rupture of the extensor tendons to the little and ring fingers.

Boutonnière is French for 'button-hole'.

Osteoarthritis

WRIST

The radiocarpal joint can develop primary or secondary osteoarthritis (after intra-articular trauma and infection). If conservative measures have failed then operative management includes limited or total wrist arthrodesis and total wrist replacement.

HAND

Females are more commonly affected than males. The commonly affected joints are the distal interphalangeal (Heberden's nodes), proximal interphalangeal (Bouchard's nodes) and the thumb carpometacarpal joints (**Figure 34.51**). Symptoms rarely correlate with the appearance, either clinically or radiographically. Treatment includes splinting, physiotherapy and steroid injections. Surgical options include arthrodesis for distal (DIP) and proximal interphalangeal (PIP) joints (**Figure 34.52**), joint replacement (PIP and metacarpophalangeal (MCP) joints) and excision arthroplasty (excision of the trapezium for thumb carpometacarpal joint arthritis). Joint arthrodesis eliminates pain at the expense of motion, but function is often well preserved.

Other forms of arthritis in the hand

Psoriasis particularly affects the interphalangeal joints, but is asymmetrical in nature and causes fusiform swelling of the digits along with nail changes. Gout causes pain, joint redness, occasionally tophi, and can be difficult to differentiate from septic arthritis. Serum urate is not always raised in acute attacks but finding negatively birefringent sodium urate crystals on microscopy of aspirated joint fluid is diagnostic.

Figure 34.51 Hand deformities secondary to osteoarthritis.

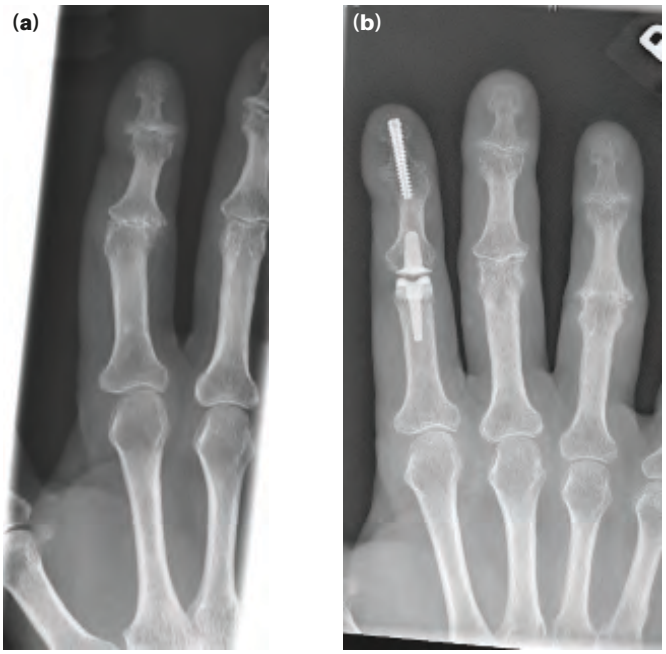

Figure 34.52 Radiographs of the distal interphalangeal and proximal interphalangeal joints treated with arthrodesis (a) and joint replacement (b).

Dupuytren's contracture

Dupuytren's contracture is most often characterised as an autosomal dominant condition, common in northern Europe, predominantly in men in the 5th–7th decades of life. Four out of seven cases occur in those with a family history but there are also many sporadic cases. It is associated with smoking, trauma, epilepsy, AIDS, hypothyroidism and alcoholic cirrhosis. It also appears very frequently as a clinical case in postgraduate exams! The characteristic features are palmar nodules, skin puckering, cords of the palm and digits and flexion contractures of the digits (**Figure 34.53**). It is commonest on the ulnar side of the hand. Garrod's knuckle pads (thickened skin on the dorsum of the PIP joint) are another feature visible on examination and seen in more severe forms of the disease (**Figure 34.54**). The condition can also produce cords in the penis, causing it to become curved (Peyronie's disease) and may also produce plantar thickening (Ledderhosen disease). Intervention is indicated when the patient cannot put the affected hand flat on the table owing to fixed deformity, or when any flexion contracture develops in the PIP joint. Milder cases may be treated by needle fasciotomy or

William Heberden (Snr.), 1710–1801, physician, who practised first in Cambridge and from 1748 in London, UK, described these nodes in 1802.
Charles Jacques Bouchard, 1837–1915, physician, Dean of the Faculty of Medicine, Paris, France.
Baron Guillaume Dupuytren, 1777–1835, surgeon, Hôtel Dieu, Paris, France, described this condition in 1831.

Figure 34.53 Dupuytren's contracture.

Figure 34.54 Garrod's knuckle pads.

collagenase injections, while more severe cases are managed surgically. Great care should be taken during surgery to avoid damage to the digital nerves, which may be trapped in the fibrous tissue. At the end of surgery, it may not be possible to obtain primary closure of the skin, so one should consider performing Z-plasties to lengthen the skin, full thickness skin grafting taken from the anteromedial proximal forearm (hairless) or occasionally leaving an open wound to heal by secondary intention.

In late stage disease a fixed contracture of the MCP and PIP joints may develop. In these cases, excision of the fibrous bands may produce no improvement in the condition, and if the contracted finger is preventing useful function of the hand then amputation may have to be considered.

Summary box 34.14

Dupuytren's contracture

- Autosomal dominant inheritance but many sporadic cases
- Fibroblastic hyperplasia with resultant skin nodules, cords and deformities
- Intervention is indicated if hand cannot be placed flat
- Severe fixed flexion deformities may mean that amputation is the only surgical option

Tendon disorders

Trigger digit

Triggering occurs in the fingers or in the thumb as a result of a size mismatch between the flexor tendon and the sheath (usually at the A1 pulley) in which it glides.

The patient complains of painful locking or snapping of the finger, usually when attempting to straighten a bent finger. Occasionally, it may present as a finger that is too painful to bend, associated with pain and tenderness at the A1 pulley. There is often a palpable nodule in the tendon. Management is a steroid injection into the sheath, and if this fails then surgical tendon sheath (A1 pulley) release should be performed under local anaesthesia, taking care not to cut too much of the pulley and create bowstringing of the flexor tendon. Trigger digits, especially the thumb, can occur in infants and usually resolve spontaneously.

De Quervain's disease

De Quervain's disease is caused by tenosynovitis of the abductor pollicis longus (APL) and extensor pollicis brevis (EPB) in the first dorsal wrist extensor compartment (1st EC). It is predominantly seen in middle-aged females and is associated with pregnancy (new mother's wrist) and inflammatory arthritis. The clinical features are radial wrist pain, tenderness, swelling (**Figure 34.55**) and a positive Finkelstein's test

Figure 34.55 De Quervain's disease.

Sir Archibald Edward Garrod, 1857–1936, Regius Professor of Medicine, the University of Oxford, Oxford, UK, described this condition in 1893.
Francois de la Peyronie, 1678–1747, surgeon to King Louis XIV of France and founder of the Royal Academy of Surgery, Paris, France.
Georg Ledderhose, 1855–1925, German surgeon, described this disease in 1894.
Fritz de Quervain, 1868–1940, Professor of Surgery, Berne, Switzerland, described this form of tenosynovitis in 1895.

(pain over the 1st EC associated with ulnar deviation of the wrist when the thumb is clasped in the palm). The management options are non-steroidal anti-inflammatories, splintage, steroid injections and surgical release of the extensor retinaculum of the first dorsal compartment. If surgery is considered, careful attention should be paid to fully releasing the APL and EPB, which frequently consist of bundles of separate tendon slips that lie in separate sheaths.

Compressive neuropathies

Median nerve (carpal tunnel syndrome)

The majority of cases of carpal tunnel syndrome are idiopathic. It is however, associated with diabetes, thyroid disorders, alcoholism, amyloidosis, inflammatory arthritis, pregnancy and obesity.

HISTORY

The patient presents with tingling and infrequently numbness of the volar aspects of the radial three and a half digits. Patients also complain of being woken at night by pain and tingling, and that hanging their hand out of the bed provides relief. They may also complain of clumsiness when picking up small objects or when carrying heavy ones. Symptoms and signs are often bilateral.

EXAMINATION

Wasting of the thenar eminence is visible **(Figure 34.56)** in chronic severe cases, and there is sometimes weakness of the abductor pollicis brevis. The tests for carpal tunnel compression are described in Chapter 31 but the most reliable are: (1) Tinel's – percussion over the carpal tunnel and (2) Phalen's test – reproduction of paraesthesia with full wrist flexion. More recently, Durkin's compression test, in which digital pressure over the carpal tunnel reproduces the symptoms, has been shown to be highly sensitive and specific. Electrophysiological studies may confirm the diagnosis, with evidence of slowing of nerve conduction through the carpal tunnel. Non-operative treatment includes night splintage of the wrist in extension and steroid injections. If surgery is required the median nerve is surgically decompressed by incising the roof of the tunnel (transverse carpal ligament), as either an open or an endoscopic percutaneous procedure.

Summary box 34.15

Carpal tunnel syndrome

- Night pain is common and relieved by shaking the hand
- Thenar wasting is an advanced sign
- Tinel's, Phalen's and Durkin's tests are useful
- Treatment includes splints and surgical decompression

Ulnar nerve (Guyon's tunnel syndrome)

Ulnar nerve compression in Guyon's canal can lead to tingling and numbness in the ring and little fingers with hypothenar wasting. There is preservation of dorsal sensation over the little and ring fingers, because although these areas are innervated by the ulnar nerve the dorsal branches do not pass through Guyon's canal. Compression is usually due to a ganglion, ulnar artery aneurysm or a fracture of the hook of hamate.

Avascular necrosis of carpal bones

Idiopathic avascular necrosis of the lunate (Kienböck's disease, **Figure 34.57**) or scaphoid (Preiser's disease) can occur. The clinical presentation is of wrist pain and the diagnosis

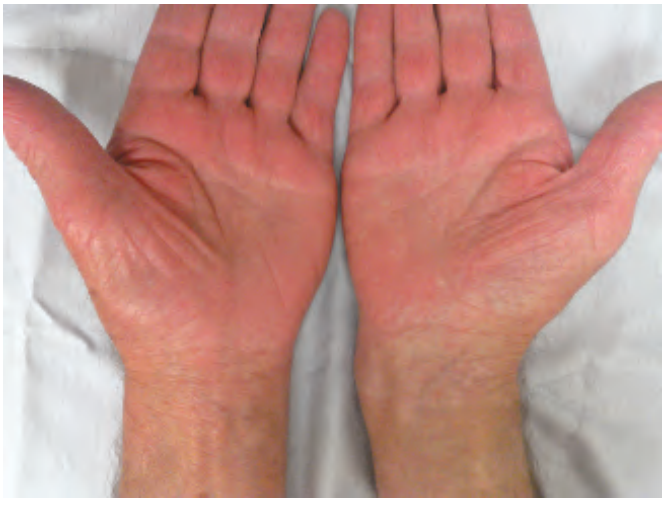

Figure 34.56 Thenar muscle wasting in carpal tunnel syndrome.

Figure 34.57 Avascular necrosis of the lunate (Keinbock's).

Jean Casimir Felix Guyon, 1831–1920, Professor of Genito-urinary Surgery, Paris, France.
Robert Keinböck, 1871–1953, Professor of Radiology, Vienna, Austria, described this condition in 1910.

can be confirmed with radiographs and MRI. The natural history of the condition is that it leads to collapse of the avascular carpal bones and subsequent arthritis of the carpus, which may be best treated with a partial or complete fusion of the wrist. This will at least give a strong and painless wrist. The limitation in movement caused by arthrodesis procedures is not as great as might be expected.

Ganglion cysts

Ganglion cysts are the commonest cause of a swelling in the hand and they are found most often on the dorsal (**Figure 34.58**) and volar (**Figure 34.59**) surfaces of the wrist, over the dorsum of the DIP joint (digital mucous cyst) or within the flexor tendon sheath at the base of the finger (seed ganglion). Dorsal and volar wrist ganglions can cause discomfort. The swellings are smooth, fluctuant and transilluminate brightly. Mucous cysts can frequently discharge and cause nail changes (**Figure 34.60**). Seed ganglions can be painful when gripping. Aspiration or surgical excision can be considered. Patients should be informed regarding possible recurrence.

Congenital malformations

There are many congenital malformations of the upper limb and these are discussed in Chapter 39. A classification summarising the main congenital defects and based on aetiology appears as **Table 34.2**

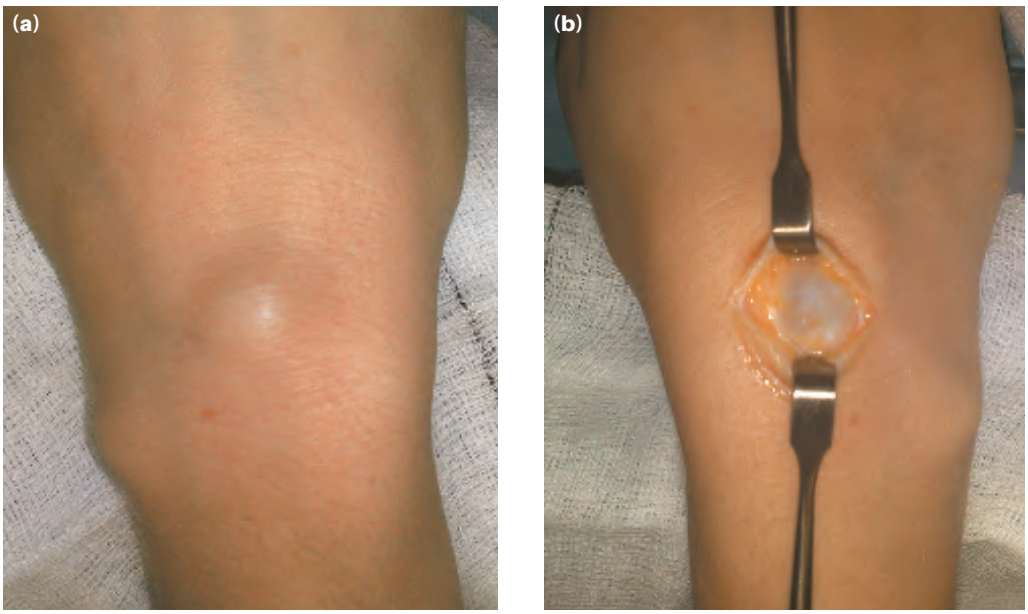

Figure 34.58
(a) Clinical and **(b)** surgical appearance of a dorsal wrist ganglion.

Figure 34.59 Volar wrist ganglion.

Figure 34.60 Myxoid cyst with changes in the nail.

TABLE 34.2 Congenital malformations (hand and wrist)

A Defects in formation due to arrested development	1 Transverse agenesis 2 Longitudinal agenesis (a) radial ray aplasia; (b) median ray aplasia; (c) ulnar ray aplasia 3 Thumb aplasia/hypoplasia
B Defects in differentiation/separation	1 Syndactyly 2 Camptodactyly 3 Clinodactyly 4 Kirner's deformity 5 Radioulnar synostosis
C Duplications	1 Supernumerary phalanges 2 Supernumerary digits (polydactyly)
D Excess development/hyperplasia	Macrodactyly
E Insufficient development/hypoplasia	Thumb hypoplasia
F Constricting (amniotic) bands	Simple amniotic band syndrome
G Generalised skeletal anomalies	Marfan, Turner and Down syndromes

Chapter 35

Hip and knee

Learning objectives

To understand:

- The anatomy and biomechanics of the hip and knee and their clinical implications
- The clinical presentation, aetiology and management of common hip and knee pathologies
- The principles of joint replacement including important complications
- The advances in surgical practice in this field

THE HIP JOINT

Applied anatomy

The hip is a ball and socket joint formed by the head of the femur and the cup-shaped acetabulum (Latin: little vinegar cup) (Figure 35.1). The joint allows a considerable range of movement in different planes, and is still inherently stable because of its bony anatomy and the static and dynamic stabilisers. The static stabilisers are composed of the ligaments (iliofemoral and pubofemoral ligaments anteriorly and the ischiofemoral ligament posteriorly), the joint capsule and the labrum. The muscles running across the joint (short external rotator muscles posteriorly, the iliopsoas anteriorly and the hip abductors laterally) constitute the dynamic stabilisers. The acetabular labrum is a fibrocartilagenous structure that is triangular in cross-section and attaches to the rim of the acetabulum except at its base, where it is replaced by the transverse ligament. It helps in deepening the socket, thereby enhancing stability. It also acts as a fluid seal and thereby helps to improve joint lubrication.The femoral head derives its blood supply mainly from the retinacular branches of the medial circumflex femoral artery and there is a small contribution from the artery of the ligamentum teres.

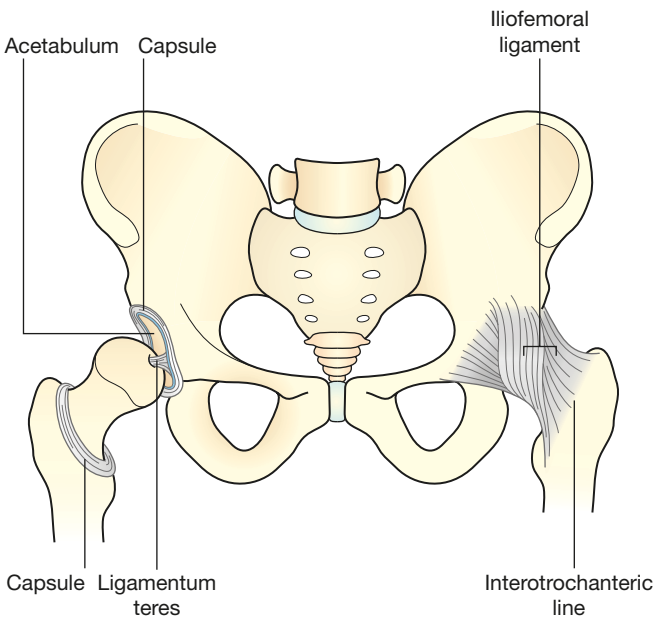

Figure 35.1 Anatomy of the hip joint.

Summary box 35.1

Anatomy

- The hip joint is a ball and socket joint, stabilised by static and dynamic stabilisers
- Static stabilisers include the capsule, ligaments and labrum
- Dynamic stabilisers consist of the muscles acting across the joint
- Blood supply to the femoral head is mainly derived from the medial circumflex femoral artery

Biomechanics of the hip joint

Kinetic analysis reveals that forces as high as three times body weight can be exerted across the hip joint during activities of daily living, and eight times body weight during physically demanding activities. This is primarily the result of contraction of muscles crossing the joint. The abductors, because of their

insertion at the greater trochanter, help in supporting the pelvis when the patient stands on one leg and thereby form the basis of a Trendelenburg test (Figure 35.2).

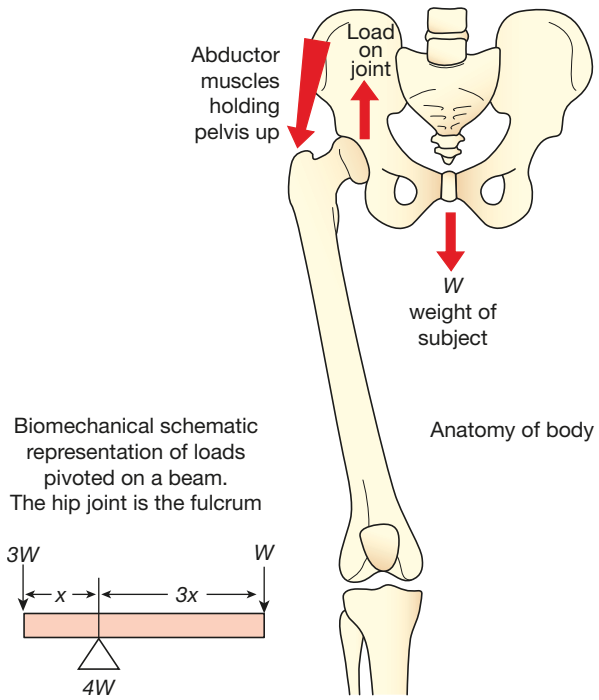

Figure 35.2 Load on the hip joint when a subject weighing W stands on one leg. Hopping increases the load from 4 to 10W.

Summary box 35.2

Forces going through the hip joint

- Lifting leg from bed – one and a half times body weight
- Standing on one leg – three times body weight
- Running and jumping – ten times body weight

Conditions affecting the hip joint

Common hip pathologies in the paediatric age group and secondary to trauma are covered in Chapters 39, 27 and 28. This chapter focuses on the acquired pathological conditions in the adult.

Avascular necrosis

Avascular necrosis (AVN), or osteonecrosis of the femoral head, occurs because of an interruption in the blood supply to the femoral head that causes bone death. This leads to collapse of the femoral head, and subsequent secondary osteoarthritis. AVN can be primary (idiopathic) or secondary to other pathology (*Table 35.1*).

TABLE 35.1 Aetiology of avascular necrosis of the femoral head.

Sickle cell disease
Haemoglobinopathies
Caisson disease ('the bends' in divers)
Hyperlipidaemia
Systemic lupus erythematosus
Gaucher's disease
Chronic liver disease
Antiphospholipid antibody syndrome
Radiotherapy
Chemotherapy
Human immunodeficiency virus
Hypercoagulable states (protein C and protein S deficiency)
Steroids
Alcohol excess
Idiopathic (see Perthes' disease, Chapter 39)

CLINICAL FEATURES

AVN usually affects men aged from 35 to 45 and is bilateral in over 50% of patients. The patient is frequently asymptomatic in the early stages. As the disease progresses the patient may complain of an ache in the groin and walk with a limp; clinical examination may reveal limitation of movement.

INVESTIGATIONS

A weight-bearing anteroposterior (AP) radiograph of the pelvis along with a lateral radiograph will show the classical features of AVN including increased sclerosis in the early stages, and the crescent sign indicating subchondral bone resorption. In the late stages there may be flattening indicating a segmental head collapse (**Figure 35.3**). However, radiographs may be normal in the early stages of the disease and, therefore, the most sensitive and specific way of investigating these patients is with magnetic resonance imaging (MRI). MRI allows accurate assessment of the extent of involvement and can also identify associated bone marrow changes. This helps in early diagnosis and prediction of prognosis (**Figure 35.4**). In 1985, Ficat classified the disease into five stages. In 1995, Steinberg modified this classification into seven stages based upon both radiograph and MRI appearance (*Table 35.2*). Stages I–IV are further divided into A, B or C depending on the extent of involvement of the femoral head.

TREATMENT

Conservative treatment usually leads to poor results and is therefore not recommended. The choice of surgical treatment depends on whether the head has collapsed or not. In the pre-collapse group the principle is to preserve and preferably encourage revascularisation of the femoral head, whereas in

Friedrich Trendelenburg, 1844–1924, Professor of Surgery successively at Rostock (1875–1882), Bonn (1882–1895) and Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.
A caisson is a watertight chamber used to protect construction workers during the building of underwater structures by means of pressurised air introduction.
Philippe Charles Ernest Gaucher, 1854–1918, physician, Hôpital St. Louis, Paris, France, described familial splenic anaemia in 1882.

Figure 35.3 (a, b) Radiological appearance of avascular necrosis of the femoral head.

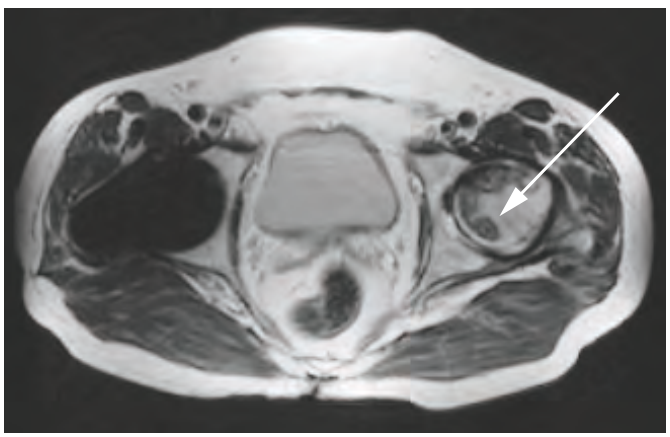

Figure 35.4 Magnetic resonance imaging scan of the hip joint showing avascular necrosis and the extent of involvement of the femoral head (arrrow).

TABLE 35.2 Steinberg's classification of avascular necrosis of the femoral head based on the type of radiological change on radiography and magnetic resonance imaging (MRI).

Stage	Description
0	Normal or non-diagnostic radiograph, bone scan or MRI
I	Normal radiograph, abnormal MRI or bone scan
II	Sclerosis and cysts
III	Subchondral collapse, crescent sign
IV	Flattening of the head, normal acetabulum
V	Acetabular involvement
VI	Obliteration of joint space

the collapse group the aim is to bring the undamaged parts of the femoral head into the load-bearing area.

The surgical treatment for the pre-collapse stage includes core decompression, which is aimed at relieving intravascular congestion in the femoral head, and thereby pain. This can be achieved with or without bone grafting; a vascularised bone graft can also be used to stimulate bone formation. Once the femoral head has collapsed, either a femoral osteotomy (which aims to transfer the weight-bearing area of the femoral head and thereby protect the collapsed segment) or a joint replacement (if degenerative changes have set in) is the preferred option (see later).

Summary box 35.3

Avascular necrosis of the femoral head

- Patients can be asymptomatic in the early stages and therefore a high index of suspicion is necessary for initial diagnosis
- MRI scans are needed for early diagnosis
- Treatment is based on whether the patient presents before or after the femoral head has collapsed
- In the pre-collapse stage, treatement focuses on revascularisation
- In the collapsed stage, the aim is to replace the damaged joint surface
- Prognosis is dependent upon the extent of femoral head involvement

Osteoarthritis (OA)

OA is referred to as primary when no predisposing cause can be found and secondary (including traumatic) when it develops after an insult to the hip joint. A multitude of factors including genetic, biochemical and mechanical influences have been implicated in the development of primary OA. The exact mechanism for the development of primary OA remains unknown and it is therefore termed idiopathic. Femoroacetabular impingement (FAI) has been proposed as an aetiological factor responsible for the development of OA. Secondary OA develops following trauma, AVN, dysplasia, slipped capital femoral epiphysis, inflammatory arthropathy

or other known predisposing cause. The causes of OA of the hip are given in *Table 35.3*.

TABLE 35.3 Aetiology of osteoarthritis.

Primary
Cause unknown, termed idiopathic
Associations: for example, genetics, gender, obesity
Secondary
Trauma
Avascular necrosis
Inflammatory arthropathy (e.g. rheumatoid arthritis)
Perthes' disease
Developmental dysplasia of the hip
Slipped capital femoral epiphysis
Septic arthritis
Femoroacetabular impingement implicated as a possible cause

CLINICAL FEATURES

Osteoarthritis of the hip affects 10–25% of those over the age of 65 years. The most consistent symptoms are groin pain and limitation of movement. The pain may also radiate down to the knee joint, and in some cases the only presenting feature may be a painful knee. In the early stages of the disease, pain is activity related but as the disease progresses the patient also complains of pain at rest. The patient frequently complains of night pain and may also find it difficult to get into a comfortable position while sleeping. Functionally, most have difficulty in putting on their shoes and socks, and getting into and out of a bath or a car. As the pain increases the joint gradually loses its movement because of muscle spasm, capsular contracture and osteophyte formation.

Clinical examination may reveal gluteal muscle wasting. There may also be a limp, with a positive Trendelenburg's test. Leg length discrepancy, usually shortening, and limitation of movement, particularly internal rotation, are consistent features. Many patients present with a fixed flexion deformity that is best elicited by a modified Thomas' test (see Chapter 31).

INVESTIGATIONS

The characteristic features on radiograph are (1) a reduction of joint space, (2) sclerosis in the subchondral bone, (3) subchondral cysts and (4) osteophyte formation (**Figure 35.5**). Eventually, a collapsed femoral head may also be evident.

TREATMENT

There is no specific pharmacological therapy for OA; however, conservative treatment with non-steroidal anti-inflammatories, regular exercise, physiotherapy and modification of lifestyle with loss of weight does help. Patients should also be encouraged to use walking aids (usually a walking stick in the opposite hand to offload the affected joint).

The indications for surgery are relentless pain, limitation of lifestyle and activities of daily living, and failure of conservative treatment. The surgical options include an arthrodesis (fusion), an osteotomy (re-alignment) or a joint replacement (**Figure 3.6**). More and more joint replacements are now being performed. The indications are based on limitation of lifestyle and individual needs, thereby making it a truly life-improving operation.

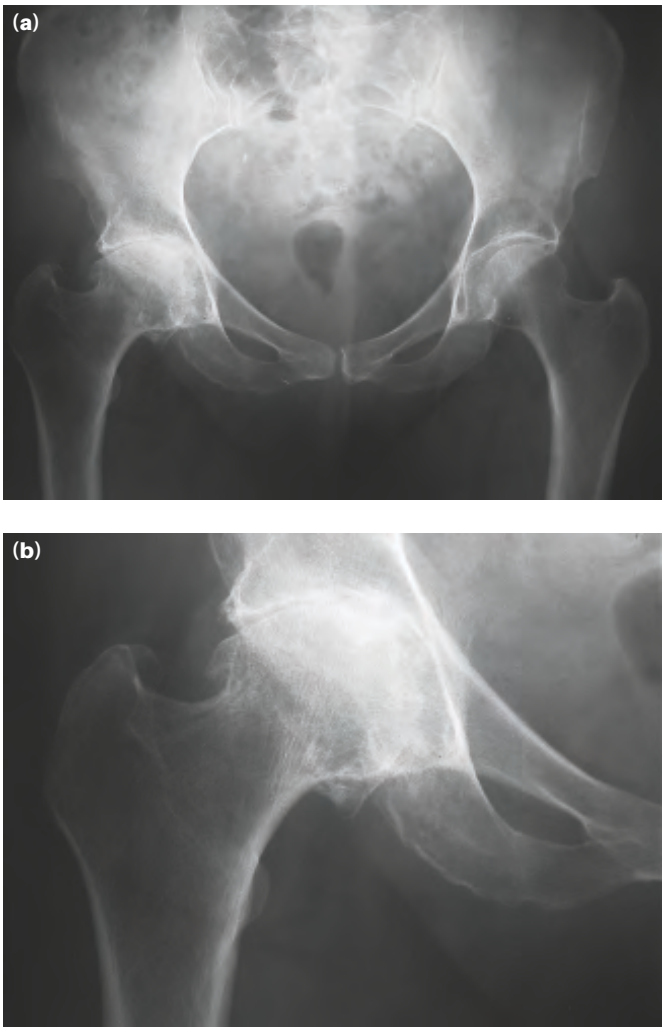

Figure 35.5 Anteroposterior **(a)** and enlarged anteroposterior **(b)** radiographs of the hip joint showing osteoarthritis.

Summary box 35.4

Osteoarthritis of the hip

- Osteoarthritis is a non-inflammatory and low-grade inflammatory condition leading to progressive damage to the articular cartilage and other joint structures
- The most consistent clinical features are groin pain and limitation of movement
- Characteristic radiological findings include reduction of joint space, subchondral sclerosis, subchondral cysts and osteophyte formation
- Conservative treatment includes walking aids, non-steroidal analgesics, physiotherapy and weight loss
- Surgical options include osteotomy, arthrodesis or a joint replacement

Georg Clemens Perthes, 1869–1927, Professor of Surgery, Tubingen, Germany, described osteochondritis of the femoral capital epiphysis in 1910.

Figure 35.6 Radiograph showing an uncemented total hip replacement *in situ*.

Inflammatory arthritis

The hip joint can also be affected by inflammatory arthritides, however these are not as common as OA. This group includes rheumatoid arthritis, ankylosing spondylitis, gout and chondrocalcinosis, juvenile rheumatoid arthritis and systemic lupus erythematosus.

Femoroacetabular impingement (FAI)

Femoroacetabular impingement has recently been recognised as a cause of hip pain in the young adult and may lead to secondary hip OA. The non-spherical portion of the femoral head is assumed to exert abnormal shear and compressive forces on the corresponding portion of the acetabular cartilage during deep hip flexion with internal rotation. Patients typically present with groin pain, and MRI-arthrograms typically reveal acetabular rim lesions and aberrant femoral head morphology.

Two distinct types of FAI have been described – cam and pincer – although many patients have a mixed picture with both morphologies occuring simultaneously. Pincer impingement is a result of anterior overcoverage or retroversion of the acetabulum, while cam impingement is secondary to abnormal morphology of the femoral head and neck junction. Treatment options for FAI depend on the patient's symptoms and vary from conservative treatment to hip arthroscopic procedures that aim to address labral and bone pathology, or osteotomy.

Surgical procedures

Arthroscopy of the hip

The hip joint presents challenges to arthroscopy in terms of access and instrumentation of the deeply recessed femoral head in the acetabulum and the surrounding thick fibrocapsular and muscular envelope. Technical advances, including an improved ability to manage the capsule and gain exposure, have led to an expanding list of applications, including the treatment of symptomatic labral tears, femoroacetabular impingement and the removal of loose bodies, e.g. synovial chondromatosis. Arthroscopy allows a clear view of the femoral and acetabular articular surfaces, the labrum, the ligamentum teres and the head–neck junction, along with the surrounding synovium and its folds and the peritrochanteric space. Advantages include minimally invasive access to all these structures coupled with rapid recovery, in comparison with open surgery.

Arthrodesis of the hip

Arthrodesis or fusion of the hip is an uncommon operation. It is generally reserved for young patients with severe osteoarthritis who have heavy manual jobs and in whom joint replacements would fail early. The aim is to achieve a painless joint by fusing it in a functional position, which is about 30° of flexion, 15° of external rotation and 5° of abduction. This can be achieved by an intra-articular dynamic hip screw or by an extra-articular plate with screws.

Several problems can occur following an arthrodesis, including altered gait and excessive loading of the ipsilateral knee, the contralateral hip and the spine. Degenerative change in these joints in the long term is the rule rather than the exception.

Osteotomies around the hip

The goal of an osteotomy around the hip is to redistribute forces evenly across the joint, thereby eliminating excessive point loading. This can be achieved by performing an osteotomy on the femoral or the acetabular side, depending upon the desired goal, e.g. an excessive valgus neck–shaft angle and an uncovered femoral head on the lateral aspect can be corrected by carrying out a varus femoral osteotomy. Similarly, a redirection osteotomy on the acetabular side can also be performed to improve coverage of the femoral head. The common indications for an osteotomy around the hip include:

- developmental dysplasia of the hip;
- Perthes' disease;
- OA in a young patient;
- slipped capital femoral epiphysis;
- AVN.

Ideally, an osteotomy should be considered in a young patient who maintains a good range of movement of the hip and whose radiographs show a reasonable amount of joint space. Thorough preoperative planning is essential to assess whether the desired position can be achieved. Three-dimensional computed tomography (CT) scans are helpful for appropriate preoperative planning.

Total hip replacement

Over 80 000 primary total hip replacements are performed annually in the UK. The results of surgery are encouraging. With evidence-based technique and selection of prosthesis, up to 95% of patients will have a well-functioning hip replacement at 10 years after surgery. In the best series, 85% will still be functioning at 20 years, although some are

still in place because the patient may have increasing comorbidities, preventing revision. Following surgery, pain is reduced, mobility increases and sleep, as well as social and sexual function, is improved. Nevertheless, with the ever-increasing number of patients with joint replacements, the number of patients whose replacement has failed and come to the point of revision, or even re-revision, is rising.

PRINCIPLES AND DESIGN OF HIP REPLACEMENTS

Any joint replacement should be biocompatible and made of inert materials. It should be well fixed to the host tissue and the design should incorporate features that allow a good range of movement and stability. The bearing surfaces should produce minimal friction to prevent early loosening, and the material released from the bearing surface should be non-toxic. It should remove the minimum amount of the patient's bone so that revision is possible, and it should create a biomechanically stable joint. Finally, any implanted joint should ideally outlive the patient and be cost effective.

Summary box 35.5

Features of an ideal joint replacement

- Biocompatible
- Well fixed to the host tissue, stable and allowing a good range of movement
- Bearing surfaces should be designed to minimise friction
- Material released from the bearings should be non-toxic
- Remove the minimum amount of bone
- Produce mechanical stability
- Should ideally outlive the patient

MATERIALS FOR THE FEMORAL COMPONENT

Most of the implants available currently are made of cobalt–chrome alloy, but stainless steel and titanium are also used. Metal implants are able to withstand high loads, are relatively inert and can be manufactured easily. However, they do pose problems in terms of ion release if they are used as bearing surfaces. Also, corrosion can be a cause for concern if two dissimilar metals are used.

BEARING SURFACES

The total hip replacement (THR) designed by Charnley used a bearing surface of metal on high-density polyethylene. This is described as a hard-on-soft bearing surface and has a low coefficient of friction. High-density polyethylene has good shock-absorbing properties but does wear slowly over the years, producing small particles that can stimulate an inflammatory response in the joint, which then leads to aseptic loosening of the implants. The activated macrophages resorb bone and may also stimulate osteoclasts to do the same. There has therefore been a move towards using bearing surfaces with a lower wear rate, such as ceramic on ceramic. With metal on metal bearing surfaces, although the wear rate is lower, the wear particles are smaller (nano rather than micro) and there is increasing evidence that these implants are less forgiving than conventional metal on polyethylene THRs, appearing to require more precise implant positioning. Ceramic femoral heads bearing on polyethylene cups have far lower friction, but ceramic femoral heads on ceramic acetabular cups have the lowest friction of all. However they are expensive to manufacture and produce small-sized wear particles. A summary of the advantages and disadvantages of each bearing surface is provided in *Table 35.4*.

FIXATION OF IMPLANTS

Artificial joints must be securely fixed to the bone on each side of the joint so that the implant does not work loose. This can be achieved with the help of cement or biological interdigitation between the prosthesis and bone (*Table 35.5*).

Traditionally, hip replacements were fixed into a bed of polymethylmethacrylate (PMMA) cement (**Figure 35.7a**). The cement acts as a grout (spacer) and not as a glue between

TABLE 35.4 Bearing surfaces for hip replacements.

Type of bearing	Advantages	Disadvantages
Metal on polyethylene	Proven efficacy; easy to manufacture; cheap	Comparatively high friction; high wear rates; wear particles excite an inflammatory response that leads to osteolysis
Ceramic on polyethylene	Lower wear rate	Expensive; ceramic fracture can be a problem
Metal on metal	Lower wear rate	Published examples of failure requiring early revision; implant recalls; metal ion release is a problem; expensive
Ceramic on ceramic	Lowest wear rate	Very expensive; ceramic can fracture; squeaking

TABLE 35.5 Fixation of implants.

Method of fixation	Advantages	Disadvantages
Cemented	Implant does not need to fit cavity exactly; well-proven results	Cement polymerisation is exothermic with possibility of thermal injury; fragments may cause third-body wear and stimulate aseptic loosening; difficult to remove at revision
Uncemented	No cement needed; fixation more secure; dynamic and biological fixation	Risk of fracture; fit must be perfect; osseous integration may not be established; expensive

Sir John Charnley, 1911–1982, Professor, Wrightington Hospital, UK, pioneer in hip replacment design, particularly the concept of low friction arthroplasty.

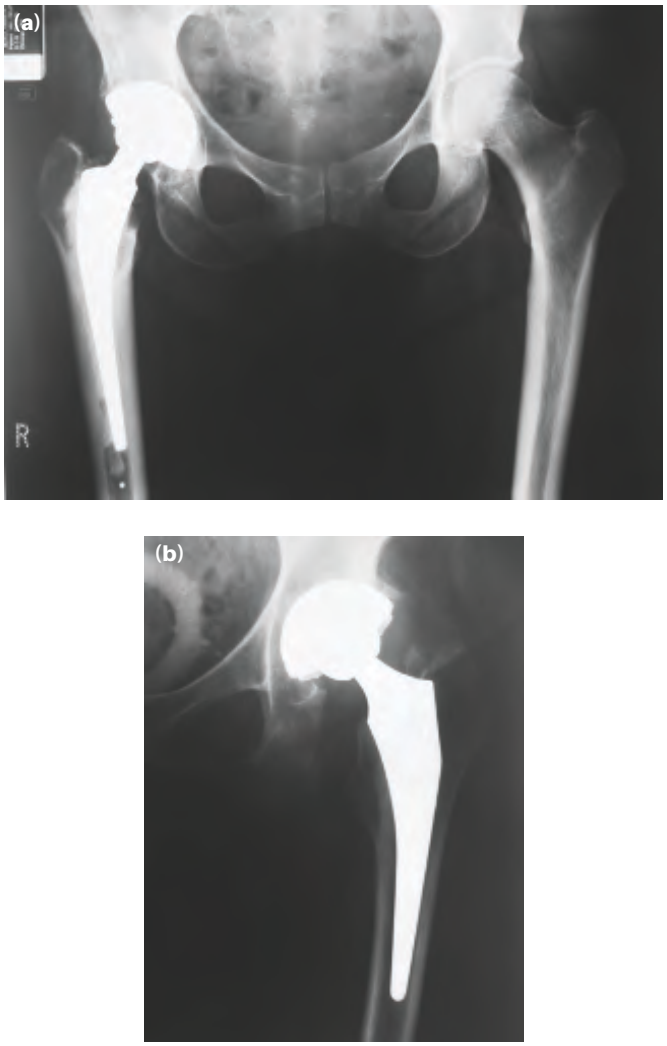

Figure 35.7 Radiographs of a cemented **(a)** and non-cemented **(b)** femoral component.

the implant and the bone. In the majority of cases it gives an excellent outcome as shown by the data in the national joint registries. However, it can cause potential problems: cement pressurisation can result in release of cement and marrow contents into the patient's blood stream. This can cause a drop in blood pressure.

On the other hand, this problem can be obviated by using an uncemented prosthesis where biological fixation can be achieved by providing a rough surface on the prosthesis for bone to grow into the prosthesis or by coating the surface of the prosthesis with hydroxyapatite, an osteoconductive agent, to encourage bone to bond to the prosthesis (**Figure 35.7b**). These uncemented devices have also shown good long-term outcomes, although they can be associated with higher implant costs, increased risk of intraoperative fracture and difficulty in removing them if revision surgery is needed.

Surgical approaches to the hip, postoperative course and complications

The operation can be performed via a posterior approach, a trochanteric osteotomy, an anterolateral or Hardinge approach or an anterior approach (*Table 35.6*). Each approach has its own advantages and disadvantages. Minimally invasive surgery has been described that shortens the size of the incision and attempts to lessen soft tissue damage. Specialised instruments have been developed to facilitate this as access can be restricted. Although the concept is attractive, no long-term benefits have been conclusively shown in hip surgery over the conventional technique. Eventually, whichever approach is used, it is essential to be able to implant a prosthesis that has the correct offset, is at the correct centre of rotation with the correct component orientation, that restores leg length and carries minimal risk of complications.

The postoperative course generally involves a 3–5 day stay in hospital, where the physiotherapist encourages the patient to mobilise safely and independently, avoiding any movements which might lead to a dislocation (**Figure 35.8**). Before discharge, the occupational therapist assesses the patient's home circumstances and arranges for any modifications that may be required to assist the patient e.g. a raised toilet seat. Follow-up visits are arranged at 6 weeks and at 1 year post surgery. Although hip replacement is a generally a successful and safe procedure, it does have associated complications. A comprehensive list of complications is given in *Table 35.7*. Deep vein thrombosis is relatively common if no precautions are taken to reduce this risk, for which the use of regional anaesthesia and early postoperative mobilisation are invaluable. In additon, either mechanical devices

TABLE 35.6 Surgical approaches to the hip.

Surgical approach	Anatomical interval and muscle
Posterior	Along the fibres of the gluteus maximus, and dividing the short external rotators
Trochanteric	A trochanteric osteotomy is required
Anterolateral/ Hardinge	Parts of the gluteus medius and minimus are reflected off the greater trochanter
Anterior	The interval is developed between the sartorius and rectus femoris and the tensor fascia lata

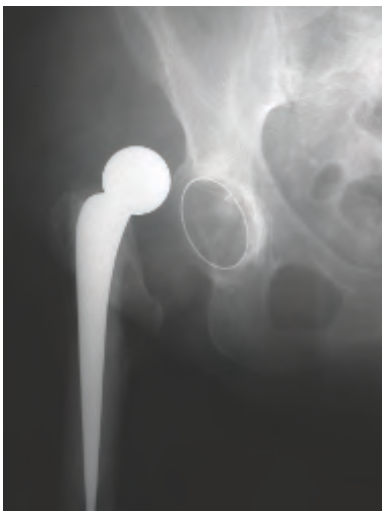

Figure 35.8 Dislocation of the hip.

TABLE 35.7 Complications of total hip replacement.

Leg length inequality
Dislocation
Infection
Aseptic loosening
Heterotopic ossification

(thromboembolic deterrent (TED) stockings, foot pumps or intermittent pneumatic calf compression devices) and medication (low molecular weight heparin, warfarin or oral anticoagulants) are commonly prescribed for a period of 4–6 weeks after surgery to reduce the risk of DVT (this will depend on local and national guidelines).

Revision total hip replacement

Revision of a total hip replacement is required if the patient is symptomatic secondary to failure of the implant by loosening (**Figure 35.9**), recurrent dislocations or a periprosthetic fracture. Loosening of the implant can occur because of an infection or as a result of aseptic osteolysis caused by an inflammatory response secondary to particle wear.

In the initial stages of loosening the patient complains of pain, which is experienced mainly on weight bearing. A history of infection in the immediate postoperative period may suggest infection as a cause of premature implant loosening. The infection can be low-grade, with *Staphylococcus epidermidis* multiplying slowly within a glycocalyx coating, and therefore normal measures of infection such as a raised C-reactive protien (CRP) may be equivocal (see Chapter 38).

Figure 35.9 Acetabular loosening (arrow).

If the loosening is secondary to infection, a two-staged revision is usually preferred. The first stage consists of implant removal, thorough debridement and implantation of an antibiotic loaded cement spacer. Multiple deep specimens are sent for bacteriology to determine the organism and its sensitivity. The patient is subsequently prescribed an appropriate antibiotic regime (see Chapter 38). At the second stage of the procedure, the cement spacer is removed and a new prosthesis implanted. In the case of aseptic loosening, revision is performed as a single-stage procedure. If there has been a significant amount of bone loss, bone grafting or trabecular metal augments may be required. The results following a revision hip replacement are not as good as those following a primary THR and the rate of complications, especially dislocation, is also higher.

THE KNEE

Applied anatomy

The knee joint is a synovial hinge joint. It consists of two condyloid tibiofemoral joints and a sellar (or saddle shaped) patellofemoral joint. The shape makes the joint inherently unstable, but stability is achieved by a combination of static (ligaments) and dynamic (muscles) stabilisers acting across the joint.

Interposed between the tibial and femoral condyles are the medial and lateral menisci. These fibrocartilaginous structures aid shock absorption, increase the area over which load is dissipated and have a role in anteroposterior stability (**Figure 35.10**). Medial meniscal tears are three times more

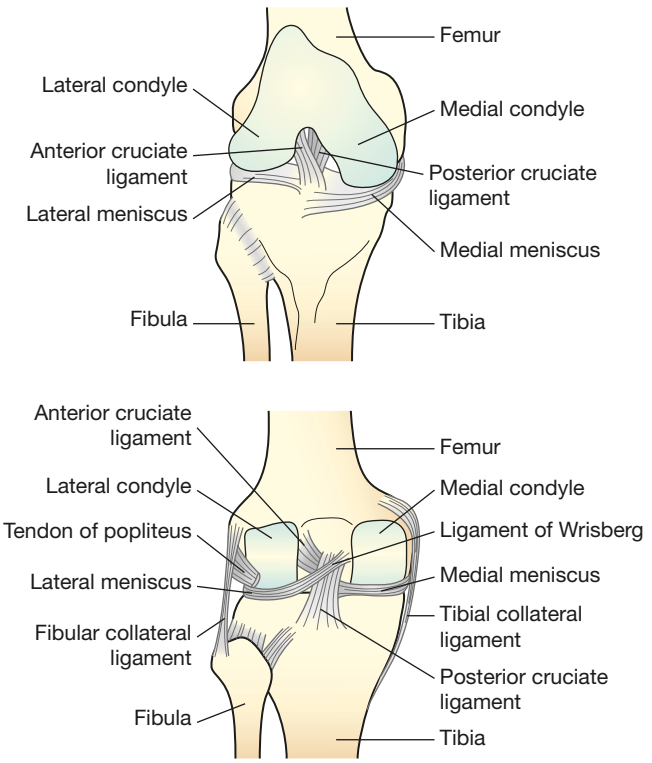

Figure 35.10 Anatomy of the knee joint.

common than those in the more mobile lateral meniscus. The outer third of the meniscus is vascular and so tears can be repaired with the prospect of healing.

The medial and lateral collateral ligaments are the primary restraints to valgus and varus stress, respectively. The medial collateral ligament is a broad, flat ligament composed of a superficial and a deep layer. The deep layer is attached to the medial meniscus. The lateral collateral ligament is a simple cord-like structure.

The cruciate ligaments are vital for anteroposterior stability. Each cruciate ligament comprises two bundles. The anterior cruciate ligament (ACL) is composed of an anteromedial bundle that is tight in flexion and a posterolateral bundle that is tight in extension. The posterior cruciate ligament (PCL) has an anterolateral bundle (tight in flexion) and a posteromedial portion (tight in extension). The ACL and PCL prevent anterior and posterior translation of the tibia on the femur respectively.

The knee has bursae surrounding it that can become inflamed and infected.

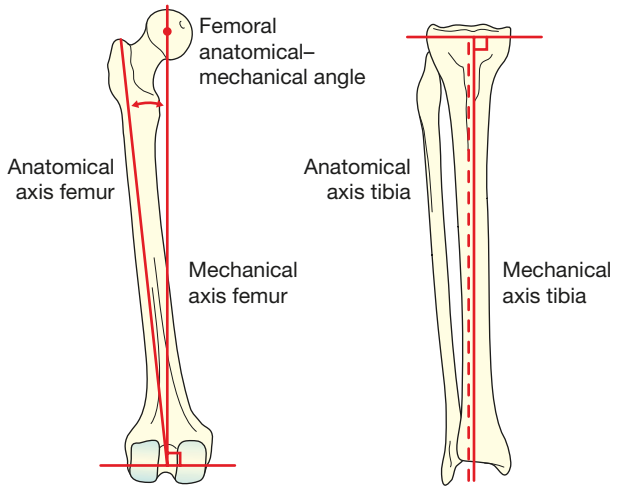

Figure 35.11 Axes of the lower limb. Anatomical and mechanical axes are coincident. Adapted from Miller, M. *Review of Orthopaedics*, 4th edn. 2004, Elsevier, Philadelphia. By kind permission of the publishers.

Summary box 35.6

Anatomy of the knee joint

- Complex synovial hinge joint
- The shape of the joint surfaces make it inherently unstable
- The static stabilisers are the joint capsule, menisci, cruciate and collateral ligaments
- The dynamic stabilisers are the quadriceps and hamstrings muscles

Biomechanics

Axes of the lower limb

The anatomical axes of the femur and tibia are defined by their medullary canal. The mechanical axis of the lower limb runs from the centre of the femoral head, through the intercondylar notch of the knee to the centre of the ankle joint. The angle between the anatomical and mechanical axes of the femur is usually between 5 and 7° (often called the valgus cut angle in arthroplasty) (**Figure 35.11**). An artificial knee joint must have the joint surface parallel with the ground, and with the load transmitted equally between the condyles. This is achieved by cutting the femur perpendicular to the mechanical axis, by measuring the valgus cut angle off the anatomical axis. The tibia is cut perpendicular to its anatomical and mechanical axes.

Kinematics and kinetics

Knee motion is predominately in the sagittal plane. A limited degree of rotation also occurs and increases as knee flexion increases. The normal range of motion is between 5° of hyperextension and 135° of flexion. MRI of cadaveric knees has revealed that, during knee flexion, a combination of rolling and sliding of the femur on the tibia occurs but there is also internal rotation of the tibia with flexion. This is because the larger medial femoral condyle rolls back less than the smaller lateral femoral condyle.

The biomechanical role of the patella is to function as a pulley for the quadriceps. It increases the power of the quadriceps by increasing the lever arm. It has the thickest articular cartilage in the body and is designed to withstand loads as high as 20 times body weight when jumping.

Summary box 35.7

Biomechanics of the knee joint

- The anatomical–mechanical angle of the femur is the angle between the anatomical and mechanical axes of the femur
- Knee motion is mainly in the sagittal plane with some rotation
- The patella acts as a pulley, increasing the lever arm of the quadriceps
- Loads of up to 20 times body weight are transmitted across the patella when jumping

Conditions affecting the knee joint

Osteoarthritis

OA commonly affects the knee joint. Females are affected more often than their male counterparts and more than 3% of women aged over 75 years are affected. Osteoarthritis can be either primary (idiopathic) or secondary. Secondary osteoarthritis may occur following a previous intra-articular fracture, meniscectomy, osteonecrosis or in a neuropathic joint.

CLINICAL FEATURES

Pain is the main symptom, made worse with use. With patellofemoral involvement, pain is worse on stairs. As the disease progresses, exercise tolerance diminishes, pain becomes constant, often disturbing sleep, and patients become increasingly reliant on walking aids. In severe cases, patients may even become housebound.

Clinical examination reveals an antalgic gait where the patient limps, spending a short time on the painful limb, and moves their centre of gravity to minimise the weight that they are taking through this limb. In osteoarthritic patients the deformity is usually varus, with bone loss on the medial side, while in rheumatoid patients valgus deformity is commonplace. An effusion is frequently present and movement is restricted, particularly extension. Crepitus can be both palpable and audible.

INVESTIGATIONS

The radiographic features are joint space narrowing, subchondral sclerosis, osteophytes and subchondral cysts (**Figure 35.12**). MRI can be used to judge both articular cartilage involvement and the integrity of the ACL, with a view to guiding future surgical intervention.

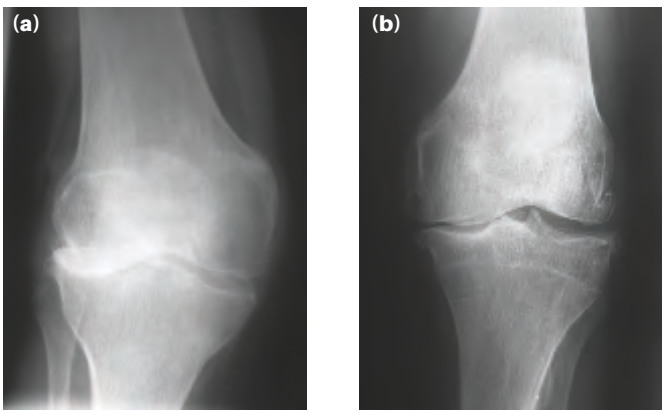

Figure 35.12 (a, b) Osteoarthritis of the knee.

TREATMENT

Non-operative methods are the first line of treatment. Patients should be encouraged to lose weight, undertake regular exercise to prevent joint stiffness and use anti-inflammatory medication. Walking aids, e.g. a stick, may be beneficial. Intra-articular steroid injections can provide long-term pain relief, although may actually cause more rapid degeneration of the joint cartilage.

Surgical options include osteotomy, arthrodesis or knee replacement. These are all discussed below.

Summary box 35.8

Knee osteoarthritis

- More common in females
- Can be primary (idiopathic) or secondary (e.g. post traumatic)
- The main symptom is pain made worse by use
- Examination reveals swelling, and reduced range of motion with or without deformity
- The key radiographic features are joint space narrowing, subchondral sclerosis and cysts, and osteophytes
- Treatment is non-operative initially. Knee replacement is reserved for end-stage disease

Soft tissue knee problems

Knee problems, in the case of injury, can present acutely or some time after the event (see Chapter 32). Problems can be associated with degenerative changes, in which case a more chronic presentation can be encountered. Specific structures commonly involved are the ligaments, tendons and menisci. Ligamentous injuries may involve the cruciate and collateral ligaments and can be combined with injury to stabilising structures, e.g. the posterolateral corner. Tendon problems include injuries to the quadriceps tendon and the patellar tendon. The pattern of meniscal injury or degeneration is variable, affecting either the medial or lateral meniscus (or both). There are several patterns of injury within a meniscal structure, some relating to blood supply and healing potential. Furthermore, soft tissue problems can be associated with chondral or osteochondral lesions.

ANTERIOR CRUCIATE LIGAMENT

The ACL is the most commonly injured ligament in the knee and injury most frequently results from pivoting injuries in high-energy contact sport. It may be associated with an audible 'pop', immediate swelling, and the need to be 'carried-off' the field.

The injury risk is higher among females, thought to be due to smaller ligaments, smaller femoral notches and different landing biomechanics.

Some controversy exists concerning the incidence of secondary osteoarthritis in ACL-deficient versus reconstructed knees. However, chronic ACL deficiency is clearly linked with an increased incidence of complex meniscal tears and chondral injury.

INVESTIGATION

MRI of the knee is useful for the identification of ligamentous and meniscal injuries, and any associated chondral lesions. An ultrasound scan is more commonly used to identify the more superficial tendon injuries.

TREATMENT

Isolated ligament injuries are generally initially managed non-operatively in a knee brace. Surgical repair, augmentation and reconstruction are considered in multiligament injuries, and in cases of chronic instability after non-operative management of isolated ligament injuries. Meniscal injuries that are associated with mechanical symptoms, e.g. catching, locking and giving way, generally respond well to arthroscopic treatment. This can include either a repair or debridement depending on the location, morphology and chronicity of the tear. Chondral lesions do not breach the subchondral bone and make no spontaneous attempt to heal. These lesions, if appropriate, are commonly managed with microfracture to stimulate bone marrow cells to form fibrocartilage repair tissue.

Some patients with ACL injuries may decide that they have adequate stability in the knee once they have been through a full rehabilitation programme. If, however, they continue to experience instability, particularly with twisting activities, they should be considered for surgical recon-

struction. Surgical reconstruction of the ACL should only be undertaken in those patients who have a full range of knee motion and good hamstring and quadriceps function preoperatively, as otherwise results are poor.

Surgical procedures

Arthroscopy of the knee

Knee arthroscopy is used in the diagnosis and treatment of injuries, e.g. ligamentous and meniscal injuries and articular cartilage defects. There are a number of other indications for knee arthroscopy summarised in *Table 35.8*.

TABLE 35.8 Indications for knee arthroscopy.

Torn meniscus resection or repair
Anterior/posterior cruciate ligament reconstruction
Loose body removal
Cartilage regeneration techniques including microfracture
Septic arthritis washout
Inflammatory arthritis – synovectomy
Diagnosis of unexplained knee pain
Tibial plateau fractures – allows intraoperative assessment and reduction of the articular surface

Cruciate reconstruction

An isolated ACL injury is most commonly treated with an arthroscopic intra-articular reconstruction. The graft can be bone–patella, tendon–bone or four-strand hamstring autograft. Postoperative rehabilitation programmes are crucial to a favourable outcome. Complications following ACL surgery are usually a result of incorrect tunnel placement (placing the femoral tunnel too far anteriorly limits knee flexion) and early surgery. The graft re-rupture rate is approximately 1% per year.

Osteotomy

Osteoarthritis can lead to varus or valgus deformity of the knee. This results in excessive stresses on the affected compartment, leading to premature degenerative change in that compartment. Osteotomy aims to divide the bone, correct the deformity and alter the load-bearing mechanics of the joint.

The most commonly performed operation is a high tibial osteotomy (HTO) for a varus knee. Realignment is achieved with either an opening-wedge medial HTO or a closing-wedge lateral HTO. In valgus knees with relatively mild deformity (less than 12°) a varus-producing HTO on the medial side can be performed. A deformity of 12° or more requires distal femoral varus osteotomy.

The ideal patient for osteotomy is a young and active, well-motivated individual with disease limited to one compartment.

Knee arthrodesis

The most common indication for knee arthrodesis is a failed total knee replacement. Other indications include uncontrollable sepsis, a neuropathic joint, post-traumatic arthritis in a young patient and disruption of the extensor mechanism. The ideal position of fusion is 7° of valgus and 15° of flexion. Arthrodesis is performed using either a custom-made intramedullary nail or an extramedullary technique such as an external fixator.

Knee joint replacement

There are three compartments within the knee: medial and lateral tibiofemoral, and patellofemoral. Osteoarthritis may affect these individually or collectively. The medial compartment is most commonly affected, producing a varus deformity. For single-compartment disease a unicompartmental replacement may be used, while in tricompartmental disease a total knee replacement (TKR) is indicated (**Figure 35.13**).

Knee replacement can be regarded as a resurfacing procedure in which the femoral articular surface is replaced with metal and the tibial articular surface is replaced by a tough polyethylene insert.

The main indication for knee replacement is pain, especially when combined with deformity and instability. Knee replacement should be reserved until a patient's quality of life is significantly impaired.

Natural knee motion is complex. It involves translation and rotation about each of the *x*, *y* and *z* axes (six degrees of freedom). It has proven very difficult to reproduce this natural

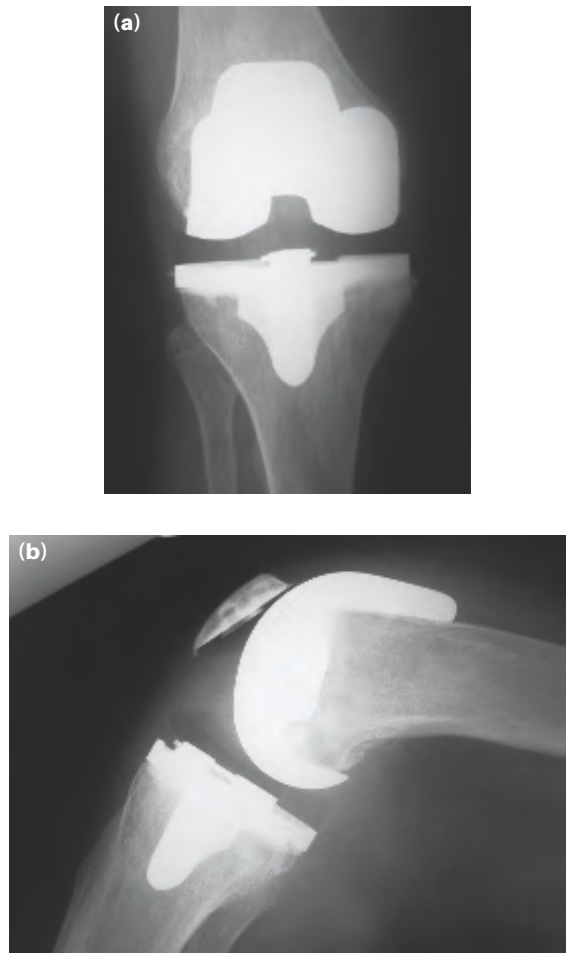

Figure 35.13 **(a, b)** Total knee replacement.

motion in TKRs. In comparison to THR, patients with TKR find it hard to forget they have a knee replacement. Consequently, patient satisfaction is lower with TKR.

There are three types of TKR currently used: unconstrained, constrained–non-hinged and constrained–hinged. Almost all primary TKR are unconstrained while the constrained types are used in revision TKR when there may be significant bone loss and ligament deficiency.

The more constrained the implant the greater the force transmitted to the implant–cement–bone interfaces, therefore increasing the risk of loosening.

The main aim of TKR is to create a mechanical axis (weight-bearing line) that passes through the centre of the femoral head, knee and ankle. The joint line should then be perpendicular to the mechanical axis. It should also be parallel with the ground. If implants of the correct size are used and exactly the right amount of bone is cut away from both the tibia and the femur, the new joint surface will be placed exactly where the patient's original surface had been before disease supervened.The collateral ligaments will then provide stability without constraint and ensure that the patella will track correctly on the femur.

Postoperatively, patients require physiotherapy to regain quadriceps strength and to achieve full extension. In addition they need at least 90° knee flexion to enable them to sit comfortably. The average length of hospital stay is between 3 and 5 days. Complications following TKR can be broadly classified into intraoperative and postoperative (*Table 35.9*).

Summary box 35.9

Aims of total knee replacement

- Mechanical axis through centre of knee
- Joint line perpendicular to mechanical axis
- Balance collateral ligaments
- Ensure patellofemoral joint tracks normally

TABLE 35.9 Complications of total knee replacement.

Intraoperative
Poor placement of implants leading to instability or stiffness, or pain
Nerve or vessel injury including tourniquet damage
Fracture
Patellar tendon avulsion
Malalignment
Fat embolism
Postoperative
Infection
Deep vein thrombosis/pulmonary embolism
Pain/stiffness
Instability
Osteolysis
Component loosening
Dislocation

Unicompartmental knee replacement (UKR)

The natural history of osteoarthritis reveals that, in up to 92% of cases, the disease begins in the medial compartment alone. This was the basis for the development of the UKR, which is available in either fixed or mobile bearing forms (**Figure 35.14**). Although generally the longevity of the implants is not as good as with TKRs, a number of series report 10-year survival figures over 90% for medial UKRs.

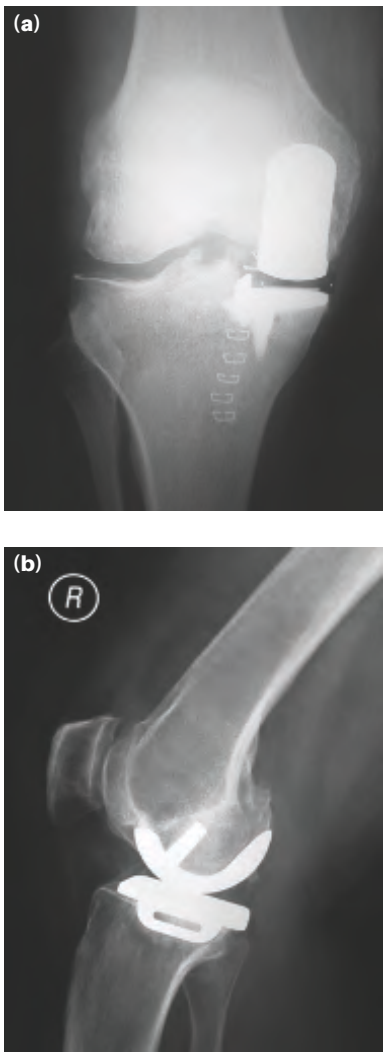

Figure 35.14 (a, b) Unicompartmental knee replacement.

Prerequisites to undertaking medial UKR include intact ligaments (especially the ACL), disease limited to one compartment and varus/flexion deformities of not more than 15°. As it is a less invasive procedure than a TKR, it is associated with a more rapid recovery, shorter hospital stay and preservation of knee kinematics. It is a bone preserving procedure, and therefore revision is generally to a TKR rather than to more constrained implants.

Lateral UKR is performed for lateral compartment disease; this is far less common than medial UKR, partly owing to a reported dislocation rate of 10%.

Patellofemoral replacement is also performed but again the longevity of the implants is not as good, and the numbers are low in view of the scarcity of patients with isolated patellofemoral disease.

Revision knee replacement

Implant loosening secondary to either infection or polyethylene-induced osteolysis is the main reason for revising TKR. Other indications include periprosthetic fracture, malalignment, instability, stiffness and patellar maltracking. Regardless of the indication, as with any type of revision procedure it is important to exclude infection because this often warrants a two-stage rather than a single-stage procedure. Although it is more technically challenging, the aims of revision TKR are no different from those of primary TKR. That is to provide a well-aligned, stable and pain-free knee (**Figure 35.15**).

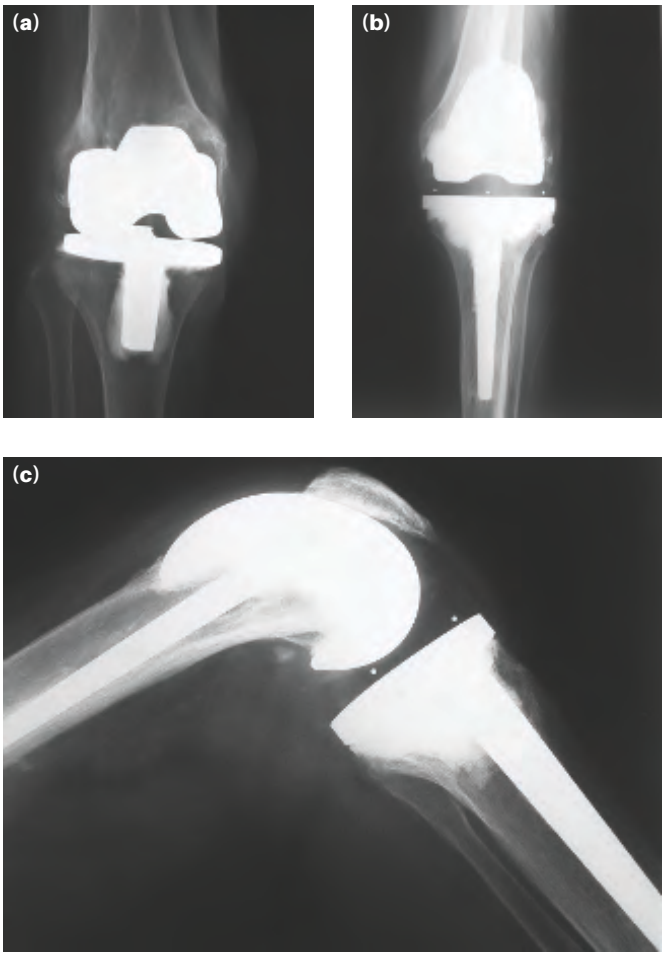

Figure 35.15 Radiographs of a malaligned knee **(a)** and a well-aligned revised knee **(b, c)**.

Chapter 36

Foot and ankle

Learning objectives

To understand:

- The basic anatomy and biomechanics of the foot and ankle
- The common problems affecting the foot and ankle in each age group
- The principles behind the treatment of each condition, be it conservative or surgical
- The significance of progressive neurological diseases

ANATOMY

There are 26 (25 with variant) main bones in the foot (seven tarsal bones, five metatarsals and 14 phalanges; 13 in the biphalangeal fifth toe varient) plus the two sesamoids of the hallux and a variable number of other sesamoid and accessory bones.

Movements at the ankle joint are mainly dorsiflexion and plantarflexion, but are more complex than this. The joint is actually a truncated section of a cone, meaning the motion is not simply a hinge and, in addition, movement of the ankle leads to rotation of the fibula at the syndesmosis. This means that the foot externally rotates with dorsiflexion and internally rotates with plantarflexion.

Stability is conferred upon the ankle by the congruence of the mortice and the integrity of principally the medial, lateral and the inferior tibiofibular ligaments.

The subtalar joint is divided into anterior, middle and posterior facets and, along with the talonavicular and calcaneocuboid joints, makes up the triple joint complex. These joints are responsible for inversion and eversion of the hind and midfoot. The joints are codependent such that limitation of one affects movement at the others. Fusion of the triple complex slightly affects movement at the ankle and vice versa.

The second tarsometatarsal joint is recessed relative to the first and third and acts as a 'keystone'. Disruption of this joint (Lisfranc's injury) leads to loss of the transverse arch and an acquired flat foot.

The lower leg is divided into four compartments:

- the superficial posterior – gastrocnemius, soleus and plantaris;
- the deep posterior – tibialis posterior, flexor digitorum longus and flexor hallucis longus;
- the lateral – peroneus brevis and peroneus longus;
- the anterior – tibialis anterior, extensor hallucis longus, extensor digitorum longus and peroneus tertius.

There is only one muscle on the dorsum of the foot, the extensor digitorum brevis. The muscles on the plantar aspect of the foot are divided into four layers, the first being the most superficial, and the course of the neurovascular structures is a favourite exam topic. The plantar fascia is a very important structure that takes its origin from the heel and inserts into the bases of the proximal phalanges of the toes. At toe-off, the fascia tightens and accentuates the medial plantar arch and helps provide a rigid lever arm, the so-called 'windlass mechanism'. This is essential in the preservation of the integrity of the arch of the foot and function of the toes.

The blood supply of the foot is from the anterior tibial, the posterior tibial and the peroneal arteries. The following nerves supply sensation to the foot: posterior tibial, saphenous, sural, superficial and deep peroneal (**Figure 36.1**).

Summary box 36.1

Anatomy of the foot

- There are 26 major bones in the foot
- There are four layers of muscles in the sole of the foot
- The blood supply of the foot is from the anterior and posterior tibial arteries plus the peroneal artery

Jacques Lisfranc, 1790–1847, Professor of Surgery and Operative Medicine, Paris, France.

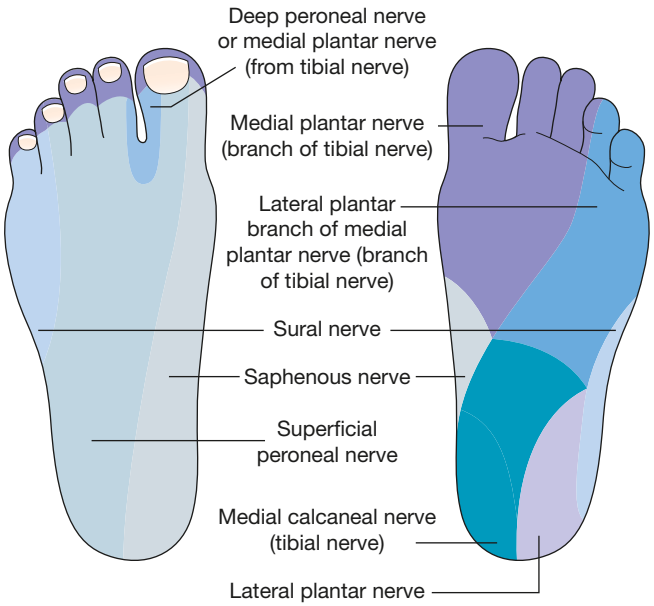

Figure 36.1 Cutaneous nerve supply of the foot (courtesy of Bartleby.com).

BIOMECHANICS

The walking cycle is divided into the stance (60%) and swing (40%) phases. The stance phase is divided into three intervals: (1) heel strike to foot flat; (2) foot flat until the body passes over the ankle; and (3) ankle joint plantarflexion to toe-off. During walking up to 12% of the gait cycle is spent with both feet in the stance phase but with running there is a period when neither foot is in contact with the ground, the 'float' phase. During running the cycle time is shortened but the forces generated are very much increased.

Summary box 36.2

Biomechanics

- The gait cycle is divided into swing and stance phases
- Running generates increased forces, shortens the gait cycle and has a float phase when neither foot touches the ground

Examination

The examination of the foot is described in Chapter 31. The patient should be watched walking, and both the foot and the footwear of the patient need examining when looking for abnormal load and wear.

PAEDIATRIC CONDITIONS

These are discussed in Chapter 39.

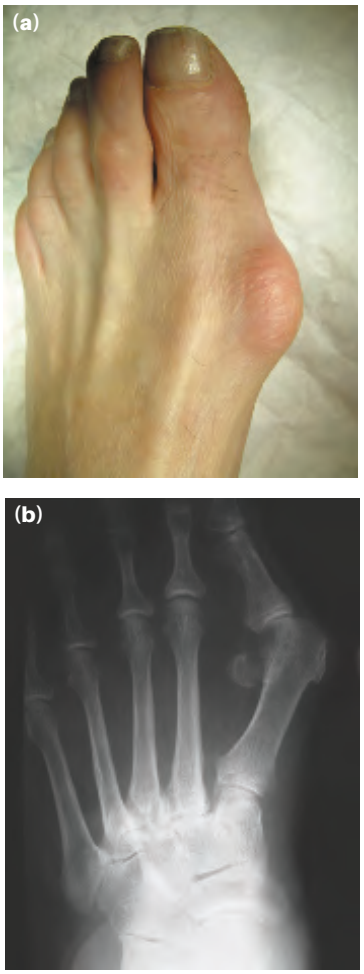

Figure 36.2 **(a, b)** Hallux valgus and bunion.

PATHOLOGY IN THE ADULT

The forefoot

Hallux valgus

Hallux valgus is deviation of the big toe away from the midline, i.e. towards the lesser toes, and is usually associated with a bunion, a swelling made up of both bone and bursa on the medial aspect of the first metatarsal head **(Figure 36.2)**. It is a common condition that affects women more than men, and which is often bilateral. It is believed that the tendency to hallux valgus is inherited and that fully enclosed shoes accelerate the development of the condition.

With increasing deformity the first ray becomes defunctional and elevated, and overload of the second metatarsophalangeal (MTP) joint often results in pain, swelling and eventually plantar plate disruption and dislocation. This can present with a prominent callosity beneath the second MTP joint and eventually hammering of the second toe.

Non-operative treatment of hallux valgus includes a wider toe box and pressure relief. Surgical intervention is commonly offered, but has a 10% rate of dissatisfaction.

For mild deformities a distal osteotomy (e.g. chevron) is usually adequate. For moderate deformities the surgeon is more likely to use a shaft e.g. Scarf **(Figure 36.3)** or Ludloff,

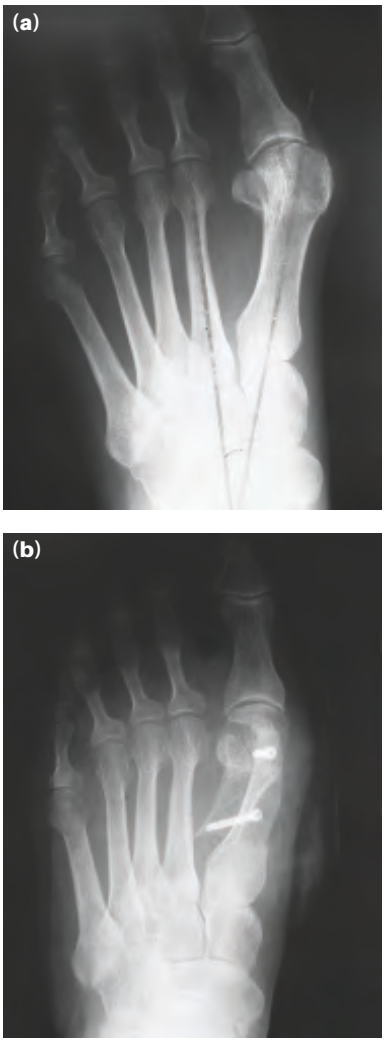

Figure 36.3 Pre- **(a)** and postoperative **(b)** radiographs of a Scarf osteotomy.

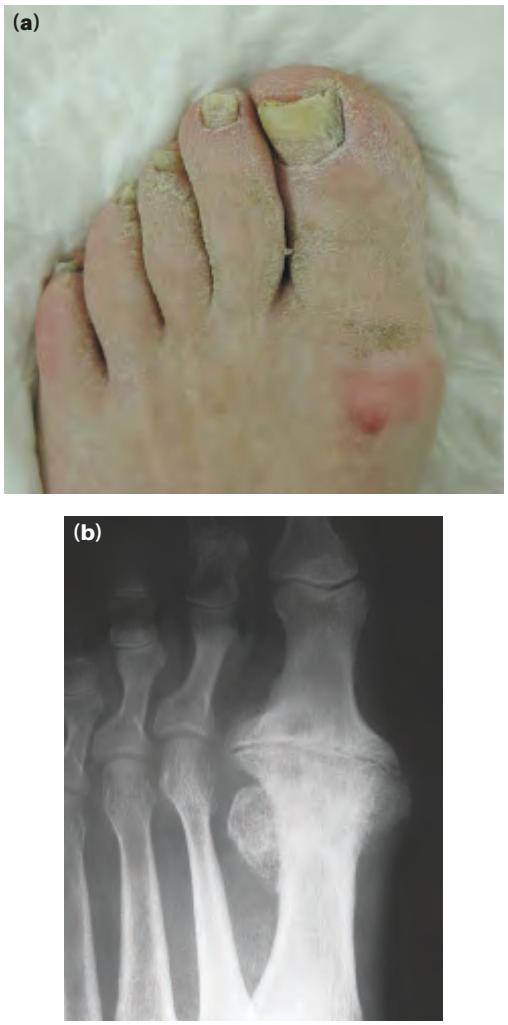

Figure 36.4 Clinical **(a)** and radiographic **(b)** appearance of hallux rigidus.

or a basal (proximal chevron or crescentic) osteotomy. Severe deformities can be corrected by shaft and basal osteotomies but sometimes a fusion of the first tarsometatarsal joint (modified Lapidus) or a first MTP joint fusion can be effective. Minimally invasive techniques are developing and are widespread, especially in Europe, but there are few peer-reviewed series of outcomes from the UK.

Basal osteotomies and fusions have a higher risk of abnomal elevation or depression of the rays, resulting in overload of the rest of the forefoot. However, they do allow a massive correction. They are best stabilised using plates.

Operations such as a Keller's excision arthroplasty, where the proximal third of the proximal phalanx is excised, serve to defunction the toe and sesamoids and are reserved for low-demand high-risk patients where there is a high risk that healing of an osteotomy might fail.

The complications of bunion surgery are infection, cutaneous nerve damage, recurrence or overcorrection of deformity, stiffness and overload of the second MTP joint (transfer lesion), and 10% of patients have reservations about their outcome. Occasionally patients develop early arthritis following surgery and require revision to fusion.

Summary box 36.3

Hallux valgus

- Bunions affect women more often than men
- Patients with hallux valgus have inherited a tendency to develop the condition
- Not all patients need surgery
- The choice of operation is determined by the severity of the deformity and presence or absence of any arthritis

Hallux rigidus

Hallux rigidus is a painful condition of the hallux MTP joint characterised by loss of motion especially in dorsiflexion and osteophyte formation on the dorsum and sides of the joint (**Figure 36.4**).

William Lordan Keller, 1874–1959, Head of the Department of Surgery, the Walter Reed Hospital, Washington, DC, USA, described this operation in 1904.

In adults there is often a history of trauma or repetitive microtrauma (sport) but, occasionally, there is a strong family history of the condition. Gout and rheumatological conditions may present in this way. Patients complain of stiffness and pain on weight bearing.

The most effective non-operative treatment is provision of a stiff-soled shoe with a deep toe box or a rocker-soled shoe, which are now available on the high street.

The mainstays of surgical management are injection/manipulation, cheilectomy (a radical debridement and excision of the part of the joint blocking movement), fusion, and interpostion arthroplasty (Keller's-type procedure or silicon interposition). Prosthetic arthroplasty, with hemi-, total, interposition or spacer arthroplasty, is available but many prostheses have been withdrawn for high failure rates and few series extend beyond 9 years.

Fusion is for the severely affected and is an effective means of abolishing pain, but affects the biomechanics and some patients are left with intractable pain beneath the sesamoids. A fusion will still usually allow sports participation.

Summary box 36.4

Hallux rigidus

- Hallux rigidus can affect adolescents as well as adults
- Stiff-soled shoes with a deep toe box are the most comfortable type of shoe
- Cheilectomy and fusion are the mainstays of surgical treatment

Sesamoid problems

Acute injuries (turf toe) can be managed non-operatively or surgically depending on the grade of the injury and the occupation of the patient. Grade 4 acute fracture may require surgery.

Chronic conditions are indistinguishable and range from stress fracture to avascular necrosis and sesamoiditis but are probably all the same phenomenon. Management includes offloading with orthotics and injections of steroids and, rarely, shaving/excison. Excision surgery carries a high risk.

Lesser toe deformities

Hammer, mallet, and claw toes are frequent and are usually non-indicative but may be secondary to other deformities in the foot or to underlying neurological disease. Non-operative treatment involves appropriate padding and footwear modification. For symptomatic flexible deformities soft-tissue surgery such as flexor/extensor tenotomies +/– capsulotomy is usually adequate, but for fixed deformities bony procedures are required such as interposition arthroplasty, fusion or excision arthroplasty.

Isolated lesser toe MTP extension/subluxation may result from a ruptured plantar plate, and repair techniques have evolved recently.

Freiberg's disease

Freiberg's disease (**Figure 36.5**) is an ischaemic necrosis of the epiphysis, resulting in pain and swelling of the joint. It will often settle with rest. Re-shaping osteotomies are described, or excision of the proximal phalangeal head for severe adult cases with joint destruction. Excision of the whole metatarsal head should never be performed.

Morton's neuroma and metatarsalgia

Metatarsalgia usually occurs secondary to joint problems, overload or irritation of a nerve. Morton's neuroma is a painful condition which in most cases arises from compression of the common digital nerve between the third and fourth metatarsal heads and is usually secondary to other forefoot pathology.

The diagnosis is confirmed by ultrasound or magnetic resonance imaging (MRI). Non-operative treatments include advice about footwear, an orthosis (premetatarsal dome) to splay the metatarsal heads or an injection of steroids.

Surgery involves resection (the affected toes will be permanently partly hemi-numb if the nerve is removed) but this is not without risk of patient dissatisfaction, pain and recurrence.

Summary box 36.5

Morton's neuroma

- Morton's neuroma most commonly affects the second or third web space
- Surgical excision of a neuroma is often successful but has a risk of pain syndrome and recurrence; guided injections form the mainstay of treatment for most

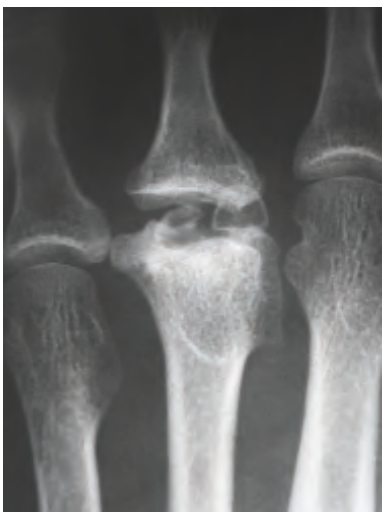

Figure 36.5 Freiberg's disease.

Albert Henry Freiberg, Professor of Orthopaedic Surgery, University of Cincinnati, Cincinnati, OH, USA, gave his account of this condition in 1926.
Thomas George Morton, 1835–1903, surgeon, the Pennsylvania Hospital, Philadelphia, PA, USA, described this condition in 1876.

Stress fracture

May be post sport or incipient. Usually presents in the forefoot and may mimic Morton's or metatarsalgia. A unexplained aetiology might require biochemical or biomechanical evaluation. Forefoot fractures can usually be managed non-operatively.

Stress fractures may occur in any bone. Those of the navicular, talus and tibial sesamoid often present with vague symptomatology but early diagnosis with MRI and management are essential, with early fixation if required.

The midfoot

The midfoot comprises the cuneiforms and the cuboid and related joints.

Midfoot arthritis

The aetiology is usually not known but the risk factors include microtrauma, rheumatological causes, flat foot, Lisfranc or similar injuries (which may have been missed), Charcot and cavus foot. Patients are best managed non-operatively with orthotics, shoes, analgesia and modifications of their lifestyle.

Pain, often with palpable dorsal osteophytes, is the commonest finding.

Injections and orthotics are the mainstay of treatment, with surgery high risk and having moderate outcomes. Fusion of the lateral two tarsometatarsal (TMT) joints has a universally poor outcome. Arthroplasty, similarly, has little evidence to support its use and has poor outcomes in the hands of most.

Charcot

An acute hot, red swollen foot (which may or may not be painful) may be indicative of Charcot (often secondary to diabetes which may as yet be undiagnosed) or other neuropathy. Immediate offloading in plaster and urgent management are indicated, and National Institute of Health and Care Excellence (NICE) guidelines are available in the UK.

Tendinopathy

Rarely, dorsal pain may be due to tibialis anterior tendinosis at its insertion; management is usually non-operative.

Ganglions

Midfoot ganglions are common and may cause neuralgia over dorsal bosses. Injection/aspiration should be attempted. Surgery may be required but recurrence is high and secondary neuralgia not infrequent.

The hindfoot and ankle

Ankle arthritis

The definitive operative treatment for arthritis of the ankle will usually be in the form of total ankle replacement (TAR) or more commonly arthrodesis (fusion); the latter is often carried out via an open approach but arthroscopic techniques have better outcomes, more rapid recovery and fewer complications. Such techniques are mandatory in the presence of poor soft-tissue envelope or in the presence of a clotting diathesis. A UK National trial is currently underway to evaluate the relative outcomes of TAR versus arthrodesis (the TARVA trial), which are as yet undefined.

The advantage of fusion is it has a known track record, good outcomes (over 90% do well) and minimal morbidity, especially with modern arthroscopic techniques, but not all do well with fusion. Function following isolated fusion is virtually normal for most patients and this is probably due to increased mobility at other joints. However, this may precipitate arthralgia elsewhere.

Total ankle replacements (TARs) are usually three-component devices (except in the USA) that allow preservation of joint mobility but at the expense of larger incisions and possible eventual failure. Revision rates of <1% to 7% per annum are reported. Two of the most widely used TARs have been withdrawn in recent years, one due to massive osteolysis.

Hindfoot (excluding ankle) arthritis

The triple complex refers to the subtalar (talocalcaneal), calcaneocuboid and talonavicular joints. These joints are often affected by arthritis. Treatment options are limited and, if simple measures have failed, a fusion should be performed. Smokers and diabetics have a massively increased non-union rate for all foot fusion procedures and should be warned of this when they give consent. Late presentation of coalitions usually requires fusion.

Ankle combined with other hindfoot arthritis

If surgical input is required, one option is to treat one set of joints and then see how the patient fares. For example, offer the patient an ankle fusion or replacement and then assess the outcome. Secondary surgery to the other joints can then be performed if required. The alternative is to treat all joints at once.

Modern techniques now use third-generation hindfoot fusion nails which fuse both ankle and subtalar joints and are inserted with an open or arthroscopic fusion technique.

A pantalar fusion is quite disabling but may be necessary in rheumatological patients with deformities/stress fractures, patients with a failed arthroplasty with subtalar joint involvement, pantalar arthritis or avascular necrosis (AVN) with collapse of the talus.

Summary box 36.6

Midfoot and hindfoot

- Joint disorders are degenerative or inflammatory
- The mainstay of surgical treatment remains fusion although ankle replacements are becoming more successful
- Rheumatoid arthritis must be medically controlled as well as possible before surgery
- Knee deformities should be corrected before tackling foot problems

Jean Martin Charcot, 1825–1893, physician, La Salpêtrière, Paris, France.

Rheumatological presentations in the foot

The early presentations of rheumatological disease may include synovitis of the lesser MTP joints and widespread small joint disease, often in association with enthesopathy such as plantar fasciitis or Achilles tendonosis. However, the classic deformity is of hallux valgus with or without hallux rigidus deformity and subluxation or even dislocation of the lesser MTP joints in the forefoot, and arthritis and deformity in the mid/hindfoot.

The patient may present with a bunion and prominent lesser metatarsal heads which can often be felt to be dislocated on clinical examination, and are painful to palpation. Joint-sparing surgery is preferred, with preservation of the metatarsal (MT) heads if possible, often shortening and relocating the MTP joints. Destruction of the joints can be treated with proximal phalangeal partial excisions. Fusion of the first MTP is the usual requirement. Late recurrence can be managed with excision arthroplasty.

Excision of the metatarsal heads produces an almost instantaneous and gratifying relief of pain. If a plantar approach is used an ellipse of skin can be excised to move the metatarsal padding back over the end of the metatarsal. While most surgeons avoid scars on the plantar aspect of the foot wherever possible, this is one procedure where the results are good. However, such surgery leaves no room for revision in later years.

The requirement for rheumatoid forefoot correction has fallen dramatically in the last 10 years with the advent of disease-modifying drugs.

MIDFOOT

Rheumatological disease may also affect the midfoot and here the outcome is usually just pain and stiffness. Options are limited to injections and fusion surgery if non-operative measures have failed.

HINDFOOT AND ANKLE

Rheumatological disease also affects the hindfoot and ankle. Many patients require surgical hindfoot fusions and the options for the ankle are discussed in the arthritis section.

The rheumatological diseases also affect soft tissues. Patients are more prone to developing enthesopathy, tendinitis and tendonosis, and even tendon rupture. The Achilles tendon should never be injected with steroid for fear of rupture and, similarly, the tibialis anterior and tibialis posterior tendons are risky for injection.

Tendon disorders

Tenosynovitis occurs as a result of injury, overuse or is secondary to inflammatory joint conditions. Rest, anti-inflammatory medication and physiotherapy are often helpful but, in inflammatory conditions, tenosynovectomy may be required.

The tendons most commonly affected by degeneration are the Achilles (**Figure 36.6**), tibialis posterior and peroneii (brevis more than longus).

Figure 36.6 Insertional Achilles tendinitis (arrow).

Ruptured Achilles tendon

The Achilles tendon rupture is relatively frequent in the 40- to 50-year-old age group who are undertaking vigorous sport after a long period away from such activities. Management of acute rupture is more frequently non-operative nowadays, provided ultrasound has shown closure of the gap in plantarflexion, and many protocols are described for non-operative management. Surgical fixation is an alternative.

Many patients do not suffer the acute rupture classically described in all textbooks and many seem to have a series of micro tears that gradually lead to total rupture. Studies have shown that elderly patients with Achilles rupture regained 70–90% of the normal power with no treatment whatsoever when reviewed at 1 year; for many patients, this is enough to allow them to return to normal function.

Non-operative options for a missed rupture include a sprung ankle–foot orthotic (AFO) ankle brace, while operative options involve reconstructive surgery with or without flexor hallucis longus (FHL) tendon augmentation.

Achilles tendinosis

Non-insertional and insertional tendinosis are frequent, often related to overuse and are usually managed non-operatively. Shockwave therapy is a recent addition to the armoury. Steroid injections may rupture the Achilles and are discouraged, but high volume saline, dry-needling and sclerosant injections have all been described. Surgery for non-insertional tendinosis has moderate success. Minimally invasive excision of the prominent posterolateral corner of the calcaneum or reshaping osteotomy forms the mainstay of modern surgical techniques for insertional problems but both conditions have a high failure rate with surgery.

Peroneal tendon problems

The peroneal tendons may develop tendinosis, may subluxate or may become involved in an inflammatory process with or without bony overgrowth at the inferior retinaculum (**Figure 36.7**). An associated varus heel will amplify the problem and will need addressing with an appropriate reconstruction/osteotomy or fusion.

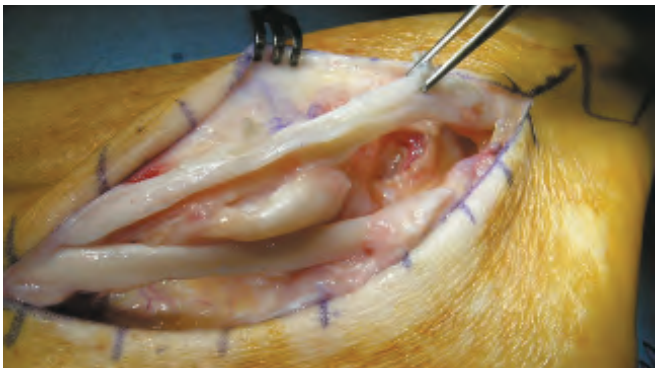

Figure 36.7 Split and degenerate peroneus brevis.

Peroneal tendon subluxation can occur spontaneously or after injury. It may be associated with the groove at the back of the fibula being too shallow to contain the peroneal tendons, but may just be secondary to a superior retinaculum tear. The patient may be able to demonstrate a tendon subluxation over the fibula. Surgical repair is usually required and involves deepening of the groove.

Tendinosis/itis can be managed non-operatively, although injections have occasionally caused rupture. Surgical debridement or repair of splits/tears/ruptures is well described but has only moderate success.

Acquired flat foot

There is a wide range of normal appearance of adult feet. Pathological causes of a flat foot include:

- tibialis posterior tendon dysfunction;
- tarsometatarsal arthritis/injury (Figure 36.8);
- Charcot neuroarthropathy, e.g. diabetes (see later);
- inflammatory/degenerative arthritis of the subtalar/talonavicular/naviculocuneiform joints;
- spring ligament rupture;
- tarsal coalition.

Summary box 36.7

Acquired flat foot

- Tibialis posterior tendon dysfunction and tarsometatarsal osteoarthritis are common causes of an acquired flat foot
- Orthoses, rest and non-steroidal anti-inflammatory drugs (NSAIDs) can help with symptomatic relief
- Surgery is a major undertaking but often highly successful at achieving symptomatic relief

The tibialis posterior tendon tends to fail in overweight individuals and those who have flat feet. Often, after unaccustomed exercise, the tendon swells and is painful. The diagnosis is rarely made early. The condition occurs mainly in women and the key test is that the patient cannot stand on tiptoe on that leg alone. Many individuals will require surgical treatment in the form of a medial displacement calcaneal osteotomy, flexor digitorum longus or FHL tendon transfer and spring ligament repair. Failure to treat this condition can lead to spectacular deformity (Figure 36.9).

An acute traumatic flat foot may develop in young athletes and military recruits after traumatic injury; here the injury is an isolated spring ligament tear and early surgery is needed to effect a repair.

Ankle instability

Most people who sustain an ankle sprain will recover, particularly if they receive prompt physiotherapy. However, some individuals develop significant instability. On examination an unstable ankle due to ligament disruption will show a marked 'anterior drawer' sign.

If physiotherapy is unsuccessful at resolving the problem, a reconstruction may be needed with ligament augmentation. Anatomical techniques such as the Brostrum procedure are favoured and may be augmented with synthetic augments for early mobilisation.

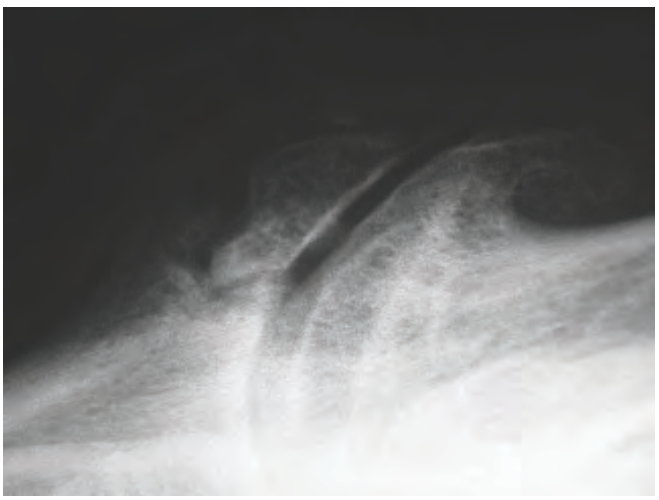

Figure 36.8 Tarsometatarsal arthritis.

Figure 36.9 A tibialis posterior tendon-deficient foot.

Osteochondral lesion of the talus

Patients with persistent pain in the ankle following an injury should be suspected of having an osteochondral lesion, with MRI or computed tomography (CT) usually required for diagnosis.

Repair of cartilage is not yet possible and large meta-analyses of experimental techniques such as grafting, cell culture, implants and stem cells have not yet shown any statistical benefit. Debridement and microabrasion/microfracture form the mainstay of treatment. Large fragments seen early might benefit from early fixation. Juveniles seem to have a high spontaneous recovery rate and surgery should not be necessary.

Synovitis

Many patients have ongoing pain following ankle injury that is simply due to synovitis within the ankle joint, prominence of the syndesmotic ligament into the joint, impaction injury or undiagnosed fracture or osteochondritis dissecans (OCD) lesion. MRI is mandatory for these cases. Synovitis may be treated non-operatively, with an injection of steroid. Persistent symptoms may require arthroscopic debridement.

Neurological foot conditions

Pes cavus

The development of unilateral pes cavus is likely to be arising from an upper motor neurone lesion so an appropriate neurological examination should be performed.

Pes cavus is usually bilateral and most cases will be associated with an underlying neurological condition, the most common being Charcot–Marie–Tooth disease. These patients may present with characteristic progressive small muscle wasting, thin calf musculature, hand symptoms, aches and pains, and cavo-varus feet. Examination may show early loss of vibration sense. Precise diagnosis is confirmed with nerve conduction studies and genetic testing.

The key deforming force is always relative preservation of the tibialis posterior (tib post) tendon. Surgical correction of the deformity is often required. The principle goal of treatment is to obtain a foot which can be placed flat on the ground, and with the power of the muscles around the ankle in balance. It will be necessary to transfer or release the tib post tendon. The most commonly performed procedure is to transfer the tib post to the dorsolateral side of the foot, followed by lateralising of the heel with an osteotomy and dorsiflexion osteotomy of the first ray with or without a Jones procedure to the great toe.

Summary box 36.8

Pes cavus

- Pes cavus needs neurological investigation
- About 80% of cases of pes cavus are associated with a neurological disease
- The commonest cause is Charcot–Marie–Tooth disease
- Unilateral pes cavus – think diastematomyelia/ tumour

Tumours

The most common benign tumours of the foot are ganglia, giant cell tumour and angioleiomyomas (**Figure 36.10**); these tumours may need surgical excision.

Pigmented villonodular synovitis (PVNS) is a locally aggressive condition found in the ankle and is diagnosed by MRI or at histology. Surveillance for recurrence is mandatory.

The most common 'tumour' seen in the foot is the plantar fibroma or 'ledderhosens disease', which presents as a painful often growing lump in the sole along the plantar fascia. The condition is linked to Dupytren's and Peyronie's disease. Surgery should be avoided. Ultrasound or MRI will confirm the multifocal nature of the disease and exclude other pathology.

Any large or growing lump in the foot needs formal work-up along tumour guidelines, especially in the presence of night pain.

Figure 36.10 Angioleiomyoma of the hallux.

Infection

Septic arthritis in the foot or ankle is rare except in diabetic patients and constitutes a surgical emergency; when it occurs it usually follows a surgical procedure but it can also arise

Pierre Marie, 1853–1940, neurologist, Hospice de Bicêtre, Paris, France, later becoming Professor of Pathological Anatomy in the Faculty of Medicine, and finally, in 1918, Professor of Neurology.

Howard Henry Tooth, 1856–1925, physician, St Bartholomew's Hospital, and the National Hospital for Nervous Diseases, Queen Square, London, UK, described peroneal muscular atrophy in 1886 independently of Charcot and Marie.

as a result of haematogenous spread. Treatment is immediate surgical drainage and administration of appropriate high-dosage antibiotics once cultures are obtained. The most common causative organism is *Staphylococcus aureus* with methicillin-resistant *S. aureus* (MRSA) becoming more common. Even with prompt treatment chondrolysis often occurs and subsequent degenerative changes develop rapidly.

In immunocompromised patients opportunistic infections can arise and, in diabetics, failure to treat with debridement can lead to amputation. It is important to realise that radiographs in the early stages of infection are usually normal and that diagnosis is made on clinical suspicion and with blood tests and more sophisticated imaging such as MRI or bone scanning.

Tuberculosis can affect the foot and is associated with major bony damage; it responds surprisingly well to debridement and appropriate antituberculous therapy (Figure 36.11).

Figure 36.11 Tuberculosis of the foot (arrow).

Diabetes

Diabetic patients have foot problems secondary to neuropathy and microvascular changes. They are at increased risk of infection and ulceration, and trauma (sometimes trivial) can lead to collapse of the foot, also known as Charcot neuroarthropathy (Figure 36.12).

Ulceration and amputation

Ulceration can lead to major morbidity and amputation (Figure 36.13). Ulcers need to be treated urgently, and when ulcer healing has occurred the aim should be to keep the foot ulcer free. NICE guidelines detail optimal management pathways with urgent admission, radiological and clinical assessment, followed by debridement, antibiotics if required and formal offloading. Ulceration is a surgical emergency.

Most amputations are preceeded by ulceration.

Charcot

Charcot is a condition in which patients develop a neuropathic destruction of the joints. It is often described as painless but actually the majority of patients have some pain. In the Western world diabetes is the biggest cause but in the rest of the world leprosy is also important. However, any other neurological condition can cause this disease.

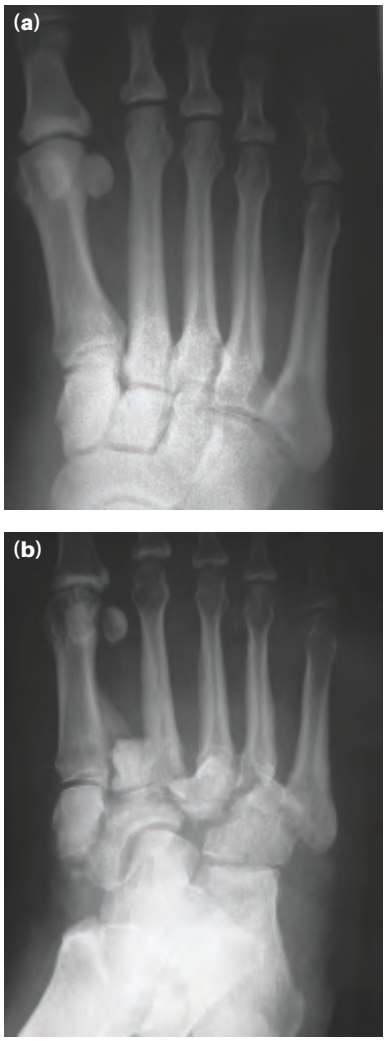

Figure 36.12 Charcot foot: radiographs taken at the time of a trivial injury (a) and 6 weeks later (b).

Figure 36.13 Diabetic foot ulcer.

Charcot often presents with a hot, swollen, red extremity. It is often misdiagnosed as cellulitis, gout, fracture or deep vein thrombosis (DVT), and many present late because of the difficulty in diagnosis.

If there is no history of skin damage, infection is unlikely, but MRI and even biopsy can help differentiate between infection and Charcot. From initiation through to bone consolidation may take up to 18 months. The principle of treatment throughout is to maintain a foot-shaped foot to prevent late pressure ulcers. The acute Charcot foot requires appropriate splintage in a Charcot retaining orthotic walker (CROW) or a total contact cast (TCC), but many surgeons offer an aggressive early surgical approach if bony prominence ulceration is thought to be inevitable. Surgical options include early stabilisation to prevent deformity, or late reconstruction or removal of bony prominences to prevent ulceration. Failure results in ulceration and amputation.

Summary box 36.9

Diabetes

- Diabetics are prone to infection because of:
  - Peripheral neuropathy
  - Peripheral vascular disease
  - Impaired resistance to infection
- A Charcot foot is often misdiagnosed but is a surgical emergency and requires urgent admission and management
- An ulcer in a diabetic foot is a surgical emergency and requires urgent admission and management

Entrapment neuropathies

Any nerve supplying the foot can become entrapped and result in pain, and treatment often requires surgical decompression. Tarsal tunnel syndrome is much rarer than carpal tunnel syndrome.

Heel pain

The commonest cause of heel pain is plantar fasciitis. Pain is located inferomedially within the heel and is worst first thing in the morning and after periods of rest. The majority of cases settle within 18 months and surgery is rarely required or successful. Ultrasound-guided injection forms the mainstay of treatment for the non-resolving cases. The differential diagnosis list includes calcaneal stress fracture, tarsal tunnel, seronegative arthropathy and lederhosens disease.

Chapter 37

Musculoskeletal tumours

Learning objectives

- List the symptoms and signs associated with a musculoskeletal tumour
- Understand why a patient with a suspected musculoskeletal tumour should be referred to a specialist centre for staging, biopsy and multidisciplinary management
- Understand why staging should be completed before biopsy
- Explain why a diagnosis is required before treatment
- Understand the principles of biopsy
- Describe the principles of surgical treatment of musculoskeletal tumours
- List the aims of surgical treatment for metastatic bone disease
- Understand how to manage patients with an impending or completed pathological fracture
- Evaluate the risk of pathological fracture

INTRODUCTION

Musculoskeletal tumours include primary and secondary benign and malignant tumours of bone and soft tissue. The most common malignant bone tumours are secondary metastatic carcinomas (Figure 37.1). Advances in oncological treatment mean that the number of patients living with metastatic bone disease is increasing. The most common carcinomas that metastasise to bone originate in the breast, prostate, lung, kidney and thyroid (Figure 37.2).

Haematopoietic tumours may also arise in bone: multiple myeloma (Figure 37.3) is a malignant neoplasm arising from plasma cells in the bone marrow, leading to multiple lesions in the skeleton. When solitary, this type of tumour is called a plasmacytoma.

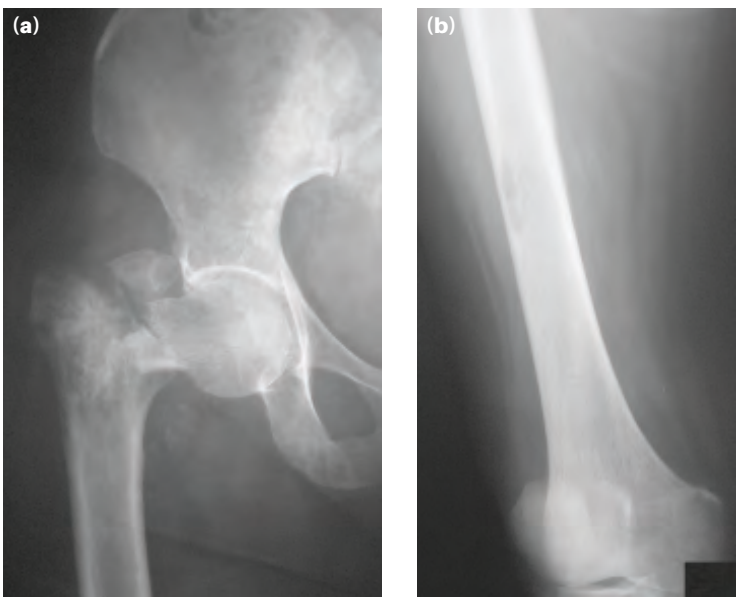

Figure 37.1 **(a)** Pathological fracture of the proximal femur through metastatic breast carcinoma. **(b)** Radiographs of the whole femur show a further, more distal metastatic deposit.

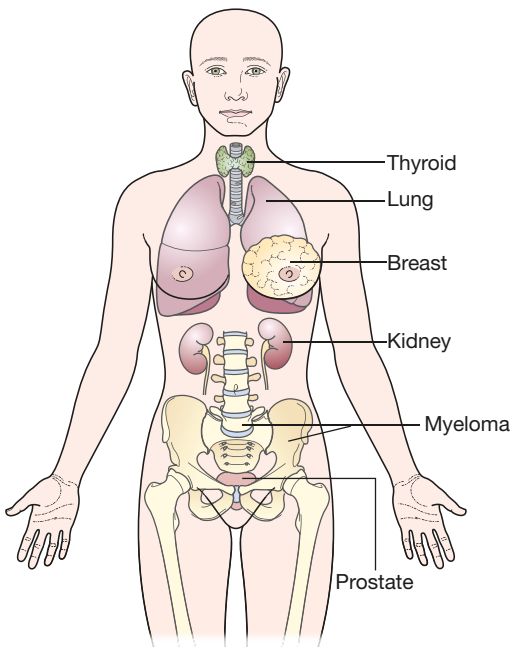

Figure 37.2 Malignant tumours that commonly metastasise to bone.

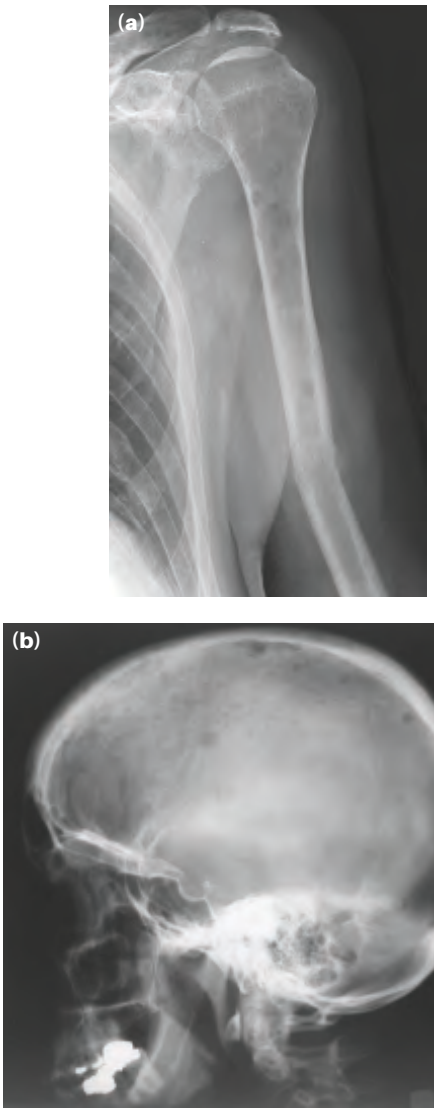

Figure 37.3 (a) Multiple myeloma affecting the left humerus with a pathological fracture. **(b)** Multiple myeloma with multiple deposits in the skull.

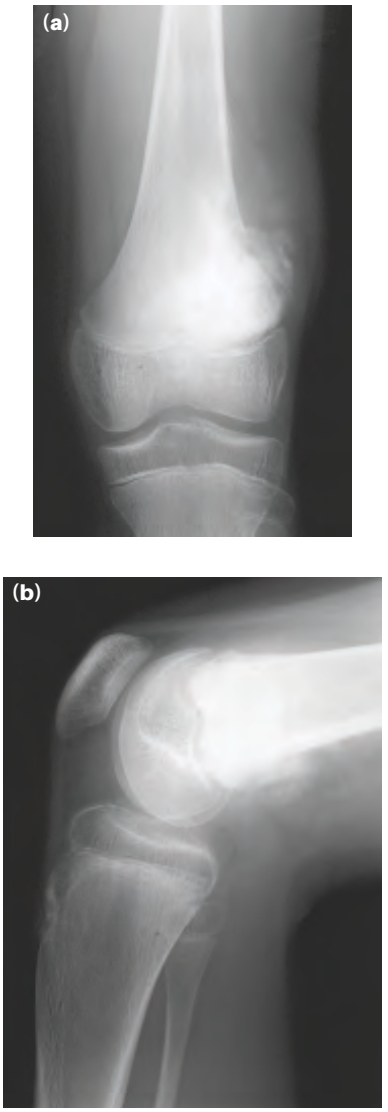

Figure 37.4 (a, b) Sclerotic osteosarcoma of the distal femur in a child.

Malignant primary bone tumours (sarcomas) are very rare, but notably can occur in children and young adults. The most common of these are osteosarcoma (**Figure 37.4**), chondrosarcoma (**Figures 37.5, 37.6** and **37.7**) and Ewing's sarcoma (**Figure 37.8**).

Soft tissue tumours are common. However, only one in a hundred is malignant (**Figure 37.9**).

BONE TUMOURS

Tumours found in bone are classified according to the tissue of origin. These include:

- metastatic carcinomas – may show histological features of their tissue of origin;
- haematopoietic tumours – e.g. myeloma;
- osteogenic tumours – e.g. osteosarcoma;
- chondrogenic tumours – e.g. chondrosarcoma;
- others – e.g. Ewing's sarcoma.

Osteosarcoma has two age incidence-peaks, one in adolescence and the other later in life. Osteosarcomas in older patients usually arise in association with Paget's disease or after radiotherapy treatment. Ewing's sarcoma occurs in adolescence, whilst the incidence of chondrosarcoma increases from middle age onwards.

Some conditions are associated with an increased likelihood of developing malignant tumours in bone and/or cartilage (*Table 37.1*).

James Ewing, 1866–1943, Professor of Pathology, Cornell University Medical College, New York, NY, USA, described this type of sarcoma in 1921.
Sir James Paget, 1814–1899, surgeon, St Bartholomew's Hospital, London, UK, described osteitis deformans in 1877.

Figure 37.8 Ewing's sarcoma of the proximal fibula. The tumour is metadiaphyseal in location with a periosteal reaction and subtle onion-skinning.

TABLE 37.1 Conditions associated with an increased risk of malignant disease in bone and cartilage.

High risk	Moderate risk	Low risk
Maffucci syndrome (enchondromatosis and angiomas of soft tissue)	Hereditary multiple exostoses	Chronic osteomyelitis
Ollier disease (enchondromatosis)	Polyostotic Paget's disease	Osteonecrosis
Familial retinoblastoma syndrome	Radiation osteitis	Fibrous dysplasia, osteogenesis imperfecta, osteoblastoma and chondroblastoma

Metastatic bone disease

Most tumours which metastasise to bone are carcinomas. Not infrequently the primary tumour is never found despite further investigation: these patients are described as having 'carcinoma of unknown primary'.

Carcinomas usually spread to bone by the haematogenous route: the spine is the third most common site for metastases, after the lung and liver. Although most patients with metastatic cancer will have bone metastases in the spine before they die, only 10% are symptomatic.

Tumour cells metastasise to the spine via Batson's venous plexus. These retroperitoneal veins have no valves and allow retrograde embolic spread to the spine and proximal long bones (Figure 37.10).

Bone metastases can be lytic, sclerotic or mixed. Lytic metastases are usually highly vascular or locally aggressive such that there is no healing response from the bone. Metastases from prostate cancer may appear sclerotic.

Metastases are rare in children, but bone metastases can occur from neuroblastoma, rhabdomyosarcoma and clear cell carcinoma of the kidney.

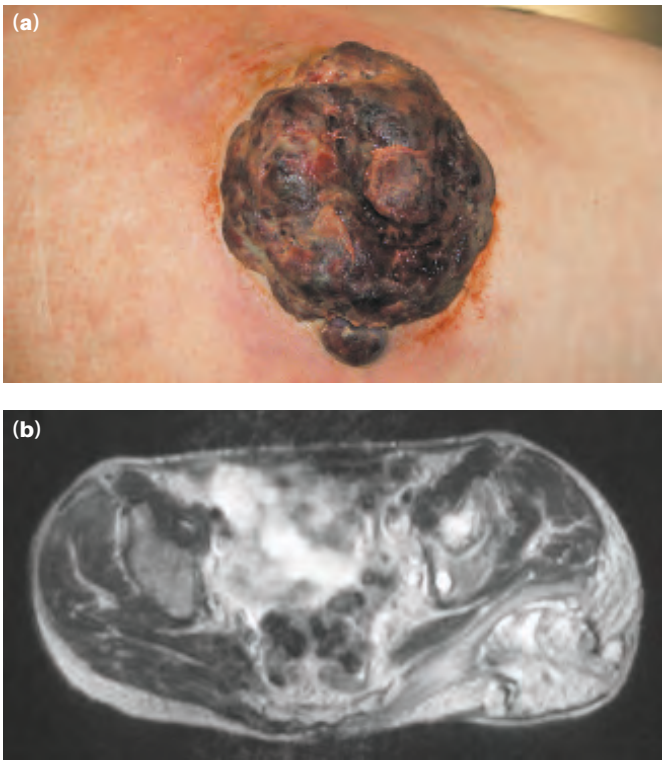

Figure 37.9 (a) Large, fungating soft-tissue sarcoma of the buttock. **(b)** Magnetic resonance imaging scan showing a large fungating sarcoma of the buttock.

Summary box 37.1

Most common tumours metastasising to bone (93%)

- Breast
- Prostate
- Lung
- Renal
- Thyroid

Figure 37.11 Radiograph showing an osteoid osteoma of the tibial diaphysis with reactive bone formation.

Summary box 37.2

Most common sites of bone metastases

- Spine
- Proximal femur
- Proximal humerus

Haematopoietic tumours

There are no benign neoplasms of the haematopoietic system. Malignant haematopoietic tumours, that commonly present in orthopaedic clinic, are either solitary plasmacytoma/multiple myeloma (arising from plasma cells, see **Figure 37.2**) or lymphomas (arising from lymphoid cells).

Summary box 37.3

Malignant bone tumours

- Plasmacytoma – solitary form of multiple myeloma
- Osteosarcoma – often secondary to Paget's disease and radiotherapy
- Chondrosarcoma
- Ewing's sarcoma

Osteogenic tumours

These tumours characteristically produce osteoid or bony matrix which may be seen on imaging studies or on histological examination.

Osteoid osteoma (**Figures 37.11** and **37.12**) is a benign bone-forming lesion which is small but very painful. Usually, pain occurs at night and is typically relieved by non-steroidal anti-inflammatory medication. Osteoid osteomas usually occur in children and adolescents. They arise in any bone, particularly

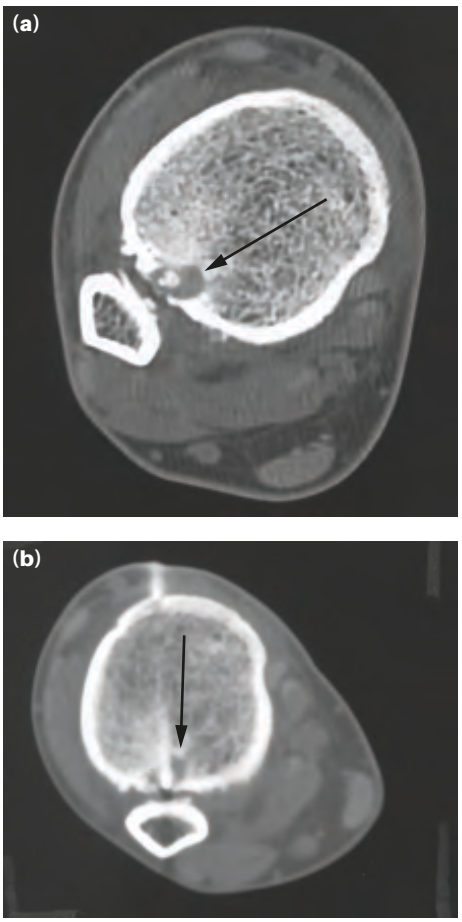

Figure 37.12 (a) Axial computed tomography (CT) scan showing an osteoid osteoma nidus in the distal tibia (arrow). **(b)** CT-guided radiofrequency thermocoagulation of an osteoid osteoma of the distal tibia. The scan shows the electrode *in situ* (arrow).

the proximal femur, and cause a dense cortical reaction in the centre of which is a nidus (Figure 37.12). Osteoid osteomas can cause irritation and effusions if they occur close to a joint.

Osteoblastoma is the larger (>2 cm), more aggressive counterpart of osteoid osteoma that more typically occurs in the spine.

Osteosarcoma (see Figure 37.4) is a malignant bone-forming tumour, most common in the distal femur, followed by the proximal tibia, proximal humerus and distal tibia. The radiological and histological classification of osteosarcomas includes sclerotic (Figure 37.4), chondroblastic, telangiectatic and other more unusual forms. Usually, osteosarcomas are intraosseous, but they can also arise from the surface of bones. Parosteal osteosarcoma (Figure 37.13) is a low-grade osteosarcoma that arises from the surface of the bone, typically of the distal femur or proximal tibia. Symptoms are often mild and longstanding.

Summary box 37.4

Tumours producing bone

- Osteoid osteoma – small, painful; produce dense cortical reaction
- Osteoblastoma – larger and more aggressive than osteoid osteoma
- Osteosarcoma – malignant; commonest in lower femur and upper tibia

Chondrogenic tumours

These tumours produce chondroid matrix and include a wide range of benign and malignant tumours.

Osteochondroma (Figures 37.14 and 37.15) is a benign cartilage-capped bony projection, thought to originate from the physis. The bony projection always grows away from the joint towards the diaphyseal region of the bone. It has no structures attached to it. Osteochondromas can be pedunculated (with a stalk) or sessile (without a stalk). The stalk or base is always continuous with the intramedullary cavity of the bone, and the continuity of the cortex of the bone into an osteochondroma is a characteristic radiological feature. They are usually solitary, but some patients have multiple osteochondromas (hereditary multiple exostoses, autosomal dominant inheritance) (Figure 37.16). Osteochondromas can cause local irritation and complications include mechanical

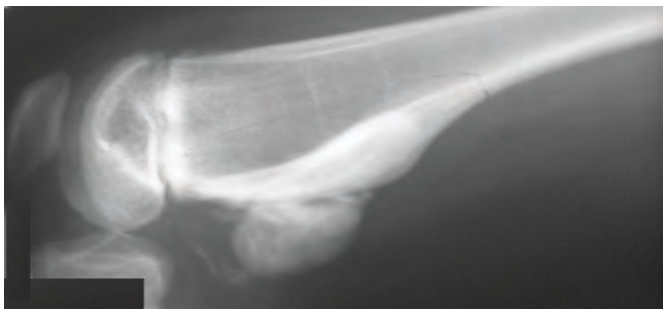

Figure 37.13 Paraosteal osteosarcoma of the distal femur in an unusually young patient. There is no continuity between the tumour and the intramedullary cavity of the femur.

Figure 37.14 Pedunculated osteochondromas of the proximal fibula with pseudoarthrosis. Osteochondromas always grow away from the physis and are in continuity with the intramedullary cavity of the bone they arise from.

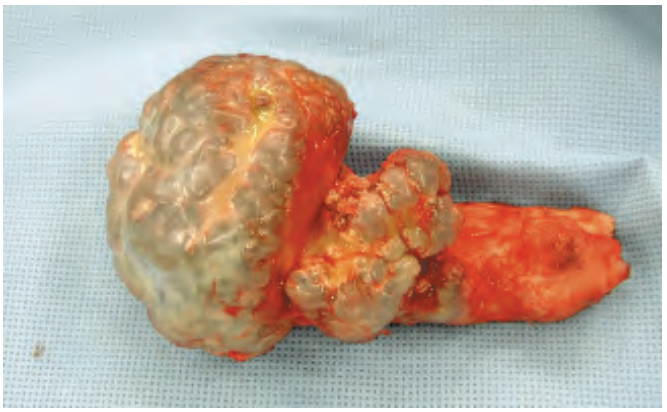

Figure 37.15 Excised pedunculated osteochondroma showing cartilage cap.

Figure 37.16 Multiple osteochondromas in hereditary multiple exostoses.

symptoms, nerve impingement, vascular pseudoaneurysm, fracture and infarction. Increasing size or pain, particularly after skeletal maturity, is concerning and may indicate malignant transformation. The incidence of malignant transformation is less than 1% in solitary osteochondromas and 1–3% in patients with multiple osteochondromas.

Enchondroma (Figure 37.17) is a benign cartilaginous neoplasm within the intramedullary cavity of bone. Approximately 50% are in the hands and feet: enchondromas are the most common bone tumours in the hand. Although they can present with pain, swelling or pathological fracture, many are entirely asymptomatic and are detected incidentally. Patchy calcification, expansion and scalloping can be visible on radiographs, but some are only diagnosed on magnetic resonance imaging (MRI) scan.

Ollier disease is a developmental condition characterised by multiple enchondromas. In Maffucci syndrome, multiple enchondromas are associated with multiple angiomas. Malignant transformation to chondrosarcoma can occur in approximately 20% of patients with Ollier disease and is almost inevitable in patients with Maffucci syndrome.

Chondroblastoma (Figure 37.18) is a benign cartilage-producing tumour that occurs in the epiphyses of bones

Figure 37.17 (a, b) Calcification and pathological fracture in a benign enchondroma of the proximal phalanx of the ring finger (arrows).

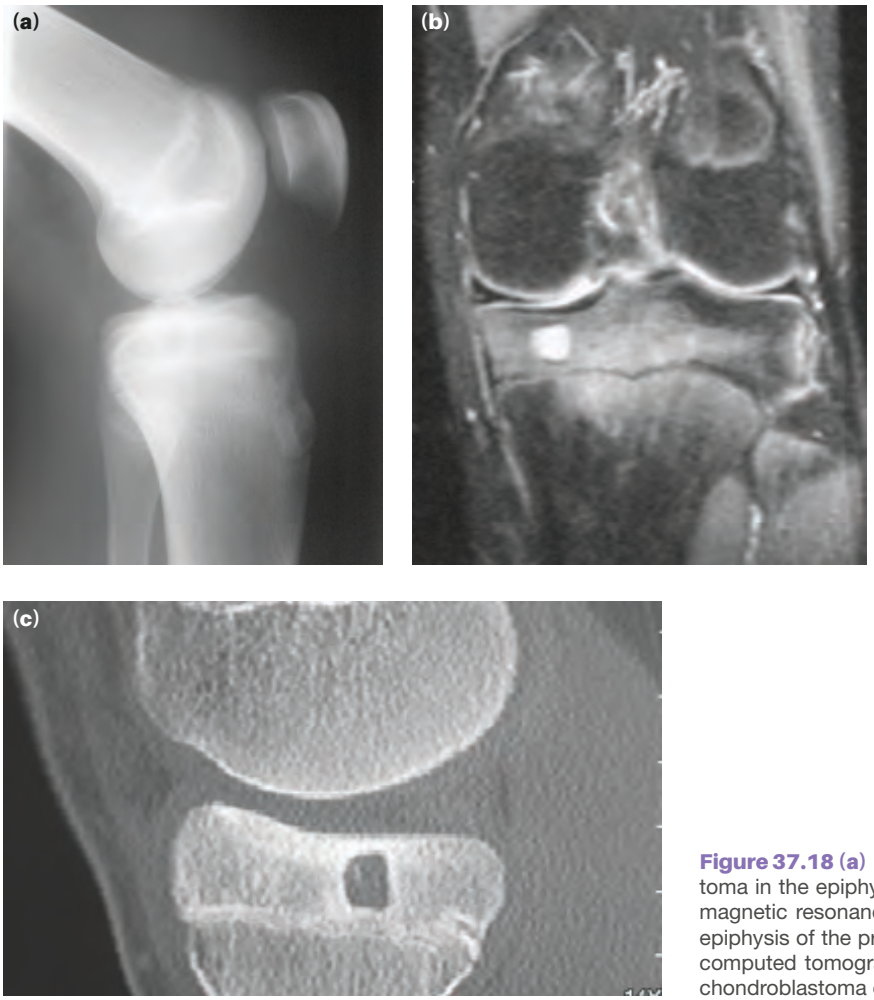

Figure 37.18 (a) Lateral radiograph with barely visible chondroblastoma in the epiphysis of the proximal tibia. **(b)** Coronal T2-weighted magnetic resonance imaging scan showing chondroblastoma in the epiphysis of the proximal tibia with surrounding oedema. **(c)** Sagittal computed tomography reconstruction showing calcification within a chondroblastoma of the proximal tibial epiphysis.

Angelo Maffucci, 1845–1903, Professor of Surgery, Lyons, France, described enchondromatosis in 1899.

in children. It is most common around the knee. Pain is often severe, with associated inflammation and possibly joint effusion. Radiologically, there is an often barely visible lytic lesion in the centre of the epiphysis. The diagnosis is often missed, and isotope bone scan can help identify the lesion.

Chondrosarcoma (see **Figures 37.5, 37.6 and 37.7**) is a malignant tumour with cartilage differentiation. The biological behaviour ranges from very low-grade lesions to highly aggressive dedifferentiated tumours. Patients usually present with pain and/or swelling and symptoms may be longstanding. Many chondrosarcomas arise in pre-existing lesions such as osteochondromas or enchondromas. Diagnosis of a chondrosarcoma requires clinical, radiological and pathological correlation. Clear cell chondrosarcoma is a rare form of chondrosarcoma that occurs in the epiphysis **(Figure 37.19)**.

Summary box 37.5

Tumours producing cartilage

- Osteochondroma – cartilage capped; grows away from physis
- Enchondroma – inside bone; commonest in hands and feet
- Chondroblastoma – in epiphyses of adolescents
- Chondrosarcoma – of varying malignancy

Others

Simple (unicameral) bone cyst **(Figure 37.20)** is a membrane-lined cavity filled with serous fluid within a bone. It usually occurs in the proximal long bones of children. Associated thinning of the cortex of the bone can lead to fracture. Such fractures usually heal with conservative treatment, but the cyst may only partially resolve.

Aneurysmal bone cyst **(Figure 37.21)** is a benign cystic lesion of bone consisting of blood-filled spaces separated by fibrous septa. The lesion is more aggressive than a simple bone cyst and often presents with pain and swelling. Plain radiographs commonly show aggressive features with eccentric expansion of the cortex and an open physis. Scans often show multiple fluid levels **(Figure 37.21b)**.

Giant cell tumour of bone **(Figure 37.22)** is a locally aggressive tumour with large osteoclast-like giant cells. It usually occurs between the ages of 20 and 45, after the physes have closed. Giant cell tumour of bone typically affects the epiphysis of long bones and erodes bone under the articular cartilage, especially around the knee, proximal humerus and distal radius. Metastases are rare.

Eosinophilic granuloma is a rare neoplasm of Langerhans cells **(Figure 37.23)**. It can be unifocal (eosinophilic granuloma), multifocal (Hand–Schuller–Christian disease) or disseminated (Letterer–Siwe disease). There is a predilection for the skull and the diaphyses of long bones. In the spine it can present with collapse, known as *vertebra plana*. Radiographs can appear aggressive and similar to Ewing's sarcoma.

Fibrous dysplasia **(Figure 37.24)** is a benign fibro-osseous lesion that can be mono- or polyostotic. It usually affects the long bones, ribs and skull. Patients can present with pain, swelling and/or fracture, but many lesions are

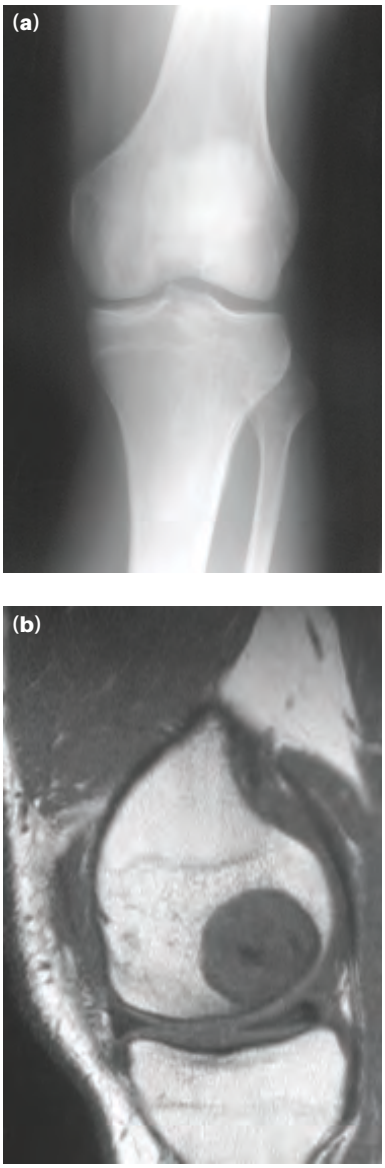

Figure 37.19 (a) Clear cell chondrosarcoma of the medial femoral condyle. **(b)** Sagittal T1-weighted magnetic resonance imaging scan showing clear cell chondrosarcoma in the medial femoral condyle. **(c)** Computed tomography scan reconstruction shows calcification within the lesion.

Figure 37.20 Pathological fracture through a simple bone cyst with the pathognomonic fallen leaf sign. The fracture healed and the cyst consolidated without operative intervention.

detected incidentally. Hip fractures can produce a 'shepherd's crook' deformity of the proximal femur. Radiologically there is often expansion and a ground glass appearance, sometimes with cystic change.

Ewing's sarcoma (see Figure 37.8) is a malignant round cell sarcoma of bone in which cells usually have a characteristic 11:22 translocation. It tends to arise in the diaphysis of a long bone or the pelvis. Patients usually present with a painful mass and may have systemic symptoms including fever, anaemia and increased erythrocyte sedimentation rate (ESR). Radiologically the bone appears moth-eaten and may show an 'onion-skin' periosteal reaction. MRI may show a large extraosseous soft tissue mass as well as significant inflammation with oedema.

Bone tumours usually occur in characteristic anatomical locations (*Table 37.2*), and epiphyseal tumours are likely to be benign (*Table 37.3*).

TABLE 37.2 Classification of bone tumours by site.

Tumour and site		
Diaphyseal	**Metaphyseal**	**Epiphyseal**
Eosinophilic granuloma	Most	Chondroblastoma
Osteoid osteoma		Intra-articular osteoid osteoma
Fibrous dysplasia		Giant cell tumour (physis closed)
Adamantinoma		Clear cell chondrosarcoma
Ewing's sarcoma		

TABLE 37.3 Common diaphyseal bone tumours according to age.

Age and most common diaphyseal tumour	
<10 years	Eosinophilic granuloma
Teenage	Ewing's sarcoma
Adult	Lymphoma
>60 years	Metastasis/myeloma

Summary box 37.6

Other bone tumours

- Simple bone cyst – proximal long bones of children
- Aneurysmal bone cyst – more aggressive, expanding
- Giant cell tumour – found in epiphyses around the knee
- Fibrous dysplasia – may be multiple; long bones, ribs and skull
- Ewing's – round cell sarcoma; patients may have fever and anaemia

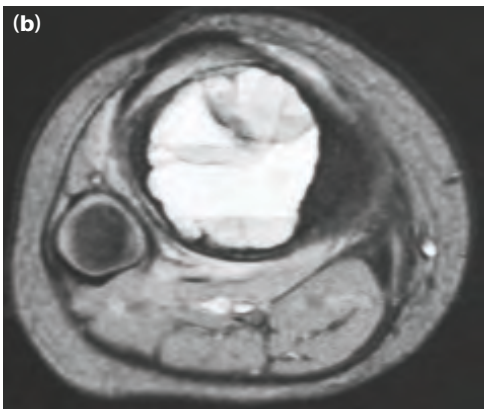

Figure 37.21 **(a)** Aneurysmal bone cyst with pathological fracture of the proximal tibia. **(b)** Magnetic resonance imaging scan shows multiple fluid levels.

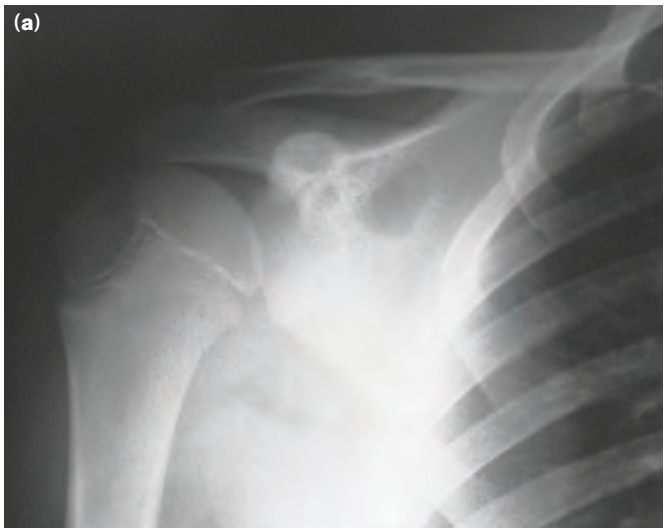
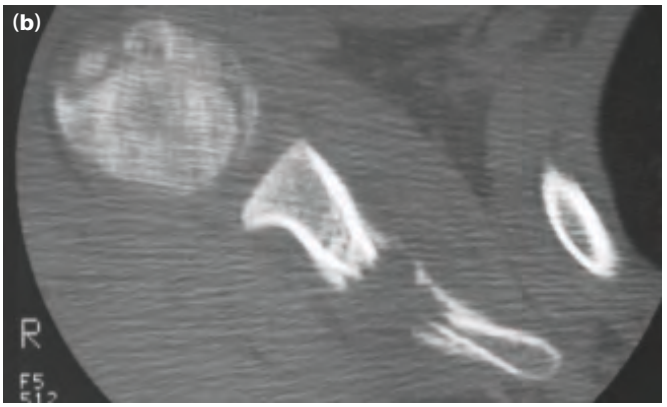
Figure 37.22 Giant cell tumour of the distal radius.





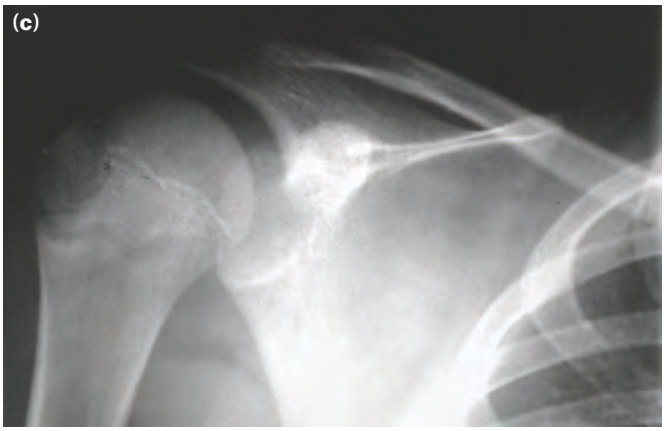


Figure 37.23 (a) Eosinophilic granuloma of the scapula. **(b)** Computed tomography scan shows a 'punched-out' lesion. **(c)** Spontaneous resolution.

Staging of primary bone tumours

In the Enneking system, benign tumours are staged as:

- latent (e.g. osteochondroma);
- active (e.g. osteoid osteoma);
- aggressive (e.g. giant cell tumour).

Latent lesions are usually asymptomatic and often discovered incidentally. Active lesions, such as osteoid osteoma, present with mild symptoms and continue to grow. Aggressive lesions tend to grow rapidly and destroy bone.

The Enneking staging system for malignant tumours combines the local extent of the tumour and the histological grade (*Table 37.4*). The compartment is the bone in which the tumour arises. A tumour is extracompartmental when it has breached the cortex of the bone. Most primary malignant bone tumours are Enneking stage 2B at diagnosis, meaning they have extended outside the bone of origin but metastases are not detectable. The American Joint Committee on Cancer (AJCC) staging system is also widely used.

Figure 37.24 Fibrous dysplasia affecting the left proximal femur. There is expansion of the bone with a ground glass appearance.

TABLE 37.4 The Enneking staging system for bone tumours.

Enneking staging of bone tumours		
Low grade	Intracompartmental	1A
	Extracompartmental	1B
High grade	Intracompartmental	2A
	Extracompartmental	2B
Any grade	Metastases	3

Summary box 37.7

Warning signs – bone tumour

- Non-mechanical bone pain
- Especially around the knee in young adolescents
- Concerning radiographs

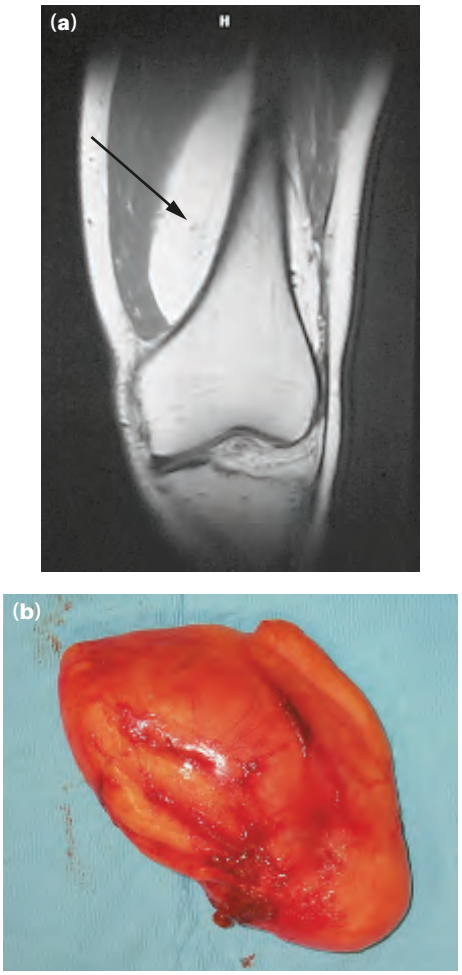

Figure 37.25 (a) Coronal T1-weighted magnetic resonance imaging scan showing a benign lipoma deep to the quadriceps muscle (arrow). **(b)** Excised benign lipoma.

SOFT TISSUE TUMOURS

Soft tissue tumours have also historically been classified according to their morphological appearance and presumed cell of origin. The range of biological behaviours is wide and most morphological types have a benign and malignant counterpart, for example lipoma (**Figure 37.25**) and liposarcoma. Other more frequent types include undifferentiated pleomorphic sarcoma and synovial sarcoma. Patients with suspected or confirmed soft tissue sarcomas should be assessed and managed in a specialist centre.

Summary box 37.8

Warning signs – soft tissue tumour

- Larger than 5 cm
- Increasing in size
- Painful
- Deep to the fascia
- Recurrence after previous excision

The Trojani system, based on tumour differentiation, mitotic count and tumour necrosis, is the standard for grading malignant soft tissue tumours. The Enneking and AJCC systems can also be used to stage malignant soft tissue tumours.

EVALUATION AND INVESTIGATION OF THE PATIENT WITH A SUSPECTED BONE OR SOFT TISSUE TUMOUR

The diagnosis and treatment of patients with primary bone and/or soft tissue tumours requires a high index of suspicion, appropriate and prompt investigation, and early referral to a specialist multidisciplinary team for diagnosis, biopsy and appropriate treatment. When a musculoskeletal tumour is suspected, clinicians should:

- stop;
- think;
- investigate.

The assessment and investigation of any patient with a bone or soft tissue tumour can be divided into three phases. The first two phases can be performed at the referring hospital, but the third phase may be best done in a specialist centre (*Table 37.5*).

TABLE 37.5 The three phases of assessment of lesions.

Phase 1 (within 24 hours)	Phase 2 (within first week)	Phase 3 (at specialist centre)
History and examination	Bone scan	CT-scan lesion
Bloods	Ultrasound scan abdomen	MRI-scan lesion
Radiograph whole bone	CT-scan chest	Biopsy
Chest radiograph		

CT, computed tomography; MRI, magnetic resonance imaging.

History and examination

It is important to take a thorough history, including a pain history. Non-mechanical and/or night pain, particularly in the young adolescent, are concerning symptoms and a primary bone tumour should be suspected. Relief with non-steroidal anti-inflammatory drugs may suggest an osteoid osteoma.

Patients with a history of malignancy who present with back pain should be considered to have metastatic disease until proven otherwise. Plain radiographs of the spine and routine blood tests are the minimum that is required. An MRI of the spine is a more sensitive test for the detection of a malignant tumour and may demonstrate soft tissue extension into the spinal canal. Multiple myeloma (see **Figure 37.3**) is the most common primary malignancy of bone in adults and should be considered in all patients over 65 years of age with back pain. Back pain associated with an ESR >100 mm/hour

indicates multiple myeloma until proven otherwise. Monoclonal gammopathy or elevated urinary and serum Bence Jones proteins are diagnostic.

Great care should be taken when managing a patient with an apparently 'solitary' bone metastasis. This could be a primary bone tumour, and further investigation including biopsy is required.

Soft tissue tumours are common and the vast majority are benign. However, a soft tissue mass meeting any of the following criteria may be malignant and the patient should be referred to a specialist centre:

- painful;
- increasing in size;
- more than 5 cm in diameter.

In addition, tumours which have recurred after previous excision and tumours located deep to the fascia are more likely to be malignant.

Investigation

The investigation of a patient with a suspected primary bone or soft tissue tumour should include the following.

- Local investigations:
  - ultrasound scan (for soft tissue tumours only);
  - plain radiographs of the whole affected bone or soft tissue lesion (see **Figure 37.1**);
  - MRI of the whole affected bone or soft tissue mass;
  - Computed tomography (CT) scan may be helpful in addition to or instead of MRI scan.
- Distant:
  - blood tests; including full blood count, ESR, urea and electrolytes, bone profile and protein electrophoresis;
  - plain radiographs or CT scan of the chest (more sensitive);
  - whole body isotope bone scan (for suspected primary or metastatic bone tumours);
  - ultrasound or CT scan of abdomen (if renal metastasis is a possibility).

Plain radiographs are usually the most useful imaging investigations in determining the diagnosis of a primary bone tumour, but further appropriate scans are usually required for confirmation and staging. Imaging should always include the whole of the affected bone to look for satellite lesions and skip metastases. Satellite lesions occur within, whilst skip lesions occur beyond, the reactive zone of the tumour.

Both primary bone and soft tissue sarcomas metastasise to the lungs, and a CT scan of the chest is an essential part of staging.

Patients who present with a lytic bone lesion could have a primary renal carcinoma and an ultrasound or CT scan of the abdomen is advised. Biopsy of a renal metastasis can lead to significant blood loss.

Summary box 37.9

Staging

- Plain radiography is most informative for bone tumours
- Always image the whole bone in case of skip lesions
- CT of the lung detects lung metastases
- Lytic lesions require ultrasound of the abdomen to check for a renal primary

Biopsy

A biopsy is performed only when staging investigations have been completed. Because removal of the biopsy track is an important principle in the treatment of sarcomas, biopsies should be performed either in, or after consultation with, the specialist centre where the definitive surgical procedure will be performed.

Image-guided biopsies (usually ultrasound- or CT-guided) have a higher diagnostic accuracy because areas of radiological concern can be targeted. If image-guided biopsy is performed, close discussion between radiologist and surgeon is required to ensure an appropriate biopsy route is used (**Figures 37.26** and **37.27**).

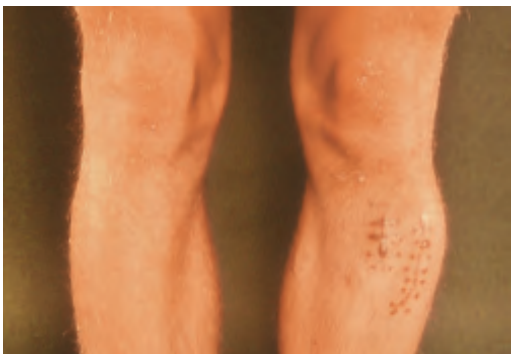

Figure 37.26 Poorly placed biopsies, making subsequent surgical excision of the track impossible.

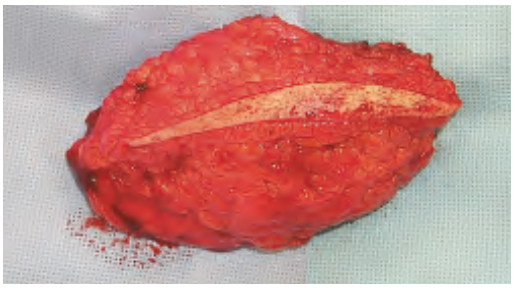

Figure 37.27 *En bloc* excised tumour and biopsy track.

Henry Bence Jones, 1813–1873, physician, St George's Hospital, London, UK.
en bloc is French for 'in a block'.

Figure 37.28 Bone biopsy instruments.

Summary box 37.10

Biopsy

- Only biopsy once staging is completed
- Biopsy should be performed at the institution undertaking the main surgery
- Imaging-guided biopsy is more reliable
- The biopsy track must be excised at definitive surgery
- Jamshidi needles for bone, Trucut needles for soft tissues

Biopsies for bone tumours are usually taken using a Jamshidi or other hollow needle (**Figure 37.28**), while Trucut needles are preferred for soft tissue tumours.

Although most biopsies are performed with a needle, sometimes an open biopsy is required, which should be performed according to the following principles.

- A tourniquet can be used; but exsanguination by compression should be avoided as this may theoretically disseminate the tumour locally or into the circulation.
- Use longitudinal incisions that are part of an extensile approach.
- Do not cross anatomical compartments or contaminate critical anatomical structures (e.g. nerves or blood vessels).
- Use a biopsy track that can be excised at the time of definitive surgery.
- Ensure specimens are sent for microbiology as well as histopathology.
- Some specimens should be sent fresh to the laboratory for cytogenetic studies.

PRINCIPLES OF TREATMENT

Primary bone tumours

Benign

Most latent and active benign bone tumours are treated by intralesional curettage. Packing of the cavity with a graft or bone substitutes is usually not required.

Simple bone cysts usually heal following pathological fracture and an initial conservative approach following fracture is best. If the cyst persists following union of the fracture, and the risk of further fracture is deemed to be high, then a variety of treatments including injection with steroid or bone marrow and surgical curettage have been described.

Osteoid osteomas can resolve spontaneously. However, symptoms are often pronounced and most patients are treated by CT-guided thermocoagulation. Surgical removal (which usually requires burring down onto the surface of the nidus and removing it) is seldom required.

Large or more rapidly growing benign bone tumours may require more extensive surgical excision and reconstruction. Giant cell tumours of bone are associated with a high local recurrence rate and are usually treated with radical curettage or, when very extensive, surgical resection of the affected bone. The RANK-ligand antibody denosumab has an evolving role in treating these tumours.

Malignant tumours

Malignant primary bone tumours require a multidisciplinary approach which may include chemotherapy and radiotherapy as well as surgery. Osteosarcoma and Ewing's sarcoma are treated with neoadjuvant (before surgery) chemotherapy and surgery. Chondrosarcomas are not sensitive to chemotherapy or radiotherapy and treatment is surgical excision where possible.

The aim of surgery for a primary malignant bone tumour is to remove it completely (usually with a layer of normal tissue around it and the biopsy track) and then to reconstruct the limb to maximise physical function.

Following excision the surgical margins can be classified as shown in *Table 37.6*.

TABLE 37.6 Classification of surgical resection margins.

Surgical margins	
Intralesional	Resection through the tumour
Marginal	Resection through the reactive zone of the tumour
Wide	Resection outside the reactive zone of the tumour
Radical	Resection of the whole anatomical compartment

In most cases, limb salvage with excision and reconstruction is possible (**Figure 37.29**). Only a minority of patients (10–15%) require primary amputation, either because of neurovascular invasion or because the reconstructed limb may be less functional than an amputation (e.g. for some tumours in the foot and ankle). Limb salvage is associated with a slightly higher rate of local recurrence than amputation. However, no difference in overall survival has been demonstrated. The surgical options for malignant primary bone tumours include:

- amputation or van Ness rotationplasty;
- excision alone (for dispensable bones or areas where reconstruction is difficult, e.g. in parts of the pelvis);
- excision and replacement with graft or massive endoprosthesis.

Figure 37.29 Endoprosthetic replacement of the distal femur.

The complications of massive endoprosthetic reconstruction of a limb include infection and wear or loosening of the prosthesis.

Summary box 37.11

Treatment of benign bone tumours

- Benign lesions can be simply curetted
- CT-guided thermocoagulation is used for osteoid osteoma
- Large benign tumours may require reconstruction

Summary box 37.12

Treatment of malignant bone tumours

- Osteosarcomas and Ewing's sarcoma require neoadjuvant chemotherapy
- Chondrosarcomas are insensitive to radiotherapy or chemotherapy
- Most malignant tumours can be treated with limb salvage
- There is no difference in survival between amputation and limb salvage

Metastatic bone disease

Patients with confirmed metastatic bone disease may require resuscitation for electrolyte imbalance, anaemia, cardiorespiratory problems or hypercalcaemia before surgical treatment can be considered. Hypercalcaemia can be treated effectively with fluid resuscitation and bisphosphonate infusion.

Surgical treatment in patients with metastatic bone disease is usually palliative; although radical resection of solitary metastases in selected patients may confer some survival benefit, the evidence for this is not strong.

Surgery of the spine may be required for stabilisation and/or decompression when tumour extension puts the spinal cord at risk. Surgery in the peripheral skeleton is mainly for treatment of (impending) pathological fracture.

Renal metastases tend to be very vascular and massive blood loss can be encountered during surgery. Therefore, preoperative embolisation should be considered just before surgery to prevent blood loss (Figure 37.30).

Treatment of myeloma is mainly haematological. Non-surgical treatments including radiotherapy can lead to healing of bone lesions in some cases. Surgical treatment is only required for complications such as fracture and spinal cord compression.

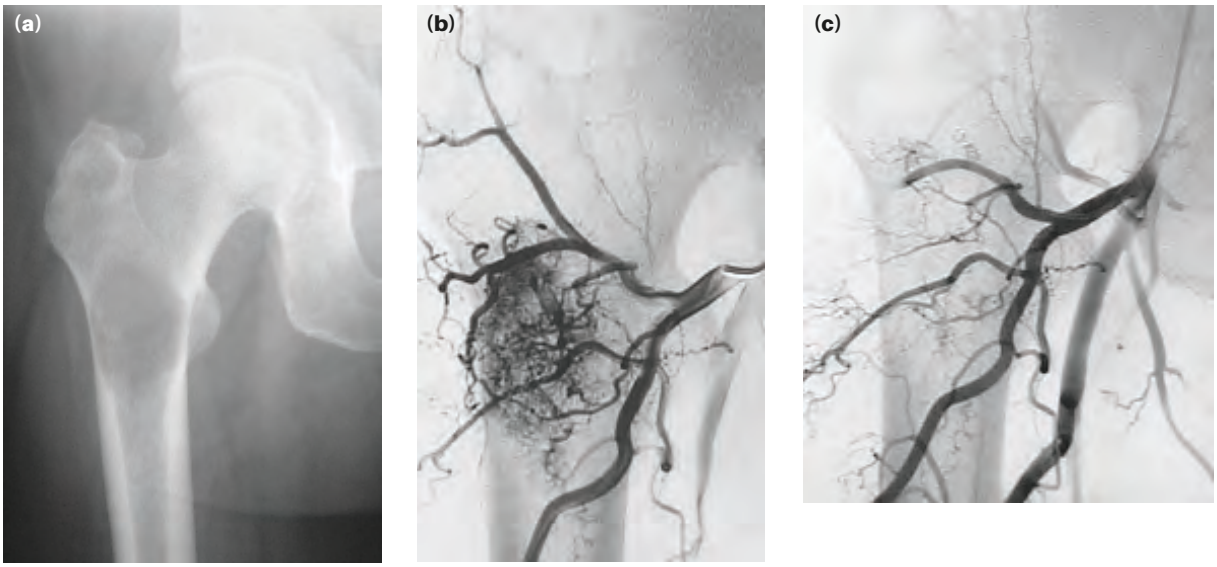

Figure 37.30 (a) Lytic metastasis of renal cell carcinoma. **(b)** Angiogram shows increased vascularity. **(c)** Following embolisation.

The following factors should be considered when contemplating surgical treatment for patients with metastatic bone disease:

- likely survival (**Figure 37.31**) – consider the primary diagnosis and performance status;
- quality of life;
- fitness for anaesthesia and surgery;
- fracture risk;
- single or multiple bone lesions;
- response to adjuvant treatment such as radiotherapy and hormonal treatment;
- radiotherapy can be administered pre- or postoperatively.

The risk of pathological fracture can be assessed using the Mirels score (*Table 37.7*).

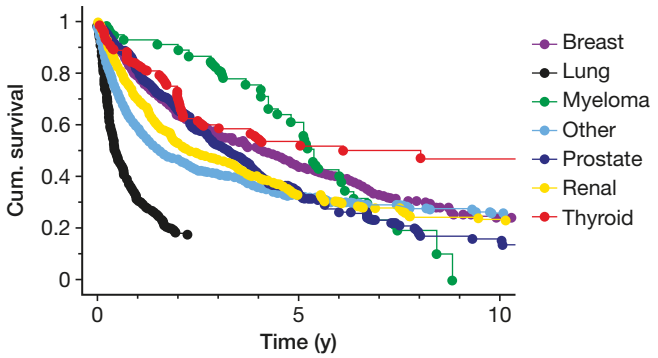

Figure 37.31 Cumulative survival curves of patients who present with bony metastasis.

TABLE 37.7 The Mirels scoring system for risk of pathological fracture.

	Score		
	1	2	3
Site	Upper limb	Lower limb	Peritrochanteric
Pain	Mild	Moderate	Functional
Size	<1/3	1/3–2/3	>2/3
Lesion	Blastic	Mixed	Lytic

Score ≥8, high risk of fracture – urgent prophylactic fixation should be considered; score <8, low risk of fracture – orthopaedic intervention may not be required.

Bone healing following a fracture through a metastasis is unpredictable and there can be local recurrence of the tumour after treatment. The approach is therefore different from the treatment of other fractures. The aim of surgery should be to improve pain and maintain mobility. Approaches which require prolonged protected weight bearing to allow healing are not appropriate in this group of patients with reduced life expectancy. Therefore, as a general rule, prosthetic replacement of bones is preferred, particularly for epiphyseal and metaphyseal lesions. Metastases in the diaphysis may be most appropriately treated with an intramedullary nail. In the shoulder, prosthetic replacements have a poor function and internal fixation may give better physical functioning. However, for hip lesions, the best treatment is often a joint replacement.

Patients with solitary breast and renal metastases can have prolonged disease-free survival so excision and replacement rather than fixation should be the treatment of choice.

Summary box 37.13

Treatment of bone metastases

- Surgery cannot lengthen life but may shorten it
- The spine may need stabilising and nerves or the cord decompressing
- Long bones will need stabilising if a pathological fracture is imminent
- Patients who have a possibility of long-term survival may need a prosthesis
- Radiotherapy relieves pain

Soft tissue tumours

The treatment of soft tissue tumours should take account of tumour type and the response to other treatments including radiotherapy. Large low-grade or benign lipomatous tumours may be excised in a deliberately marginal or close but complete fashion. Soft tissue sarcomas should however be excised with a margin of normal tissue around them wherever possible, and usually including the biopsy track (see **Figure 37.27**). Skin involvement may require resection of the skin and reconstruction with a split skin graft or skin flap.

Following surgical excision of high-grade soft tissue sarcomas, adjuvant radiotherapy should be considered. Preoperative radiotherapy can also have good results, but there is a risk of wound healing problems following surgery. Chemotherapy has a limited role in the treatment of soft tissue sarcomas.

Chapter 38

Infection of the bones and joints

Learning objectives

To understand:

- Characteristic features in the history and examination of infection of bone and joint
- Diagnostic principles in bone and joint infection
- Treatment of infection of native bone and joint
- Treatment of implant-associated orthopaedic infection

INTRODUCTION

Osteomyelitis is an old disease, identified in dinosaur bones, early hominids and skeletons from ancient civilisations. While infections of native bones and joints persist as a relevant problem in the twenty-first century, implant-associated infection has progressively emerged as a new and major challenge to healthcare systems.

Orthopaedic infection can present acutely with major systemic upset, local inflammation and purulence, or insidiously, with gradual bone destruction leading to loss of function and slowly evolving local symptoms, in the presence or absence of systemic features.

Bone and joint infection causes a substantial burden of complex morbidity. Acute infections can be life or limb threatening, while undiagnosed or incompletely treated infection can persist for decades, causing pain and interfering with activities of daily living. In turn, this has the potential for complicated psychosocial impact on patients and their families.

Figure 38.1 An infected open fracture of the tibia that has been stabilised with an external fixator. The central fracture fragment is dead.

EPIDEMIOLOGY

The pattern of bone infection is changing. Worldwide, childhood acute haematogenous osteomyelitis and septic arthritis are common, with chronic disease following inadequate initial management. In resource-rich countries, bone infection is now mostly seen after injury or surgery (contiguous focus osteomyelitis) and is often implant-related (**Figure 38.1**). The high number of patients with comorbidities (diabetes, peripheral vascular disease, immunocompromise), more frequent bone and joint surgery and longer population survival contribute to a group of patients with increased susceptibility to infection. In the UK, the number of prosthetic joint replacements (hip, knee) has doubled in 15 years. It is projected that, in the USA, there will be around 65 000 new infected joints in 2020. Although the incidence of infection after fracture has decreased, the increased use of internal fixation has increased the prevalence of post-traumatic bone infection overall. This will produce a significant economic burden for healthcare providers in the future.

Summary box 38.1

Epidemiology of bone infection

- Bone and joint infections from haematogenous spread remain common worldwide
- The increased use of implants for joint replacement and fracture fixation is an important source of new infections
- Immunocompromised patients are another increasing source (e.g. diabetes, cancer treatment)

GENERAL PRINCIPLES OF ORTHOPAEDIC INFECTION

Pathology

Acute osteomyelitis occurs when pathogenic organisms cause infection, leading to inflammation in the bone and surrounding tissues. The medullary bone may form abscesses and the infection may track through the cortex to form periosteal elevation and soft-tissue extension. This process will devascularise the bone, causing bone death – the characteristic feature of chronic osteomyelitis.

Bacteria can adhere to dead bone or implant surfaces, forming a complex community enveloped in a polysaccharide matrix, known as a biofilm. These bacteria alter their metabolic state, making them more resistant both to the host immune system and to antibiotics. Toxins and lytic enzymes from bacteria cause early damage to articular cartilage.

The infected bone reacts to the infection by separating dead fragments of bone (sequestration) and forming sinuses to drain pus and discharge small bone fragments. New bone is laid down around the infection from the periosteum (involucrum) (**Figure 38.2**).

In septic arthritis, infection may follow direct ingress of bacteria after injury or surgery, or may result from discharge of an adjacent acute osteomyelitis into the joint. Particularly in neonates or the elderly, bacteraemia may infect a previously normal joint.

Microbiology

Virulent gram-positive organisms, particularly *Staphylococcus aureus*, are the most common cause of bone or joint infection in native tissue. However, once prosthetic material is implanted, a wide range of organisms can be involved. This includes organisms with low virulence that are usually considered skin commensals, such as coagulase-negative staphylococci, alpha-haemolytic streptococci and propionibacteria (*Table 38.1*).

TABLE 38.1 Organisms most commonly involved in bone and joint infection.

Classification of infection	Group(s) of organisms	Examples of specific organisms and context in which infection occurs
Gram positive	Staphylococci	*Staphylococcus aureus* (commonest across all settings) Coagulase-negative staphylococci (common in implant-associated infection)
	Streptococci	Alpha-haemolytic streptococci, including *S. pneumoniae*, *S. milleri* group and *S. viridans* (in implant-associated infection)
		Beta-haemolytic streptococci (e.g. *S. pyogenes*, *S. agalactiae*)
	Propionibacteria	Increasingly recognised in implant-associated infection and septic arthritis of the shoulder
Gram negative	Enterobacteriaceae	*Escherichia coli* (especially at extremes of age)
		Klebsiella species
		Salmonella species (particularly associated with sickle cell disease)
	Pseudomonas species	Associated with diabetic foot infections, osteomyelitis underlying chronic wounds/ulcers, patients heavily exposed to hospital environment and/or prior antibiotics
	Haemophilus species	*H. influenzae* (consider in non-immunised children)
	Neisseria species	*N. meningitidis*
		N. gonorrhoeae (consider risk factors for sexually transmitted infection)
Others	Anaerobes	
	Fungi	(Cause infection in immunocompromised and/or heavily antibiotic-exposed hosts)
	Mycobacteria	*Mycobacterium tuberculosis*
		Atypical mycobacteria (may be a component of disseminated infection in HIV-infected patients; also cause postsurgical infection in immunocompetent hosts)
Mixed	Any combination of the above organisms	More common after trauma, recurrent surgery, with poor wound healing and sinuses, or resulting from contiguous spread from an infected source (e.g. skin, gastrointestinal tract)
'Culture negative'	No growth from cultures, but diagnosis of infection made on clinical/radiological/histopathological grounds	Most common in patients who have had recent antimicrobial exposure prior to surgical sampling

HIV, human immunodeficiency virus.

Summary box 38.2

Pathology of bone infection

- Bacteria infecting bone form a resistant biofilm on dead bone and implant surfaces
- Infected bone dies and forms a sequestrum
- The periosteum around lays down new bone – an involucrum

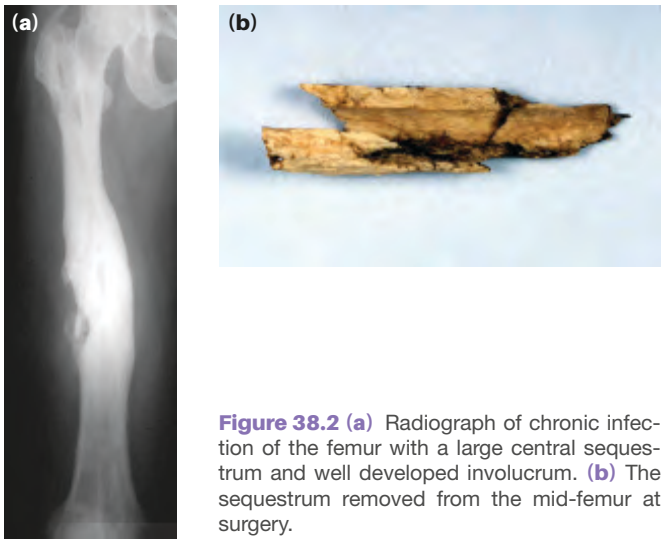

Figure 38.2 (a) Radiograph of chronic infection of the femur with a large central sequestrum and well developed involucrum. **(b)** The sequestrum removed from the mid-femur at surgery.

Diagnosis

Clinical

Diagnosis is predominantly clinical with confirmation using other tests, as outlined below.

Biomarkers

Raised inflammatory markers (erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) and white cell count (WCC)) are characteristic of acute infection, but they are insufficiently sensitive or specific to rule infection in or out.

Imaging

Plain radiographs can demonstrate dead bone, periosteal reaction, involucrum formation and loosening of implants. However, in the early stages of acute infection, plain radiographs may be normal and should not be used to exclude infection. Serial radiography is most useful in charting the onset of implant loosening, bone lysis or progression of chronic osteomyelitis.

Ultrasonography is ideal for identifying soft-tissue collections and joint effusions and can be used to guide bone biopsy and aspiration.

Computed tomography (CT) scans are helpful in assessing bone union of infected fractures. Small sequestra and cortical erosions are best seen with CT and these scans can be used to plan surgery for excision of dead bone (**Figure 38.3a**).

Isotope bone scans are of very limited value as they are non-specific and give no information which may guide diagnosis or treatment. The combination of ^{18}F-fluorodeoxyglucose positron-emission tomography (^{18}FDG-PET) with a CT scan allows localisation of active infection in chronic osteomyelitis and may facilitate planning of surgery. However, ^{18}FDG-PET/CT is not specific for infection and so cannot reliably distinguish infective from aseptic loosening in implants.

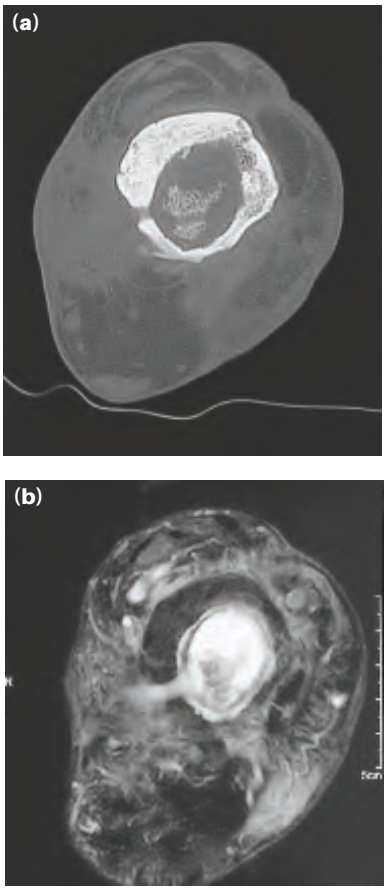

Figure 38.3 (a) Transverse computed tomography scan of femur with central sequestrum, sinus and cortical bone erosion. **(b)** Magnetic resonance imaging scan of the same femur with better resolution of medullary infection and soft-tissue involvement.

Magnetic resonance imaging (MRI) scanning is the investigation of choice. It is highly sensitive and specific, showing all components of the disease (**Figure 38.3b**). However, it can be adversely affected by metal implants and can overestimate the extent of infection when there is widespread reactive oedema.

Culture and susceptibility

Superficial samples from wounds or spontaneously draining pus are unreliable for culture, because the organisms colonising the surface may bear no relation to those causing the invasive infection in the deeper tissues. Microbiological samples may be falsely negative if antibiotics are given first. Synovial tissue samples are particularly important in producing a higher diagnostic yield for infection with mycobacteria or fungi.

In complex infections, particularly those involving prosthetic material, multiple biopsy samples are needed to help determine whether organisms such as coagulase-negative staphylococci are likely to be the causative pathogens, or whether they are simply contaminants from the skin. This distinction cannot be made on a single sample, but the growth of an indistinguishable organism from three or more culture samples is 94% specific for infection.

It is also possible to culture organisms from removed implants which have been subjected to ultrasonic vibration to disrupt biofilm (sonication).

Histopathology

The histological diagnosis of infection (rather than other sources of inflammation) depends on identifying organisms on a Gram stain, or the presence of a neutrophilic infiltrate. However, such an infiltrate may be patchy and so histological studies are incompletely sensitive. Histology is valuable in confirming the presence of infection in culture-negative cases.

Summary box 38.3

Principles of diagnosis

- ESR and CRP are neither sensitive nor specific in making a diagnosis of bone infection
- Plain radiographs may be normal in the early phase
- Ultrasound is valuable for identifying fluid/pus collections
- MRI is usually the investigation of choice
- Superficial swabs are of no value in identifying the organism causing deep infection
- If the patient is on antibiotics, cultures may be falsely negative
- Multiple biopsy specimens should be obtained to optimise microbiological diagnosis
- A neutrophil infiltrate on histology is strongly indicative of infection

Management

Successful treatment relies on the careful multidisciplinary delivery of a package of care, summarised as follows:

- Preoperative:
  - Patient assessment and clinical staging of disease.
  - Full discussion of all treatment options with potential complications.
  - Diagnostic tests for general health.
  - Optimisation of patients and treatment of comorbidities.
- Operative:
  - Exposure for multiple, deep bone sampling.
  - Excision of all non-viable tissue.
  - Intravenous antibiotics after sampling.
  - Bone stabilisation, if necessary.
  - Dead space management.
  - Soft-tissue cover which may include plastic surgery.
- Postoperative:
  - Functional rehabilitation.
  - Continued antimicrobial therapy guided by culture results, with regular clinical monitoring.

Patients with bone and joint infections should be treated in centres which have the facilities to manage all aspects of this care. With the exception of those who are acutely ill with sepsis, there is usually time to optimise comorbidities and improve general health prior to surgical treatment of the infection. Attention to diabetes control, peripheral vascular disease, nutrition and smoking cessation is essential. Many patients will benefit from psychological support or at least good counselling around the difficulties of eradicating infection and the components of treatment.

For patients requiring long courses of intravenous antibiotics, outpatient parenteral antibiotic therapy (OPAT) services can facilitate discharge from hospital. They must be delivered by a dedicated team with experience in supervising and supporting all aspects of intravenous therapy in the community, including surveillance and care of a long-line, monitoring for side effects and toxicity, management of complications and accessing appropriate psychosocial support.

Antibiotic therapy

Patients with septic shock, or with rapidly advancing local or systemic signs of infection, should receive prompt empirical antibiotic therapy. When delay in antibiotics would be unsafe, blood cultures, local aspiration of pus or radiologically guided biopsy may give valuable culture material immediately prior to starting antibiotics.

In the majority of cases, it is safe to delay antibiotics until definitive operative microbiological samples have been taken; this is particularly important when prosthetic material is involved. For patients who have already been started on antibiotics, a clinical assessment should be made, and – if safe to do so – antibiotics should be stopped at least 2 weeks before biopsy or surgery.

Local guidelines should be followed, but most hospitals recommend a 'community acquired' level of cover using an agent such as co-amoxiclav. Additional antibiotics to cover resistant gram-positive organisms (e.g. vancomycin for methicillin-resistant *Staphylococcus aureus* (MRSA)) are considered if there has been significant prior hospital exposure or if the patient is known to be colonised with these organisms. Cover for resistant gram-negative organisms (e.g. meropenem for *Pseudomonas*) is considered in certain settings, including severe diabetic foot infection.

Prolonged intravenous antibiotic courses (i.e. 4–6 weeks of treatment) are usually recommended for bone infection, although there is little evidence to support this.

Summary box 38.4

Antibiotics for osteomyelitis

- Septic shock needs treatment without delay, with antibiotics chosen empirically based on local guidelines
- In clinically stable patients, antibiotics should be delayed until specimens have been taken
- In elective surgery for osteomyelitis, antibiotics should be stopped at least 2 weeks in advance
- Agents such as co-amoxiclav or ceftriaxone are appropriate for most community acquired infections
- Vancomycin provides cover for MRSA
- Meropenem may be needed for *Pseudomonas* species and other resistant gram-negative organisms

NATIVE JOINT SEPTIC ARTHRITIS

Epidemiology

Bacterial infection of native joints occurs at an estimated incidence of 4–10 per 100 000 population per year in Western Europe, with higher rates in association with socioeconomic deprivation and in resource-poor countries. The condition most characteristically affects patients at extremes of age, and in the context of an underlying joint abnormality or immunocompromise (*Table 38.2*).

Joint infection may arise as a result of haematogenous dissemination of bacteria from another focus (e.g. endocarditis), or may occur as a result of direct inoculation or local extension from an infected source (e.g. traumatic wound).

TABLE 38.2 Risk factors for native joint septic arthritis.

- Extremes of age
- Underlying joint abnormality, especially rheumatoid arthritis
- Immunocompromise (e.g. diabetes mellitus, human immunodeficiency virus infection, immunosuppressive therapy)
- Joint instrumentation (e.g. steroid injection, arthroscopy)
- Intravenous drug abuse
- Indwelling central venous catheter
- Bacteraemia (especially *Staphylococcus aureus*)

Clinical features

Most patients present with an acute or subacute history of a single hot, swollen, painful joint. In children, there is often a history of recent minor trauma. The joint is held immobile in the 'position of comfort', and there is severe pain if any attempt is made to move the affected joint actively or passively. In children and adults, the knee joint is most frequently affected; in neonates, the hip. Fever and other systemic signs are usually present, but their absence does not rule out the diagnosis, especially in adults, where there may be no fever or only a low-grade one.

Diagnosis

Aspiration and/or biopsy of intra-articular fluid or tissue will allow a Gram stain to be performed (although this is positive in only about one-third of infected cases), and then culture of a causative organism (positive in 80–90%). However, results are delayed by the time taken to grow and identify the organism in the laboratory. A high WCC in joint fluid (e.g. 50–150 000 cells/mm^3), with a neutrophil predominance, is characteristic of infection. However, other inflammatory conditions can also cause a raised cell count, and crystals may be seen in infected joints as well as gout or pseudo-gout. The limited sensitivity and specificity of direct microscopy and Gram stain, and the time taken to obtain a positive culture result, should not delay early treatment for the infection. The decision to perform a surgical washout and give antibiotics should therefore be based on the clinical picture.

Summary box 38.5

Presentation of septic arthritis

- Children may be toxic and febrile but adults may only have a low-grade fever
- The joint is swollen and held in a characteristic 'position of comfort'
- Any movement causes extreme pain

Management

Surgical management

Medical treatment alone is rarely indicated in joint sepsis. Prompt surgical drainage is a priority in order to avoid further damage to the joint. In general, open washout is preferred to arthroscopic washout, depending on the joint involved. Inadequate clearance may lead to chronic infection with destruction of the joint (**Figure 38.4**). Treatment

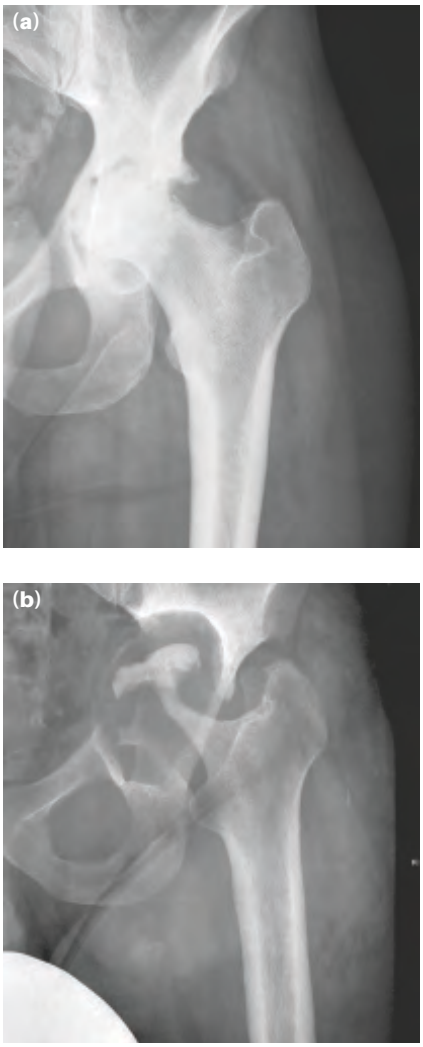

Figure 38.4 (a) Septic arthritis of the hip in an intravenous drug user. This was untreated for several weeks, resulting in destruction of the joint surface. **(b)** The same hip after 9 months without treatment. The proximal femur and acetabulum have been grossly eroded by infection.

may then require joint excision, joint fusion or staged joint replacement.

Medical management

Antibiotics are usually given for 4–6 weeks (of which at least the first 2 weeks are commonly given intravenously). There are sparse data to guide duration; in general, longer courses should be considered if the infection is slow to resolve, if more than one washout is required, if the patient is bacteraemic and/or if the infection is caused by *Staphylococcus aureus*. Choice of antibiotics can be summarised as above (see *Summary box 38.4*).

Summary box 38.6

Native joint septic arthritis

- Most common at extremes of age, in patients with rheumatoid arthritis and in association with immunocompromise
- Most commonly affects hips in neonates, and knees in adults and children
- The commonest pathogen is *Staphylococcus aureus*
- Joints should be aspirated for microbiology before starting antibiotics if safe to do so
- Management is prompt surgical joint washout, followed by 4–6 weeks of antibiotics
- Joint fluid Gram stain and WCC are poorly predictive of infection

IMPLANT-RELATED INFECTION

Epidemiology

The incidence of prosthetic joint infection in the UK is now <1% per joint per year, with hips at slightly higher risk than knees. These rates have fallen with improved operative practice and the recent introduction of surgical 'care bundles'. Risk factors include obesity, skin disease, comorbidity, prolonged or complicated surgery, revision surgery, fracture and postoperative wound infection or haematoma.

Infection complicates around 3–5% of all fracture fixations. Open tibial fractures are a high-risk group with up to 15% becoming infected after fixation. Calcaneal fractures and ankle fracture fixation in the elderly also have high infection rates.

Clinical features

Implant-related infections may present early (within 2 weeks of injury or surgery), in a delayed manner (3–10 weeks from surgery) or late (after 10 weeks).

Early infections are acquired at surgery or injury and are usually caused by virulent organisms (e.g. *Staphylococcus aureus*). They present with a discharging wound, cellulitis, pain, inflammation and swelling.

Delayed infections are more characteristically due to low-virulence organisms (e.g. coagulase-negative staphylococci or propionibacteria).

Late infections are more likely to present with an indolent clinical syndrome of joint discomfort or mechanical dysfunction ('start-up' symptoms are particularly characteristic), with or without a discharging sinus. Late presentations may represent a new haematogenous infection of a previously uninfected joint and can occur years after implantation. More often, they are due to a recurrence of a previously inadequately treated early or delayed infection.

Diagnosis

Infection should be suspected in any patient with a leaking wound over an implant, unresolved pain or new pain around a previously pain-free implant. Routine blood tests may be helpful in acute infection but are often falsely reassuring.

Plain radiographs may show features of loosening of a chronically infected prosthesis, and ultrasound may identify associated collections. Nuclear scans cannot distinguish aseptic loosening from infection. The gold standard for diagnosis is the culture of microorganisms from clean, deep samples (see above, under 'Diagnosis'). These should be taken at the time of revision surgery or open debridement.

Summary box 38.7

Implant-associated infection

- Good centres should have an infection rate of <1% per joint per year
- Internal fixation of open fractures remains a high infection risk
- Late infection may present with low-grade symptoms (grumbling pain and start-up stiffness)
- Radiographs may show lucency around the implant
- Multiple specimens need to be taken at surgery for reliable diagnosis

Management

A multidisciplinary approach is required, including orthopaedics, plastic surgery, infectious diseases/microbiology, pharmacy, nursing, occupational therapy and physiotherapy, centred on the patient's understanding and wishes regarding their condition. Many of these patients have other medical comorbidities which should also be addressed and optimised. Implant-associated infections can be associated with a range of emotional, psychological and mental health issues, ranging from anger about surgical complications to depression arising from chronic symptoms, lack of function and prolonged hospitalisation.

The choice of surgical strategy for prosthetic joints can be categorised as:

- salvage of an infected implant;
- removal of the infected implant with or without reimplantation.

Some groups have used the timing of presentation to determine this (i.e. salvage for early infection, versus removal and revision for late infection). Others regard any firmly fixed implant as potentially salvageable, irrespective of the timing (and there are now several case series suggesting that this is

feasible). However, it is agreed that loose infected implants should always be removed (**Figure 38.5**). Furthermore, it is essential to achieve soft-tissue cover of bone and prosthetic material. This may be difficult around the knee, requiring local muscle flaps and the involvement of a plastic surgical team.

Management options can be divided into the following broad approaches:

- Debridement, antibiotics and implant retention, 'DAIR': This can only be undertaken if the prosthesis is well-fixed. The surrounding infected soft tissue and bone must be fully excised and modular components exchanged. This cannot be achieved by arthroscopic surgery. Good soft-tissue cover is essential. Following debridement, the patient is treated with long-term antibiotics (frequently 6 weeks of intravenous therapy followed by 6 months or more of oral antibiotics). Prolonged infection-free intervals will be achieved in 80% of patients but success with this strategy may be lower in infections caused by *Staphylococcus aureus*.
- Two-stage joint revision surgery: A thorough excision is undertaken and all cement and loose foreign material is removed. An antibiotic-impregnated spacer may be implanted (which may be articulating). This is a temporary measure and cannot withstand full weight bearing. The patient is treated with oral or intravenous antibiotics, most commonly for 6 weeks. A new prosthesis is implanted after the course of antibiotics has been completed. Re-revision surgery for infection has a higher failure rate than a first revision, and so early referral to a specialist centre should be considered.
- Single-stage joint revision surgery: the procedure is the same as above, but removal and reimplantation are undertaken in the same operating session. Healthy soft tissues around the new implant are essential to prevent reinfection. Some centres consider single-stage revisions when less florid signs of infection are present (i.e. absence of collections or sinus tracts), or for frail patients for whom the risk of a second operation is higher. There are no adequate trial data comparing outcomes with the two-stage approach.
- Joint removal or fusion: For patients who have intolerable symptoms (either pain or profuse discharge), but for whom the surgical strategies outlined above are technically not possible or are ruled out by comorbid conditions, removal of the prosthesis without reimplantation may palliate symptoms. An example is the Girdlestone hip arthroplasty. In prosthetic infections of the knee, ankle or wrist, it may be possible to create a joint fusion after prosthesis removal. This is complex surgery, which may involve major bone reconstruction. Amputation may be necessary for knee or ankle implants.
- Suppressive therapy with antibiotics: In patients who are not medically fit for any operative intervention, or who choose to decline all surgical options, long-term treatment with antibiotics may help to suppress the symptoms of infection. There are limited data, but anecdotally the success rate of this approach seems low.

Antimicrobial therapy for implant-associated infection

Following surgical sampling, it is frequently routine practice to institute broad-spectrum antibiotic therapy (e.g. vancomycin and meropenem) and then to rationalise this in the subsequent

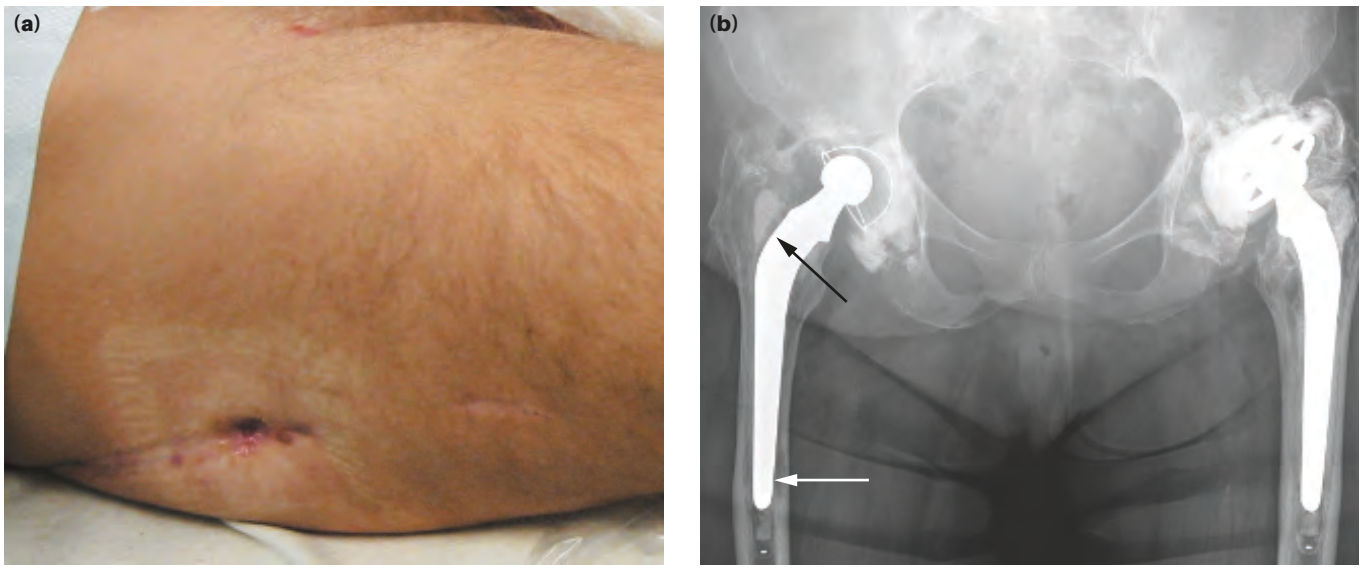

Figure 38.5 (a) Sinus draining from a scar over the lateral side of the hip. This patient had a total hip replacement 14 years before that had been complicated by a wound haematoma and infection. **(b)** Radiograph of both hips of the same patient. Both hips are loose but only the right side has definite infection (arrows).

Gathorne Robert Girdlestone, 1881–1950, Nuffield Professor of Orthopaedics, University of Oxford, UK, described excision arthroplasty of the hip for septic arthritis.

48–72 hours according to culture results. In culture-negative cases, ongoing therapy to cover the most likely pathogens should be instituted.

The duration of therapy is determined according to the surgical approach, with 6 weeks for those in whom prosthetic material is completely removed, versus 6 months for patients undergoing a 'DAIR' strategy, and prolonged (occasionally life-long) treatment for patients in whom all other options are contraindicated or intolerable. In a small subset of patients, the best therapy is no intervention, when chronic low-grade symptoms are well controlled and preferable to the risks of either surgery or long-term antibiotic therapy.

The antibiotic regimen should be planned with the advice of a microbiologist, and supervised carefully to promote compliance, and to detect and manage side effects. Monitoring of the joint is largely on clinical grounds; biomarkers including CRP are not predictive of treatment failure.

Serial radiographs are helpful to detect progressive bone loss, which may be an indicator of recurrent active infection and can predispose to periprosthetic fracture and implant loosening.

Summary box 38.8

Prosthetic joint infection

- Well-fixed prostheses may be debrided, treated with antibiotics and the implant retained ('DAIR' approach)
- Loose prostheses must be removed
- Replacement can be made at the initial surgery (one-stage) or after a delay to allow infection to be eradicated with a course of antibiotics (two-stage)
- Multiple surgical samples are crucial for identifying a pathogen
- Thorough excision of infected tissue is a key determinant of outcome
- Long-term antibiotics may be used for patients who are not suitable for major revision surgery

INFECTION FOLLOWING FRACTURE FIXATION

Many of the principles outlined above can be applied to infections associated with metalwork used to fix fractures.

There may be several clinical scenarios which must be addressed:

- Unhealed fracture with stable fixation: This is usually seen early after fixation and can be managed with deep sampling, debridement of infected tissues and management of dead spaces (often with local antibiotic carriers). It is extremely important to provide good soft tissue cover over the fracture. In the tibia, this will most often require a plastic surgical reconstruction. After surgery, systemic antibiotics must be given to suppress infection until bone union, followed by removal of the implant.
- Healed fracture with infected implant: In these cases, the implant can be removed, but there should still be a careful debridement, deep sampling, dead space management and soft tissue cover.
- Unhealed fracture with unstable fixation: Stability is essential for bone healing and eradiation of infection. If the implant is not stable, it should be removed and replaced by an external fixator. Radical excision of the infected fracture is needed and the resulting defect may present a major reconstructive challenge (**Figure 38.6**). Recently, antibiotic-coated implants have been used to stabilise infected fractures with some success.

ACUTE OSTEOMYELITIS

This presents like septic arthritis with a short history of pain, loss of function and systemic upset. In adults, the vertebral column is the commonest site; in children, long bones are most frequently affected and there may be swelling of the affected limb. In young children, a fever and refusal to bear weight may be the only clues.

Diagnosis

In the early phase (2–3 days) radiographs may be normal but MRI will show bone oedema and periosteal elevation. After 5–7 days, plain radiographs may show subtle abnormality with osteopenia and periosteal new bone formation. The WCC and CRP are often abnormal in the early phase. Treatment should not be delayed pending investigations.

Management

Acute osteomyelitis can be treated with antibiotics alone when the diagnosis is made within 2–3 days of onset of symptoms, there is no dead bone on imaging and there is no adjacent septic arthritis. Culture results help to guide therapy, so blood cultures should be taken, and radiologically guided sampling should be considered. Prompt intravenous antibiotics, active against community-acquired pathogens, should then be started (see *Summary box 38.4*).

The limb should be splinted and good analgesia given. Intravenous antibiotics may be converted to oral therapy, depending on clinical progress and the results of cultures, and therapy is continued for a total of at least 4 weeks. If the patient does not respond rapidly, the limb deteriorates or there is imaging evidence of progression of disease, surgery is indicated to prevent bone destruction and the onset of chronic osteomyelitis.

With prompt treatment, acute bone infection has a good prognosis with a 90% cure rate. Failure to treat adequately produces chronicity, with recurrent infection over many years. In children, the adjacent growth plates and joints may be affected with subsequent deformity and joint destruction.

CHRONIC OSTEOMYELITIS

This is a serious condition which may affect the patient for decades. Chronic bone infection is best treated by a dedicated multidisciplinary team, who have the skills to deal with all aspects of the condition, the associated comorbidities and the range of surgical reconstructive options.

Summary box 38.9

Acute osteomyelitis

- Presents in children with toxaemia, fever and unwillingness to move the limb
- May affect the vertebral column in adults, where back pain may be the only symptom
- Radiographs may be normal for up to 1 week so are of limited value in early diagnosis
- WCC and CRP are usually raised
- Early diagnosis is treated with high dose intravenous antibiotics, started empirically and modified with culture results
- Late diagnosis and/or failure of medical treatment requires surgical debridement

Diagnosis

Plain radiographs can delineate soft-tissue swelling, subperiosteal reaction, bone destruction and sequestra. CT scans are good for cortical bone imaging and for planning surgical excision. MRI is the imaging test of choice (see 'General principles' section). Blood tests are often normal in chronic osteomyelitis.

Management

The Cierny and Mader classification helps to define the features of the infection in the bone (four stages) and to relate this to the general condition of the patient (three groups). Patients can be divided into three physiological 'host types'

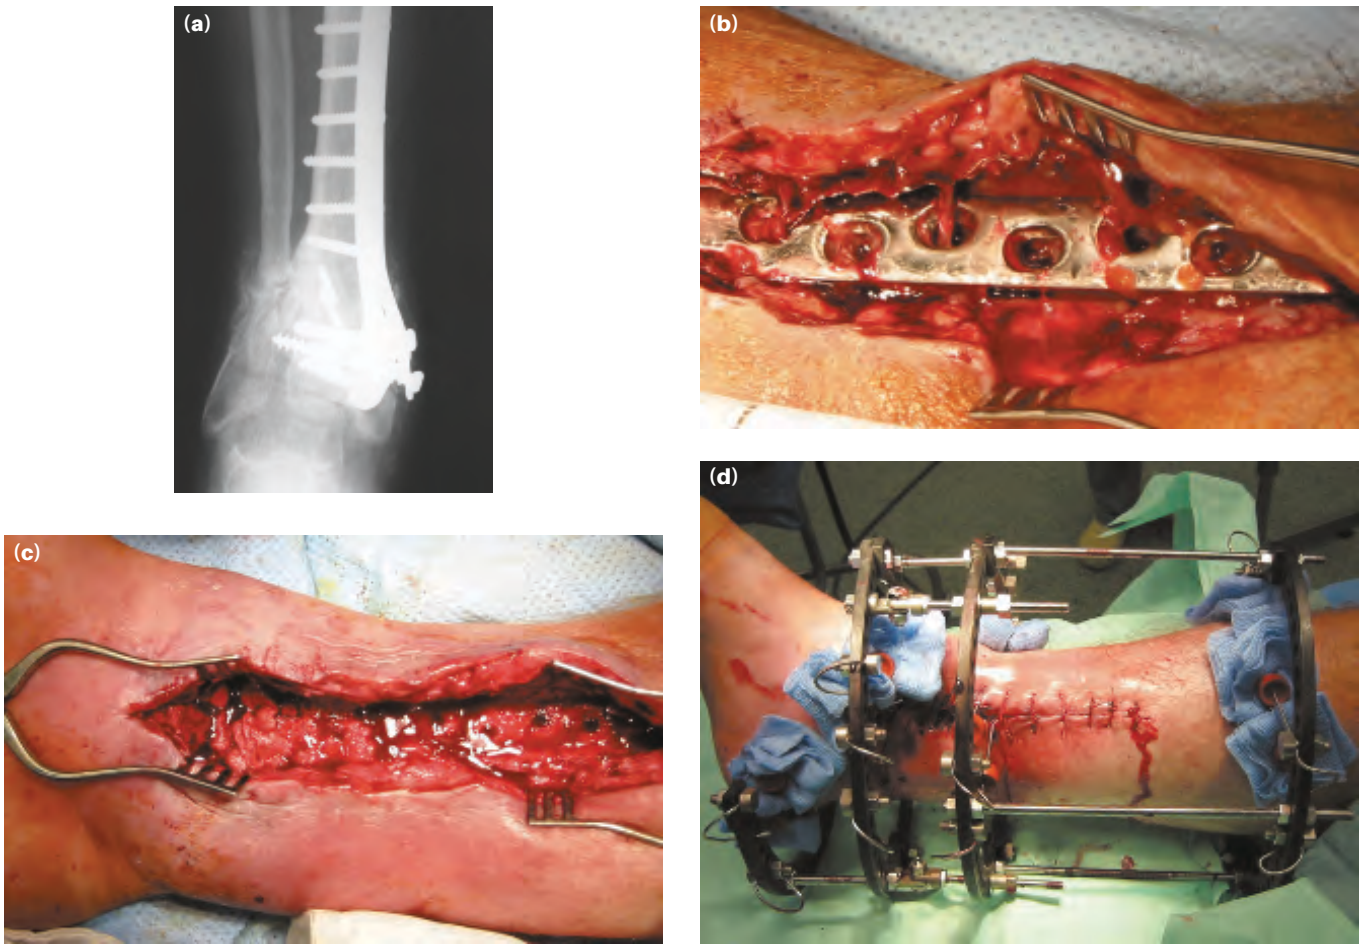

Figure 38.6 (a) Radiograph of a complex distal tibia fracture that was internally fixed but complicated by deep infection. **(b)** At operation, the plate was loose and grossly infected. **(c)** The plate was removed and all infected tissue was excised. Deep samples were sent for microbiology and histology. The defect at the lower end was filled with an absorbable antibiotic carrier. **(d)** The bone was stabilised with an Ilizarov circular external fixator and the skin primarily closed.

Goerge Cierny III, 1947–2013, osteomyelitis surgeon, San Diego, California, USA.
Jon T Mader, 1944–2002, Department of the Marine Biomedical Institute, Division of Infectious Diseases, the University of Texas Medical Branch, Galveston, USA.
Cierny and Mader described the classification in: G Cierny, JT Mader, JJ Pennick. A clinical staging for adult osteomyelitis. *Contemp Orthop* 1985; 10: 17–37. They appreciated the importance of treating the whole patient alongside the infected bone.

(A, no active concurrent disease; B, compromised host; C, severe comorbidity preventing surgery). The interaction between the patient's health status and the extent of the bone infection greatly affects the outcome after surgery. In chronic infection, it is helpful to address medical conditions which may impair wound healing (e.g. smoking, peripheral vascular disease, diabetes, steroid use) prior to surgery. This approach has been shown to improve cure rates.

Stage 1 (medullary)

Only cancellous bone is involved. Excision of the dead bone can be carried out by intramedullary reaming or by windowing the cortex. The resulting defect may be filled with antibiotic-loaded cement beads or absorbable pellets. Structural stability is rarely affected (**Figure 38.7**).

Figure 38.7 (a) Magnetic resonance imaging scan showing a typical medullary osteomyelitis of the femur, in a patient with human immunodeficiency virus. **(b)** The infected bone has been removed by reaming and the central defect filled with absorbable calcium sulphate pellets with gentamicin.

Stage 2 (superficial)

Only the cortical bone is involved and this requires excision. It often follows skin ulceration and there may be large skin defects which require complete excision and local or free muscle flaps. If more than one-third of the cortical circumference is excised, splintage is essential, usually with external fixation to prevent fracture. Secondary bone grafting may be needed.

Stage 3 (localised)

There is a limited area of dead cortical bone with medullary infection. Radical excision is required, and filling the defect and providing soft-tissue cover may be a challenge. Staged reconstruction may be necessary with cancellous bone grafting (**Figure 38.8**).

Figure 38.8 This large ulcer had been present for 30 years with underlying Stage 3 chronic osteomyelitis. Biopsy of the skin edge revealed a squamous cell carcinoma; a rare complication of a long-standing sinus (Marjolijn's ulcer).

Stage 4 (diffuse)

This involves the entire circumference of the bone and surrounding soft tissue. All infected non-unions are Stage 4. Resection must be segmental and stabilisation in an external fixator will be required. Reconstruction will involve the introduction of new bone and healthy soft tissue. The Ilizarov method, which uses distraction osteogenesis to fill bone defects, is a powerful and successful technique. It can be combined with free tissue transfer. This allows reconstruction to proceed in parallel with rehabilitation.

After surgery, patients should be given antibiotics. After total segmental excision of infection a short course may be indicated, but in most chronic infections, 6–12 weeks is often advised. If there is any doubt about the adequacy of clearance of infection, a long antibiotic course will be needed and recurrence may be more likely. In infected fractures, antibiotics should continue until fracture union.

There is now increasing interest in the use of local antibiotics with absorbable carriers. These can deliver high doses of antibiotics into the bone, without systemic effects. Some biocomposite materials (with hydroxyapatite) can form new bone in the defect, avoiding the need for secondary bone grafting.

Gavril Abramovich Ilizarov, 1921–1992, pioneered this eponymous approach to bone reconstruction in Siberia in the 1960s for the management of osteomyelitis.

Summary box 38.10

Chronic osteomyelitis

- Chronic disease requires specialist surgery with excision, stabilisation and reconstruction
- Host status should be optimised before surgery
- Following surgery, antibiotic therapy is typically continued for at least 6 weeks

DIABETIC FOOT INFECTION

The global prevalence of diabetes has increased exponentially in recent years. Foot infections are a leading cause of hospital admissions in this group, with an annual incidence of foot complications of 1–2% per year, due to the combined influence of macro- and microvascular insufficiency, mechanical disruption, peripheral and autonomic neuropathy, immune defects and impaired tissue healing. Ulceration of the calcaneum and bones of the forefoot, especially the great toe and first metatarsal head, is common, potentially leading to deep extension and osteomyelitis (**Figure 38.9**).

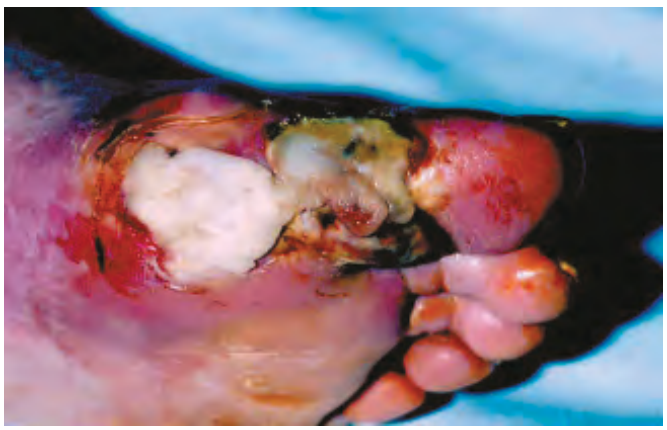

Figure 38.9 A severe diabetic foot infection, with marked infection, necrosis and soft-tissue loss. The patient was neuropathic but not ischaemic and it was possible to salvage a functional foot by 'filleting' the hallux and using the soft tissues to cover the defect.

Fever and systemic symptoms are relatively unusual in diabetic foot infections but, if present, should be acted on promptly, as they may herald rapidly advancing infection, bacteraemia or necrotising fasciitis. In unwell patients, blood cultures, imaging, careful clinical assessment with optimisation of organ function and prompt empirical antibiotics are essential.

Blood tests are frequently unhelpful, as inflammatory markers may be normal or only mildly raised. Plain radiographs may show evidence of osteomyelitis, but can be normal (particularly early in infection). MRI is the most sensitive imaging modality for diagnosis of bone involvement. Limited disease has a good prognosis, and in the absence of risk factors for resistant organisms (including prior treatment), empirical treatment can be justified. In extensive or complicated infections, antibiotic therapy should be guided by the results of culture of deep bone or tissue samples obtained surgically or radiologically. Superficial swabs or cultures from ulcers or sinus tracts are not reliable in determining the organisms responsible for underlying deep-seated infection.

The aetiological agents of diabetic foot infection are the same as for bone infection in non-diabetic individuals, namely *Staphylococcus aureus*, beta-haemolytic streptococci and aerobic gram-negative bacilli. *Pseudomonas* is over-represented, and empirical therapy for severe infections should include cover for this organism. Anaerobes may also be present, and the addition of metronidazole (particularly for abscesses and/or devitalised tissue) should be considered.

Surgical debridement is required for collections, necrotic areas or more extensive osteomyelitis. Thought should be given to distinguishing superficial osteitis (stage 2 disease) resulting from loss of soft tissue cover (often in association with vascular compromise) from more extensive bone involvement. In the former, biopsy and antibiotic therapy may be of limited importance and optimising glycaemic control, improving vascular supply and relieving pressure with appropriate footwear are much more important. This approach may avoid more extensive tissue loss or later amputation.

Vascular compromise should be considered a relative contraindication to a surgical approach. In patients with poor peripheral pulses, a full vascular assessment is mandatory. Proximal angioplasty or bypass surgery may improve distal vascularity to a level where infection surgery in the foot may be more successful.

Amputation is not an easy option in diabetic foot disease, and wound healing can be problematic. In general, excision should be adequate to remove all infected material, and excess bone may need to be resected to allow tension-free skin closure. If there is extensive peripheral neuropathy, a below-knee amputation in an area with better sensation may be appropriate.

Summary box 38.11

Diabetic foot infection

- The most important risk factor for osteomyelitis is the presence of a foot ulcer
- Ulcer swabs are not reliable in determining the pathogens responsible for osteomyelitis
- Bone biopsy for culture should be considered in extensive/complex infection, but may not be necessary in mild disease
- In severe disease, surgical debridement of collections and/or necrotic tissue is required, followed by antibiotics tailored according to culture results

MUSCULOSKELETAL INFECTION CAUSED BY MYCOBACTERIA

Tuberculous arthritis/osteomyelitis had become uncommon in the UK, but remains prevalent in resource-poor countries. There is now a resurgence in higher-income countries as a consequence of immigration and immunocompromise (including human immunodeficiency virus [HIV]). The most common organism is *Mycobacterium tuberculosis*. Around half of all cases affect the spine, typically manifesting as paradiscal

infection but also causing discitis and vertebral osteomyelitis. Native joint infection typically presents with monoarticular pain in a weight-bearing joint.

Surgery may be crucial to facilitate synovial biopsy for diagnosis by culture and histopathology, as well as to decompress the spinal cord and debride infected tissue.

For optimal management of tuberculosis, the patient must be referred to a specialist multidisciplinary team, for input that includes the following components.

- Baseline screening for HIV and other blood-borne viruses.
- Assessment for other sites of mycobacterial infection.
- Measurement of baseline renal and liver function, to be repeated at intervals throughout treatment. Drug-induced hepatitis is the commonest serious side effect that may require temporary withdrawal or alteration of therapy.
- Baseline and follow-up testing of hearing (if injectable agents to be used) and colour vision (if ethambutol to be used).
- Consideration of any potential drug interactions (rifampicin is a potent inducer of the cytochrome P450 system; it can interact with many classes of drug including anticonvulsants, antiretroviral therapy, anticoagulants, antibiotics and antifungals).
- Institution of appropriate infection control precautions and contact tracing.
- Appropriate education and support to optimise adherence to therapy.
- Prescription of an appropriate combination of drug therapy.
  - For fully sensitive *Mycobacterium tuberculosis*, the preferred regimen is oral rifampicin, isoniazid, pyrazinamide and ethambutol for 2 months, followed by rifampicin and isoniazid for a further 4 months.
  - Worldwide, there is an increase in the prevalence of drug-resistant tuberculosis, classified as multidrug resistant (MDR) and extensively drug resistant (XDR). Infection with these organisms requires a treatment regimen that includes an injectable agent (typically amikacin, kanamycin or capreomycin) together with oral agents selected according to the susceptibility profile of the isolate (these may include cycloserine, ethionamide, p-aminosalicylic acid (PAS), fluoroquinolones and linezolid). Prolongation of therapy is required, and side effects and toxicity are common.

Non-tuberculous mycobacteria are ubiquitous environmental organisms. They are best recognised as agents of disease in patients with underlying immunocompromise (including HIV, diabetes and organ transplantation), or other risk factors for introduction of infection (such as penetrating trauma or the presence of a prosthesis). However, they may occasionally also cause infection in hosts without obvious risk factors.

Treatment can be difficult. These organisms are resistant to the standard agents used for first-line antituberculous therapy; surgery to debride and drain sites of infection can therefore be particularly important to reduce the bacterial burden. There is no single standardised drug regimen or duration, so choice of therapy depends on the *in vitro* susceptibility of the organism, and length of treatment depends on the location of disease, extent of surgical debridement, the identification and phenotypic characteristics of the organism, the patient's underlying condition, presence of immunocompromise and response to therapy. As for treatment of *Mycobacterium tuberculosis*, expert medical oversight is crucial throughout treatment.

ACKNOWLEDGEMENT

Dr Philip Bejon contributed to an earlier version of this chapter, and we remain grateful for his previous input.

Chapter 39

Paediatric orthopaedics

Learning objectives

To be familiar with:

- Normal and abnormal development of the musculoskeletal system
- Normal variants versus pathological deformity
- Diagnosis and treatment of developmental hip dysplasia
- Presentation and management of other childhood hip conditions
- Management of clubfoot
- Problems associated with musculoskeletal infection in childhood

INTRODUCTION

Immature skeletons heal rapidly and can remodel with growth but physeal injury or muscle imbalance may lead to progressive deformity. The conservative treatment of common conditions, such as developmental dysplasia of the hip (DDH) combines the child's remodelling ability with an understanding of the Heuter–Volkmann principle and Wolff's law (*Table 39.1*): improving the biomechanical environment may reverse abnormal growth. In contrast, in conditions such as Blount's disease, a poorly functioning growth plate leads to asymmetrical growth and deformity. Advances in genetics and molecular science are improving our understanding of certain conditions and may lead to potential new avenues of treatment.

DEVELOPMENT OF THE MUSCULOSKELETAL SYSTEM

The upper limb bud forms on the lateral wall of the embryo 4 weeks after fertilisation, followed promptly by the lower limb bud. By 2 months' gestation, differentiation of the limb elements is complete. Most congenital limb anomalies arise during this second month.

TABLE 39.1 Laws governing the remodelling of bone.

Heuter–Volkmann principle

- Compressive forces inhibit growth
- Tensile forces stimulate growth

Wolff's Law

- Bone deposition and resorption depend on the stresses applied

Three coordinated signalling centres control limb development. The **apical ectodermal ridge** (AER) guides mesodermal differentiation (in the progress zone) in a proximal to distal direction and controls digit formation via the production of several fibroblast growth factors (FGFs). The mesodermal **zone of polarising activity** (ZPA) directs anteroposterior limb development via the sonic hedgehog protein which is itself sustained by the FGFs. The ectodermal driven **wingless-type** (Wnt) signalling centre develops dorsoventral axis configuration and limb alignment.

Certain limb anomalies are directly related to alterations in these centres. In experiments it is found that removal of the AER leads to a truncated limb, similar to a congenital amputation, and prevents interdigital necrosis. This results in syndactyly. An additional ZPA results in a mirror duplication of the distal limb, while the Wnt signalling system is critical for the transcription factor Lmx1b in the distal mesenchyme, such that absence of this gene affects the development of dorsal limb structures in the nail patella syndome.

An error during fetal limb development may disturb the formation of other organs. Thus some limb anomalies are associated with systemic disorders which may be life-threatening.

Summary box 39.1

Development of the musculoskeletal system

- Occurs 4–8 weeks after fertilisation
- AER controls proximal to distal differentiation and interdigital necrosis
- ZPA directs posterior to anterior differentiation
- Wnt influences dorsal to ventral differentiation

Richard von Volkmann, 1830–1889, Professor of Surgery, Halle, Germany.
Julius Wolff, 1836–1902, Professor of Orthopaedic Surgery, Berlin, Germany.

NORMAL VARIANTS

The many normal variants of growth and development can cause significant parental concern. The common problems are related to an intoeing gait, tripping and falling, bowlegs, knock-knees and flatfeet. In general, if they are symmetrical, symptom-free and supple and in an otherwise normal child, they require no intervention. There is often a family history of similar complaints. If the child fails to achieve their developmental milestones or there are functional problems, further investigation and help may be required.

Intoeing gait

Intoeing is defined as a negative foot progression angle. It can result from one or more lower limb torsional anomalies (**Figure 39.1** and *Table 39.2*).

Persistent anteversion of the femoral neck presents clinically with excessive internal rotation at the hip joint which is best measured with the patient prone (**Figure 39.2a**). All femurs are anteverted at birth but as the femur lengthens it also rotates, leading to spontaneous improvement in the degree of anteversion. If, by 10–12 years, a significant deformity persists associated with functional difficulties, corrective osteotomy may be justified. In such cases, the child has usually lost the ability to externally rotate the extended hip. In other cases, compensatory external tibial torsion may have developed, in which case the foot progression angle will be normal but the child may have symptoms of the miserable malalignment syndrome, which include anterior knee pain and feelings of instability.

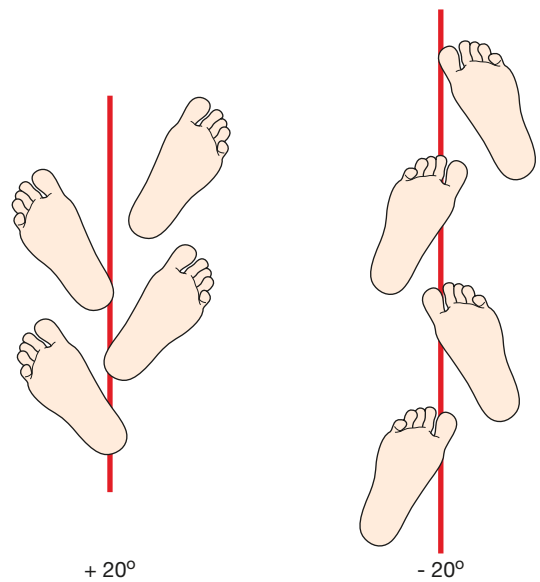

Figure 39.1 Foot progression angle: a positive angle is caused by an extoeing gait, a negative angle by an intoeing gait.

TABLE 39.2 Common sites and causes of intoeing gait in childhood.

Site	Cause
Femur/hip	Persistent femoral neck anteversion
Tibia	Internal tibial torsion
Foot	Metatarsus adductus

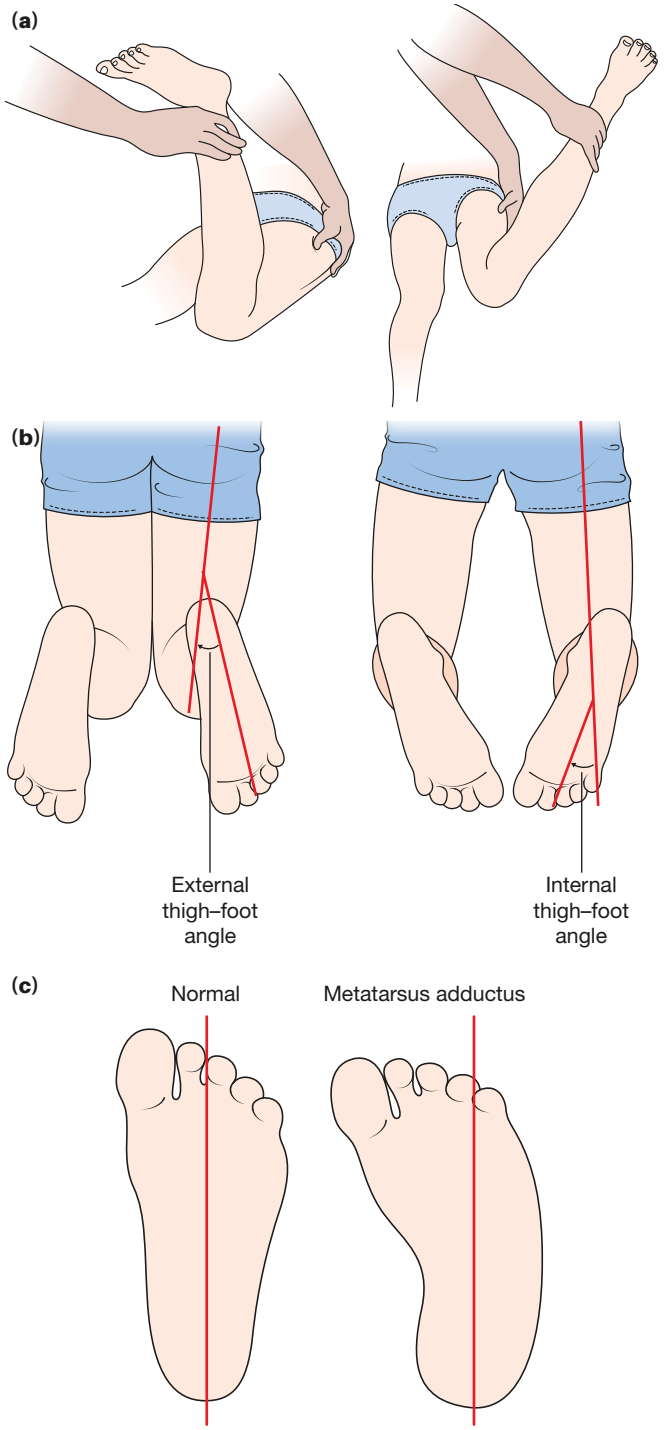

Figure 39.2 Line diagrams illustrating assessment of the torsional profile: all assessments are done with the child prone. **(a)** Femoral neck anteversion measured as the range of internal hip rotation with the child prone, the hip extended and the knee flexed. Craig's test measures the degree of internal rotation present when the greater trochanter is at its most prominent (also called the Trochanteric Prominence Test). **(b)**The thigh–foot angle (TFA) measures the angle between the relaxed hindfoot and the thigh (also measured with the child prone). **(c)** The bean-shaped foot of metatarsus adductus viewed from above: a curved lateral border with/without a medial crease. This deformity may be passively correctable.

Internal tibial torsion is assessed by the thigh–foot angle and is commonly associated with physiological tibia vara in infants (Figure 39.2b). Spontaneous correction can be expected by age 4, as the tibia also rotates as it grows.

Metatarsus adductus (Figure 39.2c) is usually flexible; spontaneous correction occurs in 90% of children by the age of 2–4 years. For the more rigid foot, stretching, with or without plaster casts or straight-last shoes, may help. Surgical release is rarely indicated.

Other abnormalities of gait

Extoeing is less common than intoeing but may result from relative femoral retroversion, external tibial torsion or flexible flat feet. The young child may be late walking because of poor balance associated with the foot posture and the overall alignment. This condition improves with growth/time.

Toe-walking is a phase in normal gait development. If the gait does not mature to a heel–toe pattern by 3 years, physiotherapy may help, and older children benefit from surgical lengthening of a contracted gastrocsoleus complex, if it is present. If toe walking starts after walking age, a spinal or neuromuscular aetiology such as a tethered cord or a muscular dystrophy must be considered and in the unilateral case, an orthopaedic cause for a short leg, such as fibula hemimelia or a dislocated hip, needs to be considered and excluded.

Knock-knees and bowlegs

In the normal child, leg shape changes dramatically over time. All children start life with bowlegs, often accompanied by internal tibial torsion. By the age of 2–3 years they have developed knock-knees, which regress towards the normal adult tibiofemoral angle of 7° valgus by the age of 7 (Figure 39.3).

Traditionally, the intercondylar or intermalleolar distance is used to quantify the deformity, rather than measuring the angle. This is not very accurate. Further investigation is needed when the deformity is severe, asymmetrical or symptomatic. The most common pathological causes are previous trauma, rickets or a skeletal dysplasia.

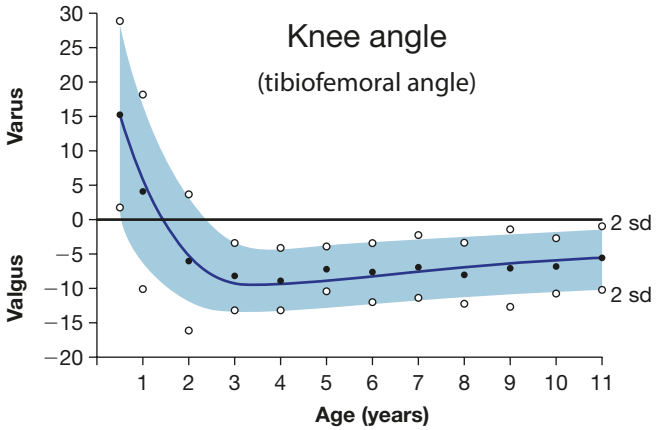

Figure 39.3 Graph to show the normal tendency of limb alignment to change from varus to valgus with growth; normal is slight valgus after the age of 7–8 years.

Flat foot

Before development of the medial longitudinal arch, all children (<3 years) have flat feet, often with a fat pad obscuring the arch. Only 15% of adults have flat feet so the natural history is for improvement, influenced by both familial and racial factors.

The painless, flexible flat foot needs no treatment. Orthoses **do not** alter the natural history but can alleviate symptoms **if** they are present. All flat feet have a flattened medial arch with a valgus heel but two major types must be distinguished (*Table 39.3*).

The symptomatic, rigid flat foot is usually the result of inflammation or a tarsal coalition and requires appropriate investigation followed by medical or surgical management (Figure 39.4).

TABLE 39.3 Flat feet.

Types	Characteristics
Flexible	On tiptoe the arch is restored and the heel corrects into varus; subtalar joint movements are full and pain free
Rigid	On tiptoe the arch fails to return and the heel remains in valgus; subtalar joint movements are restricted and often painful

Figure 39.4 Oblique radiograph of the foot that shows the most common form of tarsal coalition, a calcaneonavicular bar (arrow).

Summary box 39.2

Normal variants

- Children's legs are often bowed until age 2 years and then knock-kneed until age 6 or 7 years
- Neuromuscular pathology must be excluded in toe walkers, particularly when the onset is late
- Intoeing or extoeing may be caused by excessive femoral or tibial torsion or foot deformity
- Flexible, pain-free flat feet do not need treatment

Postural abnormalities

Many babies are subjected to moulding pressures *in utero*. At birth they exhibit 'postural abnormalities' such as torticollis, calcaneovalgus feet and plagiocephaly, which improve with time and/or stretching exercises.

CONGENITAL AND DEVELOPMENTAL ABNORMALITIES OF THE SKELETON

Although many skeletal abnormalities are identified antenatally or at birth, others only become apparent with growth. Skeletal disorders are often linked to soft-tissue abnormalities which may be generalised or focal; the presence of a skin dimple or a vascular malformation should be a warning sign as should the 'featureless' limbs of a child with arthrogryposis multiplex congenita (AMC) (*Table 39.4*, **Figure 39.5**).

Many anomalies require little treatment and cause minimal functional disability whereas others, such as proximal femoral focal deficiency (PFFD) and radial club hand, pose considerable challenges to both the patient and their doctors. In these cases the functional and cosmetic needs of the child and family must be balanced against available resources and expertise (**Figure 39.6**). Despite advances in limb reconstruction techniques there is little high-quality evidence-based data from skeletally mature patients to support their widespread use. Concurrently, considerable advances are occurring with amputation prosthetics which may result in better patient-reported quality of life outcome scores, particularly in certain regions.

Generalised skeletal dysplasias

Achondroplasia

Achondroplasia is caused by a gain in function mutation in the *FGFR3* (fibroblast growth factor receptor 3) gene, located on the short arm of chromosome (Chr) 4, which affects

TABLE 39.4 Classification of congenital limb malformations.

Category	Example
Failure of formation of parts	
Transverse	Congenital amputation of the forearm/lower limb
Longitudinal	Fibular hemimelia
Failure of differentiation	Radioulnar synostosis; vertebral body fusion
Duplication	Extra digits
Overgrowth	Gigantism; macrodactyly
Undergrowth	
Congenital constriction band syndrome	Often affects hands/feet with poor formation of the digits distally
Generalised skeletal abnormalities	Skeletal dysplasia, e.g. achondroplasia

Figure 39.5 Clinical photograph of a child with arthrogryposis multiplex congenita and featureless upper limbs (no skin creases or muscle definition). He mobilises with the help of knee–ankle–foot orthoses.

Figure 39.6 Radiograph of a child born with proximal femoral focal deficiency. A proximal femoral osteotomy improved her hip mechanics and stabilty (a screw has come loose from the plate). She opted to keep her foot and not to undergo leg lengthening. She functions well with an extension prosthesis.

enchondral bone formation. It is an autosomal dominant condition. Patients present with disproportionate short stature where the limbs are shorter than the trunk, together with classical clinical and radiographic features (**Figure 39.7**).

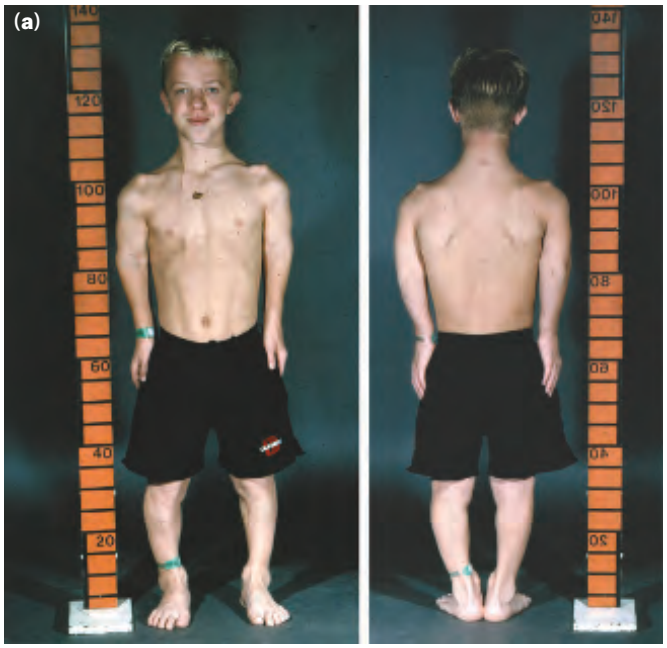

Figure 39.7 Achondroplasia. **(a)** Clinical photograph of a child with achondroplasia. **(b)** Standing leg length/alignment radiograph of a different child with achondroplasia showing short limbs, flared/widened metaphysis, an overlong fibula and slight bowing, The acetabulum is very horizontal and the pelvic wings seem square: all classical features of this condition.

Underdevelopment of the foramen magnum and spinal stenosis can cause neurological difficulties. Correction of limb alignment may be necessary and limb lengthening techniques are used in some countries.

Hereditary multiple exostoses – diaphyseal aclasis

This is an autosomal dominant condition usually related to a loss of function mutation in either the *EXT 1* (on Chr 8q) or *EXT 2* gene (Chr 11p), although it is unclear how this defect leads to the disregulated growth which results in an exostosis. Exostoses consisting of a cartilaginous cap on a bony stalk may be sessile or pedunculated. They grow as the child grows and may cause cosmetic or functional difficulties that justify excision. Differential growth between the paired bones of the forearm and lower leg can lead to joint deformity and dislocation of the radial head, exacerbated by the disorded physeal growth secondary to altered mechanical forces. Such growth abnormalities are predictable and treatment is designed to prevent deformity from developing (**Figure 39.8**). Continued growth after skeletal maturity may represent malignant transformation of a previously benign osteochondroma: a rare but recognised problem (see Chapter 37).

Enchondromatosis

This non-hereditary skeletal dysplasia is also called Ollier's disease. Enchondromas arise from rests of chondrocytes located within the medullary canal of tubular bones: they consist of mature hyaline cartilage (**Figure 39.9**). Larger lesions may show calcification on radiographs, and vertical streaks of lucency (representing cartilage columns) may run the length of the metaphysis. Pathological fractures are common. If there are also soft tissue haemangiomas and lymphangiomas, the condition is called Maffucci's syndrome (see Chapter 37).

Figure 39.8 Radiograph of the knee showing multiple broad-based osteochondromas.

Louis Xavier Edouard Léopold Ollier, 1830–1900, Professor of Surgery, Lyons, France, described enchondromatosis in 1899.
Angelo Maffucci, 1845–1903, Professor of Pathological Anatomy, Pisa, Italy, described enchondromatosis in association with soft tissue haemangiomas in 1881.

Figure 39.9 Anteroposterior radiograph of the index finger of a child showing a solitary enchondroma (arrow): note the opacity in the soft tissues that represents the extent of the cartilaginous lesion.

Figure 39.10 Standing leg length and alignment radiograph of a child with polyostotic fibrous dysplasia. The diaphyseal lesions classically have a 'ground glass' appearance. The bones are often deformed and the limb may be short, as seen particularly on the right. The femur has fractured previously and one intramedullary nail remains in place.

Fibrous dysplasia

This common disorder is often a chance finding on radiographs, particularly in its monostotic form. It is a localised defect in osteoblastic differentiation and maturation where normal bone is replaced by fibrous stroma. With polyostotic fibrous dysplasia, limb deformity and pathological fractures are common. In patients with precocious puberty and Coast of Maine café-au-lait spots, the diagnosis is McCune Albright's syndrome (**Figure 39.10**).

Summary box 39.3

Congenital and developmental abnormalities of the skeleton

- Achondroplasia affects enchondral ossification and presents with disproportionate short stature
- Exostoses may cause functional and/or cosmetic problems
- Patients with Ollier's disease (multiple enchondromatosis) often have lesions in the hands and feet

METABOLIC BONE DISEASE

Rickets

In all types of rickets, the primary problem is inadequate mineralisation of growing bone (*Table 39.5*). In severe cases, skeletal deformities, with classic radiographic features, affect every physis (**Figure 39.11**). Medical treatment improves mineralisation. Correction of the deformity then occurs with growth. Once the medical condition has been stabilised, surgery may be necessary for the management of any residual limb deformity. Guided growth techniques are often used in preference to osteotomies.

TABLE 39.5 Common causes of rickets.

Nutritional	Reduced intake of vitamin D and calcium
Environmental	Inadequate exposure to sunlight
Gastrointestinal disease	Crohn's disease, gluten-sensitive enteropathy
Genetic	X-linked hypophosphataemia
Renal disease	End-stage renal failure, renal tubular anomalies; changes related to secondary hyperparathyroidism may be present

Osteogenesis imperfecta (OI) (brittle bone disease)

OI represents a spectrum of conditions linked by a qualitative and/or quantitative malfunction of collagen production. Many specific genetic defects have been identified, most caused by mutations in the collagen genes. The bone may break easily but it heals promptly and well. All structures that

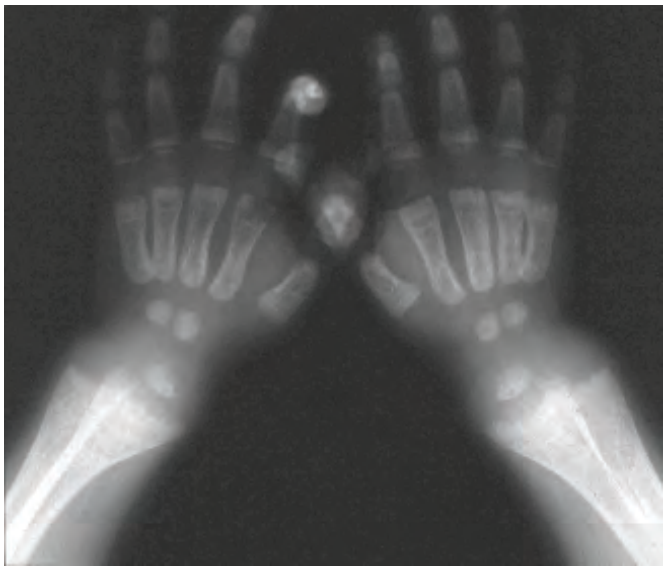

Figure 39.11 Radiographs in cases of rickets demonstrate widened physes with cupped, flared metaphyses.

contain collagen may be affected. This accounts for the ligamentous laxity, blue sclerae and poor teeth found in some phenotypes.

Cyclical bisphosphonate treatment decreases bone resorption and bone turnover. This reduces bone pain and the fracture rate, which in turn improves weight-bearing mobility and bone strength (Figure 39.12).

Following fracture, care must be taken to minimise disuse osteoporosis and to maintain bone alignment. Treatment options range from simple casting techniques to more specialised surgical procedures to correct/maintain limb alignment while allowing growth. Intramedullary techniques for reduction and stabilisation of fractures or osteotomies are preferred to plate fixation because of the associated problems with stress risers. Immobilisation must be minimised and rehabilitation commenced promptly.

Figure 39.12 Radiograph of a child with osteogenesis imperfecta who has been treated with cyclical bisphosphonates. Multiple growth lines are visible in addition to intramedullary devices in both the femur and tibia.

Summary box 39.4

Metabolic bone disease

- Rickets, from nutritional or other causes, is characterised by a failure of bone mineralisation
  - X-linked hypophosphataemic rickets is transmitted in a dominant fashion, therefore affecting both boys and girls
- In osteogenesis imperfecta:
  - There is defective type I collagen production
  - In severe forms frequent fractures lead to progressive deformity
  - Systemic treatment with bisphosphonates reduces the fracture rate

ABNORMALITIES OF THE HIP

Developmental dysplasia of the hip (DDH)

DDH defines the spectrum of hip instability, ranging from the hip that is in joint but has a shallow (dysplastic) acetabulum and may be 'pushed out' (Barlow positive) to the dislocated hip that is irreducible (Ortolani negative). These tests are described below. The associated clinical picture varies with the pathology and the age at presentation: neonatal hips may be unstable, a toddler may limp, adolescents may experience exercise-induced pain and an adult may have pain secondary to degenerative arthritis.

Incidence

The incidence of neonatal instability is ~20 per 1000 live births whereas that of true dislocation is ~2 per 1000 live births; many hips stabilise spontaneously.

Aetiology of DDH

- **Gender**. DDH is 4–5 times more common in girls than in boys, possibly related to hormonal factors causing temporary joint laxity.
- **Breech presentation**. DDH is more common in breech babies, particularly with the extended breech position.
- **Birth order**. DDH is more common in firstborns and in the left hip because of the common fetal position (LOA – left occipitoanterior) in a tight primigravid uterus where movement is restricted.
- **Oligohydramnios**. Restricts fetal movement. The presence of other postural deformities (torticollis and metatarsus adductus) raises the possibility of DDH.
- **Family history**. A positive family history significantly increases the risk of DDH. This may reflect faulty acetabular development or excessive ligamentous laxity.
- **Regional and racial variation**. DDH is more common in certain regions and in certain races, probably because of a combination of genetic, environmental and cultural factors. Swaddling the legs together will exacerbate an unstable hip whereas carrying the baby astride the carer's hip or back encourages a position of hip flexion and abduction that will help stability.

Hip dislocation is often found in association with generalised syndromes or neuromuscular conditions. These teratological hips are often resistant to the simpler surgical procedures and a holistic approach to the child's overall condition and prognosis must be taken when planning treatment.

Diagnosis

NEONATES

Clinical assessment and screening. In many countries, all neonates are screened for limitation of hip abduction and hip joint instability. In the UK, as part of the newborn and infant physical examination (NIPE) guidelines, the hips are examined again at 6 weeks. The knees and hips are flexed and the thigh held by the examiner with the thumb along the medial aspect and a finger behind the greater trochanter. The hips are abducted gently: if abduction is limited, the hip may be dislocated. The examiner's finger then lifts the greater trochanter upwards; a soft clunk – the Ortolani test – with improved hip abduction signifies hip reduction (**Figure 39.13a**). If the hip does abduct fully, then the leg is brought back up to neutral and then adducted while downward pressure is applied to the knee with the examiner's thumb and palm: an unstable hip may dislocate or subluxate – the Barlow test (**Figure 39.13b**). With an irreducible hip there is no clunk of reduction but there will be limitation of abduction. Bilateral dislocation may be missed because abduction is symmetrical and abduction may be normal when there is low muscle tone and joint laxity. In a dislocated hip, the femoral head may be palpable in the buttock.

Ultrasound assessment. Ultrasonography defines the anatomy and the stability of the hip joint. It is used to monitor early treatment (**Figure 39.14**) or as a screening tool (universally or just for 'at risk' patients). Ideally, screening scans should be performed between 4 and 6 weeks of age and treatment, when necessary, by 6 weeks. The sonographic appearance of most hips improves (both in terms of hip stability and acetabular dysplasia) spontaneously as the child grows.

Radiography. Plain radiographs are used to evaluate DDH from 4–5 months of age, but are of limited value in the newborn because no ossific nucleus is visible within the cartilaginous femoral head so its relationship to the acetabulum is difficult to judge. The appearance of the femoral ossific nucleus is also often delayed in DDH (**Figure 39.15**).

Summary box 39.5

The neonatal clinical examination must ask and answer the following questions:

- Is the hip dislocated?
  - If so is it reducible (Ortolani postive) or not (Ortolani negative)?
- If the hip is not dislocated, is it dislocatable (or subluxable)?
  - If so, it is Barlow positive.
- If the hip is not dislocated or dislocatable, is it clinically normal?
  - If so, do the risk factors in the history still demand further assessment with an ultrasound scan (USS) or plain radiograph?

INFANTS

Hip checks, looking for limitation of abduction in >90° of flexion and limb shortening, are part of routine developmental monitoring.

CHILD

Children present with a limp and sometimes with unilateral tiptoeing, because the affected leg is short. It is also externally rotated. Abduction in flexion is limited and there may be an extra thigh crease. The signs may be subtle and easily missed in an unsteady toddler. If both hips are affected there will be a waddling gait and a lumbar lordosis.

ADOLESCENT/ADULT

Discomfort after exercise is common but the pain may be in the knee. Radiographs show dysplasia, subluxation or degenerative change.

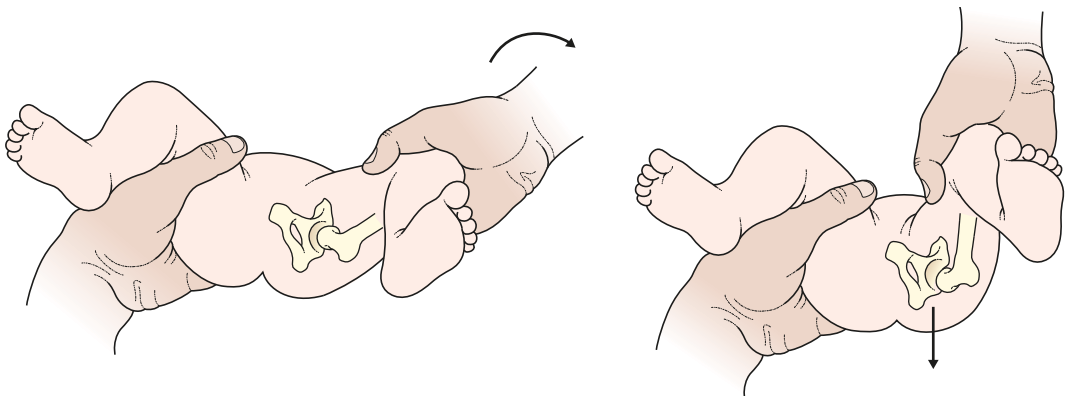

Figure 39.13 Line diagram illustrating the **(a)** Ortolani and **(b)** Barlow tests for developmental dysplasia of the hip. For the Barlow test the femur must be at 90° to the bed.

Marius Ortolani, orthopaedic surgeon, Instituto Provinciale Per L'Infanzia di Ferrara, Italy, described this test in 1937.
Thomas Geoffrey Barlow, 1915–1975, orthopaedic surgeon, the Salford Royal Hospital, Salford, UK.

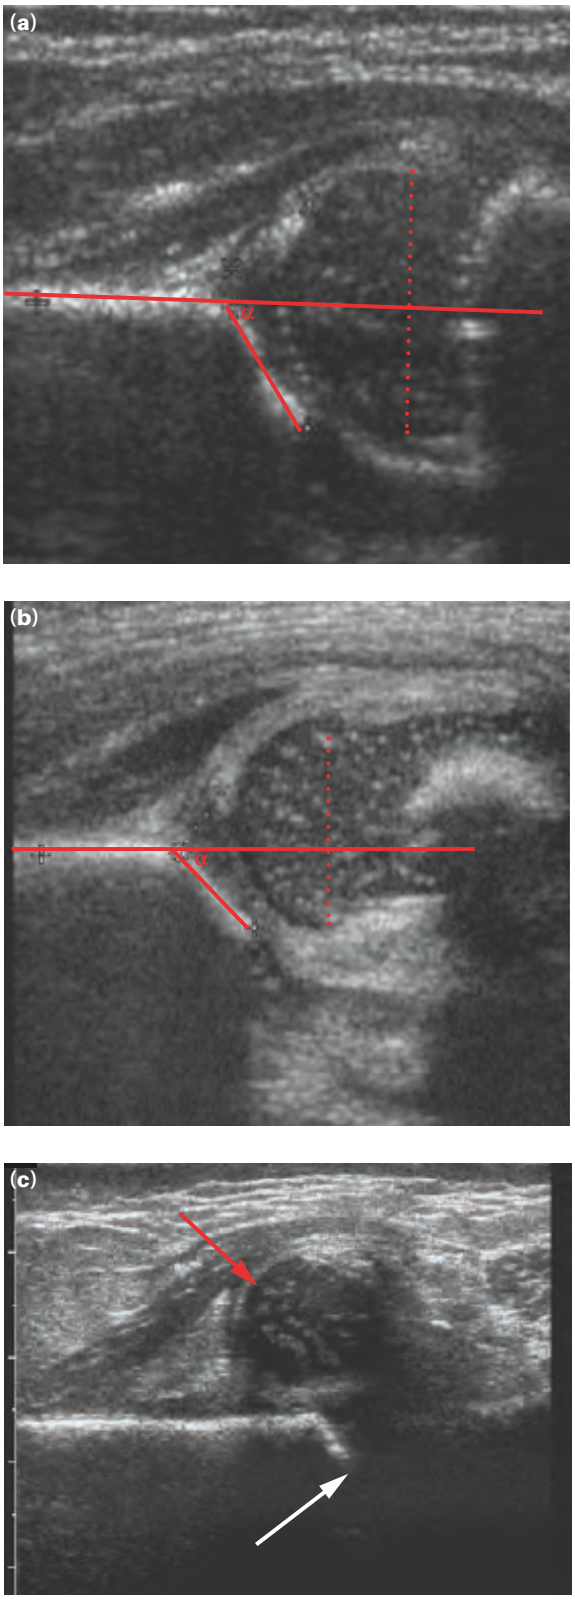

Figure 39.14 Ultrasound images of an infant hip. **(a)** Normal hip with a high α angle and a Morin index of 50% (defined as the percentage of the femoral head covered by the acetabulum, i.e. the portion lying below the horizontal red line). **(b)** Grossly dysplastic hip with a low α angle and a Morin index of <50%. This hip is likely to be unstable on dynamic ultrasound scanning, i.e. Barlow positive. **(c)** A dislocated hip joint (dislocated femoral head, red arrow; 'empty' acetabulum, white arrow).

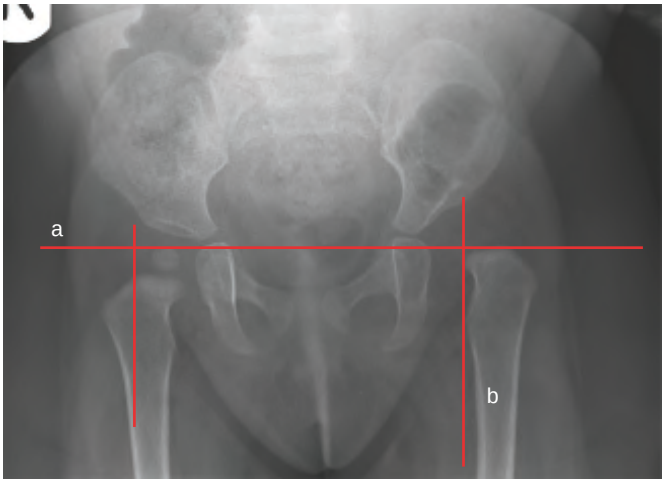

Figure 39.15 Anteroposterior pelvic radiograph showing Hilgenreiner's line **(a)** and Perkins' line **(b)**. The femoral head (ossific nucleus) of a normal hip lies in the inner lower quadrant. The right hip is normal, the left hip has developmental dysplasia of the hip.

Summary box 39.6

Diagnosis of developmental dysplasia of the hip

- Is always based on the history and clinical examination and then confirmed by appropriate investigations
- All neonates are screened clinically (Barlow and Ortolani tests), at birth and at 6 weeks
- Ultrasound is used to monitor hip stability/anatomy and often as a screening test in 'at-risk' babies
- Radiography is useful from 4 months onwards
- Older children present with a limp and/or tiptoeing.

Management

When diagnosed early, conservative treatment is usually successful, but after walking age surgery is required. The objective is to obtain a stable, congruous reduction of the femoral head into the acetabulum while avoiding damage to the capital epiphysis (avascular necrosis) or to the growth plate, which causes stiffness, coxa vara and shortening.

NEONATE

Owing to the hormonal effects in play during the perinatal period many hips are unstable initially. Most stabilise within the first few weeks of life and do **not** need treatment.

Hips that remain unstable at 6 weeks or that are dislocated at rest, are treated with harnesses or splints that obtain and then maintain hip reduction in the position of abduction and flexion. Most harnesses (**Figure 39.16**) allow controlled movement while splints hold the hips more rigidly and so may carry a greater risk of avascular necrosis (AVN). If the hips fail to relocate or stabilise then non-operative treatment should be discontinued.

INFANT

Successful treatment using a harness is unusual after the age of 4–6 months. For the late-presenting hip or the hip that

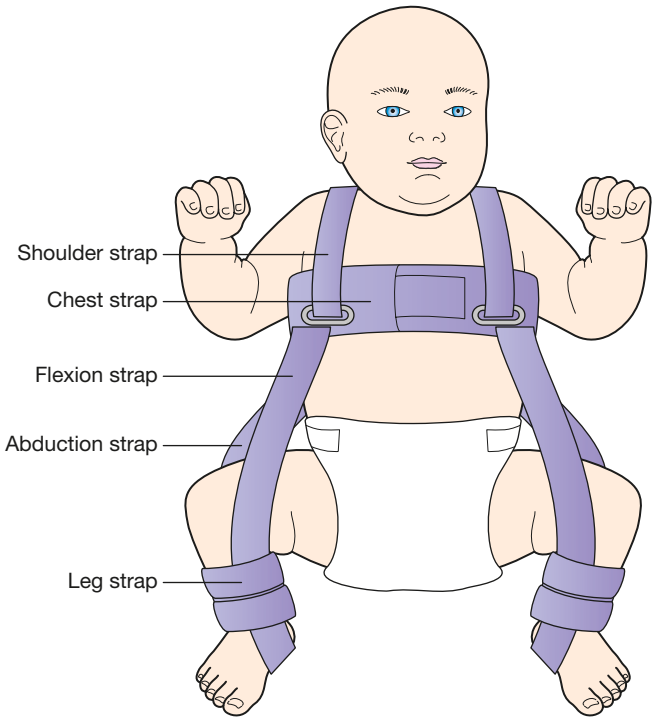

Figure 39.16 The anterior strap of the Pavlik harness controls hip flexion, whereas the posterior strap limits adduction and encourages abduction.

fails conservative treatment, an examination under anaesthetic may result in a closed reduction. The arthrogram shows whether a concentric reduction is present and, if not, it will indicate which structures are blocking reduction. A psoas/adductor release can be performed as necessary. Following a closed reduction, the hip will need to be held reduced with a hip spica cast for several months.

If the hip is irreducible or can only be held reduced in an extreme position with a small safe zone then treatment must be abandoned and an open reduction considered via a medial or anterior approach.

Summary box 39.7

Management of early developmental dysplasia of the hip

- Many hips that are unstable in the first few days/weeks of life do not need treatment as they improve spontaneously
- Up to age 4–6 months, a harness or splint is effective treatment
- In older babies, closed reduction is often possible and preferable to an open reduction
- For failed closed treatment, open surgical reduction is required

YOUNG CHILD OR TODDLER

The older the child, the less likely it is that reduction by closed methods will succeed (**Figure 39.17**) The traditional approach is then to carry out open reduction via an anterior approach around the age of 9–12 months. A pelvic osteotomy

Figure 39.17 Anteroposterior pelvic radiograph showing acetabular dysplasia with subluxation (developmental dysplasia of the hip) of the left hip. This child presented at the age of 4 years.

may be required to reorientate or close down the acetabulum, and femoral shortening or derotation osteotomies are often required to improve stability. Earlier surgery via the medial approach can be considered but no additional surgery such as capsulorraphy or bony realignment can be performed through that incision.

OLDER CHILD

In the older child a similar approach is necessary but pelvic and femoral realignment will always be needed, and the results tend to be less rewarding. Surgery is often avoided in children over the age of 6–8 years (bilateral cases) and the age of 8–10 in unilateral cases (**Figure 39.18**).

ADOLESCENT AND YOUNG ADULT

These hips are often subluxated rather than truly dislocated. On investigation, the hip may be reducible and the joint can be recreated with a combination of pelvic and femoral osteotomies. For the irreducible hip, acetabular augmentation may reduce symptoms and delay the onset of degenerative change.

Figure 39.18 Anteroposterior pelvic radiograph showing bilateral true dislocations in a 9-year-old child; the decision was made not to offer an operation. The pathology in these hips is different from that shown in Figure 39.17.

Summary box 39.8

Management of late-presenting DDH

- The older the child, the more likely it is that they will require surgery
- Femoral osteotomy can stabilise the hip and reduce pressure on the femoral head
- Pelvic osteotomy redirects or reshapes the acetabulum
- The potential for acetabular remodelling decreases after the age of 3–4 years
- Avascular necrosis is a risk with all DDH treatment

SECONDARY PROCEDURES AND COMPLICATIONS

Regular follow-up ensures that the hip development is monitored. Acetabular remodelling may be assessed objectively by measuring the acetabular index or the centre–edge angle (**Figure 39.19**).

If the acetabulum does not improve, a variety of pelvic osteotomies can be considered. AVN with overgrowth of the greater trochanter can cause a Trendelenburg limp and distal transfer of the trochanter may help (**Figure 39.20**). Occasionally, a leg length difference needs treatment. There is also an increased risk of osteoarthritis which may need arthroplasty later in life.

Legg–Calvé–Perthes' (LCP) disease

Incidence and aetiology

This rare condition, characterised by the development of avascular necrosis (AVN) of the proximal femoral epiphysis, affects boys predominantly between the ages of 4 and 7 years; 10% develop bilateral disease. Although the aetiology is unclear, several factors have been implicated (*Table 39.6*). There are also other causes of AVN of the femoral head (*Table 39.7*). Overall, the incidence appears to be declining.

TABLE 39.6 Factors implicated in the pathogenesis of Perthes' disease.

- Low birth weight
- Delayed bone age
- Short stature with rostral sparing
- Associated with congenital urogenital anomalies
- Socioeconomic deprivation

TABLE 39.7 Causes of avascular necrosis of the femoral head.

- Steroids
- Infection/surgery/previous injury or fracture
- Perthes' disease
- Sickle cell disease
- Hypothyroidism
- Skeletal dysplasia – classically multiple epiphyseal dysplasia

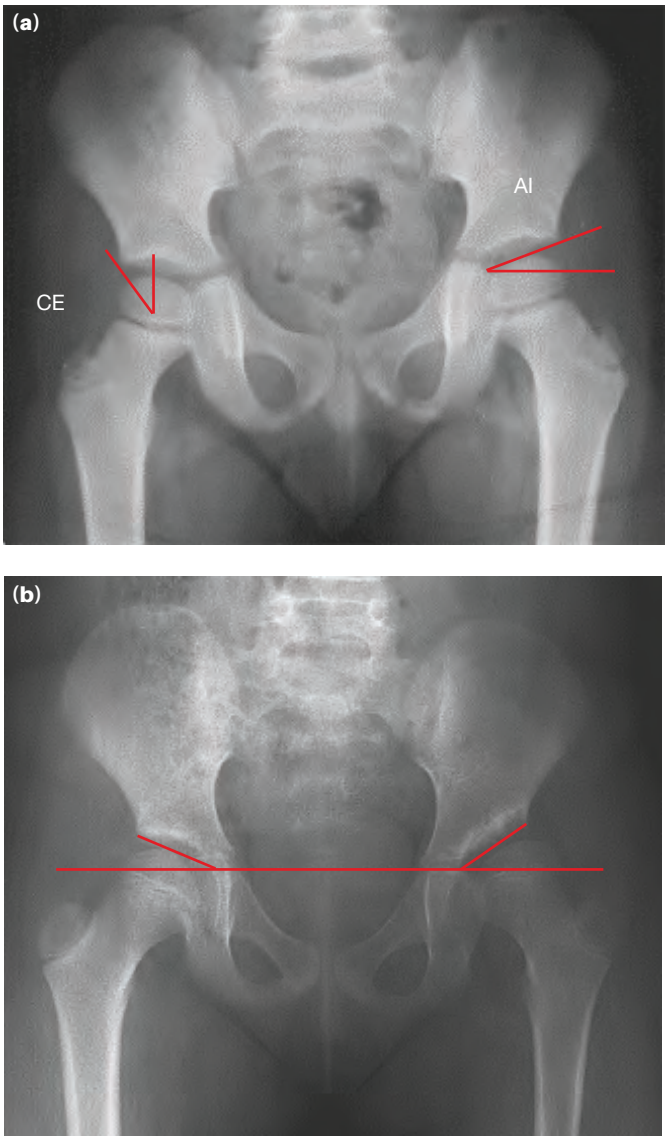

Figure 39.19 Anteroposterior pelvic radiographs demonstrating the acetabular index (AI) and the centre–edge (CE) angle: **(a)** normal hips; **(b)** the left hip shows residual dysplasia. The AI is increased when compared with the normal right hip. The left CE angle would be smaller than the right too but it has not been measured on this radiograph.

Pathology

Once established the process follows a well-described course. The avascular change may affect all or part of the femoral epiphysis. The avascular bone may collapse. This is followed by revascularisation, resorption and fragmentation of the dead ossific nucleus within the cartilaginous femoral head, and finally by reossification and regeneration ('healing') of the bony epiphysis. In this respect, Perthes' disease is a self-limiting condition but, during the collapse and fragmentation phases, femoral head deformity occurs as the cartilage 'follows' the shape of the newly reossified epiphysis. This change in

Legg, Calvé and Perthes all described osteochondritis of the head of the femur independently in 1910.
Arthur Thornton Legg, 1874–1939, orthopaedic surgeon, The Children's Hospital, Boston, MA, USA.
Jacques Calvé, 1875–1927, orthopaedic surgeon, La Fondation Franco-Americaine, Berck Plage, Pas-de-Calais, France.
Georg Clemens Perthes, 1869–1927, Professor of Surgery, Tübingen, Germany.

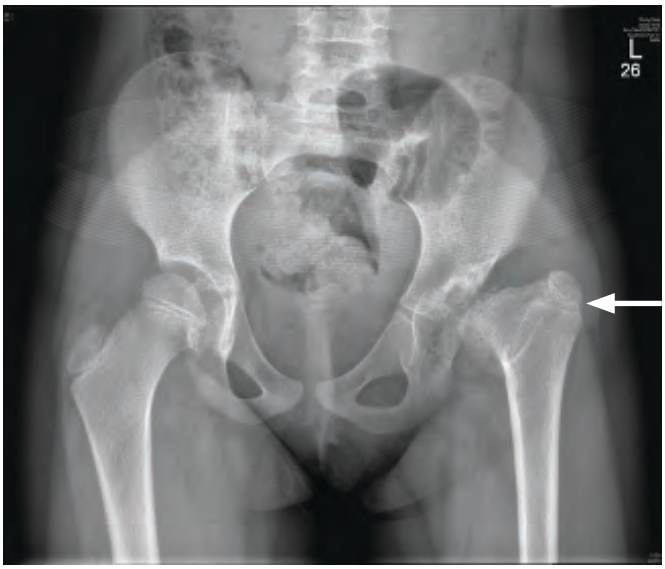

Figure 39.20 Anteroposterior pelvic radiograph of a 7-year-old girl who developed avascular necrosis secondary to a postoperative wound infection following a closed reduction of her dislocated left hip. Note the destruction of the femoral head and the proximal femoral physis, so that the femoral neck is short and the greater trochanter relatively high (arrow).

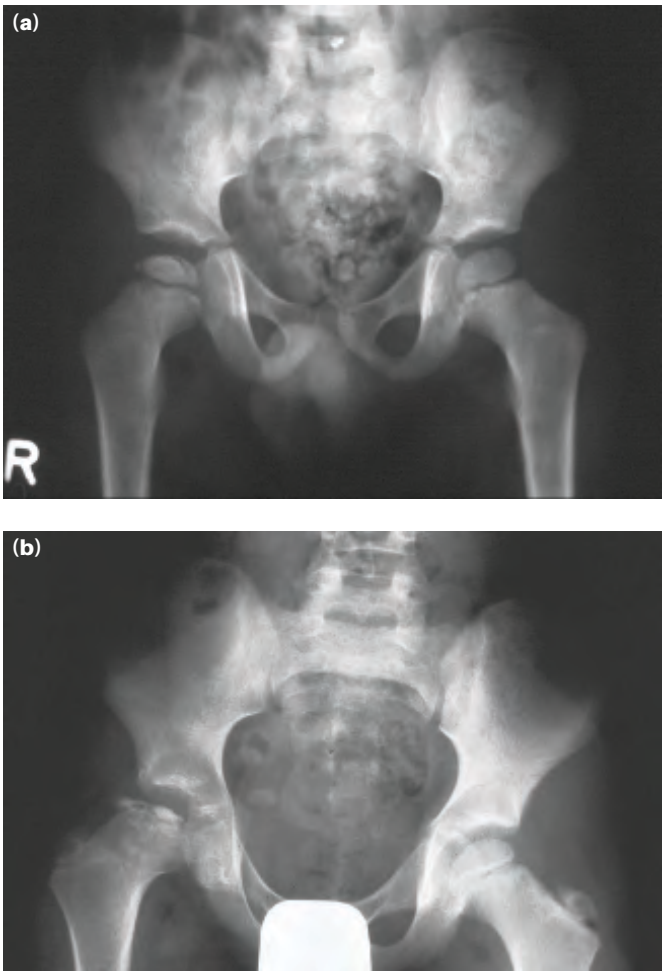

Figure 39.21 Anteroposterior pelvic radiographs of Perthes' disease demonstrating whole head involvement: **(a)** right-sided disease; the process is in an early phase and the area of dense necrotic bone is visible; **(b)** there has been collapse and fragmentation. The Catterall classification relates to how much of the epiphysis has been affected and the Herring classification relates to the height of the lateral pillar (lateral portion of the epiphysis) in the fragmentation phase of the disease.

shape is not reversible and has a permanent effect on the health of the hip joint.

Diagnosis

The history, clinical examination and anteroposterior and 'frog' lateral radiographs of the pelvis make the diagnosis. An intermittently painful hip (or knee) with a limp and irritability or restriction of hip movements requires investigation. The radiographic features vary with the disease stage and may not correlate with the clinical condition **(Figure 39.21)**.

AVN of the femoral head may be due to other causes and a differential diagnosis should be considered, particularly when changes are bilateral.

Management

The prognosis, and hence the management, is influenced by the extent of AVN and the degree of collapse. Traditionally, LCP disease has been classified with the Catterall classification but currently the popular system in use is the Herring classification; however, this can only be applied when the head is in the fragmentation phase. In both systems, if the anterolateral portion is preserved, the prognosis is good.

Treatment aims to minimise femoral head deformity and thus the likelihood of secondary acetabular dysplasia. This is achieved by maintaining a good range of joint movement, with some restriction in activity level, and using analgesia and physiotherapy as required. The routine use of crutches and/or wheelchairs is discouraged because they promote a flexion/adduction posture. Recent evidence suggests that brace management on its own does not alter the natural history of the condition.

The role of operative treatment is controversial. Surgery can be performed early to prevent deformity secondary to femoral head collapse or late to 'salvage' a poor mechanical situation when deformity is limiting movement *(Table 39.8)*. Joint distraction (arthrodiastasis) may preserve joint movement and maintain femoral head height but has not gained popularity.

Not all hips with deformity require 'salvage' surgery: young children, with more time to remodel, have a better prognosis as the acetabular changes (in response to the changed shape of the femoral head) result in an aspherical but congruent joint. Long-term follow-up may be required to deal with mechanical symptoms caused by loose osteochondral fragments, a Trendelenburg gait secondary to trochanteric overgrowth or a short-leg gait. Degenerative change may occur in adult life.

Other conditions (all eponymous) also show radiographic changes of AVN *(Table 39.9)*. Again, the radiographic changes 'heal' but the change in shape of the affected bone may lead to secondary joint stiffness and loss of function.

TABLE 39.8 A guide to some of the surgical options available for the management of Perthes' disease.

Timing	Type of procedure	Comments	Aim
Early	Femoral osteotomy	Varus and derotation Consider an opening wedge osteotomy to maintain length	To cover ('contain') the vulnerable femoral head
	Innominate osteotomy		
	Shelf acetabuloplasty		
Intermediate	Arthrodiastasis	Hinged distraction to allow movement, primarily flexion/extension	To reduce deforming pressures on the femoral head
Late	Femoral osteotomy	Valgus With extension to undo a fixed flexion deformity or flexion to remove the anterior bump from impinging on the acetabulum	To improve joint congruity and hence function; to improve joint mechanics
	Arthrotomy	To remove osteochondral fragments	
	Head-neck osteoplasty	After physeal closure	To improve head shape by reducing femoroacetabular impingement and increasing head/neck offset.
	Trochanteric epiphyseodesis or distal transfer	Epiphyseodesis probably not effective after age 7–8 years	To improve lever arm function
Contralateral limb	Distal femoral epiphyseodesis		To improve leg length discrepancy and reduce effects on hip joint mechanics

TABLE 39.9 Other conditions (commonly called osteochondroses) in which the radiographic appearance is of avascular necrosis.

Condition	Affected bone
Kienbock's disease	Lunate
Panner's disease	Capitellum of the humerus
Freiberg's disease	Metatarsal head – usually the second
Köhler's disease	Navicular

Summary box 39.9

Legg–Calvé–Perthes' disease

- Most common in boys aged 4–7 years
- AVN leads to femoral head collapse; the return of the blood supply heralds the resorption and reossification phases that allow the femoral head to 'heal'
- The prognosis is better in younger children (and in boys), who have more remodelling potential before skeletal maturity
- Management aims to maintain femoral head sphericity
- Treatment may be non-surgical (to maximise range of movement) or surgical (early for containment or late for 'salvage')

Slip of the upper (capital) femoral epiphysis (SUFE/SCFE)

The physis connects the proximal femoral epiphysis (the femoral head) to the metaphysis (femoral neck). In certain physiological or pathological conditions a 'stress fracture' through the physis allows the epiphysis to displace as it would with an intracapsular femoral neck fracture, so the leg lies short and externally rotated. There is painful limitation of hip movement. Hilton's law, which states that a joint is supplied by the same nerves as the muscles that move the joint, explains why many children present with knee pain although the pathology is in the hip.

Incidence and aetiology

SUFE or SCFE is rare, with an incidence of ~5 per 100 000 population. Boys are affected most commonly; the peak incidence is related to the start of puberty, hence it is earlier in girls. As a result of growth stimulated by hormonal changes, the strength of the growth plate, its resistance to shear and its orientation are reduced. The hip is therefore 'at risk' and normal forces, exacerbated by obesity and repetitive minor trauma, precipitate a slip. Other conditions such as hypothyroidism, renal failure and previous radiotherapy treatment (local or to the pituitary region) also increase the risk.

Diagnosis

The diagnosis is suggested by the history and examination and confirmed on plain radiograph (**Figure 39.22**). Displacement is often more obvious on a lateral view. Indeed, it can easily be missed by the unwary clinician if only the AP view is checked.

Classification

A SCFE can be classified according to three parameters: timing, severity and stability. The onset of symptoms divides

Robert Kienbock, 1871–1953, Professor of Radiology, Vienna, Austria, described this condition in 1910.
Hans Jessen Panner, 1871–1930, radiologist, of Copenhagen, Denmark, described this condition in 1927.
Albert Henry Freiberg, 1869–1940, Professor of Orthopaedic Surgery, The University of Cincinnati, Cincinnati, OH, USA, described this disease in 1926.
Alban Köhler, 1874–1947, radiologist, of Wiesbaden, Germany, described this disease in 1908.
John Hilton, 1805–1878, surgeon, Guy's Hospital, London, UK.

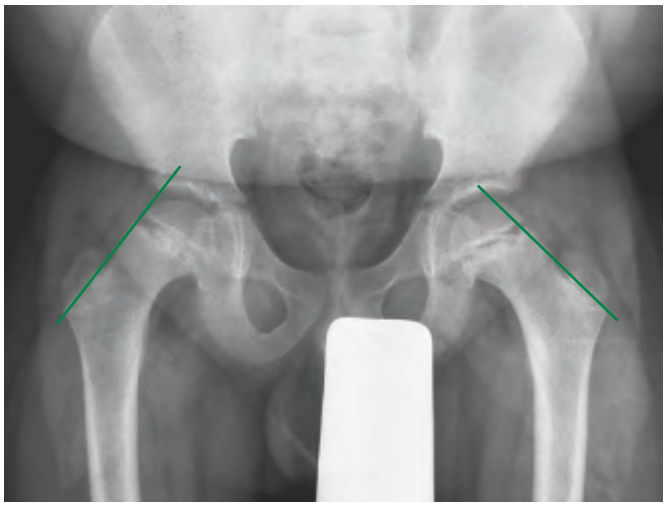

Figure 39.22 Anteroposterior pelvic radiograph demonstrating a mild slip of the upper (capital) femoral epiphysis on the right side. A line drawn along the upper margin of the femoral neck should transect the femoral head (left side) – if it does not do so (right side) a slip is present. There are many other radiographic features that help confirm the diagnosis but the changes are often subtle and may be seen first on the frog lateral view.

slips into those that are acute, chronic, or acute on chronic. Slip severity is assessed on the lateral radiograph in terms of percentage uncovering of the metaphysis (*Table 39.10*) or by measuring the slip angle of Southwick (**Figure 39.23**). An unstable slip is defined by Loder as one where the patient can not bear weight on the limb.

Management

Following an **acute** episode the patient is often completely unable to bear weight and the slip is considered to be **unstable**.

TABLE 39.10 Grading of the severity of slip of the upper (capital) femoral epiphysis.

Slip severity	Metaphysis uncovered (%)
Mild	<33
Moderate	33–66
Severe	>66

Displacement is often **moderate** or **severe**. This situation is essentially equivalent to a displaced intracapsular femoral neck fracture. This means that an acute unstable SUFE is an emergency. The AVN risk is considerable but is reduced by prompt screw fixation that stabilises the 'fracture' (**Figure 39.24**).

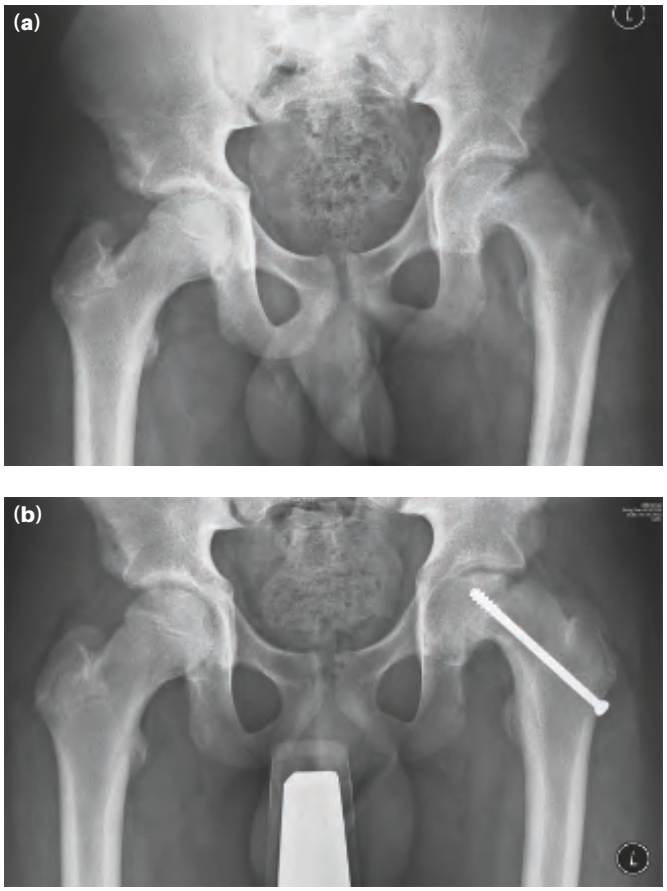

Figure 39.24 Anteroposterior pelvic radiograph showing a left-sided acute severe unstable slip of the upper (capital) femoral epiphysis: **(a)** at presentation; **(b)** following partial repositioning and fixation with a cannulated screw. When this heals, because of the incomplete reduction it is likely that the metaphysis will impinge on the acetabulum (FAI, femoroacetabular impingement) during movement, causing pain and leading to degenerative change.

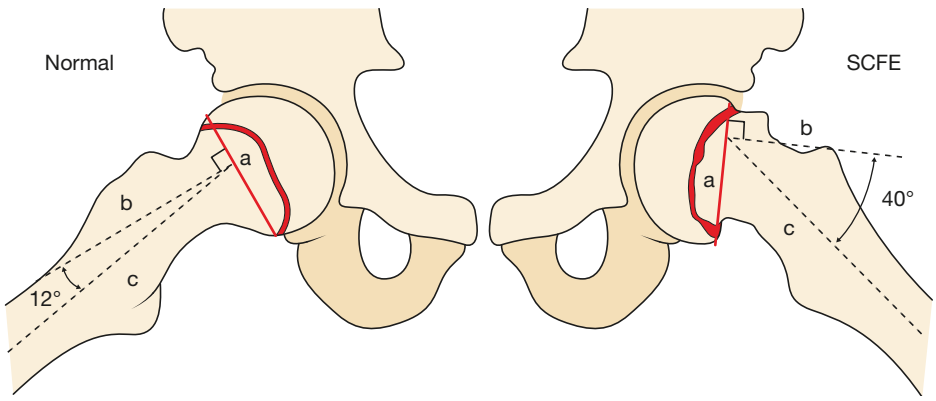

Figure 39.23 The Southwick slip angle is measured on a lateral radiograph and denotes how far the epiphysis has slipped off the metaphysis. The value on the normal side must be subtracted from the value on the abnormal side to get the true value. (SCFE, slip of the capital femoral epiphysis.)

Randall Loder, Professor of Orthopaedic Surgery, Philadelphia, PA, USA.

With the reduction in muscle spasm that accompanies a general anaesthetic, a gentle repositioning of the femoral epiphysis takes place as the externally rotated limb is lifted into the neutral position; no force must be used with this maneouvre. A capsulotomy also helps reduce the tamponade effect on the vessels to the epiphysis. To be effective such treatment must take place within 24 hours of injury. If delayed, the AVN rate increases.

With **chronic** slips the patient is usually able to bear weight, albeit with pain, and the slip is considered stable. Screw or pin fixation *in situ* relieves pain and often improves the range of movement but permanent reduction in abduction, flexion and internal rotation will be present (**Figure 39.25**). The leg will also always be slightly short.

In the **acute-on-chronic** case, repositioning of the acute element of the slip may be feasible.

In the **chronic severe** slip it may be impossible to place a screw in a satisfactory position in the epiphysis, even by starting anteriorly on the neck. In addition, once healed, there may be significant, persistent deformity leading to restriction of joint movement. In these cases a realignment osteotomy may be considered. As with all osteotomies, the closer the correction is to the site of deformity, the better the outcome. However, in this situation the centre of rotation of angulation (CORA) for the deformity is at the level of the physis; the risk of AVN or chondrolysis may be unacceptably high with an osteotomy at this level, and so an intertrochanteric osteotomy could be considered. The slipped epiphysis is associated with a 'cam' type of femoroacetabular impingement and this may require treatment with a head-neck osteoplasty to restore the offset between the head and neck.

Bilateral slips do occur and prophylactic pinning of the normal but 'at-risk' hip may be indicated.

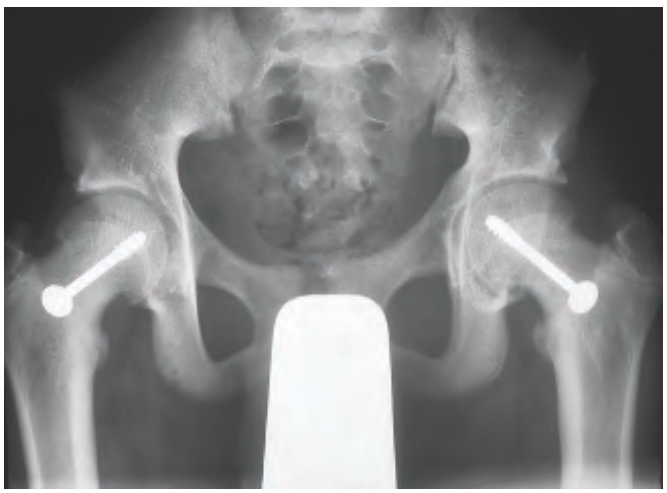

Figure 39.25 Anteroposterior radiograph showing screw fixation *in situ* of a case of bilateral chronic slip of the upper (capital) femoral epiphysis. Note the position of the screw: the more severe the slip, the more proximal and more anterior the screw entry point has to be on the femoral neck.

Summary box 39.10

Slip of the upper (capital) femoral epiphysis

- Occurs in prepubertal children, boys more commonly than girls
- Often presents with knee pain, and the leg may be short and externally rotated
- Classification systems relate to timing, severity and stability–all affect the prognosis
- Most slips are pinned *in situ* with a single screw into the centre of the epiphysis
- AVN is the most feared complication of both the condition and its treatment

ABNORMALITIES OF THE KNEE AND LOWER LEG

Many knee problems in children or adoloescents are self-limiting. Others require surgical consideration to reduce the risk of later degenerative change.

Osteochondritis dissecans (OCD)

OCD most commonly affects the lateral aspect of the medial femoral condyle of the distal femur (but also the talus and the humerus). An osteochondral fragment becomes partially or completely separated from the joint surface. Magnetic resonance imaging (MRI) is the best method for demonstrating the site, extent and stability of the lesion. In mild cases, the osteochondral fragment remains attached and heals, particularly if treated early with rest and activity modification. If it detaches, partially or completely, mechanical symptoms necessitate treatment either to encourage bone healing via fixation of the fragment or to remove a loose body. Younger children have a better prognosis.

Discoid meniscus

This invariably affects the lateral meniscus, which is abnormally thick and covers most of the tibial plateau. The child presents with a painful clunk on knee extension. MRI is usually diagnostic. Surgery is indicated for relief of pain or mechanical symptoms.

Anterior knee pain

In adolescents the extensor mechanism of the knee is a common site of knee pain.

Osgood–Schlatter disease is a traction apophysitis of the patellar tendon insertion. Pain, tenderness and swelling at the tibial tubercle, exacerbated by exercise, are diagnostic and radiographs are unnecessary (except in unilateral cases, where it is important to exclude a diagnosis such as a malignancy). Treatment is relative rest and analgesia, and the condition resolves once the apophysis has fused.

Robert Bailey Osgood, 1873–1956, Professor of Orthopaedic Surgery, Harvard University Medical School, Boston, MA, USA.
Carl Schlatter, 1864–1934, Professor of Surgery, Zurich, Switzerland. Osgood and Schlatter described osteochondritis of the tibial tubercle independently in 1903.

Patellofemoral pain is common and often attributed to an adolescent growth spurt: symptoms are exacerbated either by activity or by rest with the knee in the flexed position. Alterations to activity levels and sitting position, physiotherapy to stretch and strengthen both the hamstrings and the quadriceps muscles and time usually result in a return to normal within a few months.

Anterior knee pain may be associated with a degree of patellar maltracking and/or instability. Treatment starts with physiotherapy to develop the quadriceps muscles, particularly the vastus medialis oblique (VMO) and to counteract any wasting secondary to the pain. There are a multitude of operations described to improve patellar tracking and these include options for realignment of the extensor mechanism both proximally and distally.

Fibular hemimelia

In fibular hemimelia there is a congenital failure of formation of the lateral 'column' of the lower leg (**Figure 39.26** and *Table 39.11*).

Management is tailored to the severity of the deficiency. Treatment options range from a shoe raise, through multiple episodes of limb equalisation surgery, to amputation for the worst cases. An early prediction of the leg length discrepancy at maturity allows a realistic treatment plan to be devised for the patient, which should include consideration of a contralateral epiphysiodesis.

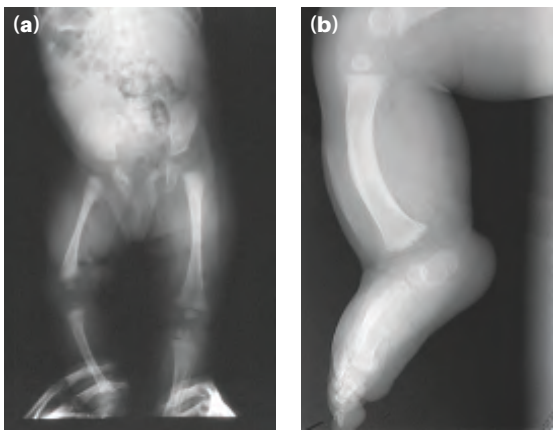

Figure 39.26 Anteroposterior **(a)** and lateral **(b)** radiographs of two lower limbs showing some of the features of a fibular hemimelia: absent 5th ray in the foot, absent fibula and deformed tibia.

TABLE 39.11 Classical radiographic features of fibular hemimelia.

Foot and ankle	Absent lateral rays; tarsal coalition; ball and socket ankle joint
Lower leg	Absent or deficient fibula; short bowed tibia
Knee	Absent tibial spine (no cruciate ligament); deficient lateral femoral condyle
Femur	Relative hypoplasia
Limb length and alignment	Short; external rotation ± valgus

Blount's disease

The aetiology of this disordered growth in the posteromedial proximal tibial physis is unknown. The infantile form is more common in Afro-Caribbeans but the adolescent-onset disease affects all ethnic origins. The child presents with progressive and often severe tibia vara with significant intoeing. The radiographic features are diagnostic **(Figure 39.27)**.

Treatment is surgical: following correction of limb alignment via an osteotomy, an epiphyseodesis of the remaining physis may be necessary to prevent recurrence. In unilateral cases, the limb once straightened is short and concomitant tibial lengthening with an external fixator is often an attractive option.

Congenital pseudarthrosis of the tibia

This rare condition presents clinically with an anterolateral bow of the tibia with or without a fracture. Classic radiographic changes are noted and 50% are associated with neurofibromatosis. Once fractured the tibia is reluctant to heal. Long-term orthotic treatment may be necessary, with subsequent surgical procedures designed to obtain bony union and restore leg length **(Figure 39.28)**.

Figure 39.27 Standing leg length and alignment radiograph of a child with bilateral asymmetrical bow legs. Both proximal and medial tibial physes/epiphyses are abnormal: this is bilateral Blount's disease.

Walter Putnam Blount, 1900–1992, Professor of Orthopaedic Surgery, Marquette University, Milwaukee, WI, USA, described this condition in 1937.

Figure 39.28 Anteroposterior radiograph of a child showing a congenital tibial pseudarthrosis. She was actually born with a bowed lower leg that subsequently fractured. She has a family history of neurofibromatosis.

Figure 39.29 Anteroposterior photograph of a foot showing the classic deformities associated with a clubfoot. The hindfoot is in equinus and varus, there is midfoot cavus and the forefoot lies adducted and apparently supinated, although actually pronated relative to the hindfoot.

Summary box 39.11

Abnormalities of the knee and lower leg

- Osteochondritis dissecans – better prognosis in children than adults
- Discoid meniscus – usually lateral, may require surgery
- Anterior knee pain – treatment almost always conservative
- Fibular hemimelia – associated with abnormalities from the foot proximally (foot worse than hip), the tibial bow has an anteromedial apex
- Blount's disease – clinically, a sharp proximal tibial angulation
- Congenital pseudarthrosis of the tibia – the tibial bow has an anterolateral apex
- Posteromedial apex tibial bow – largely physiological, the bow improves with time but the limb may be short

ABNORMALITIES OF THE FOOT AND ANKLE

Parents are often concerned that minor foot abnormalities will cause their child to be clumsy or slow. This is rarely the case, so reassurance is a cornerstone in the management of abnormalities of the foot and ankle in children.

Congenital talipes equinovarus (CTEV) (the 'club foot')

The club foot is deformed in three planes (**Figure 39.29**). In true CTEV the deformity is fixed. Intrauterine moulding can cause an identical pattern of deformity that is postural and therefore correctable.

Incidence and aetiology

The reported incidence varies from 1 to 6 per 1000 live births, depending on racial differences. It is more common in boys and bilateral in approximately 50% of cases. A family history is common but inheritance is multifactorial. The diagnosis of CTEV may be made during an antenatal ultrasound: the sensitivity is higher in bilateral cases, and these patients are statistically more likely to have a syndromic association. In some countries, the detection of such an abnormality leads to consideration of a termination of the pregnancy but the parents can be reassured that with treatment their child will walk, run and play with his/her peers.

Most cases are idiopathic but because the outcome varies with the aetiology it is important to consider the cause when planning treatment (*Table 39.12*). Many of the idiopathic cases will have some weakness of the evertor muscles.

Pathology

The talonavicular joint is subluxated, with the navicular displaced medially with respect to a deformed talar head and neck. Ligaments, particularly the calcaneofibular ligament, and tendon sheaths, such as the posterior tibial tendon sheath, are shortened and thickened and contain contractile myofibroblasts. The gastrocsoleus and posterior tibial muscles are smaller than normal, with reduced myofibrils and increased connective tissue, possibly because of a local neuromuscular abnormality. The vascular supply via the dorsalis pedis may be diminished. It remains unclear which abnormalities are primary and which occur as the deformity develops.

Clinical assessment

It should be possible to distinguish the postural clubfoot from the structural (rigid) foot soon after birth. The postural clubfoot may benefit from physiotherapy stretches but, by

TABLE 39.12 Several different types of clubfoot are recognised.

Type	Example
Postural	
Idiopathic	
Neuromuscular	Spina bifida; arthrogryposis;
Syndromic	Trisomy 15

definition, it must be completely normal by 3 months of age with 45° of forefoot abduction, full ankle dorsiflexion with the calcaneus well down in the heel pad, no significant medial crease and only shallow/multiple posterior creases.

In contrast, the structural idiopathic clubfoot has fixed deformity with elements of hindfoot equinus and varus, midfoot adductus and pronation of the first ray, giving the appearance of forefoot cavus. The heel feels 'empty' as the calcaneus is held up by the shortened tendo Achilles. There is a deep medial and a single posterior crease.

All children with structural clubfoot deformity will have a small calf and foot and some tibial shortening but this may not be apparent until later in childhood. Children should be examined carefully for neurological signs of intraspinal pathology.

Both Pirani and Dimeglio have developed scoring systems, based on the appearance of the foot in its position of maximal correction, which predict treatment response and hence outcome.

Summary box 39.12

Clubfoot

- Multiplanar deformity: hindfoot equinus and varus, midfoot adductus and forefoot cavus
- Incidence is 1–6 per 1000 live births, more common in boys and with a familial tendency
- Most cases are idiopathic but neuromuscular causes include spina bifida and arthrogryposis
- Scoring systems (Pirani/Dimeglio), are used to assess the severity

Treatment

PONSETI METHOD

The method described by Ponseti corrects foot deformity in 95% of idiopathic cases without the need for a formal surgical release and has now become the treatment of choice for all such feet. Treatment commences within a few days of birth. A specific series of manoeuvres, followed by a series of well-moulded above-knee plaster casts, results in gradual correction of the deformity (**Figure 39.30**). The head of the talus is the fulcrum around which the rest of the foot rotates. After the forefoot has been corrected, most feet (about 80%) require a percutaneous Achilles tenotomy (performed under local anaesthetic in the clinic setting) in order to dorsiflex the foot satisfactorily.

Figure 39.30 A photograph of a series of casts documenting the stepwise correction of the foot deformity with the Ponseti method of serial manipulation and casting.

Once corrected the foot position is maintained by a foot abduction orthosis (FAO) that holds the feet in external rotation and slight dorsiflexion. The FAO is worn full-time for 3 months and at 'night and nap-time' for up to 4 years. Poor compliance with the FAO is associated with a higher relapse rate. Recurrent deformity can be treated with further plasters, but a tibialis anterior tendon transfer may be required around the age of 2.5–4 years for persisting dynamic supination.

Feet treated with the Ponseti method are less stiff, less likely to be painful and less subject to overcorrection than those treated surgically. The Ponseti method is significantly better than other reported conservative regimes. It also works reasonably well in non-idiopathic feet but both the failure and relapse rates are higher.

SURGICAL TREATMENT

When conservative treatment fails, surgical intervention is required, ideally before walking age.

Surgical release is generally performed 'à la carte', with sequential release of the pathologically tight structures via either a Turco incision or the Cincinnati incision (*Table 39.13*) to reduce the subluxated joints. Stabilisation may require the use of temporary Kirschner wires. Deformity correction should not be compromised by wound closure and the Cincinnati incision can be left to heal by secondary intention if necessary.

TABLE 39.13 The four stages of a peritalar release that may be required for the correction of a severe clubfoot deformity.

Site	Structures requiring lengthening or release
Posterior	Tendo Achilles
	Ankle and subtalar joints
	Calcaneofibular ligament
	Posterior elements of the peroneal tendon sheaths
Medial	Abductor hallucis
	Tibialis posterior
	Talonavicular joint
	Toe flexors
Lateral	Calcaneocuboid joint
Plantar	Plantar ligaments
	Plantar fascia
Protect	*Neurovascular bundle*
	Talocalcaneal interosseous ligament (if possible)

Martin Kirschner, 1879–1942, Professor of Surgery, Heidelberg, Germany, introduced the use of skeletal traction wires in 1909.

Postoperative casting is followed by splinting and physiotherapy as required. Good or excellent results are reported in 60–80% of children treated surgically but stiffness and over- or undercorrection are common complications.

Surgery for residual or recurrent deformity is often difficult and requires a careful assessment of the forefoot, hindfoot and tibial torsion. Surgical procedures may involve further soft-tissue releases or tendon transfers but, in the presence of fixed deformity, bony correction is often necessary. The foot becomes progressively stiffer with each surgical intervention.

Summary box 39.13

Treatment of clubfoot

- The Ponseti method of serial casting is successful in 95% of feet when defined as avoiding formal surgical release
  - The standard sequence of manipulations is:
    C – correction of the apparent forefoot **cavus** by elevation of the first ray
    A – gradual forefoot **abduction** to 60°, and simultaneous
    V – correction of the hindfoot **varus**
    E – correction of hindfoot **equinus** which usually follows a percutaneous Achilles tenotomy, which is an integral part of this treatment method
- Tibialis anterior tendon transfer (TATT) can be used to correct dynamic supination in older children

If the Ponseti method fails:

- Surgical release may be needed to address posterior, medial, plantar and lateral structures, and will result in a stiffer foot than one treated conservatively

Figure 39.31 Congenital vertical talus: **(a)** lateral photograph demonstrating a 'rocker-bottom foot'; **(b)** lateral radiograph showing hindfoot equinus and suggesting dorsal subluxation of the non-ossified navicular and forefoot with respect to the head of the talus.

Other foot and ankle conditions

Most postural deformities such as metatarsus adductus and calcaneovalgus feet improve spontaneously.

Congenital vertical talus (CVT) is rare and often associated with neuromuscular conditions such as arthrogryposis and spinal dysraphism. Clinically, there is a stiff 'rocker-bottom' foot with dorsal dislocation of the navicular on the talus (**Figure 39.31**). Correction is surgical although a 'reverse' Ponseti method with a limited surgical approach to reduce the talonavicular joint and a percutaneous Achilles tenotomy is showing some good early results.

In **tarsal coalition** there is failure of segmentation of adjacent tarsal bones. School-age children present with hindfoot pain and recurrent ankle sprains. The stiff subtalar joint cannot accommodate uneven ground. The most common coalitions are talocalcaneal and calcaneonavicular (see **Figure 39.4**). Radiographs, computed tomography (CT) or MRI may be required to confirm the diagnosis. Treatment is initially conservative but if the coalition requires surgical excision, this should be carried out before significant degenerative changes develop.

Curly toes that are flexed and medially deviated are common, often familial and rarely need treatment. Strapping is ineffective. Flexor tenotomy is used when there are symptoms or cosmetic concerns.

Other causes of foot pain in children include osteochondroses:

- **Freiberg's osteochondrosis** presents with forefoot pain and avascular change in the second metatarsal head. It may be asymptomatic and present as an incidental finding on a radiograph. Symptomatic bony spurs and osteochondral fragments may need excision.

Summary box 39.14

Other foot and ankle conditions

- Congenital vertical talus – presents as 'rocker-bottom' foot
- Tarsal coalition – presents as a stiff, painful flat foot
- Curly toes are common – most do not need treatment
- Osteochondroses – almost always self-limiting

Ignacio Ponseti, 1914–2009, faculty member of the University of Iowa, USA. Born in Menorca, fled Spain during the Civil War because of the political situation, worked as a general practitioner in Mexico and then went to Iowa to train in orthopaedics. The technique that bears his name only became popular years after he retired – but it brought him back to work for another 20 years.

- **Köhler's disease** presents with dorsal forefoot pain and swelling in young children. The navicular becomes avascular and there is alteration in the ossification process. The alarming radiological appearance resolves spontaneously and without sequelae.
- **Sever's disease** (enthesopathy of the calcaneal apophysis) presents with heel pain related to activity. Tightness in the calf muscle complex may be a contributing factor. The 'features' on a radiograph are, in fact, part of normal growth and development.

ABNORMALITIES OF THE UPPER LIMB

Minor finger abnormalities are common (*Table 39.14*) but not all require surgical intervention. Comfort and function are more important than appearance.

Function is also the most important consideration when managing more extensive upper limb abnormalities. Treatment is often delayed until hand dominance is established and it is clear what problems a specific deformity is causing a given child. Children are very adaptable and cope with disabilities much more readily than their parents/doctors expect.

Radial club hand

This longitudinal failure of formation is commonly associated with other malformations, for example as part of the VACTERL syndrome (abnormal **v**ertebrae, **a**nus, **c**ardiovascular system, **t**rachea, o**e**sophagus, **r**enal system and **l**imb buds). The clinical problem depends, most specifically, on whether the thumb is present and functional (**Figure 39.32**). Treatment is a balance of conservative measures, including physiotherapy and splinting, and judicious surgery to centralise and stabilise the hand and wrist on the single bone forearm.

TABLE 39.14 Common minor congenital anomalies affecting the hand.

Anomaly	Definition	Treatment
Extra/accessory digits		Excise/amputate when necessary
Syndactyly	Failure of separation of digits	Separation with/without skin grafting for functional or cosmetic reasons
Trigger thumb (digit)		Release of the A1 pulley of the flexor tendon sheath
Clinodactyly (usually the fifth digit)	Abnormal angulation of the digit in the radioulnar plane	Surgical treatment of the delta phalanx if deformity progressive or interfering with hand function
Camptodactyly (usually the fifth digit)	Fixed flexion deformity of proximal interphalangeal joint	Splinting/physiotherapy; surgery rarely indicated

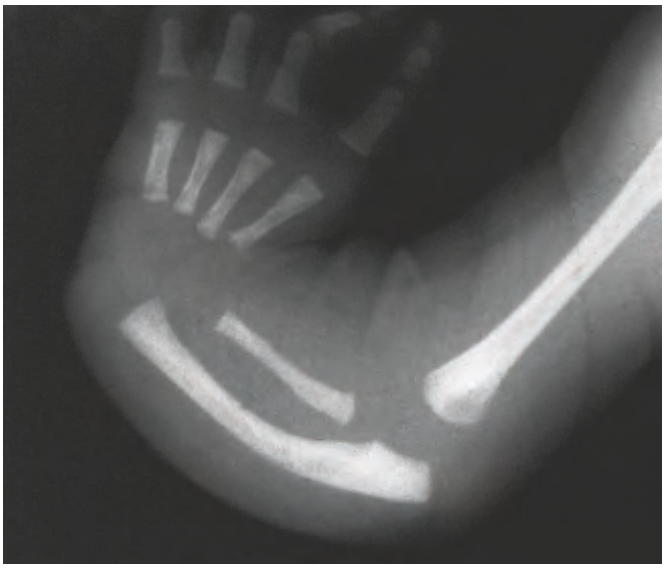

Figure 39.32 Anteroposterior radiograph of a radial club hand demonstrating a short radius, a deformed ulna and an absent thumb.

Thumb reconstruction may be technically challenging. In later childhood, forearm lengthening may be considered.

Radioulnar synostosis

Failure of proximal separation of the embryonic radius and ulna means that the forearm never develops the ability to pronate or supinate. The hand, on the end of the forearm, is therefore in a fixed position somewhere along the arc from full pronation–neutral–full supination and the child presents if this fixed position results in a functional problem. Osteotomy of the forearm bones can change the fixed position (for example, from pronation to neutral) but does not restore movement. Attempts at undoing the synostosis are not successful. If surgery is comtemplated, the choice of the position post surgery will depend on hand dominance, cultural considerations and functional demands.

Congenital radial head dislocation

The dislocation is usually posterolateral, compared with the classic traumatic anterior dislocation (**Figure 39.33**). Some restriction of elbow joint movement and forearm rotation is noted along with discomfort on activity. Radial head excision may be required after skeletal maturity.

Summary box 39.15

Upper limb abnormalities

- Radial club hand is frequently associated with other congenital anomalies, for example the VACTERL or Holt–Oram syndromes
- Radioulnar synostosis presents with a fixed forearm position in childhood
- Congenital radial head dislocation is usually posterolateral

James Warren Sever, 1878–1964, orthopaedic surgeon, The Children's Hospital, Boston, MA, USA, described apophysitis of the os calcis in 1912.

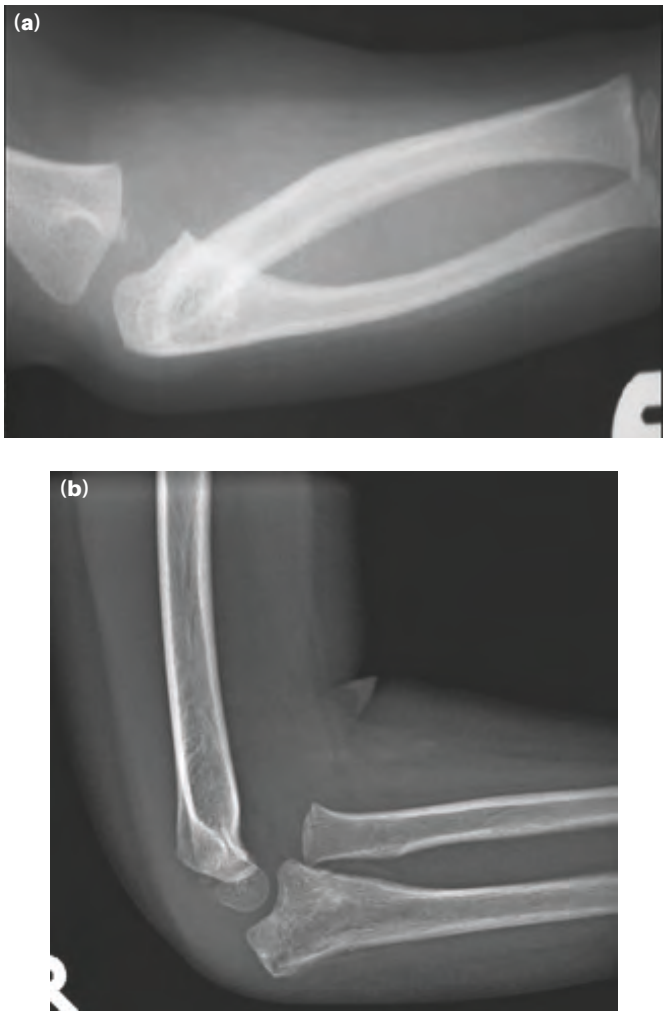

Figure 39.33 Radial head dislocation: **(a)** lateral radiograph of a forearm showing a proximal radioulnar synostosis with a congenital posterolateral dislocation of the radial head. Note the underdeveloped radial head and neck and compare with **(b)**, a lateral radiograph of a traumatic anterior dislocation of the radial head with a normal appearance to the head and neck and a deformity in the proximal ulna.

SPINAL DEFORMITIES AND BACK PAIN

Congenital deformities

Congenital vertebral deformities are failures either of formation (a hemivertebra) or of segmentation (unilateral or bilateral fusions or bars). The clinical result is usually a scoliosis (**Figure 39.34**). Treatment should be based on the potential for curve progression. When a kyphosis develops, progressive neurological deficit is common. Bracing is ineffective for congenital vertebral deformities.

Scoliosis

The term 'scoliosis' describes spinal deformity in three planes: lateral curvature is the most obvious deformity while the rotational component is most apparent in forward flexion when

Figure 39.34 Anteroposterior radiograph of the spine demonstrating multiple congenital vertebral anomalies including hemivertebrae.

the rib asymmetry creates a 'rib hump' (**Figure 39.35**). The cause may be idiopathic, neuromuscular, syndrome-related or congenital. Both the aetiology and the age of onset affect the natural history (*Table 39.15*). In general, the earlier the onset, the more likely the deformity is to be progressive. As so much lung development occurs in early childhood, the management of early-onset scoliosis must preserve growth: casting techniques or the use of 'growing rods' may be appropriate.

The adolescent idiopathic curve is the most common, affecting girls more than boys. Idiopathic scoliosis is generally not painful and, therefore, in the presence of significant pain

TABLE 39.15 Classification of idiopathic scoliosis.

Type	Age at onset
Early onset	<10 years
Adolescent	11–18 years
Adult	Onset at maturity

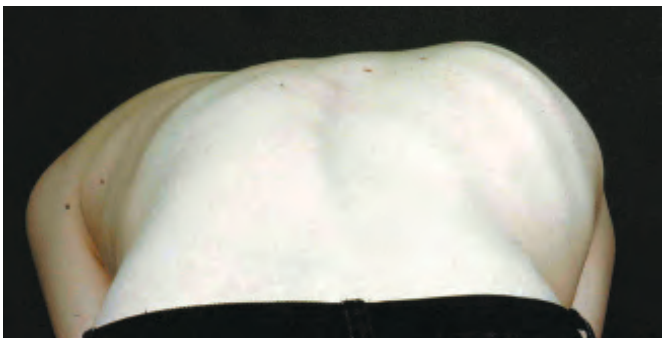

Figure 39.35 Clinical photograph of the Adams forward bend test that demonstrates the presence of a rib hump and the level of the curve.

tumour and infection must be excluded. The Cobb angle is a radiological measurement that defines severity and helps to guide treatment (**Figure 39.36**). Curves <20° do not need treatment, progressive curves of 25–40° may be braced, and those >40° are considered for surgery, which involves instrumenting the spine and fusing it (see also Chapter 33).

Summary box 39.16

Scoliosis

- Multiplanar deformity includes an unsightly rotational component
- Aetiology may be congenital (underlying bony malformation), neuromuscular, syndromic or idiopathic
- A leg length discrepancy causes a postural scoliosis
- Adolescent idiopathic scoliosis is the most common structural scoliosis
- Back pain associated with scoliosis may be due to infection or tumour
- Treatment depends on the severity and likelihood of curve progression – it varies from observation, through bracing, to surgery

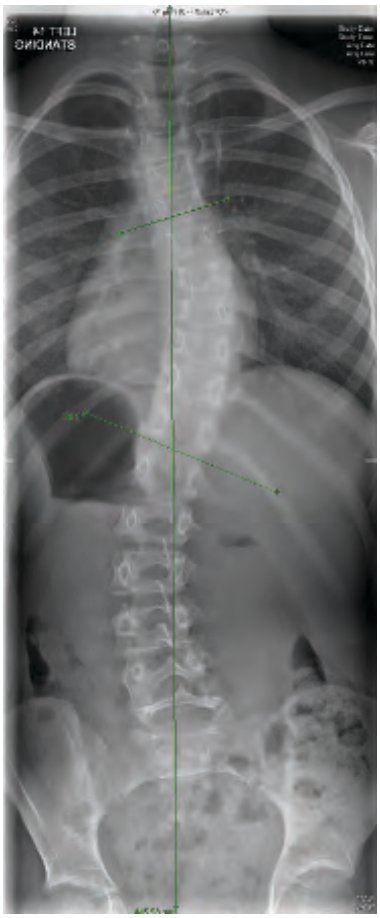

Figure 39.36 Anteroposterior radiograph of a spine with a scoliosis (right thoracic), with a Cobb angle of 40°.

Kyphosis

When a kyphosis exceeds the normal 20–50° the cause may be postural or structural. Structural kyphosis is commonly secondary to **Scheuermann's disease**, presenting as a progressive adolescent kyphosis characterised radiologically by ≥5° vertebral wedging at three adjacent levels and end-plate changes. The aetiology is unknown. Treatment ranges from physiotherapy and bracing to surgery, depending on severity, progression and symptoms.

Spondylolisthesis

Spondylolysis defines a defect in the pars interarticularis of the vertebra. There are six types: congenital (dysplastic facet joints), isthmic (weak or elongated pars), degenerative, post-traumatic, pathological and post-surgical. **Spondylolisthesis** occurs when the upper vertebra slips forward on the lower; it is graded according to the percentage slip, measured by relating the slipped vertebra to the one below (*Table 39.16*).

Mild slips are often asymptomatic and do not require treatment. Treatment (physiotherapy, bracing and surgery) depends on the degree of slip and symptoms; mechanical back pain may respond to conservative methods but neurological involvement usually requires surgical intervention.

Torticollis

In torticollis the head is tilted towards and rotated away from the tight sternocleidomastoid muscle.

Congenital torticollis is usually secondary to intrauterine moulding but may present with fixed sternocleidomastoid contracture or with a palpable 'tumour' within the muscle. There is a strong correlation with DDH. Most cases resolve with stretching but persistent cases develop facial asymmetry and require surgical release of the sternocleidomastoid at one or both ends.

Acquired torticollis is less common and may be caused by gastro-oesophageal reflux, posterior fossa tumour/other regional abnormality, inflammation/infection, ocular problems or atlantoaxial rotatory subluxation.

TABLE 39.16 Classification of spondylolisthesis according to severity of the slip.

Grade	Percentage slip
0	No slip
1	<25%
2	26–50%
3	51–75%
4	>75%
Spondyloptosis	>100% – complete translation

Holger Werfel Scheuermann, 1877–1960, radiologist, The Municipal Hospital, Sundby, Copenhagen, Denmark, described juvenile kyphosis in 1920.

Back pain

Children report back pain less frequently than adults, although >50% will have had an episode by late adolescence. Back pain in a child is a 'red flag' for serious spinal pathology but if mild, intermittent or occurring only on strenuous activity, it is usually self-limiting: many children do suffer posture related discomfort. Physiotherapy designed to improve core strength and stability leads to a reduction in symptoms, if exercises are performed regularly.

Summary box 39.17

'Red flag' symptoms and signs for spinal pathology

- Systemic illness, fever or weight loss
- Progressive neurological deficit
- Unrelenting or night pain
- Spinal deformity

All 'red flag' signs require urgent further investigation with a full blood count (FBC), erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), plain radiograph and MRI or other appropriate imaging. Other causes of back pain include intra-abdominal, renal and systemic pathology; all must be considered.

Summary box 39.18

Other spinal conditions

- Excessive kyphosis may be caused by Scheuermann's disease
- Spondylolisthesis is forward slip of one vertebra on another; it may cause mechanical and, rarely, neurological symptoms
- Torticollis may be congenital and usually responds to stretching of the fibrosed sternocleidomastoid muscle
- Acquired torticollis may be due to one of several significant pathologies
- Back pain with red flag symptoms and signs requires urgent investigation

NEUROMUSCULAR CONDITIONS

Joint stability and limb function rely on the complex integration of the musculoskeletal and neurological systems. Damage to either leads to one of several conditions linked only by the fact that they are incurable and often progressive, particularly during the period of skeletal growth. Management is directed at helping the child cope with their disability, minimising further deterioration and maximising function. It is important to have an understanding of what the damage is and what the future holds (*Table 39.17*).

Spina bifida and polio are classic lower motor neurone lesions, whereas cerebral palsy and head injuries affect upper motor neurones and the higher centres. There are often other disabilities such as blindness, epilepsy and intellectual difficulties to consider.

TABLE 39.17 Factors to be considered in the assessment of a neuromuscular disability.

Is the insult to the neurological system progressive or nonprogressive?
Is it located centrally or peripherally?
Is it general or focal?
Is it associated with other abnormalities or not?
If the insult is not neurological, is is myopathic?

In children, even if the initial insult to the neuromuscular system is non-progressive, the effects of the insult change with growth. Damage at any level of the neuromuscular system leads to an alteration in tone and muscle imbalance associated with decreased control of movement. Abnormal muscle pull, particularly in combination with the effects of gravity, alters bone growth, leading to deformity and joint contracture. Muscles are relatively weak and, with body growth and a weight increase, they are no longer strong enough to control a heavier limb, particularly when deformity means they are working at a mechanical disadvantage.

A multidisciplinary approach to management is essential. Good physiotherapists and orthotists will reduce the need for surgical intervention and in the postoperative period they help ensure that the surgical benefits are maximised. In conditions such as Duchenne muscular dystrophy there is substantial evidence for the benefits of certain surgical procedures; however, in other conditions (cerebral palsy) there are fewer such long-term validated studies.

In general, it is important to maintain a full range of joint movement, muscle length and tendon excursion. This is easier to achieve in patients with a flaccid paralysis or low tone. The maintenance of muscle strength is also important. The use of splints, positioning techniques, seating and sleeping systems is common with the aim of preventing fixed contractures.

Surgery has a valuable role in the management of selected patients (*Table 39.18*).

The surgeon must understand that altering ankle posture may affect knee and hip posture/function and vice versa. The patient must have the intellectual ability and motivation to recover from the surgical procedure. Some of the factors mentioned previously (see *Table 39.17*) must be considered in any holistic approach to the patient.

Summary box 39.19

Principles of treatment of neuromuscular conditions

- A neurological defect, whether progressive or not, may cause progressive deformity as the skeleton grows
- A multidisciplinary approach is essential
- Primary therapy aims to maintain range of movement and prevent fixed contractures with an emphasis on managing tone and position
- Surgery has a limited role in the management of neuromuscular conditions

Guillaume Benjamin Amand Duchenne (Duchenne de Boulogne), 1806–1875, neurologist, worked successively in Boulogne and Paris, France, but who never held a hospital appointment.

TABLE 39.18 General types of surgical procedure that may be considered in the management of a patient with a neuromuscular condition.

Surgical procedure	Aim of treatment
Lengthening of the muscle–tendon unit	Restores joint range (but results in relative muscle weakness)
Tendon transfer	Improves functional movement; rebalances muscle forces, after correction of fixed deformity
Release of joint contracture; correction of bony deformity	Restores mechanical alignment, and allows muscles to work in a more efficient manner
Fuse/stabilise/relocate joints	Improves posture/function; reduces pain
Neurological procedures: • selective dorsal rhizotomy (SDR) • intrathecal baclofen pumps (ITB)	Reduce spasticity (not primarily useful in dystonia)
Leg equalisation procedures	Improve lower limb mechanics

Cerebral palsy

Cerebral palsy is caused by a non-progressive insult to the developing brain in the perinatal period; in most cases only risk factors, such as prematurity, rather than specific causes, such as hypoxia (HIE, hypoxic ischaemic encephalopathy), can be identified. The effects of cerebral palsy may only become apparent as the child grows and fails to reach expected developmental milestones. At this stage investigations may help with aetiology and may predict the pattern of the cerebral palsy: premature babies may show evidence of periventricular leucomalacia (PVL) on a brain MRI, which is associated with the development of spastic diplegia with relative preservation of intellectual function.

In general, the pattern of involvement can be classified according to the anatomical site involved and the effect on muscle tone (*Table 39.19*). The prognosis for walking can be predicted by identifying evidence of neurological development, i.e. gaining motor skills with the loss of primitive reflexes. The age related Gross Motor Function Classification System (GMFCS) has five categories which also relate to mobility and prognosis (GMFCS I – near normal versus GMFCS V – wheelchair based). Many children with GMFCS V cerebral palsy have multiple associated problems and 40% will die before they reach their mid-20s.

An important aspect of management is the control of high tone. Tone can be reduced with drugs such as diazepam and baclofen. Alternatively, neuromuscular blockers such as botulinum toxin can bring about a focal reduction in tone by preventing acetylcholine release at the neuromuscular junction The effect is temporary, giving a 'window' during which the physiotherapists can stretch agonists and strengthen antagonists. It is important to differentiate between dynamic and fixed contractures; the latter will not respond to tone management or splinting.

The classic cerebral palsy gait patterns demonstrate flexor spasticity. The child with spastic diplegia has problems at all levels of the lower limb. Single event multilevel surgery (SEMLS) is popular, and gait analysis (both observational and computerised) contributes to the selection of an appro-

TABLE 39.19 Classification of cerebral palsy with respect to muscle tone and site of involvement.

	Characteristics
Tone	
Spastic ('high')	Commonest type of abnormality; due to damage to the pyramidal system Velocity-dependent increased muscle tone and brisk reflexes
Dyskinetic • Dystonic • Choreoathetoid	Increased tone but reduced activity – stiff movements Low tone but increased activity – uncoordinated jerky movements • Due to damage in the extrapyramidal system
Ataxia	Generalised low tone, loss of muscle coordination • Due to damage in the cerebellum
Mixed	No one tone/movement disorder predominates • Combination of spasticity and dystonia is common
Hypotonia	Usually a phase (which may last years) before the features of spasticity develop
Site	
Unilateral	
• Hemiplegia	Arm more affected than leg
Bilateral • Diplegia	Legs more affected than arms
• Total body involvement	Often significant intellectual impairment and associated difficulties

priate management plan for an individual patient. Computerised analysis provides objective evidence of joint movement and mechanics in multiple planes (Figure 39.37). Appropriate bone and soft-tissue procedures can then be planned. Botulinum toxin helps with postoperative pain and spasm.

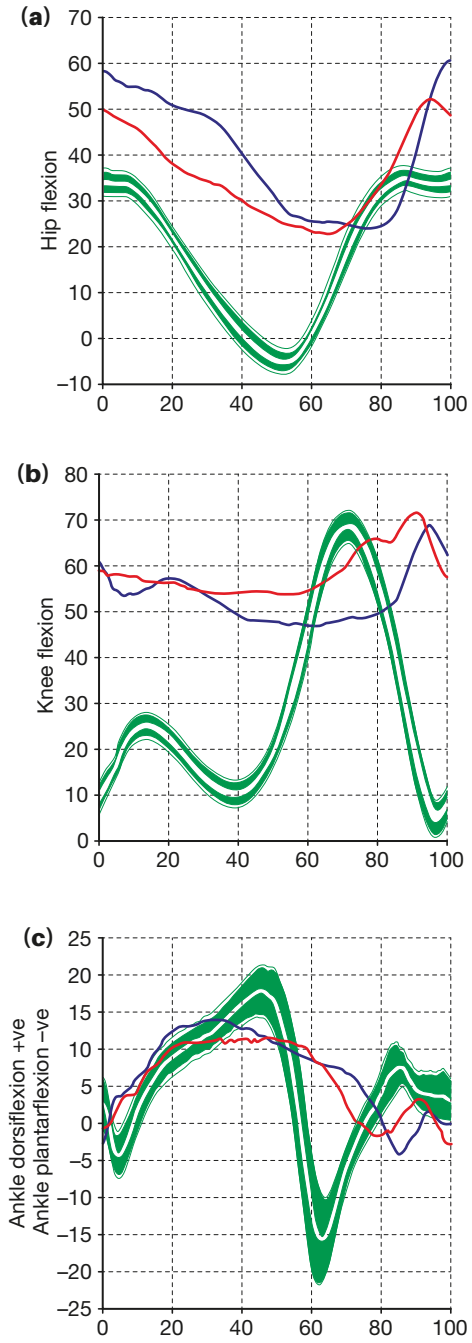

Figure 39.37 Gait analysis graphs such as these demonstrate the normal range of joint movements (green band) at hip (a), knee (b) and ankle (c) during the stance and swing phases of the gait. The abnormal joint ranges are shown in red (right leg) and blue (left leg) and demonstrate the excessive hip flexion and lack of knee extension and abnormal ankle mechanics associated with the 'crouch' gait of a child with cerebral palsy.

In the child with total body involvement (TBI) and high muscle tone, hip subluxation and eventual dislocation are common but often relatively asymptomatic (Figure 39.38). Current thinking is that symmetry and pelvic position are important so the hips should be kept in joint by the simplest means possible, with early surgical intervention if necessary. Aggressive management of a spinal deformity will initially concentrate on seating position and subsequently emphasise spinal bracing or surgery.

Overall, it is important to remember what the child's needs will be once they have reached adulthood. Independent mobility and an effective means of communication are two of the most important requirements. Hence, it may not be appropriate to invest time and effort in gaining an upright posture if mobility will be achieved via an electric wheelchair and a hand-controlled car and life expectancy is limited.

Summary box 39.20

Cerebral palsy

- Brain injury is non-progressive
- Classified as unilateral or bilateral involvement: hemiplegia, diplegia or TBI
- Tone may be high, low or variable but there is always a generalised, relative muscle weakness
- In ambulant children, gait analysis may be used to plan surgery or botulinum toxin injections
- In TBI, primary concerns are hip subluxation and spinal deformity

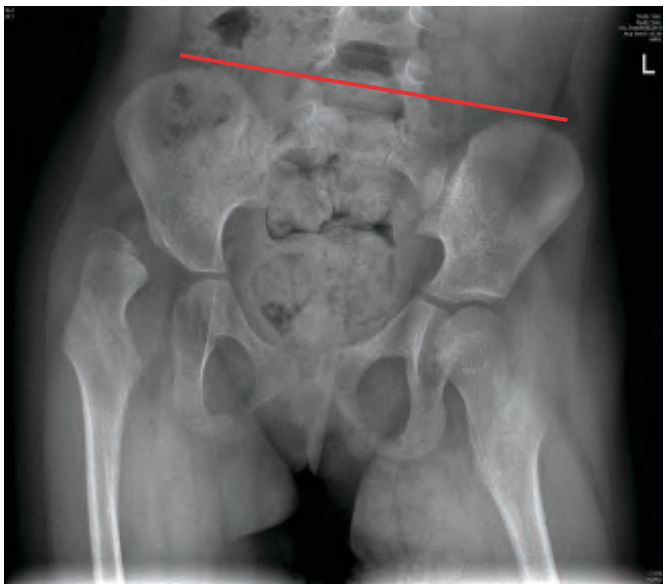

Figure 39.38 Anteroposterior pelvic radiograph of a child with spastic cerebral palsy. The right hip is essentially dislocated: none of the head lies medial to the vertical Perkins line. The acetabulum is dysplastic and the leg lies in slight adduction. The left leg is in abduction. There is often this 'windswept' appearance with one leg stiff in abduction and the other stiff in adduction. The line demonstrates the pelvic obliquity; many children also have a scoliosis.

Polio

Despite an effective polio vaccine, this disease still occurs. About 1–2% of patients develop neurological problems when the virus affects the anterior horn cells. Muscle weakness is proportionate to the number of motor units destroyed. Patients often develop trick movements to cope with their muscle weakness and minor joint contractures may actually improve function (for example, ankle equinus in the presence of weak quadriceps muscles). Careful assessment before surgery is essential and both the surgeon and the patient must understand the goals of treatment.

Spina bifida

The extent of the disability varies with the level of the lesion: upper motor neurone involvement will produce spasticity while the more classic lower motor neurone lesion will merely produce a flaccid paralysis. Hydrocephalus may contribute to the complexity of the situation. Muscle imbalance leads to secondary joint deformity but the, often profound, accompanying sensory disturbance may affect the choice of surgical and non-surgical options. Many children require a ventriculoperitoneal (VP) shunt to drain the hydrocephalus that develops following closure of the myelocoele. A tethered cord may develop, with growth adversely influencing the neurological picture.

Muscular dystrophy

Many types of muscular dystrophy exist that vary in terms of severity and distribution of involvement. Surgical intervention aims to improve quality of life. This is best achieved by operating early to release joint contractures and facilitate the maintenance of walking abilities and good spinal posture.

Brachial plexopathy

The neonatal brachial plexus injury is still common, with a devastating effect on upper limb function, particularly if antigravity motor activity has not recovered by 6 months. Physiotherapy is the mainstay of early treatment to maintain muscle length and joint range of movement and thus reduce the risk of glenohumeral dislocation. Neural repair may be necessary in the infant. Later surgical interventions aim to release joint/muscle contractures and improve function, perhaps with tendon transfers.

INFECTION

Worldwide, osteoarticular infection remains a frequent cause of significant morbidity.

Septic arthritis

Joint infection is usually secondary to haematogenous spread but direct inoculation can occur, for example during a neonatal venepuncture. Diagnosis can be difficult in the very young and in those presenting with overwhelming sepsis. Neonates, children with immunocompromise and those with sickle cell disease are at increased risk. At the other end of the spectrum the differentiation between joint sepsis and transient synovitis of the hip can also be difficult.

Classically, the child presents with pain, fever and a reluctance to use the joint; in the lower limb this implies a reluctance to weight bear. On examination, local tenderness and painful restriction of movement are apparent and in superficial joints inflammation may be obvious, with a hot, swollen joint.

Investigations include FBC, ESR, CRP and blood cultures. Plain radiographs help to exclude other diagnoses and may identify osteomyelitis. Ultrasound scans of deep seated joints, such as the hip, will identify joint effusions (**Figure 39.39**). Increasingly, MRI is considered the investigation of choice but this resource is not available to all (in a timely manner) and, in young children, it requires a general anaesthetic if useful information is to be obtained. Good clinical skills, regular patient review and a high index of suspicion are still the most valuable tools. Four clinical predictors can differentiate between septic arthritis and transient synovitis (*Table 39.20*).

Pus in a joint is destructive: the proteases produced by leukocytes destroy both the bacteria and the collagen matrix of the articular cartilage. AVN may occur secondary to pressure effects or ischaemic infarction. The treatment of a presumed septic arthritis therefore requires the prompt removal of pus from the joint and appropriate adequate antibiotic therapy. Pain relief and rest are also important, as are the general health and nutrition of the patient. The joint is aspirated and, if pus is confirmed, a formal washout is mandatory; standard teaching states that the joint must be opened, irrigated and free drainage encouraged via the capsulotomy. Recent literature supports repeated aspiration/irrigation via a large-bore cannula or a small arthroscope for all joints except the hip joint. Antibiotic usage is guided by the local hospital policy, the source of the infection, the Gram stain and, in due course,

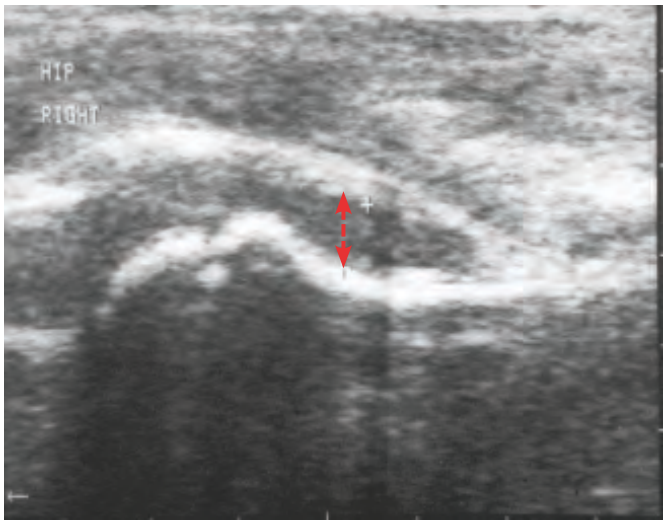

Figure 39.39 Ultrasound scan of a hip joint. A large effusion is distending the joint capsule. The dotted line represents the distance between the femoral neck and the joint capsule.

TABLE 39.20 Septic arthritis.

(a) The clinical predictors of Kocher *et al.* for the diagnosis of septic arthritis:

- History of fever >38.5°C
- Non-weight bearing
- Erythrocyte sedimentation rate >40 mm/hour
- White cell count >12 × 10^9/L

(b) The value of the clinical predictors of Kocher *et al.* in determining the likelihood of a joint being septic:

Number of positive predictors	Predicted probability of joint sepsis
0	2.0%
1	9.5%
2	35.0%
3	72.8%
4	93.0%

the culture and sensitivity of the organism identified. Joint instability, particularly in the hip joint (Figure 39.40), may require the joint to be splinted in the reduced position while the inflammatory process settles.

The most frequently identified organism is *Staphylococcus aureus*. Streptococcal infection is also common and other organisms are more prevalent in certain age groups, e.g. the neonate, in certain conditions, e.g. sickle cell disease, or in certain countries. The *Haemophilus influenzae* type B (Hib) vaccine has essentially eliminated *H. influenzae* as a cause of infection, but in some countries *Kingella kingae* has taken its place.

Improvement is judged clinically and by monitoring the inflammatory markers. Reaccumulation of pus does occur and must be suspected and treated promptly if the child fails to improve.

Summary box 39.21

Septic arthritis

- Diagnosis is difficult in neonates and the immunocompromised
- Typical presentation is pain, fever and a reluctance to move the joint or weight bear
- Investigations should include FBC, ESR, CRP, blood cultures and appropriate imaging studies, combined with astute clinical skills
- Pus in a joint can destroy articular cartilage and cause avascular necrosis
- Treatment is prompt removal of pus, appropriate antibiotic therapy, pain relief and splintage

Osteomyelitis

As with septic arthritis, bone infection is usually caused by haematogenous spread. Infection often occurs in the metaphyses of long bones where the slow flow through the looped vessels combined with microtrauma is believed to encourage seeding of infection during a bacteraemia (Figure 39.41a). Inflammation follows and, if purulent material forms, the pressure effects secondary to the formation of an abscess will lead to

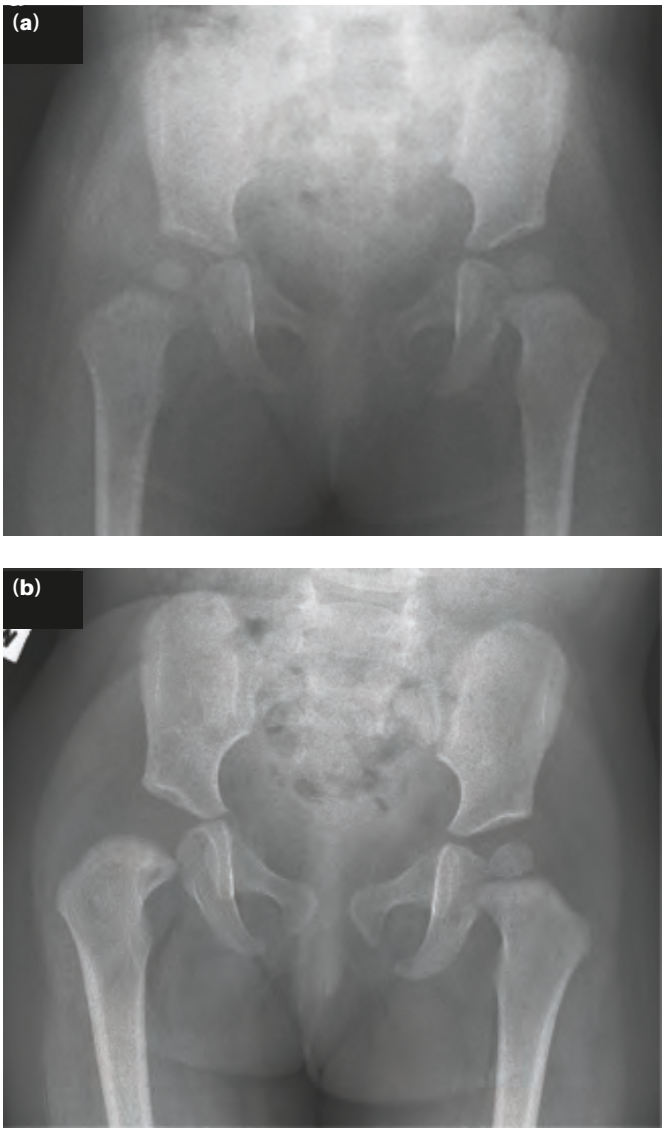

Figure 39.40 Septic arthritis of the right hip: **(a)** anteroposterior pelvic radiograph with subtle signs of right hip subluxation; **(b)** anteroposterior pelvic radiograph 6 months later showing destruction of the femoral head secondary to late treatment of a septic joint.

progressive bony destruction. Pus can pass through cortical bone and when it does so it elevates the strong periosteum, which may render the cortical bone avascular. As in cases of trauma or tumour, the periosteal elevation is a potent stimulus for new bone formation. In cases of untreated or chronic infection this new bone or involucrum may surround the dead bone, the sequestrum, leading to a 'bone-within-a-bone' appearance (Figure 39.41b).

The presentation and investigation of osteomyelitis can be similar to those for joint sepsis. The differentiation between the two may be difficult and a sympathetic joint effusion may occur with metaphyseal osteomyelitis. Thus, if there are no organisms seen on microscopy of a joint aspirate, the possibility of a coexisting osteomyelitis must be considered. The metaphysis of a long bone may be intracapsular and infection may spread easily into the joint once the periosteum is breached. In the neonate, proximal femoral osteomyelitis

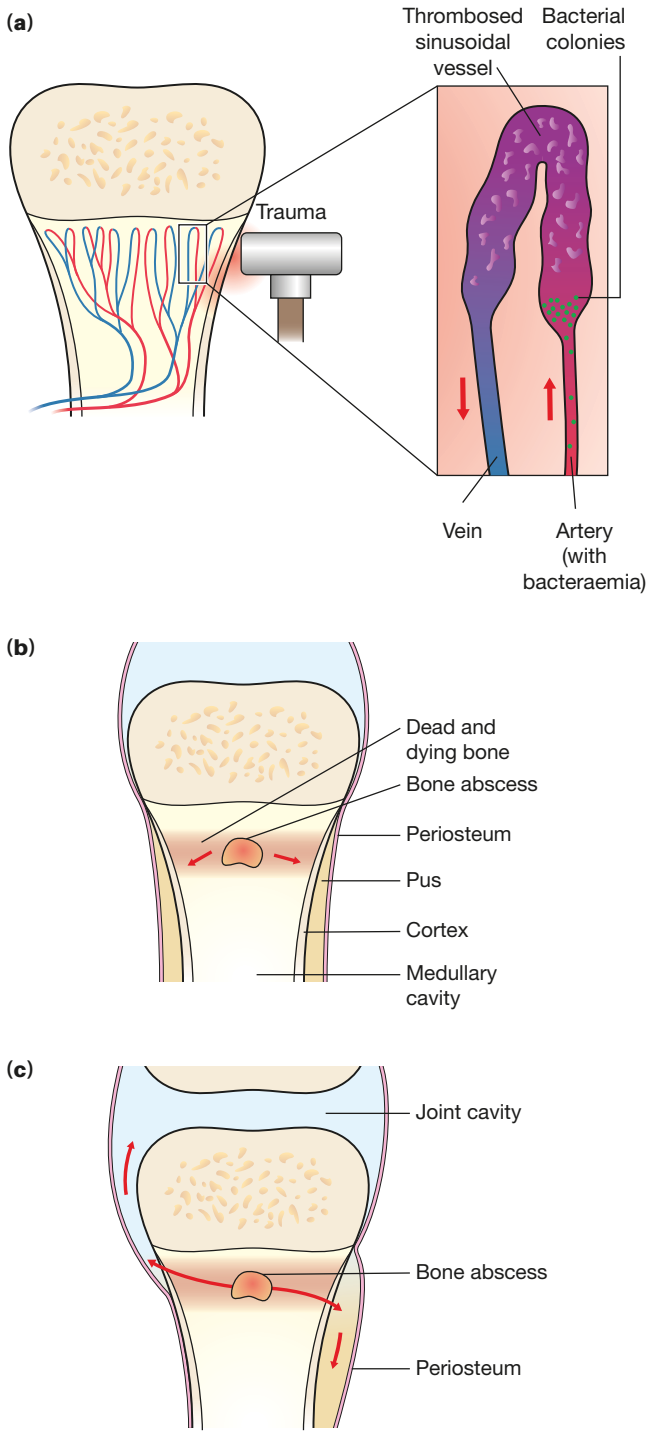

Figure 39.41 (a–c) Diagrams illustrating the pathology underlying the development of osteomyelitis. The longer the infection goes untreated the greater the destruction, with the possibility of sequestrum formation and secondary joint infection.

and septic arthritis are essentially the same condition (**Figure 39.41c**).

General principles for the management of infection should be followed. Pus needs to be drained but otherwise the treatment is medical. Debate continues over the duration of treatment and indeed whether antibiotics should be parenteral or oral: management varies from region to region and relates to the local bacteriological prevalences. Methicillin-resistant *Staphylococcus aureus* (MRSA) is common in some areas and not in others: the *Staphylococcus aureus*-associated *Panton Valentine leucocidin* gene significantly alters the morbidity associated with *S. aureus* infection.

It must be noted that the reduced intravenous and oral treatment times published recently are for **uncomplicated** cases of osteomyelitis and septic arthritis only, and only for those patients who are improving promptly both clinically and haematologically.

Summary box 39.22

Occurence and treatment principles for bone and soft tissue infection

- Occurs by haematogenous spread, enhanced by microtrauma
- In untreated and/or chronic osteomyelitis, new involucrum envelops dead sequestrum
- In addition to antibiotics, treatment consists of:
  - Rest/splintage of affected limb
  - Analgesia
- A joint effusion may be sympathetic or caused by direct spread from the adjacent metaphysis
- Treatment involves drainage of pus when present
- Appropriate and often prolonged antibiotic therapy: parenteral and then oral
- Treatment of the underlying condition, e.g. nutritional deficiency, sickle cell disease

Complications of bone and joint sepsis

Treated appropriately, most cases of bone and joint sepsis resolve with no sequelae. However, significant complications can occur, particularly in terms of chronic infection and in cases in which there has been damage to the joint and/or the physis and the epiphyseal growth centres. In the neonate, vascular channels pass through the physis, connecting the metaphysis with the epiphysis, and a poorer outcome may ensue (see **Figure 39.40b**). Orthopaedic follow-up should be continued until normal growth patterns are documented.

Meningococcal sepsis

The often debilitating, late orthopaedic sequelae of meningococcal septicaemia are secondary to endotoxin-induced microvascular injury and ischaemic physeal damage (**Figure 39.42**).

Tuberculosis

Tuberculosis is still common. The clinical presentation is often insidious, with malaise and weight loss combined with a boggy joint swelling, muscle wasting and joint contractures. Spinal deformity and neurological symptoms are particular problems.

Figure 39.42 Anteroposterior leg length and alignment radiograph of a child who had meningococcal septicaemia as a child; he was left with multiple problems. He has a below-knee amputation of the right leg. Many of his lower limb physes are not growing well so he has deformity of his remaining right proximal tibia, a very short left tibia and an overgrown fibula. His right femur is also short.

Chronic relapsing/recurrent multifocal osteomyelitis

The radiographic features suggest subacute or chronic osteomyelitis (or tumour) but laboratory and histopathological findings are usually non-specific and cultures negative. This is probably an inflammatory rather than an infective condition.

Discitis

Children who refuse to weight bear and complain of back pain may have discitis. The aetiology of this condition may be infective or inflammatory but if vertebral bodies are involved, infection is assumed.

Brodies's abscess

Chronic infections may present with radiographic features of a sclerotic walled cyst.

CLINICAL DILEMMAS

The limping child

Children may limp because of pain, weakness, deformity or to gain attention; the causes vary from sepsis to a spinal tumour and from a leg length discrepancy to a shoe that rubs. Serious causes must be excluded and the 'surgical sieve' helps identify the most likely diagnoses. See *Table 39.21*.

TABLE 39.21 A guide to the clinical assessment of the limping child.

Symptom onset: sudden or gradual?
Symptom duration
Concurrent events: recent viral infection, trauma, new shoes, new sport?
General health: is the child well?

The examination must include all joints and soft tissues and, in addition, a brief neurological examination, measurement of leg length and an assessment of pain at rest or on weight bearing.

Many conditions, such as sepsis and juvenile arthritis, can present at any age but certain hip conditions are more likely in particular age groups (*Table 39.22*).

Plain radiographs should usually include both anteroposterior and 'frog' lateral views of the pelvis. Always bear in mind the possibility of a tumour; further imaging such as MRI may be required.

TABLE 39.22 Age at presentation of certain hip conditions.

Age (years)	Diagnosis
1–3	Late presenting developmental dysplasia of the hip; sepsis
3–10	Transient synovitis; Perthes' disease
11–15	Slipped upper femoral epiphysis

Non-accidental injury (NAI)

No child is exempt but some children are at particular risk, including those under 3 years of age and those with disabilities in a family who are suffering socioeconomic deprivation. A careful clinical assessment is required (**Figure 39.43** and *Table 39.23*). Characteristic patterns should warn the clinician to consider the possibility of NAI (*Table 39.24*).

Child abuse occurs in different forms: emotional, physical, sexual and neglect. When suspected it should be discussed with the relevant child safeguarding team. All injuries should be documented carefully. It may be prudent to admit the child until further checks have been made.

Sir Benjamin Collins Brodie, 1783–1862, surgeon, St. George's Hospital, London, UK, described 'Brodie's abscess' in 1828.

Figure 39.43 Anteroposterior radiograph of a knee showing metaphyseal corner fractures that are often considered to be pathognomonic of non-accidental injury. Non-accidental injury must also be considered in any fracture that presents late or without an adequate explanation.

TABLE 39.23 Factors that raise concern in the clinical assessment of suspected non-accidental injury.

History
Delay in seeking medical advice
Variable story
Mechanism inconsistent with injury pattern
Examination
Unexpected bruising to the buttocks/back of legs
'Finger-mark' bruises
Bruises of various ages
Burns, deep scratches, etc.

TABLE 39.24 Fracture patterns with a high specificity for non-accidental injury.

PART 6

Skin and subcutaneous tissue

Chapter 40

Skin and subcutaneous tissue

Learning objectives

To understand:

- The structure and functional properties of skin
- The classification of vascular skin lesions
- The cutaneous manifestations of generalised disease as related to surgery
- The classification of benign skin tumours
- The management of malignant skin tumours

FUNCTIONAL ANATOMY AND PHYSIOLOGY OF SKIN

Skin can be divided into two layers: the outer epidermis and the inner dermis. Deep to the dermis lies subcutaneous fat and remnants of the panniculus carnosus.

Epidermis

The epidermis is 5% of the skin and is composed of five layers of keratinised, stratified squamous epithelium; the strata: basalis (deep), spinosum, granulosum, lucidum and corneum (superficial).

Most epidermal cells are keratinocytes arranged in layers. The basal epidermis (stratum basalis) also contains melanocytes. Keratinocytes are classified according to their depth in the epidermis and their degree of differentiation. Keratinocytes grow and are replaced via mitoses in the cells of the stratum granulosum as they progress from deep to superficial, losing their nuclei and organelles as they ascend, before forming the stratum corneum. The other keratinocyte layers in the skin (strata lucidum; granulosum and spinosum) are variably thick according to body site – for instance all three are thick in the glabrous skin of the palms and soles of the feet and almost absent in eyelid skin.

Melanocytes are dendritic cells of neural crest origin, usually located in the basal epidermis. Each melanocyte synthesises melanin, a brown-black pigment, which is transferred via membrane processes to the keratinocytes in the strata granulosum and spinosum. Melanin provides protection against ultraviolet radiation. Ethnic differences in skin colour are determined by variations in the amount, combination and distribution of melanin within the keratinocytes, not by differences in the number of melanocytes.

Dermis

Dermis comprises 95% of skin and is structurally divided into a superficial papillary layer; composed of delicate collagen and elastin fibres in ground substance, into which a capillary and lymphatic network ramifies and a deeper reticular layer; composed of course branching collagen, layered parallel to the skin surface (**Figure 40.1**).

The epidermis and dermis meet at the dermo-epidermal junction in a three-dimensional wave-like arrangement in which epidermal rete ridges project down, interdigitating with upward-pointing, dermal papillae containing vascular and lymphatic plexi.

The skin also contains specialised cells such as Langerhan's cells, whose role is to engulf antigens and present them to T cells. Merkel cells, Meissner's and Pacinian corpuscles have roles in mechano-sensation.

Skin adnexa

Adnexal structures such as hair follicles, sebaceous and sweat glands span both the epidermal and dermal layers and contain some keratinocytes in their ducts. In injuries where epidermis is lost, re-epithelialisation occurs from these structures as well as from the wound margins.

Paul Langerhans, 1847–1888, Professor of Pathological Anatomy, Freiberg, Germany.
Filippo Pacini, 1812–1883, Professor of Anatomy and Physiology, Florence, Italy.

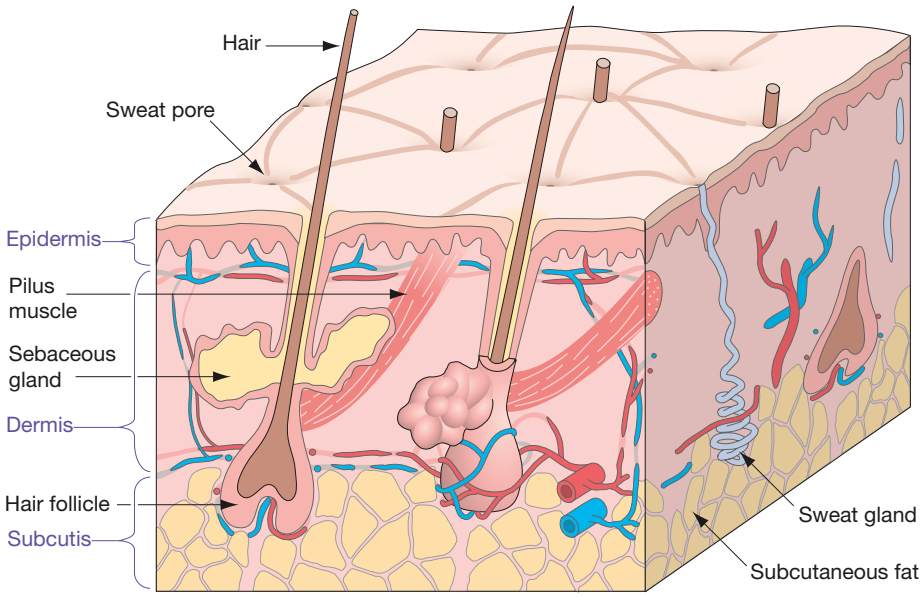

Figure 40.1 Three-dimensional diagram of the structural layers of the skin and its adnexal structures. (Reproduced from Simonsen T, Aarbakke J, Kay I *et al*. *Illustrated pharmacology for nurses*. London: Hodder Arnold, 2006 with kind permission of the illustrator Roy Lysaa.)

Hair follicles

Hair follicles are tubular invaginations of the epidermis, from which grow hair shafts (dead keratinised tissue). Strips of smooth muscle (arrector pili) are inserted into the wall of the hair follicle and lead to hair elevation in times of stress and cold.

Sebaceous glands

Sebaceous glands are hair follicle appendages situated between each hair follicle and the associated arrector pili muscle. When the arrector pili muscle contracts to elevate the hair, it compresses the gland and sebum is released (holocrine secretion).

Sweat glands

Simple eccrine and apocrine sweat glands open into pores in hair follicles. Eccrine glands are distributed throughout the entire body surface, except the lips. They secrete sweat in response to emotion or during thermoregulation. Apocrine glands are found in the axillae and groins and become active at puberty. Their secretion, characteristically malodourous after bacterial degradation, is in response to emotion and hormone secretion.

Skin thickness

Skin thickness varies with age, location and sun damage, but in any given region it is thinner in children than adults. The dermis is between 15 and 40 times thicker than the epidermis, but starts to thin during the fourth decade. The epidermis is thickest on the palms, soles, back and buttocks and thinnest on eyelids (0.5–1 mm on the sole of the foot, 0.05–0.09 mm on the eyelid).

Blood supply of the skin

The body can be envisaged as three-dimensional segments of tissue called angiosomes, each with an arterial supply and a venous drainage. Blood equilibrates and flows between neighbouring angiosomes via 'choke' vessels, which tend to be situated within muscles. Cutaneous arteries, direct branches of segmental arteries (concentrated at the dorsoventral axes and intermuscular septae), perforate the underlying muscles or run directly within fascial layers to the skin from the deep tissues (**Figure 40.2**).

The blood supply to the skin anastomoses in subfascial, fascial, subdermal, dermal and subepidermal plexi. The epidermis contains no blood vessels so cells there derive nourishment by diffusion.

The venous drainage of the skin is via both valved and unvalved veins. Unvalved veins allow oscillating flow in the subdermal plexus between cutaneous territories, equilibrating flow and pressure. The valved cutaneous veins drain via plexi to the deep veins.

Anomalies of skin metabolism

Blood flow to the skin can vary between 5 and 100 mL/100 g/min in the temperature range 20–40°C. Thus, skin has the potential for a blood supply 20–100 times greater than its metabolic and thermoregulatory requirements. This apparent excess enables restitution of mechanical integrity after the myriad trivial injuries (scratching, stretching, compressing, thermal) to which skin is subjected; however, blood supply is inadequate to support full-thickness wound healing, which requires primary closure or granulation tissue.

Skin functions optimally at temperatures below body core temperature and can tolerate long periods of ischaemia (allowing it both to be grafted and/or expanded for use in reconstruction (see Chapter 42 on plastic surgery).

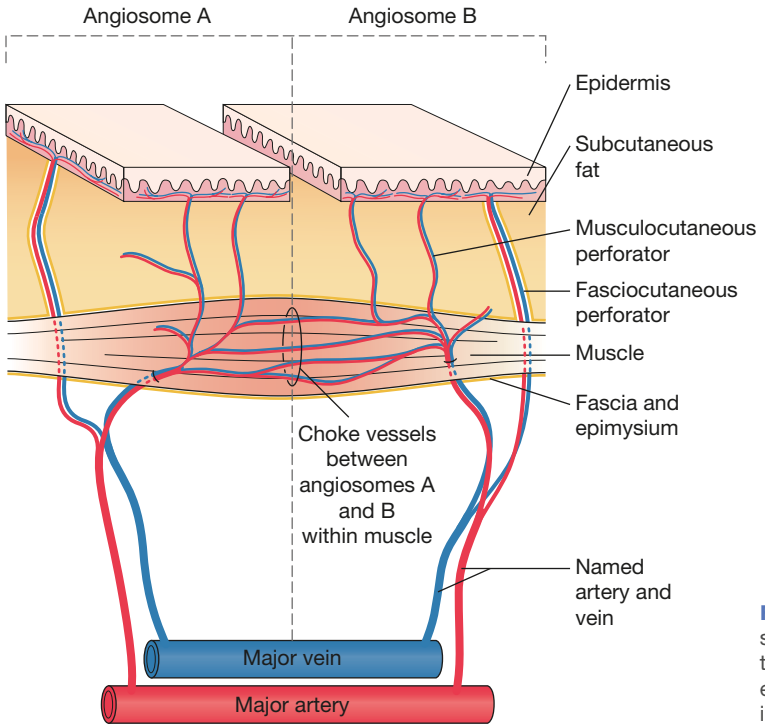

Figure 40.2 Schematic showing two neighbouring angiosomes. Note the choke vessels within the muscle spanning the two cutaneous territories of angiosome A and B; two common examples of myocutaneous flaps that utilise this physiology include the rectus abdominus and the latissimus dorsi flaps.

FUNCTION OF THE SKIN

Human skin and subcutaneous tissue have several important functions:

- Barrier to the environment enveloping the body and protecting against trauma, radiation and pathogens.
- Regulates temperature and water homeostasis.
- Organ of excretion for urea, sodium chloride, potassium and water, as well as sulphur-containing metabolites from drugs (e.g. dimethyl sulphoxide) or food (garlic, cumin).
- The skin has significant endocrine and metabolic functions and interactions. Skin cells contain receptors for and respond to: peptides, steroid sex hormones, thyroid hormones and neurotransmitters and they both produce (cholecalciferol) and metabolise (androgens) hormones and precursors to activate, potentiate and inactivate their functions.
- Sensory organ with multiple receptors for pain, pressure and movement.

PATHOPHYSIOLOGY OF THE SKIN AND SUBCUTANEOUS TISSUES

Radiation damage

Ultraviolet radiation (UVR) and ionising radiation (IR) damage cellular deoxyribonucleic acid (DNA) via the tumour suppressor gene *p53*, inhibiting cellular repair and apoptotic mechanisms. There is also evidence that efferent immune responses are impaired after skin exposure to UVR, facilitating neoplasia.

Ultraviolet radiation

UVR is divisible into A, B and C according to wavelength. UVR is the principal cause of skin cancer in all skin types. Its effects are attenuated by melanin and there is an inverse relationship between melanin content and skin susceptibility to UV-induced neoplasia. Some protection is afforded by the stratum corneum, which reflects and refracts UVR, and by clothing, protective creams, cloud cover, particulate air pollution and buildings.

Ionising radiation

The effects of IR are dose, wavelength and time dependent. The skin with its rapid cellular turnover exhibits signs soon after exposure. High-frequency rays cause electron coupling at the molecular level, damaging proteins, polysaccharides and lipids.

Infrared radiation

Infrared radiation generates heat; cumulative exposure can cause thermal burns.

Congenital/genetic disorders

Neurofibromatosis

There are two distinct neurofibromatosis (NF) syndromes, where Schwann cells form tumours (**Figure 40.3**). Each is

Friedrich Theodor Schwann, 1810–1882, Professor of Anatomy successively at Louvain (1839–1848) and Liege, Belgium (1849–1880). Original researches before the age of 27 laid the foundation of physiology of nerve and muscle. The first to deal with problems related to living matter on a purely physical and chemical basis, and to recognise the cell as the unit of living matter. Discoverer of pepsin, and role of living organisms in fermentation.

Figure 40.3 Neurofibromatosis (courtesty of St John's Institute for Dermatology, London, UK).

caused by different genes on different chromosomes. 70% are autosomal dominant and 30% arise from sporadic mutations. NF 1 (Von Recklinghausen's disease) is the commoner variant, affecting approximately 1:4000 births. It arises from a gene mutation on chromosome (Ch.) 17. Skin manifestations appear in early life, with the development of more than five smooth surfaced café-au-lait spots, subcutaneous neurofibromata, armpit or groin freckling and Lisch nodules.

Naevoid basal cell carcinoma (Gorlin's) syndrome

This is an autosomal dominant inherited condition caused by an abnormal tumour suppressor gene on Ch. 9q 22-31 coding the 'patched' protein. 90% of patients develop multiple basal cell carcinomas (BCCs). Patients may exhibit specific phenotypical characteristics including: over-developed supraorbital ridges; broad nasal roots; hyperteliorism; bifid ribs; scoliosis; brachymetacarpalism; palmar pits and molar odontogenic cysts.

Xeroderma pigmentosum

This syndrome is caused by an abnormality on the 'patched' gene of Ch. 9q resulting in aberrant nucleotide repair during cellular DNA maintenance. It confers a >2000-fold increase in skin cancer risk and has autosomal recessive inheritance. Sufferers are intolerant of UVR, leading to premature skin ageing and development of multiple neoplasms. Most affected individuals die in early adulthood from metastatic disease (60% mortality by 20 years of age).

Gardner's syndrome

This syndrome is an autosomal dominant disease variant of familial adenomatous polyposis (FAP) caused by an abnormal gene on Ch. 5. Gardner's syndrome can cause the development of cutaneous pathology such as multiple epidermoid cysts and lipomata.

Ferguson-Smith syndrome

This is a rare, autosomal-dominantly inherited abnormality on Ch. 9q in which affected individuals develop multiple self-healing squamous cell carcinomas (SCC).

Cutaneous manifestations of generalised disease

Many diseases have cutaneous manifestations that present in surgical practice. These include: necrobiosis lipoidica, granuloma annulare in diabetes mellitus and pyoderma gangrenosum in inflammatory bowel disease. Their management should be sought in appropriate texts.

Hyperhydrosis

This involves excessive eccrine sweating of the palms, soles of the feet, axillae and groins, causing functional and social problems. It can be treated with antiperspirants or periodic local injections with botulinum toxin A. More resistant cases are treated by laparoscopic cervical sympathectomy.

Lipodystrophy

Lipodystrophy (lipoatrophy) is a localised or generalised loss of fatty tissue, which can be primary or secondary. It can be a complication of long-term administration of insulin, following treatment of human immunodeficiency virus (HIV) with protease inhibitors or in transplant recipients.

It can be treated in selected cases by autologous fat grafting, injections of poly-L-lactic acid and free tissue transfer.

Inflammatory conditions

HIDRADENITIS SUPPURATIVA (HS)

Follicular occlusion followed by folliculitis and secondary infection with skin flora (usually *Staphylococcus aureus* and *Propionibacterium acnes*) culminates in chronic suppurative, painful, skin abscesses, sinus tracts and scarring. HS occurs in skin containing apocrine glands, commonly in the axillae and groins; but also the scalp, breast, chest and perineum **(Figure 40.4)**. It appears to have a genetic predisposition with variable penetrance, and is strongly associated with obesity and smoking. It affects four women for every man.

Management Patients should stop smoking and lose excess weight. Symptoms can be reduced by the use of antiseptic soaps, tea tree oil and wearing non-compressive and aerated underwear. Medical treatments include topical and oral antibiotics and antiandrogen drugs. In selected cases, patients require radical excision of the affected skin and subcutaneous tissue. Reconstruction after excision avoids contracture and functional impairment.

Friedrich Von Recklinghausen, 1833–1910, German Professor of Pathology, also described haemochromatosis.
Karl Lisch, 1907–1999, ophthalmologist, Wörgl, Austria.
Robert J Gorlin, 1923–2006, American dentist and Professor of Oral Pathology, published over 400 articles on craniofacial syndromes.
John Ferguson-Smith, 1888–1978, Glaswegian dermatologist.

Figure 40.4 Hidradenitis suppurativa affecting the axilla (courtesy of St John's Institute for Dermatology, London, UK).

PYODERMA GANGRENOSUM (PG)

Characterised by cutaneous ulceration with purple undermined edges, PG is secondary to heightened immunological reactivity, usually from another disease process, such as inflammatory bowel disease, rheumatoid arthritis, non-Hodgkin's lymphoma or Wegener's granulomatosis (**Figure 40.5**). Ulcers generally respond to steroids; surgery is rarely indicated and may exacerbate the condition.

Figure 40.5 Pyoderma gangrenosum affecting the legs **(a)** and the breasts **(b)** (courtesy of St John's Institute for Dermatology, London, UK).

Infections

Skin and soft tissue infections can be localised or spreading, necrotising or non-necrotising. Localised or spreading, non-necrotising infections usually respond to broad spectrum antibiotics. Localised necrotising infections need surgical debridement as well as antibiotic therapy. Spreading, necrotising soft-tissue infection constitutes a life-threatening surgical emergency, requiring immediate resuscitation, intravenous antibiotic therapy and urgent surgical intervention with radical debridement.

Impetigo

Impetigo is a superficial infection of skin with staphylococci, streptococci or both (**Figure 40.6**). It is highly infectious, characterised by blisters that rupture and coalesce to form a honey-coloured crust and usually affects children. Treatment is directed at washing the affected areas and applying topical antistaphyloccocal treatments, and broad spectrum oral antibiotics if streptococcal infection is also implicated.

Figure 40.6 Impetigo. Note the honey-coloured crust (courtesy of St John's Institute for Dermatology, London, UK).

Erysipelas

Erysipelas is a sharply demarcated streptococcal infection of the superficial lymphatics, usually associated with broken skin on the face (**Figure 40.7**). The area affected is erythematous

Thomas Hodgkin, 1798–1866, curator of the Museum and demonstrator of Morbid Anatomy, Guy's Hospital, London, UK.

Figure 40.7 Erysipelas (courtesy of St John's Institute for Dermatology, London, UK).

Figure 40.8 Cellulitis affecting the left leg (courtesy of St John's Institute for Dermatology, London, UK).

and oedematous. The patient may be febrile and have a leucocytosis. Prompt administration of broad spectrum antibiotics after swabbing the area for culture and sensitivity is usually all that is necessary.

Cellulitis/lymphangitis

This is a bacterial infection of the skin and subcutaneous tissue that is more generalised than erysipelas. It is usually associated with broken skin or pre-existing ulceration. It is characterised by an expanding area of erythematous, oedematous tissue that is painful, in association with fever, malaise and leucocytosis. Erythema tracking along lymphatics may be visible (lymphangitis) (**Figure 40.8**). The commonest causative organism is *Streptococcus*. Blood and skin cultures for sensitivity should be taken before prompt administration of broad spectrum, intravenous antibiotics and elevation of the affected extremity.

Necrotising fasciitis

Meleney's synergistic gangrene and Fournier's gangrene are variants of a similar disease process.

Necrotising fasciitis results from synergistic, polymicrobial infection; most commonly a streptococcal species (Group A β-haemolytic) in combination with *Staphylococcus*, *Escherichia coli*, *Pseudomonas*, *Proteus*, *Bacteroides* or *Clostridia*. 80% have a history of previous trauma/infection and over 60% commence in the lower extremities. Predisposing conditions include: diabetes mellitus; smoking; penetrating trauma; pressure sores; immunosuppression; intravenous drug abuse; perineal infection (perianal abscess, Bartholin's cysts); and skin damage/infection (abrasions, bites, boils).

Summary box 40.1

Necrotising fasciitis

- Surgical emergency
- Polymicrobial synergistic infection
- 80% history of previous trauma or infection
- Rapid progression to septic shock
- Urgent resuscitation, antibiotics and surgical debridement
- Mortality 30–50%

Classical clinical signs include: oedema stretching beyond visible skin erythema; a woody-hard texture to the subcutaneous tissues; an inability to distinguish fascial planes and muscle groups on palpation; disproportionate pain in relation to the affected area, with associated skin vesicles and soft-tissue crepitus (**Figure 40.9**). Lymphangitis tends to be absent. Early on, patients may be febrile and tachycardic, with a very rapid progression to septic shock. Radiographs, that should not have delayed urgent treatment, may demonstrate air in the tissues.

Management should commence with urgent fluid resuscitation, monitoring of haemodynamic status and administration of high-dose, intravenous broad spectrum, antibiotics.

Frank Meleney, 1889–1963, American surgeon in the First World War, then became a Professor at Columbia Medical School in New York.
Jean Fournier, 1832–1914, French dermatologist, also described tertiary syphilis.

Figure 40.9 Necrotising fasciitis affecting the left orbit and facial skin (courtesy of St John's Institute for Dermatology, London, UK).

This is a surgical emergency and the diseased area should be debrided as soon as possible until viable, healthy, bleeding tissue is reached. Early surgical review and further debridement is advisable, together with the use vacuum-assisted dressings. Early skin grafting in selected cases may minimise protein and fluid losses. Mortality of between 30% and 50% can be expected, even with prompt with operative intervention.

Purpura fulminans

This is a relatively rare condition in which intravascular thrombosis produces rapid skin necrosis and haemorrhagic infarction, which progresses rapidly to septic shock and disseminated intravascular coagulation. Usually seen in children, it can occur in adults and may be subdivided into three types based on aetiological mechanism: 'acute infectious'; 'neonatal' and 'idiopathic' purpura fulminans.

Acute infectious is the commonest form. It is associated with a mortality rate of 40–50%, usually from multiorgan failure and is secondary to either an acute bacterial (*Neisseria meningitidis*) or viral infection (varicella). It is most common in children under 7 years, following an upper respiratory tract infection, or in asplenia. Endotoxins produce an imbalance in procoagulant and anticoagulant endothelial activity, producing protein C deficiency; this gives the clinical picture of an initial petechial rash developing into confluent ecchymoses and haemorrhagic bullae, which necrose to form well-demarcated lesions that form hard eschars. Extensive tissue loss is common, which often culminates in limb amputation (**Figure 40.10**).

Figure 40.10 Acute infectious purpura fulminans caused by meningococcal septicaemia. Note the sharply demarcated necrotic areas distal to the affected end or perforating arteries with surrounding normal skin (courtesy of St John's Institute for Dermatology, London, UK).

Skin and soft tissue cysts

Milia

Milia are small, hard, keratin retention cysts seen both in babies and, after chronic sun exposure, in the elderly (**Figure 40.11**).

Figure 40.11 Milia (courtesy of St John's Institute for Dermatology, London, UK).

Epidermal cysts

These cysts are lined with true, stratified-squamous epithelium, derived from hair follicle infundibuli or traumatic inclusion. Commonly known as sebaceous cysts, they can occur anywhere. They are fixed to the skin and usually have a central punctum (**Figure 40.12**).

Treatment depends on the clinical state of the cyst. When inflamed or infected, they should be incised and drained initially, and removed later once the inflammation and

Albert Ludwig Seigmund Neisser, 1855–1916, Director of the Dermatological Institute, Breslau, Germany (now Wroclaw, Poland).

Figure 40.12 Multiple scrotal epidermal cysts (courtesy of St John's Institute for Dermatology, London, UK).

induration has subsided. It is important to excise the cyst in its entirety as failure to do so usually results in recurrence.

Meibomian cysts are epidermal cysts found on the free edge of the eyelid. Tricholemmal (pilar/pilosebaceous) cysts are derived from the epidermis of the external root sheath of the hair follicle. 90% are found in the scalp and 70% are multiple; they are usually distinguished from epidermal cysts by pathologists, rather than clinically.

SKIN TUMOURS

Benign lesions

Basal cell papilloma (seborrhoeic keratosis, senile keratosis, verruca senilis)

These vary from macular to soft, excrescent, warty lesions, which are often pigmented and hyperkeratotic. They are formed from the basal layer of epidermal cells and contain melanocytes.

Papillary wart (verruca vulgaris)

This is a benign skin tumour arising from infection with the human papilloma virus (HPV), which is also responsible for plantar warts and condylomata acuminata.

Freckle (ephelis)

A freckle is an area of skin that contains a normal number of melanocytes, producing an abnormally large number of melanin granules.

Lentigo

These are small, circumscribed pigmented macules, which stem from sun damage and some systemic syndromes. Solar lentigos are commoner in fairer skins.

Moles/naevi

Melanocytes migrate from the neural crest to the basal epidermis during embryogenesis. When melanocytes aggregate in the dermis or at the dermo-epidermal junction, they are called naevus cells.

Junctional naevus

A junctional naevus is a dermo-epidermal proliferation of naevus cells, visible as deeply pigmented macules or papules that occur commonly in childhood or adolescence, usually progressing to form compound or intradermal naevi with advancing age. Benign mucosal lesions tend to be junctional naevi **(Figure 40.13)**.

Figure 40.13 Junctional naevus (courtesy of St John's Institute for Dermatology, London, UK).

Compound naevus

This is a maculopapular, pigmented lesion that becomes most prominent during adolescence **(Figure 40.14)**. It represents a junctional proliferation of naevus cells, with nests and columns in the dermis.

Intradermal naevus

Intradermal naevi are faintly pigmented papules in adults showing no junctional proliferation, but a cluster of dermal melanocytes **(Figure 40.15)**.

Spitz naevus

These are reddish brown (occasionally deeply pigmented) nodules, previously termed 'juvenile melanoma' **(Figure**

Heinrich Meibom (Meibomius), 1638–1700, Professor of Medicine, History and Poetry, Helmstadt, Germany, described these glands in 1666.
Sophie Spitz, 1910–1956, American dermatopathologist at Sloan-Kettering Cancer Center, published the first case series of 'juvenile melanoma' in 1948. Died at the age of 46 from carcinoma of the colon.

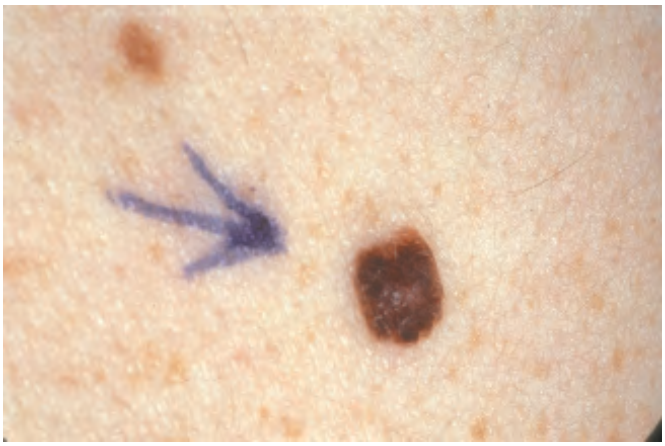

Figure 40.14 Compound naevus (courtesy of St John's Institute for Dermatology, London, UK).

Figure 40.16 Spitz naevus (courtesy of St John's Institute for Dermatology, London, UK).

Figure 40.15 Intradermal naevus (courtesy of St John's Institute for Dermatology, London, UK).

40.16). They most commonly occur on the face and legs, growing rapidly initially then remaining static or regressing. The differential diagnosis is melanoma and excision biopsy is warranted if there is doubt as to the diagnosis.

Spindle cell naevus

Spindle cell naevi are dense black lesions, which contain spindle cells and atypical melanocytes at the dermo-epidermal junction. They are commonly seen on the thighs and affect women more frequently. They may have malignant potential.

Halo naevus

The halo of depigmentation around any benign naevus represents an antibody response to melanocytes. Depigmentation may also be a feature of a malignant melanoma. Halo naevi are associated with vitiligo (Figure 40.17).

Café-au-lait spots

These are coffee-coloured macules of variable size (from a few mm to 10 cm) (Figure 40.18). Multiple lesions are associated with NF 1 and McCune–Albright syndromes. They are more common in dark-skinned races.

Naevus spilus (speckled lentiginous naevus)

These are similar in appearance to a café-au-lait spots, but with hyperpigmented speckles throughout (Figure 40.19). They are benign lesions that are associated with various cutaneous diseases, but whose speckled appearance can be confused with malignant change. The mainstay of management is observation and serial photography as malignant transformation is rare.

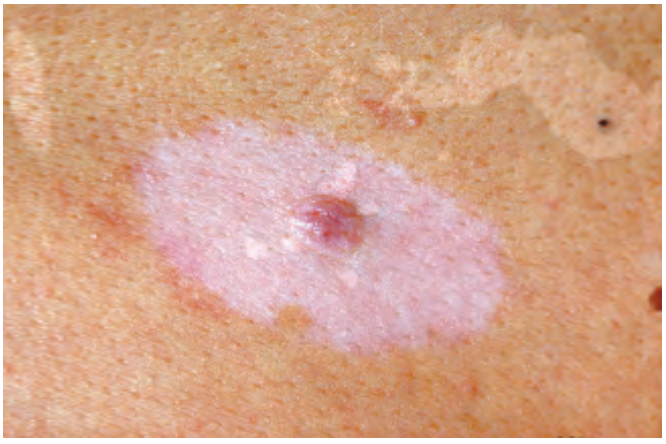

Figure 40.17 Halo naevus (courtesy of St John's Institute for Dermatology, London, UK).

Donovan James McCune, 1902–1976, American paediatrician.
Fuller Albright, 1900–1969, physician, Massachusetts General Hospital, Boston, MA, USA.

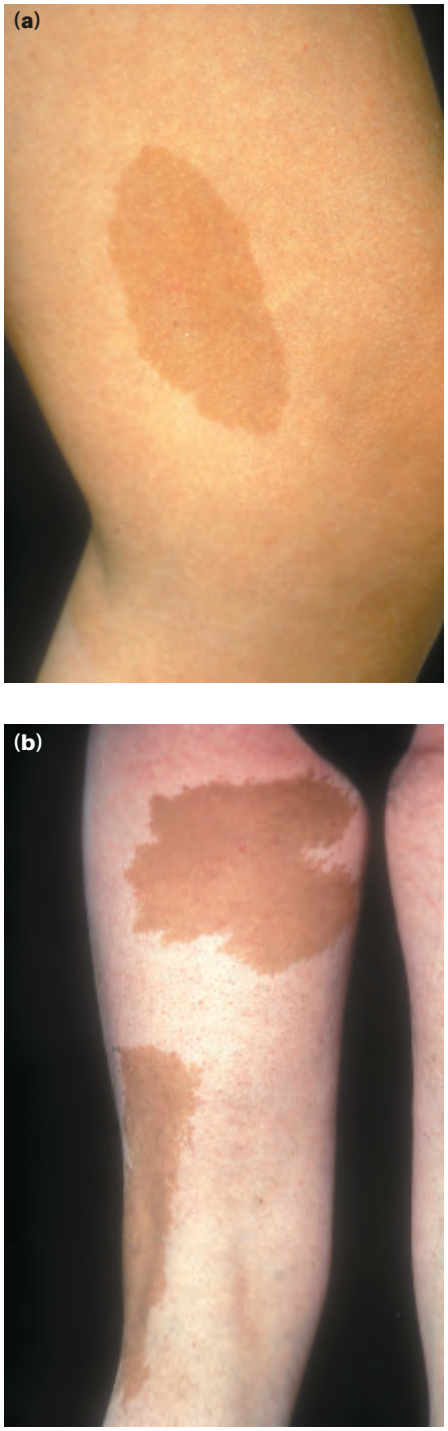

Figure 40.18 Café-au-lait spots. Note the two topographical variants: in **(a)** the spot has a smooth 'coast of California' border, whereas the upper spot in **(b)** has an irregular 'coast of Maine' border. Multiple smooth-bordered lesions are commonly associated with syndromes (courtesy of St John's Institute for Dermatology, London, UK).

Mongolian spot

A Mongolian spot is a congenital blue grey macule found on the sacral skin **(Figure 40.20)**. Pigmentation initially deepens and then regresses completely by age 7 years.

Figure 40.19 Naevus spilus (courtesy of St John's Institute for Dermatology, London, UK).

Figure 40.20 Mongolian spot (courtesy of St John's Institute for Dermatology, London, UK).

Blue naevus

This is a benign skin lesion that is four times more common in children, typically affecting the extremities and face **(Figure 40.21)**.

Naevi of Ota and Ito

A naevus of Ota is a dermal, melanocytic hamartoma visible as a blue or grey macule in the trigeminal V1 and V2 dermatomes. It is four times more common in women and most frequently seen in Oriental and African races **(Figure 40.22)**.

Minoru Ito, 1892–1986, Professor of Dermatology, Tohoku University, Sendai, Honshu, Japan.

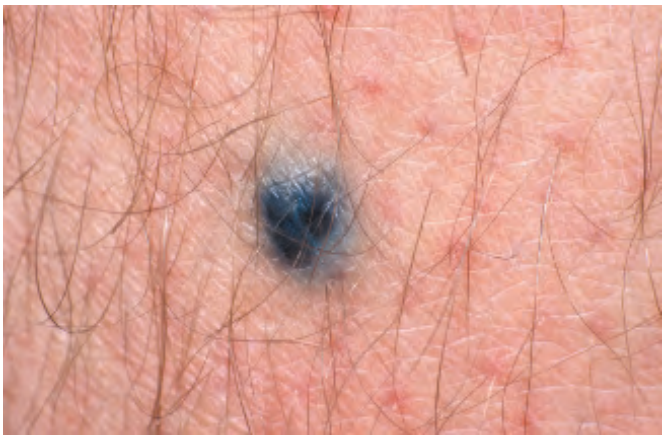

Figure 40.21 Blue naevus (courtesy of St John's Institute for Dermatology, London, UK).

Figure 40.22 Naevus of Ota (courtesy of St John's Institute for Dermatology, London, UK).

Figure 40.23 Naevus of Ito (courtesy of St John's Institute for Dermatology, London, UK).

A naevus of Ito is characterised by dermal melanocytosis in the shoulder region and can occur simultaneously in patients with naevus of Ota (Figure 40.23).

Hair follicles

Trichoepithelioma

These are small skin-coloured nodules, found most often in the nasolabial folds. It is clinically and histologically similar to a basal cell carcinoma.

Pilomatrixoma (calcifying epithelioma of Malherbe)

These are benign hair matrix cell tumours that often calcify. 40% are found in the under-10 age group.

Tricholemmoma (naevus sebaceous of Jadassohn)

Tricholemmoma is a congenital hamartoma with the appearance of a linear verrucous naevus. 10% form a BCC life-long (Figure 40.24).

Figure 40.24 Naevus sebaceous of Jadassohn (courtesy of St John's Institute for Dermatology, London, UK).

Adenoma sebaceum (tuberous sclerosis, Bourneville disease)

These are typically red, facial papules (angiofibromas), usually on the nasolabial folds, cheek and chin. They usually appear in children before 10 years of age and increase in size and

Josef Jadassohn, 1863–1936, dermatologist, Breslau, Germany (now Wroclaw, Poland).
Desire M Bourneville, 1840–1909, physician, Le Bicêtre, Paris, France.

number until adolescence. Cosmetic removal by argon or pulse dye lasers or scalpel is indicated (Figure 40.25).

Rhinophyma

Rhinophyma is the end-stage sequela of nasal acne rosacea (Figure 40.26). It is nasal sebaceous gland hypertrophy and hyperplasia and tends to affect elderly men (M:F12:1). Occult BCCs exist in 3%. Treatment by dermabrasion or laser resurfacing produces good results.

Figure 40.25 Adenoma sebaceum (courtesy of St John's Institute for Dermatology, London, UK).

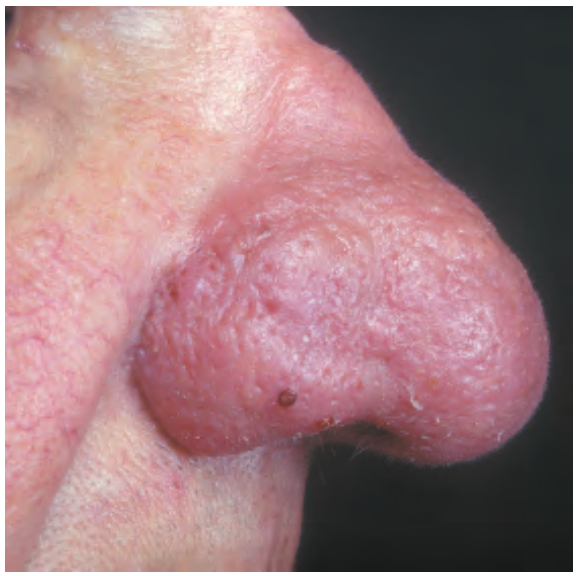

Figure 40.26 Rhinophyma (courtesy of St John's Institute for Dermatology, London, UK).

Sweat glands

Cystadenoma (hydrocystadenomas, hidradenomas)

These are 1–3 cm translucent blue cystic nodules.

Eccrine poroma (papillary syringoma)

These are single raised or pedicled lesions found most often on the palm or sole.

Cylindroma (turban tumour)

A variant of eccrine spiradenoma, which coalesce when multiple on the scalp, forming a 'turban tumour'.

Premalignant lesions

Extramammary Paget's disease (intraepidermal adenocarcinoma)

This occurs in cutaneous sites rich in apocrine glands such as the axillae, genital and perianal regions. Approximately 25% are associated with an underlying *in situ* or invasive adenocarcinoma. Early skin changes are subtle and may present as an eczematous lesion or intertrigo. Surgical excision forms the basis of treatment, with up to 20% demonstrating invasive disease after pathology assessment (Figure 40.27).

Figure 40.27 Extramammary Paget's disease involving the perineum (courtesy of St John's Institute for Dermatology, London, UK).

Giant congenital pigmented naevus (GCPN) or giant hairy naevus

This naevus causes a great deal of confusion as its definition and management is contentious. It is a hamartoma of naevo-melanocytes that has a tendency to dermatomal distribution (Figure 40.28). It has a similar histology to compound naevi, but the naevus cells are distributed variably from the epidermis throughout all layers and into the subdermal fat and muscle. GCPNs are precursors of melanoma, but the magnitude of this risk is unclear, largely due to the lack of well-conducted studies and variable classification of the naevus. A 3–5% lifetime risk of melanoma is quoted. 1 in 3 childhood malignant melanomas (MM) arise in patients with GCPN, but the risk decreases with age: 15% of MMs present at birth; 62% present by puberty and 99% by 45 years of age.

Figure 40.28 Giant congenital pigmented naevus (courtesy of St John's Institute for Dermatology, London, UK).

A multidisciplinary management approach is advocated, with initial investigations examining for neurocutaneous melanosis as there may be leptomeningeal involvement. Removal of GCPN should be considered for both aesthetic and oncological reasons.

Atypical (dysplastic) naevus

To be 'atypical naevi', lesions must have three of the following characteristics: variegated pigmentation; ill-defined borders; undulating irregular surfaces; or measure >5 mm. Histologically, they are irregular proliferations of melanocytes at the basal layer of epidermis. They can be sporadic or familial (familial atypical multiple mole-melanoma (FAMMM) syndrome). Possession of more than five confers a relative risk of melanoma six times greater than usual; within FAMM syndrome, they confer a life-long 10% risk of MM (**Figure 40.29**).

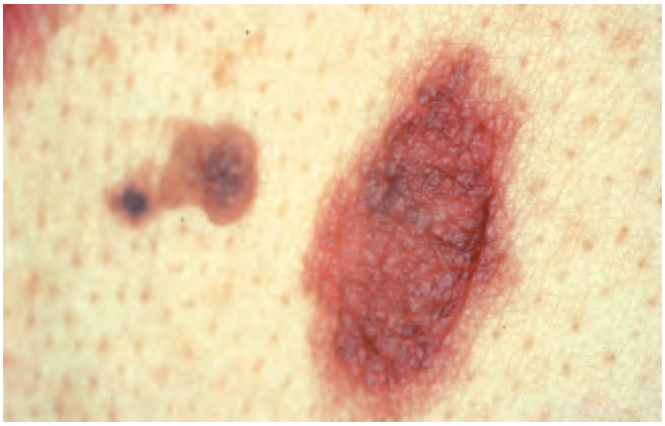

Figure 40.29 Dysplastic naevus (courtesy of St John's Institute for Dermatology, London, UK).

Malignant lesions

WHO data suggest both non-melanoma and melanoma skin cancers continue to increase in incidence, despite educational programmes and wide-ranging changes in uptake of sun protective measures and improvements in sun-screens. Annually, global figures reveal 33% of all recorded malignancy affects the skin, with 2–3 million new non-melanoma skin cancers and 132 000 new malignant melanomas diagnosed each year.

Basal cell carcinoma

This is usually a slow-growing, locally-invasive, malignant tumour of pluripotential epithelial cells arising from basal epidermis and hair follicles; hence, it affects the pilo-sebaceous skin.

Summary box 40.2

Basal cell carcinoma

- Slow growing
- Risk factor – ultraviolet radiation
- 90% nodular/nodular cystic
- High- and low-risk basal cell carcinoma

EPIDEMIOLOGY

The strongest predisposing factor to BCC is UVR. It occurs in the elderly or the middle-aged after excessive sun exposure, with 95% occurring between the ages of 40 and 80 years. The incidence of BCC rises with proximity to the equator, although 33% arise in parts of the body not usually sun-exposed. Other predisposing factors include exposure to arsenical compounds, coal tar, aromatic hydrocarbons, ionising radiation and genetic skin cancer syndromes. White-skinned people are almost exclusively affected. BCC is more common in men than women.

PATHOGENESIS

BCCs have no apparent precursor lesions and their development is proportional to the initial dose of the carcinogen, but not duration of exposure. The most likely model of pathogenesis for BCCs involves mesodermal factors as intrinsic promoters coupled with an initiation step.

BCCs metastasise extremely rarely.

MACROSCOPIC

BCC can be divided into localised (nodular; nodulocystic; cystic; pigmented and naevoid) and generalised (superficial: multifocal and superficial spreading; or infiltrative: morphoeic, ice pick and cicatrizing). Nodular and nodulocystic variants account for 90% of BCC.

MICROSCOPIC

Twenty-six histological subtypes have been described. The characteristic finding is of ovoid cells in nests with a single 'palisading' layer. It is only the outer layer of cells that actively divide, explaining why tumour growth rates are slower than

their cell cycle speed would suggest, and why incompletely excised lesions are more aggressive. Morphoeic BCCs synthesize type 4 collagenase and so spread rapidly (Figure 40.30).

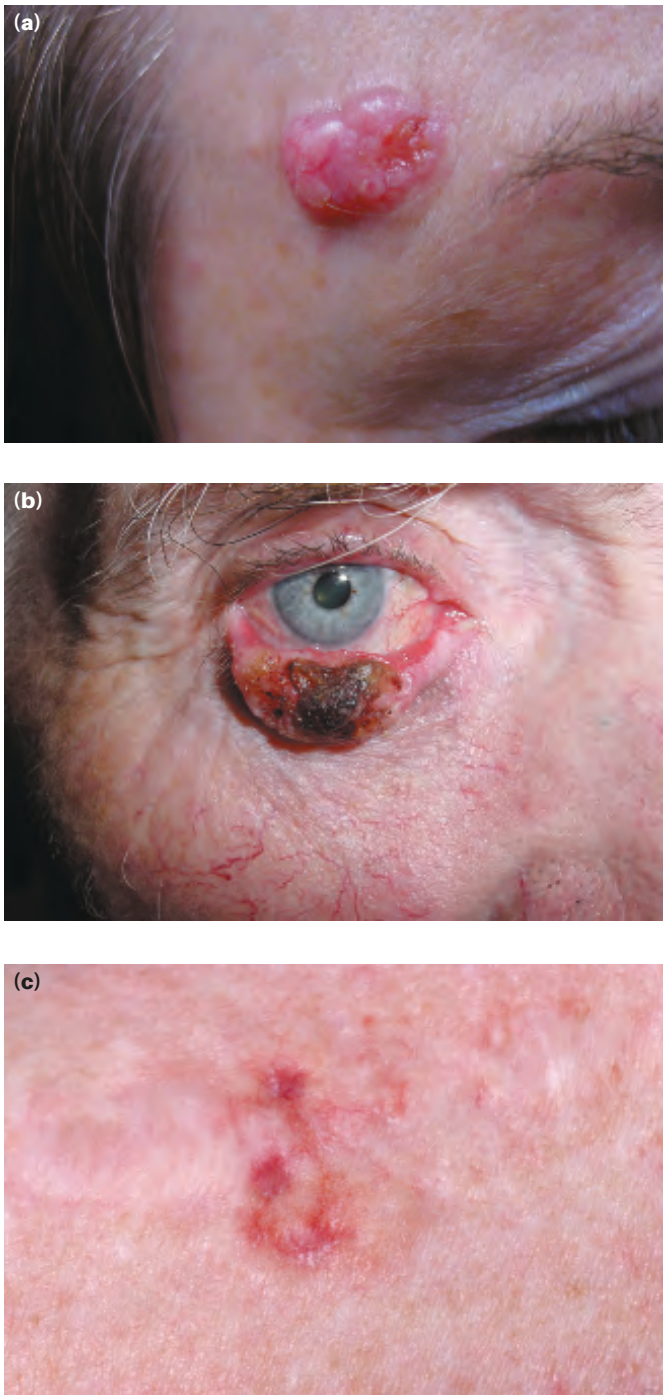

Figure 40.30 **(a)** A nodulocystic basal carcinoma (BCC). Note the characteristic pearly surface with telangectasia. **(b)** An ulcerating BCC on the lower eyelid. **(c)** A recurrent morphoeic BCC. ((**a**) and (**b**) courtesy of Mr AR Greenbaum; (**c**) courtesy of St John's Institute for Dermatology, London, UK.)

PROGNOSIS

There are 'high-risk' and 'low-risk' BCCs. High-risk BCCs are: large (>2 cm); located at sites where direct invasion gives access to the cranium (near the eye, nose and ear); recurrent tumours; tumours forming in the presence of immunosuppression; or that have micronodular or infiltrating histological subtypes.

MANAGEMENT

Treatment can be surgical or non-surgical. Tumour and surrounding surgical margins should always be assessed and marked under loupe magnification; the latter varying between 2 and15 mm, depending on the macroscopic variant. Where margins are ill-defined, or tissue at a premium (nose, eyes) then either a two-stage surgical approach with subsequent reconstruction after confirmation of clear margins, or Mohs' micrographic surgery is advisable. The histological sample must be orientated and marked for pathological examination.

Mohs' micrographic surgery is a method used by dermatological surgeons (dermatologists who have undergone extra training in techniques of cutaneous surgery and histopathology) to excise skin cancer under microscopic control.

In the elderly or infirm patients, radiotherapy produces similar recurrence rates to surgery; but with the risk of generating further malignancy after 1–2 decades. Biopsy-proven, superficial tumours can be treated with topical treatments (5-fluorouracil, imquimod).

Unless excision of a BCC is complete, there is a 67% recurrence rate if margins are grossly involved and a 33% recurrence rate within 2 years with microscopic involvement or when reported 'close'.

Patients with uncomplicated, completely-excised lesions can be discharged. Follow-up is reserved for patients with tumours in high-risk areas; with globally, sun-damaged skin; with syndromes; and for those who decline further surgery after incomplete excisions.

Cutaneous squamous cell carcinoma

SCC is a malignant tumour of keratinising cells of the epidermis or its appendages. It arises from the stratum basalis of the epidermis and expresses cytokeratins 1 and 10.

EPIDEMIOLOGY

Four BCCs occur for every SCC, which is the second most common form of skin cancer. It is strongly-related to cumulative sun exposure and damage, especially in white skinned individuals living nearer the equator. In the northern hemisphere it affects the elderly, whereas it is not uncommon in sun-damaged, middle-aged, white people in the southern hemisphere. Everywhere, it is more common in men than women. SCC is also associated with chronic inflammation (chronic sinus tracts, pre-existing scars, osteomyelitis, burns, vaccination points) and immunosuppression. When a SCC appears in a scar it is known as a Marjolin's ulcer.

Frederic E Mohs, 1910–2002, twentieth century American physician and general surgeon, University of Wisconsin, Madison, WI, USA, developed the Mohs micrographic surgical technique in 1938 for cutaneous malignant lesions.
Jean-Nicholas Marjolin, 1780–1850, surgeon, Paris, France, described the development of carcinomatous ulcers in scars in 1828.

Summary box 40.3

Squamous cell carcinoma

- Associated with ultraviolet radiation, chronic inflammation and chemical carcinogens
- High- and low-risk squamous cell carcinoma
- Metastasis in 2% cases

IR causes SCC, as do chemical carcinogens (arsenicals, tar) and infection with HPV 5 and 16. There is also evidence that current and previous tobacco use doubles the relative risk of SCC.

In the past, actinic (solar) keratoses (AK), i.e. cutaneous horns and keratoacanthomas, were considered to be premalignant lesions leading to SCC. Current thinking is to classify these lesions on a continuum of lesions, some of which can improve, as with other squamous cell tumours such as cervical intraepithelial neoplasia.

AKs are areas of permananent sun damage in which there is dyskeratosis and partial-thickness, cellular atypia, subepidermal inflammation, but an intact basement membrane (**Figure 40.31**). They 'wax and wane' macroscopically between macular and papular, with and without, keratinous surfaces. Most improve after moisturisation and remain as erythematous macules; however, up to 20% form SCC.

Figure 40.31 Actinic keratosis (courtesy of St John's Institute for Dermatology, London, UK).

When an AK has a keratinous surface with a height greater than its base diameter, it is termed a keratin horn. 10% will have an underlying SCC (**Figure 40.32**).

Keratoacanthomas are rapidly-growing, nodular tumours, exhibiting symmetry around a central, keratin-filled crater.

Figure 40.32 Cutaneous horn (courtesy of St John's Institute for Dermatology, London, UK).

Current thought is that rather than being separate premalignant entities, they are better considered as self-healing SCCs and as such, are often reported by pathologists as 'keratoacanthoma-like SCCs' (**Figure 40.33**). Keratoacanthomas are twice as common in men than women and usually found on the face or limbs of chronically, sun-damaged 50–70-year-old white-skinned individuals. They may be caused by HPV in a hair follicle during growth phase and are also associated with smoking and chemical carcinogen exposure. Excision is recommended, rather than observation, as the differential diagnosis includes anaplastic SCC and the excision scar is often better than that which remains after resolution.

Bowen's disease is SCC *in situ* and often develops as full-thickness dysplasia in hypertrophic AKs (**Figure 40.34**). SCC in situ usually presents as a slowly enlarging, erythematous scaly plaque and may occur anywhere on the mucocutaneous surface of the body. On the glans penis, it is called erythroplasia of Queyrat (**Figure 40.35**). Topical therapy with 5-fluorouracil or imiquimod are effective treatments. Alternatives include surgical excision with a 4 mm margin, or Mohs' micrographic surgery for larger or recurrent lesions.

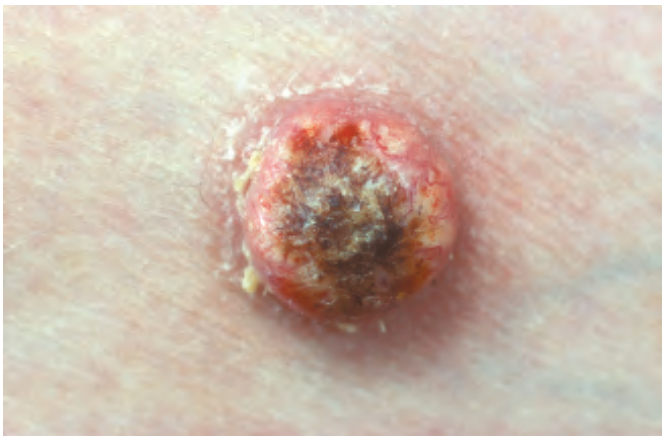

Figure 40.33 Keratocanthoma (courtesy of St John's Institute for Dermatology, London, UK).

John T Bowen, 1857–1940, Professor of Dermatology at Harvard, USA.
August Queyrat, 1856–1933, dermatologist, Paris, France, described this condition in 1911.

Figure 40.34 Bowen's disease – squamous cell carcinoma *in situ* (courtesy of St John's Institute for Dermatology, London, UK).

MACROSCOPIC

The appearance of SCC may vary from smooth nodular, verrucous, papillomatous to ulcerating lesions. All ulcerate eventually, as they grow. The ulcers have a characteristic everted edge and are surrounded by inflamed, indurated skin. Differential diagnoses of SCC include: AK; BCC; pyoderma gangrenosum; warts; and lichen simplex chronicus (**Figure 40.36**).

Figure 40.35 Erythroplasia of Queyrat – squamous cell carcinoma *in situ* on the glans penis; also called Paget's disease of the penis (courtesy of St John's Institute for Dermatology, London, UK).

MICROSCOPIC

Characteristic irregular masses of squamous epithelium are noted to proliferate and invade the dermis from the basal layer. The tumour stains positive for cytokeratins 1 and 10. SCC can be graded histologically according to Broder's grading, which describes the proportion of dedifferentiated cells in the tumour. *Table 40.1* presents tumour classification and staging.

PROGNOSIS

There are several independent prognostic variables for SCC:

- Depth: the deeper the lesion, the worse the prognosis. For SCC <2 mm, metastasis is highly unlikely; whereas if >6 mm, 15% of SCC will have metastasised.

TABLE 40.1 TNM Classification and staging.

Size	Nodes	Mets	Stages
TX Primary tumour cannot be assessed	NX Nodal involvement cannot be assessed	M0 No metastatic disease	Stage 0 Tis, N0, M0
T0 No evidence of primary tumour	N0 No regional nodes	M1 Metastatic disease present	Stage I T1, N0, M0
Tis In situ (confined to full thickness epidermal) disease	N1 Spread to 1 ipsilateral, nearby node that is <3 cm diameter		Stage II T2, N0, M0
T1 Primary <2 cm	N2a Spread to 1 ipsilateral nearby node that is 3–6 cm diameter		Stage III T3, N0, M0 or T1–T3, N1, M0
T2 Primary >2 cm	N2b Spread to >1 ipsilateral, nearby nodes, but none >6 cm diameter		Stage IV T1–T3, N2, M0 or any disease that is N3, or T4 or M1
T3 Primary invasion of a facial bone	N2c Spread to contralateral node(s), but none are >6 cm diameter		
T4 Invasion of muscle, base of skull or other bones	N3 Spread to any node >6 cm diameter		

Albert Compton Broders, 1885–1964, American pathologist of Minnesota, USA and Chairman of the Department of Surgical Pathology, The Mayo Clinic, Rochester, Minnesota, MN, USA; for 1 year in 1935 Professor of Surgical Pathology and Director of Cancer Research, University of Virginia, VA, USA. Broders graded rectal cancer in the USA in a manner that Cuthbert Dukes classified them in the UK. A combination of Broders' grading and Dukes' classification gave a more accurate prognosis for rectal carcinoma than either method alone.

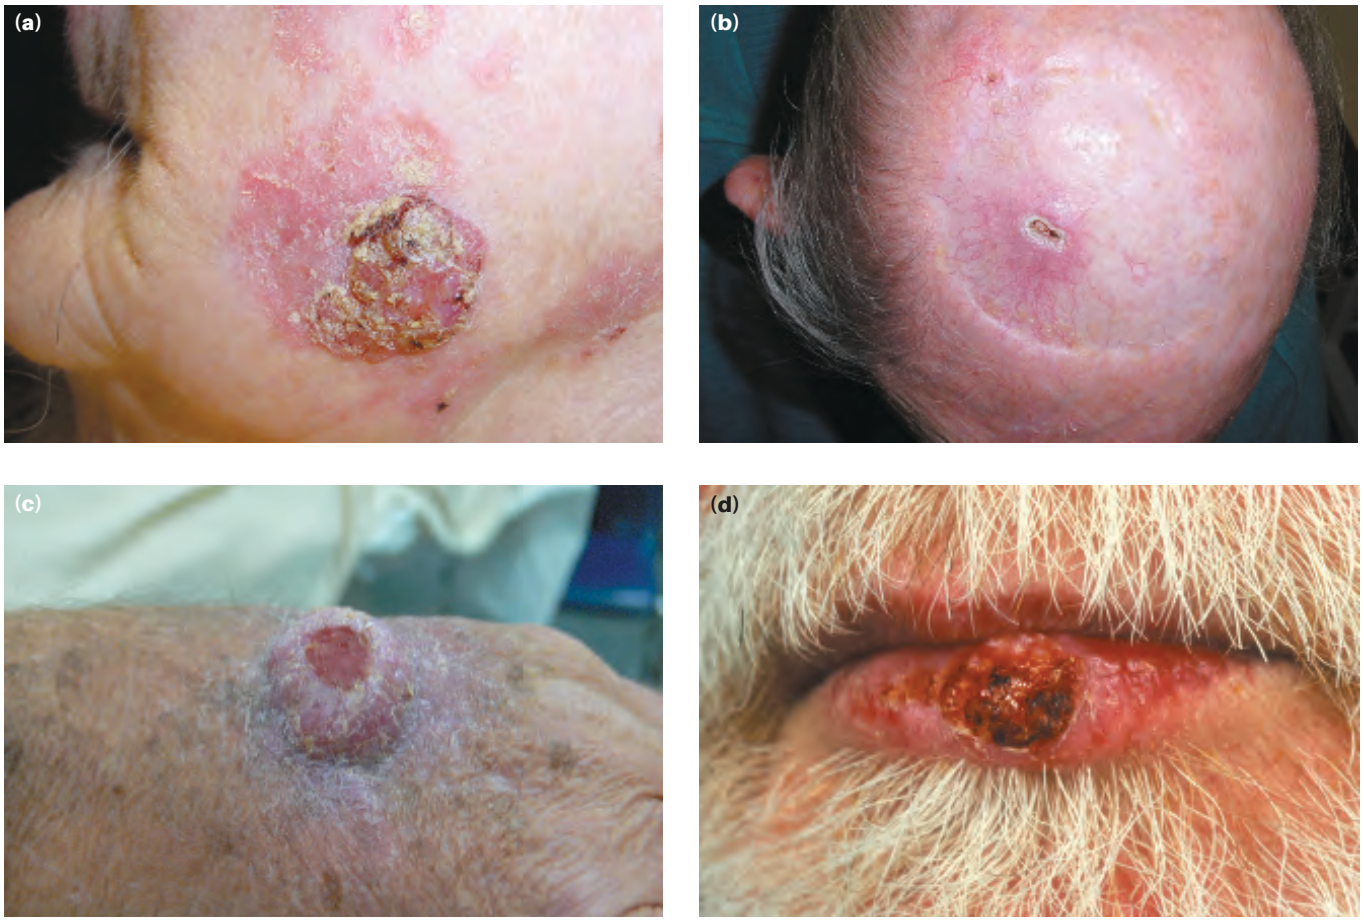

Figure 40.36 **(a)** A squamous cell carcinoma (SCC) on the face. **(b)** A recurrent SCC arising in a previously skin-grafted area of the scalp. **(c)** SCC arising on the dorsum of the hand in a renal transplant recipient on immunosuppressive therapy. **(d)** SCC arising on the lip of a smoker who worked outside on a farm. (**(a–c)** courtesy of Mr AR Greenbaum; **(d)** courtesy of St John's Institute for Dermatology, London, UK.)

- Surface size: lesions >2 cm have a worse prognosis than smaller ones.
- Histological grade: the higher the Broder's grade, the worse the prognosis.
- Microscopic invasion of lympho-vascular spaces or nerve tissue carries a high risk of metastatic disease.

Therefore, as well as information on pathological pattern, cellular morphology and Broder's grade, any histopathology report for SCC should include the depth of invasion, the presence of perineural or lymphovascular invasion and the deep and peripheral margin clearance.

- Site: SCCs on the lips and ears have higher local recurrence rates than lesions elsewhere, and tumours at the extremities fare worse than those on the trunk.
- Aetiology: SCCs that arise in burn scars, osteomyelitis skin sinuses, chronic ulcers and areas of skin that have been irradiated have a higher metastatic potential.
- Immunosuppression: SCCs will invade further in those with impaired immune response.

The overall rate of metastasis is 2% for SCC (usually to regional nodes) with a local recurrence rate of 20%.

MANAGEMENT

SCC is a heterogeneous tumour with a malignant potential that varies between subtypes. Management must address the tumour's tendency for lymphatic metastasis and the possibility of in-transit metastasis.

Surgical excision is the only means of providing accurate information on histology and clearance. The margins for primary excision should be tailored to surface size in the first instance. This should ideally be assessed using surgical loupe magnification. A 4 mm clearance margin should be achieved if the SCC measures <2 cm across, and a 1-cm clearance margin if >2 cm. 95% of local recurrence and regional metastases occur within 5 years, thus follow-up beyond this period is not indicated.

Cutaneous malignant melanoma

Melanoma is a cancer of melanocytes and can, therefore, arise in skin, mucosa, retina and the leptomeninges.

EPIDEMIOLOGY

Cutaneous melanoma is caused by exposure to UVR. Its rise in incidence reflects increased recreational activity in the sun

and emigration among white skinned races, not suited to sun exposure. Although it accounts for less than 5% of skin malignancy (and 1.6% of all malignancy worldwide), it is responsible for over 75% of skin malignancy-related deaths.

It is the commonest cancer in young adults (20–39 years) and the most likely cause of cancer-related death.

Distribution between the sexes varies around the world and reflects occupational and recreational exposure to sunlight. Likewise, geographical distribution reflects exposure of white-skinned individuals to sunlight: Taranaki in New Zealand, a country with a predominantly white-skinned, immigrant population, currently reports the highest (and rising) incidence per capita. 5% of all patients with MM will develop a second primary melanoma. 7% of MM presents as occult metastasis from an unknown primary.

PATHOPHYSIOLOGY

Cumulative UV exposure favours the development of lentigo maligna melanoma (LMM) and later onset of disease, whereas 'flash fry' exposure, typical of rapidly-acquired, holiday tans, favours the other morphological variants and early onset of disease.

A small proportion of MM is genetically-mediated and develops at an earlier age. People at most risk of developing MM include: those with genetic syndromes; a past history of MM or with first-degree relatives who have MM; those who have more than 30 sun-acquired naevi or a history of five significant sun-burns before the age of 16; fair-skinned/red-haired people living close to the equator; anyone with excessive UVR exposure (environmental or salon-delivered); or anyone with immunosuppression (which increases MM incidence 20–30-fold).

Summary box 40.4

Malignant melanoma

- Rising incidence
- Genetic and acquired risk factors
- Superficial spreading form the most common
- Breslow thickness most important prognostic indicator
- Sentinel node biopsy useful for staging

MACROSCOPIC

Only 10–20% of MM form in pre-existing naevi, with the remainder arising *de novo* in previously normally pigmented skin. The most likely naevi to form MM are atypical naevi, atypical junctional lenitiginous naevi (usually facial) and giant pigmented congenital naevi.

Macroscopic features in a pre-existing naevus that suggest malignant change are listed in *Summary box 40.5*.

There are four common macroscopic variants of MM and several other notable, but rarer forms:

Summary box 40.5

Macroscopic features in naevi suggestive of malignant melanoma

- Change in size
- Shape
- Colour
- Thickness (elevation/nodularity or ulceration)
- Satellite lesions (pigment spreading into surrounding area)
- Tingling/itching /serosanguinous discharge (usually late signs)

Superficial spreading melanoma (SSM) This is the most common presentation (70%), usually arising in a pre-existent naevus after several years of slow change, followed by rapid growth in the preceding months before presentation **(Figure 40.37)**. Nodularity within SSM heralds the onset of the vertical growth phase.

Nodular melanoma (NM) Nodular melanoma accounts for 15% of all MM and tends to be more aggressive than SSM, with a shorter clinical onset. These lesions often arise *de novo* in skin and are more common in men than women, often presenting in middle age and usually on the trunk, head or neck **(Figure 40.38)**. They typically appear as blue/black papules, 1–2 cm in diameter, and because they lack the horizontal growth phase, they tend to be sharply demarcated. Up to 5% are amelanotic.

Lentigo maligna melanoma LMM was previously also known as Hutchinson's melanotic freckle. This variant

Figure 40.37 Superficial spreading melanoma (courtesy of St John's Institute for Dermatology, London, UK).

Sir Jonathan Hutchinson, 1828–1913, surgeon, St Bartholomew's Hospital, London, UK.

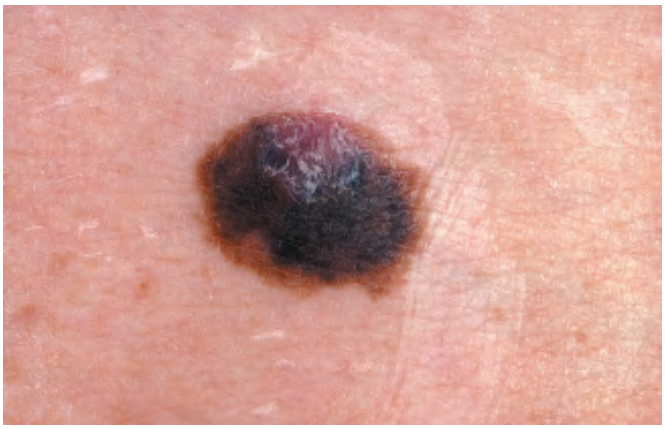

Figure 40.38 Nodular melanoma (courtesy of St John's Institute for Dermatology, London, UK).

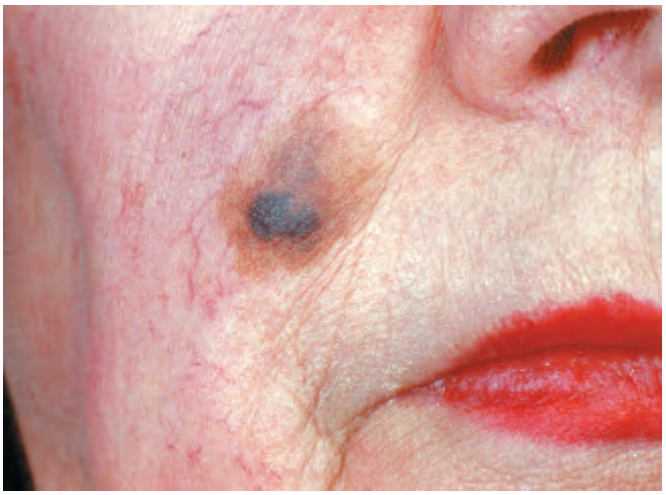

Figure 40.39 Lentigo maligna melanoma (courtesy of St John's Institute for Dermatology, London, UK).

presents as a slow-growing, variegated brown macule on the face, neck or hands of the elderly (Figure 40.39). They are positively correlated with prolonged, intense sun exposure, affecting women more than men. They account for between 5% and 10% of MM.

LMM are thought to have less metastatic potential than other variants as they take longer to enter a vertical growth phase. Nonetheless, when they have entered the vertical growth phase their metastatic potential is the same as any other melanoma.

Acral lentigious melanoma (ALM) ALM affects the soles of feet and palms of hands. It is rare in white-skinned individuals (2–8% of MM) but more common in the Afro-Caribbean, Hispanic and Asian population (35–60%). It usually presents as a flat, irregular macule in later life. 25% are amelanotic and may mimic a fungal infection or pyogenic granuloma.

MM under the finger nail are usually SSM rather than ALM. For finger or toe nail lesions it is vital to biopsy the nail matrix, rather than just the pigment on the nail plate. A classical feature of a subungual melanoma is Hutchinson's sign: nail fold pigmentation that widens progressively to produce a triangular pigmented macule with associated nail dystrophy. The differential diagnosis is 'benign racial melanonychia', which produces a linear dark streak under a nail in a dark-skinned individual. Malignancy is unlikely if the nail fold is uninvolved (Figure 40.40).

Miscellaneous

- Amelanotic melanoma may present as a flesh-coloured, skin lesion; as a metastasis from an unknown skin primary; or, in the gastrointestinal tract, with obstruction or intussusception.
- Desmoplastic melanoma is mostly found on the head and neck region. It has a propensity for perineural infiltration and often recurs locally if not widely excised. It may be amelanotic clinically.

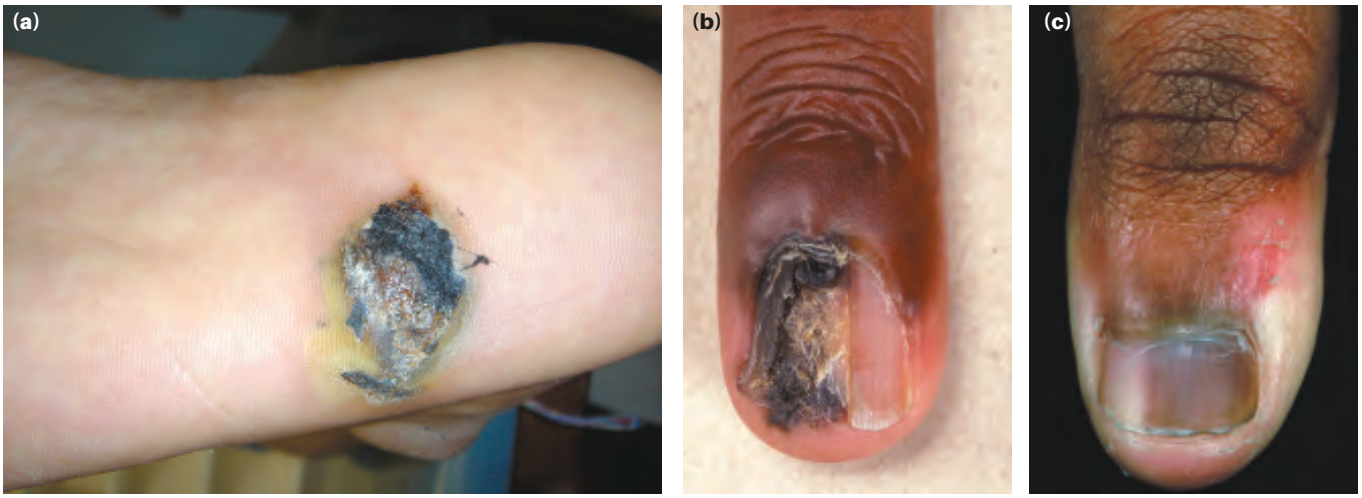

Figure 40.40 **(a)** Acral lentiginous melanoma on the sole of the foot (courtesy of Mr AR Greenbaum). **(b)** Subungual melanoma – probably a superficial spreading melanoma. Note the swelling proximal to the nail fold. **(c)** Benign racial melanonychia. (**(b)** and **(c)** courtesy of St John's Institute for Dermatology, London, UK.)

MICROSCOPIC

Malignant change occurs in the melanocytes in the basal epidermis, while *in situ*, atypical melanocytes are limited to the dermo-epidermal junction and show no evidence of dermal involvement. During the horizontal growth phase, cells spread along the dermo-epidermal junction and although they may breach the dermis, their migration is predominantly radial. During the vertical growth phase, the dermis maybe invaded. The greater the depth of invasion, the greater is the metastatic potential of the tumour.

MANAGEMENT

History and clinical examination should be directed at discovering the primary lesion and identification of local, regional or distant spread.

An excision biopsy with 2–3 mm margin of skin and a cuff of subdermal fat is acceptable. Incision biopsy is occasionally indicated: for instance, in large lesions on the face where an excision biopsy of the whole lesion would be disfiguring.

In experienced hands, observation and review every 2 months may avoid biopsies in equivocal cases, but serial clinical and dermoscopic photography by a clinician with expertise in dermoscopy is mandatory when observation is chosen, rather than excision biopsy, for definitive histopathological diagnosis.

Biopsy and pathological examination provide the first step towards staging melanoma. The Breslow thickness of a melanoma (measured to nearest 0.1 mm from granular layer to base of tumour) is the most important prognostic indicator in the absence of lymph node metastases. The American Joint Committee on Cancer (AJCC) staging system then takes lymph node and distant metastases into account *(Table 40.2)*.

INVESTIGATIONS

Guidelines for staging are controversial. The authors suggest investigations should be directed towards detecting occult disease, so as to upstage patients and treat them accurately and appropriately, the only cure for MM currently being appropriate surgery. Thus, offering sentinel node biopsy to patients with T2a disease and greater is prudent and investigations for T3a disease and greater should be directed to individual clinical presentation.

LOCAL TREATMENT

The treatment for melanoma is surgery. Lentigo maligna (melanoma *in situ*) should be excised completely in most clinical situations because of the risk of it entering the vertical growth phase to become LMM. A complete excision requires no further treatment.

For *in situ* melanoma a wide excision of 5 mm is sufficient; for melanoma <1 mm deep, a 1 cm margin is sufficient; and for deeper lesions, a 2 cm only margin is recommended, as there is no evidence that wider margins make a difference.

TABLE 40.2 AJCC 2009 melanoma staging.

Primary tumour		Regional nodes		Distant metastases
Tx Primary tumour cannot be assessed (has been curettage or severely regressed)		NX Patients in whom nodes cannot be assessed (e.g. previous excision)		
T0 No evidence of primary tumour		N0 No node involvement		M0 No detected distant metastases
Tis melanoma in situ				
T1 ≤1.0 mm	a: no ulceration or mitoses b: with ulceration, or >1 mitosis/mm2	N1 1 node	a: micrometastasis b: macrometastasis	M1a Skin, subcutaneous, or distant lymph node metastases (normal serum LDH levels)
T2 1.01–2.0 mm	a: no ulceration b: with ulceration	N2 2–3 nodes	a: micrometastasis b: macrometastasis c: in transit mets/ satellite(s), without metastatic node(s)	M1b Lung metastases (normal serum LDH levels)
T3 2.01–3.0 mm	a: no ulceration b: with ulceration	N3	≥4 nodes, or matted nodes, or in transit mets/ satellite(s), with metastatic node(s)	M1c All other visceral metastases or any distant metastases with elevated serum LDH levels
T4 >4 mm	a: no ulceration b: with ulceration			
Clinical staging of melanoma				
Stage 0: Tis, N0, M0 Stage Ia: T1a, N0, M0 Stage Ib: T1b or T2a, N0, M0		Stage IIa: T2b or T3a, N0, M0 Stage IIb: T3b or T4a, N0, M0 Stage IIc: T4b, N0, M0		Stage III: any T, ≥ N1, M0 Stage IV: any T, Any N1, M1

LDH, lactate dehydrogenase.

Alexander Breslow, 1928–1980, American pathologist. George Washington University, Washington DC, USA, first reported in 1970 that the prognosis depends upon the thickness of the tumour.

REGIONAL LYMPH NODES

The likelihood of metastatic spread to regional lymph nodes is proportional to the Breslow thickness of the melanoma. Management of regional lymph nodes has been a contentious topic for well over a century. Some advocated simultaneous elective lymph node clearance at the time of wide excision of the primary melanoma. Others favoured a therapeutic lymphadenectomy if regional metastases became clinically evident. Evidence from retrospective studies demonstrate that patients with thick melanomas had better survival after elective lymphadenectomy, while data from prospective randomized studies were less convincing, except in specific subgroups. Ideally, one would like to be able to select for treatment those patients with the highest risk of metastatic spread. Sentinel node biopsy (SNB), an investigation based on the fact that lymphatic metastases proceed in an orderly fashion and can be predicted by mapping the lymphatic drainage from a primary tumor to the first or 'sentinel' node in the regional lymphatic basin, offered that potential; but extensive studies show no survival benefit, so SNB in melanoma is currently a staging investigation for patients with tumours of Breslow thickness >1 mm.

ADJUVANT THERAPY

Since the last edition of this book, great advances have occurred in treatment for unresectable and metastatic MM.

When mutation locks B-RAF protein signalling to 'on', it affects the mitogen-activated protein kinase (MAPK) cellular pathway, promoting initiation, malignant transformation, tumour progression and metastasis in the 50% of MM with B-RAF V600 mutations. Targeted therapy in stage IV melanoma using dabrafenib or vemurafenib, which block B-RAF action has shown promising results with metastatic melanoma. Trametinib has a different action on the MAPK pathway: stopping cell growth and promoting apoptosis. Combined use with dabrafenib to counter acquired tumour resistance via MAPK pathway reactivation, shows promising results in stage 4 disease. Also, selective immune checkpoint inhibitors ipilimumab or nivolimumab demonstrate benefit in metastatic or unresectable melanoma.

PROGNOSIS

The Breslow thickness of the primary tumour offers the best correlation with survival in stage I disease. The higher the mitotic index, the poorer is the prognosis of the primary tumour. This has greater significance than the presence or absence of ulceration.

The presence of lymph node metastases is the single most important prognostic index in melanoma, outweighing both tumour and host factors. The number of affected nodes and the presence of extranodal extension are also significant outcome predictors. Once regional nodes are clinically involved, 70–85% of patients will have occult distant metastases.

Merkel cell (dermal mechanoreceptor) tumour

This is an aggressive malignant tumour of Merkel cells and usually affects the elderly. It is four times more common in women than men **(Figure 40.41)**. Treatment is with wide local excision aiming for a 25–30 mm margin, followed by radiotherapy.

Figure 40.41 Merkel cell tumour (courtesy of St John's Institute for Dermatology, London, UK).

VASCULAR LESIONS

Congenital: haemangiomata and vascular malformations

These can be subclassified *biologically* into vascular tumours or vascular malformations based on their endothelial characteristics, or *radiologically* into haemangiomata, vascular and lymphatic malformations based on their vascular dynamics.

Haemangiomata

These are benign endothelial tumours that affect three girls for every boy. 30% have a herald patch at birth, which then grows rapidly in the first year of life and slowly involutes over several years, with 70% having resolved by 7 years of age. Large hamangiomata can trap platelets leading to thrombocytopenia (Kasabach–Merritt syndrome).

Friedrich Sigmud Merkel, 1845–1919, Professor of Anatomy successively at Rostock, Koningsberg (now Kaliningrad in Russia) and Göttingen, Germany.
Haig H Kasabach, 1898–1943, radiologist, the Presbyterian Hospital, New York, NY, USA.
Katharine K Merritt, b.1886, American paediatrician, Department of Paediatrics, the Babies Hospital, Columbia University College of Physicians and Surgeons, New York, NY, USA. Kasabach and Merritt described the condition as a joint paper in 1940.

Vascular malformations

Vascular malformations affect boys and girls equally and are associated with numerous syndromes. They are invariably present at birth, but may be missed if deep to the skin. Vascular malformations subsequently grow in proportion to the child's growth (other than in response to sepsis or hormonal stimulation). Stasis can lead to a localised, consumptive coagulopathy in large venous malformations. Low-flow malformations may cause skeletal hypoplasia, while high-flow malformations can cause hypertrophy.

Common vascular birthmarks

Salmon patch

A salmon patch is a haemangioma that presents as a pinkish macule, usually at the nape of neck (**Figure 40.42**). It is caused by an area of persistent fetal dermal circulation, which usually disappears at 1 year.

Figure 40.42 Salmon patch (courtesy of St John's Institute for Dermatology, London, UK).

Capillary haemangioma (strawberry naevus)

This is the commonest 'birth mark', occurring most commonly on the head and neck (**Figure 40.43**). 90% appear at birth, and, as a consequence of intravascular thrombosis, fibrosis and mast cell infiltration, 10% resolve each subsequent year, with 70% resolved by 7 years old.

Whites skin is affected most commonly and girls are affected three times more than boys.

Figure 40.43 Capillary haemangioma (courtesy of St John's Institute for Dermatology, London, UK).

Capillary vascular malformations 'port-wine' stains

Capillary vascular malformations ('port-wine stains' (PWS)) are 20 times less common than capillary haemangiomata and result from defective maturation of cutaneous sympathetic innervation during embryogenesis, leading to localised intradermal capillary vasodilatation (**Figure 40.44**). They appear at birth as flat, smooth, intensely purple-stained areas, most frequently on the head and neck, often within the maxillary and mandibular dermatomes of the trigeminal nerve.

Treatment with intense pulsed light and pulse dye laser are successful. PWS may be associated with various syndromes.

Figure 40.44 'Port-wine' stain (courtesy of St John's Institute for Dermatology, London, UK).

Acquired

Campbell de Morgan spots

These are arteriovenous fistulae at the dermal capillary level in sun-exposed skin of older patients (**Figure 40.45**).

Campbell Greig de Morgan, 1811–1876, surgeon, the Middlesex Hospital, London UK.

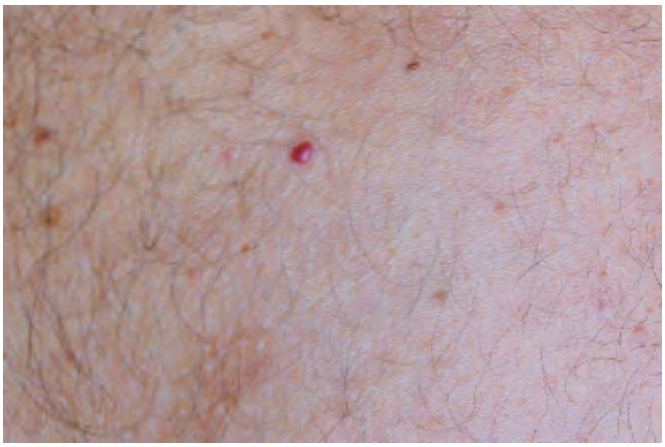

Figure 40.45 Campbell de Morgan spot (courtesy of Mr AR Greenbaum).

Spider naevi

These are angiomata that appear (and may disappear) spontaneously at puberty or in two-thirds of pregnant women, usually disappearing in the puerperium (Figure 40.46). Spider naevi are also associated with chronic liver disease. They can be treated with intense pulsed light or pulse dye laser.

Figure 40.46 Spider naevus (courtesy of St John's Institute for Dermatology, London, UK).

Pyogenic granuloma

These share many histological characteristics of haemangiomas and are probably a subtype thereof (Figure 40.47). Most are small (0.5–1.5 cm), raised, pedunculated, soft red nodular lesions showing superficial ulceration and a tendency to bleed after trivial trauma. They should be excised with a minimal margin.

Glomus tumour

These arise from a subcutaneous arteriovenous shunt (Sucquet–Hoyer canals), especially in the corium of the nail bed. Typically, it is a small, purple nodule measuring a few millimetres in size, which is disproportionately painful in response to insignificant stimuli, including cold exposure (Figure 40.48). Subungual varieties may be invisible causes of paroxysmal digital pain.

Figure 40.47 Pyogenic granuloma (courtesy of St John's Institute for Dermatology, London, UK).

Figure 40.48 Glomus tumour (courtesy of St John's Institute for Dermatology, London, UK).

JP Sucquet, 1840–1870, anatomist, Paris, France.
Heinrich Hoyer, 1834–1907, Professor of Histology, Embryology and Anatomy, the Central Medical School, The Polish University, Warsaw, Poland.

Angiosarcoma ('malignant angioendothelioma')

A rare, highly malignant tumour arising from the endothelial cells (Figure 40.49). The lymphangiosarcoma variant arises from lymphatic endothelium and can develop in lymphoedematous tissue, particularly an extremity. Proliferation is rapid with early systemic spread.

Figure 40.49 Angiosarcoma (courtesy of St John's Institute for Dermatology, London, UK).

Kaposi's sarcoma

Kaposi's sarcoma is a malignant, proliferative tumour of vascular endothelial cells, which was first described in elderly Jewish men but is now most commonly associated with immune compromise after transplantation or HIV infection (Figure 40.50). There appears to be a causal link with infection by human herpes virus 8. Kaposi's sarcoma usually starts as a red brown, indurated, plaque-like, skin lesion that becomes nodular and then ulcerates. Treatment is with radiotherapy.

Figure 40.50 Kaposi's sarcoma (courtesy of St John's Institute for Dermatology, London, UK).

WOUNDS

Congenital

Cutis aplasia congenita

This is a rare condition characterised by the congenital absence of epidermis, dermis and, in some cases, subcutaneous tissues, with underlying bony defects in 20%. Treatment depends on the severity of the presentation, but usually involves plastic surgery.

Parry–Romberg disease

Parry–Romberg disease is an uncommon and poorly understood progressive, hemifacial atrophy of skin, soft tissue and bone. Its incidence is unknown and its inheritance uncertain, but it affects women more commonly than men.

The disease commonly starts in a patient's late 20s, but can present in childhood, when the resulting deformity is worse because it is magnified by differential growth elsewhere. The condition is self-limiting, usually by 5–10 years after onset. Once stable, plastic surgical techniques can be employed alone or in combination to reconstruct an aesthetic contour.

Spina bifida

Failure of closure of the caudal neuropore during the 4th week *in utero* results in incomplete development of some or all of the structural elements posterior to the spinal cord. This can occur anywhere, but is commonest in lumbar vertebrae and presents as gross variants: spina bifida occulta, in which there is a bony defect without neural protrusion and spina bifida cystica, in which there is herniation of the meninges (meningocoele), spinal cord (myelocoele) or, most commonly, both (menigomyelocoele) and is therefore asymptomatic. Management ideally involves a multidisciplinary approach and is directed towards protecting the spinal cord, preventing cerebrospinal fluid contamination and secondary hydrocephalus and meningitis.

Acquired

Pressure sores

These begin with tissue necrosis at a pressure point and develop into a cone-shaped volume of necrotic loss. As many as 10% of acute hospital in-patients will suffer some degree of pressure sore. The majority affect the elderly and patients with spinal injury or decreased sensibility; 80% of paraplegics will get a pressure sore and 8% die as a result.

The pathogenesis of pressure sores revolves around unrelieved pressure: an increase in local tissue pressure above that of perfusion pressure produces ischaemic necrosis that is directly proportional to the duration and degree of pressure and inversely proportional to the area over which it is applied. Muscle and fat are more susceptible to pressure than skin.

Moricz K Kaposi, 1837–1902, Austrian dermatologist, described xeroderma pigmentosum in 1874. He also described a rare cutaneous sarcoma in Ashkenazi Jews; now more often an AIDS-defining condition.
Caleb Hillier Parry, 1755–1822, physician, The General Hospital, Bath, UK.
Moritiz Heinrich Romberg, 1795–1873, German neurologist, Director of the University Hospital, Berlin, Germany.

In a patient who has no predisposing factors management is aimed at debridement and repair of the defect, on the assumption that recurrence will not occur once normal function and sensibility returns. In the paraplegic patient recurrence is likely, so management should involve a multidisciplinary approach. Primary treatment involves relieving pressure (special mattress; nursing care; relief of muscle spasm and contractures); optimising nutrition; correcting anaemia; and preventing infection and dressings. Surgery involves thorough debridement to promote healing and plastic surgery to reconstruct the defect.

Ulcers

An ulcer is a discontinuity of an epithelial surface. It is characterised by destruction of the surface epithelium and a granulating base. Ulcers can be classified as non-specific, specific and malignant (Figure 40.51).

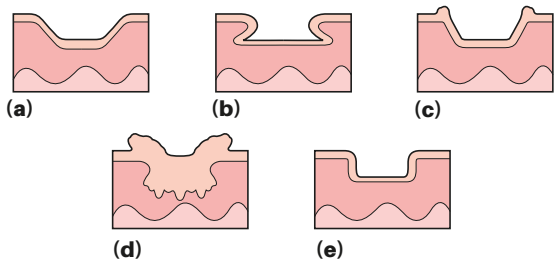

Figure 40.51 Some characteristic shapes of the edges of ulcers. **(a)** Non-specific ulcer: note the shelving edge. **(b)** Tuberculous ulcer: note the undermined edge. **(c)** Basal cell carcinoma (rodent ulcer): note the rolled edge, which may exhibit small blood vessels. **(d)** Epithelioma: note the heaped-up, everted edge and irregular thickened base. **(e)** Syphilis: note the punched-out edge and thin base, which may be covered with a 'wash-leather' slough.

Sinus

A sinus is a blind-ending tract connecting a cavity lined with granulation tissue (often an abscess cavity) to an epithelial surface (Figure 40.52a). Sinuses may be congenital or acquired. Congenital sinuses arise from the remnants of persistent embryonic ducts. Acquired sinuses can result from: a retained foreign body (ingrown hair or suture material); chronic infection (tuberculosis, osteomyelitis or actinomycosis); chronic inflammation (Crohn's disease); malignancy; or inadequate surgical drainage of the cavity.

Treatment of a sinus is directed at removing the underlying cause. Biopsies should always be taken from the wall of a sinus to exclude malignancy or specific infection. For specific management of the disease conditions, please refer to the appropriate chapter.

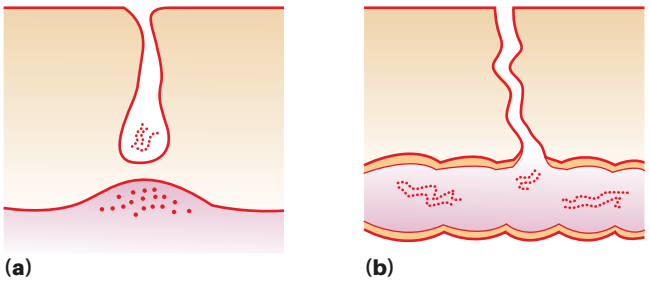

Figure 40.52 A sinus **(a)** and a fistula **(b)**; both usually arises from a preceding abscess. **(a)** This is a blind track, in this case a pilondial abscess. **(b)** This is a track connecting two epithelium-lined surfaces, in this case a colocutaneous fistula from colon to skin.

Fistula

A fistula is an abnormal communication between two epithelial-lined surfaces (Figure 40.52b). This communication or tract may be lined by granulation tissue, but may become epithelialised in chronic cases. Fistulas may be congenital (for example, tracheo-oesophageal and branchial fistulas) or acquired (for example, enterocutaneous complicating Crohn's disease or surgery, or arteriovenous). Management of a fistula is directed at the underlying aetiology (see the appropriate chapters).

Chapter 41

Burns

Learning objectives

To assess:
- The area and depth of burns

To understand:
- Methods for calculating the rate and quantity of fluids to be given
- Techniques for treating burns and the patient
- The pathophysiology of electrical and chemical burns

INTRODUCTION

The incidence of burn injury varies greatly between cultures. In the United Kingdom (with its population of 65 million), each year around 175 000 people visit accident and emergency (A&E) departments suffering from burns, of whom about 13 000 need to be admitted. About 1000 have severe burns requiring fluid resuscitation, and half of the victims are under 16 years of age.

The majority of burns in children are scalds caused by accidents with kettles, pans, hot drinks and bath water. Among adolescent patients, the burns are usually caused by young males experimenting with matches and flammable liquids. In adults, scalds are not uncommon, but are less frequent than flame burns. Most electrical and chemical injuries occur in adults. Cold and radiation are very rare causes of burns. Associated conditions in adults, such as mental disease (attempted suicide or assault), epilepsy and alcohol or drug abuse, are underlying factors in as many as 80% of patients with burns admitted to hospital in some populations.

Legislation, health promotion and appliance design have reduced the incidence of burns, with regulations regarding flame-retardant clothes and furniture, the promotion of smoke alarms, the design of cookers and gas fires, the almost universal use of cordless kettles and the education of parents to keep their hot water thermostat to 60°C all playing their part.

The last 50 years have seen great strides made to reduce both morbidity and mortality from burn injuries. The coming years will see a better understanding of the control of physiology along with improvements in reconstruction and rehabilitation.

A large burn injury will have a significant effect on the patient's family and friends and the patient's future. The importance of multidisciplinary care needs to be stressed for the adequate and effective care of the burn patient.

Summary box 41.1

Prevention of burns

A significant proportion of burns can be prevented by:
- Implementing good health and safety regulations
- Educating the public
- Introducing of effective legislation

THE PATHOPHYSIOLOGY OF BURN INJURY

Burns cause damage in a number of different ways, but by far the most common organ affected is the skin. However, burns can also damage the airway and lungs, with life-threatening consequences. Airway injuries occur when the face and neck are burned. Respiratory system injuries usually occur if a person is trapped in a burning vehicle, house, car or aeroplane and is forced to inhale the hot and poisonous gases.

Summary box 41.2

Warning signs of burns to the respiratory system
- Burns around the face and neck
- A history of being trapped in a burning room
- Change in voice
- Stridor

INJURY TO THE AIRWAY AND LUNGS

Physical burn injury to the airway above the larynx

The hot gases can physically burn the nose, mouth, tongue, palate and larynx. Once burned, the linings of these structures will start to swell. After a few hours, they may start to interfere with the larynx and may completely block the airway if action is not taken to secure an airway.

Summary box 41.3

Dangers of smoke, hot gas or steam inhalation

- Inhaled hot gases can cause supraglottic airway burns and laryngeal oedema
- Inhaled steam can cause subglottic burns and loss of respiratory epithelium
- Inhaled smoke particles can cause chemical alveolitis and respiratory failure
- Inhaled poisons, such as carbon monoxide, can cause metabolic poisoning
- Full-thickness burns to the chest can cause mechanical blockage to rib movement

Physical burn injury to the airway below the larynx

This is a rare injury as the heat exchange mechanisms in the supraglottic airway are usually able safely to absorb the heat from hot air. However, steam has a large latent heat of evaporation and can cause thermal damage to the lower airway. In such injuries, the respiratory epithelium rapidly swells and detaches from the bronchial tree. This creates casts, which can block the main upper airway.

Metabolic poisoning

There are many poisonous gases that can be given off in a fire, the most common being carbon monoxide, a product of incomplete combustion that is often produced by fires in enclosed spaces. This is the usual cause of a person being found with altered consciousness at the scene of a fire. Carbon monoxide binds to haemoglobin with an affinity 240 times greater than that of oxygen and therefore blocks the transport of oxygen. Levels of carboxyhaemoglobin in the bloodstream can be measured. Concentrations above 10% are dangerous and need treatment with pure oxygen for more than 24 hours. Death occurs with concentrations around 60%.

Another metabolic toxin produced in house fires is hydrogen cyanide, which causes a metabolic acidosis by interfering with mitochondrial respiration.

Inhalational injury

Inhalational injury is caused by the minute particles within thick smoke, which, because of their small size, are not filtered by the upper airway, but are carried down to the lung parenchyma. They stick to the moist lining, causing an intense reaction in the alveoli. This chemical pneumonitis causes oedema within the alveolar sacs and decreasing gaseous exchange over the ensuing 24 hours **(Figure 41.1)**, and often gives rise to a bacterial pneumonia. Its presence or absence has a very significant effect on the mortality of any burn patient.

Figure 41.1 The swelling that occurs with inflammation due to burns.

Mechanical block on rib movement

Burned skin is very thick and stiff, and this can physically stop the ribs moving if there is a large full-thickness burn across the chest.

INFLAMMATION AND CIRCULATORY CHANGES

The dangers to the airway and respiration described above are readily apparent, but the cause of circulatory changes following a burn are more complex. The changes occur because burned skin activates a web of inflammatory cascades. The release of neuropeptides and the activation of complement are initiated by the stimulation of pain fibres and the alteration of proteins by heat. The activation of Hageman factor

John Hageman was a 37-year-old railroad brakeman in whom this factor deficiency was discovered by Dr Oscar Ratnoff in 1955.

initiates a number of protease-driven cascades, altering the arachidonic acid, thrombin and kallikrein pathways.

At a cellular level, complement causes the degranulation of mast cells and coats the proteins altered by the burn. This attracts neutrophils, which also degranulate, with the release of large quantities of free radicals and proteases. These can, in turn, cause further damage to the tissue. Mast cells also release primary cytokines such as tumour necrosis factor alpha (TNF-α). These act as chemotactic agents to inflammatory cells and cause the subsequent release of many secondary cytokines. These inflammatory factors alter the permeability of blood vessels such that intravascular fluid escapes. The increase in permeability is such that large protein molecules can also now escape with ease. The damaged collagen and these extravasated proteins increase the oncotic pressure within the burned tissue, further increasing the flow of water from the intravascular to the extravascular space (**Figure 41.2**).

The overall effect of these changes is to produce a net flow of water, solutes and proteins from the intravascular to the extravascular space. This flow occurs over the first 36 hours after the injury, but does not include red blood cells. In a small burn, this reaction is small and localised but, as the burn size approaches 10–15% of total body surface area (TBSA), the loss of intravascular fluid can cause a level of circulatory shock. Furthermore, once the area increases to 25% of TBSA, the inflammatory reaction causes fluid loss in vessels remote from the burn injury. This is why such importance is attached to measuring the TBSA involved in any burn. It dictates the size of inflammatory reaction and therefore the amount of fluid needed to control shock.

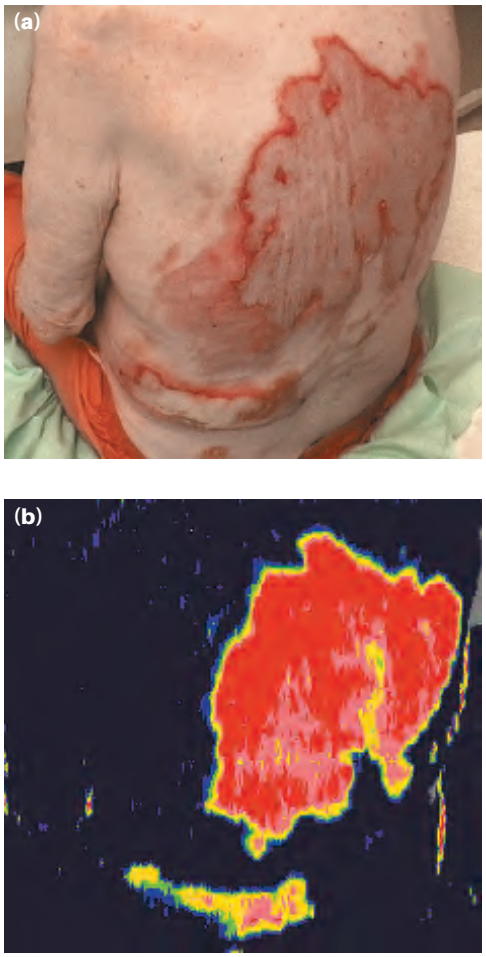

Figure 41.2 A scald burn **(a)** and its laser doppler image **(b)** showing burn depth. Red and pink areas are superficial burns, which should heal with conservative dressings.

Summary box 41.4

The shock reaction after burns

- Burns produce an inflammatory reaction
- This leads to vastly increased vascular permeability
- Water, solutes and proteins move from the intra- to the extravascular space
- The volume of fluid lost is directly proportional to the area of the burn
- Above 15% of surface area, the loss of fluid produces shock

OTHER LIFE-THREATENING EVENTS WITH MAJOR BURNS

The immune system and infection

The inflammatory changes caused by the burn have an effect on the patient's immune system. Cell-mediated immunity is significantly reduced in large burns, leaving them more susceptible to bacterial and fungal infections. There are many potential sources of infection, especially from the burn wound and from the lung if this is injured, but also from any central venous lines, tracheostomies or urinary catheters present.

Changes to the intestine

The inflammatory stimulus and shock can cause microvascular damage and ischaemia to the gut mucosa. This reduces gut motility and can prevent the absorption of food. Failure of enteral feeding in a patient with a large burn is a life-threatening complication. This process also increases the translocation of gut bacteria, which can become an important source of infection in large burns. Gut mucosal swelling, gastric stasis and peritoneal oedema can also cause abdominal compartment syndrome, which splints the diaphragm and increases the airway pressures needed for respiration.

Danger to peripheral circulation

In full-thickness burns, the collagen fibres are coagulated. The normal elasticity of the skin is lost. A circumferential full-thickness burn to a limb acts as a tourniquet as the limb swells. If untreated, this will progress to limb-threatening ischaemia.

Summary box 41.5

Other complications of burns

- Infection from the burn site, lungs, gut, lines and catheters
- Malabsorption from the gut
- Circumferential burns may compromise circulation to a limb

Summary box 41.6

Major determinants of the outcome of a burn

- Percentage surface area involved
- Depth of burns
- Presence of an inhalational injury

IMMEDIATE CARE OF THE BURN PATIENT

Prehospital care

The principles of prehospital care are:

- **Ensure rescuer safety**. This is particularly important in house fires and in the case of electrical and chemical injuries.
- **Stop the burning process**. Stop, drop and roll is a good method of extinguishing fire burning on a person.
- **Check for other injuries**. A standard ABC (airway, breathing, circulation) check followed by a rapid secondary survey will ensure that no other significant injuries are missed. Patients burned in explosions or even escaping from fires may have head or spine injuries and other life-threatening problems.
- **Cool the burn wound**. This provides analgesia and slows the delayed microvascular damage that can occur after a burn injury. Cooling should occur for a minimum of 10 minutes and is effective up to 1 hour after the burn injury. It is a particularly important first aid step in partial-thickness burns, especially scalds. In temperate climates, cooling should be at about 15°C, and hypothermia must be avoided.
- **Give oxygen**. Anyone involved in a fire in an enclosed space should receive oxygen, especially if there is an altered consciousness level.
- **Elevate**. Sitting a patient up with a burned airway may prove life-saving in the event of a delay in transfer to hospital care. Elevation of burned limbs will reduce swelling and discomfort.

Hospital care

The principles of managing an acute burn injury are the same as in any acute trauma case:

- A, Airway control.
- B, Breathing and ventilation.
- C, Circulation.
- D, Disability – neurological status.
- E, Exposure with environmental control.
- F, Fluid resuscitation.

The possibility of injury additional to the burn must be sought both clinically and from the history, and treated appropriately. The major determinants of severity of any burn injury are the percentage of TBSA that is burned, the presence of an inhalation injury and the depth of the burn.

Not all burned patients will need to be admitted to a burns unit, but the main criteria are given in *Table 41.1*.

TABLE 41.1 The criteria for acute admission to a burns unit.

Suspected airway or inhalational injury
Any burn likely to require fluid resuscitation
Any burn likely to require surgery
Patients with burns of any significance to the hands, face, feet or perineum
Patients whose psychiatric or social background makes it inadvisable to send them home
Any suspicion of non-accidental injury
Any burn in a patient at the extremes of age
Any burn with associated potentially serious sequelae, including high-tension electrical burns and concentrated hydrofluoric acid burns

Airway

The burned airway creates problems for the patient by swelling and, if not managed proactively, can completely occlude the upper airway. The treatment is to secure the airway with an endotracheal tube until the swelling has subsided, which is usually after about 48 hours. The symptoms of laryngeal oedema, such as change in voice, stridor, anxiety and respiratory difficulty, are very late symptoms. Intubation at this point is often difficult or impossible owing to swelling, so acute cricothyroidotomy equipment must be at hand when intubating patients with a delayed diagnosis of airway burn. Because of this, early intubation of suspected airway burn is the treatment of choice in such patients. The time-frame from burn to airway occlusion is usually between 4 and 24 hours, so there is time to make a sensible decision with senior staff and allow an experienced anaesthetist to intubate the patient.

Summary box 41.7

Initial management of the burned airway

- Early elective intubation is safest
- Delay can make intubation very difficult because of swelling
- Be ready to perform an emergency cricothyroidotomy, if intubation is delayed

The key in the management of airway burn is the history and early signs, rather than the symptoms. The history is of inhalation of hot gases such as in a house or car fire. Clues on examination include blisters on the hard palate, burned nasal mucosa and loss of all the hair in the nose (the anterior hairs are often burned), but perhaps the most valuable signs are the presence of deep burns around the mouth and in the neck.

Summary box 41.8

Recognition of the potentially burned airway

- A history of being trapped in the presence of smoke or hot gases
- Burns on the palate or nasal mucosa, or loss of all the hairs in the nose
- Deep burns around the mouth and neck

Breathing

Inhalational injury

Time is also a factor; anyone trapped in a fire for more than a couple of minutes must be observed for signs of smoke inhalation. Other signs that raise suspicion are the presence of soot in the nose and the oropharynx and a chest radiograph showing patchy consolidation.

The clinical features are a progressive increase in respiratory effort and rate, rising pulse, anxiety and confusion and decreasing oxygen saturation. These symptoms may not be apparent immediately and can take 24 hours to 5 days to develop.

Treatment starts as soon as this injury is suspected and the airway is secure. Physiotherapy, nebulisers and warm humidified oxygen are all useful. The patient's progress should be monitored using respiratory rate, together with blood gas measurements. If the situation deteriorates, continuous or intermittent positive pressure may be used with a mask or T-piece. In the severest cases, intubation and management in an intensive care unit will be needed.

The key, therefore, in the management of inhalational injury is to suspect it from the history, institute early management and observe carefully for deterioration.

Thermal burn injury to the lower airway

These rare injuries can occur with steam injuries. Their management is supportive and the same as that for an inhalational injury.

Metabolic poisoning

Any history of a fire within an enclosed space and any history of altered consciousness are important clues to metabolic poisoning. Blood gases must be measured immediately if poisoning is a possibility. Carboxyhaemoglobin levels raised above 10% must be treated with high inspired oxygen for 24 hours to speed its displacement from haemoglobin. Metabolic acidosis is a feature of this and other forms of poisoning.

Once again, the key to diagnosing these injuries is suspicion from the history. Blood gas measurement will confirm the diagnosis. The treatment is oxygen.

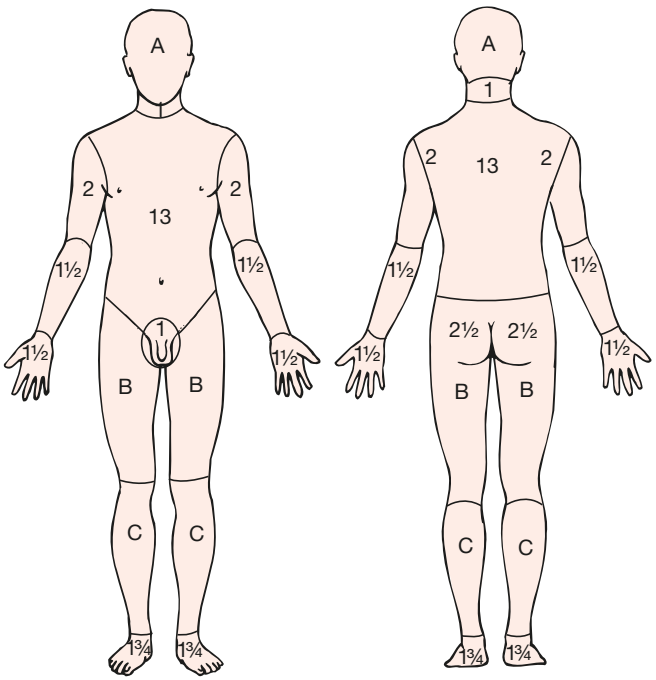
Mechanical block to breathing

Any mechanical block to breathing from the eschar of a significant full-thickness burn on the chest wall is obvious from the examination. There will also be carbon dioxide retention and high inspiratory pressures if the patient is ventilated. The treatment is to make some scoring cuts through the burned skin to allow the chest to expand (escharotomy). The nerves have been destroyed in the skin, and this procedure is not painful for the patient.

ASSESSMENT OF THE BURN WOUND

Assessing size

Burn size needs to be formally assessed in a controlled environment. This allows the area to be exposed and any soot or debris washed off. Care should be taken not to cause hypothermia during this stage. In the case of smaller burns or patches of burn, the best measurement is to cut a piece of clean paper the size of the patient's whole hand (digits and palm), which represents 1% TBSA, and match this to the area. Another accurate way of measuring the size of burns is to draw the burn on a Lund and Browder chart (**Figure 41.3**), which maps out the percentage TBSA of sections of our anatomy. It also takes into account different proportional body surface area in children according to age. The 'rule of nines', which states that each upper limb is 9% TBSA, each lower limb 18%, the torso 18% each side and the head and neck 9%, can be used as a rough guide to TBSA outside the hospital environment.



Relative percentage of area affected by growth

Age in years	0	1	5	10	15	Adult
A Head	9	8	6	5	4	3
B Thigh	2	3	4	4	4	4
C Leg	2	2	3	3	3	3

Figure 41.3 The Lund and Browder chart.

Summary box 41.9

Assessing the area of a burn

- The patient's whole hand is 1% TBSA, and is a useful guide in small burns
- The Lund and Browder chart is useful in larger burns
- The 'rule of nines' is adequate for a first approximation only

Assessing depth from the history

The first indication of burn depth comes from the history (*Table 41.2*). The burning of human skin is temperature- and time-dependent. It takes 6 hours for skin maintained at 44°C to suffer irreversible changes, but a surface temperature of 70°C for 1 s is all that is needed to produce epidermal destruction. Taking an example of hot water at 65°C: exposure for 45 s will produce a full-thickness burn, for 15 s a deep partial-thickness burn and for 7 s a superficial partial-thickness burn.

TABLE 41.2 Causes of burns and their likely depth.

Cause of burn	Probable depth of burn
Scald	Superficial, but with deep dermal patches in the absence of good first aid. Will be deep in a young infant
Fat burns	Deep dermal
Flame burns	Mixed deep dermal and full thickness
Alkali burns, including cement	Often deep dermal or full thickness
Acid burns	Weak concentrations superficial; strong concentrations deep dermal
Electrical contact burn	Full thickness

Summary box 41.10

Assessing the depth of a burn

- The history is important – temperature, time and burning material
- Superficial burns have capillary filling
- Deep partial-thickness burns do not blanch, but have some sensation
- Full-thickness burns feel leathery and have no sensation

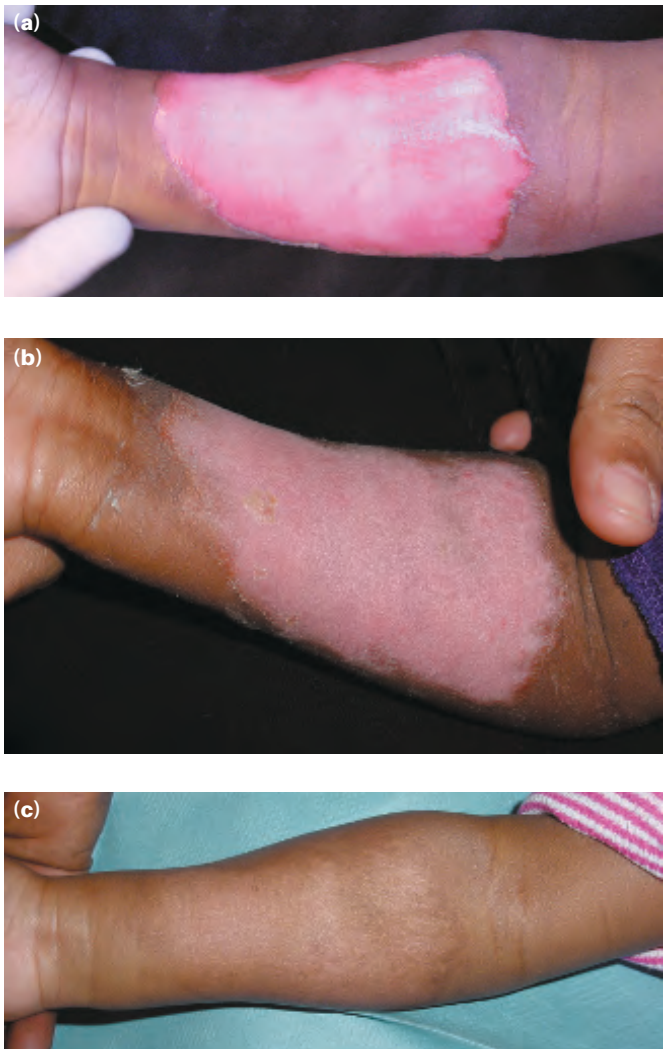


Figure 41.4 **(a)** A superficial partial-thickness scald 24 hours after injury. The dermis is pink and blanches to pressure. **(b)** At 2 weeks, the wound is healed but lacks pigment. **(c)** At 3 months, the pigment is returning.

Superficial partial-thickness burns

The damage in these burns goes no deeper than the papillary dermis. The clinical features are blistering and/or loss of the epidermis. The underlying dermis is pink and moist. The capillary return is clearly visible when blanched. There is little or no fixed capillary staining. Pinprick sensation is normal. Superficial partial-thickness burns heal without residual scarring in 2 weeks. The treatment is non-surgical **(Figure 41.4)**.

Deep partial-thickness burn

These burns involve damage to the deeper parts of the reticular dermis **(Figure 41.5)**. Clinically, the epidermis is usually lost. The exposed dermis is not as moist as that in a superficial burn. There is often abundant fixed capillary staining, especially if examined after 48 hours. The colour does not blanch with pressure under the examiner's finger. Sensation is reduced, and the patient is unable to distinguish sharp from blunt pressure when examined with a needle. Deep dermal burns take 3 or more weeks to heal without surgery and usually lead to hypertrophic scarring **(Figure 41.6)**.

Full-thickness burns

The whole of the dermis is destroyed in these burns **(Figure 41.7)**. Clinically, they have a hard, leathery feel. The appearance can vary from that similar to the patient's normal skin to charred black, depending upon the intensity of the heat. There is no capillary return. Often, thrombosed vessels can be seen under the skin. These burns are completely anaesthetised: a needle can be stuck deep into the dermis without any pain or bleeding.

FLUID RESUSCITATION

The principle of fluid resuscitation is that the intravascular volume must be maintained following a burn, in order to provide sufficient circulation to perfuse not only the essential visceral organs such as the brain, kidneys and gut, but also the peripheral tissues, especially the damaged skin.

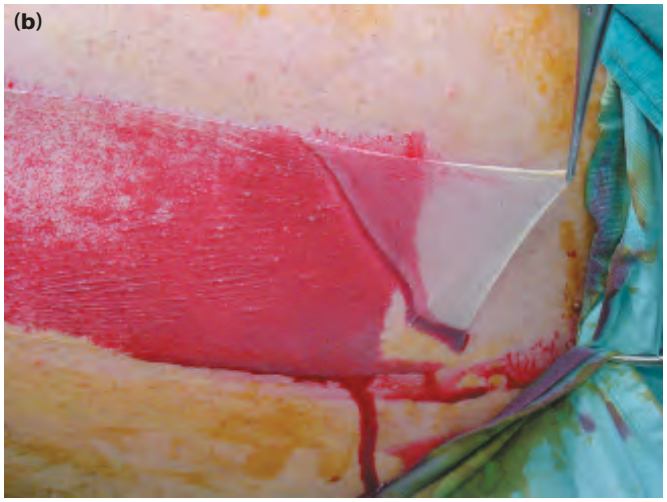

Figure 41.5 **(a)** A deep dermal burn undergoing tangential shaving. The dead dermis is removed layer by layer until healthy bleeding is seen. The burn is pale because it was dressed with silver sulphadiazine cream, but no blanching was visible under this layer. The patient was unable to differentiate between pressure from the sharp and blunt ends of a needle. **(b)** A thin, split-thickness graft harvested from the thigh. **(c)** The thin graft is placed in the dermal remnants. The rete pegs can be seen between the remnants of the dermis through the graft.

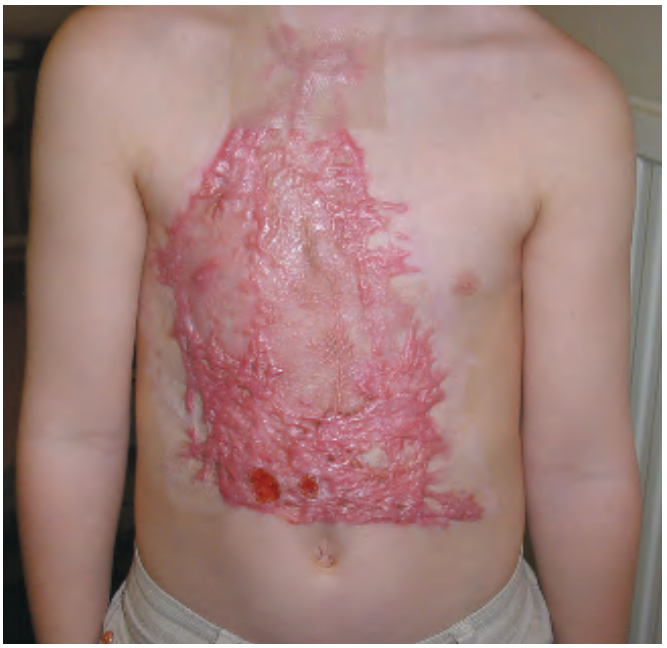

Figure 41.6 Hypertrophic scarring following a deep dermal burn.

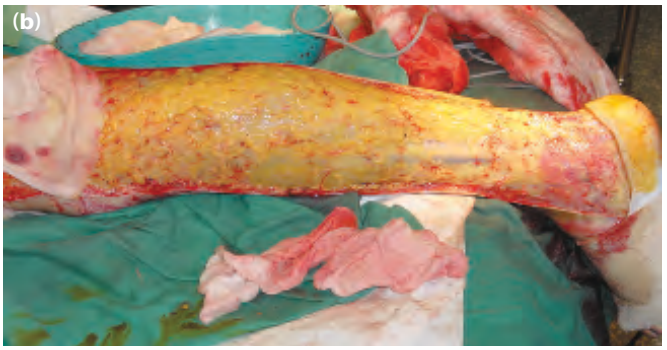

Figure 41.7 **(a)** A full-thickness burn on admission just prior to escharotomy. The wound is wrapped in cling film while in transit. The patient's facial burn is shown in Figure 41.10. **(b)** Excision of the same full-thickness burn, down to healthy fat.

Summary box 41.11

Fluids for resuscitation

- In children with burns over 10% TBSA and adults with burns over 15% TBSA, consider the need for intravenous fluid resuscitation
- If oral fluids are to be used, salt must be added
- Fluids needed can be calculated from a standard formula
- The key is to monitor urine output

Intravenous resuscitation is appropriate for any child with a burn greater than 10% TBSA. The figure is 15% TBSA for adults. In some parts of the world, intravenous resuscitation is commenced only with burns that approach 30% TBSA. If oral resuscitation is to be commenced, it is important that the water given is not salt free. It is rarely possible to undergo significant diuresis in the first 24 hours in view of the stress hormones that are present. Hyponatraemia and water intoxication can be fatal. It is therefore appropriate to give oral rehydration with a solution such as Dioralyte®.

The resuscitation volume is relatively constant in proportion to the area of the body burned and, therefore, there are formulae that calculate the approximate volume of fluid needed for the resuscitation of a patient of a given body weight with a given percentage of the body burned. These regimes follow the fluid loss, which is at its maximum in the first 8 hours and slows, such that, by 24–36 hours, the patient can be maintained on his or her normal daily requirements.

There are three types of fluid used. The most common is Ringer's lactate or Hartmann's solution; some centres use human albumin solution or fresh-frozen plasma; and some centres use hypertonic saline.

Perhaps the simplest and most widely used formula is the Parkland formula. This calculates the fluid to be replaced in the first 24 hours by the following formula: total percentage body surface area × weight (kg) × 4 = volume (mL). Half this volume is given in the first 8 hours and the second half is given in the subsequent 16 hours.

Crystalloid resuscitation

Ringer's lactate is the most commonly used crystalloid. Crystalloids are said to be as effective as colloids for maintaining intravascular volume. They are also significantly less expensive. Another reason for the use of crystalloids is that even large protein molecules leak out of capillaries following burn injury; however, non-burnt capillaries continue to sieve proteins virtually normally.

In children maintenance fluid must also be given. This is normally dextrose–saline given as follows:

- 100 mL/kg for 24 hours for the first 10 kg;
- 50 mL/kg for the next 10 kg;
- 20 mL/kg for 24 hours for each kilogram over 20 kg body weight.

Hypertonic saline

Hypertonic saline has been effective in treating burns shock for many years. It produces hyperosmolarity and hypernatraemia. This reduces the shift of intracellular water to the extracellular space. Advantages include less tissue oedema and a resultant decrease in escharotomies and intubations.

Colloid resuscitation

Human albumin solution (HAS) is a commonly used colloid. Plasma proteins are responsible for the inward oncotic pressure that counteracts the outward capillary hydrostatic pressure. Without proteins, plasma volumes would not be maintained as there would be oedema. Proteins should be given after the first 12 hours of burn because, before this time, the massive fluid shifts cause proteins to leak out of the cells.

The most common colloid-based formula is the Muir and Barclay formula:

- 0.5 × percentage body surface area burnt × weight = one portion;
- periods of 4/4/4, 6/6 and 12 hours, respectively;
- one portion to be given in each period.

Monitoring of resuscitation

The key to monitoring of resuscitation is urine output. Urine output should be between 0.5 and 1.0 mL/kg body weight per hour. If the urine output is below this, the infusion rate should be increased by 50%. If the urine output is inadequate and the patient is showing signs of hypoperfusion (restlessness with tachycardia, cool peripheries and a high haematocrit), then a bolus of 10 mL/kg body weight should be given. It is important that patients are not over-resuscitated and urine output in excess of 2 mL/kg body weight per hour should signal a decrease in the rate of infusion.

Other measures of tissue perfusion such as acid–base balance are appropriate in larger, more complex burns, and a haematocrit measurement is a useful tool in confirming suspected under- or over-hydration. Those with cardiac dysfunction, acute or chronic, may well need more exact measurement of filling pressure, preferably by transoesophageal ultrasound or with the more invasive central line.

TREATING THE BURN WOUND

Escharotomy

Circumferential full-thickness burns to the limbs require emergency surgery **(Figure 41.8)**. The tourniquet effect of this injury is easily treated by incising the whole length of full-thickness burns. This should be done in the mid-axial line, avoiding major nerves *(Table 41.3)*. One should remember that an escharotomy can cause a large amount of blood loss; therefore, adequate blood should be available for transfusion if required.

Thereafter, the management of the burn wound remains the same, irrespective of the size of the injury. The burn needs to be cleaned, and the size and depth need to be assessed. Full-thickness burns and deep partial-thickness burns that will require operative treatment will need to be dressed with an antibacterial dressing to delay the onset of colonisation of the wound.

Alexis Frank Hartmann, 1898–1964, paediatrician, St Louis, MO, USA.
Thomas Laird Barclay, d.2007, formerly plastic surgeon, The Royal Infirmary, Bradford, UK.
Ian Fraser Kerr Muir, 1921–2008, formerly plastic surgeon, Aberdeen Royal Infirmary, Aberdeen, UK, referred to as 'a gentle giant of plastic surgery'.

Figure 41.8 A full-thickness burn to the upper limb with a mid-axial escharotomy. The soot and debris have been washed off.

TABLE 41.3 Key features of escharotomy placement.

Upper limb	Mid-axial, anterior to the elbow medially to avoid the ulnar nerve
Hand	Midline in the digits. Release muscle compartments if tight. Best done in theatre and with an experienced surgeon
Lower limb	Mid-axial. Posterior to the ankle medially to avoid the saphenous vein
Chest	Down the chest lateral to the nipples, across the chest below the clavicle and across the chest at the level of the xiphisternum
General rules	Extend the wound beyond the deep burn Diathermy any significant bleeding vessels Apply haemostatic dressing and elevate the limb postoperatively

Full-thickness burns and obvious deep dermal wounds

The four most common dressings for full-thickness and contaminated wounds are listed in *Table 41.4*.

TABLE 41.4 Options for topical treatment of deep burns.

1% silver sulphadiazine cream
0.5% silver nitrate solution
Mafenide acetate cream
Serum nitrate, silver sulphadiazine and cerium nitrate

Dressings with nanocrystalline silver

- **Silver sulphadiazine cream (1%)**. This gives broad spectrum prophylaxis against bacterial colonisation and is particularly effective against *Pseudomonas aeruginosa* and also methicillin-resistant *Staphylococcus aureus*.
- **Silver nitrate solution (0.5%)**. Again, this is highly effective as a prophylaxis against *Pseudomonas* colonisation, but it is not as active as silver sulphadiazine cream against some of the gram-negative aerobes. The other disadvantage of this solution is that it needs to be changed or the wounds resoaked every 2–4 hours. It also produces black staining of all the furniture surrounding the patient.
- **Mafenide acetate cream**. This is popular, especially in the United States, but is painful to apply. It is usually used as a 5% topical solution, but has been associated with metabolic acidosis.
- **Silver sulphadiazine and cerium nitrate**. This is also a very useful burn dressing, especially for full-thickness burns. It induces a sterile eschar on the burned skin and has been shown in certain instances, especially in elderly patients, to reduce some of the cell-mediated immunosuppression that occurs in burns. Cerium nitrate forms a sterile eschar and is especially useful in treating burns when a conservative treatment option has been chosen. Cerium nitrate has also been shown to boost cell-mediated immunity in these patients.

Superficial partial-thickness wounds and mixed-depth wounds

Around the world, a wide variety of substances are used to treat these wounds, from honey or boiled potato peel to synthetic biological dressings with live cultured fibroblasts within the matrix. This is testament to the fact that superficial partial-thickness burns will heal almost irrespective of the dressing. Thus, the key lies with dressings that are easy to apply, non-painful, reduce pain, simple to manage and locally available. The choice of dressings does, however, become crucial in the case of burns that border on being deep dermal **(Figure 41.9)**. Here, the choice of dressing can make the difference between scar and no scar and/or operation and no operation. Some of the options for dressing choice are described below.

If the wound is heavily contaminated as a result of the accident, then it is prudent to clean the wound formally under a general anaesthetic. With more chronic contamination, silver sulphadiazine cream dressing for 2 or 3 days is very effective and can be changed to a dressing that is more efficient at promoting healing after this period.

The simplest method of treating a superficial wound is by exposure. The initial exudate needs to be managed by frequent changes of clean linen around the patient but, after a few days, a dry eschar forms, which then separates as the wound epithelialises. This is often used in hot climates and for small burns on the face. However, this method is painful and requires an intensive amount of nursing support. A variation on this theme is to cover the wound with a permeable wound dressing, such as Mefix® or Fixamol®. This allows the wounds to dry but, because it is a covering, it avoids the problems of the wound adhering to the sheets and clothes. A similar method of managing these types of burn is to place a Vaseline-impregnated gauze (with or without an antiseptic, such as chlorhexidine) over the wound. An alternative is a fenestrated silicone sheet (e.g. Mepitel®). These can then be backed with swabs to absorb the exudate. The Vaseline gauze or silicone layer is used to prevent the swabs adhering to the wound and reduces the stiffness of the dry eschar, preventing it from cracking so easily. The swabs need to be changed after the first 48 hours as they are often soaked. After that, they can be left for longer.

More interactive dressings include hydrocolloids and biological dressings. Hydrocolloid dressings need to be changed

Figure 41.9 **(a)** A scald to the chest from boiling water, mainly superficial but in some areas close to being deep dermal. This was treated with a hydrocolloid dressing. **(b)** There are two tiny areas of hypertrophy indicating how close the burn was to being deep dermal. The good first aid this patient received probably made a difference to the outcome.

every 3–5 days. They are particularly useful in mixed-depth burns as the high protease levels under the occlusive dressings aid with the debridement of the deeper areas of burn. They also provide a moist environment, which is good for epithelialisation. Duoderm® is a hydrocolloid dressing. There is good evidence for its value in burns.

Biological, synthetic (e.g. Biobrane®) and natural (e.g. amniotic membranes) dressings also provide good healing environments and do not need to be changed. They are ideal for one-stop management of superficial burns, being easy to apply and comfortable. However, they will become detached if applied to deep dermal wounds as the eschar needs to separate. They are therefore not as useful in mixed-depth wounds.

Early debridement and grafting is the key to effectively treating deep partial- and full-thickness burns in a majority of cases.

Summary box 41.12

Principles of dressings for burns

- Full-thickness and deep dermal burns need antibacterial dressings to delay colonisation prior to surgery
- Superficial burns will heal and need simple dressings
- An optimal healing environment can make a difference to outcome in borderline depth burns

ADDITIONAL ASPECTS OF TREATING THE BURNED PATIENT

Analgesia

Acute

Analgesia is a vital part of burns management. Small burns, especially superficial burns, respond well to simple oral analgesia, paracetamol and non-steroidal anti-inflammatory drugs. Topical cooling is especially soothing. Large burns require intravenous opiates. Intramuscular injections should not be given in acute burns over 10% of TBSA, as absorption is unpredictable and dangerous.

Subacute

In patients with large burns, continuous analgesia is required, beginning with infusions and continuing with oral tablets, such as slow-release morphine. Powerful, short-acting analgesia should be administered before dressing changes. Administration may require an anaesthetist, as in the case of general anaesthesia or midazolam and ketamine, or less intensive supervision, as in the case of morphine and nitrous oxide.

Energy balance and nutrition

One of the most important aspects in treating burns patients is nutrition. Any adult with a burn greater than 15% (10% in children) of TBSA has an increased nutritional requirement. All patients with burns of 20% of TBSA or greater should receive a nasogastric tube. (Feeding should start within 6 hours of the injury to reduce gut mucosal damage.) A number of different formulae are available to calculate the energy requirements of patients.

Burn injuries are catabolic in the acute episode. Successful management of the patient's energy balance involves a

Summary box 41.13

Nutrition in burns patients

- Burns patients need extra feeding
- A nasogastric tube should be used in all patients with burns over 15% of TBSA
- Removing the burn and achieving healing stops the catabolic drive

number of strategies. The catabolic drive continues while the wound remains unhealed and, therefore, rapid excision of the burn and stable coverage of the wound are the most significant factors in reversing this. Obligatory energy utilisation must be reduced to a minimum by keeping the patient warm with good environmental control. The excess energy requirements must be provided for and the nutritional balance monitored by measuring weight and nitrogen balance *(Table 41.5)*.

TABLE 41.5 Commonly used feeding formulae.

Curreri formula	Age 16–59 years: (25)W + (40)TBSA Age 60+ years: (20)W + (65)TBSA

Protein needs	Greatest nitrogen losses between days 5 and 10 20% of kilocalories should be provided by proteins
Davies formula	Children: 3 g/kg + 1 g%TBSA Adults: 1 g/kg + 3 g%TBSA

TBSA, total body surface area; W, weight.

Monitoring and control of infection

Patients with major burns are immunocompromised, having large portals of entry to pathogenic and opportunistic bacteria and fungi via the burn wound. They have compromised local defences in the lungs and gut due to oedema, and usually have monitoring lines and catheters, which themselves represent portals for infection.

Summary box 41.14

Infection control in burns patients

- Burns patients are immunocompromised
- They are susceptible to infection from many routes
- Sterile precautions must be rigorous
- Swabs should be taken regularly
- A rise in white blood cell count, thrombocytosis and increased catabolism are warnings of infection

Control of infection begins with policies on hand-washing and other cross-contamination prevention measures. Bacteriological surveillance of the wound, catheter tips and sputum helps to build a picture of the patient's flora. If there are signs of infection, then further cultures need to be taken and antibiotics started. This is often initially on a best guess basis, hence the usefulness of prior surveillance; close liaison with a bacteriologist is essential. In patients with large burns that remain catabolic, the core temperature is usually reset by the hypothalamus above 37°C. Significant temperatures are those above 38.5°C, but often other signs of infection are more useful to the clinician. These include significant rise or fall in the white cell count, thrombocytosis, increasing signs of catabolism and decreasing clinical status of the patient.

Nursing care

Burns patients require particularly intensive nursing care. Nurses are the primary effectors of many decisions that directly affect healing. Bandaged hands and joints that are stiff and painful need careful coaxing. Personal hygiene, baths and showers all become time-consuming and painful, but are vital parts of the patient's physiotherapy. Their success or failure has a powerful psychological impact on the patient and his or her family.

Physiotherapy

All burns cause swelling, especially burns to the hands. Elevation, splintage and exercise reduce swelling and improve the final outcome. The physiotherapy needs to be started on day 1, so that the message can be reinforced on a daily basis.

Psychological

A major burn is an overwhelming event, outside the normal experience, which stretches the patient's coping ability, suspends the patient's sense of safety and causes post-traumatic reactions. These are normal and usually self-limiting, receding as the patient heals. The features of this intensity of experience are of intrusive reactions, arousal reactions and avoidance reactions.

SURGERY FOR THE ACUTE BURN WOUND

Any deep partial-thickness and full-thickness burns, except those that are less than about 4 cm^2, need surgery. Any burn of indeterminate depth should be reassessed after 48 hours. This is because burns that initially appear superficial may well deepen over that time. Delayed microvascular injury is especially common in scalds.

The essence of burns surgery is control. First and foremost, the anaesthetist needs good control of the patient. A wide-bore cannula should be used and the patient's blood pressure must be monitored adequately. If a large excision is considered, then an arterial line (to monitor blood pressure) and a central venous pressure monitor are needed. The anaesthetist also needs measurements and control of the acid–base

Summary box 41.15

Surgical treatment of deep burns

- Deep dermal burns need tangential shaving and split-skin
- grafting
- All but the smallest full-thickness burns need surgery
- The anaesthetist needs to be ready for significant blood loss
- Topical adrenaline reduces bleeding
- All burnt tissue needs to be excised
- Stable cover, permanent or temporary, should be applied at once to reduce burn load

balance, clotting time and haemoglobin levels. The core temperature of the patient must not drop below 36°C, otherwise clotting irregularities will be compounded.

For most burn excisions, subcutaneous injection of a dilute solution of adrenaline 1:1 000 000 or 1:500 000 and tourniquet control are important for controlling blood loss.

In deep dermal burns, the top layer of dead dermis is shaved off until punctate bleeding is observed and the dermis can be seen to be free of any small thrombosed vessels (**Figure 41.5a**). A topical solution of 1:500 000 adrenaline also helps to reduce bleeding, as does the application of the skin graft. The use of a tourniquet during burn excisions in the limbs helps to decrease blood loss and maintain control.

Full-thickness burns require full-thickness excision of the skin (**Figure 41.7b**). In certain circumstances, it is appropriate to go down to the fascia but, in most cases, the burn excision is down to viable fat. Wherever possible, a skin graft should be applied immediately. With very large burns, the use of synthetic dermis or homografts provides temporary stable coverage and will allow complete excision of the wound and thus reduce the burn load on the patient.

Postoperative management of these patients obviously requires careful evaluation of fluid balance and levels of haemoglobin. The outer dressings will quickly be soaked through with serum and will need to be changed on a regular basis to reduce the bacterial load within the dressing.

Physiotherapy and splints are important in maintaining range of movement and reducing joint contracture. Elevation of the appropriate limbs is important. The hand must be splinted in a position of function after grafting, although the graft needs to be applied in the position of maximal stretch. Knees are best splinted in extension, axillae in abduction. Supervised movement by the physiotherapists, usually under direct vision of any affected joints, should begin after about 5 days.

Delayed reconstruction and scar management

Delayed reconstruction of burn injuries is common for large full-thickness burns. In the early healing period, acute contractures around the eye need particular attention. Eyelids must be grafted at the first sign of difficulty in closing the eyelids, and this must be done before the patient has any symptoms of exposure keratitis (**Figure 41.10**). Other areas that require early intervention are any contracture causing significant loss of range of movement of a joint. This is particularly important in the hand and axilla.

An established contracture can be treated in a number of ways. Burn alopecia is best treated with tissue expansion of the unburned hair-bearing skin. Tissue expansion is also a useful technique for isolated burns and other areas with adjacent normal skin. Z-plasty is useful where there is a single band and a transposition flap is useful in wider bands of scarring (**Figure 41.11**). In areas of circumferential or very broad areas of scarring, the only real treatment is incision and replacement with tissue. By far the best tissue for replacement is from either a full-thickness graft or vascularised tissue as in a free flap. Occasionally, the situation requires the less ideal covering of split skin, possibly with an artificial dermis, such as Integra® (**Figure 41.12**). These last two options require prolonged scar management after their use.

Hypertrophy of many scars will respond to pressure garments. These need to be worn for a period of 6–18 months. Where it is difficult to apply pressure with pressure garments, or with smaller areas of hypertrophy, silicone patches will speed scar maturation, as will intralesional injection of steroid. Itching and dermatitis in burn scar areas are common. Pharmacological treatment of itch is an essential adjunct to therapy.

Summary box 41.16

Delayed reconstruction of burns

- Eyelids must be treated before exposure keratitis arises
- Transposition flaps and Z-plasties with or without tissue expansion are useful
- Full-thickness grafts and free flaps may be needed for large or difficult areas
- Hypertrophy is treated with pressure garments
- Pharmacological treatment of itch is important

MINOR BURNS/OUTPATIENT BURNS

Local burn wound care

Blisters

Whether to remove blisters or leave them intact has been the subject of much debate. Proponents of blister removal quote laboratory studies that show that blister fluid depresses immune function, slowing down chemotaxis and intracellular killing and also acting as a medium for bacterial growth.

Conversely, other authors advocate leaving blisters intact as they form a sterile stratum spongiosum. Leaving a ruptured blister is not advised.

Initial cleaning of the burn wound

Washing the burn wound with chlorhexidine solution is ideal for this purpose.

The Guinea Pig Club. Sir Archibald McIndoe (1900–1960), born in New Zealand, was appointed in 1938 as Consultant Plastic Surgeon to the Royal Air Force. He trained with his cousin, **Sir Harold Gillies**, another internationally reputed plastic surgeon. McIndoe became world famous for his pioneering work on Battle of Britain pilots who were badly burnt. His work on these airmen, who needed several operations, and using his innovative technical and psychological methods, was the start of a life-long service. The young fighter pilots were therefore referred to as 'guinea pigs' – thus was formed The Guinea Pig Club. McIndoe referred to his patients as 'the boys' who in turn called him 'the boss' or 'the maestro'. To this day, some of the members of the Guinea Pig Club from all over the world still meet on an annual basis in Sussex. McIndoe founded the British Association of Plastic Surgeons (BAPS).

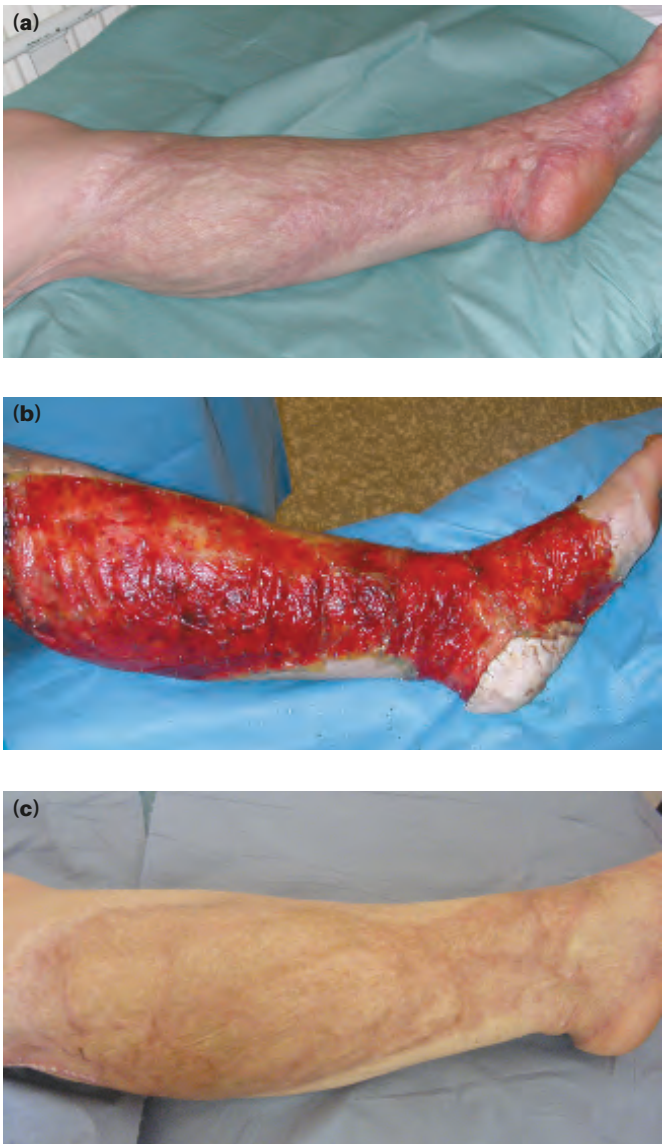

Figure 41.12 **(a)** A healed full-thickness leg burn prior to resurfacing with Integra. **(b)** The burn scar has been excised and Integra applied prior to split-thickness skin grafting. **(c)** Six months after Integra resurfacing. The skin is smoother and more supple and the scar has faded.

Topical agents

For initial management of minor burns that are superficial or partial thickness, dressings with a non-adherent material, such as Vaseline-impregnated gauze or Mepitel are often sufficient. These dressings are left in place for 5 days. These burns, by definition, should be healed after 7–10 days. Various topical creams and ointments have been used for the treatment of minor burns. All published comparative data show no advantage of these agents over petroleum gauze.

Silver sulphadiazine (1%) or Flamazine® is the most commonly used topical agent. However, it should be avoided in pregnant women, nursing mothers and infants less than 2 months of age because of the increased possibility of kernicterus in these patients.

Dressing the minor burn wound

The aims of dressing are to decrease wound pain and to protect and isolate the burn wound. The small superficial burn requires Vaseline gauze or another non-adherent dressing, such as Mepitel, as the first layer. Following this, gauze or Kerlix® is wrapped around with sufficient tightness to keep the dressing intact, but not to impede the circulation. This is further wrapped with bandage. It is important to realise that bulkiness of dressings in the minor burn wound depends upon the amount of wound discharge. A special case is burns of the hands where dressings should be minimised so as not to impede mobilisation and physiotherapy.

Synthetic burn wound dressings are popular as they:

- decrease pain associated with dressings;
- improve healing times;
- decrease outpatient appointments;
- lower overall costs.

Biobrane® is a bilaminar dressing made up of an inner layer of knitted nylon threads coated with porcine collagen and an outer layer of rubberised silicone impervious to gases, but not to fluids and bacteria. Wounds to be dressed with Biobrane should be carefully selected. Burn wounds should be fresh (less than 24 hours), sensate, show capillary blanching and refill. Biobrane should be applied to the wound after removal of all blisters. It should be checked at 48 hours for adherence and any signs of infection. It should be removed if any sign of infection is found.

Duoderm® or hydrocolloid dressings are not bulky, help in healing and can be kept in place for 48–72 hours. They provide a moist environment, which helps in re-epithelialisation of the burn wound.

Healing of burn wounds

Burns that are being managed conservatively should be healed within 3 weeks. If there are no signs of re-epithelialisation in this time, the wound requires debridement and grafting.

Infection

Infection in the minor burn should be tackled very aggressively as it is known to convert a superficial burn to a partial-thickness burn and a partial- to a deep partial-thickness

burn, respectively. It should be managed using a combination of topical and systemic agents. Debridement and skin grafting should also be considered.

Itching

Most burn patients have itchy wounds. Histamine and various endopeptides are said to be the causative factors of itching. Antihistamines, analgesics, moisturising creams, aloe vera and antibiotics have all been tried with varying degrees of success. Sometimes gabapentin has been used in patients with severe itch. Examples of therapeutic agents described include cyproheptadine, loratidine and topical doxepin cream.

Traumatic blisters

The healed burn wound is prone to getting traumatic blisters because the new epithelium is very fragile. Non-adherent dressings usually suffice; regular moisturisation is also useful in this condition.

NON-THERMAL BURN INJURY

Electrical injuries

Electrical injuries are usually divided into low- and high-voltage injuries, the threshold being 1000 v.

Summary box 41.17

Electrical burns

- Low-voltage injuries cause small, localised, deep burns
- They can cause cardiac arrest through pacing interruption without significant direct myocardial damage
- High-voltage injuries damage by flash (external burn) and conduction (internal burn)
- Myocardium may be directly damaged without pacing interruption
- Limbs may need fasciotomies or amputation
- Look for and treat acidosis and myoglobinuria

Low-tension injuries

Low-tension or domestic appliance injuries do not have enough energy to cause destruction to significant amounts of subcutaneous tissues when the current passes through the body. The resistance is too great. The entry and exit points, normally in the fingers, suffer small deep burns; these may cause underlying tendon and nerve damage, but there will be little damage between. The alternating current creates a tetany within the muscles, and thus patients often describe how they were unable to release the device until the power was turned off. The main danger with these injuries is from the alternating current interfering with normal cardiac pacing. This can cause cardiac arrest. The electricity itself does not usually cause significant underlying myocardial damage, so resuscitation, if successful, should be lasting.

High-tension injuries

High-tension electrical injuries can be caused by one of three sources of damage: the flash, the flame and the current itself.

When a high-tension line is earthed, enormous energy is released as the current travels from the line to the earth. It can arc over the patient, causing a flash burn. The extremely rapid heating of the air causes an explosion that often propels the victim backwards. The key here is that the current travelled from the line to the earth directly and not through the patient. The flash, however, can go on to ignite the patient's clothes and so cause a normal flame burn.

In accidents with overhead lines, the patient often acts as the conduction rod to earth. In these injuries, there is enough current to cause damage to the subcutaneous tissues and muscles. The entry and exit points are damaged but, importantly, the current can cause huge amounts of subcutaneous damage between these two points. These can be extremely serious injuries.

The damage to the underlying muscles in the affected limb can cause the rapid onset of compartment syndrome. The release of the myoglobins will cause myoglobinuria and subsequent renal dysfunction. Therefore, during the resuscitation of these patients, efforts must be made to maintain a high urine output of up to 2 mL/kg body weight per hour. Severe acidosis is common in large electrical burns and may require boluses of bicarbonate. These patients are also at risk of myocardial damage as a result of direct muscle damage, rather than by interference with cardiac pacing. This gives rise to significant electrocardiogram changes, with raised cardiac enzymes. If there is significant damage, there is rapid onset of heart failure. In the case of a severe injury through a limb, primary amputation is sometimes the most effective management (**Figure 41.13**).

Chemical injuries

There are over 70 000 different chemicals in regular use within industry. Occasionally, these cause burns. Ultimately, there are two aspects to a chemical injury. The first is the physical destruction of the skin and the second is any poisoning caused by systemic absorption.

The initial management of any chemical injury is copious lavage with water. There are only a handful of chemicals for which water is not helpful, for example phosphorus, which is a component of some military devices, and elemental sodium, which is occasionally present in laboratory explosions. These substances need to be physically removed with forceps; however, it is extremely rare that any medical practitioner will encounter these in his or her lifetime. The more common injuries are caused by either acids or alkalis. Alkalis are usually the more destructive and are especially dangerous if they have come into contact with the eyes. After copious lavage, the next step in the management of any chemical injury is to identify the chemical

Summary box 41.18

Chemical burns

- Damage is from corrosion and poisoning
- Copious lavage with water helps in most cases
- Then identify the chemical and assess the risks of absorption

Figure 41.13 **(a)** An exit wound of a high-tension injury, with a dead big toe and significant damage to the medial portion of the second toe. **(b)** Amputation and cover with the lateral portion of the second toe.

and its concentration and to elucidate whether there is any underlying threat to the patient's life if absorbed systemically.

One acid that is a common cause of acid burns is hydrofluoric acid. Burns affecting the fingers and caused by dilute acid are relatively common. The initial management is with calcium gluconate gel topically; however, severe burns or burns to large areas of the hand can be subsequently treated with Bier's blocks containing calcium gluconate 10% gel. If the patient has been burnt with a concentration greater than 50%, the threat of hypocalcaemia and subsequent arrhythmias then becomes high, and this is an indication for acute early excision. It is best not to split-skin graft these hydrofluoric acid wounds initially, but to do this at a delayed stage.

Ionising radiation injury

These injuries can be divided into groups depending on whether radiation exposure was to the whole body or localised. The management of localised radiation damage is usually conservative until the true extent of the tissue injury is apparent. Should this damage have caused an ulcer, then excision and coverage with vascularised tissue is required.

Whole-body radiation causes a large number of symptoms. The dose of radiation either is, or is not, lethal. A patient who has suffered whole-body irradiation and is suffering from acute desquamation of the skin has received a lethal dose of radiation, which can cause a particularly slow and unpleasant death. Non-lethal radiation has a number of systemic effects related to the gut mucosa and immune system dysfunction. Other than giving iodine tablets, the management of these injuries is supportive.

Summary box 41.19

Radiation burns

- Local burns causing ulceration need excision and vascularised flap cover, usually with free flaps
- Systemic overdose needs supportive treatment

Cold injuries

Cold injuries are principally divided into two types: acute cold injuries from industrial accidents and frostbite.

Exposure to liquid nitrogen and other such liquids will cause epidermal and dermal destruction. The tissue is more resistant to cold injury than to heat injury, and the inflammatory reaction is not as marked. The assessment of depth of injury is more difficult, so it is rare to make the decision for surgery early.

Frostbite injuries affect the peripheries in cold climates. The initial treatment is with rapid rewarming in a bath at 42°C. The cold injury produces delayed microvascular damage similar to that of cardiac reperfusion injury. The level of damage is difficult to assess, and surgery usually does not play a role in its management, which is conservative, until there is absolute demarcation of the level of injury.

RECENT ADVANCES

Advanced technology, newer drugs and skin substitutes are the major advances in burn care. An intelligent use of these modalities is essential to make an effective case for cost–benefit ratios.

The introduction of new modalities needs to be carried out within critically reviewed and controlled clinical protocols, working towards building appropriate clinical evidence.

Chapter 42

Plastic and reconstructive surgery

Learning objectives

To understand:

- The spectrum of plastic surgical techniques used to restore bodily form and function
- The relevant anatomy and physiology of tissues used in reconstruction
- The various skin grafts and how to use them appropriately
- The principles and use of flaps
- How to use plastic surgery to manage difficult and complex tissue loss

HISTORICAL CONTEXT

Reconstructive plastic (from the ancient Greek *plassein*, to mould or shape – which is also the stem for our modern use of the materials termed 'plastics') surgery involves using various techniques to restore form and function to the body when tissues have been damaged by injury, cancer or congenital loss. Its origins can be traced back to ancient Egypt, with wound care depicted in hieroglyphs on papyrus, to India in the sixth century BC, where Sushruta described using the forehead flap to reconstruct a nose, and to Al-Zahrawi, the tenth-century Islamic surgical scholar from Cordoba. Modern techniques were developed after the First World War, especially with Sir Harold Gillies' work on reconstructing facial injuries (**Figure 42.1**), which was enabled by new safe anaesthetic intubation (Sir Ivan Magill). Later in the twentieth century, renewed understanding of detailed soft tissue anatomy led to an explosion in the use of new flaps, which with microsurgical methods, craniofacial surgery and tissue expansion resulted in an entirely new set of techniques becoming available to surgeons for reconstructing parts.

Today, the need for reconstructive plastic surgery, especially in resource-poor countries, has never been greater. Road, war and domestic injury inflict life-diminishing effects, which plastic surgery can reduce. The reconstructive surgeon's 'toolbox' is now very diverse and will continue to grow in order to address problem wounds and tissue defects, which arise as modern medical care is more successful in treating cancer, preserving life into old age and salvaging victims of trauma.

Figure 42.1 Sir Harold Gillies operating during the First World War – 'the birth of plastic surgery'. Picture by Henry Tonks (by kind permission of the Royal College of Surgeons of England).

Sushruta, regarded as the father of modern surgery, lived in the Indian city of Kashi (now called Banaras) in 600BC (while the exact period is unclear, most scholars maintain that he practised between 600 and 1000BC). A large part of his practice was plastic surgery in the form of rhinoplasty carried out on criminals who had their noses amputated as a punishment for their crimes. His medical pursuits were recorde d in 'Sushsruta Samhita (compendum)'.

Sir Harold Delf Gillies, 1882–1960, born New Zealand, studied medicine at the University of Cambridge, pioneer of plastic surgical techniques during and after World War 1.

Sir Ivan Whiteside Magill, 1888–1986, anaesthetist, Westminister Hospital, London, UK.

Henry Tonks, 1862–1937, commenced a career in surgery, but abandoned it for art and became, from 1917 to 1930, Slade Professor at the Westminster School of Art, London, UK.

ANATOMY RELATED TO RECONSTRUCTIVE SURGERY

Skin

The surface of the skin is important as a biological layer for homeostasis. Restoring the skin surface is therefore critical, even if the underlying structures can await later reconstruction. Epidermis regenerates from deeper follicular elements, with the most superficial layer losing vascularity and acting as a barrier to fluid loss and providing important protection against invasion by microorganisms. (Epidermal keratinocytes can be artificially cultured *in vitro* and are used in some wound management systems.)

The depth of the dermis and the amounts of elastin and skin adnexal elements, such as sweat glands and hair follicles, vary depending on the functional requirements of the area concerned. This means that some areas are much more vulnerable to injury than others, e.g. the fine flexible elastic skin of the eyelid rapidly suffers a full-thickness burn after a flash burn, whereas thick back skin suffers only a partial loss after the same flash burn.

Skin vascularity is derived from fine perforating vessels that run through underlying muscles or through fascial septal layers, and then horizontally in a subcutaneous plane from which capillaries branch (Figure 42.2). Nerves run axially out from major trunks and are less well defined than most perforating blood vessels.

When local, random-pattern skin flaps are raised, they are lifted at the subcutaneous level and are nourished by the subdermal plexus of blood vessels. However, this plexus can only survive a limited distance from the more substantial arterial branches running in the fascial, septal or muscle-perforating planes. Understanding the detailed anatomy of different parts of the skin and tissues to be moved is a key element of successful plastic surgery.

Without skin, wounds heal by **secondary intention** with fibrosis and contracture (Figure 42.3), and underlying structures are vulnerable to necrosis, chronic infection and dysfunction.

Graft anatomy

Split-thickness skin grafts

Split-thickness skin grafts are harvested by taking all of the epidermis together with some dermis, leaving the remaining dermis behind to heal the donor site. The thicker the dermis that is taken (seen by more brisk punctate bleeding at the donor site; Figure 42.4), the more durable will be the graft once healed (although it might take longer and require more care), but also the more difficult will be donor site healing.

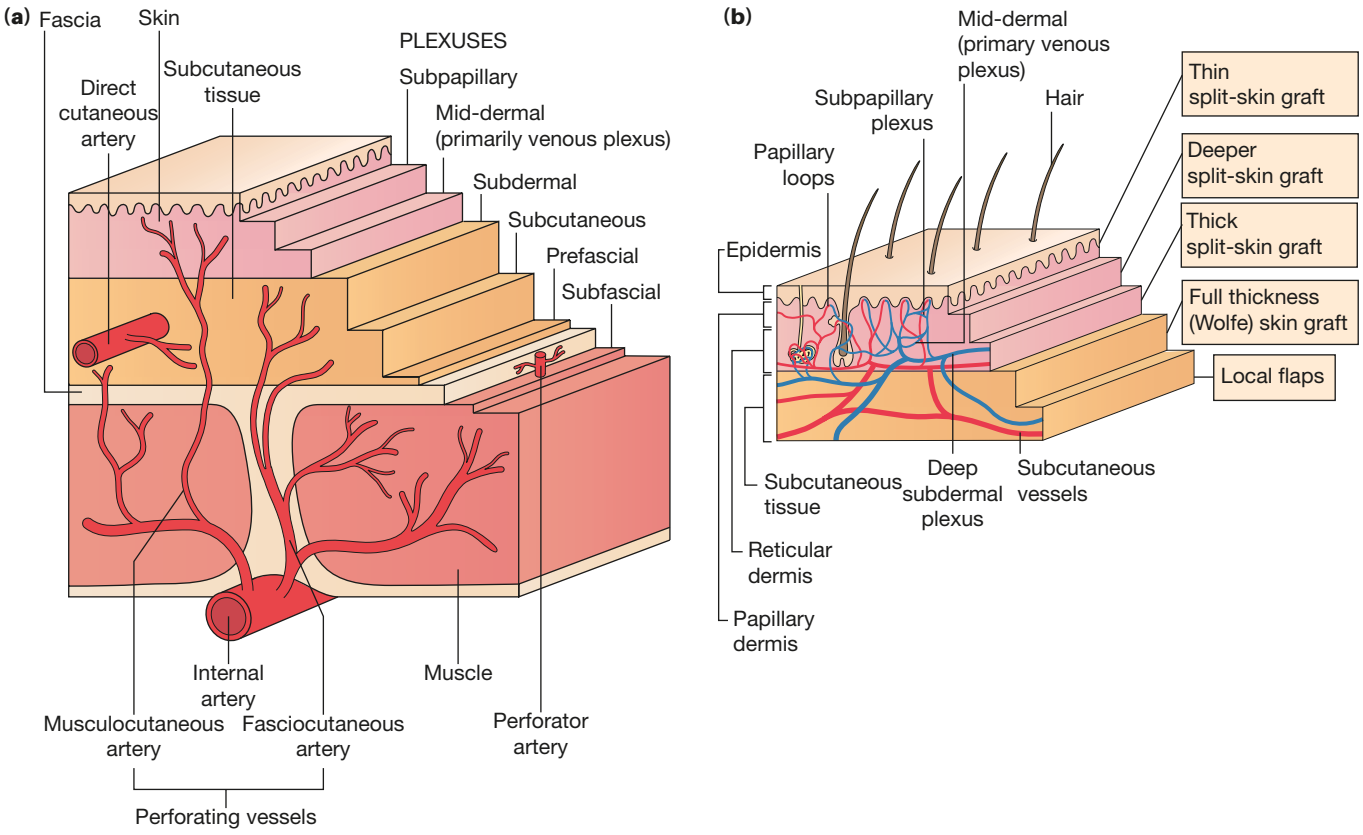

Figure 42.2 Diagram of skin anatomy with vascular plexus.

in vitro is Latin for 'in the glass'.

Figure 42.3 A severely contracted hand following burn to the dorsal aspect.

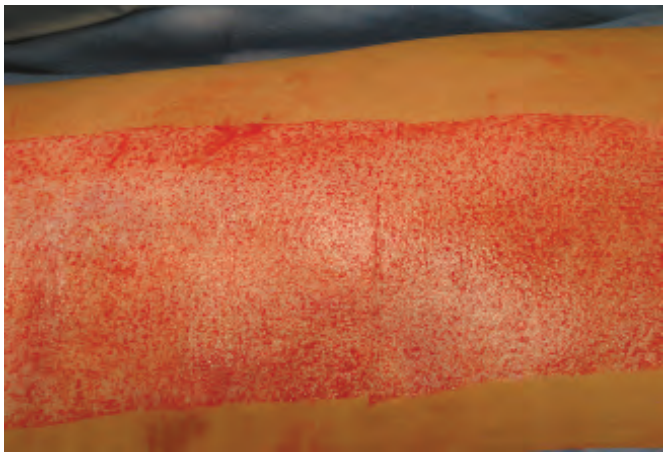

Figure 42.4 Fine punctate bleeding from a split-thickness skin graft donor site.

Summary box 42.1

Split-thickness skin grafts

- Thicker knife-gap settings give rise to fewer but brisker bleeding points on the donor site.
- Thicker grafts heal with less contracture and are more durable.
- Thinner donor sites heal better.
- Grafts are hairless and do not sweat (these structures are not transferred).

Full-thickness skin grafts

Full-thickness grafts are harvested to incorporate the whole dermis, with the underlying fat trimmed away – unless elements of fat (or even cartilage as well) are deliberately left attached to form a **composite graft**. Full-thickness and composite grafts require the most careful handling and postoperative nursing to help ensure that they 'take' in their transplanted site.

How does a skin graft survive?

Split-thickness skin grafts survive initially by **imbibition** of plasma from the wound bed; after 48 hours, fine anastomotic connections are made, which lead to **inosculation** of blood. Capillary ingrowth then completes the healing process with fibroblast maturation. Because only tissues that produce granulation will support a graft, it is usually contraindicated to use grafts to cover exposed tendons, cartilage or cortical bone.

Skin grafts inevitably contract, with the extent of contracture determined by the amount of dermis taken with the graft and the level of postoperative splintage and physiotherapy applied to the grafted site.

CLASSIFICATION

The reconstructive toolbox

Plastic surgery offers a variety of techniques to address clinical problems. Sometimes, a problem is managed using a 'ladder' approach, with the simplest methods being used first and only moving to more complex methods when absolutely necessary. However, this is frequently not the ideal approach for best outcomes. If resources permit, it is often more cost-effective and better functionally for the patient to begin with a more complex treatment, with other easier management options held in reserve as 'lifeboats'. Plastic surgeons now prefer to think of the range of options available as a toolbox from which they can take the most appropriate method to solve a problem, taking into account available skill, resources and the consequences of failure.

The scope of plastic surgery

The tools of reconstruction are used for a wide range of conditions:

- trauma:
  - soft-tissue loss (skin, tendons, nerves, muscle);
  - hand and lower limb injury;
  - faciomaxillary;
  - burns;
- cancer:
  - skin, head and neck, breast, soft tissue sarcoma;
- congenital:
  - clefts and craniofacial malformations;
  - skin, giant naevi, vascular malformations;
  - urogenital;
  - hand and limb malformations;
- miscellaneous:
  - Bell's (facial) palsy;
  - pressure sores;
  - aesthetic surgery;
  - chest wall reconstruction.

Sir Charles Bell, 1774–1842, surgeon, Middlesex Hospital, London, UK and from 1835 until his death, Professor of Surgery, the University of Edinburgh, Edinburgh, UK.

A few key principles that can also be applied to other surgical specialties should be observed. In many reconstructions, success depends upon good rapid wound healing, which itself depends upon attention to detail from the surgeon. Adequate debridement, careful technique, gentle handling of tissues and consideration of blood supply are all key factors that influence outcome (*Table 42.1*).

The placement of incisions can be critical, especially in reducing the appearance of scars on the face and in areas of tension. When possible, incisions should lie in the lines of minimal tension (described by Langer, but frequently different from those originally noted) (**Figure 42.5**).

TABLE 42.1 Plastic surgery principles.

Optimise wound by adequate debridement or resection
Wound or flap must have a good blood supply to heal
Place scars carefully – 'lines of election'[a]
Replace defect with similar tissue – 'like with like'[b]
Observe meticulous surgical technique
Remember donor site 'cost'

[a]Lines of election – analogous to Langer's lines of minimal skin tension.

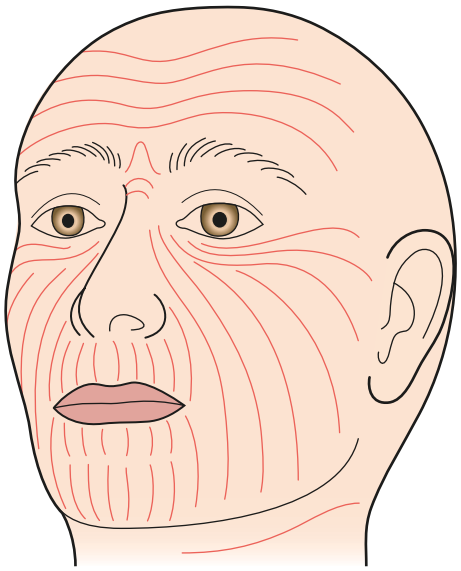

Figure 42.5 Lines of relaxed skin tension.

Grafts

Grafts are tissues that are transferred without their blood supply, which therefore have to revascularise once they are in a new site. They include the following:

- **Split-thickness skin grafts (of varying thickness)**. These are sometimes called Thiersch grafts. They are used to cover all sizes of wound, are of limited durability and will contract. They may be used to provide valuable temporary wound closure before better cosmetic secondary correction after rehabilitation.
- **Full-thickness skin grafts (Wolfe grafts)**. Used for smaller areas of skin replacement where good elastic skin that will not contract is required (such as fingers, eyelids, facial parts).
- **Composite skin grafts (usually skin and fat, or skin and cartilage)**. Often taken from the ear margin and useful for rebuilding missing elements of nose, eyelids and fingertips.

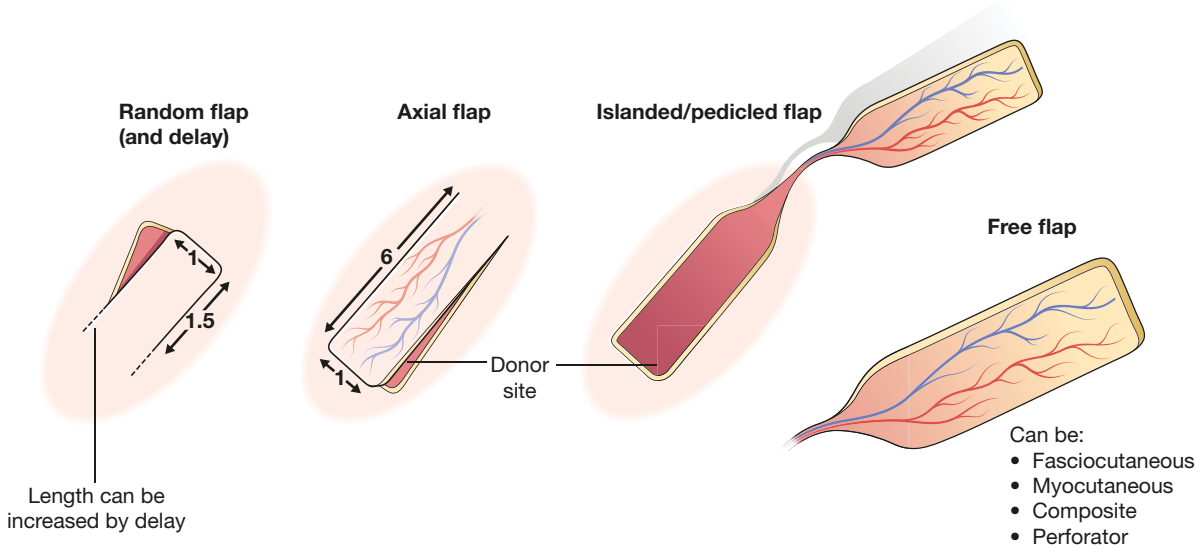

Figure 42.6 Skin flaps, from simple to complex.

Karl Ritter von Edenberg Langer, 1819–1887, Professor of Anatomy, Vienna, Austria described these lines in 1862.
Karl Thiersch, 1822–1895, Professor of Surgery, Leipzig, Germany, pioneer of free skin grafts and described his method of skin grafting in 1874.
John Reissburg Wolfe, 1824–1904, ophthalmic surgeon, Glasgow, UK, described full thickness skin grafts in 1875 and in the same year used forearm skin to construct an eyelid.

- **Nerve grafts**. Usually taken from the sural nerve, but smaller cutaneous nerves may be used.
- **Tendon grafts**. Usually taken from the palmaris longus or plantaris tendon (runs just anteromedial to the Achilles tendon) and used for injury loss or nerve damage correction.

Flaps

Flaps are tissues that are transferred with a blood supply. They therefore have the advantage of bringing vascularity to the new area. Flaps can be raised to consist of any specific tissue; for skin the following will illustrate the types that exist (Figure 42.6):

- **Random flaps**. Three sides of a rectangle, bearing no specific relationship to where the blood supply enters; the length to breadth ratio is no more than 1.5:1. This pattern can be lengthened by 'delaying' the flap, a process in which the cuts are partially made and the flap is part lifted at a first operation; it is then replaced, thus 'training' the blood supply from a single border of the rectangle. At a second procedure, it is raised further and finally transferred.
- **Axial flaps**. Much longer flaps, based on known blood vessels supplying the skin. This technique was rediscovered in the 1960s and 1970s and enables many long thin flaps to be safely moved across large distances.
- **Pedicled/islanded flaps**. The axial blood supply of these flaps means that they can be swung round on a stalk or even fully 'islanded' so that the business end of the skin being transferred can have the pedicle buried (Figure 42.7).
- **Free flaps**. The blood supply has been isolated, disconnected and then reconnected using microsurgery at the new site (Figure 42.8).
- **Composite flaps**. Various tissues are transferred together, often skin with bone or muscle (osseocutaneous or myocutaneous flaps, respectively).
- **Perforator flaps**. This description refers to a whole new subgroup of axial flaps, in which tissues are isolated on small perforating vessels that run from more major blood vessels to supply the surface.

Skin substitutes

One solution to the problem presented by major skin loss with inadequate skin donor sites has been to use artificially engineered skin substitutes. These vary from thin sheets of autologous keratinocytes, to artificial collagen matrices with embedded fibroblasts and a keratinocyte sheet covering. They are costly, but are becoming widely used, and it is likely that tissue-engineered products will continue to be developed in an attempt to solve difficult reconstructive problems.

Tissue expansion

This technique is valuable in using 'local' tissue for reconstruction. The natural ability of tissue to expand has been harnessed clinically since the experiments of Austad and the clinical work of Radovan in the 1970s. It is a technique borrowed from nature, and it is observed during pregnancy when skin expands over the underlying mass. It involves placing a device – usually an expandable balloon constructed from silicone – beneath the tissue to be expanded, and progressively enlarging the volume with fluid while the overlying tissue accommodates to the changed vascular pressure (Figure 42.9). The fluid (usually sterile saline coloured blue in Figure 42.9) is introduced via a self-sealing port attached to a filling tube that enters the balloon. It may be introduced as frequently as can be tolerated by the patient until the tissues are

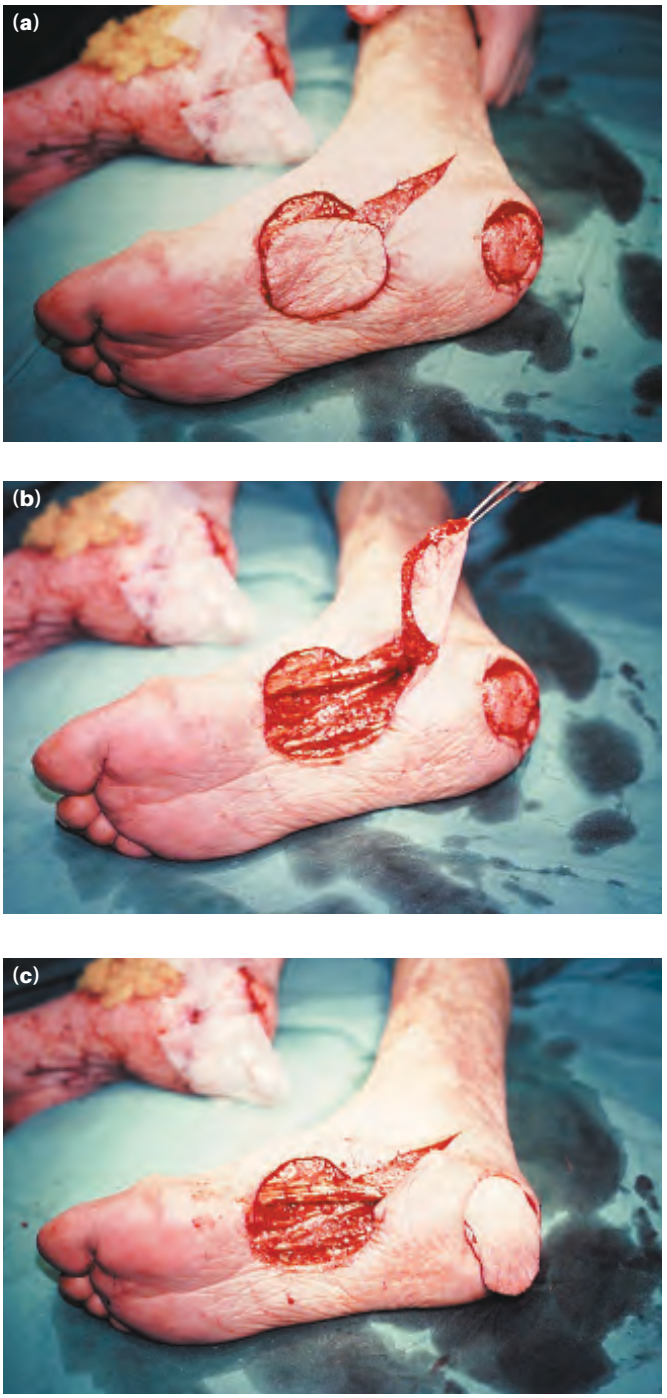

Figure 42.7 (a-c) Islanded pedicled flap used from the instep to resurface a heel defect.

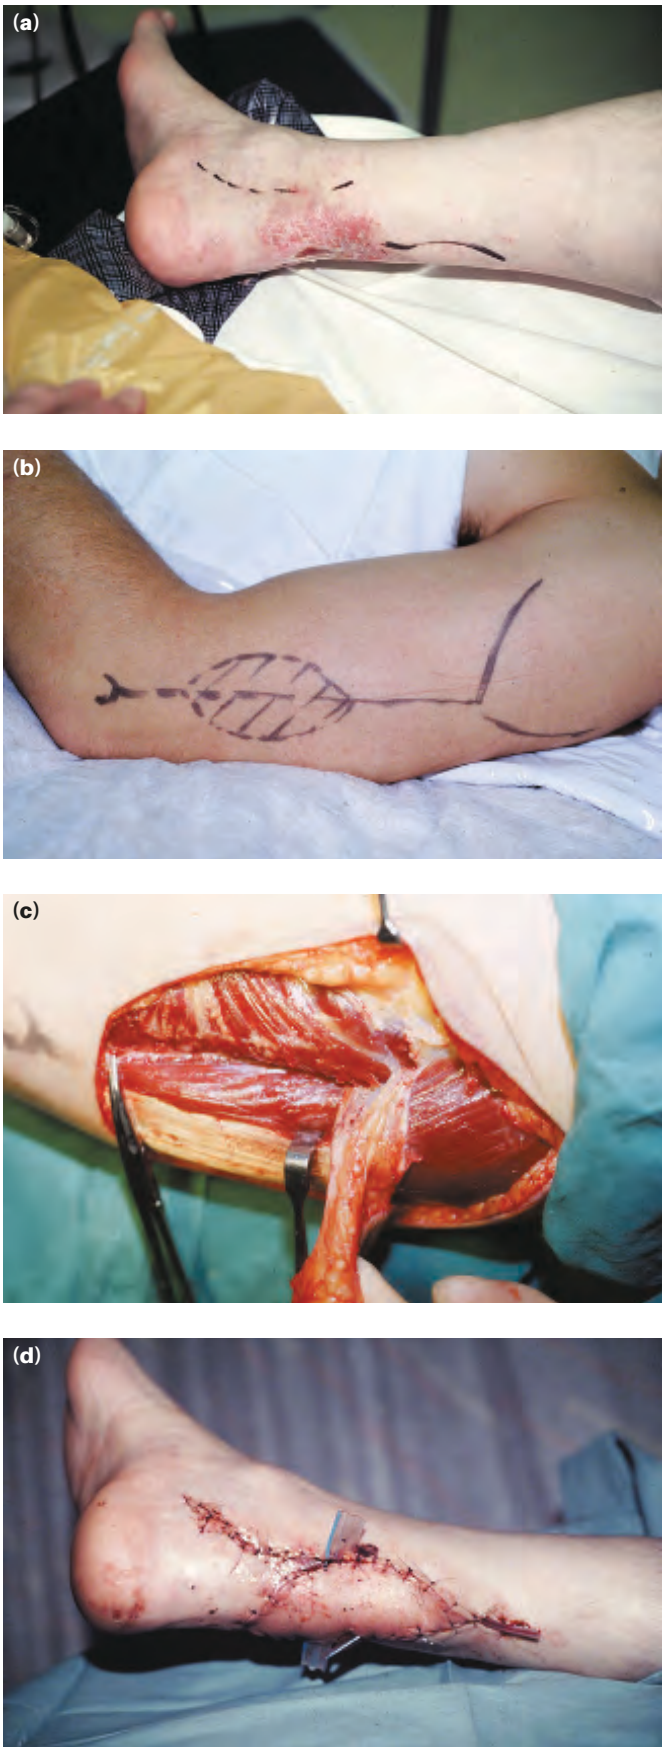

Figure 42.8 (a-d) Free lateral arm fasciocutaneous flap used to resurface a tendo Achilles defect.

Figure 42.9 Tissue expander.

stretched enough to be used for reconstruction. The tissues expanded do not hypertrophy, but there are major changes in the collagen structure.

The process is time-consuming, although it can be very valuable in problematic cases. It is invaluable for sharing remaining areas of scalp hair after severe burns, removing major congenital skin naevi and restoring full-thickness skin over previously grafted limb wounds.

It must never be used under irradiated tissues (such as mastectomy sites), which will not expand but necrose.

Summary box 42.2

Tissue expansion

Advantages

- Well-vascularised tissue
- Tissue next to defect, so likely to be of similar consistency
- Good colour match

Disadvantages

- Multiple expansion episodes (sometimes painful)
- Cost of device
- High incidence of infection and extrusion (especially limbs)

Vacuum-assisted closure

The use of negative pressure applied to a tissue defect has positive effects on wound closure, as well as making difficult and complex wounds more manageable during the early stages of granulation.

Exudate is removed and the suction pressure affects angiogenesis and tissue regeneration. The technique can be applied as part of early wound management before definitive surgical closure has been planned, or in some cases to avoid the need for surgery altogether. The foam sponge dressing is connected by a tube to a negative pressure pump that can be controlled to give intermittent suction (Figure 42.10).

Implants and prosthetics

Many tissue deficiencies cannot be adequately reconstructed with autologous tissue, however sophisticated the technique used. In such circumstances, implants are part of the reconstructive surgical 'toolbox'; they include solid and soft

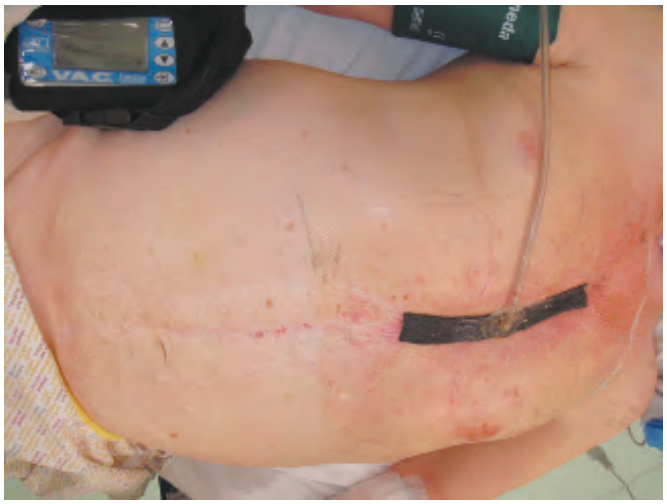

Figure 42.10 VAC™ device used to temporarily close a sternal dehiscence prior to definitive debridement and flap cover.

silicone materials, many forms of filler including collagen and polymers, and osseointegratable anchor points for prosthesis fixation.

Lipofilling and transfer

The use of fat as a reconstructive tissue is longstanding, but has recently become a well-established tool in the armamentarium of plastic surgery. It follows the systematisation of the technique for harvesting and subsequent management of the fat by Sydney Coleman in the late 20th century. Early scepticism for the value of the technique has given way to a recognition that a proportion (variable) of transferred fat can indeed survive injection, and the high volume of stromal and stem cells within fat give it possible advantages for whatever area it is used to manage. Current debate surrounds the best method for each stage in harvesting and preparation, including what preliminary infiltration to use, what dimension cannula is least destructive, whether centrifugation of the aspirate is of value and how best to place the transferred liquid.

The main use for small-volume fat transfer to date has been to provide autologous permanent filling of facial defects and scars. Such small volumes can be harvested and transferred under local anaesthesia, and should be used with care to avoid intravascular escape of fat that can produce emboli and associated injury. Larger volumes of fat have been used to 'lipo-fill' residual defects after conventional breast reconstruction as well as postinjury subcutaneous fat deformities. There is also some evidence that such transfers, rich in stromal and stem cells, have a beneficial effect on the adverse tissue damage induced by radiotherapy, and advances in this area are anticipated.

ASSESSMENT AND DIAGNOSTIC PLANNING

Formation of a definitive treatment plan, carefully considering all available options for care with the whole of the patient's needs in mind, is a vital component of wise plastic surgical practice. This is never more so than when managing major trauma cases in the acute setting or when planning major cancer management, which might be staged over a period of treatments and procedures. If the reconstructive surgeon can be involved in early wound debridement and incisions, vital flap pedicles can be protected and the functional and cosmetic outcome made optimal. This pattern of shared team care has become the norm in many units demonstrating good outcomes from major trauma salvage.

The initial assessment of wounds involves adequate removal of devitalised tissue, assessment of which vital structures will need reconstruction immediately and which might be better reconstructed later, and assessment of the degree of contamination involved, which will require further cleaning. Further planning will include the definitive soft-tissue cover of the wound and functional rehabilitation with full psychosocial rehabilitation.

TREATMENT AND COMPLICATIONS

Split-thickness skin grafts

Split-thickness skin grafts are taken with either hand-held **(Figure 42.11)** or powered skin knives **(Figure 42.12)**. The most used donor site is the thigh, with the buttock preferable in children and cosmetically sensitive individuals. For larger grafts, almost any flat surface can be harvested, including the scalp if shaved (a very good and useful donor site). The thickness of the graft harvested, ease of graft 'take' and donor site healing must be weighed against the lack of durability of thin split-thickness skin grafts.

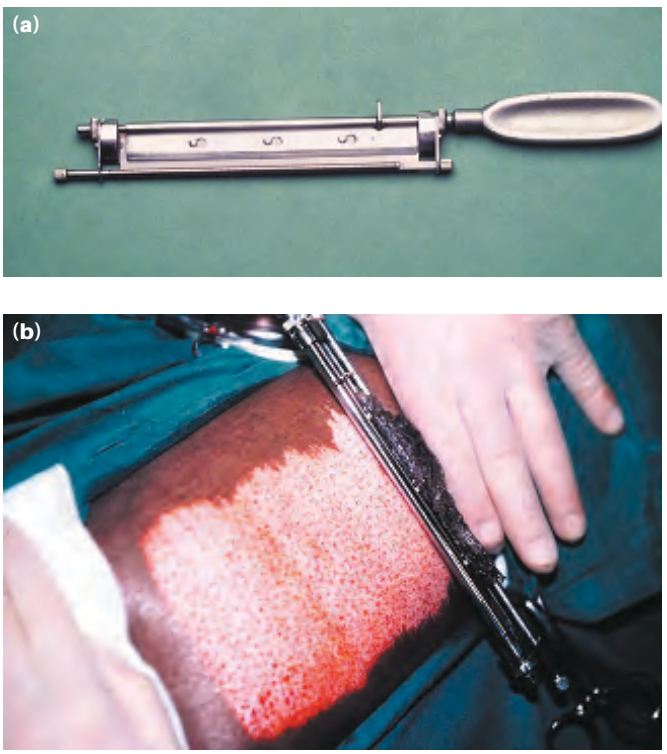

Figure 42.11 Hand-held skin knife **(a)** and harvesting skin with a hand-held knife **(b)**.

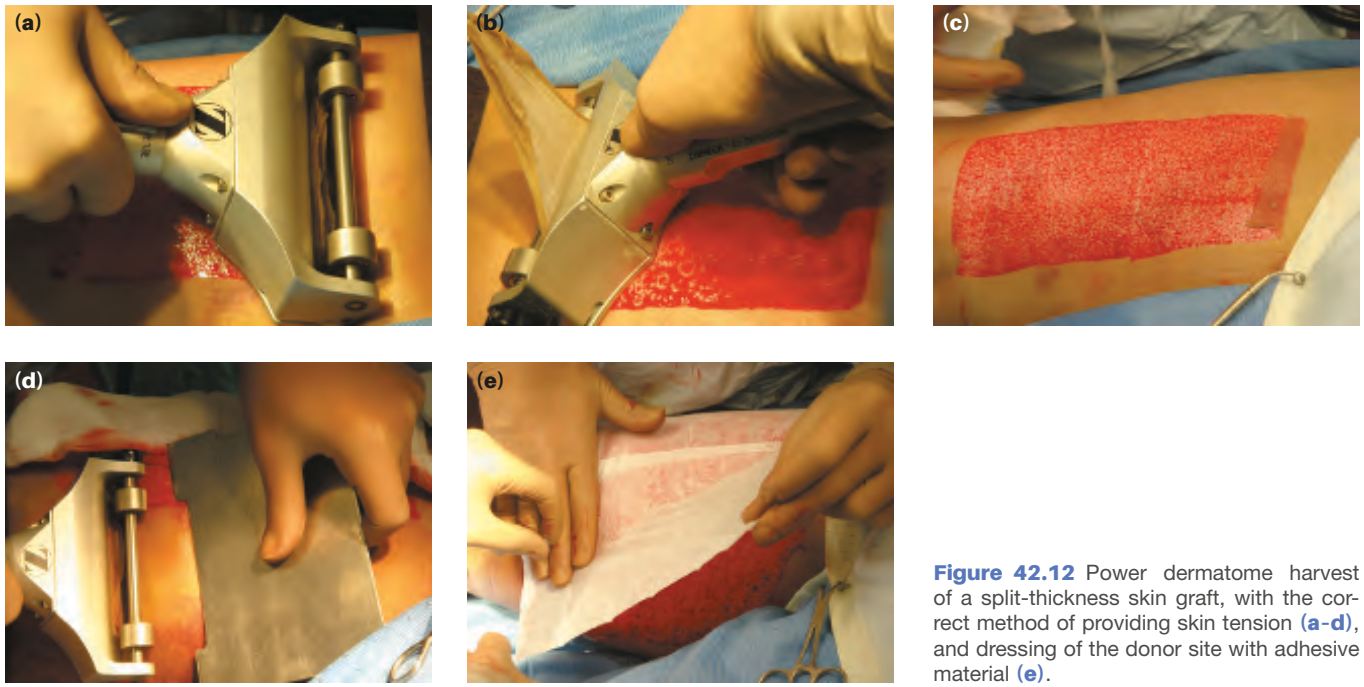

Figure 42.12 Power dermatome harvest of a split-thickness skin graft, with the correct method of providing skin tension **(a–d)**, and dressing of the donor site with adhesive material **(e)**.

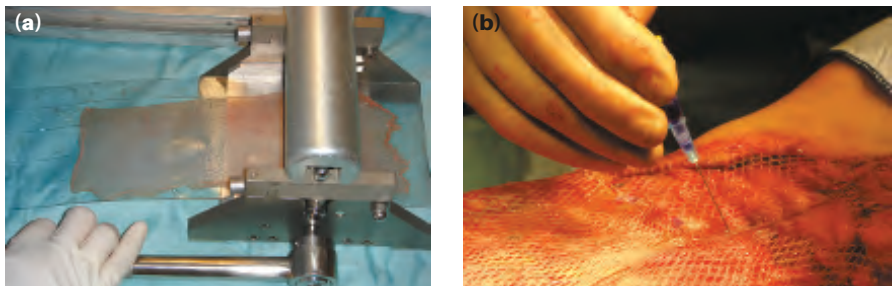

Figure 42.13 Split-thickness skin graft mesher **(a)** and meshed skin applied to the wound **(b)**.

Split grafts can be perforated to allow exudates to escape and improve 'take'; they can be further meshed to allow expansion **(Figure 42.13)**. This is carried out on a device that cuts a series of slits along the skin, allowing it to expand from a ratio of anything from 1:1.5 to about 1:6.

Grafts will only take on a bed on which they can become vascularised. Preparation of the wound bed is therefore an essential part of a successful graft **(Figure 42.14)**. Graft failure is commonly caused by pus, exudate or residual dead tissue beneath the skin, haematoma or shearing forces. A clean healthy wound bed with a meshed graft tied in place to stop movement will encourage success. The group A β-haemolytic *Streptococcus* can destroy split grafts completely (and also convert a donor site to a full-thickness defect) and so the presence of this microorganism is a contraindication to grafting.

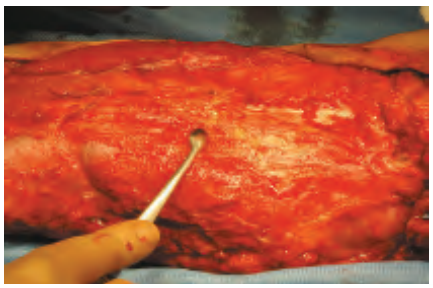

Figure 42.14 Cleaning a wound of excessive granulation tissue before grafting.

Full-thickness skin grafts

Small dermal grafts (Wolfe grafts) can be taken from behind the ear, the groin creases and the neck, with easy direct closure of the donor site. Older people can sustain larger harvests because of skin laxity. Large full-thickness skin graft use is uncommon and requires great care to obtain a good take. Large donor sites require secondary split-thickness skin grafting. Major secondary burn contractures of the face and flexion creases can achieve remarkable functional and cosmetic improvement using such large grafts, particularly as the remaining facial muscle function can still produce a more natural appearance than when covered by a bulky full-thickness skin flap. Smaller full-thickness grafts are useful for contracture release around sensitive facial and extremity structures.

Technique

The shape of the graft needed is drawn and copied onto a small template (paper or cloth), which is used to transfer the same shape to the donor site. Full-thickness skin is cut; grafts take best if additional underlying fat is removed, after which the graft is applied with normal skin tension and tied down with a pressure dressing. The graft will remain vulnerable to shearing forces for several weeks after application.

Flaps

Local flaps

A local flap is raised next to a tissue defect in order to reconstruct it. Basic patterns include (Figure 42.15):

- **Transposition flap**. The most basic design, leaving a graftable donor site (Figure 42.16);
- **Z-plasty**. For lengthening scars or tissues;
- **Rhomboid flap**. For cheek, temple, back and flat surface defects;
- **Rotation flap**. For convex surfaces;
- **Advancement flap**. For flexor surfaces; may need triangles excised at the base to make it work (commonly called Burow's triangles);
- **V-to-Y advancement**. Commonly used for fingertips and extremities;
- **Bilobed flap**. For convex surfaces, especially the nose (Figure 42.17);
- **Bipedicle flap**. For eyelids, rarely elsewhere.

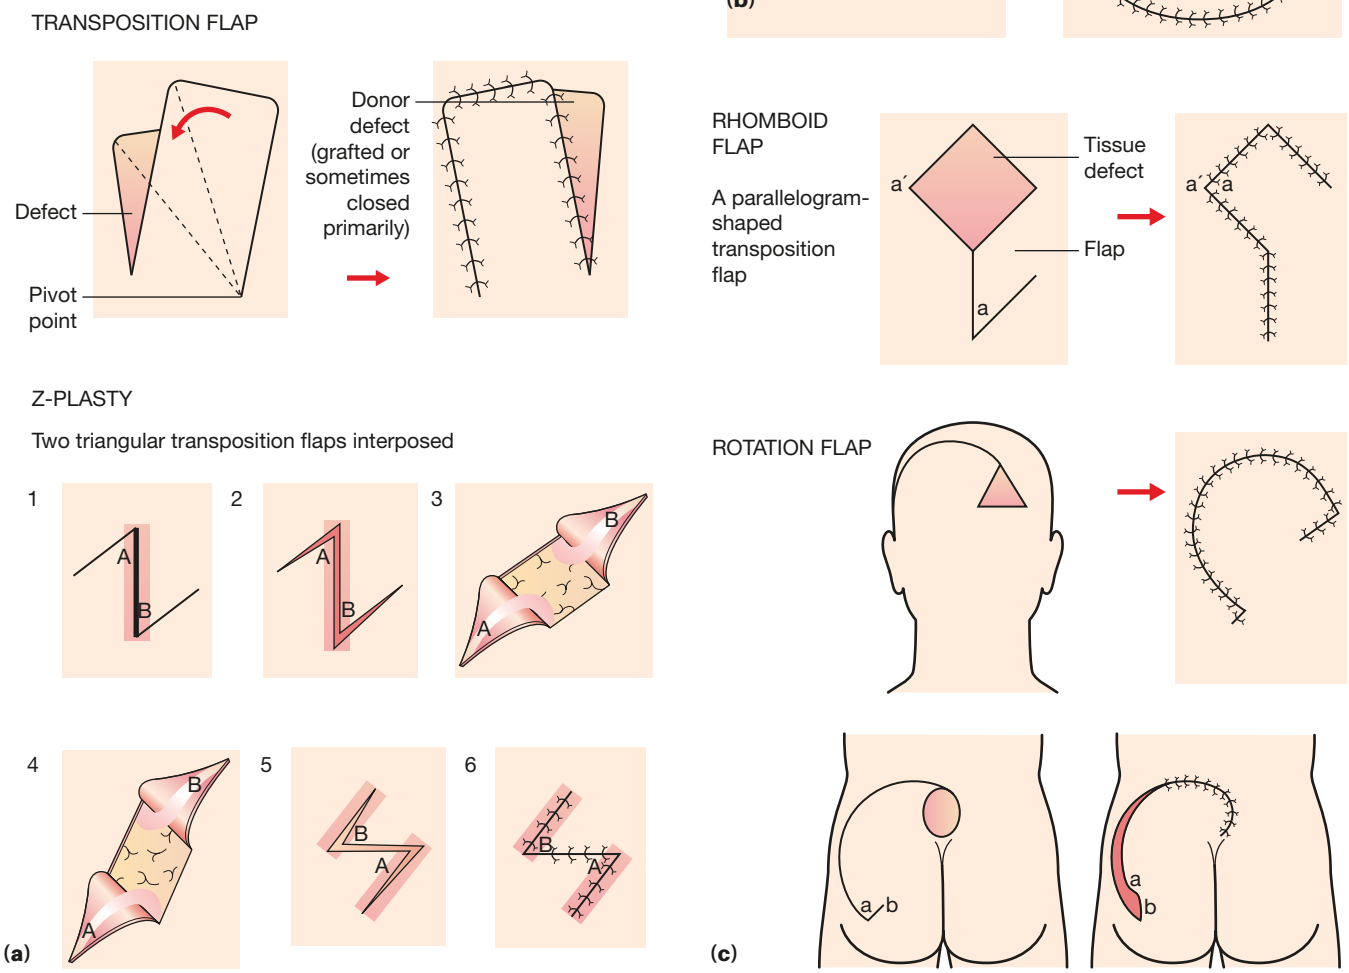

Figure 42.15 Local flap diagrams: **(a)** transposition and Z-plasty flaps; **(b)** bilobed and bipedicled flaps; **(c)** rhomboid and rotation flaps. (*continued overleaf*)

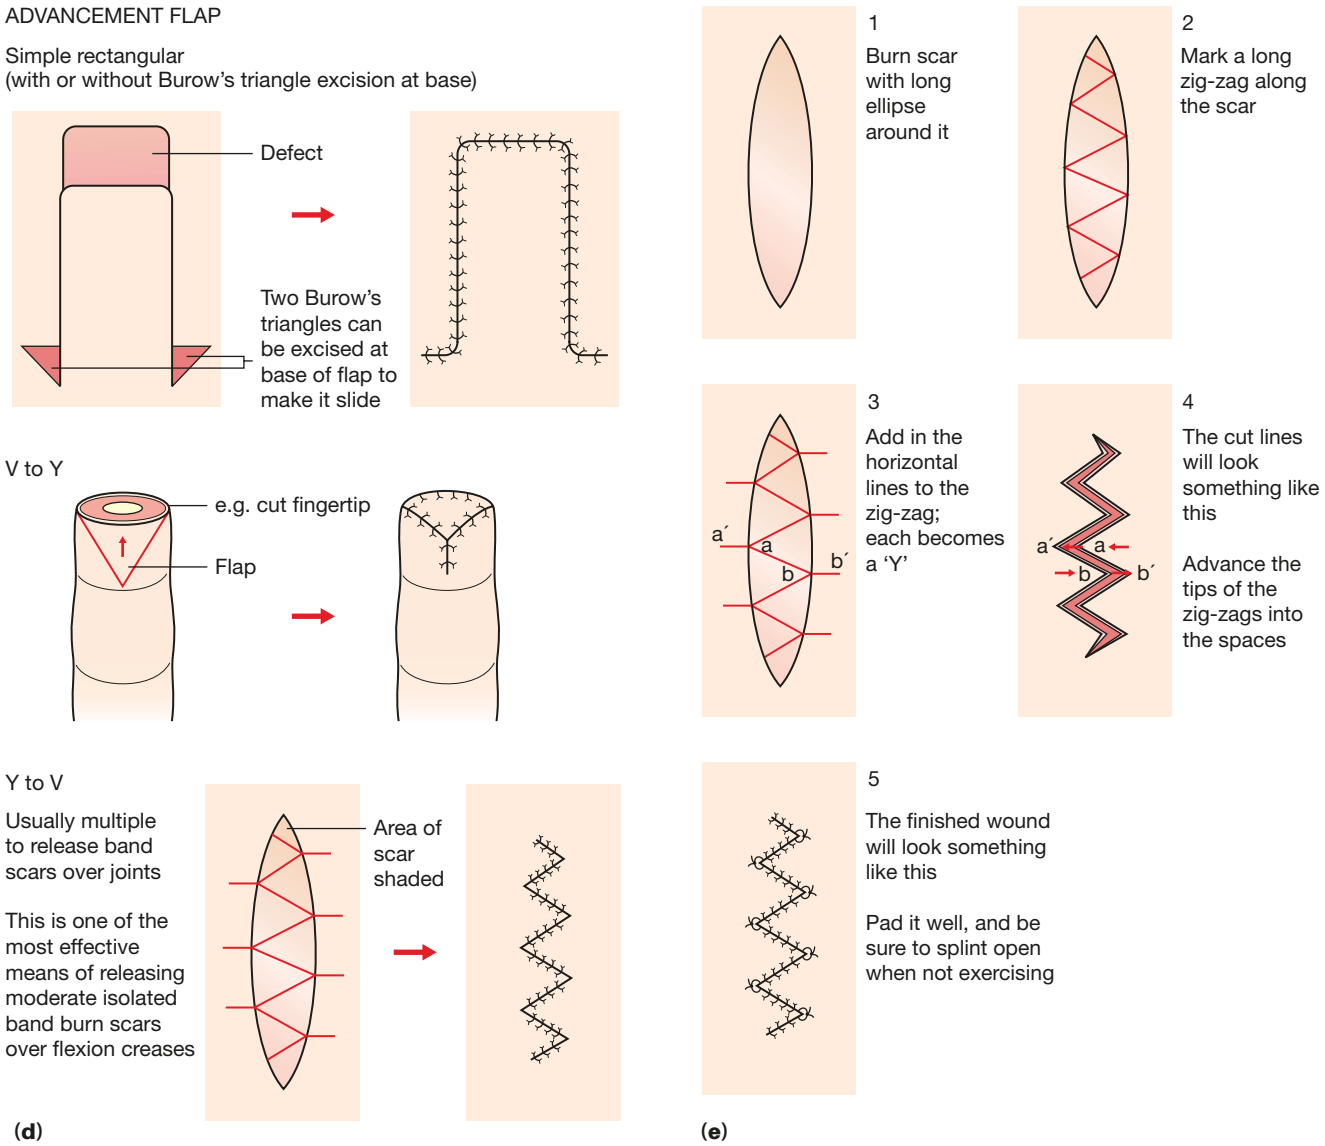

Figure 42.15 (*continued*) Local flap diagrams: **(d)** advancement flaps; **(e)** multiple Y-to-V plasty for burn scar.

All flaps must be raised in the subcutaneous plane. Gentle undercutting of margins helps to close the donor site. The art of making local flaps work is to pull available local spare lax skin into the defect, so that the scar when closed sits in a good 'line of election'. Local flaps are usually not based on specific blood vessels, but are very useful in head and neck and smaller defect reconstructions. Good planning is essential to gain the best result from these flaps.

Summary box 42.3

Local flaps

Benefits

- Best local cosmetic tissue match
- Often a simple procedure
- Local or regional anaesthesia option

Disadvantages

- Possible local tissue shortage
- Scarring may exacerbate the condition
- Surgeon may compromise local resection

Karl August von Burow, 1809–1974, surgeon, Konigsberg, Germany.

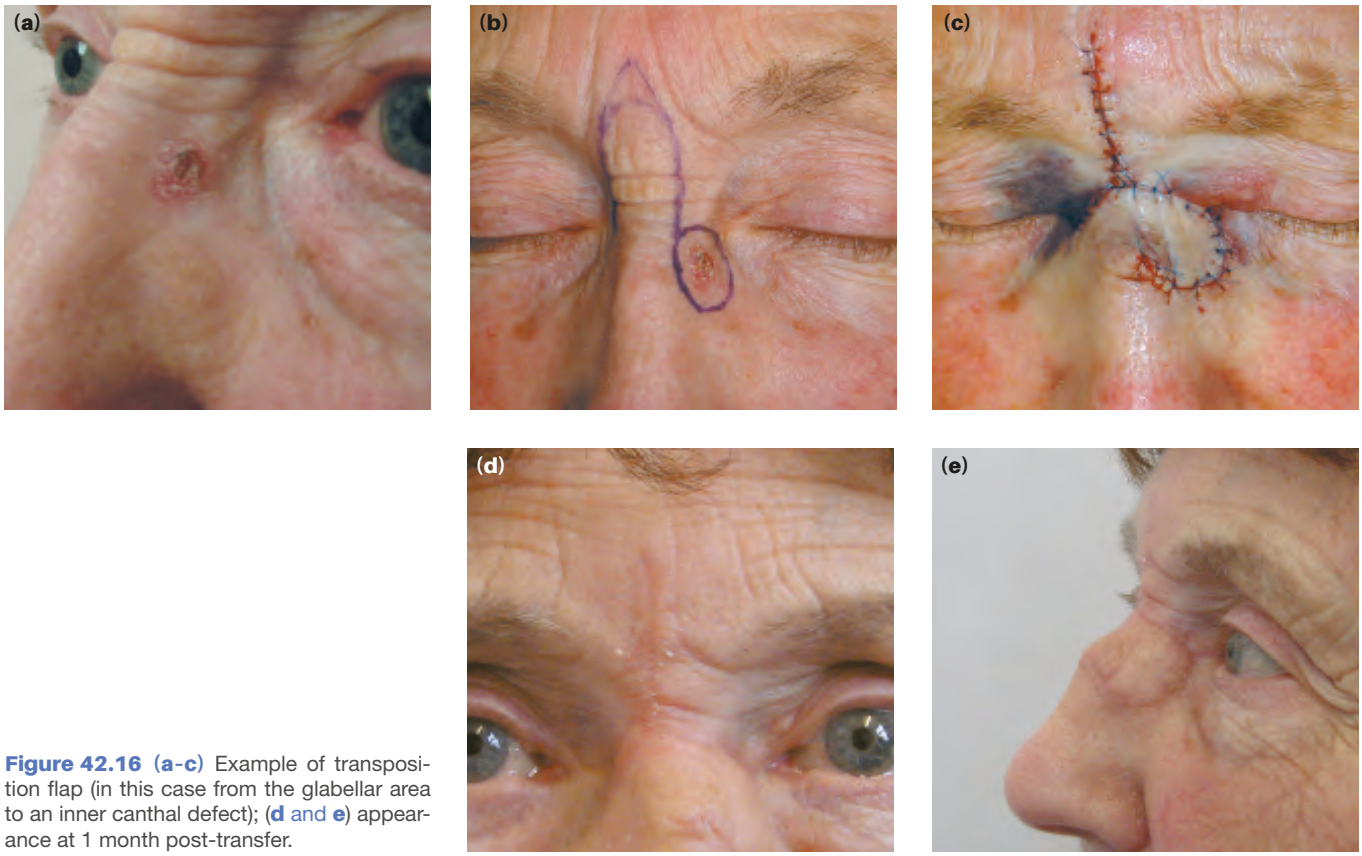

Figure 42.16 **(a-c)** Example of transposition flap (in this case from the glabellar area to an inner canthal defect); (**d** and **e**) appearance at 1 month post-transfer.

Figure 42.17 **(a-c)** Example of a bilobed flap (in this case from the nose to a defect on the tip following excision of a basal cell carcinoma); **(d)** appearance at 6 weeks post-transfer.

Combined local flaps

In some circumstances, such as burn contracture release, local flaps can usefully be combined to import surplus tissue from a wide area adjacent to a scar or defect that needs removal. Examples are the W-plasty and the multiple Y-to-V plasty, which is a very versatile means of releasing an isolated band scar contracture over a flexion crease (Figure 42.18).

Distant flaps

To repair defects in which local tissue is inadequate, distant flaps can be moved on long pedicles that contain the blood supply. The pedicle may be buried beneath the skin to create an island flap or left above the skin and formed into a tube.

The most common means of moving flaps long distances while still attached are with a long muscular pedicle that contains a dominant blood supply (a myocutaneous flap) (Figure 42.19) or with a long fascial layer that likewise contains a major septal blood supply (a fasciocutaneous flap) (Figure 42.20). These flaps can carry large composite skin parts for reconstruction very great distances, e.g. from the abdomen to the chest (for breast reconstruction), from the chest to the face (for oral cancer reconstruction) and from the calf to the knee.

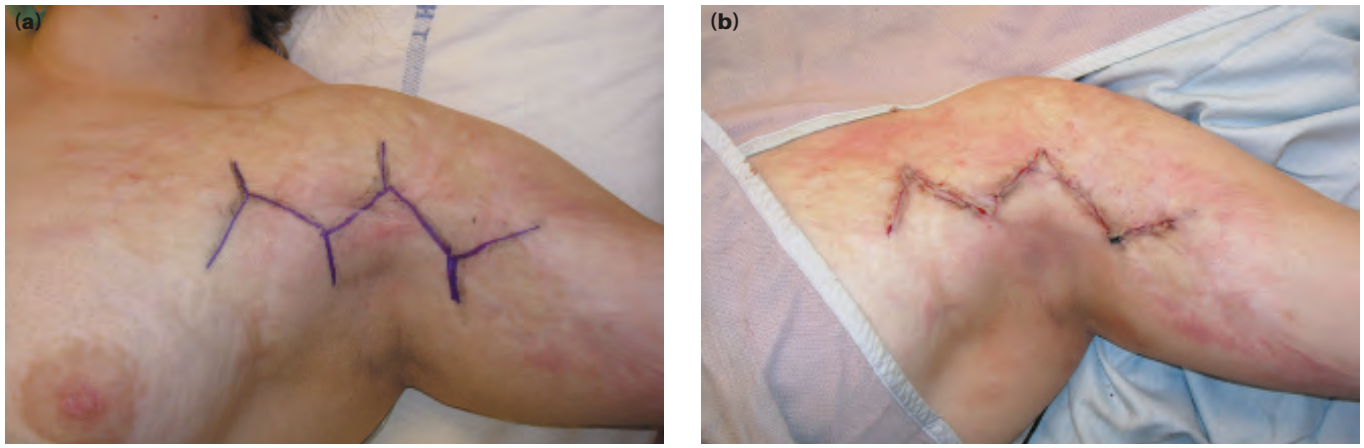

Figure 42.18 (a, b) Y-to-V flap to release axillary contracture.

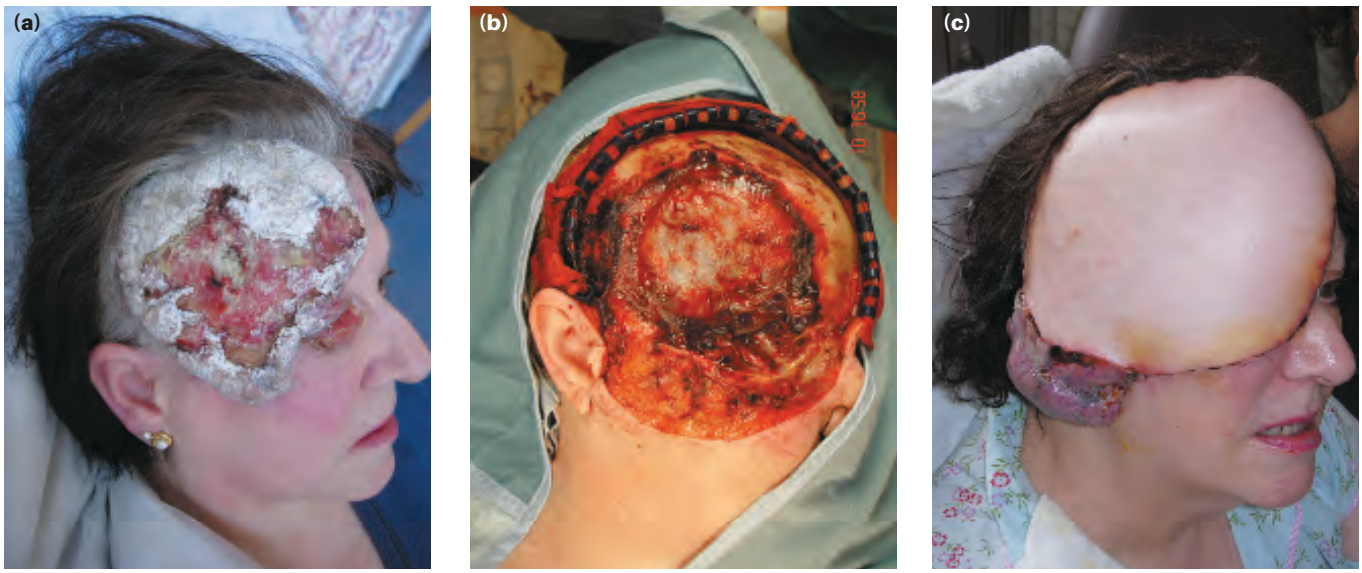

Figure 42.21 **(a-c)** Large myocutaneous free flap (latissimus dorsi) to cover an exposed cranial defect following the excision of advanced basal cell carcinoma (case courtesy of Mr David Johnson FRCS(Plast)).

There are a vast number of carefully described myocutaneous and fasciocutaneous flaps throughout the body, all of which are based on known blood vessels. They are reliable when the anatomy of the blood supply is known by the surgeon and the skin is raised carefully in continuity with the underlying fascia or muscle, through which the small perforating vessels run to supply the piece of skin that is being transferred. They are the 'workhorse' of plastic surgery worldwide because they do not require complex equipment to raise them and they can solve the majority of reconstructive problems.

Microsurgery and perforator flaps

With fine instruments and materials, it has become commonplace to be able to disconnect the blood supply of the flap from its donor site and reconnect it in a distant place using the operating microscope.

The free tissue transfer is now the best means of reconstructing major composite loss of tissue in the face, jaws, lower limb and many other body sites, as long as resources allow it (**Figure 42.21**). The operative procedure is similar whether the defect is newly produced from a recent injury or cancer

resection or whether it is to be used for the secondary correction of a deformity, such as rebuilding a mastectomy deformity. At the site of the defect, the surgeon must be sure that all contaminated and dead tissue has been thoroughly cleared and cleaned, a process commonly described as debridement, although that term strictly refers to the release of constricting tissue. If this removal of poorly viable tissue is in doubt, then consideration should be given to delaying the reconstruction.

The surgeon must then find a suitable blood supply for the tissue transfer at the site to be reconstructed. A good arterial flow in and venous return out, without external tissue pressure (such as from surrounding wound induration), is of paramount importance in achieving a successful transfer. The flap is then raised *(Table 42.2)* and transferred using magnification **(Figure 42.22)**. Free muscle transfers should be reanastomosed within 1–2 hours if possible; fasciocutanous flaps are more robust and can survive slightly greater ischaemic times.

TABLE 42.2 Common free tissue transfer donor sites.

Muscle only	Latissimus dorsi Rectus abdominis Gracilis
Myocutaneous	Latissimus dorsi Transverse rectus abdominis
Fasciocutaneous	Radial forearm flap Scapular Lateral arm Anterolateral thigh Groin
Osseous	Fibula (may be cutaneous as well) Forearm (taking sliver of radius bone) Iliac crest
Fascial	Temporoparietal
Miscellaneous	Jejunum – for oesophageal reconstruction Pectoralis minor – for facial reanimation Omentum – for chest wall and limb defects

Summary box 42.4

Free tissue transfer (or free flap)

Advantages

- Being able to select exactly the best tissue to move
- Only takes what is necessary
- Minimises donor site morbidity

Disadvantages

- More complex surgical technique
- Failure involves total loss of all transferred tissue
- Usually takes more time unless the surgeon is experienced

Further developments have led to surgeons dissecting distant flaps free from the carrier muscle or fascia, to reduce the donor morbidity further. These distant 'perforator' flaps increase the flexibility of the use of the flap tissue while reducing donor site problems. Flap design has moved towards delivering individualised tissue transfers that are customised to cater for the specific reconstructive and aesthetic requirements of treatment. This has led to numerous combinations of tissue raised on common vascular pedicles **(Figure 42.23)**.

Combined flaps

The difficulty presented by defects needing multiple parts to reconstruct is now often managed using various forms of 'combined flap'. These use parts fully separated (but blood supplied by a single vascular pedicle) in order to make reconstruction more flexible and therefore not only better functioning but also cosmetically more accurate.

'Conjoined' flaps have two or more 'territories' of tissue supplied by separate pedicles. These may be conjoined by skin in continuity at the extremes of each pedicle's reach (such as the raising of a latissimus dorsi flap in continuity with a groin flap with a pedicle at each end), or be separate perforator-based territories on the same 'mother' blood supply.

'Chimeric' flaps again have multiple flap territories, each with an independent vascular supply, but are independent of any physical connection except when they are linked by a common feeder vascular pedicle **(Figure 42.22)**. Such flaps have become amongst the most widely used, in circumstances when several elements of soft tissue need reconstructing, along with perhaps a bony element as well as a functional muscle transfer. The antero-lateral thigh flap is very amenable to separation into several parts and muscle elements, as is the scapular/subscapular array of flaps.

The chimeric principle can be extended yet further by the joining of additional flaps to the main flap-feeding vessels using microsurgical anastomosis. This is to prefabricate the most suitable tissue element for the reconstructive purpose in hand, which although requiring considerable technical expertise to accomplish, can achieve excellent outcomes in single-staged procedures.

Supermicrosurgery

In the last decade, Koshima's description of anastomosing vessels with a diameter of 0.8 mm or less has been utilised to improve on perforator flap donor site morbidity, as well as speed of flap harvest. So-called 'perforator to perforator' anastomoses can make reconstruction very accurate in skilled hands. It begins to make the previously constrained selection of flap donor sites and recipient vessels redundant, with terms such as 'free style free flap' being coined to describe such versatility in reconstructive work.

The technique has also been used to advance the art of lymphatico-venous anastomosis to treat lymphoedema. In correctly selected cases and with good facilities, such surgery has begun to offer new therapeutic options to those with chronically morbid conditions.

Care of flaps and monitoring

After a flap has been moved, it should be observed for tissue colour, warmth and turgor, and be pressed to assess blanching and capillary refill time. Loss of arterial inflow results in pale, cold, flaccid tissue; loss of venous outflow results in blue congestion, increased turgor, rapid capillary refill and initially a warm flap. In a pedicled flap, such venous congestion may be relieved by releasing suture tension; applying leeches to suck

out excess venous blood is a last resort when no other means of restoring venous drainage can be obtained.

The most common causes of flap failure are:

- poor anatomical knowledge when raising the flap (such that the blood supply is deficient from the start);
- flap inset with too much tension;
- local sepsis or a septicaemic patient;
- the dressing applied too tightly around the pedicle;
- microsurgical failure in free-flap surgery (usually caused by problems with surgical technique);
- tobacco smoking by patient.

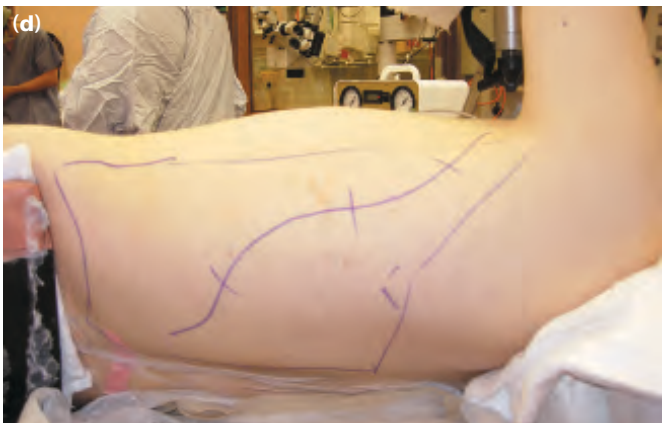

Figure 42.22 Large 'chimeric flap' of latissimus dorsi and serratus anterior muscles **(a)**, to cover a complex open wound of the foot and ankle **(b)**, illustrating the donor site **(c, d)** and fully covered defect **(e, f)** (case courtesy of Mr David Johnson FRCS(Plast)).

'Wet, warm and comfortable'

The best advice for postoperative flap care for major tissue transfers is to keep the patient 'wet, warm and comfortable'. This means that the patient should be well hydrated with a hyperdynamic circulation, a very warm body temperature and well-controlled analgesia to reduce catecholamine output.

Reconstructing complex areas

Certain areas, such as the eyelids, nose, lips, ears, genitalia, fingers, breast and intraoral structures, often require a combination of methods to produce the most functional and acceptable outcome for the patient. Planning such reconstruction involves considering each cosmetic subunit involved in the

defect and bringing the best tissue to rebuild it. An example is the Indian forehead rhinoplasty of Sushruta, which involves transposition of a pedicled fasciocutaneous flap from forehead to nose, with the donor site usually thin skin grafted, but occasionally closed primarily in small flaps. It remains the finest means of transporting cosmetically correct tissue to the nose.

FUTURE TRENDS

Vascularised composite allografting (VCA)

Plastic surgeons have long sought to use transplanted tissue to solve the problems posed by the most severe tissue defects. Esser, in the early twentieth century, pioneered much innovative surgery and urged research into this area. Later, Joe Murray, a plastic surgeon in the United States, undertook the first kidney transplant and was awarded the Nobel Prize for his work. Improved understanding of immunology and means of tolerance induction are now leading to the use of transplanted composite tissues for the most intractable cases of loss of tissue following injury and cancer.

In the latter part of the 20th century, the constraints of total systemic immunosuppression alongside the difficulties in overcoming the inherent problems of cutaneous immunosensitivity led to transplants being confined predominantly to solid organs in clinical practice.

Recent refinements in immune suppression therapy and anticipated advances in tolerance induction strategies have opened the door to the use of more complex transplants including skin for non-life-threatening disorders. The first hand transplant was performed in Lyon, France in 1998, and limb transplantation now has an established place in reconstructive plastic surgery. Other composite allografts have followed, including facial tissue and abdominal wall reconstruction (**Figure 42.24**).

Figure 42.24 Abdominal wall transplant: **(a)** open abdomen with transplanted small bowel that cannot be closed using the patient's own skin cover; **(b)** donor transplant abdominal wall element harvested; **(c)** abdominal wall with transplant *in situ* (courtesy of Mr Henk Giele, FRACS).

Johannes Fredericus Samuel Esser, 1877–1946, born in Leyden, Netherlands. He was a Dutch plastic surgeon who pioneered reconstructive surgery on soldiers wounded in the First World War and is thought to have coined the term 'stent' in 1917 to describe his use of a dental impression compound invented in 1856 by the English dentist Charles Stent (1807–1885) to create a form for facial reconstruction.

Joseph E Murray, b.1919, Professor Emeritus of Plastic Surgery, Harvard University Medical School, Boston, MA, USA, shared the 1990 Nobel Prize for Physiology or Medicine with E Donnall Thomas for his work on organ and cell transplantation. Murray's interest in transplantation began during his military service in the Second World War. The early experiences with skin transplantation for burns in pilots formed the basis for Murray's interest in solid organ transplantation. He performed the world's first kidney transplantation in identical twins in Peter Brent Brigham Hospital, Boston in 1954.

As immunotolerance strategies develop (especially the probable use of TReg cell therapy in some form or other) it is likely that there will be a burgeoning of microsurgically transferred VCAs to facilitate complex reconstruction throughout the body. This will precede the development of more sophisticated tissue engineered substitutes that are decades away from use for more complex composite tissue reconstructions.

Tissue and bioengineering

Improved understanding of tissue behaviour is leading to numerous innovations in wound manipulation using biological mechanisms. Tissue-engineered biological substitutes for tendon, nerve, larynx and other vital structures are becoming established, and will greatly influence the spectrum of reconstructive procedures in the coming years (see Chapter 4).

Novel polymers and biologically tolerated materials are also being developed to act as nerve conduits, facial muscle substitutes and self-inflating expansion devices. The interface of new material science with reconstructive surgery is still in its infancy.

PART 7

Head and Neck

Chapter 43

Cranial neurosurgery

Learning objectives

- To recognise the features of raised intracranial pressure, hydrocephalus and infection typical to acute neurosurgical presentations.
- To be familiar with aneurysmal subarachnoid haemorrhage and other causes of intracranial haemorrhage.
- To recognise common brain tumours, their presentation, investigation and treatment.
- To be aware of common developmental and other pathologies encountered in paediatric neurosurgical practice.
- To understand the indications and approaches available for the management of epilepsy, pain syndromes and movement disorders.
- To note key practical and ethical issues relating to consent and risks, Creutzfeldt–Jacob disease (CJD) precautions and diagnosis of brainstem death.

RAISED INTRACRANIAL PRESSURE

The importance of intracranial pressure (ICP) management in the context of head injury has been discussed elsewhere (Chapter 24). Likewise, intracranial pressure is key to presentation and management across the spectrum of cranial neurosurgery.

Clinical features of raised ICP

Symptoms of raised ICP include a 'high pressure headache', worse on coughing or bending forward; low pressure headaches, encountered after excessive cerebrospinal fluid (CSF) drainage, are typically worse on standing. High pressure headaches may be accompanied by nausea and vomiting, blurred vision and double vision; cranial nerve compression can result in eye movement and pupil abnormalities. Fundoscopy can detect papilloedema (**Figure 43.1**), but this takes time to develop so may be absent in the acute phase.

In infants, the fontanelle is tense and bulging, with an increase in head circumference and bulging scalp veins. As pressure rises, conscious level is impaired. In children Parinaud's syndrome results from dorsal midbrain compression, with a loss of upgaze known as sunsetting (**Figure 43.2**).

Raised ICP requires urgent evaluation and management: delay risks progression to cerebral herniation (see Chapter 24) resulting in cardiovascular instability, neurological deficit and death. Vision may also deteriorate rapidly and irreversibly.

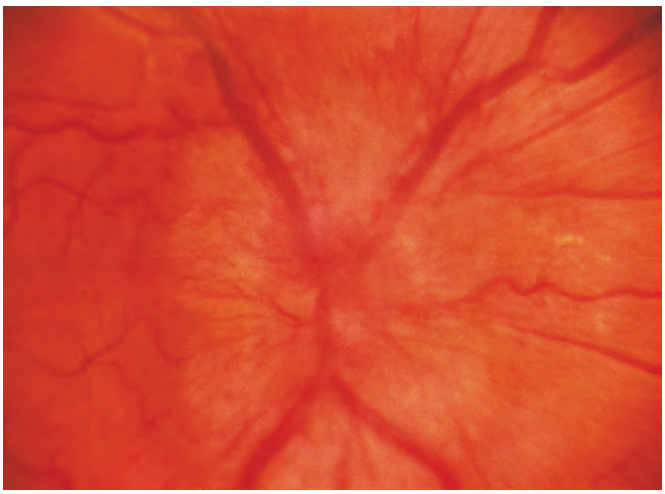

Figure 43.1 Papilloedema. The optic disc is swollen with blurred margins.

Figure 43.2 Parinaud's syndrome with sunsetting.

Investigation of raised ICP

Causes of raised ICP include mass lesions, cerebral oedema and hydrocephalus. Where raised ICP is suspected, computed tomography (CT) is a first line investigation to demonstrate these and other pathologies, and to evaluate the degree of mass effect and the patency of the basal cisterns, the spaces surrounding the brainstem. This is key to management since lumbar puncture in the setting of raised ICP can result in downward herniation of brain structures. Many pathologies, as well as the anatomy relating to potential treatments such as third ventriculostomy, may be better visualised on magnetic resonance imaging (MRI). Where high pressure is suspected but not clearly demonstrated by imaging, ICP monitoring by placement of a transducer in the brain substance allows continuous monitoring over hours or days (**Figure 43.3**).

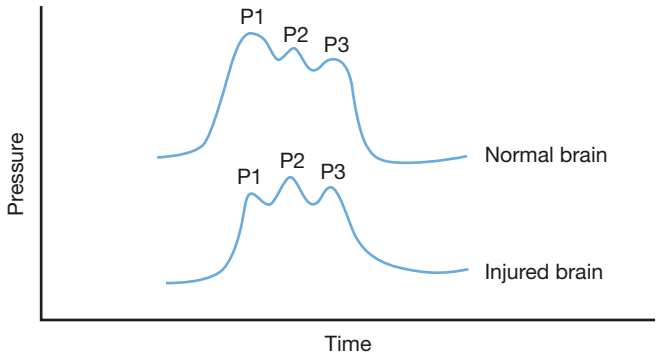

Figure 43.3 The intracranial pressure waveform. The P1 percussion wave corresponds to arterial pulsation. Reduced brain compliance in the setting of traumatic brain injury among others is associated with a prominent P2 tidal wave. The P3 dicrotic wave represents venous pulsation.

Summary box 43.1

Raised intracranial pressure

Acutely raised ICP is a neurological emergency. The presentation includes:

- Headache
- Nausea and vomiting
- Diplopia and blurred vision
- Drowsiness then coma

HYDROCEPHALUS

The total CSF volume is normally about 150 mL. Production from the walls of the ventricles and the choroid plexus is about 20 mL per hour. Hydrocephalus refers to an increase in CSF volume with ventricular enlargement, often presenting symptoms of raised ICP.

Physiology of CSF flow

CSF flows from the lateral ventricles through the foramen of Monro to the third ventricle, then down the cerebral aqueduct to the fourth ventricle, where it exits to the subarachnoid space via the midline foramen of Magendie and the lateral foramina of Luschka (**Figure 43.4**). CSF is reabsorbed into the arachnoid villi along the superior sagittal sinus.

Obstructive and communication hydrocephalus

Hydrocephalus almost always reflects obstruction to circulation (an obstructive hydrocephalus) or failure of reabsorption (a communicating hydrocephalus) (*Table 43.1*) (**Figures 43.5–43.7**). The distinction is important since obstructive hydrocephalus especially can cause very

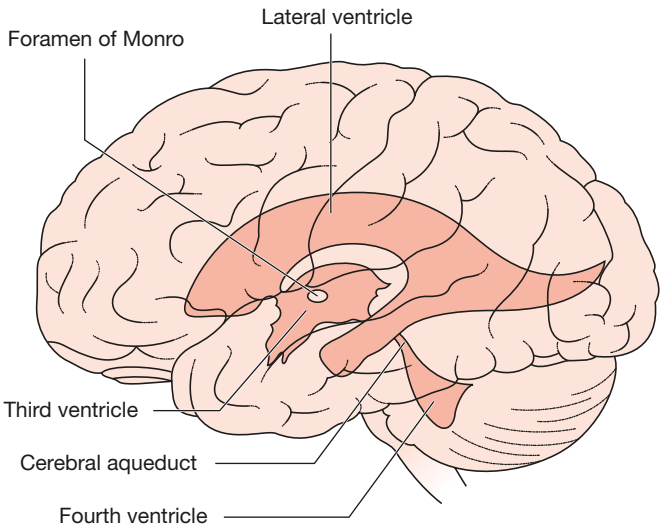

Figure 43.4 'CSF pathways'. Cerebrospinal fluid (CSF) is produced by the choroid plexus of the lateral ventricles and flows through the ventricular system to exit into the subarachnoid space through the foramina of Magendie and Luschka in the fourth ventricle.

TABLE 43.1 Aetiology of hydrocephalus.

Obstructive hydrocephalus	Lesions within the ventricle
	Lesions in the ventricular wall
	Lesions distant from the ventricle but with a mass effect
Communicating hydrocephalus	Post haemorrhagic
	CSF infection
	Raised CSF protein
Excessive CSF production (rare)	Choroid plexus papilloma/ carcinoma

CSF, cerebrospinal fluid.

Alexander Monro, 1733–1817, Professor of Anatomy at Edinburgh University, a post also held by his father, Alexander Monro (primus), and son, Alexander Monro (tertius)

Francois Magendie, 1783–1855, physician and Professor of Pathology and Physiology, Paris, also described the Magendie sign, a downward and inward rotation of the eye due to a cerebellar lesion.

sudden deterioration with coma and death, and because lumbar puncture in this context carries a risk of herniation of the brainstem and cerebellar tonsils due to the resulting differential pressure changes (sometimes termed 'coning'). For communicating hydrocephalus, lumbar puncture is of diagnostic value, deriving an opening pressure and assessment of the CSF contents. It is also therapeutic; drainage of typically between 10 and 30 mL of CSF, with the goal of halving the opening pressure, can relieve the hydrocephalus at least temporarily.

Treatment of hydrocephalus in the emergency setting usually involves CSF diversion, for example using an external ventricular drain. Management is discussed further under Treatment of hydrocephalus. Disorders of CSF flow with poorly understood mechanisms manifest in two syndromes: normal pressure hydrocephalus and idiopathic intracranial hypertension (IIH).

Figure 43.5 Pathological specimen of a hydrocephalic brain.

Normal pressure hydrocephalus

This is an important cause of dementia since it is readily reversible. It typically presents with the triad of gait disturbance, incontinence and cognitive decline. It may occur de novo or on a background of previous brain insults including subarachnoid haemorrhage (SAH), head injury, meningitis and tumour. Ventriculomegaly is evident on imaging, although this is also seen in the context of cortical atrophy due to other dementia pathologies. The CSF pressure at lumbar puncture (LP) is typically normal, but it is believed that intermittent elevations in pressure may be involved in the aetiology. Lumbar infusion testing involves insertion of a fine drain at LP, followed by measurement of the CSF pressure changes associated with a fluid challenge administered through this. This allows evaluation of the likely benefit from definitive treatment by shunt insertion.

Figure 43.6 Pineal region tumour (arrow) causing obstructive hydrocephalus.

Figure 43.7 Gross hydrocephalus in a neonate with very prominent temporal horns (arrows) and fourth ventricle.

Idiopathic intracranial hypertension

This condition presents with features of raised ICP without an underlying tumour, explaining the old terms for the condition, pseudotumour cerebri or benign intracranial hypertension. This description is misleading, since IIH can progress rapidly to blindness. The patient, typically a young overweight female, describes a headache typical of raised pressure, and visual deterioration. Examination may reveal papilloedema, and occasionally cranial nerve palsies. Imaging is unremarkable, but LP demonstrates a raised opening pressure >25 mm Hg. The diagnosis is one of exclusion and the aetiology is not well understood. Impaired CSF resorption may reflect raised venous pressure, either as a result of sinus thrombosis or secondary to raised intra-abdominal pressure in obese patients. Weight loss and cessation of certain medications including the oral contraceptive pill is often effective. This is combined with medical therapy using acetazolamide to reduce CSF production. For patients with visual field loss or visual failure, despite medication, lumboperitoneal or ventriculoperitoneal shunting is offered. Optic nerve sheath fenestration by an ophthalmologist may also be employed.

Summary box 43.2

Hydrocephalus and disorders of CSF flow

- Obstructive or communicating hydrocephalus may occur as a result of neurosurgical pathology or its treatment
- CT is the first line of investigation. For communicating hydrocephalus, LP can confirm raised CSF pressure and relieve it temporarily
- Idiopathic intracranial hypertension results in symptomatic raised CSF pressure without ventricular enlargement, typically in young, overweight women. CSF diversion may be necessary to prevent permanent visual loss
- Normal pressure hydrocephalus is a potentially reversible cause of dementia, presenting with gait disturbance, incontinence and cognitive decline

Treatment of hydrocephalus

Acute obstructive hydrocephalus is an emergency because of the risk of rapid progression to coma and death, sometimes with very sudden deterioration, a 'hydrocephalic attack'. It may be relieved by addressing the underlying pathology, for example by excision of a tumour responsible for an obstructive hydrocephalus. Most often, however, temporary ventricular drainage is required, either as an emergency in an obtunded or deteriorating patient or as a precaution during definitive surgery considering the possibility for postoperative swelling.

External ventricular drain

External ventricular drains (EVDs) are an effective temporary measure to relieve hydrocephalus. Most commonly they are inserted to the right of midline, anterior to the coronal suture, so that the catheter tip rests adjacent to the foramen of Monro in the lateral ventricle. The catheter is then connected to a drain set such that CSF drains when the ventricular pressure exceeds a threshold typically set at 10–20 mm Hg. Intrathecal antibiotics may also be delivered through the EVD. Lumbar drains are an alternative means of temporary CSF diversion, often used to manage CSF leaks resulting from communicating hydrocephalus.

Ventriculoperitoneal shunts

Ventriculoperitoneal shunting comprises insertion of a ventricular catheter into the frontal or occipital horn of the lateral ventricle, while a distal catheter is tunnelled subcutaneously to the abdomen. Ventriculoatrial and ventriculopleural shunting is also possible, and lumbar-peritoneal shunts may be used in communicating hydrocephalus or IIH. A shunt valve, with an opening pressure that may be high, medium or low, is inserted at the junction of these catheters (**Figure 43.8**). Selection of the shunt valve is a balance and must be tailored to each patient: high pressure valves may fail to allow adequate CSF drainage, whereas low pressure valves can overdrain (see below). An anti-siphon system may be incorporated to prevent excessive drainage in the standing position. Programmable valves offer variable opening pressures, adjusted magnetically using a device applied externally over the valve. The valve system will also typically incorporate a CSF reservoir, which allows for percutaneous sampling.

Figure 43.8 Examples of ventriculoperitoneal shunt valves.

Shunt complications

Overdrainage can result in low-pressure headaches, which are typically worse on standing. Collapse of the ventricles can cause accumulation of fluid or blood in the subdural space, resulting in subdural hygroma or subdural haematoma. The **slit ventricle syndrome** describes the situation in children treated with shunts, whose ventricles and subarachnoid spaces are underdeveloped, resulting in poor brain compliance. In these patients normal fluctuations in ICP are exaggerated so that coughing and straining may cause symptoms of raised ICP. Any shunt blockage may not be evident on scan, as the ventricles fail to enlarge.

Shunts are vulnerable to disconnection, infection and blockage, with the result that 15–20% require replacement within 3 years. Seventy five per cent of infections present

within 1 month, reflecting introduction at the time of insertion. Risk factors include very young patients, open myelomeningocoele, long operation time and staff movement in and out of theatre. The shunt is removed, and external CSF drainage or serial lumbar puncture instituted to cover a course of antibiotic therapy. Once CSF sampling confirms resolution of the infection and a normal protein concentration, a shunt can be inserted at a new site.

The majority of blockages are attributable to cellular and proteinaceous debris, especially due to infection, but choroid plexus adhesion, blood clot or failure of the valve mechanism may also be responsible.

Endoscopic third ventriculostomy

This procedure is especially useful in obstructive hydrocephalus due to aqueduct stenosis. A neuroendoscope is inserted into the frontal horn of the lateral ventricle and then into the third ventricle via the foramen of Monro. The floor of the ventricle is then opened between the mammillary bodies and the pituitary recess. Free drainage between the third ventricle and the adjacent subarachnoid cisterns is then possible, without the infection risk posed by implanted tubing. Reblockage of this route is common, however, and many patients will subsequently require a shunt. Rare but serious complications include damage to the basilar artery, or fornicial damage resulting in permanent memory impairment.

Summary box 43.3

Treating hydrocephalus

- Temporary CSF diversion can be achieved with an EVD
- In the long term a shunt, usually connecting the lateral ventricles with the peritoneal cavity in the abdomen (VP shunt), is the mainstay of management
- Shunt blockage and infection are common complications

INTRACRANIAL INFECTION

Meningitis

Meningitis describes inflammation of the meninges of the brain and spinal cord, most commonly and most seriously due to bacterial infection. The clinical features of meningeal irritation or meningism are fever, headache, neck stiffness and photophobia. Community-acquired bacterial meningitis can progress rapidly without antibiotic treatment to subpial encephalopathy, venous thrombosis, cerebral oedema and death. Meningitis as a complication of head injury or surgery typically follows a more insidious course, but nonetheless remains a feared complication requiring prompt intervention. Typical organisms are *Staphylococcus aureus*, Enterobacteriaceae, *Pseudomonas* and pneumococci.

Meningitis after head injury is common, affecting 25% of patients with base of skull fracture and CSF leak. Repair of the CSF leak may be required, and empirical antibiotics should have activity against commensal nasal organisms including gram-positive cocci and gram-negative bacilli in the presence of symptoms/signs of clinical meningitis.

Summary box 43.4

Meningitis

- A feared complication of neurosurgery and of head injury
- CT head allows exclusion of raised ICP prior to LP
- CSF should be sent for microscopy and culture, and for assay of protein and glucose levels
- Treatment, pending identification of an organism, is with broad-spectrum antibiotics including anaerobic cover

Brain abscess and empyema

Abscesses arise when the brain is exposed directly, for example as a result of fracture or infection of an air sinus, or at surgery. They also result from haematogenous spread, typically in association with respiratory and dental infections, or endocarditis. In 25% of cases, no underlying primary infection is found. The organisms involved are normally bacteria, but immunocompromised hosts in particular are vulnerable to a broad range of pathogens (Box 43.1).

Box 43.1 Common causative organisms.

- Sinus/mastoid infection: aerobic and anaerobic streptococci; bacteroides; enterobacteria; staphylococci; *Pseudomonas*
- Haematogenous spread: bacteroides; streptococci
- Penetrating trauma: *Staphylococcus aureus*; clostridia; bacillus; enterobacteria
- Food contamination: *Toxoplasma*, pork tapeworm (producing neurocysticercosis)
- Immunocompromise (e.g. HIV/AIDS): protozoal (e.g. *Toxoplasma*), fungal (e.g. *Cryptococcus*), viral (e.g. JC virus producing multifocal leukoencephalopathy) and mycobacterial abscesses are encountered

Typical presenting features include low-grade fever, confusion, seizures and focal deficits, often with equivocal blood markers of inflammation; blood cultures should be obtained at an early stage. CT scan with contrast is the initial imaging modality of choice. Hypodense oedematous brain representing early cerebritis is visible in the first few days (**Figure 43.9**). The classic appearances of a smooth-walled, well-defined, ring-enhancing mass develop as the abscess matures (**Figure 43.10**). The distinction between abscess and tumour can be difficult and has important management implications, since abscesses generally require urgent drainage. Diffusion-weighted MRI is a valuable tool in this context (**Figure 43.11**).

Early surgical drainage of abscesses is the mainstay of management, helping to prevent dangerous complications: mortality for these patients is about 4%, but is greater than 80% in the case of ventriculitis due to rupture of an abscess into the ventricles. Intravenous antibiotic therapy is administered, broad spectrum initially and then according to sensitivities of the organisms responsible once identified. Treatment should last at least 6 weeks, but a switch to oral therapy may be appropriate after an interval and in consultation with microbiology. Up to 50% of patients with brain abscess will develop seizures at some stage, therefore prophylactic anticonvulsants should be considered.

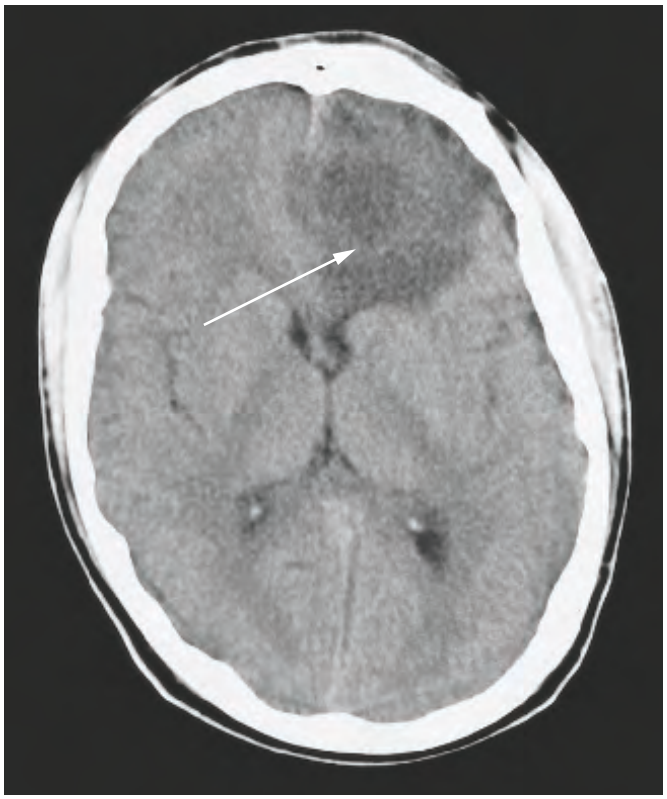

Figure 43.9 Axial computed tomography scan with contrast of a patient with frontal sinusitis presenting with seizures. Early cerebritis is evident in the left frontal region (arrow).

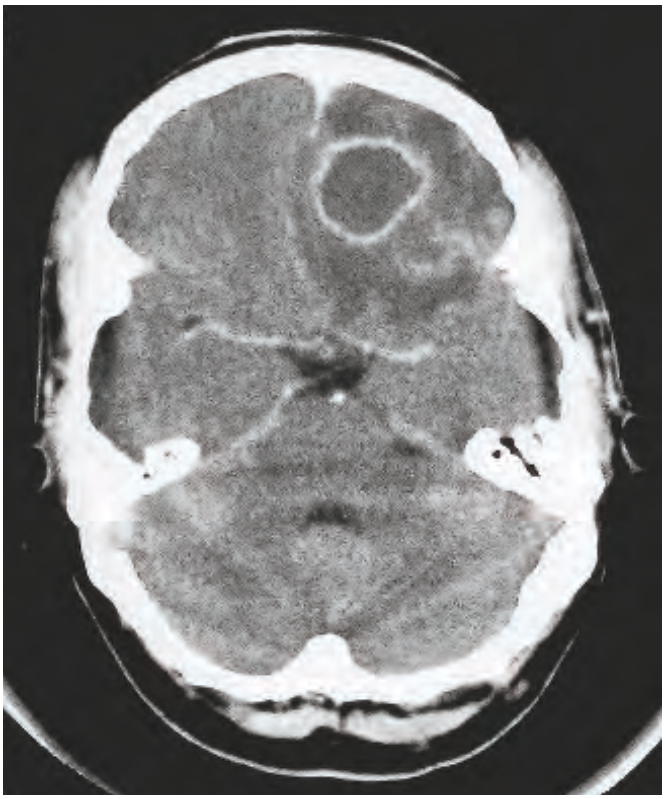

Figure 43.10 Axial computed tomography scan with contrast of the same patient as in Figure 43.9 2 weeks later. A ring-enhancing smooth-walled lesion is evident, an abscess suitable for image-guided drainage.

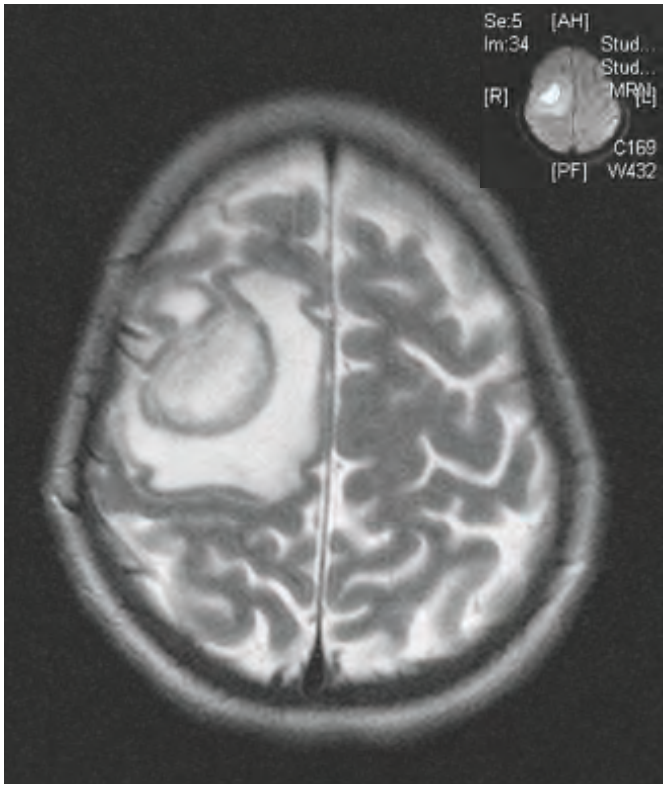

Figure 43.11 The right frontal lesion evident on T2-weighted magnetic resonance imaging (MRI) (main image) exhibits high signal on diffusion-weighted MRI sequences (top right inset) indicative of brain abscess.

Summary box 43.5

Brain abscesses

- Presenting features are those of infection and of intracranial mass lesion
- Imaging reveals a 'ring-enhancing lesion', with tumour usually the main differential
- Early diagnosis, usually followed by drainage, is key for good outcome.

Subdural empyema

Subdural empyema refers to an infective collection in the subdural space. This may develop as a result of sinusitis, mastoiditis or meningitis, and can complicate trauma or surgery. Figure 43.12 shows a subdural empyema associated with osteomyelitis of the frontal bone and associated scalp swelling (Pott's puffy tumour). In empyema, pus will generally collect in the parafalcine region and over the convexity, triggering inflammation and thrombosis in the cortical veins, which helps to explain the high mortality of 8–12%. Presentation mimics that of meningitis and cerebral abscess; typical CT appearances are of hypodense or isodense subdural collection, with contrast enhancement at the margins, and a degree of swelling and midline shift. The empyema may be difficult to visualise especially on non-contrast CT. LP should not be performed given the risk of herniation.

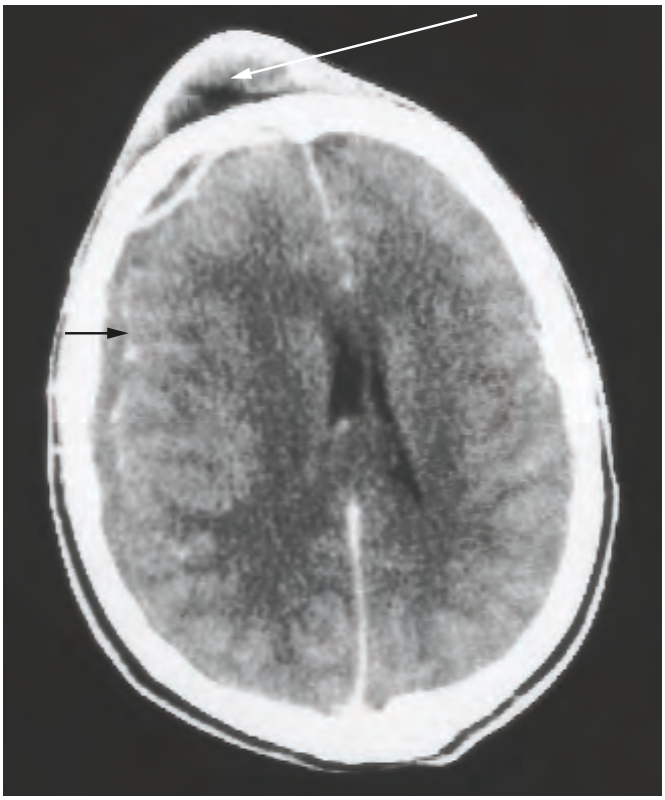

Figure 43.12 Axial computed tomography scan with contrast showing a right hemisphere subdural empyema (short arrow) and a right frontal Pott's puffy tumour (long arrow) (osteomyelitis of the frontal bone).

Craniotomy or craniectomy allows drainage of the collection and relieves raised ICP and is the treatment of choice. Burrhole drainage, and occasionally IV antibiotics without surgical intervention, may also be considered.

Summary box 43.6

Subdural empyema

- Presenting features are similar to those of meningitis or cerebral abscess
- Typically a crescentic collection with a contrast-enhancing rim is evident on CT
- Drainage is the mainstay of treatment

Tuberculosis

Tuberculosis (TB) infection of the central nervous system (CNS) represents haematogenous spread from primary pulmonary foci. A high index of suspicion is required, especially when population or individual risk factors are present. TB can result in a diverse but overlapping spectrum of pathology, including in the head:

- tuberculous meningitis – this commonly affects young children; CT demonstrates intense meningeal enhancement, and hydrocephalus is a common sequela;
- tuberculoma – discrete tumour-like granulomas at the base of the cerebral hemispheres, presenting with mass effect;
- tuberculous abscess – seen predominantly in immunocompromised hosts, this represents progression of a tuberculoma with prominent central caseating necrosis;
- miliary tuberculosis – describes a diffuse distribution of multiple small tuberculomas through brain substance.

Where the meninges are involved, lymphocytes can be expected to predominate in the CSF, rather than the polymorphs seen with other bacterial meningitides. The increase in protein content and reduction in glucose concentration are also less marked. Ziehl–Neesen staining for myobacteria is frequently negative, and polymerase chain reaction testing offers relatively rapid diagnosis compared to culture for acid-fast bacilli which may take weeks. A 20–30 mL CSF sample allows spinning to increase the culture yield. Management is with anti-tuberculous therapy; hydrocephalus may require shunt insertion.

VASCULAR NEUROSURGERY

Subarachnoid haemorrhage

'Spontaneous' subarachnoid haemorrhage (SAH) is usually the result of bleeding from a ruptured aneurysm (~80% of SAH) or an arteriovenous malformation (AVM). Most ruptured aneurysms are located in the circle of Willis, at branch points in the arterial tree associated with turbulent blood flow (**Figure 43.13**). A distinct subgroup of SAH patients suffer bleeds confined to the basal cisterns anterior to the midbrain and pons, without an underlying lesion evident on angiogram. This is termed **perimesencephalic SAH**, is believed to represent venous bleeding and has an excellent prognosis. Aneurysms may also develop as a result of infective infiltration of arterial walls in the context of bacteraemia (mycotic aneurysm), often in the setting of intravenous drug use or infective endocarditis. Pseudoaneurysms may also develop after trauma or after surgery.

Aneurysmal bleeding has an incidence of 10–15 per 100 000 population per year. Risk factors include age, female sex, hypertension, smoking, cocaine abuse and a family history with two first-degree relatives affected. A range of genetic disorders, in particular adult polycystic kidney disease, fibromuscular dysplasia, neurofibromatosis type 1, Ehlers–Danlos and Marfan's syndromes, are known to predispose patients to this condition.

Percival Pott, 1714–1788, surgeon, St Bartholomew's Hospital, London, UK, described the 'Puffy Tumour' in 1760. In 1756 he sustained a broken leg after a fall from his horse. As he lay on the ground, he sent a servant to buy a door which acted as a stretcher. While his surgeons were contemplating amputating his leg, he persuaded them to splint the leg instead as a result of which he recovered completely. Although some think that Pott's fracture of the ankle was described after this injury of his, it is not so. He sustained a compound fracture of the femur. Pott was the first to link an environmental factor to the aetiology of cancer when he demonstrated that chimney sweeps developed squamous cell scrotal cancer.

Thomas Willis, 1621–1675, Sedleian Professor of Natural Philosophy at Oxford, was the first anatomist to number the cranial nerves in the order used today.

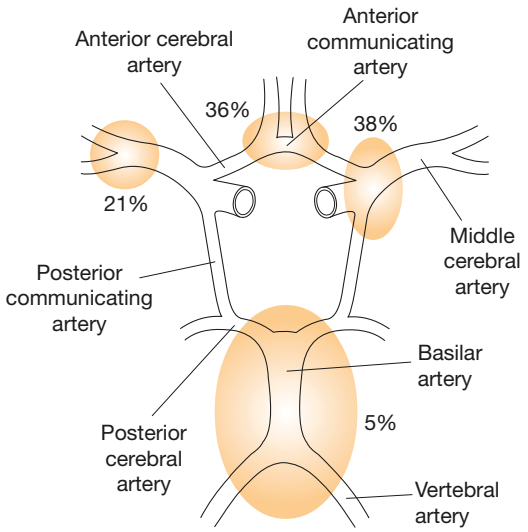

Figure 43.13 Common sites of aneurysm in the circle of Willis.

History and examination

The typical presentation of a SAH includes a 'thunderclap' headache, which is both sudden and severe and is outside the patient's normal experience. Some patients describe prodromal headaches preceding the event, potentially representing aneurysm growth or subclinical bleeds. The sudden onset occurs commonly but not exclusively during exertion, and may be associated with seizure (10%), unresponsiveness (50%) and vomiting (70%). Sometimes it is difficult to establish whether SAH has caused a fall, or whether a fall with head injury is responsible for the SAH. Approximately one-third of SAHs are incorrectly diagnosed at initial presentation. They are then at high risk of succumbing to early complications, especially a rebleed.

Neurological examination may be normal ('good clinical grade') or the patient may have focal deficits and an impaired conscious level ('poor grade'). The World Federation of Neurological Surgeons (WFNS) grading of SAH is measured against the condition of the patient after resuscitation rather than at the time of ictus (*Table 43.2*). A painful third nerve palsy is typically the result of compression from a posterior communicating artery aneurysm. Meningitic features of neck stiffness and photophobia often develop over hours. Intraocular haemorrhages, classically subhyaloid, may be visible on fundoscopy. The combination of SAH and vitreous haemorrhage is known as Terson's Syndrome and occurs in 15–20% of patients. Papilloedema should be sought, but may not be evident early in the course of a developing hydrocephalus.

TABLE 43.2 World Federation of Neurological Surgeons (WFNS) grading of subarachnoid haemorrhage.

Grade	Glasgow Coma Scale	Focal deficits[a]
I	15	–
II	13–14	–
III	13–14	+
IV	7–12	±
V	3–9	±

[a]Focal deficit = dysphasia or limb weakness.

Investigation

CT scan is the imaging of first choice, and, when performed within 12 hours of ictus, will confirm bleeding in more than 98% of cases. This makes a diagnostic LP unnecessary (**Figure 43.14**).

The sensitivity of a CT scan, however, deteriorates to less than 50% at 1 week after a bleed. In light of this, patients with a suggestive history and negative CT scan will require LP, especially where presentation is delayed. The CSF supernatant should be analysed by spectrophotometry (visual inspection is not reliable) for the spectra of haemoglobin breakdown products oxyhaemoglobin and bilirubin. These are clearly detectable in samples taken at least 6 and preferably 12 hours after SAH, but not in CSF mixed with fresh blood due to traumatic puncture, and analysed immediately. Failure to exclude SAH with an appropriate delayed LP may necessitate formal cerebral angiography, and the risks this entails.

Catheter angiography generally involves access to both vertebral and carotid arteries through the femoral artery under local anaesthetic. This allows visualisation of the vascular anatomy by injection of contrast medium with simultaneous screening (**Figures 43.15 and 43.16**). The serious potential risks include ischaemic stroke or arterial dissection (1–2%), and renal failure or allergic reactions attributable to contrast.

Surgical/interventional management

CT angiography has a high sensitivity for aneurysms and AVMs, but digital subtraction angiography remains the gold standard.

Aneurysms demonstrated may be removed from the circulation surgically by craniotomy and 'clipping' or by endovascular embolisation, also known as 'coiling'. Sometimes mesh stents may also be used to help secure the metal coils within the aneurysm sac as part of this procedure. Class 1 evidence suggesting a lower risk of poor outcomes, at least for small anterior circulation aneurysms, has driven the uptake of coiling. However, a surgical approach remains necessary or

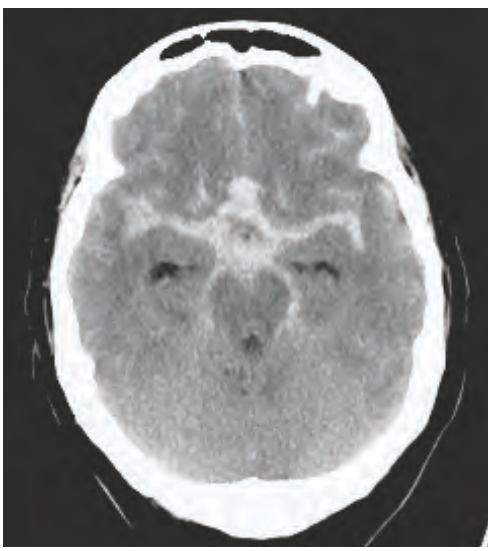

Figure 43.14 Diffuse subarachnoid bleeding from a ruptured anterior communicating artery aneurysm extends to the prepontine and ambient cisterns around the brainstem, and into both Sylvian fissures.

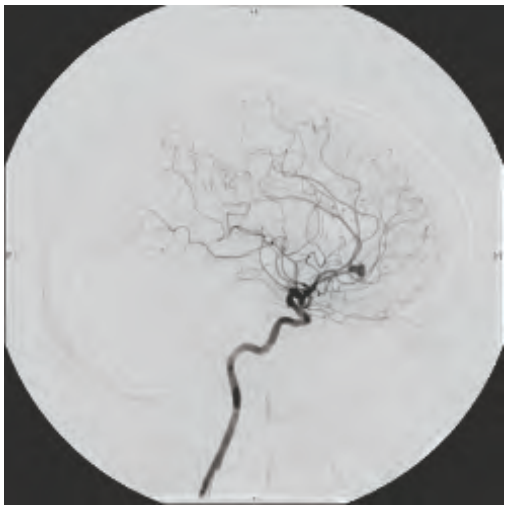

Figure 43.15 There is a small saccular aneurysm of the pericallosal branch of the anterior cerebral artery.

preferable in many cases. A rebleed risk of 4% in the first 24 hours, then 1.5% per day thereafter is quoted for aneurysms, and 80% of patients who rebleed have an eventual poor outcome. For this reason, and to permit optimal management of vasospasm, the current consensus favours early intervention, despite the surgical challenges presented by brain swelling and blood load.

Overall survival of SAH is about 50%, and one-third of survivors remain dependent. Only 50% of WFNS grade 1 patients return to work. Treated aneurysms can regrow and rebleed, especially after coiling, so that a programme of surveillance is necessary.

Unruptured aneurysms represent a thorny management problem: incidentally detected small anterior circulation aneurysms represent a minimal bleeding risk. Screening, even in high risk groups, is therefore of questionable benefit.

Medical management

Patients should be placed on bed rest with hourly neuro observations. They require strict input–output monitoring and intravenous fluid replacement with normal saline initially. Oral nimodipine at a dose of 60 mg every 4 hours reduces the rate of poor outcome (see Vasospasm below). Analgesics, laxatives, anti-emetics, gastric protection and compression stockings are also likely to be necessary. After resuscitation, the priorities in subarachnoid haemorrhage are:

1 to prevent rebleeding by identifying and controlling any underlying lesion;
2 to recognise and manage:
   - neurological complications, especially vasospasm (or delayed ischaemic neurologic deficit) and hydrocephalus;
   - systemic complications, including electrolyte imbalance, severe hypertension, cardiac infarct and arrhythmia, and neurogenic pulmonary oedema.

These goals are best served by early transfer of the patient to a neurosurgical centre. In elderly patients with a poor WFNS grade, a decision to offer only supportive management may be appropriate.

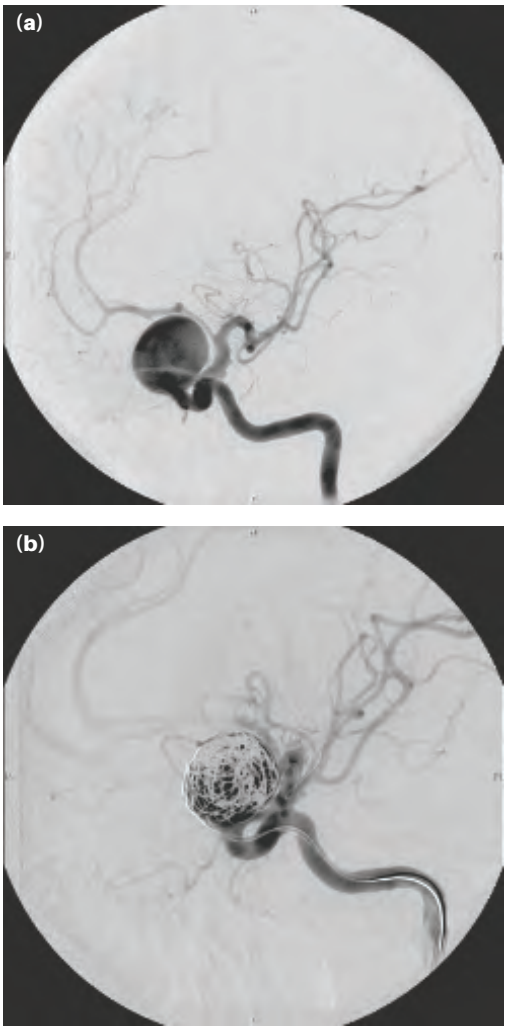

Figure 43.16 **(a)** A giant aneurysm of the internal carotid artery. **(b)** Angiographic embolisation (coiling) of the giant aneurysm. Note the single displaced coil passing into the distal internal carotid artery and then the middle cerebral artery.

Neurological deterioration should prompt a repeat scan to exclude evidence of rebleeding and of hydrocephalus. This is typically the communicating type, which is a common sequela of haemorrhage. Where these complications are not demonstrated, deterioration is often attributable to **delayed ischaemic neurological deficit** (DNID), which commonly develops 3 to 10 days after aneurysmal haemorrhage and can progress rapidly to infarction. The process is attributed to cerebral vasospasm in response to, and correlating with, the blood load. This process can be visualised angiographically, and the velocity of bloodflow in the cerebral vasculature, measured using transcranial Doppler ultrasound, provides an indirect assessment of the degree of stenosis. Outcomes are optimised by the prophylactic administration of nimodipine and maintenance of fluid volume, typically with 2.5–3 litres per day of normal saline. In established vasospasm, the goal is to maintain cerebral perfusion by administration of fluid and inotropes.

Hyponatraemia is a frequent complication of SAH, attributed to cerebral salt wasting in the context of fluid depletion, and otherwise to the syndrome of inappropriate antidiuretic

hormone secretion. This is associated with a higher incidence of DNID, and practical management, irrespective of the underlying pathology, is based on sodium replacement, with hypertonic infusions if necessary. Fluid restriction is not appropriate in these patients since this risks further compromising perfusion.

Summary box 43.7

Subarachnoid haemorrhage

- Most result from rupture of an aneurysm of the circle of Willis
- Plain CT and LP are first line investigations
- Even 'good grade' patients treated promptly have a significant morbidity due to vasospasm, cardiac arrhythmias, neurogenic pulmonary oedema, etc.

Intracerebral haemorrhage

Spontaneous intracerebral haemorrhage accounts for 10–15% of strokes and has a mortality of 40% at 1 year. The majority occur in the context of hypertension or amyloid angiopathy, or as a complication of ischaemic stroke. Coagulation disorders, especially patients being treated with warfarin, are a major risk factor.

Patients typically present with sudden focal deficit and reduced conscious level. Following initial resuscitation, these patients will require CT scan to establish the diagnosis, and the size and position of the bleed (**Figure 43.17**). They require reversal of anticoagulation, ongoing hourly neuro observations and blood pressure monitoring. High blood pressure may be longstanding and associated with adaptations to autoregulation, so attempts at lowering it acutely with intravenous antihypertensives should be made only if the values are very high (e.g. mean arterial pressure >130 mm Hg).

Craniotomy and evacuation may be used to alleviate raised ICP, just as it can be in a subgroup of patients with ischaemic strokes in the posterior fossa or in the middle cerebral artery territory. Importantly, this surgery may be life-saving but cannot reverse focal deficits. Young patients with haematomas close to the cortical surface, demonstrating progressive neurological deterioration, represent good surgical candidates. Posterior fossa clot is also a strong indication for surgery because of the potential for rapid deterioration due to brainstem compression and hydrocephalus. A substantial minority of intracerebral bleeds are attributable to focal vascular lesions (see above). This must be considered when planning any surgery, and may be an indication for acute vascular imaging in discussion with neurovascular specialists. Delayed follow-up imaging is often recommended to exclude underlying tumour as a cause for bleed.

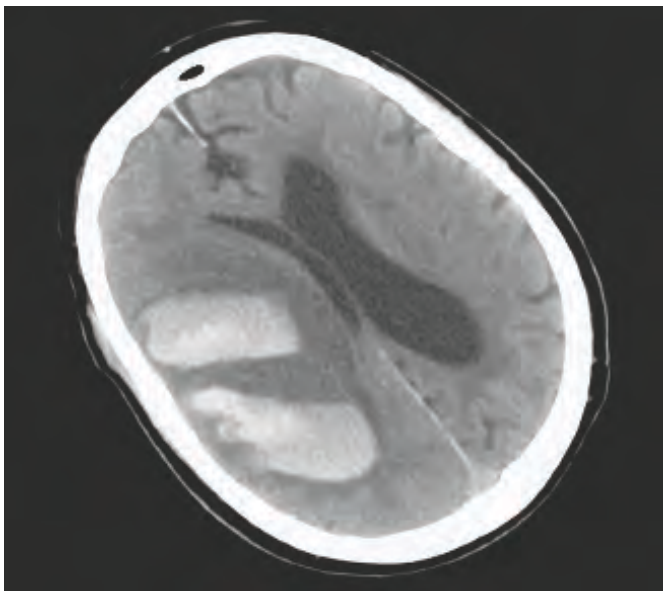

Figure 43.17 Large acute intracerebral haemorrhages in the right frontal and parietal lobes are evident, with surrounding oedema and midline shift.

Summary box 43.8

Intracerebral haemorrhage

- These account for 10–15% of strokes
- Presentation is with headache, focal deficits and signs of raised ICP
- High blood pressure may be chronic so should only be reduced with care
- Anticoagulants should be reversed
- In fit patients, clot evacuation is an option to relieve raised ICP but not reverse deficits
- Further imaging may be required to exclude an underlying vascular or neoplastic lesion

Vascular malformations

Vascular malformations are usually congenital in origin, with certain key exceptions discussed below. They may present with headaches, pulsatile tinnitus, seizures or focal deficit, or else acutely with rupture and haemorrhage.

AVMs are responsible for a small proportion of subarachnoid and intracerebral haemorrhages. Vessels and calcification may be apparent on CT or MRI, and the lesion is confirmed on angiography (**Figure 43.18**)

When AVMs present with bleeding, there is an approximately 4% risk of rebleed per annum. The risk is particularly high in the first 6 weeks and where the bleed is from an aneurysm related to the AVM. Surgery is the generally preferred treatment, but this may not be possible for some lesions which are large, in eloquent brain or with deep venous drainage. Radiosurgery and endovascular embolisation with tissue glue are options here.

Vein of Galen malformations are AVMs feeding into an embryological venous remnant dorsal to the brainstem presenting in childhood. High-flow malformations may cause cardiac failure. They may be treated by embolisation.

Dural arteriovenous fistulae (DAVFs) are shunts between dural arteries and veins or sinuses. They are proposed to arise as a result of vessel remodelling in response to dural sinus thrombosis and subsequent recanalisation. They may present with subarachnoid, intracerebral or subdural bleeding, or with headache and pulsatile tinnitus. A carotid cavernous fistula is a spontaneous or traumatic DAVF between the internal carotid artery and surrounding cavernous sinus, typically

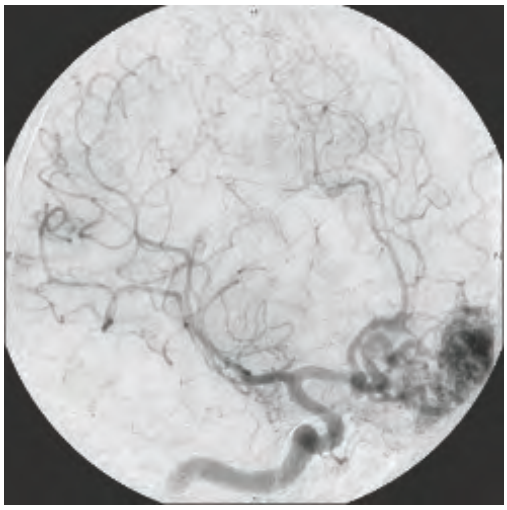

Figure 43.18 An arteriovenous malformation supplied by the anterior cerebral, middle cerebral and middle meningeal arteries is demonstrated at the 4 o'clock position in this angiogram.

producing eye pain, ocular muscle palsies and exophthalmos. Angiography is diagnostic.

Cavernomas (Figure 43.19) are venous anomalies, demonstrated on MRI but not with angiography, which may require operation if they cause progressive deficits, intractable epilepsy or recurrent bleeding.

Related lesions, usually clinically silent, include developmental venous anomalies and capillary telangectasia.

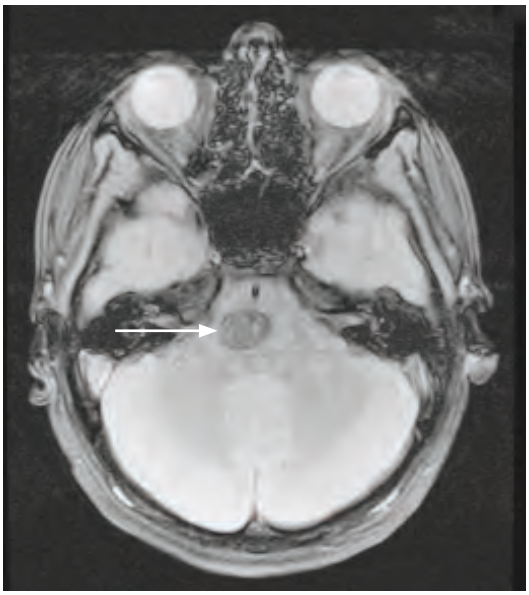

Figure 43.19 A brainstem cavernoma (arrow).

Occlusive vascular disease

In a subgroup of young patients with completed posterior fossa or non-dominant middle cerebral artery territory infarcts, there is a role for decompressive craniectomy in the acute setting to manage the brain swelling and raised ICP associated with the infarct.

There is class 1 evidence for the role of carotid endarterectomy in reducing the risk of stroke in patients with symptomatic carotid stenosis, and a debatable role for the procedure in patients with no previous transient ischaemic episodes.

Moya moya disease describes the progressive obliteration of one or both internal carotid arteries, thought to represent an autoimmune process. The development of external carotid circulation collaterals produces the angiographic 'puff of smoke' appearance responsible for this Japanese-derived name. It presents in youth or early middle age with ischaemia or haemorrhage. Untreated, the majority of patients suffer major deficit or die within 2 years. Ischaemia may be addressed by a variety of bypass techniques, for example by anastomosing the superficial temporal artery (arising from the external carotid) to the middle cerebral artery.

BRAIN TUMOURS

The term 'brain tumour' applies to a wide array of pathologies detailed in the World Health Organisation (WHO) classification. Many are malignant, but even histologically benign tumours may carry a grave prognosis where they encroach on key structures that also limit surgical access. The commonest brain tumour is a metastasis. Primary brain tumours represent 1.5% of all cancers, with an incidence of 19 per 100 000 person years. Nevertheless, many, especially glial tumours, present commonly in younger age groups and are incurable, so they account for disproportionate morbidity and mortality.

Classification

The WHO classifies primary brain tumours on the basis of cell of origin and histological grade. A simplified classification is shown in Figure 43.20.

Common adult primary brain tumours include gliomas, meningiomas (15–20% of total), pituitary adenomas (10–15% of total) and vestibular schwannomas. Grade 1 is applied to 'benign' lesions, while grade 4 implies high-grade malignancy.

Aetiology

The common primary brain tumours mentioned above occur sporadically. There is no proven risk due to environmental factors, except for radiation exposure, but genetic abnormalities may also predispose (*Table 43.3*).

Presentation

Most tumours present with one or more features belonging to three cardinal categories: these are seizure, raised ICP and focal neurological deficit. Pituitary adenomas may also present with endocrine disturbance.

Seizures

Seizures are a common presenting feature, especially of low-grade gliomas arising in the cortical hemispheres. Simple partial seizures, involving focal twitching or similar with preserved consciousness, are the rule, but temporal location will commonly produce complex partial seizures, and any seizure may progress to a secondary generalized tonic-clonic fit.

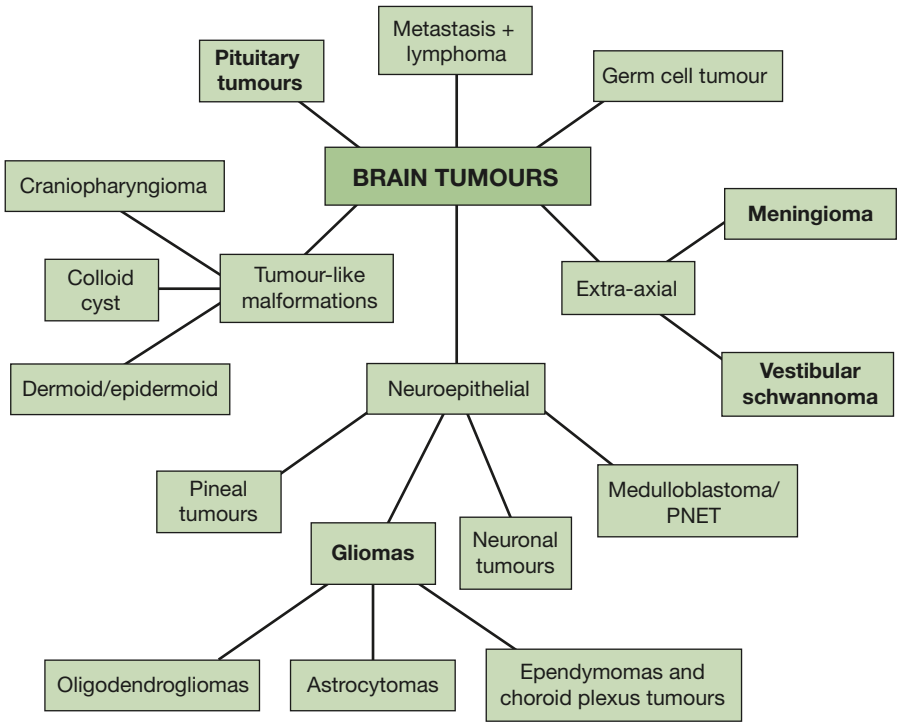

Figure 43.20 Brain tumour classification. A simplified schema encompassing some of the key brain tumour categories. Highlighted in bold are the pathologies discussed in more detail in this chapter.

TABLE 43.3 Chromosomal abnormalities associated with brain tumours.

Syndrome	Gene defect	Tumour
Neurofibromatosis type 1	*Neurofibromin* (Chr 17)	Astrocytomas; neurofibromas
Neurofibromatosis type 2	*Schwannomin* (Chr 22)	Acoustic neuromas (bilateral); meningiomas
Cowden's disease	*PTEN* (Chr 10)	Astrocytomas
Hereditary non-polyposis colorectal cancer	Multiple	Astrocytomas
Li–Fraumeni syndrome	*p53* (Chr 17)	Astrocytomas

Patients who have had a seizure should be started on an antiepileptic drug, usually phenytoin, levetiracetam or carbamazepine. Therapeutic levels of phenytoin can be achieved rapidly with intravenous loading, but its enzyme-inducing effect can complicate the administration of chemotherapy. Routine prophylaxis in patients with tumours who have no history of seizures is not recommended, although a short course at the time of craniotomy for tumour excision may be warranted.

Raised intracranial pressure

Headache is a presenting feature in only about 50% of patients. It is classically worse in the morning and on straining, and accompanied by nausea and vomiting. Pressure effect develops due to tumour mass effect and surrounding oedema, especially in fast growing metastases and high-grade gliomas (see Raised intracranial pressure). Where the differential diagnosis of abscess can be confidently excluded (see Brain abscess), mass effect is controlled initially using high-dose glucocorticoids (e.g. dexamethasone) to reduce swelling. Acute deterioration in this group may represent a developing obstructive hydrocephalus due to compression of CSF drainage pathways (see Hydrocephalus), a neurosurgical emergency.

Focal neurological deficit

A focal deficit progressive over time, as opposed to the sudden onset of a vascular accident, is suspicious of tumour. Lesions generally produce characteristic deficits due to local pressure effect, and reflecting location (*Table 43.4*).

Common brain tumours

Cerebral metastases

Cerebral metastases (**Figure 43.21**) are the most common intracranial tumours, and affect about one quarter of cancer sufferers, a proportion that is increasing with extended survival associated with more effective treatment of primary cancers. The tumours of origin and their contribution to the burden of cerebral metastases is detailed in *Table 43.5*. In general patients with multiple cerebral metastases are not suitable for surgery. Occasionally, diagnostic biopsy may be warranted where the primary is unknown. In patients with good functional status and well controlled systemic disease, craniotomy for resection of a single metastasis, and exceptionally up to three metastases, may be considered.

TABLE 43.4 Patterns of deficit generally associated with certain tumours.

Tumour location	Expected deficit
Pituitary (e.g. pituitary adenoma)	Bitemporal hemianopia; gaze palsies
Cerebellopontine angle (e.g. vestibular schwannoma)	Hearing loss; balance disturbance; tinnitus
Anterior skull base (e.g. olfactory groove meningioma)	Anosmia; ipsilateral optic atrophy; contralateral papilloedema (Foster-Kennedy syndrome)
Occipital (e.g. glioma, metastasis)	Homonymous hemianopia with central sparing
Parietal (dominant hemisphere)	Acalculia; agraphia; left-right disorientation; finger agnosia (Gerstmann syndrome)
Parietal (e.g. glioma)	Sensory inattention; dressing apraxia; astereognosis
Temporal (e.g. glioma)	Memory disturbance; contralateral superior quadrantanopia; dysphasia (dominant hemisphere)
Frontal (e.g. glioma)	Personality change; gait disturbance; urinary incontinence
Brainstem (e.g. brainstem glioma)	Multiple cranial nerve deficits; long tract signs; nystagmus
Posterior fossa (e.g. medulloblastoma)	Ataxia; hydrocephalus

Summary box 43.9

Brain tumours

- Most brain tumours will present with one or more feature related to the following triad:
  - Raised ICP
  - Seizures
  - Focal deficit

Glioma

These are tumours of glial cell origin, with subtypes including astrocytomas, oligodendrogliomas, ependymomas and mixed tumours. The diagnosis is histological, but imaging often predicts both a glial origin and the grade of tumour (Figure 43.22): MRI of the head with and without contrast is the preferred modality, generally combined with CT of the chest/abdomen/pelvis to exclude an extracranial primary, since metastasis is usually the main differential diagnosis. Diffusion-weighted MRI sequences are valuable in excluding another differential diagnosis, brain abscess, which is associated with prominent restricted diffusion in these images.

Initial management of these tumours should generally include high-dose steroids to alleviate any mass effect, combined with a proton pump inhibitor to address the potential steroid side effect of stomach ulcers. Antiepileptics are administered where seizures are a presenting feature, or are likely in

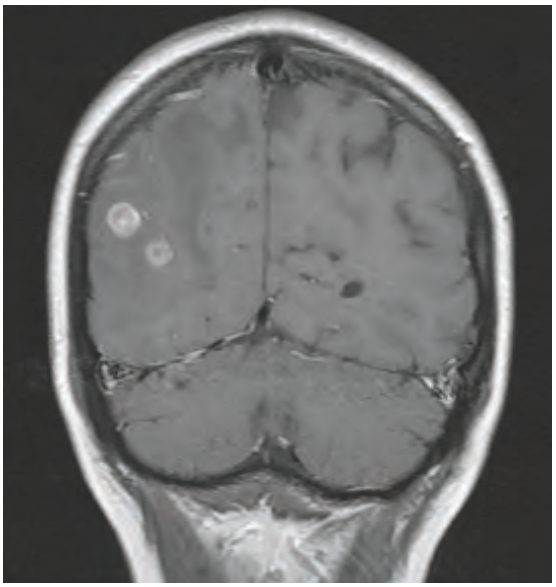

Figure 43.21 T1-weighted magnetic resonance imaging with contrast. Two right occipital lung metastases are demonstrated. They are well demarcated and enhance with gadolinium contrast.

TABLE 43.5 Tissue of origin for brain metastases (approximate).

Origin	Percentage
Lung	40
Breast	15
Melanoma	10
Renal/genitourinary	10
Other/unknown	25

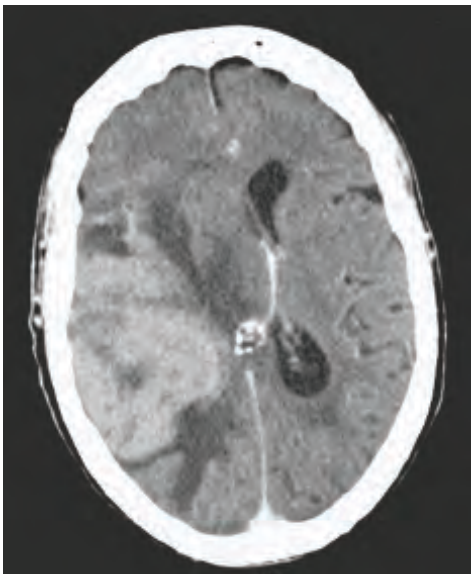

Figure 43.22 Computed tomography with contrast demonstrates a heterogeneous right frontoparietal lesion with mass effect and midline shift, almost certainly a glioblastoma multiforme. A magnetic resonance imaging scan with and without contrast will aid evaluation.

Robert Foster Kennedy, British neurologist, awarded the Chevalier de la Legion d'honneur for his service in French front line field hospitals in World War 1.
Josef Gerstmann, Austrian neurologist who fled to America in 1938 to escape the Nazis.

view of temporal location. Surgical resection is usually the primary treatment, aiming to reduce disease burden and to obtain tissue for diagnosis. Except for the grade I pilocytic astrocytoma, which typically occurs in children, gliomas are notable for their diffuse infiltration into surrounding brain, so that recurrence after even macroscopically complete resection is the rule.

Low-grade gliomas (WHO grade II) have a peak incidence in the fourth decade of life, and commonly present with seizures initially. Where tumours encroach on eloquent cortex, especially the speech areas of the dominant hemisphere, awake craniotomy allows mapping of function with surface electrodes at operation, to limit resection and minimise postoperative deficit. High-grade gliomas include anaplastic astrocytoma (WHO grade III) and glioblastoma (WHO grade IV), the commonest glial tumour (**Figure 43.23**). They typically present *de novo* with peak incidence in the fifth and sixth decades of life, respectively, or they may represent transformation of previously diagnosed, or clinically silent, low-grade gliomas. Active treatment consists of maximal resection, high-dose focused radiation therapy, and chemotherapy administered locally as carmustine wafers at the time of resection and/or systemically with oral temozolomide. Median survival for glioblastoma remains just over 12 months.

Meningioma

Meningiomas are usually benign lesions, although anaplastic variants do occur. They arise from the meninges, and typically present due to mass effect from the tumour, compounded by vasogenic oedema in the adjacent brain and obstructive hydrocephalus where CSF drainage is impaired. Imaging will demonstrate a contrast-enhancing mass distinct from the brain with a dural base (**Figure 43.24**).

These are generally slow-growing lesions. Smaller lesions, perhaps detected incidentally in an elderly patient, may well warrant a 'watch-and-wait' approach. If the lesion is large or positioned so as to impinge on key structures, the patient may require steroids and early surgery. The degree of resection predicts recurrence, with rates of 10% at ten years for total excision with a clear dural margin and 30% at ten years for subtotal excision. Lesions that are difficult to approach surgically may be managed with radiotherapy or stereotactic radiosurgery.

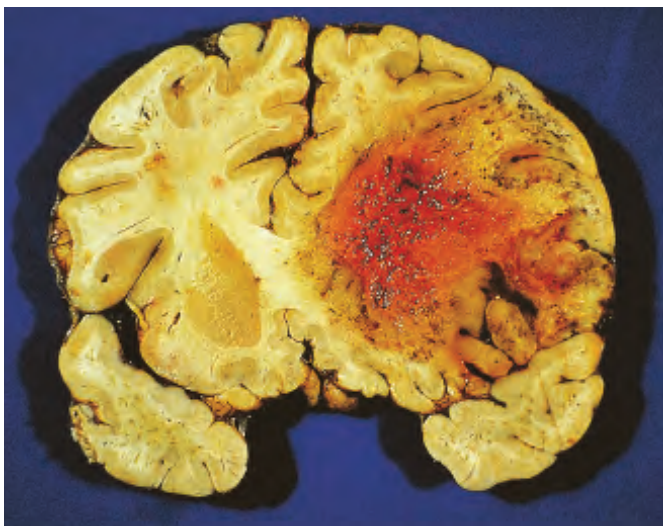

Figure 43.23 Pathological specimen of glioblastoma multiforme.

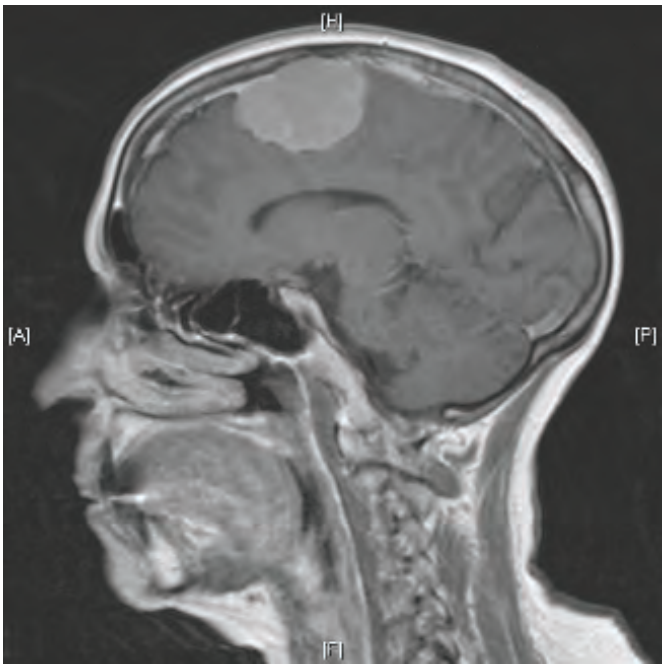

Figure 43.24 On T1-weighted magnetic resonance imaging an extra-axial, durally-based lesion is seen to arise in the region of the falx. This is a meningioma.

Summary box 43.10

Common supratentorial brain tumours

- Metastases and gliomas are common tumours arising within brain substance, appearing as 'ring-enhancing' lesions on contrast CT. Surgery is usually life-extending rather than curative
- Meningiomas arise from the meninges around the brain and typically enhance uniformly on contrast CT. Most are benign and amenable to curative resection
- MRI is usually the best modality for evaluating brain tumours. Diffusion-weighted sequences help to exclude abscess when glioma or metastasis is suspected
- Metastasis is the main differential diagnosis, and CT of the body is useful in identifying extracranial primary tumours
- Steroids with proton-pump inhibitor cover are administered to control swelling and mass effect in the short term

Pituitary tumours

Most tumours in the sellar region are benign pituitary adenomas, but pathology in this region can also include malignant variants, craniopharyngioma, meningioma, aneurysm and Rathke's cleft cyst (**Figure 43.25**).

Microadenomas are less than 10 mm in size and usually present incidentally or with endocrine effects. Macroadenomas are larger than 10 mm, and often present with visual field deficits. Thirty per cent of adenomas are prolactinomas, 20%

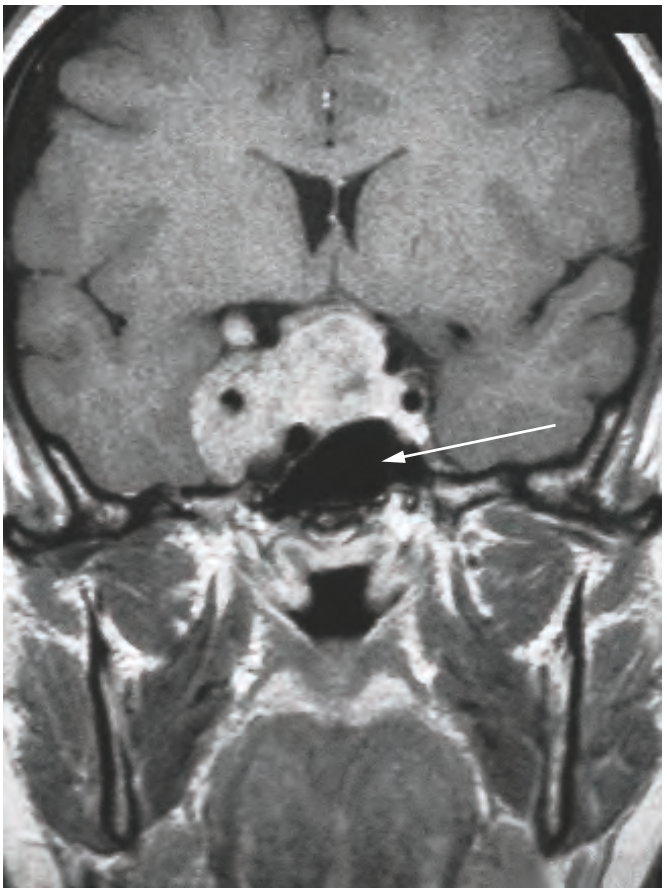

Figure 43.25 Non-functioning pituitary macroadenoma (arrow) compressing the optic chiasm superiorly, extending into the right cavernous sinus and encasing the right carotid artery.

are non-functioning, 15% secrete growth hormone and 10% secrete ACTH.

Features of note in the initial assessment include any history of galactorrhoea (suggestive of prolactinoma), and Cushingoid or acromegalic features pointing to ACTH- or growth hormone-secreting tumours, respectively. Baseline assessment of pituitary function should include serum prolactin, follicle-stimulating hormone and luteinising hormone together with testosterone in males or oestradiol in females, thyroid function tests and fasting serum growth hormone and cortisol. Preoperative prolactin levels are crucial since prolactinomas may be managed without the need for surgery. Prolactinomas are managed initially with dopamine agonists such as bromocryptine and cabergoline. Growth hormone-secreting tumours may also respond to dopamine agonists or to somatostatin analogues such as octreotide. The cortisol level is also important, since deficiency must be corrected, especially in the perioperative period. Diagnosis of ACTH-secreting tumours can be difficult and may require the use of specialised tests such as petrosal sinus sampling and the dexamethasone suppression test.

Effective treatment requires close cooperation between the neurosurgical team and an endocrinologist. Compression of the chiasm with any evidence of visual compromise is the main indication for urgent surgical intervention.

Surgical resection is usually performed by a transsphenoidal approach through the nose, using a microscope or endoscope. Sometimes large tumours also require a craniotomy. After operation patients are at risk of CSF leak (3%), and pituitary insufficiency. Diabetes insipidus resulting from manipulation of the pituitary stalk is common in the immediate postoperative period and usually resolves spontaneously. Where it is suspected, the patient will require hourly measurement of urine output, and blood and urine samples for calculation of sodium concentration and osmolality. If confirmed, the condition can be managed with DDAVP in consultation with endocrinology.

Pituitary apoplexy is the syndrome associated with haemorrhagic infarction of a pituitary tumour. It presents with sudden headache, visual loss and ophthalmoplegia with or without impaired conscious level. Endocrine resuscitation with intravenous steroids is the priority, and surgical decompression may be required.

Vestibular schwannoma

These are nerve sheath tumours arising in the cerebellopontine angle, which present with hearing loss, tinnitus and balance problems. Facial numbness and weakness are less common, while large tumours may present with features of brainstem compression or hydrocephalus. The differential diagnosis includes meningioma, metastasis and epidermoid cyst (**Figure 43.26**).

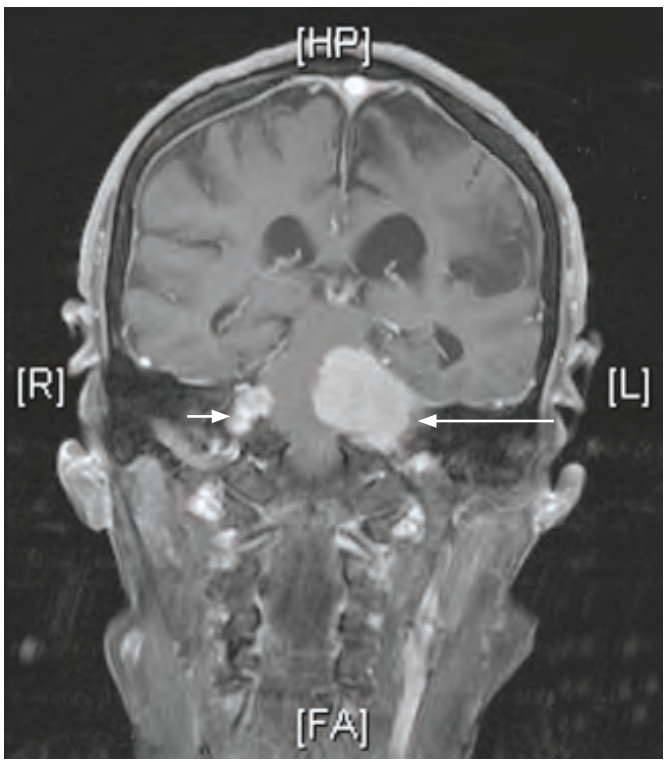

Figure 43.26 The appearances of a meningioma in the left cerebellopontine angle (CPA) (long arrow), with a coexisting vestibular schwannoma in the right CPA (short arrow).

Harvey Williams Cushing, 1869–1939, Professor of Surgery at Harvard University Medical School, credited as the father of modern neurosurgery, and described the eponymous disease, but also pioneered new techniques in bacteriology, blood pressure measurement and electrocautery.

Small intracanalicular tumours (within the internal auditory canal) may be managed with surveillance. For intermediate size tumours, radiosurgery is an alternative to operation. Large lesions (>4 cm), especially with brainstem compression, will require excision and consideration of ventriculoperitoneal shunt to relieve hydrocephalus. Translabyrinthine, retrosigmoid and middle fossa approaches are possible, the latter options offering potential preservation of hearing in smaller tumours with some intact function at presentation. In removing larger tumours, it is often impossible to preserve hearing, or indeed facial nerve function.

Brain tumours in children

Brain tumours are the most common solid tumours in children.

Neonates develop predominantly neuroectodermal tumours in supratentorial locations:

- teratoma;
- primitive neuroectodermal tumour (PNET);
- high-grade astrocytoma;
- choroid plexus papilloma/carcinoma.

Older children tend to suffer infratentorial tumours, especially:

- medulloblastoma (an infratentorial PNET);
- ependymoma;
- pilocytic astrocytoma.

Summary box 43.11

Skull base and paediatric tumours

- Pituitary tumours typically present with endocrinological disturbance (microadenomas) or visual deficits due to compression (macroadenomas). Some of these tumours are managed surgically, in close cooperation with endocrinologists
- Vestibular schwannomas (acoustic neuromas) are benign nerve sheath tumours, usually presenting with hearing loss, tinnitus and balance problems. Their proximity to the brainstem allows them to cause significant morbidity and mortality, and can present a major surgical challenge
- A large variety of mostly neuroectodermal brain tumours represent the most common solid organ tumours in children

PAEDIATRIC NEUROSURGERY

Paediatric neurosurgery presents a wide range range of isolated and syndrome-associated developmental abnormalities including cysts, neural tube defects and posterior fossa malformations. In general these present with combinations of developmental delay, seizures and macrocephaly or hydrocephalus. Early fusion of one or more cranial sutures, craniosynostosis, is also a common neonatal presentation.

Cysts

These benign fluid-filled intracranial lesions typically present incidentally or with mass effect or hydrocephalus. Treatment of symptomatic or enlarging lesions is usually surgical, involving excision, endoscopic fenestration into a cistern or ventricle, or shunting for hydrocephalus. Cyst types include:

- arachnoid cyst: typically middle fossa, CSF enclosed in an envelope of arachnoid mater;
- colloid cyst: occur in the roof of the third ventricle, believed to represent embryonic endoderm remnants;
- dermoid and epidermoid cysts: epithelial lined structures arising from displaced ectodermal remnants, typically in the posterior fossa (midline) and cerebellopontine angle respectively;
- porencephalic cysts: brain cavities lined with gliotic white matter, containing CSF in communication with the ventricles or subarachnoid space.

Neural tube defects

Failure of closure of the neural tube is associated with folate deficiency, family history and some anticonvulsants. Prenatal screening, using serum alphaprotein levels and ultrasound, and diagnostic testing, using amniocentesis, are possible. The spectrum of conditions associated with failed closure of the posterior neuropore includes the conditions described below.

Spina bifida occulta

A congenital absence of a spinous process, without exposure of meninges or neural tissue, but presenting a characteristic shallow hair-covered hollow at the base of the spine. This is common and rarely clinically significant. Sometimes it may be associated with **tethered cord syndrome**, which involves thickening of the filum terminale, resulting in traction on the cord. Presentation is with progressive deficits, spasticity, bladder dysfunction or scoliosis, and treatment involves surgical exploration and untethering of the cord.

Meningocoele

A sac of meninges, covered by skin and containing CSF alone, herniates through an anterior or posterior bony defect.

Myelomeningocoele

A herniating sac of meninges without covering skin contains spinal cord, nerves or both. This is always associated with Chiari II malformation (see below). Open myelomeningocoele presents a high infection risk and requires early surgical repair.

Lipomyelomeningocoele

Adipose tissue adherent to the spinal cord herniates through a bony defect to the sacrolumbar soft tissue. This may be associated with bladder dysfunction and require surgical relief of the resultant cord tethering.

Failure of closure of the anterior neuropore produces anencephaly, which is uniformly fatal; the spectrum of spinal dysraphisms, however, is replicated in the skull. Cranium bifidum is a failure of fusion, often in the occipital region. This may be associated with herniation of meninges and CSF (meningocoele) and, potentially, also brain substance (encephalocoele) (Figure 43.27).

Figure 43.27 An occipital encephalocoele.

Posterior fossa malformations

Chiari malformations involve cerebellar herniation through the foramen magnum:

- Normal: up to 5 mm of cerebellar tonsillar descent through the foramen magnum;
- Chiari I: >5 mm of tonsillar descent: presents typically in young adults with cough headaches and neurological disturbance reflecting brainstem/cerebellar compression and/or formation of a fluid-filled syrinx in the spinal cord as a result of disordered CSF flow. Shunting and foramen magnum decompression are the mainstay of treatment;
- Chiari II: descent of the tonsils and vermis associated with myelomeningocoele and hydrocephalus, so clinically apparent in infancy.

Dandy Walker malformations present in infancy with macrocephaly, developmental delay and hydrocephalus; most patients have associated abnormalities in the CNS and other organ systems. Imaging demonstrates a hypoplastic cerebellar vermis, with the posterior fossa occupied by a large thin-walled cyst. Treatment usually involves shunt placement.

Craniosynostosis

Normal fusion of the coronal, lambdoidal, squamosal and sagittal sutures occurs between 6 and 12 months of age; others such as the frontal suture fuse later. Craniosynostosis is the premature fusion of one (simple craniosynostosis) or more (complex craniosynostosis) cranial sutures, preventing growth perpendicular to the suture. This results in a range of skull deformities (*Table 43.6*; **Figures 43.28 and 43.29**) and hydrocephalus. Syndromic craniosynostosis, often associated with abnormalities of the fibroblast growth factor receptor genes, is accompanied by developmental delay and other abnormalities. The surgical treatment aims to correct deformity and prevent development of raised ICP.

TABLE 43.6 Types of craniosynostosis.

Type	Suture involved	Clinical features
Scaphocephaly	Sagittal suture	Narrow boat-shaped head
Brachycephaly	Coronal suture	Shortened/ broad forehead
Microcephaly	All sutures involved	Small head
Plagiocephaly	Unilateral coronal/ lambdoid suture	Asymmetric skull
Trigonocephaly	Metopic suture	Pointed narrow forehead

Summary box 43.12

Paediatric neurosurgery

Children manifest a range of developmental pathologies requiring neurosurgical management including:

- Cysts
- Neural tube defects
- Posterior fossa abnormalities
- Craniosynostosis
- In general intracranial pathologies present with features including developmental delay, seizures, macrocephaly and hydrocephalus

FUNCTIONAL NEUROSURGERY

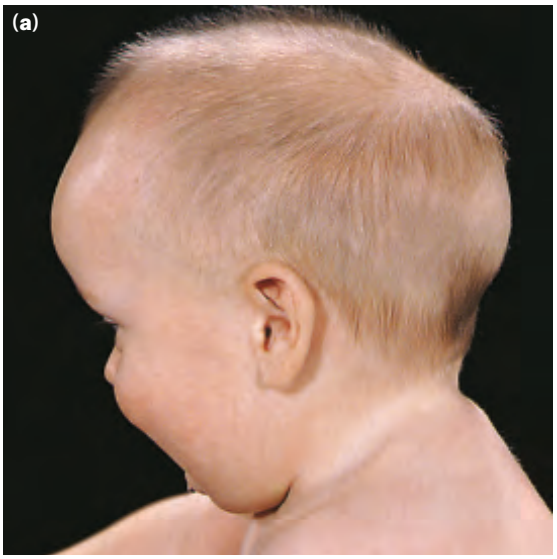
Where most neurosurgery seeks to avoid disruption of neural tissue as far as possible, functional procedures aim to relieve epilepsy, movement disorders or pain by ablation or stimulation of brain tissue and nerves.

Epilepsy

Up to 10% of the population will suffer a seizure at some point in their lives, and epilepsy, a syndrome of recurrent unprovoked seizures, represents the most common neurological disorder. About 20–30% of patients fail to achieve adequate seizure control with drugs, and many of these focal epilepsies may benefit from surgery. Where a primary lesion such as a tumour, AVM or cavernoma is present, lesionectomy alone may be appropriate. In other cases the clinical picture, including seizure type, focal features and investigation results, can be used to identify the seizure focus. Dual pathology refers to the presence of an extrahippocampal lesion plus hippocampal atrophy, important because removal of both the lesion and the atrophic hippocampus will be necessary to achieve seizure control.

Investigation

MRI is a mainstay, demonstrating for example reduced hippocampal volume and distorted architecture in mesial temporal sclerosis. Nuclear medicine modalities including single-photon emmision CT and positron emission tomography are sometimes used to demonstrate ictal and inter-ictal metabolic abnormalities.



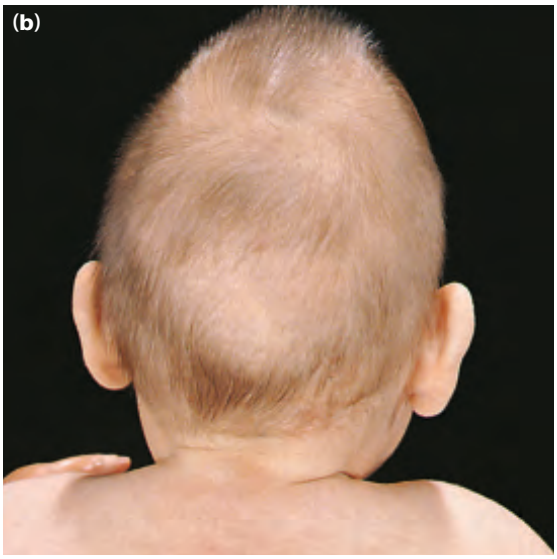


Figure 43.28 (a-c) Characteristic appearance of scaphocephaly due to sagittal suture synostosis.

Electroencephalography entails recording from an array of scalp electrodes, and comparison between ictal and inter-ictal recordings. This is especially helpful in lateralising the focus of complex partial seizures in temporal lobe epilepsy, and is combined with video monitoring of the seizure in a videotelemetry suite. A more detailed localisation may be achieved invasively by the preoperative placement of subdural or depth electrodes or by intraoperative electrocorticography.

Neuropsychological evaluation is used to evaluate the patient's preoperative function looking for concordant focal impairments, and, using the Wada test (Box 43.2), to assess the risk of postoperative language and memory deficits in temporal lobe epilepsy surgery.

Box 43.2

Wada test. Sodium amytal is injected into each internal carotid artery in turn, with simultaneous speech and memory testing to localise function. The aim is to confirm language laterality that resection on the side of the lesion will not significantly impair verbal memory functions.

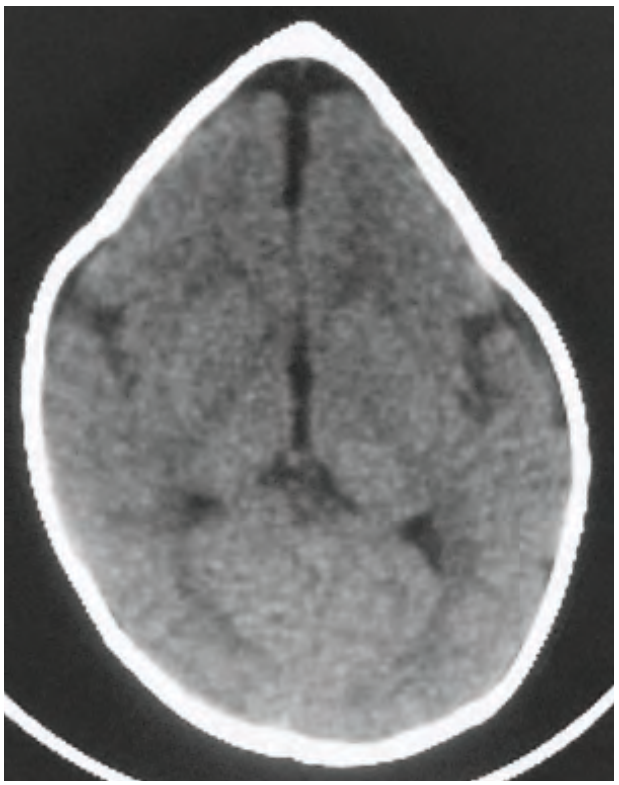

Figure 43.29 Axial computed tomography scan showing severe trigonocephaly due to premature fusion of the metopic suture.

Juhn Atsushi Wada, b.1924 Tokyo, appointed as Professor of Neurology, University of British Columbia, Vancouver, Canada, in 1956. The test is also known as 'intracarotid sodium amobarbitol' procedure.

Surgical management

The seizure focus may be resected, generally where it is in non-eloquent brain, or otherwise a disconnection can be performed. Awake craniotomy, allowing mapping particularly of speech centres, is increasingly employed.

Mesial temporal epilepsy is commonly medically refractory and can be addressed surgically by amygdalohippocampectomy or resection of the temporal lobe including the mesial structures. The extent of resection is limited by the potential for damage to the optic tracts and to speech areas in the dominant hemisphere. With careful patient selection, cure rates of up to 70% or greater can be achieved.

Functional or, rarely, anatomical hemispherectomy (**Figure 43.30**) may be performed for specific epilepsy syndromes associated with hemiplegia, such as infantile hemiplegia syndrome. This is usually considered in the early years of life when plasticity and potential for functional recovery is greatest.

Disconnection procedures include corpus callosotomy, used for patients suffering drop attacks, and subpial transections to isolate a seizure focus in eloquent brain from the surrounding cortex.

Vagal nerve stimulators can be implanted in severe drug refractory epilepsy, with electrodes applied to the vagus nerve in the carotid sheath in the neck. This option can achieve effective seizure control, especially in children, although the mechanism is not clear.

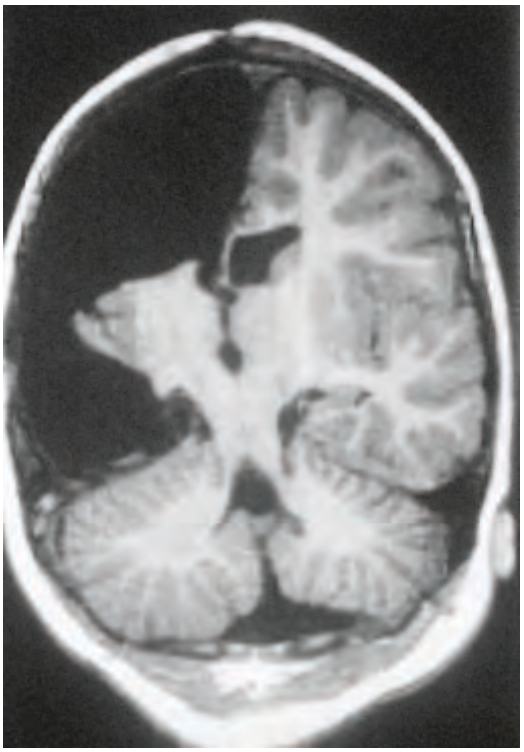

Figure 43.30 Coronal T2-weighted magnetic resonance image following anatomical hemispherectomy.

Movement disorders

Prior to the development of levodopa drug therapy, surgical ablation of the subthalamic nucleus or globus pallidus interna (GPi) was a mainstay of management for Parkinson's. Inhibition of the action of these centres remains a valuable tool later in the course of the disease as the therapeutic window using levodopa narrows, but this is now generally achieved using deep brain stimulation with electrodes. This offers the advantage of an adjustable and reversible effect, and can be performed bilaterally where equivalent lesioning surgery would likely result in deficits.

Deep brain stimulation is also an option for other movement disorders where less invasive approaches are ineffective. These include dystonias, which may be amenable to bilateral GPi stimulation, and essential tremor where the Vim nucleus of the thalamus is the target.

Pain syndromes

Neurosurgical approaches to the relief of pain may address the underlying aetiology directly or may seek to interrupt or modulate the transmission responsible for the pain. The contrasting approaches are demonstrated in the management of trigeminal neuralgia. This manifests, generally in middle age or later, with paroxysmal lancinating pain in the distribution of one or more divisions of the trigeminal nerve. The pain occurs without other neurological disturbance, and may be triggered by trivial stimuli such as eating or brushing the teeth. The pain is often attributable to impingement on the nerve by the superior cerebellar artery or other vessels, as first postulated by Walter Dandy. Occasionally another primary lesion is responsible; for example bilateral trigeminal neuralgia in younger patients is suggestive of multiple sclerosis. Where medications such as gabapentin and carbamazepine cannot achieve control, surgical options include:

- **Craniotomy and microvascular decompression**: this is designed to address the proposed origin of the neuropathic pain, by applying material between the nerve and adjacent vessel to prevent direct contact and stimulation. It achieves long-lasting relief of symptoms in about 80% of patients, but is associated with the standard risks of craniotomy and a significant incidence of cranial nerve deficit.
- **Peripheral nerve injections** can achieve good short-term relief of pain restricted to small areas supplied by terminal branches of the trigeminal.
- **Percutaneous Gasserian rhizolysis**: this involves needle placement under radiological guidance at the Gasserian ganglion in Meckel's cave. This permits lesioning of the ganglion by glycerol injection, radiofrequency thermocoagulation or balloon compression, with the aim of disrupting aberrant pain transmission. A similar effect can also be achieved using stereotactic radiosurgery. Facial numbness and late recurrence of pain are common after these procedures.

James Parkinson, 1755–1824, general practitioner, Shoreditch, London, UK.

Treatment of pain elsewhere may also be based on lesioning of nerve tracts. For example, pain related to brachial plexus infiltration or injury, may be treated by sectioning the spinothalamic tract (cordotomy) or the dorsal root entry zone (DREZ operation). These approaches are limited by the potential for producing deficits, and especially by the occurrence of deafferentation ('phantom limb') pain syndromes, which are particularly unpleasant and difficult to treat.

Electrical stimulation is used to modulate pain transmission: for example spinal cord stimulators can be applied to a range of pain syndromes especially associated failed spinal surgery. Deep brain stimulation targeting the periaqueductal grey and sensory thalamic nuclei has a role in chronic pain arising in the context of thalamic stroke. Implanted devices may also be used for intrathecal delivery of opiates for pain control, or baclofen to alleviate spasticity.

Summary box 43.13

Functional neurosurgery

- Intractable epilepsy can be treated surgically by implantation of a vagal nerve stimulator or by resection of one or more seizure foci
- Deep brain stimulation using implanted electrodes has largely replaced lesioning of these structures for management of drug-refractory Parkinson's disease
- Microvascular decompression is offered for trigeminal neuralgia, and other neuropathic pain syndromes may respond to lesioning of nerve tracts

PRACTICAL AND ETHICAL ISSUES

Creutzfeldt–Jakob disease

Creutzfeldt–Jakob disease (CJD) is a rare transmissible spongiform encephalopathy producing a rapidly progressive dementia, and is uniformly fatal. The causative agent seems to be a misfolded protein, a prion, which is not destroyed by conventional sterilisation techniques. UK practice involves undertaking preoperative checks to exclude any risk factors for CJD infection. These include family history, receipt of pituitary-derived human growth hormone, cadaveric dura mater grafts and previous brain or spinal surgery prior to 1997. Where risk factors are present, instruments must be quarantined or destroyed postoperatively.

Risks of craniotomy

The risks associated with craniotomy are important to appreciate in discussing operations with patients and family, and in evaluating patients who deteriorate postoperatively. Specific risks depend on the anatomy of each approach and the figures quoted in brackets will vary significantly between individual procedures and even between centres:

- infection (5%) and wound breakdown;
- intracerebral haemorrhage;
- seizures;
- CSF leak;
- permanent neurological deficit;
- death (1%).

Brainstem death

This is defined as the irreversible loss of cerebral and brainstem function. Brainstem death is legally equivalent to death, and is a precondition for the harvesting of organs for transplant from heart-beating donors.

Diagnosis requires:

- identification of the cause of irreversible coma;
- exclusion of reversible causes of coma;
- clinical demonstration of the absence of brainstem function.

In the UK, this entails testing twice, by two clinicians, to demonstrate the absence of:

- response to pain;
- respiratory drive (apnoea despite a pCO_2 >6.7 kPa);
- pupillary light reflex;
- corneal reflex;
- vestibulo-ocular reflex;
- oculo-cephalic reflex;
- gag reflex.

Chapter 44

The eye and orbit

Learning objectives

To understand and appreciate:

- The anatomy of the eye and orbit
- The common ocular disorders and their symptoms and specific signs
- The value of special investigations
- When specialist referral is appropriate
- Recent advances in ocular surgery

OCULAR ANATOMY

Adnexae

The lids comprise skin, connective tissue, the orbicularis oculi (cranial nerve VII) and the tarsal plate, with multiple meibomian glands opening posterior to the lashes and lined with conjunctiva, which is reflected onto the sclera. The upper lid is elevated by the levator muscle (cranial nerve III) and has a horizontal strip of sympathetically innervated Müller's muscle, giving rise to 2 mm of ptosis in Horner's syndrome. The frontalis muscle may also contribute to eyelid elevation, particularly when the levator muscle is weak. Both lids are attached to the orbital rim by the medial and lateral canthal tendons. Both have a rich vascular supply and are innervated by the V1 division of the trigeminal nerve (cranial nerve V) above and the V2 division below.

Lacrimal system

The almond-shaped lacrimal gland lies under the upper outer orbital rim and opens into the upper conjunctival fornix through 10–15 ducts. Tears are swept across the globe by the lids and evaporate or pass into the upper and lower lid puncta, and then into the canaliculi to join the common canaliculus, which passes into the lacrimal sac under the medial canthal tendon. The sac is drained by the nasolacrimal duct into the nose, opening in the inferior meatus under the inferior turbinate.

The globe

The cornea is the 12 mm-diameter window of the eye, 550 micrometres thick centrally on average; its clarity is due to the regular arrangement of collagen bundles and relative dehydration. It merges into the sclera at the corneoscleral junction (the limbus), the insertion of the bulbar conjunctiva. The sclera, which is 1 mm thick, comprises four-fifths of the wall of the eye, and gives attachment to the extraocular muscles (Figure 44.1). It is perforated by the long and short posterior ciliary arteries and the vortex veins and is contiguous with the optic nerve sheath. The uvea comprises iris,

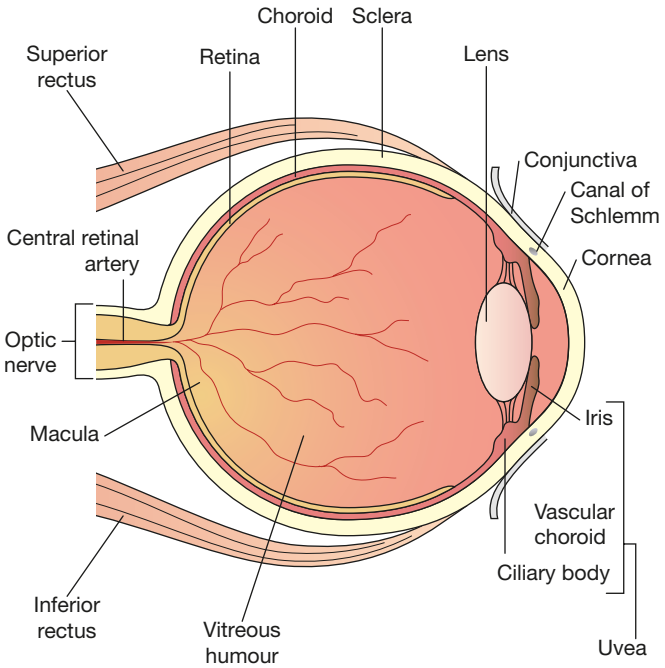

Figure 44.1 Anatomy of the eye.

Johannes Peter Müller, 1801–1858, Professor of Anatomy and Physiology, Berlin, Germany.
Johan Friedrich Horner, 1831–1886, Professor of Ophthalmology, Zurich, Switzerland, described this syndrome in 1869.

ciliary body and vascular choroid. Photoreceptor cells in the outer retina sense light and send impulses to retinal ganglion cells in the inner retina via bipolar cells. The retinal pigment epithelium underlies the photoreceptors and is responsible for reprocessing of photopigments. The optic nerve conveys the axons of retinal ganglion cells from the eye to the brain. The most high-resolution part of the retina, the macula, lies at the posterior pole within the vascular arcade. The biconvex lens and capsule are suspended by the lens zonules, over 300 tiny fibres attached to the ciliary muscle. Aqueous humour arises from the ciliary processes, hydrates the vitreous gel, passes through the pupil into the anterior chamber between the iris and the cornea and then drains out through the trabecular meshwork into Schlemm's canal in the drainage angle and from there to the episcleral venous circulation. The balance between production and drainage of aqueous humour determines the intraocular pressure, which in most normal eyes is regulated at a level of 10–21 mmHg. The inner retina is supplied by the central retinal artery and drained by the central retinal vein.

Orbit

The orbit is four-sided and pyramidal in structure, housing the globe, optic nerve, the four rectus and two oblique muscles, the lacrimal gland, orbital fat, the cranial nerves III, IV, V and VI, the ophthalmic artery with its tributaries and the ophthalmic veins, which anastamose anteriorly with the face and posteriorly with the cranial cavity. Above is the frontal lobe of the brain, temporally the temporal fossa, inferiorly the maxillary sinus and nasally the lacrimal sac and ethmoidal and sphenoidal air sinuses. The optic nerve passes through the optic canal to the chiasm, with other nerves and vessels passing through the superior ophthalmic fissure.

PERIORBITAL AND ORBITAL SWELLINGS

Swellings related to the supraorbital margin

Dermoid cysts

Dermoid cysts are benign congenital choristomas of the orbit that originate from fetal bone suture lines during development, most commonly the frontozygomatic suture (**Figure 44.2**) although they may also occur more medially. Dermoid cysts account for about half of childhood orbital neoplasms and consist of keratinised epithelium and adnexal structures such as sweat glands and hair follicles. They often cause a bony depression and they may have a dumbbell extension into the orbit, which is of particular importance should they need to be excised. Dermoid cysts can also erode the orbital plate of the frontal bone to become attached to dura and for this reason it is important to image the area by computed tomography (CT) before excision.

Figure 44.2 External angular dermoid.

Neurofibromatosis

Neurofibromatosis may also produce swellings above the eye. The diagnosis can usually be confirmed by an examination of the whole body, as there are often multiple lesions. Proptosis can also result (**Figure 44.3**). Other ophthalmic features may be present.

Figure 44.3 Neurofibroma in the orbit with proptosis, and also similar lesions in the forehead.

Swellings of the lids

Meibomian cysts (chalazion)

These are the most common lid swellings (**Figure 44.4**). A meibomian cyst is a chronic granulomatous inflammation of a meibomian gland. It may occur on either upper or lower lids and presents as a smooth, painless swelling. It can be felt by rolling the cyst on the tarsal plate. It can be distinguished

Friedrich Schlemm, 1795–1858, Professor of Anatomy, Berlin, Germany.
Heinrich Meibom (Meibomius), 1638–1700, Professor of Medicine, History and Poetry, Helmstadt, Germany, described these glands in 1666.

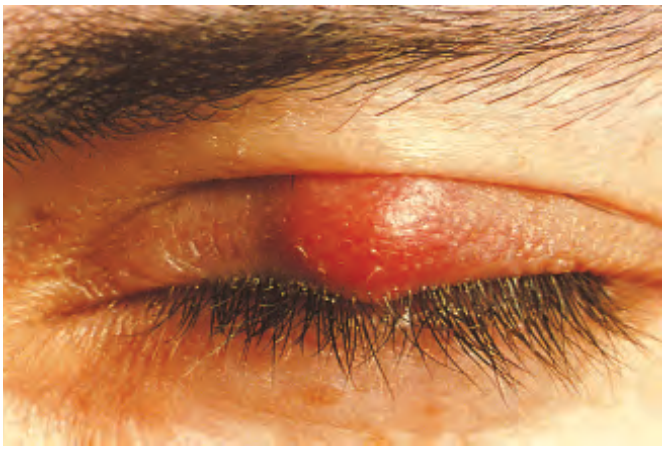

Figure 44.4 Meibomian cyst (courtesy of Mr D Spalton, FRCS).

from a stye (hordeolum), which is an infection of a hair follicle and is usually painful. Persistent meibomian cysts that do not resolve with conservative treatment (hot compresses) are treated by incision and curettage from the conjunctival surface. Styes are treated by antibiotics and local heat.

Basal cell carcinoma (rodent ulcer)

This is the most common malignant tumour of the eyelids (Figure 44.5). Basal cell carcinomas may be locally invasive but do not tend to metastasise. They are more common on the lower lids, often start as a small pimple that ulcerates and has raised edges ('rodent ulcer') and are usually easily excised in the early stages. Histological confirmation that the excision is complete is required. More extensive lesions may require specialist techniques such as Mohs' micrographic surgical excision controlled by frozen section. Local radiotherapy or cryotherapy can be carried out; however, recurrence is more common, more aggressive and more difficult to detect.

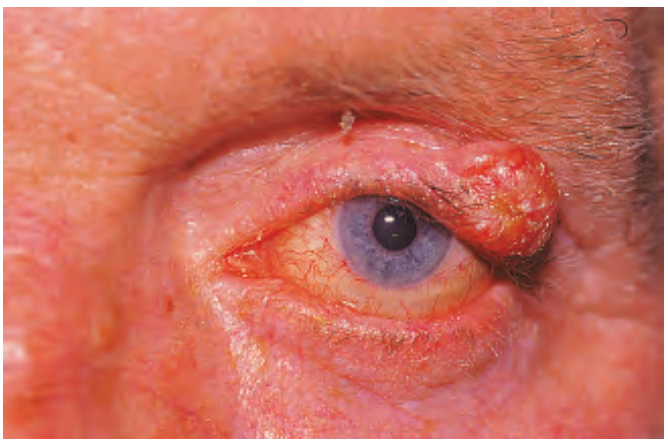

Figure 44.5 Rodent ulcers (courtesy of Mr J Beare, FRCS).

Summary box 44.1

Basal cell carcinomas

- Basal cell carcinomas are the most common malignant eyelid tumour
- Treatment is by wide local excision with careful histopathological margin control
- All unusual eyelid lesions (especially in the elderly) should be biopsied

Other lid swellings

Other types of lid swelling are less common. They include squamous cell carcinoma and malignant melanoma, sebaceous cyst, papilloma, keratoacanthoma, cyst of Moll (sweat glands) (Figure 44.6) or Zeis (sebaceous glands) and molluscum contagiosum. When molluscum contagiosum occurs on the lid margin, it can give rise to a mild viral chronic keratoconjunctivitis and should be curetted or excised.

Carcinoma of the meibomian glands and rhabdomyosarcomas are rare lesions; they need to be treated by radical excision. Atypical or meibomian cysts that recur should be biopsied to exclude sebaceous gland carcinoma.

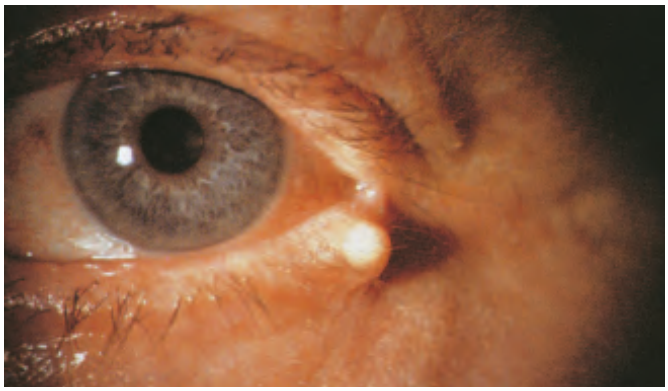

Figure 44.6 Cyst of Moll.

Swellings of the lacrimal system

Lacrimal sac mucocoele

This occurs from obstruction of the lacrimal duct beyond the sac and results in a fluctuant swelling that bulges out just below the medial canthus. It can become infected to give rise to a painful tense swelling (acute dacryocystitis). If untreated, it may give rise to a fistula. Treatment is by performing a bypass operation between the lacrimal sac and the nose (a dacryocystorrhinostomy). Watering of the eye can also occur due to eversion of the lower lid (ectropion), which causes loss of contact between the lower punctum and the tear film, or

Frederic E. Mohs, 1910–2002, developed the technique of micrographic surgical excision while a medical student at University of Wisconsin, USA.
Jacob Antonius Moll, 1832–1913, ophthalmologist of The Hague, The Netherlands.
Edward Zeis, 1807–1868, Professor of Surgery, Marburg, (1844–1850), who later worked at Dresden, Germany, described these glands in 1835.

from reflex hypersecretion as a result of irritation, for example by inturning lashes in entropion, and these must be distinguished from a mucocoele.

Lacrimal gland tumours

These are swellings of the lacrimal glands, which lie in the upper lateral aspect of the orbit. Eventually they lead to impairment of ocular movements and displacement of the globe forwards, downwards and inwards. Pathologically the tumours resemble parotid tumours and they can be pleomorphic adenomas with or without malignant change, carcinomas or mucoepidermoid tumours.

Orbital swellings

Orbital swellings result in displacement of the globe and limitation of movement. A full description of orbital swellings is outside the realm of this text, but some of the most common causes include the following:

- **Pseudoproptosis**. This results from a large eyeball, as seen in congenital glaucoma or high myopia.
- **Orbital inflammatory conditions** that result in orbital cellulitis (**Figure 44.7**).
- **Haemorrhage** after trauma or retrobulbar injection.
- **Neoplasia** affecting the lacrimal gland, the optic nerve, the orbital walls or the nasal sinuses (e.g. glioma [neurofibromatosis, **Figure 44.3**], meningioma and osteoma (**Figure 44.8**).
- **Thyroid eye disease** (**Figures 44.9–44.11**). This is the most common cause of unilateral and bilateral proptosis in adults and may occur in the absence of active thyroid disease or after thyroidectomy. Management of severe thyroid eye disease may require large doses of systemic steroids, radiotherapy or even orbital lateral wall decompression if the eyeball is threatened by exposure or optic nerve compression. The disease is often more severe in smokers and those with poorly controlled thyroid function. CT

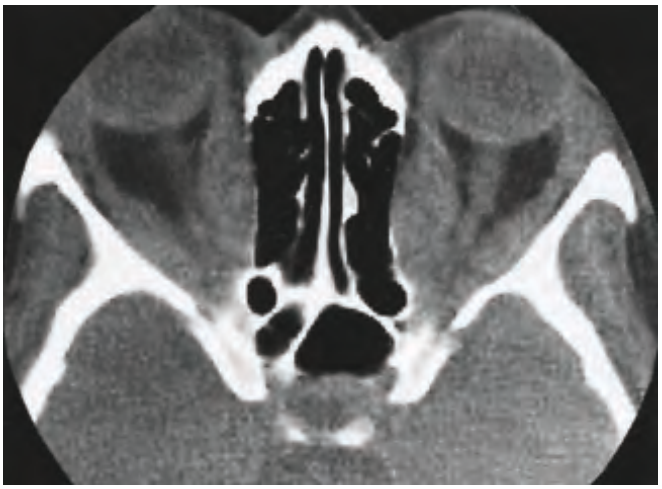

Figure 44.9 Computed tomogram of the orbit in dysthyroid exophthalmos, showing swollen muscles (courtesy of Dr Glyn Lloyd).

Figure 44.7 Orbital cellulitis.

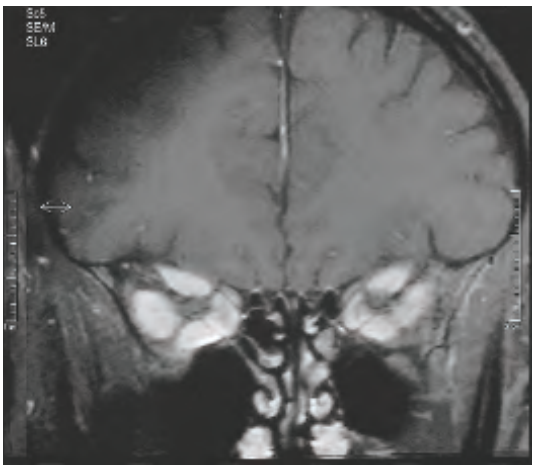

Figure 44.10 Magnetic resonance imaging scan of a coronal view of the orbit, showing enlarged muscles in thyroid disease (courtesy of Dr Juliette Britton).

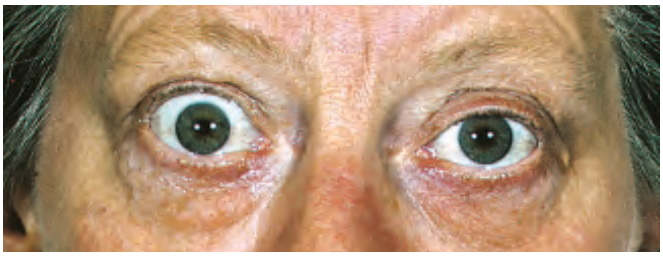

Figure 44.11 Exophthalmos in dysthyroid eye disease.

and magnetic resonance imaging (MRI) scans are useful in diagnosis. MRI with STIR sequences is particularly useful for identification of active inflammation within the orbital tissues.

- **Pseudotumour**, or malignant lymphoma.
- **Haemangiomas** of the orbit (Figure 44.12).
- **Tumour metastases**. These are rare. In children they usually arise from neuroblastomas of the adrenal gland, whereas in adults the oesophagus, stomach, breast and prostate can be sites of primary lesions.

Diagnostic aids

Diagnostic aids include radiography, CT, MRI, ultrasonography and, less commonly, tomography and orbital venography.

Treatment

Treatment is directed to the cause of the lesion taking care to prevent exposure of the eye, diplopia or visual impairment from optic nerve compression.

INTRAOCULAR TUMOURS

Children

Retinoblastoma, the most common ocular malignancy of childhood, is a malignant tumour of the retina that can be bilateral in around one-third of cases. Half of cases are hereditary (autosomal dominant) due to mutation of the RB1 gene on chromosome 13 and children with a family history should be carefully monitored from birth. Remaining cases occur sporadically. Inherited retinoblastoma is more likely to be bilateral. Retinoblastoma is often not spotted until the tumour fills the globe and presents as a white reflex in the pupil or as a squint (Figure 44.13). The differential diagnosis includes retinopathy of prematurity, primary hyperplastic vitreous and intraocular infections. If the tumour is large, enucleation may be required, but radiotherapy, cryotherapy, chemotherapy or laser treatment can cure small lesions. Liaison with a paediatric oncologist is essential.

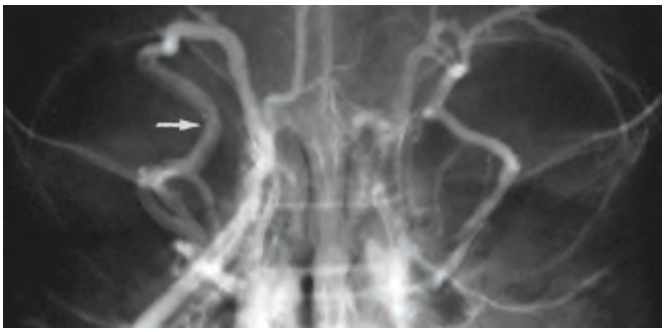

Figure 44.12 Capillary haemangioma in a child. An orbital venogram demonstrates displacement of the second part of the superior ophthalmic vein (arrow) (courtesy of Dr Glyn Lloyd).

Figure 44.13 Retinoblastoma giving rise to a white pupillary reflex. This child was first seen with a convergent squint and discharged without a fundus examination. He was next seen many years later with a 'white reflex' and died soon after diagnosis (courtesy of MA Bedford, FRCS).

Summary box 44.2

Intraocular tumours

- Any child with a white pupil (leukokoria) should be referred to an ophthalmologist to exclude retinoblastoma, although congenital cataracts may also cause this sign
- A blind painful eye may hide a melanoma or other ocular tumour

Adults

Malignant melanoma is the most common primary malignant tumour of the eye and originates in the pigmented cells of the choroid (Figure 44.14), ciliary body or iris. It can present with a reduction in vision, a vitreous haemorrhage or by the chance finding of an elevated pigmented lesion in the eye. Tumour growth is variable but, as a general rule, the more posterior the lesion, the more rapidly progressive it is likely to be. Spread may be delayed for many years; however, the liver is frequently involved, hence the advice 'beware of the patient with a glass eye and an enlarged liver'. Treatment options vary by size and location of the tumour but include laser photocoagulation, radioactive plaque, radiotherapy/proton beam therapy, enucleation and, in selected cases, local excision. Diagnosis is made by direct observation and/or ultrasound, which shows a solid tumour, often with low internal reflectivity on ultrasound (Figure 44.15).

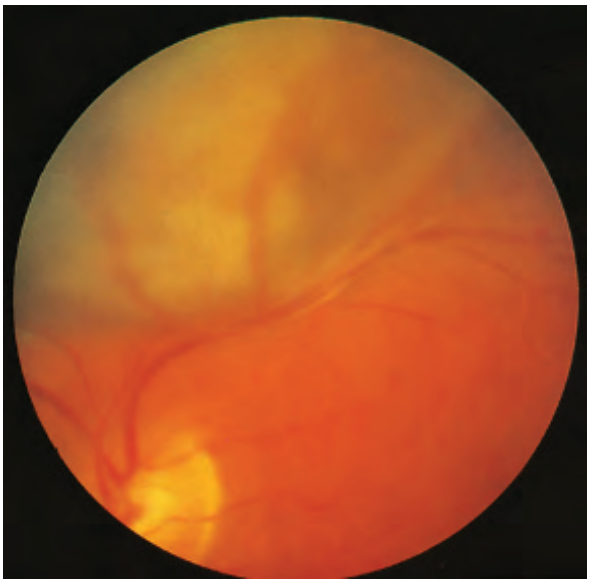

Figure 44.14 Choroidal melanoma.

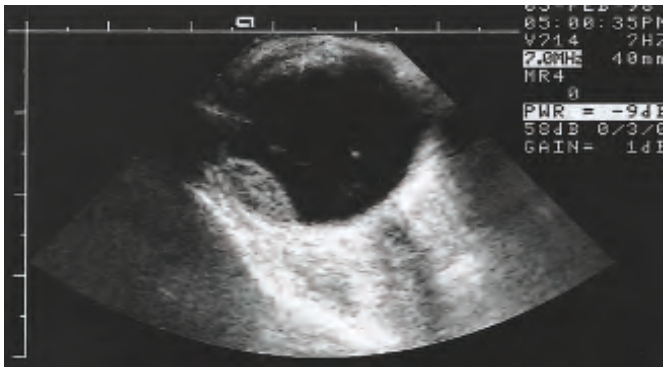

Figure 44.15 B-scan showing choroidal melanoma (courtesy of Dr Marie Reston).

INJURIES INVOLVING THE EYE AND ADJACENT STRUCTURES

Corneal abrasions and ulceration

The cornea is frequently damaged by direct trauma or by foreign bodies (Figure 44.16). Ulceration can occur with infection, exposure (for example in severely ill patients with incomplete eye closure) or after damage to the facial nerve. Post-herpetic ulceration is common and serious if not treated. Fluorescein instillation illuminated by blue light shows up corneal ulceration at an early stage, with areas of epithelial loss fluorescing green.

Treatment of sterile corneal abrasions or exposure is by topical lubrication or padding of the eye. If bacterial infection is suspected, a swab or scrape may be performed for microbiological diagnosis and topical antibiotics such as 0.5% chloramphenicol or ofloxacin eye drops are commonly used. The eye is made more comfortable by the use of mydriatics such as cyclopentolate to reduce photophobia. Herpes simplex dendrititc ulcers are treated with aciclovir ointment.

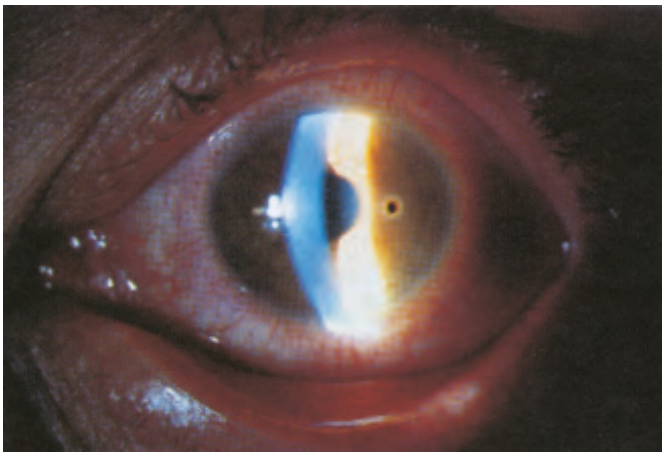

Figure 44.16 Corneal foreign body.

In countries in the Far and Middle East, chronic infection with trachoma can cause corneal opacification and blindness, although the worldwide incidence of this condition is falling. Corneal grafting is the only cure for an opaque cornea. Until recently, full-thickness penetrating keratoplasty was the only corneal graft technique. For some conditions this has largely been replaced by lamellar or partial-thickness graft surgery, in a technique termed DSEK or 'Descamets stripping endothelial keratoplasty'. However, penetrating keratoplasy remains the treatment of choice for severe corneal damage due to infection or injury. Rarely, osteo-odonto keratoprosthesis can be attempted in very severe cases of opaque corneas that are not suitable for grafting. Artifical corneal prostheses have also been developed. Acanthamoeba is a rare serious cause of corneal infection. This infection usually follows the use of contact lenses. Specialist management and treatment is recommended.

Summary box 44.3

Corneal abrasions

- A drop of fluorescein dye illuminated by a blue light reveals even the smallest corneal abrasion
- Corneal ulcers are often more serious in contact lens wearers and require prompt assessment and treatment
- Development of white infiltate in/around a corneal abrasion is a sign of infection

Blunt injuries to the eye and orbit

The floor of the orbit is its weakest wall and in blunt trauma, such as a blow from a fist, it is often fractured without fractures of the other walls. This is called a blow-out fracture. Clinical signs are enophthalmos, bruising around the orbit, maxillary hypoaesthesia, limitation of upward gaze due to entrapment of the inferior rectus muscle leading to vertical diplopia. This occurs when the extraocular muscles or orbital septa become trapped in the fracture and can be identified as a soft-tissue mass in the antrum on a radiograph (Figure 44.17), although CT scans or tomograms may be necessary.

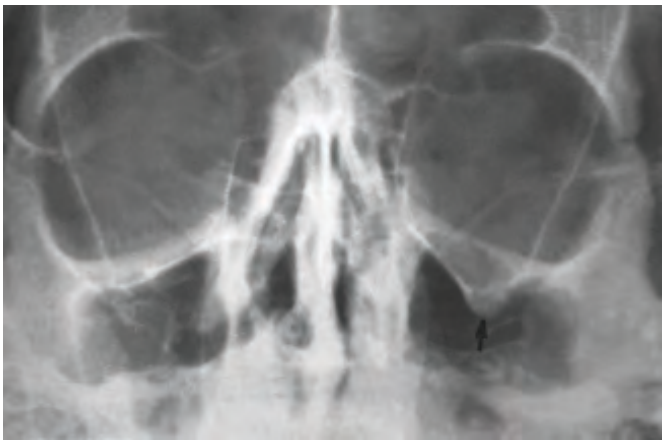

Figure 44.17 Radiograph showing a blow-out fracture of the orbit (left) with soft tissue in the antrum (courtesy of Dr Glyn Lloyd).

Surgical repair of the orbital floor with freeing of the trapped contents may be necessary if troublesome diplopia persists or enophthalmos is marked. A child with an orbital floor fracture requires urgent assessment, particularly if upgaze is restricted, as trapping of the inferior rectus muscle may cause ischaemia and require urgent surgery. If an orbital haemorrhage is too extensive to examine the eye, it may be necessary to examine the eye under anaesthesia because there may be a hidden perforation of the globe. Injuries to the lids and lid margins must be repaired, and if the lacrimal canaliculi are damaged, they should be repaired if possible, especially the lower canaliculus, as 75% of tear drainage goes through it.

Blunt injuries can also cause damage to the optic nerve, which can result in blindness and a total afferent nerve defect (**Figures 44.18 and 44.19**).

Blunt ocular injuries

Blunt injuries to the eye can give rise to several problems, which include the following:

- **Iritis**. Inflammation; treated with topical steroids.
- **Hyphaema** (blood in the anterior chamber) (**Figure 44.20**). Rest and sedation, particularly in children, are advised because the main danger in this condition is secondary bleeding, resulting in an acute rise in intraocular pressure and blood staining of the cornea. The use of anti-fibrinolytic agents (ε-aminocaproic acid) has been advocated and, if the pressure rises, surgery to wash out the blood may be necessary.
- **Subluxation of the lens**. This is suspected if the iris, or part of the iris, 'wobbles' on movement (iridodonesis).
- **Secondary glaucoma**. This is often associated with recession of the iridocorneal drainage angle.
- **Retinal and macular haemorrhages and choroidal tears** (**Figure 44.21**).
- **Retinal dialysis**. This may lead to a retinal detachment and permanent damage to vision (**Figure 44.22**).

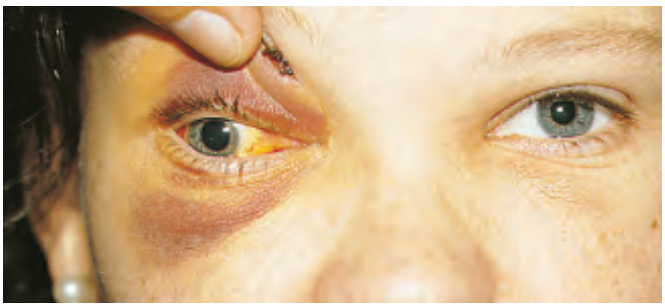

Figure 44.18 Injury from a ski pole into the right brow. Vision reduced to 'no perception of light' (courtesy of J Beare, FRCS).

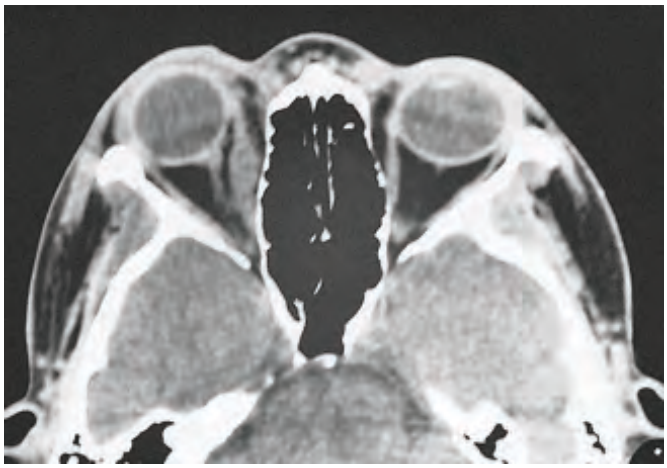

Figure 44.19 Scan of orbit from Figure 44.18 showing a massive swelling of the medial rectus (courtesy of J Beare, FRCS).

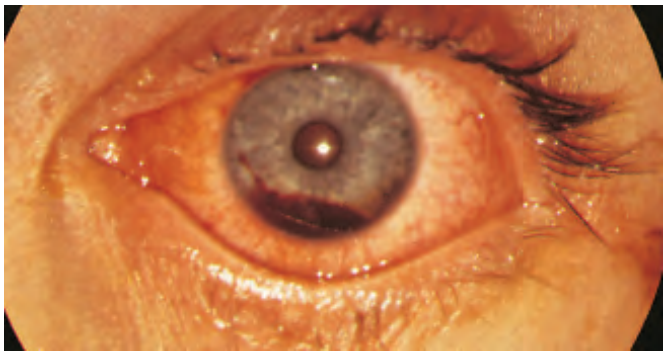

Figure 44.20 Hyphaema. Blood in the vitreous chamber after a concussional injury.

Penetrating eye injuries

These occur when the globe is penetrated, often in road traffic and other major accidents (**Figure 44.23**), and also in injuries from sharp instruments. The compulsory wearing of seat belts in motor vehicles has substantially reduced the incidence of this type of eye injury, by up to 73% in the UK. The presence of an irregular pupil suggests prolapse of the iris and should arouse suspicion of a penetrating injury. Treatment is prompt primary repair to restore the integrity of the globe. If a perforation is suspected, extensive eye examination should not be attempted before anaesthesia because this may lead to further extrusion of the intraocular contents. If the fundal view is poor, ultrasonography and orbital imaging are

Figure 44.21 Retinal haemorrhage from a cricket bat injury (courtesy of J Beare, FRCS).

Figure 44.22 Retinal dialysis after a concussional injury.

Figure 44.23 Facial lacerations from a windscreen injury. Beware of a perforating eye injury.

indicated. Secondary corneal grafting, lensectomy and vitrectomy have considerably improved the visual prognosis; these must be done by an experienced eye surgeon. Injuries to the optic nerves must also be excluded in severe accidents.

Intraocular foreign bodies

Intraocular foreign bodies must always be excluded when patients attend the accident and emergency department with an eye injury and a history of working with a hammer and chisel or a history of a potentially high-velocity injury. Radiography of the orbits must be performed. Ferrous and copper foreign bodies should always be removed, sometimes requiring the use of a magnet. B-scan ultrasonography can also assist in localising foreign bodies when a vitreous haemorrhage or cataract is present. CT can be used, but MRI is contraindicated if a ferrous intraocular foreign body is suspected.

Summary box 44.4

Penetrating eye injuries

- A distorted and irregular pupil warrants the careful exclusion of a penetrating eye injury
- Avoid extensive eye examination if globe rupture is suspected to avoid worsening the injury prior to surgical repair

Burns

Radiation burns

Corneal injury may occur after exposure to ultraviolet radiation, for example after arc welding or excessive sunlight (snow blindness) and sun lamps. Such burns cause intense gritty burning pain and photophobia as a result of keratitis (corneal inflammation), which starts some hours after exposure. Mydriatic and local steroids with antibiotic drops ease the condition, and healing usually occurs after 24 hours.

Thermal burns

If these involve the full thickness of the lids, corneal scarring may occur from exposure, and immediate corneal protection is necessary. A splash of molten metal may cause marked local necrosis and may lead to permanent corneal scarring. Treatment is to remove any debris by irrigation and to instill local atropine, antibiotics and steroids to prevent superadded infection and scarring. Lid reconstruction may be necessary.

Chemical burns

Chemical burns, and especially alkali burns, can be serious because ocular penetration occurs quickly and ischaemic necrosis can result (**Figure 44.24**). Immediate copious irrigation until the pH is neutral will ensure that the chemical is diluted as much as possible, and all particles should be removed from the fornices. Treatment can then be continued as with thermal burns. Well-fitting goggles should prevent such injuries.

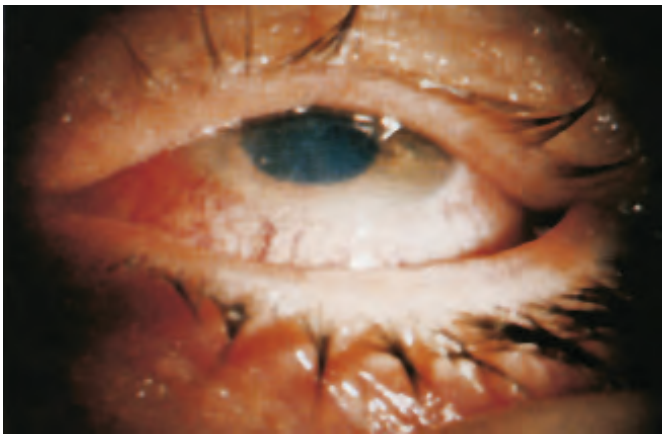

Figure 44.24 Chemical burn showing conjunctival necrosis.

DIFFERENTIAL DIAGNOSIS OF THE ACUTE RED EYE

This is important in the management of minor ocular complaints and the recognition of conditions that require expert attention. Possible causes of the acute red eye include:

- subconjunctival haemorrhage;
- conjunctivitis;
- keratitis;
- uveitis;
- episcleritis and scleritis;
- acute glaucoma.

Any condition with pain, visual impairment or a pupil abnormality suggests a more serious diagnosis.

Subconjunctival haemorrhage

This presents as a bright red eye, often noticed incidentally with only minimal discomfort and normal vision. Causes include coughing, sneezing, minor trauma, hypertension and, rarely, a bleeding disorder. Subconjunctival haemorrhages are more common in those receiving antiplatelet or anticoagulation therapy. Reassurance and treatment of the underlying cause are required. Most settle within a week, but can recur.

Conjunctivitis

Symptoms are grittiness, redness and discharge. Causes are infective, chemical, allergic or traumatic. In the newborn it can be serious; gonococcal and chlamydial infection must be excluded. Bacterial conjunctivitis is purulent, usually self-limiting and treated with topical broad-spectrum antibiotics. Chlamydial and adenovirus infections must be considered. Adenoviral infections are common and usually affect one eye much more in severity and onset, tending to be more watery than sticky, and are often associated with a palpable preauricular gland.

Vernal conjunctivitis (**Figure 44.25**) is a form of allergic conjunctivitis, characterised by itchy eyes, usually worse in the spring and early summer and often associated with other allergic problems such as hay fever. Clinically, most signs are under the upper lid, which may have a cobblestone appearance instead of a smooth surface.

Giant pupillary conjunctivitis with large papillae under the upper lid may be seen in soft contact lens wearers. This is usually caused by an allergy to the sterilising solutions and lens protein and may be helped by either using a preservative-free solution or using daily-wear disposable lenses.

Kaposi's sarcoma, often associated with HIV infection, can rarely present like a subconjunctival haemorrhage (**Figure 44.26**).

Considerable conjunctival and corneal irritation can be caused by the lids turning in (entropion) (**Figure 41.27**) or turning out (ectropion) (**Figures 41.28 and 41.29**), and by ingrowing lashes. The lids should be repaired surgically to their normal position.

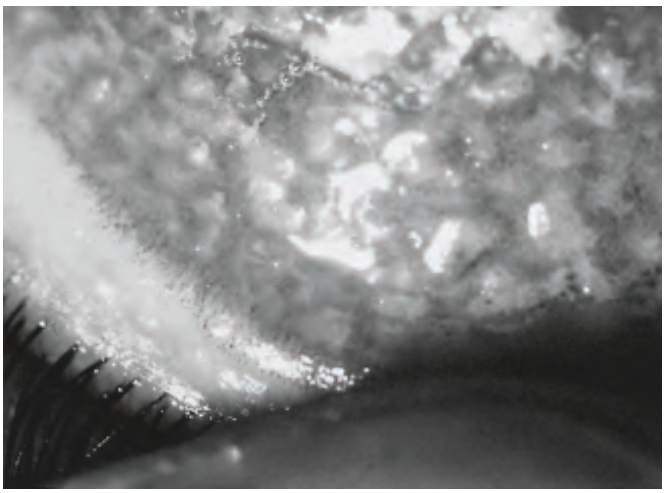

Figure 44.25 Vernal conjunctivitis (spring catarrh) showing cobblestone appearance under the upper lid.

Figure 44.26 Kaposi's sarcoma of conjunctiva.

Moritz Kaposi, 1837–1902, Professor of Dermatology, Vienna, Austria, described pigmented sarcoma of the skin in 1872.

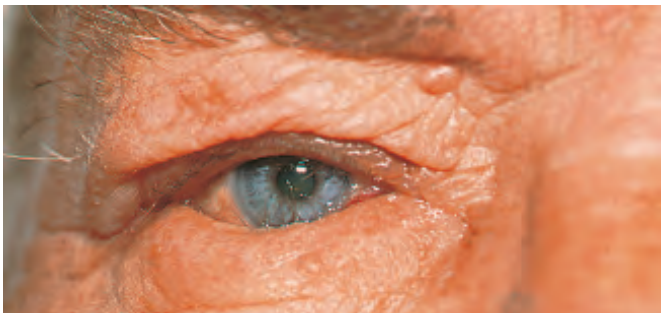

Figure 44.27 Entropion (courtesy of J Beare, FRCS).

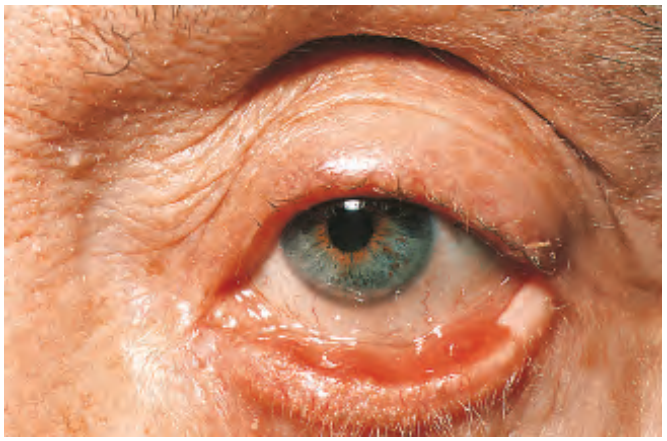

Figure 44.28 Ectropion, lower lid (courtesy of J Beare, FRCS).

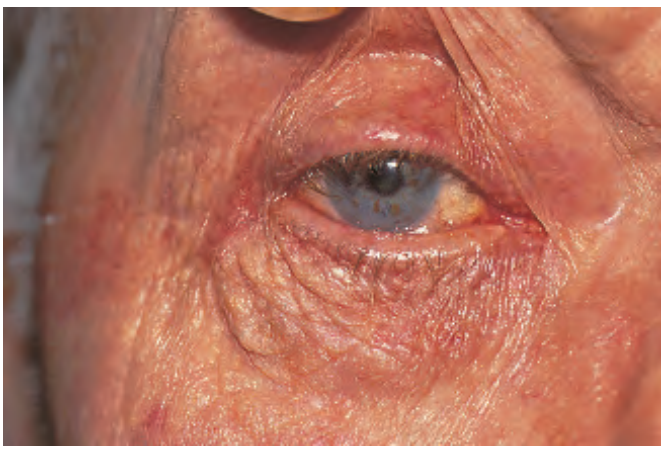

Figure 44.29 Ectropion, upper lid – chronic staphylococcal infection (courtesy of J Beare, FRCS).

Vision is not commonly affected in conjunctivitis but, with some viral infections, a keratitis may be present and result in visual impairment and pain. All of the other conditions below are painful and usually affect vision.

Keratitis (inflammation of the cornea)

Herpes simplex infection presents as a dendritic (branching) ulcer, shown easily by staining with fluorescein or Bengal Rose. It is treated with aciclovir ointment five times per day. The use of steroid drops must be avoided as this can make the condition much worse (**Figure 44.30**).

Corneal ulceration may occur as a result of ingrowing lashes or corneal foreign bodies, marginal ulceration and infected abrasions. Infected ulcers can occur in patients wearing soft contact lenses or elderly immunocomprimised individuals. Herpes zoster (shingles) may affect the ophthalmic division of cranial nerve V and can give rise to a keratitis and uveitis. It is important to avoid the use of steroid drops until a diagnosis has been made. Local anaesthetic drops should also not be given on a regular basis.

Uveitis

This can be anterior (iritis) or, more rarely, posterior. In anterior uveitis, the pupil is sometimes small and/or irregular due to formation of posterior synechiae (adhesions between the iris and the lens). There is often circumcorneal injection and there may be keratic precipitates present on the posterior surface of the cornea. Pain, photophobia and some visual loss are usually present. Posterior uveitis can present with a white eye and blurred vision. It usually takes a chronic course. Granulomatous diseases, Behçet's disease, Reiter's syndrome, toxoplasmosis and cytomegalovirus infection should be excluded. Topical systemic steroids and, sometimes, immunosuppressive drugs are useful in treating these conditions; management should be under the care of an ophthalmologist.

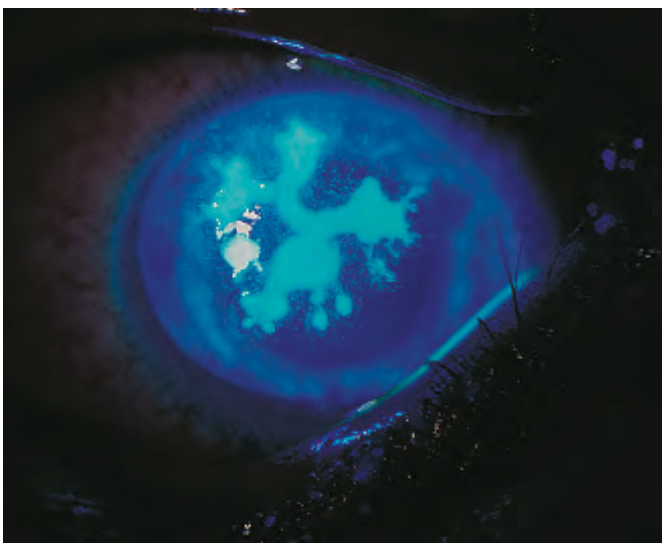

Figure 44.30 Dendritic staining caused by herpes keratitis.

Bengal Rose (or Rose Bengal) is dichlortetraiodofluorescein.
Hulusi Behçet, 1889–1948, Professor of Dermatology, Istanbul, Turkey, described this disease in 1937.
Hans Conrad Julius Reiter, 1881–1968, President of the Health Service and Honorary Professor of Hygiene at the University of Berlin, Germany, described this disease in 1916.

Episcleritis and scleritis

Episcleritis or inflammation of the episcleral tissue often occurs as an idiopathic condition (Figure 44.31). Scleritis is a less common, more serious, condition in which the deeper sclera is involved. There is often an associated uveitis and severe pain. Thinning of the sclera may result. Systemic nonsteroidal anti-inflammatory drugs or steroids/other immunomodulatory agents may be required to treat the condition adequately. Appoximately half of patients with scleritis have an underlying systemic disorder.

Scleritis is often associated with severe rheumatoid conditions. The presence of scleritis suggests that there is active systemic disease and this requires systemic work-up including renal function tests.

Acute angle closure glaucoma

This usually occurs in older, often hypermetropic, patients. The prevalence is much higher in some Asian populations. The cornea becomes hazy, the pupil oval, dilated and non-reacting, the vision poor and the eye feels hard. In severe cases pain may be accompanied by vomiting and the condition can be mistaken for an acute abdominal problem. Tonometry (intraocular measurement) and examination of the iridocorneal angle by gonioscopy (using a prism placed on the cornea) is diagnostic. Urgent treatment to reduce the pressure with pilocarpine eyedrops, oral acetazolamide and, if refractory, mannitol should be started, followed by YAG laser iridotomy, laser iridoplasty, anterior chamber paracentesis or surgical iridectomy. The condition is usually bilateral and the second eye usually needs a prophylactic iridotomy at the same time.

Except for a simple conjunctivitis and subconjunctival haemorrhage, which are self-limiting, the management of an acute red eye requires expert treatment and a specialist opinion should be sought. A painful eye with a cranial nerve III palsy (ptosis, dilated pupil, globe down and out) often signifies an intracranial aneurysm and should be investigated immediately.

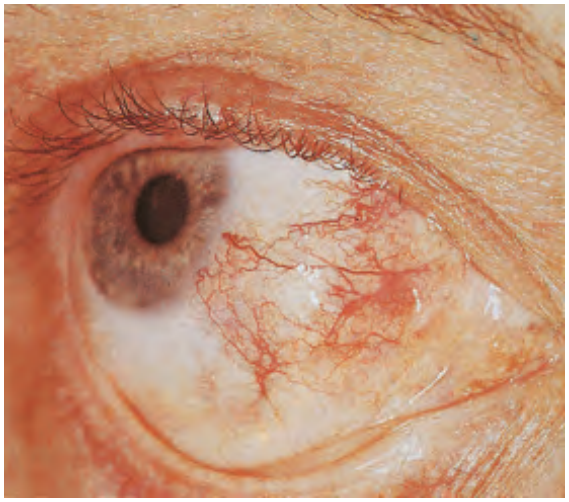

Figure 44.31 Episcleritis.

PAINLESS LOSS OF VISION

This may occur in one or both eyes, and the visual loss may be transient or permanent. Possible causes are:

- **Acute**:
  - obstruction of the central retinal artery (Figure 44.32);
  - obstruction of the central retinal vein (Figure 44.33);
  - ischaemic optic neuropathy;
  - migraine and other vascular causes;
  - vitreous and retinal haemorrhages;
  - retinal detachment (Figure 44.34);
  - macular hole, cyst or haemorrhage;
  - cystoid macular oedema, often after surgery;
  - hysterical blindness.
- **Chronic**:
  - cataract;
  - glaucoma;
  - macular degeneration.
  - diabetic retinopathy.

Figure 44.32 Retinal artery occlusion.

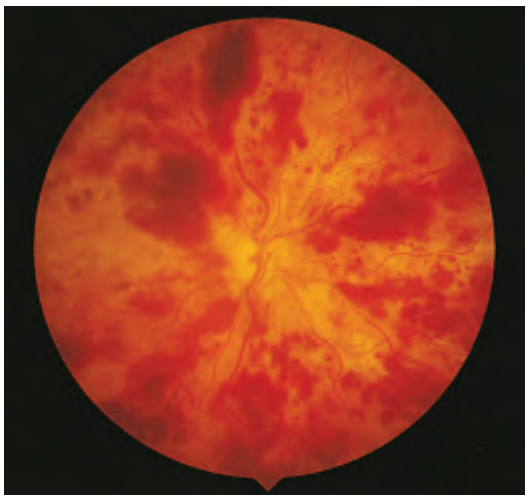

Figure 44.33 Central retinal vein occlusion.

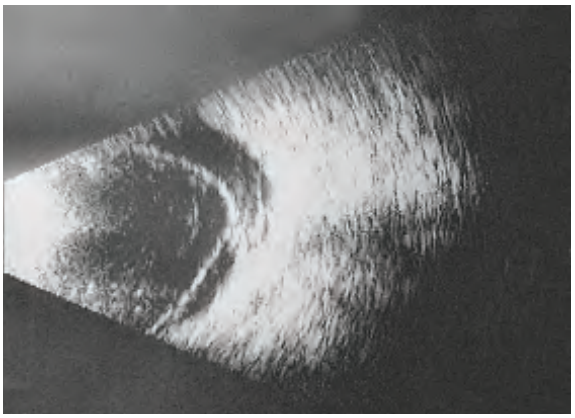

Figure 44.34 B-scan of a retinal detachment.

Specialist help should be sought in any case of loss of vision. The possibility of temporal arteritis should always be considered in the differential diagnosis of sudden visual loss, as prompt treatment of this condition is extremely important. Elderly patients with sudden visual loss should be specifically asked for symptoms of scalp tenderness and jaw claudication and temporal arteries should be palpated for pulsation and tenderness. The erythrocyte sedimentation rate and C-reactive protein should be measured immediately if temporal arteritis is suspected, and the carotid system should be examined for bruits and other signs of arteriosclerosis in cases of ischaemic optic neuropathy and central retinal artery occlusion. Glaucoma, hypertension, hyperviscosity syndromes and diabetes should be looked for in cases of central vein thrombosis.

RECENT DEVELOPMENTS IN EYE SURGERY

In the last three decades, eye surgery has become a microsurgical specialty. Cataract surgery has been transformed by changes in local anaesthesia, implants, phacoemulsification and small-incision surgery, which allows compressible/foldable silicone or acrylic implants to be inserted through a 2-mm incision. The implant power can be more accurately measured by new formulae and the use of A-scan ultrasonography or laser wavefront biometry, and multifocal and accommodative lenses are now available. An even more recent advance in cataract surgery is the development of femtosecond laser technology, which allows extremely controlled corneal incisions, lens capsule opening and lens fragmentation to be achieved automatically together with the facility to adjust the shape of the cornea at the time of surgery to improve visual outcome for some patients. The extent to which this technology improves long-term visual outcomes remains to be seen.

There are new treatments for eye disorders that involve abnormal growth of blood vessels in the back of the eye, such as the wet form of age-related macular degeneration. Anti-vascular endothelial growth factor (VEGF) antibodies, such as the drug ranibizumab, may be injected directly into the vitreous cavity to reduce new vessel proliferation. Intravitreal steroid injections or anti-VEGF agents are now also being used to treat patients with macular oedema caused for example by diabetic retinopathy or retinal vein occlusion.

Developments in vitreous surgery have enabled membranes to be peeled off the retina and macular holes to be repaired, and have also increased success rates in retinal detachment surgery with the additional use of gases and silicone oil or heavy liquid inserted into the vitreous cavity to tamponade the retina. Advances in technology have also led to to the development of photosensitive chips and camera systems that can be implanted into the eye to restore some vision in patients with severe and otherwise untreatable macular diseases.

Some paralytic squints can be helped by the use of adjustable sutures or injections of botulinum toxin into the overacting muscles.

Refractive errors can be treated by the excimer laser. These can be combined with laser *in situ* keratomeilusis (LASIK) surgery, which involves cutting a corneal flap (by femto second laser or surgery) and performing the laser surgery at a deeper level. There have been some concerns about defective contrast sensitivity and problems with night vision after laser correction of myopia. Phakic implants have also been used to correct high refractive errors. Corneal topography aids the accuracy of corneal and refractive surgery and the increased use and quality of CT and MRI scans has revolutionised the diagnosis of orbital and intracranial lesions involving the optic pathways (**Figures 44.35–44.37**).

Fluorescein angiography and ocular coherence tomography (OCT) are invaluable in the diagnosis and treatment of macular conditions. OCT angiography has recently been developed; this allows assessment of the retinal microvasculature without the need for systemically-administered agents. This technology may reduce the need for fluroscein angiography in the future. OCT as well as scanning laser polarimetry of the retinal nerve fibre layer and Heidelberg retinal tomography (HRT) are widely used in the diagnosis and management of glaucoma. Surgical glaucoma management is also developing rapidly. Trabeculectomy surgery, where eye pressure is reduced by creating a fistula between the anterior chamber

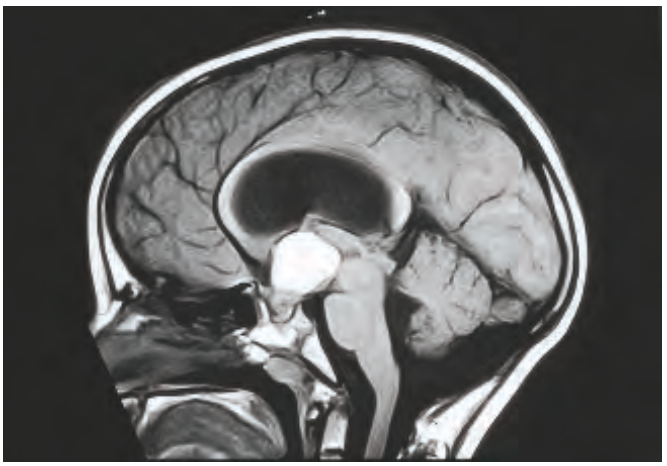

Figure 44.35 Magnetic resonance imaging scan, sagittal view. Craniopharyngioma. The mass in the suprasellar cistern is of high signal intensity because of the proteinaceous fluid that the cyst contains (courtesy of Dr Juliette Britton).

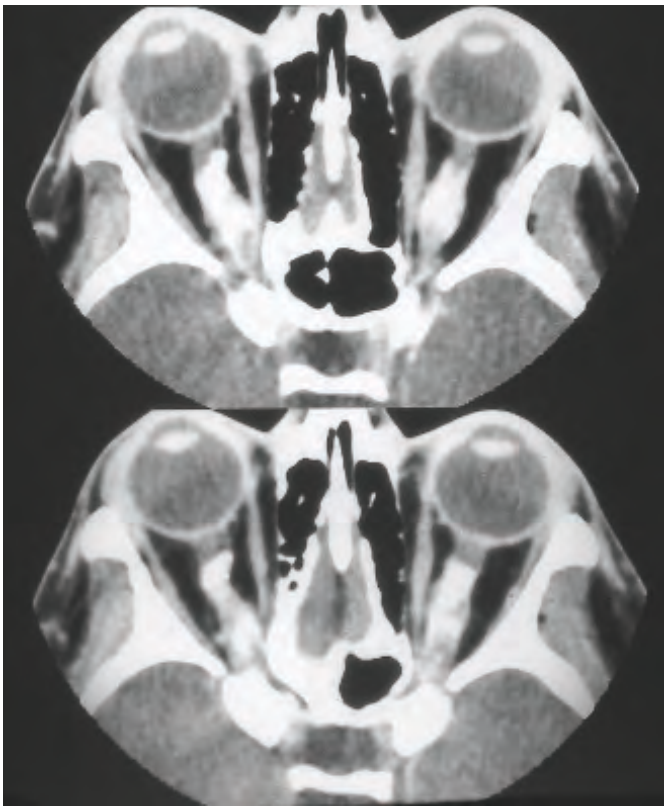

Figure 44.36 High-resolution computed tomography through the orbits showing dense calcification of the optic nerve sheaths typical of optic nerve meningioma (courtesy of Dr Juliette Britton).

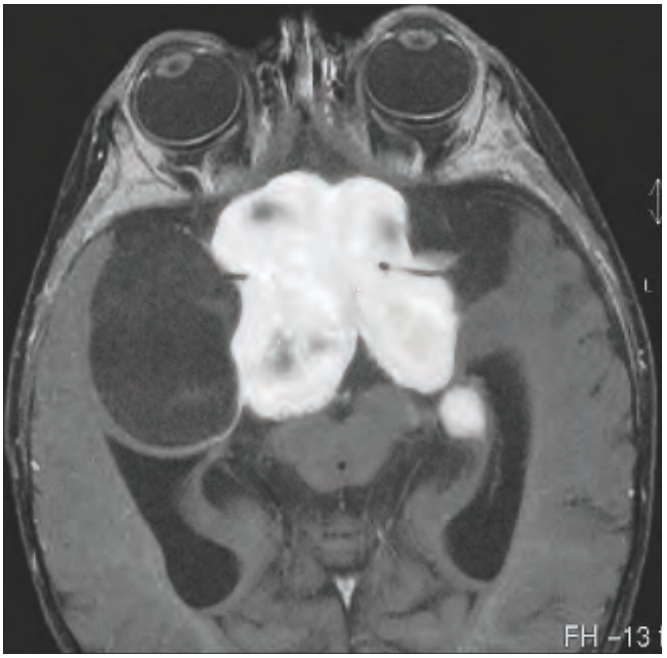

Figure 44.37 Axial enhanced magnetic resonance imaging scan showing a mass involving the optic chiasma and extending down the optic nerves and tracts.

and the subconjunctival space, remains widely used and has become more refined in recent years, with better control of wound healing using topical application of anti-scarring drugs such as mitomycin C. Alternatives to trabeculectomy have been developed using devices such as Baerveldt and Ahmed shunts that drain aqueous from the eye to lower the pressure. A new revolution is also underway using minimally invasive glaucoma surgical techniques, with a variety of tiny devices now available to shunt aqueous and reduce eye pressure.

LASERS IN OPHTHALMOLOGY

Blue-green lasers (argon or frequency-doubled YAG) or diode lasers are used to treat the retina in diabetic retinpoathy (pan-retinal photocoagulation for proliferative disease or focal treatment for leaky microanuerysms) and may also used to close retinal tears or breaks that might lead to retinal detachment.

Argon laser or selective laser trabeculoplasty can be used to open the drainge angle to control elevated intraocular pressure in open angle glaucoma. Trans-scleral diode photocoagulation of the ciliary body is used to treat refactory secondary glaucoma with uncontrolled ocular pressure.

Laser iridotomy with the Nd-Yag laser is used to treat both the affected and fellow eye in acute angle closure glaucoma. The Nd-Yag laser is also used to photodisrupt and clean an opaque posterior capsule, which occurs in 5–10% of cases following cataract surgery.

SURGICAL PROCEDURES

Excision of an eyeball/ enucleation

Indications include a blind, painful eye, a blind, cosmetically poor eye/intraocular neoplasm and, in cadavers, for use in corneal grafting.

The operation

The speculum is introduced between the lids and opened. The conjuctiva is picked up with toothed forceps and divided completely all round as near as possible to the cornea. Tenon's capsule is entered and each of the four rectus and two oblique muscle tendons is hooked up on a strabismus hook and divided close to the sclera. The speculum is now pressed backwards and the eyeball projects forwards. Blunt scissors, curved on the flat, are insinuated on the inner side of the globe, and these are used to sever the optic nerve. The eyeball can now be drawn forwards with the forceps, and the oblique muscles, together with any other strands of tissue that are still attaching the globe to the orbit, are divided. A swab, moistened with hot water and pressed into the orbit, will control the haemorrhage. If an orbital implant is inserted to give better eye movement, the muscles are sutured to the implant at the appropriate sites. The subconjunctival tissues and conjunctiva are closed in layers.

George G Baerveldt, contemporary, ophthalmologist, Emeritus Professor of Ophthalmology, UC Irvine, CA, USA.
Ike K Ahmed, contemporary, ophthalmologist, Toronto, Canada.
Jacques Rene Tenon, 1724–1816, surgeon, La Salpêtrière, Paris, France.

Evisceration of an eyeball

Evisceration is preferred to excision in endoophthalmitis, minimising the risk of orbital and intracranial spread with meningitis. The sclera is transfixed with a pointed knife a little behind the corneosclerotic junction, and the cornea is removed entirely by completing the encircling incision in the sclera. The contents of the globe are then removed with a curette, care being exercised to remove all of the uveal tract. At the end of the operation the interior must appear perfectly white. A ball orbital implant made of acrylic or hydroxyapatite may be placed within the orbit behind the sclera to improve the appearance when the artificial eye is fitted.

Incision and curettage of chalazion (meibomian cyst)

The lid margin is everted to allow the application of a meibomian clamp. The ring of the clamp is placed on the palpebral conjunctiva with the granuloma in the centre. An incision is made with a small blade in the axis of the gland. The herniating granulomatous tissue is removed with a curette and the cavity is scraped clean. Recurrent cysts may have to have the cyst wall dissected away with scissors. A biopsy may be necessary in atypical or recurrent cysts to exclude malignant change.

Chapter 45

Cleft lip and palate: developmental abnormalities of the face, mouth and jaws

Learning objectives

To understand:

- The aetiology and classification of developmental abnormalities of the face, mouth and jaws
- Perinatal and early childhood management
- The principles of reconstruction of cleft lip and palate
- The key features of perioperative care
- The management of complications associated with cleft lip and palate

INTRODUCTION

Developmental abnormalities of the face, mouth and jaws are relatively rare and because of the complexity of developmental abnormalities an ideal classification system is not available. Consequently, there are a number of different systems available, some purely descriptive (e.g. Tessier's classification of clefts), while others apply only to single conditions, such as the OMENS (O, orbital alteration; M, mandibular deformity; E, ear deformity; N, nerve involvement; and S, soft tissue alterations) classification of hemifacial (craniofacial) microsomia, which has utility in instituting treatment protocols.

Van der Meulen and his colleagues proposed a classification that has significant utility in helping to understand the variety and complexity of craniofacial malformations. This classification considered the embryological development of the craniofacial region firstly in terms of the formation and fusion of the processes (branchial arches) – the failure of the fusion of these processes leading to clefting disorders, thus the failure of fusion between the frontonasal process and the maxillary process resulting in a cleft lip, either unilaterally or bilaterally; secondly in relation to the formation of bone and cartilage. If this is abnormal, it is termed dysostosis or dyschondrosis; and thirdly in relation to the formation and growth at the sutures between the various bones of the craniofacial skeleton – premature fusion leading to synostosis. Superimposed on this concept is the consideration of the development of the central nervous system. This leads to a number of types of abnormality, as outlined in *Table 45.1*.

TABLE 45.1 Types of developmental abnormalities of the face, mouth and jaws.

Type	Examples
Cerebrocranial dysplasias	Anencephaly, microcephaly
Cerebrofacial dysplasias	Rhinencephalic and oculo-orbital dysplasias
Craniofacial dysplasias with clefting	Latero-naosmaxillary, medionasomaxillary, intermaxillary, maxilomandibular clefting
Craniofacial dysplasias with dysostosis	Sphenoidal, sphenoidal frontal, frontal, fronto-frontal, fronto-nasoethmoidal, internasal, nasal, premaxillo-maxillary, nasomaxillary, maxillo-zygomatic, zygomatic, zygo-auro madibular, temporoauromandibular, mandibular, intermandibular
Craniofacial dysplasias with synostosis	Craniosynostosis: lambdoid and sagittal. Craniofaciosynostosis: metopic, coronal, bicoronal Faciosynostosis: vomeropremaxillary (Binder syndrome)
Craniofacial dysplasias with dysostosis and synostosis	Crouzon, Apert and Pfiffer syndromes
Craniofacial dysplasias with dyschondrosis	Achondroplasia

After van der Meulen JC, Mazzola R, Vermey-Keers C, Stricker M *et al*. A morphogenetic classification of craniofacial malformations. *Plast Reconstr Surg* 1983; **71**(4): 560–72.

Jacques van der Meulen, b.1929, Professor in Plastic and Reconstructive Surgery, Erasmus University, Rotterdam, The Netherlands.

In addition and in common with all classification systems, there is another large group of conditions that does not sit within the system outlined above.

EPIDEMIOLOGY

The incidence of congenital craniofacial anomalies varies in different parts of the world and is often not easy to quantify. *Table 45.2* outlines the various incidences of the more common craniofacial abnormalities.

DIAGNOSIS

The diagnosis of the craniofacial anomalies has, in recent years, undergone a massive change on two fronts. Firstly, advances in ultrasonography have increased the rate of prenatal diagnosis and impacted significantly on management. Secondly, the rapid expansion in genetic understanding has led to many more mutations being linked to particular phenotypes. Despite these advances the diagnosis of the majority of these conditions is clinical.

MANAGEMENT

In considering the management of this vast range of heterogeneous congenital abnormalities it is very difficult to generalise about management protocols. In the majority, management is delivered by multidisciplinary teams within specialist centres.

Prenatal management

Should a diagnosis be made or suspected prenatally there have been a few reported case of prenatal surgery; however, these procedures at present remain experimental and in general the options open are for termination or best supportive care in preparation for the birth. This can often provide the parents a period of time to adjust to the impending birth of a child with additional demands and needs. The opportunity to meet parents, adults and children who have experienced the same condition is often very valuable. Termination and its therapeutic uses is obviously a contentious and very personal issue; however, some parents may request this for very treatable conditions (e.g. isolated cleft lip) and in these circumstances the local ethics board must be involved and ultimately on occasions the advice of the courts must also be sought.

TABLE 45.2 Approximate incidence data from multiple sources.

Condition	Incidence
Apert syndrome	1 in 100 000
Pfeiffer syndrome	1 in 100 000
Crouzon syndrome	1 in 62 500
Treacher Collins syndrome	1 in 50 000
Unicoronal synostosis	1 in 10 000
Metopic synostosis	1 in 7000
Sagittal synostosis	1 in 5000
Hemifacial microsomia	1 in 3500
Neurofibromatosis	1 in 2600
Cleft lip and palate	1 in 600

Neonatal management

In the neonatal period management is aimed at addressing the urgent issues relating to the airway, breathing, eye protection and establishing feeding.

In many craniofacial conditions, the airway can be affected and either fully or partially obstructed due to a retropositioned hypoplastic maxilla with the tongue falling back to close off the upper airway, often compounded by a hypoplastic mandible. The trachea itself may also be abnormal and tracheomalacia can also lead to respiratory problems. Neonates are obligate nasal breathers and some forms of nasal obstruction can also precipitate airway symptoms. In the most severe cases intubation is not possible as a result of the abnormal anatomy and a tracheostomy may be necessary. In emergency situations it may be helpful to nurse the baby prone, allowing the tongue to fall forward.

In some cases, particularly the syndromic craniosynostoses such as Apert syndrome, Pfeiffer syndrome or Crouzon syndrome, the combination of the midface retrusion and the brachycephalic forehead shape can lead to severe exorbitism. In the worst cases this can cause ocular dislocation with the eyelids closing behind the globe. In severe exorbitism, the eyelids do not close adequately to moisturise and protect the cornea and without intervention this may lead to irreversible corneal damage.

In neonates with airway embarrassment, even without anatomical abnormalities, the effort of breathing can be exhausting and this can significantly compromise the ability to feed. Structural anomalies can also affect the ability to feed and expert input from a specialist feeding nurse is often helpful. The use of specialised teats may be helpful, but in some cases naso- or orogastric feeding may be necessary.

Management in infancy (0–12 months)

At this age treatment falls into two categories: first, that directed at major functional issues as a continuum of neonatal care; and second, skull surgery in cases of craniosynostosis.

Craniosynostosis results in premature fusion of one or more of the skull sutures. The condition may be isolated or part of a syndrome. This can result in abnormalities of both the skull and, particularly in syndromic cases, the facial skeleton.

Eugene Apert, 1868–1940, physician L'Hôpital des Infants Malades, Paris, France, described this syndrome in 1906.
Rudolf Arthur Pfeiffer, 1931–2012, geneticist, Münster, Germany, described this syndrome in 1964.
Louis Edouard Octave Crouzon, 1874–1938, neurologist, Paris, France, described this syndrome in 1912.

In 10–20% of single suture cases and a higher proportion of syndromic multisuture cases the infants develop raised intracranial pressure, which presents with episodes of distress, listlessness and disturbed sleep. This may be associated with papilloedema and untreated, can lead to visual failure. The diagnosis is confirmed with intracranial pressure monitoring.

Some congenital lesions may obstruct the vision of one or both eyes and this needs to be addressed to minimise the chances of amblyopia developing. An example of this would be the development of a large true haemangioma of the eyelids threatening to obscure the child's vision out of one eye.

In the older child the indications for surgery remain the same; however, there is the possibility of surgery to advance the mandible in the severely retrognathic patient. This can be used to obviate the need for a tracheostomy or allow for early decannulation. The most effective technique is distraction osteogenesis (or distraction histogenesis), which utilises the same basic principles as in limb lengthening. The bone is cut and a device placed across the osteotomy site and after a short latent period the bone ends gradually separate, distracting the callus. In the mandible, unlike the long bones, it is not necessary to limit the bone cut to the cortex (corticotomy) and a complete osteotomy is used. The technique allows for a lengthening of approximately 1 mm per day, after which there is a retention period to allow for consolidation of the callus.

Management in early childhood (1–12 years)

In early childhood management should be aimed at dealing with functional problems, airway obstruction, speech and feeding issues, but there is an increasing imperative for surgery to address the appearance of the child. There is no doubt that visible differences can affect the development, socially and emotionally; however, there is a significant role for psychological and emotional support for the whole family and in some cases for the school community to help the child, family and school understand and deal with the additional pressures that visible difference makes. Surgery can make a significant difference for some cases, but for many surgery should be delayed as long as possible for an optimal outcome in the long term.

In the older child airway issues can become a problem and their identification is more difficult. The usual presentation is of sleep apnoea, which often has an insidious onset and the history should be actively sought; parents are used to noisy snoring and daytime tiredness in the child and may not consider it abnormal. Initial investigation is with a home overnight oxygen saturation monitor, which if abnormal should trigger a comprehensive sleep study. The management of obstructive sleep apnoea includes the use of tonsillectomy/adenoidectomy, midface advancement and mandibular distraction as well as a variety of ventilator support devices.

Management in late childhood to maturity

Airway and other functional issues are usually stabilised by this time and interventions are aimed at optimising the overall appearance. The transition from primary school to secondary school is often a period of distress for patients with visible differences and their families and if there are pressing psychological reasons, corrective surgery can be offered, although usually this is best postponed until growth is complete. In general, a comprehensive integrated corrective plan should be developed within the multidisciplinary team. This would usually address the skeletal and dental abnormalities first and secondarily address the soft tissues. The majority of the major craniofacial abnormalities should be managed by a formal multidisciplinary team.

CLEFT LIP AND PALATE

Clefts of the lip, alveolus and hard and soft palate are the most common congenital abnormalities of the orofacial structures. They frequently occur as isolated deformities but can be associated with other medical conditions, particularly congenital heart disease. They are also an associated feature in over 300 recognised syndromes.

All children born with a cleft lip and palate need a thorough paediatric assessment to exclude other congenital abnormalities. In certain circumstances genetic counselling must be sought if a syndrome is suspected.

Incidence

The incidence of cleft lip and palate is 1:600 live births and of isolated cleft palate is 1:1000 live births. The incidence increases in Oriental groups (1:500) and decreases in the black population (1:2000). The highest incidence reported for cleft lip and palate occurs in the Indian tribes of Montana, USA (1:276).

Although cleft lip and palate is an extremely diverse and variable congenital abnormality, several distinct sub-groups exist, namely cleft lip with/without cleft palate (CL/P), cleft palate (CP) alone and submucous cleft palate (SMCP).

The typical distribution of cleft types is:

- cleft lip alone: 15%;
- cleft lip and palate: 45%;
- isolated cleft palate: 40%.

Cleft lip/palate predominates in males, whereas cleft palate alone appears to be more common in females. In unilateral cleft lip the deformity affects the left side in 60% of cases.

Aetiology

Contemporary opinion on the aetiology of cleft lip and palate is that cleft lip and palate and isolated cleft palate have a genetic predisposition and a contributory environmental component. A family history of cleft lip and palate in which the first-degree relative is affected increases the risk to 1:25 live births. Genetic influence is more significant in cleft lip/palate than cleft palate alone, in which environmental factors exert a greater influence.

Environmental factors implicated in clefting include maternal epilepsy and drugs (e.g. steroids, diazepam and

phenytoin). The role of antenatal folic acid supplements in preventing cleft lip and palate remains equivocal.

Although most clefts of the lip and palate occur as an isolated deformity, Pierre Robin sequence is an important association. This sequence comprises isolated cleft palate, retrognathia and a posteriorly displaced tongue (glossoptosis), which is associated with early respiratory and feeding difficulties.

Isolated cleft palate is more commonly associated with a syndrome than cleft lip/palate and cleft lip alone. Over 150 syndromes are associated with cleft lip and palate, although Stickler (ophthalmic and musculoskeletal abnormalities), Shprintzen (cardiac anomalies), Down, Apert and Treacher Collins syndromes are most frequently encountered.

Summary box 45.1

Cleft lip and palate

- Associated with other congenital abnormalities
- Incidence varies between 1:300 to 1:2000
- Aetiology is both genetic and environmental

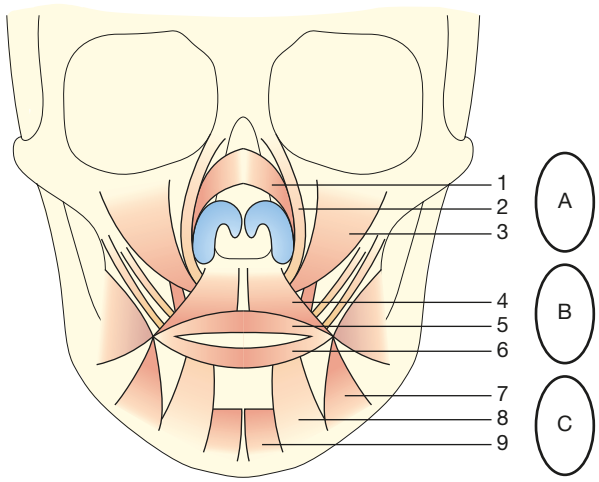

Figure 45.1 The muscle chains of the face: frontal view. The nasal cartilages are represented in blue. A, nasolabial (muscles 1–3); B, bilabial (muscles 4–6); C, labiomental (muscles 7–9); 1, transverse nasalis; 2, levator labii superioris alaeque nasi; 3, levator labii superioris; 4, orbicularis oris (oblique head) – upper lip; 5, orbicularis oris (horizontal head) – upper lip; 6, orbicularis oris – lower lip; 7, depressor anguli oris; 8, depressor labii inferioris; 9, mentalis.

ANATOMY OF CLEFT LIP AND PALATE

Cleft lip

The abnormalities in cleft lip are the direct consequence of disruption of the muscles of the upper lip and nasolabial region. The facial muscles (Figure 45.1) can be divided into three muscular rings of Delaire: the nasolabial muscle ring surrounds the nasal aperture; the bilabial muscle ring surrounds the oral aperture; and the labiomental muscle ring envelops the lower lip and chin regions.

Unilateral cleft lip

In the unilateral cleft lip, the nasolabial and bilabial muscle rings are disrupted on one side, resulting in an asymmetrical deformity involving the external nasal cartilages, nasal septum and anterior maxilla (premaxilla) (Figure 45.2). These deformities influence the mucocutaneous tissues causing a displacement of nasal skin onto the lip and a retraction of labial skin, as well as changes to the vermilion and lip mucosa. All these changes need to be considered in planning the surgical repair of the unilateral cleft lip.

Bilateral cleft lip

In the bilateral cleft lip the deformity is more profound but symmetrical. The two superior muscular rings are disrupted on both sides, producing a flaring of the nose (caused by lack of nasolabial muscle continuity), a protrusive premaxilla and an area of skin in front of the premaxilla devoid of muscle, known as the prolabium (Figure 45.3). As in the unilateral cleft lip, the muscular, cartilaginous and skeletal deformities influence the mucocutaneous tissues, which must be respected in planning the repair of the bilateral cleft lip.

Cleft palate

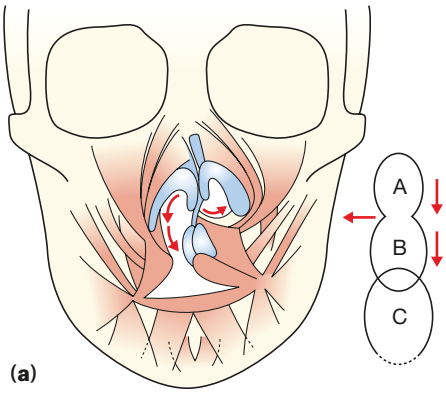
Embryologically, the **primary** palate consists of all anatomical structures anterior to the incisive foramen, namely the alveolus and upper lip. The **secondary** palate is defined as the remainder of the palate behind the incisive foramen, divided into the hard palate and, more posteriorly, the soft palate.

Cleft palate results in failure of fusion of the two palatine shelves. This failure may be confined to the soft palate alone or involve both hard and soft palate. When the cleft of the hard palate remains attached to the nasal septum and vomer, the cleft is termed **incomplete**. When the nasal septum and vomer are completely separated from the palatine processes, the cleft palate is termed **complete**.

Soft palate

In the normal soft palate, closure of the velopharynx, which is essential for normal speech, is achieved by five different muscles functioning in a complete but coordinated fashion.

Pierre Robin, 1867–1950, Professor, The French School of Dentistry, Paris, France, described this syndrome in 1929.
Gunnar B Stickler, 1925–2010, born in Germany, Chair of Section of Paediatrics and later Paediatric Cardiology, The Mayo Clinic, Rochester, MN, USA.
Robert J Shprintzen, b.1946, surgeon, Syracuse, NY, USA.
John Langdon Haydon Down (sometimes given as Langdon-Brown), 1828–1896, physician, The London Hospital, UK, published 'observations on the ethnic classification of idiots' in the London Hospital Reports in 1866.
Edward Treacher Collins, 1862–1932, ophthalmic surgeon, the Royal London Ophthalmic Hospital, and Charing Cross Hospital, London, UK, described this syndrome in 1900.



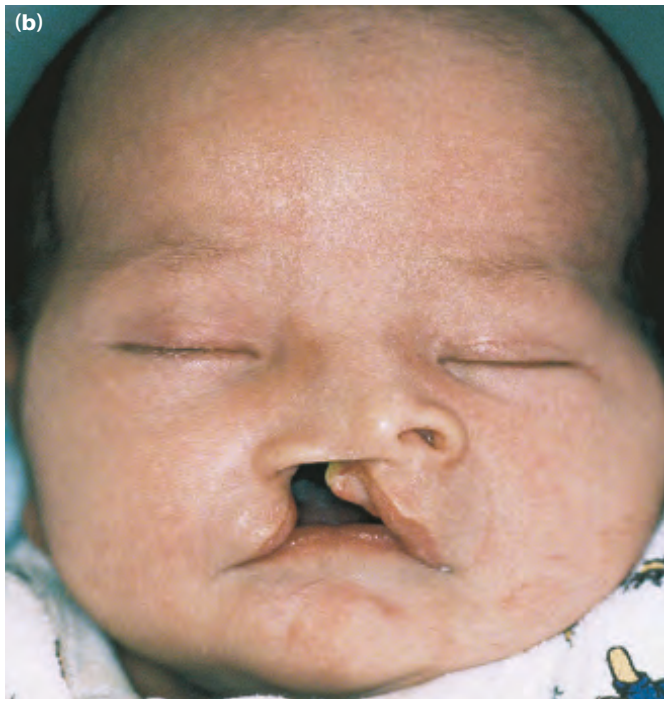


Figure 45.2 **(a)** Schematic representation of disruption of the nasolabial and bilabial muscle chains in unilateral (left) cleft lip. A, nasolabial; B, bilabial; C, labiomental. **(b)** Unilateral cleft lip before muscular reconstruction.

Summary box 45.2

Types of cleft palate

- May involve the soft palate or the soft and hard palate
- It is complete when nasal septum and vomer are separated from the palatine process

In general, the muscle fibres of the soft palate are orientated transversely with no significant attachment to the hard palate.

In a cleft of the soft palate (Figure 45.4a) the muscle fibres are orientated in an anteroposterior direction, inserting into the posterior edge of the hard palate (Figure 45.4b).

Hard palate

The normal hard palate can be divided into three anatomical and physiological zones (Figure 45.5). The central **palatal fibromucosa** is very thin and lies directly below the floor of nose. The **maxillary fibromucosa** is thick and contains the greater palatine neurovascular bundle. The **gingival fibromucosa** lies more lateral and adjacent to the teeth.

In performing surgical closure of cleft palate the changes associated with the cleft must be understood to obtain an anatomical and functional repair. In complete cleft palate the median part of the palatal vault is absent and the palatal fibromucosa is reduced in size. The maxillary and gingival fibromucosa are not modified in thickness, width or position.

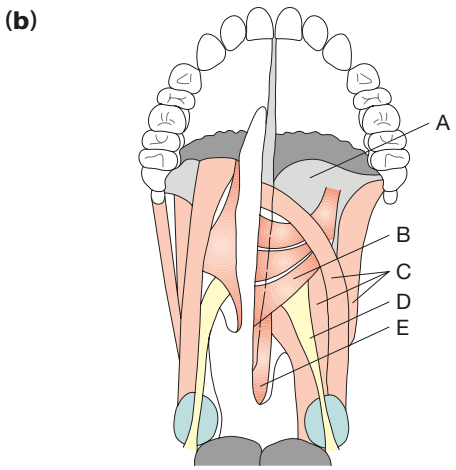

Figure 45.4 **(a)** Cleft of soft palate and incomplete cleft of hard palate. **(b)** Muscles of the soft palate: left, cleft palate; right, normal anatomy. A, tensor palati; B, levator palati; C, palatopharyngeus; D, palatoglossus; E, musculus uvulae.

PRIMARY MANAGEMENT

Antenatal diagnosis

An antenatal diagnosis of cleft lip, whether unilateral or bilateral, is possible by ultrasound scan after 18 weeks of gestation. Isolated cleft palate cannot be diagnosed by antenatal scan. When an antenatal diagnosis is confirmed, referral to a cleft surgeon is appropriate for counselling to allay fears. Photographs of cleft lip shown to parents 'before and after' surgery are invaluable. Introduction to a parent support group and meeting parents of a child with a similar cleft who has undergone surgery may also be extremely helpful.

Summary box 45.3

Antenatal diagnosis and counselling

- All but isolated cleft palate can be diagnosed by ultrasound after 18 weeks' gestation
- Parents need counselling and support

Feeding

Most babies born with cleft lip and palate feed well and thrive, provided that appropriate advice is given and support is available. Some mothers are successful in breast-feeding, particularly when the cleft is incomplete and confined to the lip. Good feeding patterns can be established with soft bottles (e.g. Mead Johnson) and modified teats (orthodontic, Nuyk). Simple measures such as enlarging the hole in the teat often suffice. Feeding plates, constructed from a dental impression of the upper jaw, are rarely necessary to improve feeding. Some babies are provided with an active plate that aims not only to improve feeding but also reduce the width of the cleft lip and palate prior to surgery. The long-term benefit of such a regime remains unproven.

Airway

Major respiratory obstruction is uncommon and occurs exclusively in babies with Pierre Robin sequence. Hypoxic episodes during sleep and feeding can be life-threatening. Intermittent airway obstruction is more frequent and is managed by nursing the baby prone. More severe and persistent airway compromise can be managed by 'retained nasopharyngeal intubation' to maintain the airway. Surgical adhesion of the tongue to the lower lip (labioglossopexy) in the first few days after birth is an alternative but less commonly practised method of management. Early mandibular surgery, in the form of distraction osteogenesis, is indicated for a proportion of cases and may avoid the need for a tracheostomy.

Summary box 45.4

Problems immediately after birth

- Some babies are able to feed normally but others require assistance
- Breathing problems in Pierre Robin sequence may be life threatening

PRINCIPLES OF CLEFT SURGERY

The ultimate goal in cleft lip and palate management is a patient with a normal appearance of lip, nose and face, whose speech is normal and whose dentition and facial growth fall within the range of normal development.

Surgical techniques are aimed at restoring normal anatomy. With the exception of rare conditions such as holoprosencephaly, there is no true hypoplasia of the tissues involved on either side of the cleft. There is, however, displacement, deformation and underdevelopment of the muscles and facial skeleton. Emphasis is placed on muscular reconstruction of the lip, nose and face as well as muscles of the soft palate. Normal or near-normal anatomy promotes normal function, thereby encouraging normal growth and development of lip, nose, palate and facial skeleton. An in-depth understanding of the anatomy of the cleft is invaluable if the surgeon is to achieve normal, or near-normal, anatomical reconstruction.

Summary box 45.5

Surgical anatomy

- Normal lip, face and nose
- Underdevelopment and displacement of muscles
- Restoration of normal anatomy encourages normal facial growth and function

Surgical techniques

There have been many different surgical techniques and sequences advocated in cleft lip and palate management, leading to considerable debate between surgeons regarding surgical regime and philosophy; however, all modern approaches have functional muscle reconstruction as their core principle. Cleft lip repair is commonly performed between 3 and 6 months of age, whereas cleft palate repair is frequently performed between 6 and 18 months.

The Delaire technique and sequence (*Table 45.3*) is one of the many regimes currently practised.

Cleft lip surgery

Skin incisions (**Figures 45.6** and **45.7**) are developed to restore displaced tissues, including skin and cartilage, to their normal position, while gaining access to the facial, nasal and lip musculature.

Muscular continuity is achieved by subperiosteal undermining over the anterior maxilla. Nasolabial muscles are anchored to the premaxilla with non-resorbable sutures. Oblique muscles of orbicularis oris are sutured to the base of the anterior nasal spine and cartilaginous nasal septum. Closure of the cleft lip is completed by suturing the horizontal fibres of orbicularis oris to achieve a functioning oral sphincter (**Figures 45.8** and **45.9**).

When the cleft lip is incomplete (**Figures 45.10a** and **45.11a**), meticulous assessment of the cleft deformity is of paramount importance, as complete muscle disruption may be present leading to nasal and skeletal deformity. Full muscular exposure and reconstruction is imperative in many incomplete clefts if facial symmetry is to be achieved (**Figures 45.10b** and **45.11b**).

TABLE 45.3 Timing of primary cleft lip and palate procedures (after Delaire).

Cleft lip alone		
Unilateral (one side)	One operation at 5–6 months	
Bilateral (both sides)	One operation at 4–5 months	
Cleft palate alone		
Soft palate only	One operation at 6 months	
Soft and hard palate	Two operations	Soft palate at 6 months
		Hard palate at 15–18 months
Cleft lip and palate		
Unilateral	Two operations	Cleft lip and soft palate at 5–6 months
		Hard palate and gum pad with or without lip revision at 15–18 months
Bilateral	Two operations	Cleft lip and soft palate at 4–5 months
		Hard palate and gum pad with or without lip revision at 15–18 months

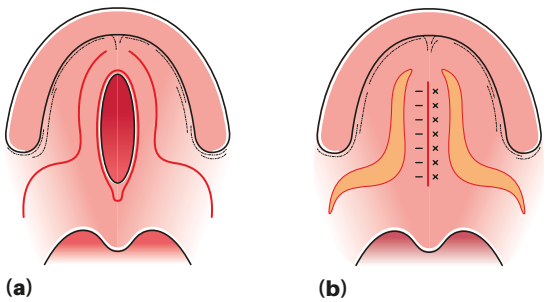

Figure 45.13 (a, b) Schematic representation of closure of the hard palate. Second-stage palatoplasty achieved with two-layered closure. Red lines represent incisions and orange areas raw surfaces.

reconstruction of the aberrant soft palate musculature (Figure 45.12) together with closure of the residual hard palate cleft by minimal dissection and subsequent scar formation (Figure 45.13). Excess scar formation in the palate adversely affects growth and development of the maxilla. The philosophy of two-stage closure encourages a physiological narrowing of the hard palate cleft to minimise surgical dissection at the time of the second procedure.

Summary box 45.6

Principles of surgery

- Cleft lip surgery attaches and reconnects the muscles around the oral sphincter
- Cleft patate surgery aims to bring together mucosa and muscles with minimal scarring
- Two-stage procedures minimises dissection

SECONDARY MANAGEMENT

Following primary surgery, regular review by a multidisciplinary team is essential. Many aspects of cleft care require long-term review:

- hearing;
- speech;
- dental development;
- facial growth.

Hearing

Eustachian tube dysfunction plays a central role in the pathogenesis of otitis media, with effusion in babies and children born with a cleft palate. Children with a cleft lip alone exhibit the same frequency of otitis media as their age-matched non-cleft counterparts; however, a child with a craniofacial anomaly, including cleft lip and palate, is at increased risk of

a sensorineural hearing deficit. All children born with a cleft lip and palate should undergo assessment before 12 months of age for **sensorineural and conductive hearing loss** by auditory brainstem responses and tympanometry, respectively.

Sensorineural hearing loss is managed with a hearing aid whereas the management of secretory otitis media remains more controversial. Early (6–12 months) prophylactic myringotomy and grommet insertion temporarily eliminates middle ear effusion. Regular audiological testing may be as appropriate, reserving surgery for established secretory otitis media with infection. No firm evidence is available to support the interventional approach over the conservative regime. Nevertheless, the relationship between hearing loss and potential speech problems remains important. Regular audiological assessment during childhood is of utmost importance.

Speech

Initial speech assessment should be performed early (18 months) and repeated regularly to ensure that problems are identified early and managed appropriately.

Common speech problems associated with cleft lip and palate are:

- **Velopharyngeal incompetence**. This is associated with increased nasal airflow and resonance producing a nasal or 'hypernasal' quality to speech. It frequently reflects poor function of the soft palate associated with inadequate muscle repair.
- **Articulation problems**. These arise either as a compensatory mechanism to overcome velopharyngeal incompetence or, less commonly, are caused by jaw/dental and occlusal abnormalities. Videofluoroscopy, nasal airflow studies (aerophonoscopy) and nasendoscopy are helpful in defining the exact mechanism of the problem, aiding management.
- **Speech problems**. These are managed by speech and language therapy; secondary palatal surgery, either intravelar veloplasty (muscular reconstruction of soft palate) or pharyngoplasty; and speech training devices .

Summary box 45.7

Associated hearing and speech problems

- Higher incidence of sensineural and conductive hearing loss
- Regular hearing tests are important if speech is to develop normally
- Speech problems may result from airflow problems

Dental

Dental anomalies are common findings in children with cleft lip and/or palate. Various phenomena including delayed tooth development, delayed eruption of teeth and morphological abnormalities are well documented. The number of teeth may be reduced (hypodontia) or increased (hyperdontia), occurring most commonly in the region of the cleft alveolus involving the maxillary lateral incisor tooth. These abnormalities can occur in both primary and secondary dentition.

All children with cleft lip and palate should undergo regular dental examination. Dental management should also include preventive measures such as dietary advice, fluoride supplements and fissure sealants.

A well-maintained and disease-free dentition in childhood is an absolute prerequisite for orthodontic treatment.

Summary box 45.8

Dental problems

- Too many/too few teeth or problems with eruption of teeth are common
- Good dentition is essential for successful reconstructive surgery

Orthodontic management

Many children with cleft lip and palate require orthodontic treatment. Orthodontic treatment is commonly carried out in two phases:

- Mixed dentition (8–10 years) – to expand the maxillary arches as a prelude to alveolar bone graft.
- Permanent dentition (14–18 years) – to align the dentition and provide a normal functioning occlusion. This phase of treatment may also include surgical correction of a malpositioned/retrusive maxilla by maxillary osteotomy (Figure 45.14).

Secondary surgery for cleft lip and palate

Good outcome in cleft lip and palate is directly attributable to the quality of the primary surgery. Secondary cleft procedures include:

- cleft lip revision (unilateral and bilateral);
- alveolar bone graft;
- simultaneous lip revision and alveolar bone graft;
- secondary palate procedures (e.g. veloplasty and pharyngoplasty, closure of a palatal fistula);
- dentoalveolar procedures, including transplantation of teeth/insertion of osseo-integrated dental implants;
- orthognathic surgery;
- rhinoplasty.

Cleft lip revision

Indications for revisional surgery to a previously repaired cleft lip are dependent on the site and severity of the residual deformity.

Revisional surgery should be delayed for 2 years after primary lip closure unless the surgeon is of the opinion that the initial procedure was inadequate, particularly with respect to muscular reconstruction.

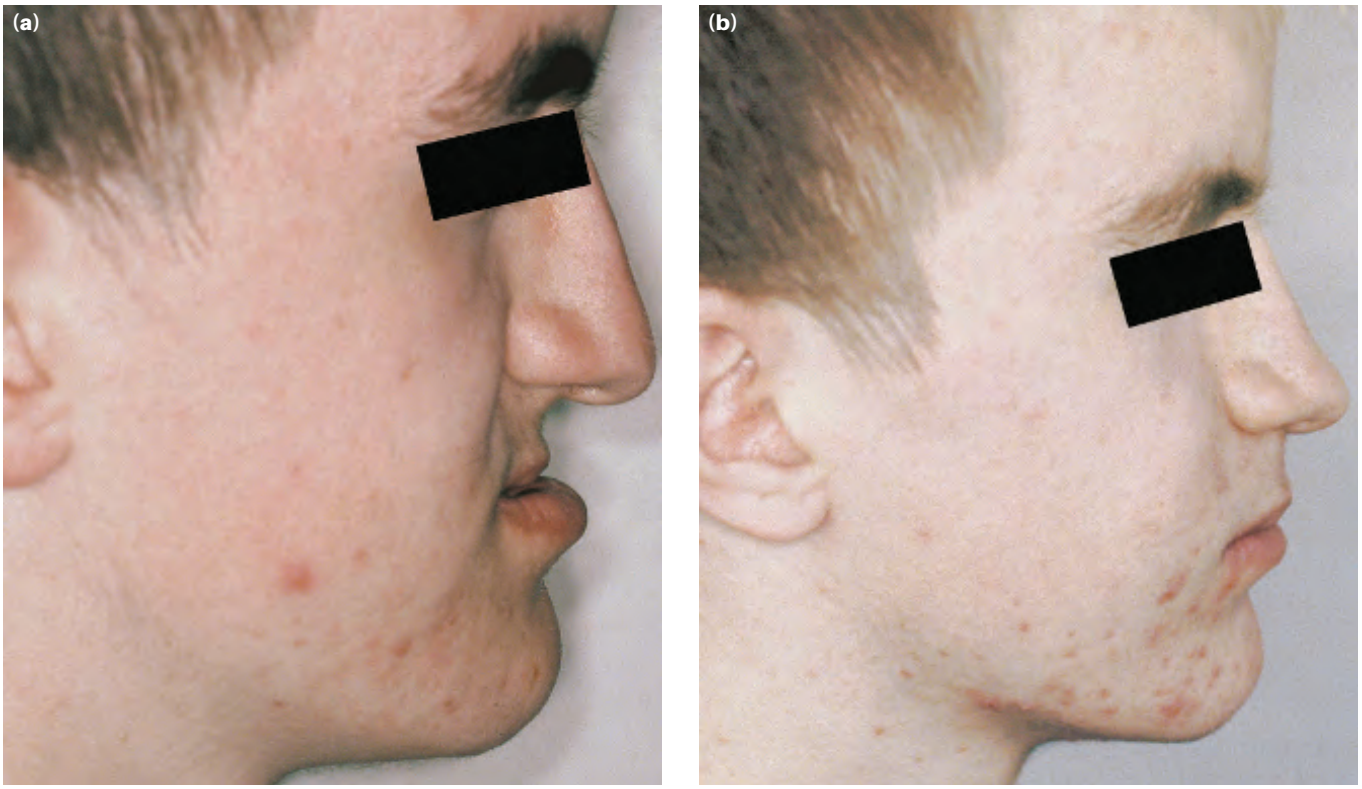

Figure 45.14 Correction of midface retrusion by maxillary advancement osteotomy, before **(a)** and after **(b)** surgery.

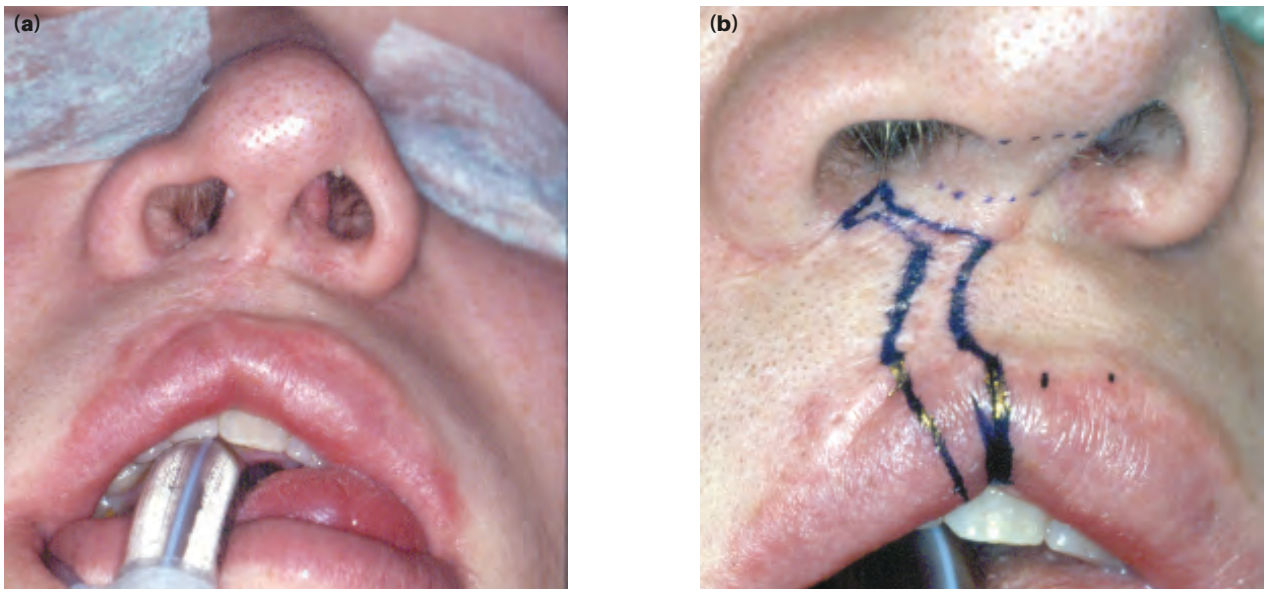

Figure 45.15 **(a)** Revision of unilateral complete cleft lip, seen from below. **(b)** Skin incisions. **(c)** Wide exposure of nasolabial and orbicularis oris muscle. **(d)** Lip closure highlighting improved nasal symmetry.

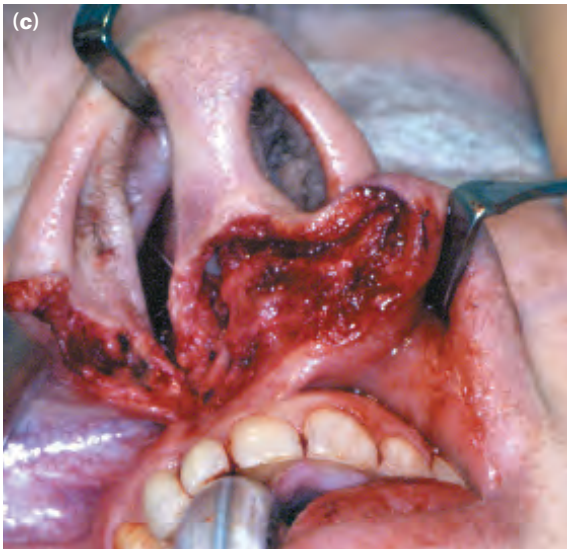
Indications for revision include:

- lip deformity:
  - malaligned vermilion;
  - asymmetrical Cupid's bow;
  - muscle discontinuity or malalignment;
- nasal deformity:
  - lateral drift of alar base;
  - poor nasal tip projection;
  - deviation of cartilaginous nasal septum into the non-cleft nostril.



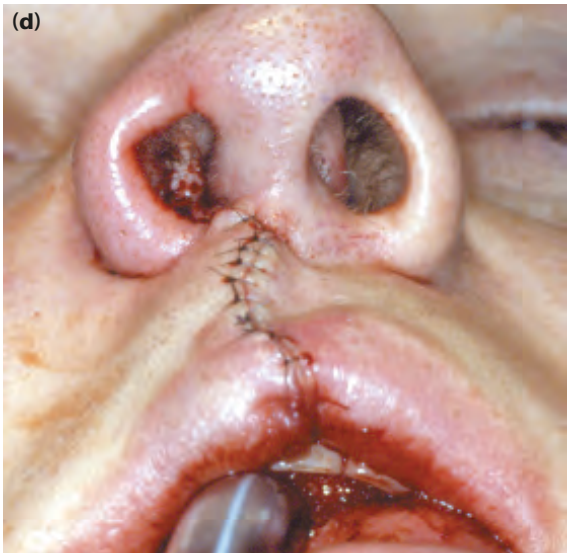


Figure 45.15 (*Continued*)

Figure 45.16 **(a)** Asymmetrical Cupid's bow. Revision of unilateral cleft lip – skin markings. **(b)** Identification and realignment of orbicularis oris muscle. **(c)** Postoperative appearance.

Residual nasal deformity is an external manifestation of incomplete reconstruction of the nasolabial muscle ring.

Examples of lip revision are shown in **Figures 45.15–45.18**.

Summary box 45.9

Cleft lip revisional surgery

- Should be delayed for at least 2 years after primary surgery
- Aims to improve incomplete primary reconstruction

Alveolar bone grafting

Alveolar bone grafting in a mixed dentition is a well-established procedure for patients with a residual alveolar cleft associated with cleft lip and palate. The rationale for performing alveolar bone grafting includes:

- stabilisation of maxillary segments;
- to promote eruption of the canine tooth into the cleft site;
- to enhance bony support of the teeth adjacent to the cleft alveolus;
- to promote closure of the oronasal fistula;
- to close residual fistula of the anterior palate;
- to provide adequate bone stock to receive an osseo-integrated dental implant where a tooth is congenitally absent.

Normally patients undergo a period of orthodontic treatment prior to bone grafting. The maxillary segment is expanded orthodontically (if necessary) to widen the cleft

alveolus. The surgery is best performed before the canine tooth erupts (between 8 and 11 years of age). Earlier bone grafting may be beneficial not only for the unerupted canine tooth but also to promote eruption and bony support to the adjacent central and lateral incisor when present. Alveolar bone grafting can also be performed simultaneously with secondary lip revision (Figure 45.19).

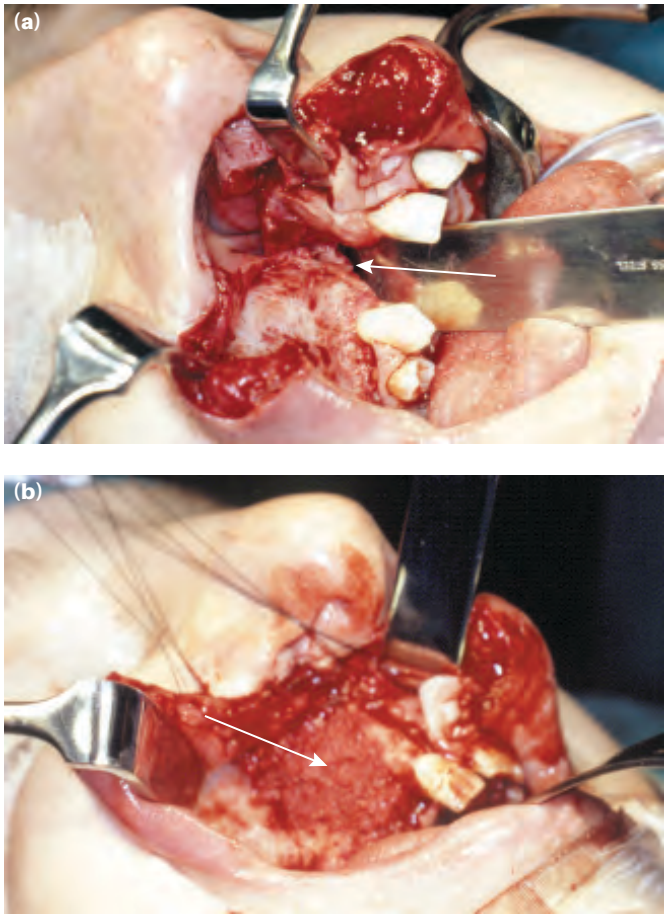

Figure 45.19 (a) Peroperative view of alveolar bone graft demonstrating defect in alveolus (arrow) (simultaneous lip revision). (b) Cancellous bone graft (arrow) packed into the defect.

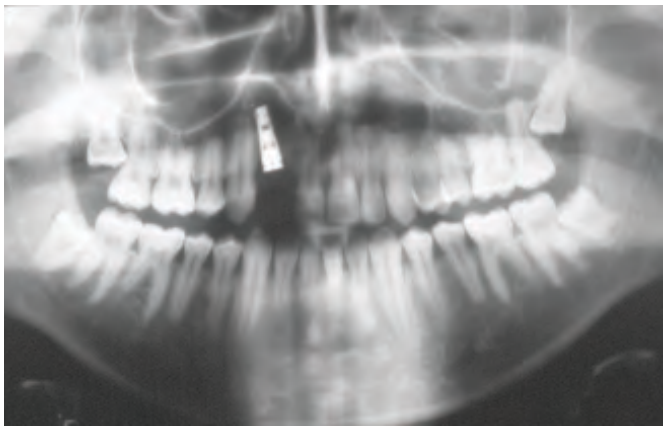

Figure 45.20 Radiographic appearance of an implant in an alveolar bone graft site.

Bone grafting is a highly successful procedure when carried out in experienced hands, with over 90% of patients achieving acceptable interdental alveolar bone height, but it does require the interaction of surgeon and orthodontist. When the lateral incisor is absent and the canine tooth fails to erupt, surgical exposure of the canine tooth may be required to aid its eruption. It is a fundamental principle that, following alveolar bone grafting, efforts should be made to ensure that a tooth erupts into the alveolar bone graft site. Failure to provide a tooth in the alveolar bone graft site usually results in bony resorption in the long term. This can be overcome by the insertion of an osseo-integrated implant into the grafted site, thereby preserving bone stock (Figure 45.20)

Orthognathic surgery

Impaired growth of the midface (maxilla) is now attributed to poor primary surgery. Surgical techniques must endeavour to minimise scarring, although in many cases patients also have a genetic predisposition to poor midfacial growth. Elective maxillary advancement or bimaxillary surgery is often indicated to restore aesthetics and dental occlusal harmony. Orthognathic surgery is usually performed when facial growth is complete (16–17 years in female patients, 17–19 years in male patients).

The principal dentofacial deformity associated with cleft lip and palate is underdevelopment in both the horizontal and vertical direction of the maxilla. This jaw size discrepancy can be corrected with orthognathic surgery (Figure 45.21)

Open septorhinoplasty

Following revisional cleft lip and palate surgery, orthognathic surgery and alveolar bone grafting, many patients still require definitive surgical nasal correction. In patients with cleft lip and palate, open rhinoplasty is preferred to gain access to the external cartilaginous framework, which is frequently deformed (Figure 45.22). The principal deformity is a collapse of the lower lateral cartilage on the cleft side together with a dislocation of the cartilaginous septum into the non-cleft nostril. The open method ensures adequate access and repositioning of the cartilaginous framework as a tertiary procedure to improve nasal tip projection, correct septal deformity and relocate alar cartilages. A postauricular onlay graft to the middle crus of the cleft nostril lower lateral cartilage may be required to enhance good nasal tip projection and symmetry.

Summary

The management of children with cleft lip and palate is complex, requiring the skill of a multidisciplinary team. Each team should include professionals who are appropriately qualified with specialist training, treating an adequate number of patients per year in centralised units. Meticulous record keeping of photography, radiology, dental casts and speech recordings are indispensable to permit regular audits and improve outcomes.

DEVELOPMENTAL ABNORMALITIES OF THE JAWS

Jaws

Disproportionate growth between the maxilla and mandible can occur, which results in derangement of the dental occlusion. The dental occlusion (the way in which the teeth bite and mesh together) can be classified into three different subtypes:

- class I: a normal relationship of upper and lower incisors and molar dentition;
- class II: the mandibular teeth are placed posterior to the maxillary teeth;
- class III: the mandibular teeth are placed anterior to the maxillary teeth.

This classification is usually, but not invariably, the consequence of aberrant skeletal development of the maxilla and mandible, such that in a class II condition there is usually underdevelopment of the mandible (mandibular retrognathia), whereas in a class III condition there may be simultaneous overgrowth of the mandible (mandibular prognathism) and underdevelopment of the maxilla (maxillary hypoplasia).

In the Caucasian population the most common deformity of the facial skeleton is underdevelopment of the mandible (retrognathia), producing a class II relationship often associated with excessive vertical growth of the maxilla. Bimaxillary protrusion is rare but is a characteristic of African races.

Condylar hyperplasia is an idiopathic condition seen in patients between 15 and 30 years of age, more common in women than men, in which there is hyperplasia or overgrowth of the neck of the mandibular condyle. This gives an asymmetrical growth to the jaw in both a vertical and horizontal plane.

Facial disproportionate growth is also a characteristic of many syndromes. Examples include:

- Treacher Collins syndrome;
- Crouzon syndrome;
- Apert syndrome;
- Pierre Robin sequence.

Orthognathic surgery

Orthognathic surgery is the term given to the surgical correction of deformities of the jaw. It is usually undertaken in close cooperation between orthodontic and maxillofacial surgeons. Surgery is directed at simultaneously changing the position of both maxilla and mandible at the end of the growth period. This is termed bimaxillary osteotomy. Treatment planning usually commences at the age of 12–13 years, in which the orthodontist aligns the dental arches in correct relation for each jaw. This frequently results in an accentuation of the facial deformity at the end of the orthodontic phase of treatment. Treatment normally takes 2 years, in which orthognathic surgery is performed towards the end of orthodontic treatment, although orthodontic treatment in the form of fixed appliances usually continues postoperatively for up to 6 months after surgery. Surgical planning should be meticulous and involves clinical examination and cephalometric assessment in the form of radiograph analysis, as well as study model analysis, working in close cooperation with maxillofacial technologists.

Orthognathic surgery is generally carried out through intraoral incisions, in which the upper and lower jaws are mobilised by achieving osteotomy cuts with saws and drills (**Figure 45.23**). Following mobilisation of the mandible and maxilla, the jaws are repositioned and held with titanium

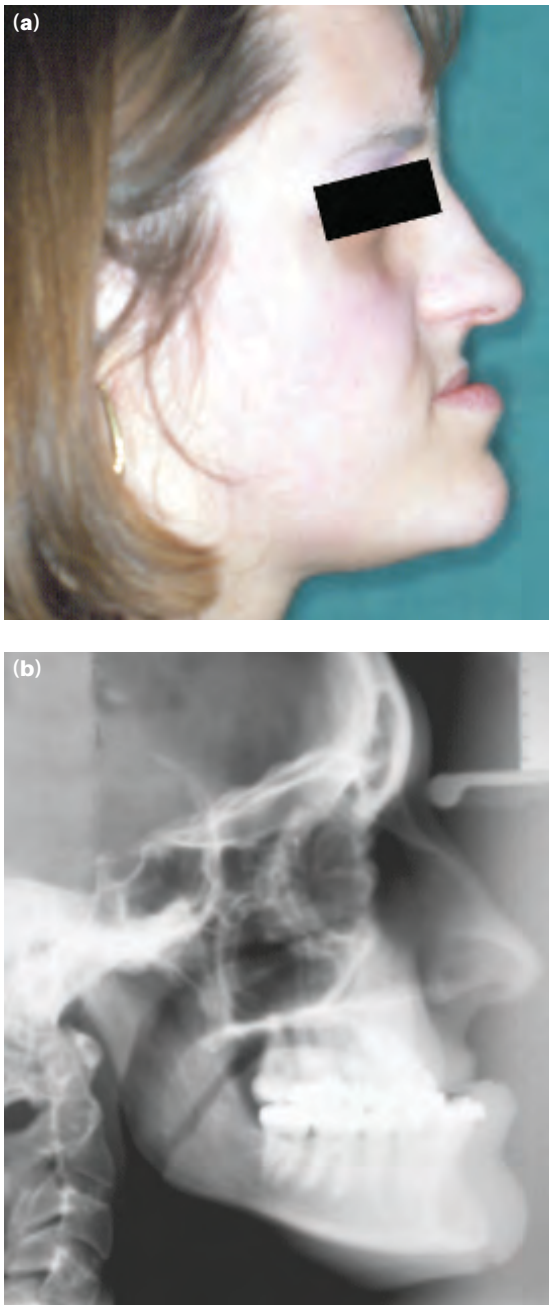

Figure 45.23 **(a)** Profile of class III skeletal relationship and maxillary hypoplasia and mandibular prognathism. **(b)** Lateral skull radiograph. (*Continued*)

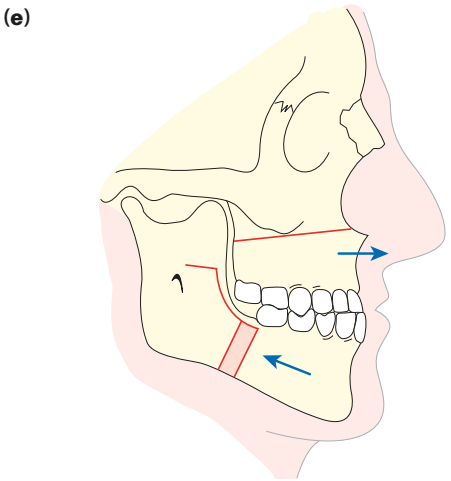

plates and screws placed through an intraoral approach. This frequently avoids the use of intermaxillary fixation and allows earlier function of the jaws as well as improved early dietary intake.

Patients with syndromic conditions such as hemifacial microsomia and Crouzon syndrome and Treacher Collins syndrome require the services of a craniofacial surgeon. As these syndromes are extremely rare, management and surgery should only be carried out in designated centres. The principal treatment is to correct the deformity from the cranium downwards, with correction of the cranial deformity within the first 3 years of life and correction of the residual midfacial and lower facial deformity in childhood and adolescence.

The use of distraction osteogenesis in the management of craniofacial deformity has reduced the requirements for major orthognathic surgery in patients with severe facial deformity.

Summary box 45.10

Principles of orthognathic surgery

- Orthodontist aligns the dental arches
- Surgery then corrects the jaw deformity

Chapter 46

The ear, nose and sinuses

Learning objectives

To be familiar with:

- The anatomy of the ear
- The conditions of the outer, middle and inner ear
- The examination of the ear including hearing tests
- The basic anatomy of the nose and paranasal sinuses
- The principles of managing post-traumatic nasal and septal deformity
- The causes and management of epistaxis

To understand that:

- The outer layer of the tympanic membrane migrates outwards
- The facial nerve can be damaged by trauma and ear disease
- Chronic ear disease can lead to intracranial sepsis
- There are two types of hearing loss: conductive and sensorineural
- The clinical features of sinus infection, its treatment and potential complications
- The diagnosis and management of chronic rhinosinusitis with and without nasal polyposis
- The common sinonasal tumours, their presentation, investigation and principles of treatment

INTRODUCTION

Disorders affecting the ear, nose and sinus are common reasons for primary care attendance; however, few surgeons will encounter such diseases in day to day practice. Nonetheless, traumatic, infective and neoplastic processes can impact on these organs and their anatomical proximity to critical anatomical structures demands a basic understanding in order to efficiently diagnose, refer and treat conditions. A full and detailed review of the management of ear and nose conditions is beyond the scope of this text. Instead, the aim of this chapter is to familiarise the reader with the basic anatomy and pathology relevant to patients who present with conditions affecting the ear, nose and sinuses.

THE EAR

The mammalian ear is an evolutionary masterpiece. Its highly complex 'three-dimensional anatomy' is best learnt by dissecting cadaver temporal bones.

The external ear

The external and middle ear develop from the first two branchial arches. The external ear canal is 3 cm in length; the outer two-thirds is cartilage and the inner third is bony. The skin on the lateral surface of the tympanic membrane is highly specialised and migrates outwards along the ear canal. As a result of this migration most people's ears are self-cleaning. The external canal is richly innervated and the skin is tightly bound down to the perichondrium so that swelling in this region results in severe pain.

The lymphatics of the external ear drain to the retroauricular, parotid, retropharyngeal and deep upper cervical lymph nodes.

The tympanic membrane and middle ear

The anatomy of the tympanic membrane and ossicles is shown in (Figure 46.1). The relations of the middle ear are important (Figure 46.2). The tympanic membrane and ossicles act as a transformer of vibrations in the air to vibrations within the fluid-filled inner ear.

The inner ear

The inner ear comprises the cochlea and vestibular labyrinth (saccule, utricle and semicircular canals). These structures are embedded in dense bone called the otic capsule.

The cochlea is a coiled shell of two and three-quarter turns. Within the cochlea is a spiral structure called the cochlear duct (Figure 46.3) containing endolymph that is partitioned by Reissner's membrane from the perilymph of the scala vestibuli, which joins the round window and the basement membrane from the perilymph of the scala tympani, which joins the oval window and stapes footplate. The endolymph has a

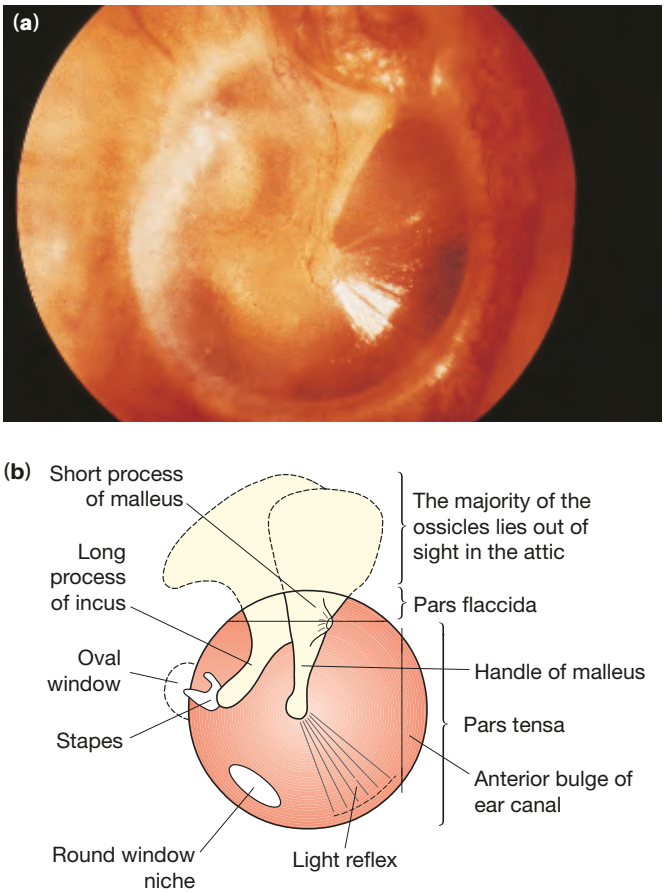

Figure 46.1 **(a)** Right tympanic membrane and **(b)** diagram to illustrate the anatomy of the tympanic membrane and ossicles (courtesy of Dr Christian Deguine).

high concentration of potassium, similar to intracellular fluid, and the perilymph has a high sodium concentration and communicates with the cerebrospinal fluid (CSF). Maintenance of the ionic gradients is an active process and is essential for neuronal activity.

There are approximately 15 500 hair cells in the human cochlea. They are arranged in rows of 3500 inner and 12 000 outer hair cells. The inner hair cells act as mechanicoelectric transducers, converting the acoustic signal into an electric impulse. The outer hair cells contain contractile proteins and serve to tune the basilar membrane on which they are positioned.

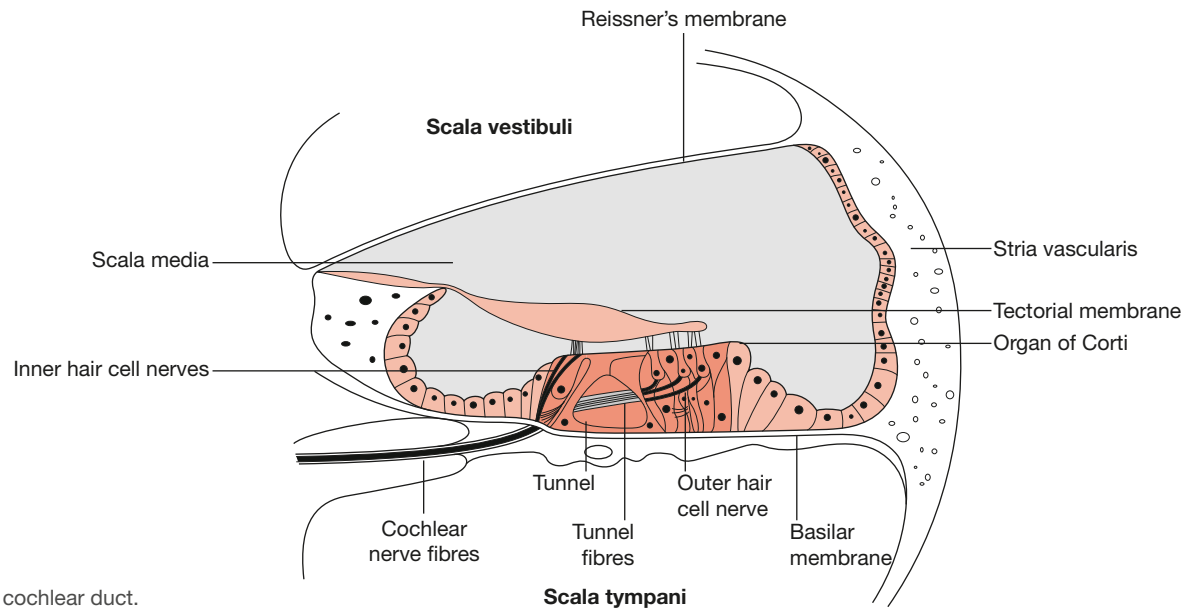

Figure 46.3 The cochlear duct.

Ernst Reissner, 1824–1878, Professor of Anatomy at Dorpat and later at Breslau, Germany (now Wroclaw, Poland), described the vestibular membrane of the cochlea in 1851.

Each inner hair cell responds to a particular frequency of vibration. When stimulated, it depolarises and passes an impulse to the cochlear nuclei in the brainstem.

The vestibular labyrinth consists of the semicircular canals, utricle and saccule and their central connections. The three semicircular canals are arranged in the three planes of space at right angles to each other. Like the auditory system, hair cells are present. In the lateral canals, the hair cells are embedded in a gelatinous cupula. Shearing forces, caused by angular movements of the head, produce hair cell movements and generate action potentials. In the utricle and saccule the hair cells are embedded in an otoconial membrane, which contains particles of calcium carbonate. These respond to changes in linear acceleration and the pull of gravity.

Impulses are carried centrally by the vestibular nerve and connections are made to the spinal cord, cerebellum and external ocular muscles. Its function is to record the position and movements of the head.

The sensory nerve supply

The external ear is supplied by the auriculotemporal branch of the trigeminal nerve (cranial nerve [CN] V) and the greater auricular nerve (C2/3), together with branches of the lesser occipital nerve (C2.) CNs VII, IX and X also supply small sensory branches to the external ear. The middle ear is supplied by the glossopharyngeal nerve (CN IX).

This complicated and rich sensory innervation means that referred otalgia is common and may originate from the normal area of distribution of any of the above nerves. A classic example is the referred otalgia caused by cancer of the larynx.

Taking a thorough history is the most important part of the assessment; the symptoms that need to be enquired after are listed in *Table 46.1*.

Summary box 46.1

Applied anatomy

- The skin on the outer surface of the eardrum migrates outwards so that the ear canal is 'self-cleaning'
- Infection of the middle ear and mastoid can easily spread to the cranial cavity
- The facial nerve pursues a tortuous course through the middle ear
- The ear has a rich sensory innervation so that 'referred otalgia' is common
- Cancer of the larynx can present with otalgia

Figure 46.4 Tools of the trade: a fibreoptic otoscope, with pneumatic attachment and a selection of specula. Also a 512 Hz tuning fork.

Figure 46.5 The correct method of holding the otoscope. Note the pinna is retracted to straighten the ear canal. Hold the barrel of the otoscope so that the examiner's little finger is balanced on the patient's cheek; this prevents the speculum impinging on the tympanic membrane in case of sudden movement.

EXAMINATION OF THE EAR

The instruments required for examination are shown in **Figure 46.4**. Examination of the ear is part of the general ear, nose and throat (ENT) examination. Rinne and Weber tuning fork tests are used to distinguish between a conductive and a sensorineural hearing loss. The correct way to hold an otoscope is shown in **Figure 46.5**.

The CNs and especially the function of the facial nerve should be examined. Although conversational testing can

Friedrich Heinrich Adolf Rinne, 1819–1868, otologist, Gottingen, Germany, described his test in 1855.
Friedrich Eugen Weber-Liel, 1832–1891, otologist, University of Berlin and Jena, Germany, described the operation of tenotomy of the tensor tympani used for certain forms of partial deafness.

give a useful guide to the level of hearing, pure tone audiometry in a soundproof booth is the best way of establishing the air and bone hearing levels (Figure 46.6). Other common audiological tests include speech audiometry, tympanometry, stapedial reflexes, electric response audiometry, otoacoustic emissions, caloric testing and electronystagmography (see Further reading).

Figure 46.6 Audiometry. The patient sits in a soundproof room and the audiologist presents sounds at different thresholds and records the responses.

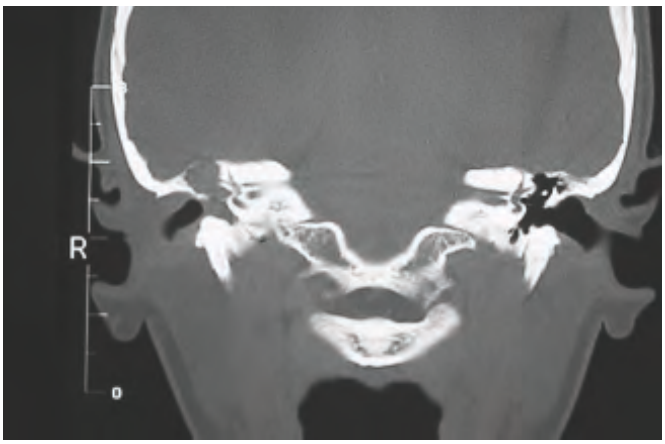

Figure 46.7 Computed tomography scan showing a normal left ear. The air-filled middle ear and the incus and stapes and the lateral and semicircular canals and internal acoustic meatus can be seen. In the right ear the entire middle ear and mastoid is opaque and filled with soft tissue. This is the typical appearance of a cholesteatoma.

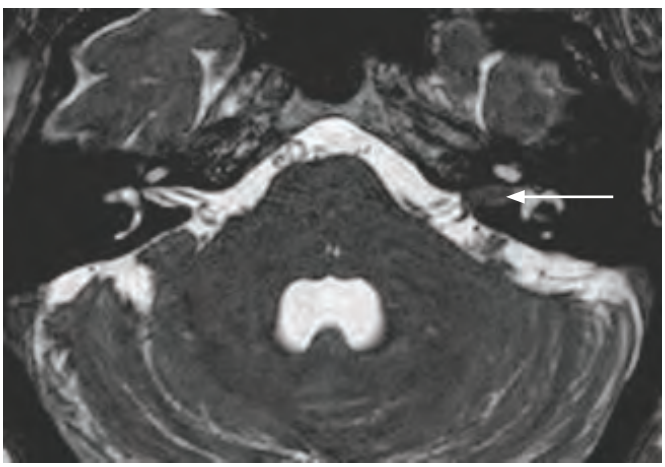

Figure 46.8 Computed tomography scan showing a vestibular schwannoma occluding the left internal acoustic meatus (arrow).

Radiological investigation

Computed tomography (CT) scanning of the temporal bones is commonly performed before mastoid surgery to show detailed individual anatomy, as well as alerting the surgeon to anatomical variants. Pus, bone and air are shown well on high-resolution CT (Figure 46.7).

Magnetic resonance imaging (MRI) is better than CT at imaging soft tissue (e.g. facial and auditory nerve) and is the best method for imaging tumours of the acoustic nerves (Figure 46.8). Diffusion-weighted MRI is also commonly used to detect recurrent cholesteatoma.

CONDITIONS OF THE EXTERNAL EAR

Congenital anomalies

The external and middle ear originate from the first and second branchial arches, but the cochlea is neuroectodermal in origin. An individual can have a congenital abnormality of the pinna and middle ear with a normal cochlea and therefore the potential for normal hearing.

Trauma

A haematoma of the pinna occurs when blood collects under the perichondrium. The cartilage receives its blood supply from the perichondrial layer and will die if the haematoma is not evacuated, resulting in a so-called cauliflower ear. A generous incision under anaesthetic, with a pressure dressing or compressive sutures and antibiotic cover, is recommended (Figure 46.9).

Figure 46.9 Haematoma of the pinna.

Foreign bodies in the ear canal are most easily removed at the first attempt by an experienced practitioner with the aid of a microscope. General anaesthesia may be required in children and those with learning difficulties. Batteries need to be removed within the hour (Figure 46.10).

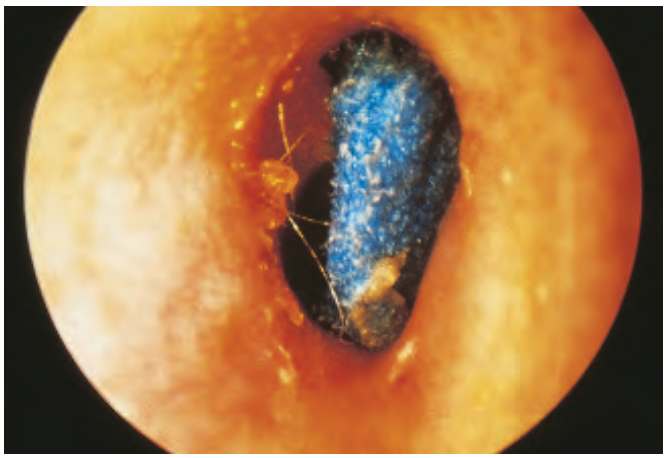

Figure 46.10 Removal of a foreign body from the ear canal can be a challenge (courtesy of Dr Christian Deguine).

Summary box 46.2

Trauma of the external ear

- A haematoma of the pinna requires thorough drainage, antibiotics and a compressive dressing or sutures
- Foreign bodies in the ear canal are most easily removed at the first attempt with the aid of a microscope
- Batteries need to be removed urgently

Inflammation and infection

Otitis externa is very common and consists of generalised inflammation of the skin of the external auditory meatus. The cause is often cotton bud use, moist enviroment, immunocompromise, allergies or skin disorders, such as psoriasis and eczema. Common pathogens are *Pseudomonas* and *Staphylococcus* bacteria, *Candida* and *Aspergillus*. Once the skin of the ear canal becomes oedematous, skin migration stops and debris collects in the ear canal. This acts as a substrate for the pathogens. Movement of the pinna elicits pain, which distinguishes it from otitis media.

The initial treatment is with a topical antibiotic and steroid ear drops together with analgesia. If this fails, meticulous removal of the debris with the aid of an operating microscope is required. Fungal infection can be recognised by the presence of hyphae within the canal (Figure 46.11). Fungal infection causes irritation and itch. The treatment is meticulous removal of the fungus and any debris, as well as stopping any concurrent antibiotics. Systemic antibiotics are rarely required for otitis externa but should be used if cellulitis of the pinna occurs (Figure 46.12).

Necrotising otitis externa is a rare but important condition. It presents as a severe, persistent, unilateral otitis

Figure 46.11 Fungal otitis externa. Note the spores.

Figure 46.12 Cellulitis of the pinna.

Summary box 46.3

Types of otitis externa

- Acute bacterial otitis externa is very common and painful; treat with topical steroid and antibiotic drops
- Systemic antibiotics should be reserved for cellulitis of the pinna
- Chronic otitis externa needs the underlying dermatitis to be treated
- Fungal otitis externa itches and can be diagnosed by the presence of hyphae and spores; treat with meticulous cleaning and stop antibiotics
- Necrotising otitis externa is a progressive skull base infection that occurs in immunocompromised individuals and can be life-threatening; intensive long-term antibiotic treatment is required

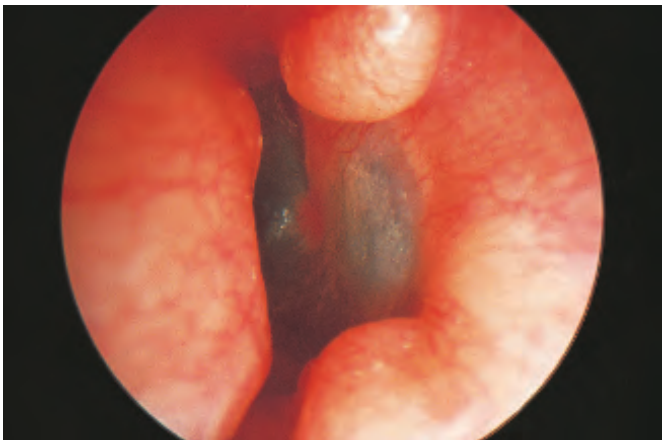

Figure 46.13 Exostoses grow from the bony part of the ear canal in response to cold and so are found in swimmers, surfers and divers. Treatment is only required if the exostoses occlude the ear canal.

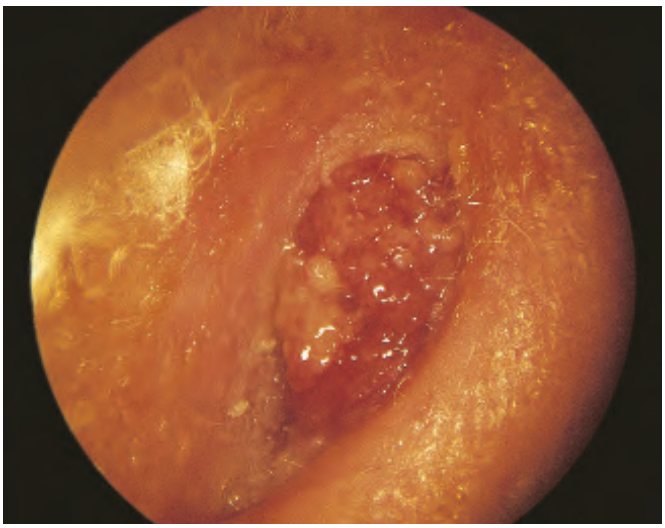

Figure 46.14 Squamous cell carcinomas of the external ear usually originate from the pinna. In this case the tumour is growing from the canal (courtesy of Mr P Beasley).

externa possibly with facial weakness in an immunocompromised individual (e.g. elderly diabetic patient). Usually the infecting organism is *Pseudomonas aeruginosa*. Osteomyelitis of the skull base may result in lower CN palsy (VII–XII). Intensive systemic antibiotics are required and the disease process should be monitored by high-resolution imaging.

Neoplasms

Exostosis is an area of hyperostosis rather than a neoplasm that arises from the bone of the ear canal in individuals who swim in cold water (syn: 'surfer's ear') (**Figure 46.13**). No treatment is required unless the exostosis obstructs the canal. Osteomas are true neoplasms, often singular and more lateral than exostosis. Other benign tumours include papillomas and adenomas.

Malignant primary tumours of the external ear are either basal cell or squamous cell carcinomas (**Figure 46.14**). Both may present as ulcerating or crusting lesions that grow slowly and may be ignored by elderly patients. Squamous cell carcinomas metastasise to the parotid and/or neck nodes. The ear canal may be invaded by tumours from the parotid gland and postnasal space carcinomas, which 'creep' up the Eustachian tube. All resectable malignant tumours of the ear are treated primarily with surgery, with or without the addition of radiation therapy.

CONDITIONS OF THE MIDDLE EAR

Congenital anomalies

Aural atresia and congenital anomalies of the middle ear occur in 1/10000 to 1/20000 births and are typically unilateral and nonsyndromal but may be associated with other branchial arch syndromes (e.g. Pierre Robin, craniofacial dysostosis, Down's and Treacher Collins syndromes).

Trauma

Trauma to the middle ear can result in a perforated tympanic membrane (**Figure 46.15a**). 90% of such perforations heal spontaneously with 6 weeks (**Figure 46.15b**). Trauma can also result in ossicular discontinuity and it is usually the incus that is displaced. Damaged ossicular chain and tympanic membrane are repaired by ossiculoplasty or tympanoplasty, respectively.

Summary box 46.4

Congenital anomalies and trauma of the middle ear

- Congenital anomalies may be isolated or associated with general congenital deformities
- Traumatic perforations of the tympanic membrane usually heal spontaneously but explosive and welding injuries do not
- A myringoplasty is an operation that repairs the tympanic membrane
- With severe head trauma the incus can be displaced, which leads to a conductive hearing loss

Acute otitis media

Acute otitis media (AOM) occurs in 70% of children by the age of 2 and 90% by the age of 6. It is characterised by purulent fluid in the middle ear. The tympanic membrane bulges

Bartolomeu Eustachio (Eustachius), 1513–1574, Professor of Anatomy, appointed physician to the Pope in 1547.
John Langdon Haydon Down, (sometimes given as Langdon-Brown), 1828–1896, physician, The London Hospital, London, UK, published the classification of ailments in 1866.
Edward Treacher Collins, 1862–1932, ophthalmic surgeon, The Royal London Ophthalmic Hospital and Charing Cross Hospital, London, UK, described this syndrome in 1900.

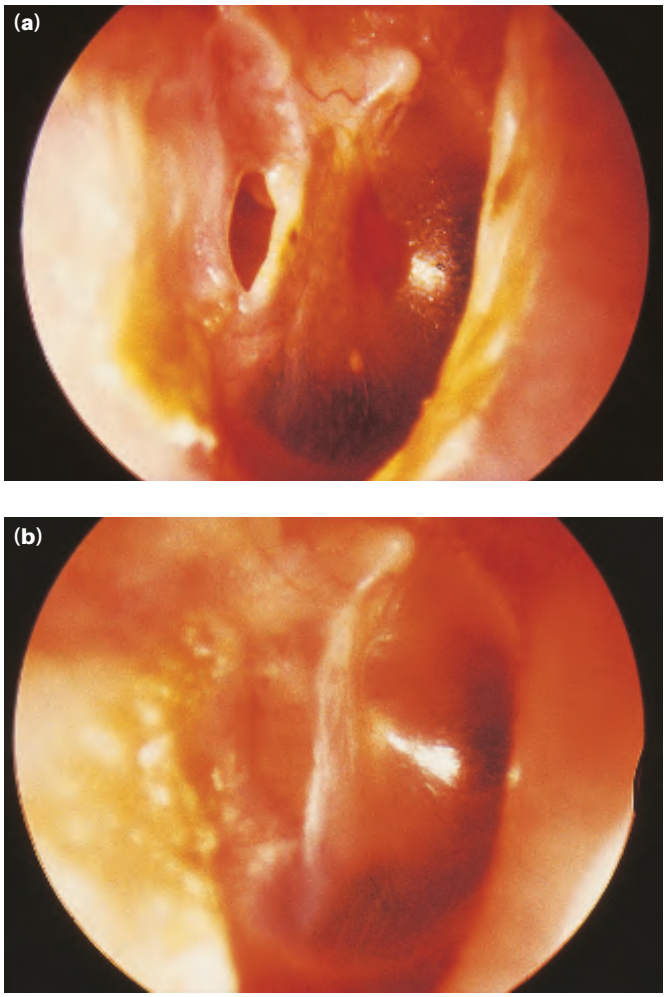

Figure 46.15 **(a)** Traumatically perforated tympanic membrane. **(b)** The same tympanic membrane 2 days later (courtesy of Dr Christian Deguine). (Reproduced from O'Donoghue GM, Bates GJ, Narula A (1991) *Clinical ENT*, with permission from Oxford University Press, Oxford.)

because of pressure from the pus in the middle ear (**Figure 46.16**). The child suffers extreme pain until the tympanic membrane bursts. The most common infecting organisms are *Streptococcus pneumoniae* and *Haemophilus influenzae*. Treatment is with analgesics and antipyretics. Systemic antibiotics should be reserved for children under 2 with bilateral disease or those with other risk factors for complications

Complications are rare, but can be categorised as: intratemporal – otitis media with effusion, chronic otitis media, mastoiditis, facial palsy and labyrinthitis; extratemporal extradural such as abscess; extratemporal intradural such as meningitis, intracranial abcess and sigmoid sinus thrombosis.

The most common complication is mastoiditis because the mastoid air cells connect freely with the middle ear space. Mastoiditis (**Figure 46.17**) requires hospital admission for intravenous antibiotics and to monitor for complications. If complications arise or the infection does not resolve quickly, a cortical mastoidectomy is required, which decompresses the mastoid cavity, together with a myringotomy and grommet insertion to ventilate the middle ear space.

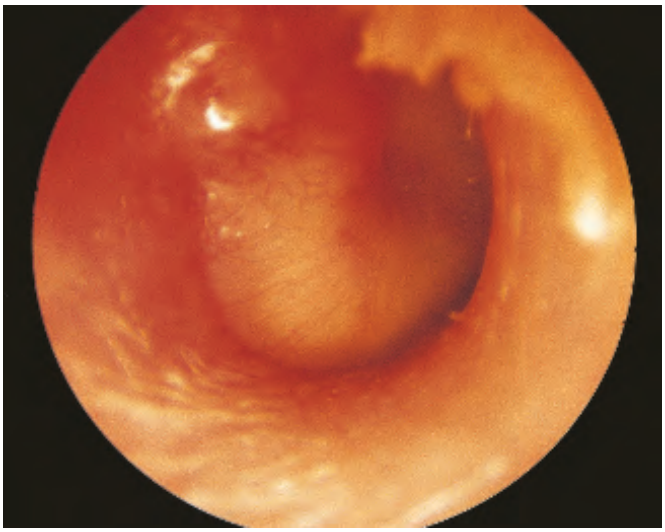

Figure 46.16 Acute otitis media of the left ear. Note the bulging tympanic membrane.

Figure 46.17 Child with acute mastoiditis whose tympanic membrane is shown in Figure 46.16.

Otitis media with effusion (glue ear)

Otitis media with effusion (OME) is a middle ear effusion with no evidence of infection. It has a bimodal incidence affecting 40% of 2 year olds and 20% of 5 year olds mainly in the winter months, suggesting an infective aetiology. Infection and inflammation of the immature Eustachian tube results in poor middle ear ventilation, negative pressure and the transudation of fluid.

The following symptoms may be associated with glue ear:

- hearing impairment, which often fluctuates;
- delayed speech;
- behavioural problems;
- recurrent ear infections (the exudate is an ideal culture medium for microorganisms);
- reading and learning difficulties at school.

Otoscopic findings with glue ear

The otoscopic findings of exudative glue ear are of a dull drum that is immobile on pneumatic otoscopy. The tympanic membrane is retracted and radial blood vessels may be present (Figure 46.18).

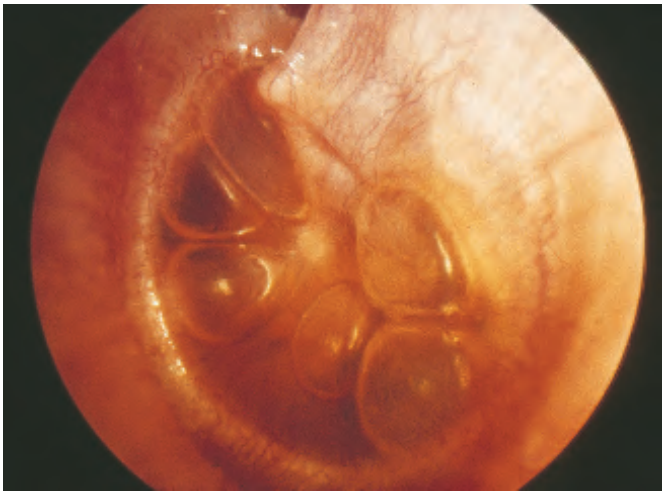

Figure 46.18 The initial serous transudate of glue ear, left ear (courtesy of Dr Christian Deguine). (Reproduced from O'Donoghue GM, Bates GJ, Narula A (1991) *Clinical ENT*, with permission from Oxford University Press, Oxford.)

In children first presenting with bilateral glue ear, 50% will be better within 12 weeks, therefore a 'wait and watch' policy is appropriate. If a bilateral conductive hearing loss persists, there is some evidence of reduced IQ and behaviour changes. However, speech delays are reversed by age 8.

Medical treatment is of limited value. Valsalva manouvres and the Otovent® device (Figure 46.19) are worth trying for patients old enough to comply in an attempt to improve Eustachian tube function. Surgical insertion of ventilation tubes (grommets) (Figure 46.20) and adenoidectomy are effective and should be discussed if there is no resolution after a period of watchful waiting. A middle ear effusion in adults is often associated with an upper respiratory tract infection. A persistent unilateral effusion in an adult requires examination of the postnasal space to exclude obstructive nasopharyngeal carcinoma, which is the most common carcinoma in men in southern China.

Summary box 46.5

Acute otitis media and otitis media with effusion

- Acute otitis media is very common but rarely associated with severe complications such as mastoiditis
- OME is very common in children and usually resolves without treatment
- Persistent OME and/or recurrent AOM is best treated with grommets and/or adenoidectomy
- A persistent middle ear effusion in an adult may be caused by a cancer of the postnasal space, especially in Chinese and Asian races

Figure 46.19 Otovent® device.

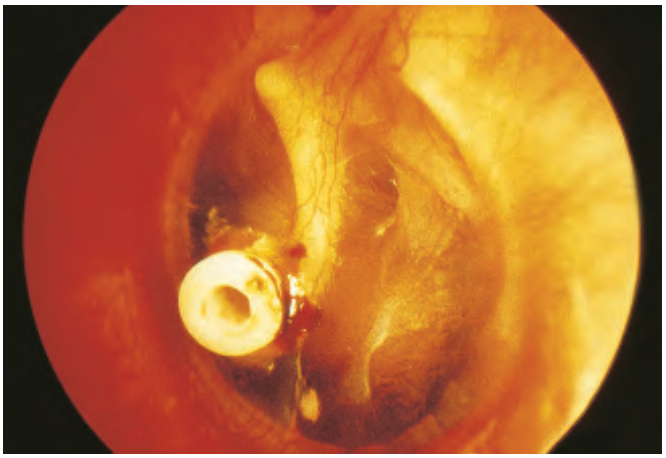

Figure 46.20 Ventilation tube in tympanic membrane, left ear (courtesy of Dr Christian Deguine).

Chronic otitis media

Chronic otitis media (COM) is a permenant abnormality of the tympanic membrane from previous recurrent AOM and/or OME. It is classified as active (i.e. inflamation and pus present) or inactive. Active and passive are then further subclassified as mucosal or squamous (Figure 46.21)

Active mucosal COM implies a perforation with otorrheoa (ear discharge) due to inflamed middle ear mucosa with or without granulation tissue. Inactive mucosal COM implies a dry perforation without inflamation. Surgery in the form

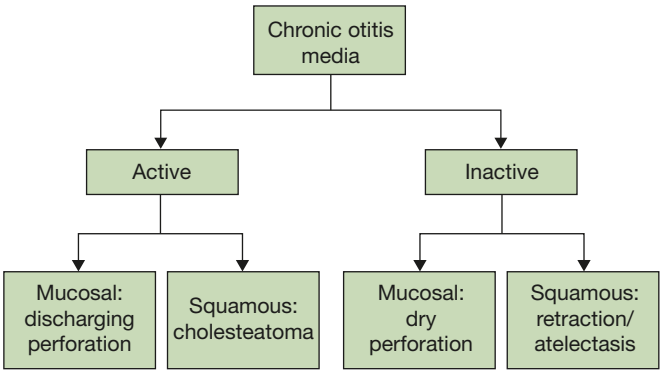

Figure 46.21 Classification of chronic otitis media.

of tympanoplasty (repair of the perforation) is indicated in patients getting recurrent infection (to reduce symptoms of otorrheoa and prevent further deterioration of the hearing due to the ototoxic effects of infection) and where there is a likelyhood that it will restore hearing in the operated ear to 30 dB or better or to within 15 dB of the contralateral ear (this is known as the Belfast rule of thumb).

Active squamous COM is otherwise known as cholesteatoma and usually presents with persistent otorrheoa and hearing loss as a result of keratinising squamous epithelium within the middle ear. The cholesteatoma matrix destroys the structures in its path through the release of lytic enzymes, inflammatory mediators and pressure necrosis. If left, there is a risk of all the complications attributable to AOM. The lifetime risk of intracerebral abscess is 1/200 in a 30-year-old patient. The recommended treatment is mastoid surgery using a drill under microscopic or endoscopic guidence to access and remove the cholesteatoma. Often the ossicles are involved or eroded so an ossiculoplasty (to restore hearing by reconstructing the ossicular chain) is performed at the same time.

Otosclerosis

This is an autosomal dominant condition of variable penetrance in which excess bone is laid down around the footplate of the stapes, impeding mobility of the stapes and resulting in a conductive hearing loss (**Figure 46.22**). A diagnosis should be suspected in any patient with a conductive hearing loss and a normal tympanic membrane.

The treatment options are simple reassurance, a convetional hearing aid, a stapedotomy operation or bone conduction hearing aid (**Figure 46.23**).

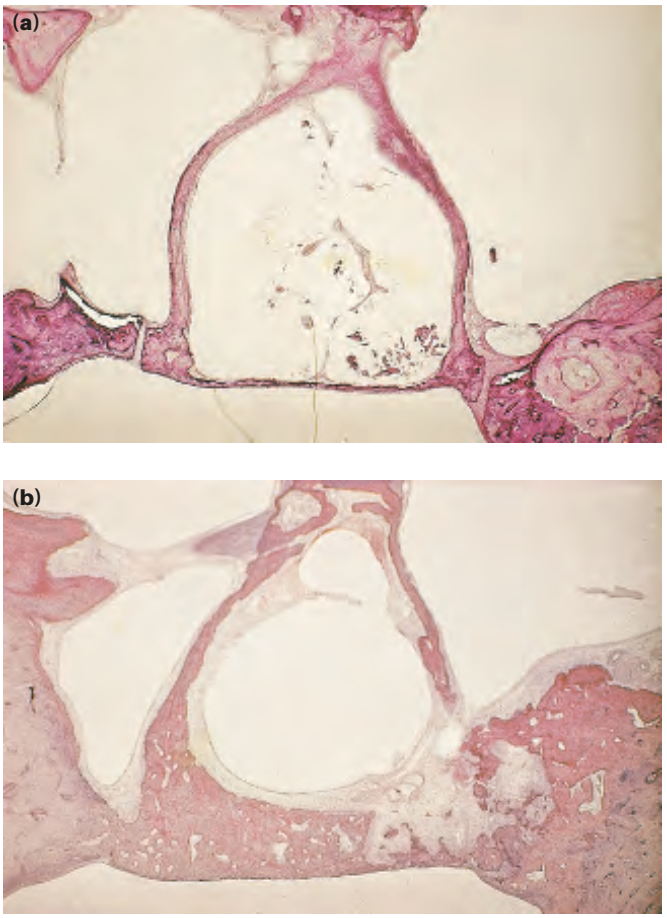

Figure 46.22 Section of normal stapes **(a)** and section of stapes affected by otosclerosis **(b)**.

Neoplasms

Middle ear tumours are rare with the most common being a glomus tumour (**Figure 46.24**). Glomus tumours arise from nonchromaffin paraganglionic tissue. The carotid body tumour arising in the neck is an example of this type of tumour. In the temporal bone, three types of glomus tumour are recognised and classification depends on the location: glomus tympanicum (arising in the middle ear), glomus jugularae (arising next to the jugular bulb) and glomus vagale (skull base).

Symptoms include pulse synchronous tinnitus, conductive and sensorineural hearing loss, and lower cranial nerve palsies. Palsies of CNs VII, IX, X, XI and/or XII may occur. The classic sign is a cherry-red mass lying behind the tympanic membrane. The treatment of choice is preoperative embolisation followed by surgical excision. Radiotherapy is also effective.

Squamous cell carcinoma may also occur within the middle ear. It usually presents with deep-seated pain and a blood-stained discharge. Facial paralysis often occurs. Squamous carcinomas usually arise in a chronically discharging ear and can arise in a chronically infected mastoid cavity. Radical surgical excision with or without radiotherapy provides the only chance of cure.

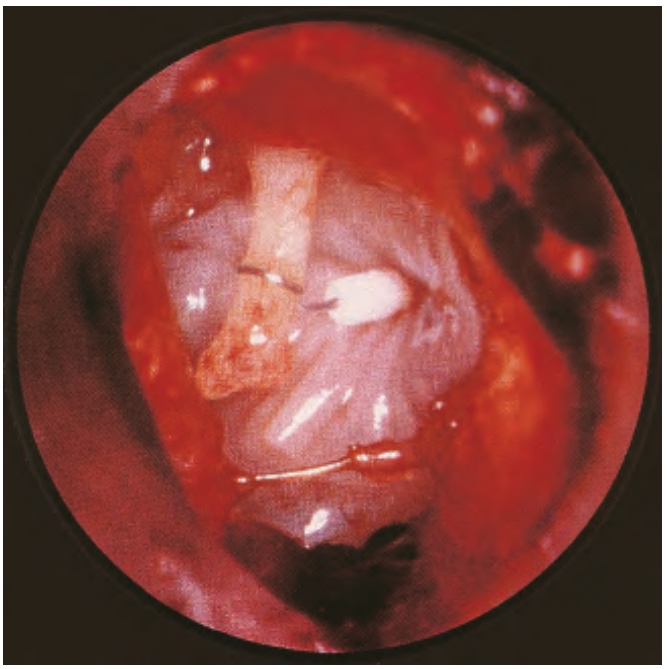

Figure 46.23 The stapedotomy operation showing the piston linking the incus to the vein graft, left ear.

Figure 46.24 Glomus tumour in the middle ear, left ear.

Figure 46.25 Evoked-response audiometry. A simple non-invasive objective test of hearing thresholds. (Reproduced from O'Donoghue GM, Bates GJ, Narula A (1991) *Clinical ENT*, with permission from Oxford University Press, Oxford.)

Summary box 46.6

Neoplasms of the middle ear

- Highly vascular glomus tumours are rare and may present with pulsatile tinnitus
- Squamous cell cancer usually presents with pain and facial paralysis

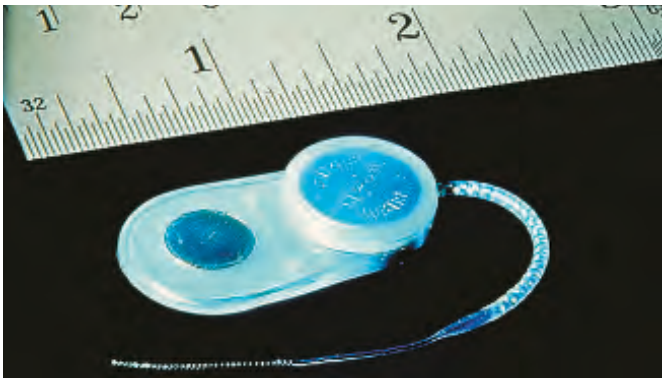

Figure 46.26 Multichannel cochlear implant (Cochlear Corporation).

CONDITIONS OF THE INNER EAR

Congenital sensorineural hearing loss

Half of congenital sensorineural hearing loss is genetic and half is aquired. Of the genetic hearing loss 75% is non-syndromic, of which the most common is a connexin 26 gene mutation. Syndromic causes include Usher, Pendred, Jervell and Lange-Nielsen, Waardenberg, Treacher Collins, Alport, Stickler neurofibromatosis type 2 and branchio-oto-renal syndromes.

Aquired causes are intrauterine infections, including rubella, toxoplasmosis and cytomegalovirus infection; perinatal hypoxia, jaundice and prematurity; and postnatal meningitis

All newborn babies in the UK are now screened at birth for deafness by measuring otoacoustic emisions in response to 'clicks' in the ear. Children failing this are referred for auditory brainstem response to establish hearing thresholds (**Figure 46.25**). If some hearing is present, the early fitment of hearing aids can maximise the neural plasticity that is present in the developing brain. If a child has a profound hearing loss, early intervention with a cochlear implant is essential for the development of the auditory cortex (**Figure 46.26**). Most cases of profound sensorineural hearing loss are due to loss of cochlear hair cells, so an implant inserted through the round window can selectively stimulate the cochlear neurones, which usually remain intact.

Presbycusis

Presbycusis is characterised by a gradual loss of hearing in both ears, with or without tinnitus. The hearing loss usually affects the higher frequencies and a classical audiogram is shown in **Figure 46.27**. The consonants of speech lie within the high-frequency range, which makes speech discrimination difficult.

Many patients with presbycusis are concerned that they may lose their hearing completely and they need reassurance.

Charles Howard Usher, 1865–1942, ophthalmologist Aberdeen Royal Infirmary, Aberdeen, UK.
Vaughan Pendred, 1869–1946, general practitioner, Durham, UK.
Anton Jervell, 1901–1987, physician, University of Oslo, Norway.
Fred Lange-Nielsen, 1919–1989, physician and jazz musician, Oslo, Norway.
Petrus Johannes Waardenburg, 1886–1979, ophthalmologist, Utrecht, Nederlands.
Arthur Cecil Alport, 1880–1959, Professor of Medicine, King Faud I Hospital, University of Cairo, Egypt.
Gunnar B Stickler, 1925–2010, paediatrician, Mayo Clinic, USA.

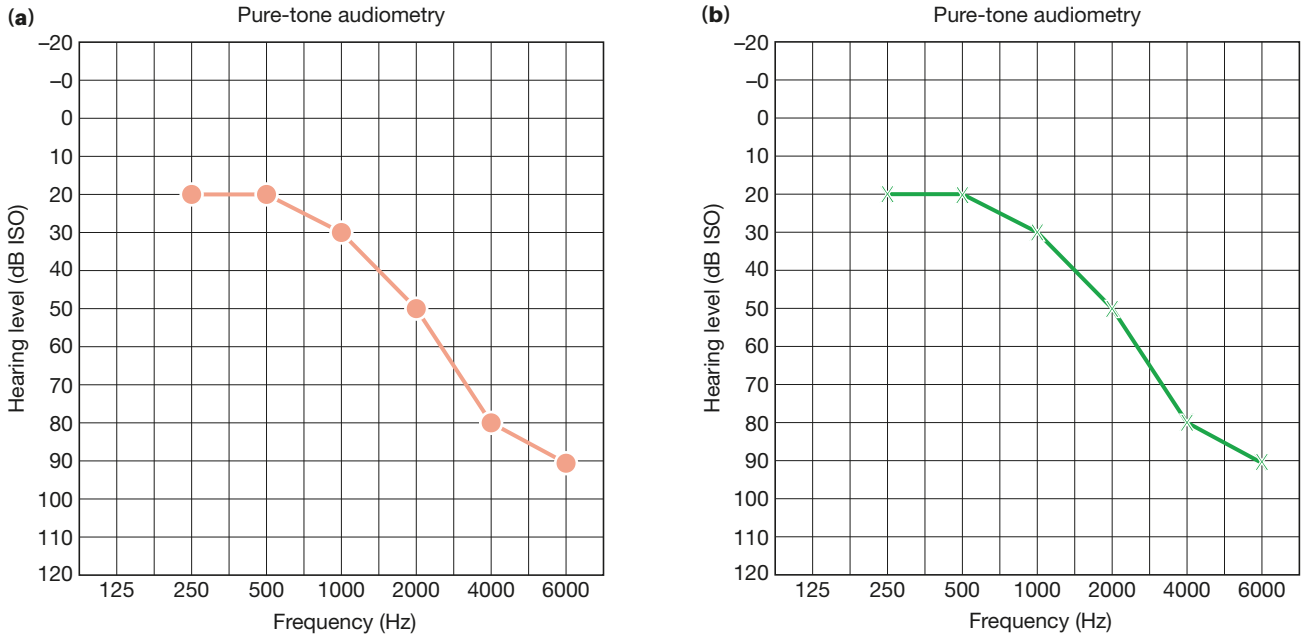

Figure 46.27 Typical audiogram of presbycusis: **(a)** right ear; **(b)** left ear.

Hearing aid technology has improved dramatically over recent years and most patients can derive benefit (Figure 46.28).

Figure 46.28 Modern hearing aid.

Tinnitus

Tinnitus is the perception of sound when no external sound source is present. It may have an extrinsic cause; for example, the pulsatile tinnitus of a glomus tumour. Usually, however, the tinnitus is generated within the internal auditory pathway. Thirty per cent of people will experience tinnitus at some time in their lives. Tinnitus frequently accompanies presbycusis, as well as any other condition that affects hearing. Most individuals habituate to the presence of tinnitus but in some patients it proves intrusive. Treatment is with reassurance, masking and hearing aids (for patients with hearing loss).

Sudden sensorineural hearing loss

Defined as >30 dB sensorineural hearing loss at 3 frequencies within 3 days. History and examination should focus on a cause, which may be infective, neoplastic, traumatic, ototoxic, neurological or autoimmune. Investigations such as MRI are important (1% of acoustic neuromas present as sudden sensorineural hearing loss) but screening blood tests are of low yield where there is nothing in the history to suggest a cause. Sixty per cent are idiopathic and the recommended treatment is oral +/- intratympanic steroids with salvage intratympanic steroids for those that do not recover after a month.

Trauma

Noise exposure

Hair cells within the cochlea are damaged by sudden acoustic trauma (blast injury or gunfire) or prolonged exposure to excessive noise. The sensorineural hearing loss that results is greatest between 3 and 6 KHz and is often accompanied by tinnitus (Figure 46.29). The law in the UK requires that workers are protected from noise

Head injury

The otic capsule is the hardest bone in the body but, if trauma to the head is severe, temporal bone fractures may occur. These are traditionally described as either longitudinal (80%) or transverse (20%); however, the majority have longitudinal and transverse components. Longitudinal fractures may lead to fracture of the external auditory canal, conductive hearing loss and CSF otorrhoea. Transverse fractures may involve the

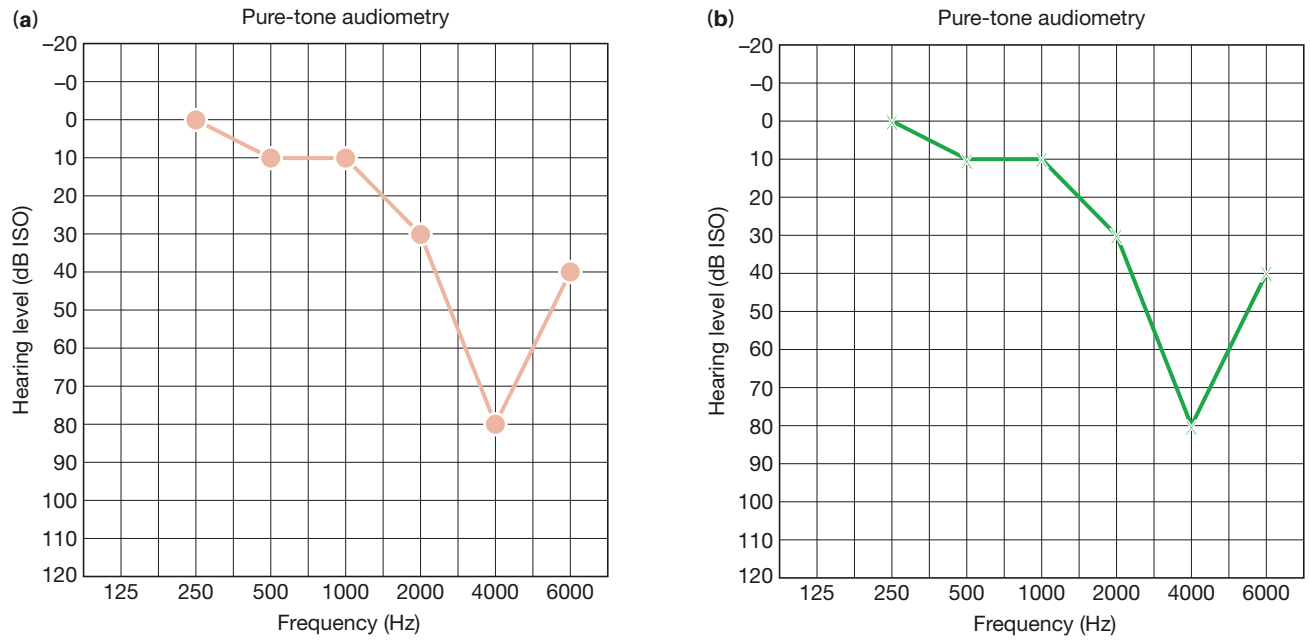

Figure 46.29 A typical audiogram of noise damage: **(a)** right ear; **(b)** left ear.

facial nerve leading to palsy and labyrinth leading to a sensorineural hearing loss that is permanent. Profound vertigo occurs initially, followed by gradual compensation.

Drug ototoxicity

Antibiotics such as aminoglycosides, vancomycin and erythromycin, loop diuretics such as frusemide, chemotherapy agents such as cisplatin and carboplatin, and salicylates such as aspirin and quinine are all ototoxic. Recognition of risk factors, such as poor renal function in patients being treated with aminoglycosides, is therefore important. Although many topical ear drops contain aminoglycosides, there is little evidence that short periods of topical treatment cause sensorineural hearing loss

Balance disorders

Vertigo is the halucination of movement.

Benign paroxysmal positional vertigo

Benign paroxysmal positional vertigo (BPPV) is the most common form of vertigo. It is caused by otoliths (calcium carbonate crystals) within the posterior semicircular canal abnormally triggering the ampullary hair cells. Typically, the vertigo is triggered by turning, only lasts for a few seconds and is not associated with other otological symptoms. A positive Hallpike test confirms the diagnosis. The condition is usually self-limiting but recovery may be expediated by an Epley manoeuvre.

Vestibular neuronitis

Infection or inflamation of the supererior vestibular nerve, often caused by a upper respiratory or chest infection, results in persistent vertigo lasting a few days. If the hearing is also affected, this is known as labrinthitis. Treatment is supportive with vestibular sedatives such as prochlorperazine in the first week followed by early mobilisation. There is emerging evidence for systemic steroids as well.

Menière's disease

It has been said that not only can clinicians not agree on the cause of Menières disease, they cannot even agree on the spelling. There is certainly evidence of endolymphatic hydrops (long-standing high pressure changes within the inner ear) in pathological specimens of patients who have had the condition. The condition is characterised by a triad of symptoms: intermittent attacks of vertigo, a unilateral fluctuating sensorineural hearing loss and tinnitus. The patient often has a sensation of pressure in the affected ear before an attack. The hearing loss typically affects the lower frequencies. The vertigo characteristically lasts between 30 minutes and 6 hours and is often accompanied by nausea and vomiting. The investigations include pure tone audiometry and an MRI scan to exclude an acoustic neuroma. The only evidence-based treatment is intratympanic therapy whereby repeated injections of dexamethasone or gentamicin are given into the middle ear. Traditional medical treatment starts with a low salt diet, betahistadine and diuretics, but this is not evidence based

Charles Skinner Hallpike, 1900–1979, aural surgeon, National Hospital for Neurology and Neurosurgery, Queen Square, London, UK.
John W Epley, contemporary, Director, Portland Otology Clinic, Portland, Oregon, USA, established his clinic in 1975; he developed the Epley manoeuvre for treating benign paroxysmal positional vertigo (BPPV).
Prosper Menière, 1799–1862, physician, The Institute of Deaf Mutes, Paris, France, described this condition in 1861.

Vestibular migraine

Five times more prevalent than Menière's disease, this condition presents with similar symptoms but without the hearing loss or tinnitus. It is thought that the migrainous process affects the labyrinth and therfore treatment is along the lines of migraine management, with attention paid to risk factors such as dietary triggers, and prophlatic medication such as propranolol, tricyclic antidepressants and antiepileptic medication.

Facial paralysis

Seventy-five per cent of all facial palsies are due to Bell's palsy. This probably results from a herpes simplex viral infection of the facial nerve. The nerve swells and is compressed within the temporal bone. Early treatment with high-dose steroids and eye protection is mandatory. Not all facial nerve palsies are due to viral infection and a thorough otoneurological examination is required. The facial nerve can be damaged at the cerebellopontine angle, within the internal auditory meatus, within the middle ear, at the skull base and within the parotid gland. It is essential to consider these potential sites of facial nerve damage in any patient with CN VII paralysis and perform an MRI scan if appropriate.

Summary box 46.7

Facial paralysis

- The facial nerve passes through the middle ear and mastoid
- When considering a paralysis, think 'complete' or 'partial'
- Protect the eye: carry out a full otoneurological examination to find the cause
- If acute, consider steroids

Ramsay Hunt syndrome

This is caused by herpes zoster virus and is characterised by facial paralysis, pain and the appearance of vesicles on the tympanic membrane, ear canal, pinna or inside of the cheek (Figure 46.30). It ay be accompanied by vertigo and sensorineural hearing loss (CN VIII). Treatment with aciclovir is effective if given early.

Neoplasms

These are uncommon but can present with sensorineural hearing loss, tinnitus and vertigo. Acoustic neuromas, which are actually schwannomas of the vestibular division of CN VIII, are the most common, followed by meningiomas. Acoustic

Figure 46.30 Herpes zoster infection of cranial nerve (CN) VII (a) and CN VIII (b) with vesicles on the pinna.

Sir Charles Bell, 1774–1842, surgeon, The Middlesex Hospital, London, UK, and from 1835 until his death, Professor of Surgery, The University of Edinburgh, Edinburgh, UK

James Ramsay Hunt, 1874–1937, Professor of Neurology, The Columbia College of Physicians and Surgeon, New York, USA.

neuromas grow slowly and somewhat unpredictably and as they expand can cause CN palsies, brainstem compression and raised intracranial pressure. The early symptoms are a unilateral sensorineural hearing loss or unilateral tinnitus, or both. Therefore, it is essential to perform an MRI on all patients with persistent unilateral sensorineural hearing loss or tinnitus. Relatively asymptomatic acoustic neuromas that are less than 2 cm in diameter and growing less than 2 mm a year (70%) are generally treated with a 'watch, wait and rescan' policy or occasionally stereotactic radiotherapy. Tumour volumes greater than 2 cm in diameter are often best treated by skull base surgery in the form of a translabyrinthine, retrolabyrinthine or middle fossa approach.

Summary box 46.8

Conditions of the inner ear

- Presbycusis is the bilateral high-frequency loss associated with ageing
- Unilateral tinnitus or sensorineural hearing loss needs to be investigated to exclude acoustic neuroma
- Sudden sensorineural hearing loss needs immediate treatment with steroids and routine MRI to exclude acoustic neuroma
- Menière's disease presents with the triad of sensorineural hearing loss, tinnitus and vertigo

THE NOSE AND SINUSES

BASIC ANATOMY OF THE NOSE AND PARANASAL SINUSES

The supporting structures of the nose are shown in Figure 46.31. The septum consists of the anterior quadrilateral cartilage, the perpendicular plate of the ethmoid and the vomer (Figure 46.32). The lateral wall of the nasal cavity contains the superior, middle and inferior turbinates, which warm and moisten nasal airflow (Figure 46.33). There are paired frontal, sphenoid, maxillary and anterior and posterior ethmoid sinuses. The anterior nasal sinuses (frontal, maxillary and anterior ethmoid) drain into the middle meatus (between the middle turbinate and lateral wall of nose). The posterior ethmoid and sphenoid sinuses drain into the superior meatus and sphenoethmoidal recess (between the superior turbinate and nasal septum), respectively (Figures 46.34 and 46.35).

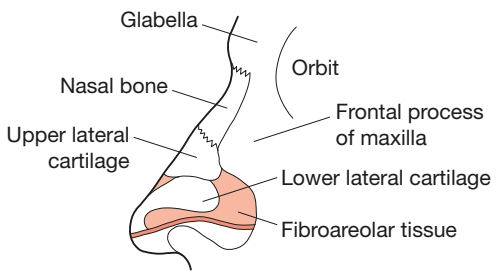

Figure 46.31 The nasal skeleton.

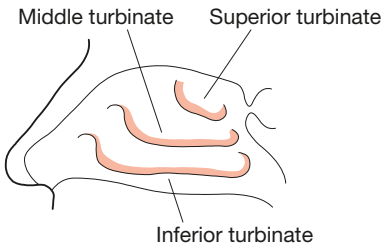

Figure 46.33 The right lateral nasal wall.

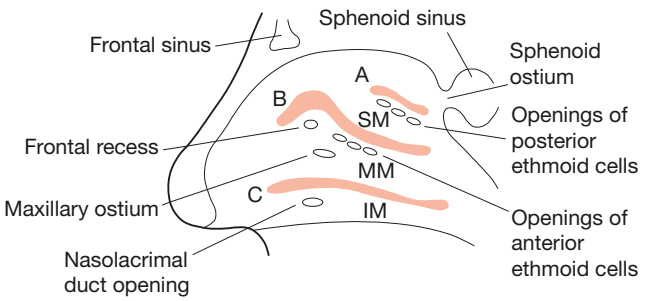

Figure 46.34 The right lateral nasal wall with turbinates removed to show the sinus ostia. A, insertion of superior turbinate; B, insertion of middle turbinate; C, insertion of inferior turbinate; IM, inferior meatus; MM, middle meatus; SM, superior meatus.

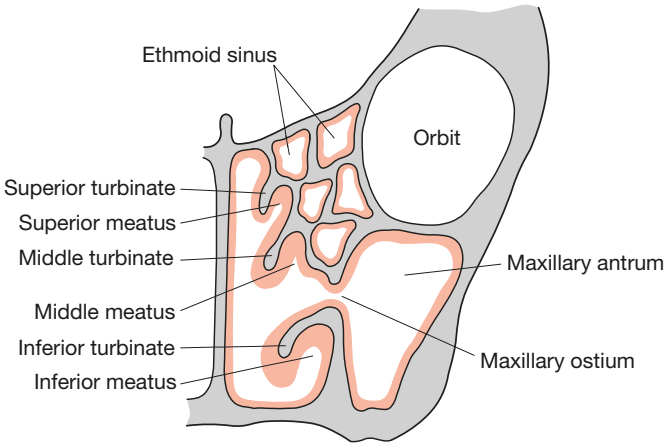

Figure 46.35 Coronal section through the left maxillary and ethmoid sinuses.

The nasal fossae and sinuses receive their blood supply via the external and internal carotid arteries. The external carotid artery supplies the interior of the nose via the maxillary and sphenopalatine arteries. The greater palatine artery supplies the anteroinferior septum via the incisive canal. The contribution from the internal carotid artery is via the anterior and posterior ethmoidal arteries, which are branches of the ophthalmic artery (**Figure 46.36**). All of these arteries anastomose to form a plexus of vessels (Kiesselbach's plexus) on the anterior part of the nasal septum. Venous drainage is via the ophthalmic and facial veins and the pterygoid and pharyngeal plexuses. Intracranial drainage into the cavernous sinus via the ophthalmic vein is of particular clinical importance because of the potential for intracranial spread of nasal sepsis.

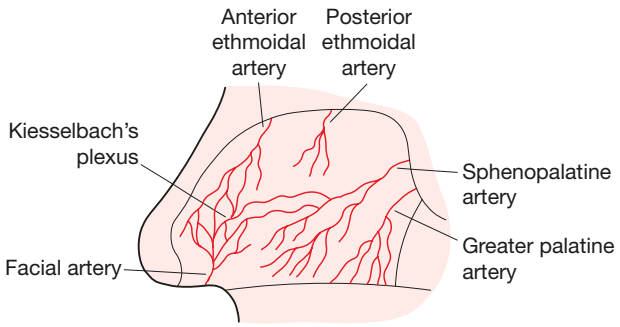

Figure 46.36 Arterial blood supply to the left side of the nasal septum.

EXAMINATION OF THE NOSE AND PARANASAL SINUSES

Internal inspection of the nasal fossae can be achieved to a limited extent with the use of a Thudichum's speculum. The anterior nasal septum, nasal vestibule and anterior inferior turbinate can be assessed. A more detailed examination of the nose is possible with the use of either rigid or flexible endoscopes.

IMAGING OF PARANASAL SINUSES

Plain radiographs are of limited value in the assessment of sinus disease. CT is far superior in demonstrating sinus pathology and to assess bony anatomy to plan any surgical intervention. CT scans are acquired and reconstructed to produce images in axial, coronal and sagittal planes. The three planes allow the drainage of the frontal sinus to be identified and important surgical landmarks can be reviewed preoperatively, including the cribiform plate, anterior skull base, lamina papyracea and location of the anterior ethmoid artery. MRI is useful in sinus pathology to assess any intracranial or orbital extension of disease.

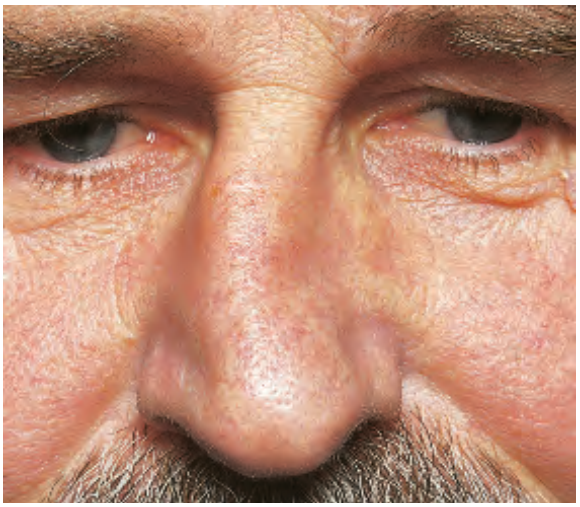

Figure 46.37 Fracture of the nasal bones with displacement of the bony nasal complex to the right side.

TRAUMA TO THE NOSE AND PARANASAL SINUSES

Fracture of the nasal bones

Blunt injury to the nose may fracture the nasal bones (**Figure 46.37**). The fracture line can extend into the lacrimal bone and tear the anterior ethmoidal artery, producing catastrophic haemorrhage. This may be delayed, occurring only as the soft-tissue swelling subsides, reducing the tamponade effect on the torn vessel.

Violent trauma to the frontal area of the nose can result in a fracture of the frontal and ethmoid sinuses with potential extension into the anterior cranial fossa. Dural tears and brain injuries, either open or closed, are then at risk from sinonasal ascending infection, which may progress to meningitis or brain abscess. CSF rhinorrhoea is a certain sign of a dural tear. CSF rhinorrhoea can be confirmed by collecting a sample of the fluid and sending for beta-2 transferrin. A bony defect in the anterior skull base following trauma can be identified on high-resolution CT. The CSF leak will often settle with conservative management but if persistent, can be repaired endoscopically.

Management of fractured nasal bones

Fractured nasal bones are normally accompanied by extensive overlying soft-tissue swelling and bruising, which may hinder the assessment of any underlying bony deformity. Reviewing after 4–5 days when the soft-tissue swelling has diminished will allow a better assessment of any deformity. If there is a significant degree of nasal deformity, then this can be corrected by manipulation of the nasal bones under local or general anaesthesia. This should be carried out within 3 weeks of the injury while the bony fragments are still mobile. After this period, if there is significant cosmetic or functional issues, a septorhinoplasty can be performed at least 6 months following the injury.

Wilhelm Kiesselbach, 1839–1902, Professor of Otology, Erlangen, Germany.
Johann Ludwig Wilhelm Thudichum, 1829–1901, biochemist and general practitioner, London, UK.

Septal injury

A blunt injury of moderate force may lead to lateral displacement or deformity of the septal cartilage, restricting the nasal airway. Unlike the nasal bones the nasal septum cannot be manipulated back into position and requires a formal septoplasty procedure to restore the anatomy and the patency of the nasal airways.

Bleeding under the mucoperichondrium of the septum will cause a septal haematoma and nasal obstruction. Untreated, a septal haematoma will progress to abscess formation and ultimately result in necrosis of the septal cartilage, septal perforation and nasal collapse. A septal haematoma should be treated by incision and drainage of the blood clot, insertion of a small silicone drain and packing of the nasal fossa. A broad-spectrum prophylactic antibiotic should be prescribed.

Summary box 46.9

Nasal trauma

- Do not overlook a septal haematoma
- Displaced nasal bone fractures should be reduced within 3 weeks of injury
- Severe persistent epistaxis after trauma suggests lacrimal bone fracture and injury to the anterior ethmoid artery
- CSF rhinorrhoea indicates a fracture involving the anterior skull base with a dural tear

THE NASAL SEPTUM

Septal deformity

Deviation of the nasal septum may occur naturally or arise as a result of nasal trauma and is readily apparent on anterior rhinoscopy (**Figure 46.38**). Surgical correction can be achieved by a submucous resection (SMR) of the septum where the deformed septal cartilage is excised while preserving a caudal and dorsal strut for support (**Figure 46.39**). The alternative is a septoplasty procedure during which the septal cartilage is preserved but the anatomical abnormalities giving rise to its deformity, such as a twisted maxillary crest or inclination of the bony septum posteriorly, are corrected.

Complications of septal surgery include septal perforation. If too much cartilage is excised in the SMR procedure, loss of support to the dorsum of the nose may result in a supra-tip depression or drooping of the tip of the nose.

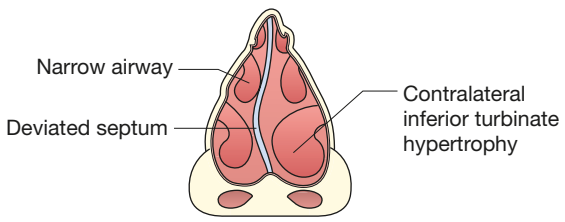

Figure 46.38 Coronal section through the anterior nasal fossae with deviated nasal septum to the right side.

Septal perforation

A hole in the nasal septum causes a turbulent airflow through the nose and a resulting sensation of nasal blockage, extensive nasal crusting, bleeding and whistling. The causes of septal perforation are listed in *Summary box 46.10*.

Septal perforations seldom heal spontaneously. A great variety of operations have been described to close septal perforations but none has met with universal success. These have included closing the perforation using cartilage or synthetic material and covering with local flaps. Alternatively, the perforation may be occluded by inserting a Silastic biflanged prosthesis or 'septal button' (**Figures 46.40 and 46.41**). In some cases, particularly those patients with significant

Summary box 46.10

Causes of septal perforations

- Trauma
  - Iatrogenic following septal surgery
  - Nose picking
  - Following a septal haematoma from nasal injury
- Infection
  - Syphilis
  - Tuberculosis
- Vasculitis
  - Granulomatosis with polyangiitis
- Tumours
- Toxins
  - Chrome salts
  - Cocaine
- Idiopathic

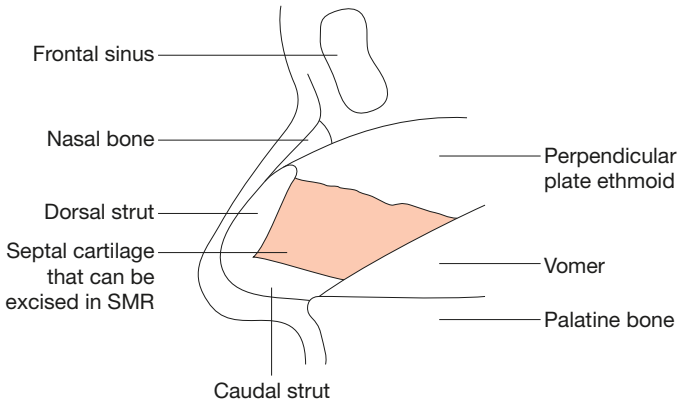

Figure 46.39 Area of cartilage that can be removed in submucous resection (SMR) leaving dorsal and caudal strut for support.

Figure 46.41 Silastic prosthesis for septal perforation.

whistling and bleeding from the posterior edge, the perforation can be enlarged and mucosa folded around the posterior edge to stabilise it.

Granulomatosis with polyangiitis is a systemic idiopathic autoimmune disease affecting the nose, lungs and kidneys. Mucosal granulations on the nasal septum destroy cartilage, producing a septal perforation with saddle deformity of the nose. Laboratory findings include a high erythrocyte sedimentation rate, impaired creatinine clearance and antineutrophil cytoplasmic antibodies (c-ANCA) in most cases.

EPISTAXIS

The causes of epistaxis are listed in *Table 46.2*. The most common site of bleeding is from Kiesselbach's plexus in Little's area of the anterior portion of the septum (see **Figure 46.36**). Anterior bleeding is common in children and young adults as a result of nose blowing or picking. In the elderly, anticoagulants and hypertension are the underlying causes of arterial bleeding from the posterior part of the nose.

Hereditary haemorrhagic telangiectasia (Osler's disease) gives rise to recurrent multifocal bleeding from thin-walled vessels deficient in muscle and elastic tissue (**Figure 46.42**).

Juvenile angiofibroma is an uncommon condition that affects adolescent boys and may lead to massive life-threatening episodes of bleeding. Diagnosis is made with contrast CT or MRI. Anterior bowing or indentation of the posterior antral wall (Holman–Miller or antral sign) is the classical finding, but may be seen in other expansive lesions in this area. It is a very vascular tumour, which should not be biopsied because of the risk of uncontrollable haemorrhage. Excision is best carried out by an experienced surgeon and is usually performed endoscopically often using image guidance (**Figure 46.43**). Preoperative embolisation of the feeding blood vessels may help to reduce blood loss during surgery.

Management of epistaxis

Anterior bleeding from Kiesselbach's plexus may be controlled by silver nitrate cautery under local anaesthesia. Even in more posterior epistaxis, the bleeding point can often be identified using rigid nasendoscopy and controlled with the use of a topical vasoconstrictor, and then dealt with directly using electrocautery. However, posterior bleeding, as seen in the elderly, may require anterior nasal packing either with

Erik Adolf von Willebrand, 1870–1949, physician, Diakonissanstaltens Hospital, Helsinki, (Helsingfors), Finland, described hereditary pseudohaemophilia in 1926.
Sir William Osler, 1849–1919, Professor of Medicine successively at McGill University, Montreal, Canada, The University of Philadelphia, Pennsylvania, PA, and The Johns Hopkins University, Baltimore, MD, USA, finally becoming Regius Professor of Medicine at Oxford University, Oxford, UK, in 1904.

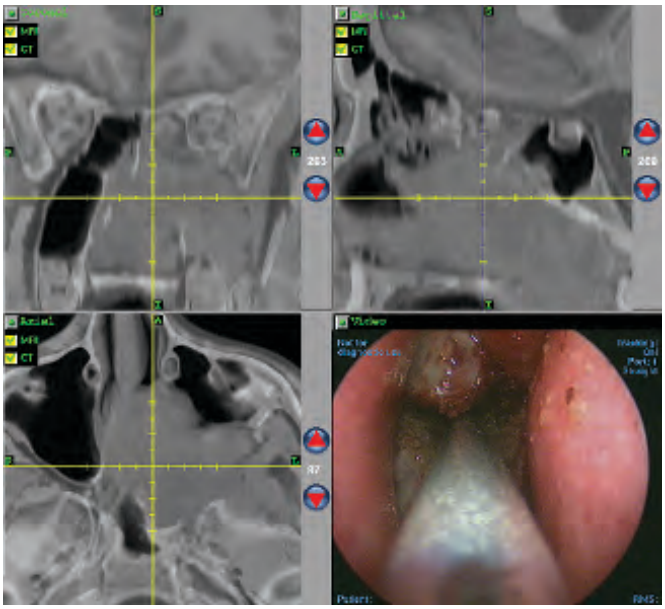

Figure 46.43 Endoscopic resection of juvenile angiofibroma using image-guidance (merged computed tomography and magnetic resonance imaging scans).

Figure 46.44 Epistaxis balloon catheter.

Vaseline-impregnated ribbon gauze or a non-absorbable sponge. There are also many haemostatic, absorbable materials that can be used to pack the nose to help control bleeding. An alternative to anterior packing is the use of an inflatable epistaxis balloon catheter (**Figure 46.44**). The catheter is passed into the nose and the distal balloon is inflated in the nasopharynx to secure it. The proximal balloon, which is sausage shaped, is then inflated within the nasal fossa to compress the bleeding point. Although usually effective, they can be uncomfortable.

Postnasal packing may be required in refractory cases whereby a gauze pack is positioned in the nasopharynx under general anaesthesia. Endoscopic sphenopalatine artery clipping is an effective treatment for significant epistaxis not responding to direct cautery or nasal packing.

For uncontrolled life-threatening epistaxis in which the above methods have proved ineffective, haemostasis is secured by vascular ligation. Depending on the origin of bleeding it may be necessary to ligate the internal maxillary artery in the pterygopalatine fossa (which can be accessed endoscopically) and the anterior and posterior ethmoidal arteries. An alternative measure is external carotid artery ligation above the origin of the lingual artery. Another option is to involve the interventional radiologist for possible embolisation. It is also important to recognise, and if possible treat, any factors contributing to the epistaxis, such as clotting or platelet abnormalities.

In Osler's disease, anterior nasal packing is best avoided if at all possible because it is most likely to lead to further mucosal trauma and bleeding. High-dose oestrogen induces squamous metaplasia of the nasal mucosa and has been used effectively in treating this condition.

Summary box 46.11

Epistaxis

- The most common causes are nose picking, hypertension and anticoagulant therapy
- Young people bleed from the anterior septum – Kiesselbach's plexus
- Elderly people bleed from the posterior part of the nose
- Epistaxis is ideally treated with direct cautery to bleeding point under endoscopic guidance
- Silver nitrate cautery can be used to control anterior bleeding
- Moderate bleeding may require anterior nasal packing
- Severe bleeding may require anterior and posterior nasal packing
- Persistent bleeding may require endoscopic sphenopalatine artery ligation

RHINOSINUSITIS

Rhinosinusitis is inflammation of the sinonasal mucosa and is defined as the presence of nasal congestion or nasal discharge and at least one of facial pain or hyposmia with endoscopic and/or CT changes to confirm the diagnosis. It can be divided into acute rhinosinusitis (ARS) and chronic rhinosinusitis (CRS) depending on the timing of symptoms. Symptoms are present for less than 12 weeks in ARS and more than 12 weeks in CRS.

Acute rhinosinusitis

ARS is thought to result from bacterial superinfection of virally damaged mucosa. The commonest bacteria involved are *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Moraxella catarrhalis*. Upper dental sepsis may also predispose to acute maxillary sinusitis. Patients with maxillary sinusitis have a mucopurulent discharge, facial pain and nasal obstruction. Irritation of the superior alveolar nerve may give rise to referred upper toothache. In ARS nasendoscopy reveals inflammed and swollen nasal mucosa with mucopurulent secretions in the middle meatus. Dental sepsis from anaerobic organisms causes around 10% of cases of maxillary sinusitis. The resultant mucopurulent nasal secretion has a foul taste and smell. Plain sinus radiographs may show a fluid level in the antrum or complete opacity (**Figure 46.45**). However, plain radiographs are now seldom used and have been superceded by CT scans to investigate ARS. CT scans confirm opacifiction and mucosal thickening of the maxillary sinus as well as providing anatomical detail prior to endoscopic surgical intervention (**Figure 46.46**).

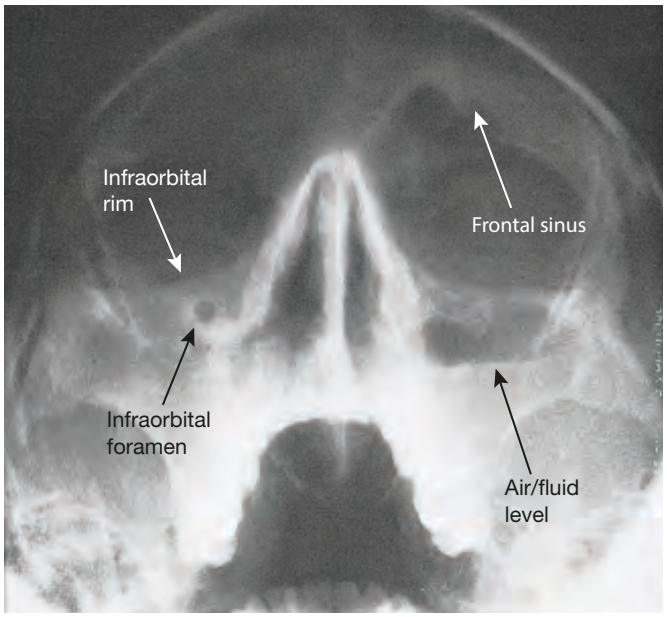

Figure 46.45 Plain radiograph showing the fluid level in the left maxillary antrum and total opacity of the right antrum.

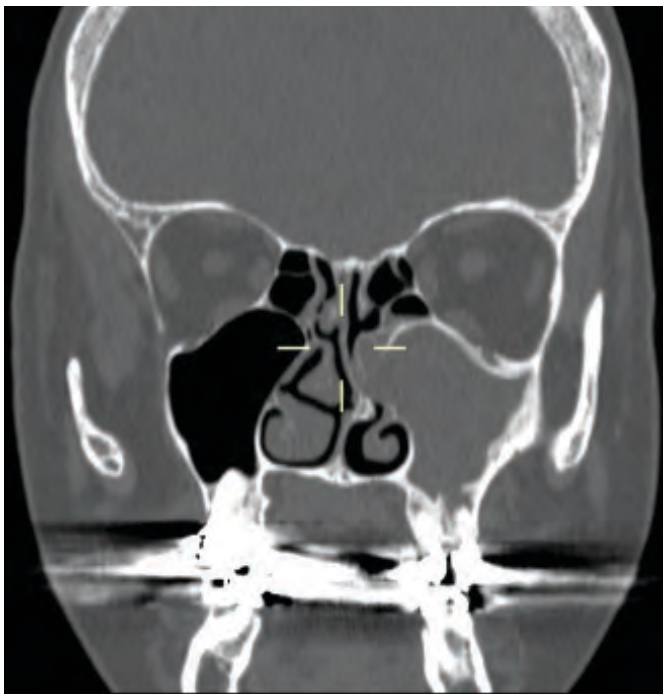

Figure 46.46 Coronal computed tomography scan showing left-sided maxillary sinus opacification due to maxillary sinusitis.

Acute frontoethmoidal sinusitis can also occur and presents with mucopurulent discharge, facial pain (including frontal headache), nasal congestion and hyposmia. Again, mucopus is seen on endoscopy in the middle meatus and is investigated with CT.

Treatment

Penetration of antibiotics into chronically inflamed sinus mucosa is reduced and, therefore, treatment may need to be prolonged. Topical nasal decongestants, such as ephedrine nasal drops, will often encourage the sinus to drain and topical corticosteroids are used to reduce inflammation. Saline douches can also be beneficial.

Antral lavage under local or general anaesthesia was previously used to confirm the diagnosis and provided the opportunity to obtain samples for bacteriology. Nowadays, pus in the middle meatus can simply be sampled endoscopically in clinic and antral lavage is rarely performed. Endoscopic sinus surgery allows a more functional approach to diseases of the paranasal sinuses and enables the drainage pathways of the paranasal sinuses to be opened. Most cases of ARS can be treated conservatively with antibiotics and topical treatment. Surgery is used for those patients unresponsive to medical management or with complications. The majority of patients with ARS who require surgery are treated endoscopically. However, in some cases an open surgical approach may be necessary.

Complications

Complications as a result of ARS include orbital and intracranial problems. The spread of infection from the sinuses occurs either through diploic veins or directly through bone erosion. This can result in epidural, subdural or cerebral abscesses, or meningitis/encephalitis. Cavernous sinus thrombosis may also result and can present with bilateral ptosis, proptosis, retro-ocular pain, opthalmoplegia, papilloedema and spiking fevers.

Orbital complications of ARS are more common. Most often this is related to ethmoid sinus infection (**Figure 46.47**). An opthalmology review is essential due to the threat to vision and IV antibiotics covering aerobic and anaerobic organisms are used. If there are any concerns regarding the eye, including proptosis, chemosis, opthalmoplegia, or reduced visual acuity, then CT with contrast is required

Summary box 46.12

Acute rhinosinusitis

- The most common causative organisms are *Streptococcus pneumoniae, Haemophilus influenzae, Moraxella cattarhalis*
- Anaerobic infection of the maxillary sinus may result from dental sepsis
- Acute infection should be treated with antibiotics, topical decongestants and corticosteroids
- Endoscopic sinus surgery may be required

Summary box 46.13

Complications

- Orbital – cellullitis, abscess
- Orbital infections may threaten sight
- Intracranial spread may cause meningitis, cerebral abscess or cavernous sinus thrombosis
- Osteomyelitis of the bones, particularly frontal, may occur

Figure 46.47 Left periorbital cellulitis complicating acute left ethmoiditis.

Figure 46.48 Axial computed tomography scan showing a subperiosteal abscess in the left orbit.

Summary box 46.14

Chandler classification of orbital complications of sinusitis

- I – preseptal cellulitis
- II – orbital cellulitis
- III – subperiosteal abscess
- IV – orbital abscess
- V – cavernous sinus thrombosis

(Figure 46.48). If an abscess is identified, then this should be drained (endoscopically or open).

Osteomyelitis of the frontal bones can also occur as a result of ARS. If the anterior table of the frontal sinus is involved, it can present with significant swelling of the skin of the forehead and a mass (Pott puffy tumour).

Chronic rhinosinusitis

CRS is common affecting around 11% of the population. The cause is unknown but a number of factors have been linked to CRS including ciliary dyskinesia, allergy, asthma, bacteria (*Staphylococcus aureus*) and fungi, and a number of host factors including anatomical variations (deviated septum, concha bullosa of the middle turbinates). CRS can be divided into CRS with nasal polyps (CRSwNP) and without (CRSsNP).

Pathology

Nasal polyps are benign swellings of the sinus mucosa of unknown origin. Histologically, the polyps contain an oedematous stroma infiltrated with inflammatory cells and eosinophils. Inflammatory polyps tend to be bilateral and extend into the middle meatus. A single large polyp arising from the maxillary antrum is referred to as an antrochoanal polyp (Figure 46.49). This usually fills the nose and eventually prolapses posteriorly down into the nasopharynx.

Clinical features

CRSwNP patients present with nasal obstruction, watery rhinorrhoea, postnasal drip and often hyposmia/anosmia. Pain does not tend to be a significant feature. Polyps are easily identifiable within the nose as pale semitransparent grey masses, which are mobile and insensitive when palpated with a fine probe. This allows them to be distinguished from hypertrophied turbinates (Figure 46.50). In CRSsNP the middle meatus is often congested, with mucopus present.

Malignancy should be considered in adults with unilateral nasal polyps whereas in children such polyps must be distinguished from a meningocoele or encephalocoele by high-resolution CT scanning of the anterior cranial fossa. Nasal polyps are unusual in children; however, they do occur in conjunction with cystic fibrosis in 10% of cases.

Figure 46.49 Antrochoanal polyp.

Percivall Pott, 1714–1788, surgeon, London, UK.

Figure 46.50 Nasal polyp in the right nasal vestibule.

Management

Medical treatment for CRSwNPs with systemic steroids will often reduce the size of the nasal polyps and give short-term relief of nasal blockage. Unfortunately, the polyps tend to recur when the treatment stops. Topical corticosteroid drops and sprays are also used along with saline douching. In CRSsNP, in addition to topical treatments a long course of low-dose antibiotics (macrolides) can be used in those patients with a normal IgE. Surgical treatment is indicated in patients that do not respond to medical treatment. Endoscopic nasal polypectomy and functional endoscopic sinus surgery (FESS) is performed following a CT scan which confirms the extent of disease and shows the important bony anatomy preoperatively. Serious complications following FESS include CSF leak and orbital problems, including orbital haematoma, and so it is important to review the level and symmetry of the anterior skull base and the integrity of the lamina papyracea on the CT scan prior to surgery. Endoscopic polypectomy is performed using a powered nasal microdebrider (**Figure 46.51**).

Image guidance can be used in endoscopic sinus surgery, and extended endoscopic procedures such as pituitary and anterior skull base surgery, to provide real-time feedback of instrument position in the nose based on preoperative CT or MRI scans.

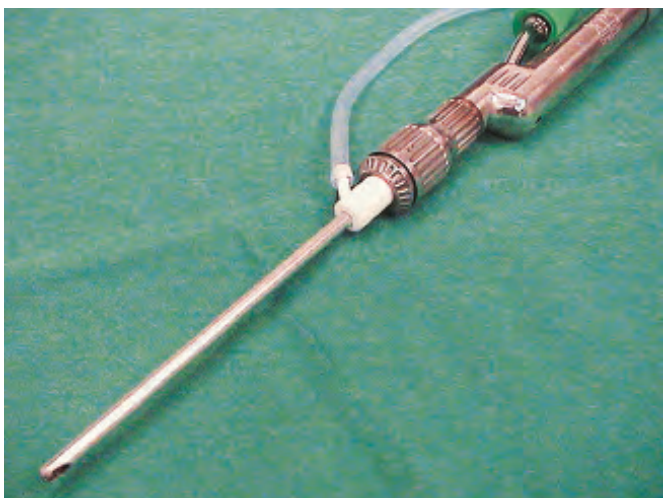

Figure 46.51 Powered nasal microdebrider.

Summary box 46.15

Nasal polyps

- Polyps are insensitive to touch and are mobile
- Inflammatory polyps are usually bilateral
- Unilateral nasal polyps should be removed for histology
- Bleeding polyps may indicate malignancy
- Meningocoele and encephalocoele must be excluded in children with polyps
- Polyps are removed using a powered microdebrider

TUMOURS OF THE NOSE AND SINUSES

Tumours arising in the nose or paranasal sinuses may present with unilateral nasal obstruction, persistent unilateral anterior rhinorrhoea, postnasal drip, epistaxis, unilateral blood-stained rhinorrhoea, facial swelling or proptosis.

Benign tumours

Simple papillomas or viral warts can grow inside the nasal vestibule. They can be confused with carcinomas and are best excised for histological diagnosis.

Osteomas of the nasal skeleton are not uncommon and are usually detected on radiology as an incidental finding (**Figure 46.52**). In symptomatic individuals the osteoma can be removed endoscopically or via an open procedure.

Inverted (transitional cell) papillomas can occur both in the nasal cavity and the nasal sinuses. They are inverted papillomas because histologically the hyperplastic epithelium inverts into the underlying stroma. The papillomas are covered with transitional epithelium. Calcification within the tumour may be seen on CT along with sclerosis of bone at the margins of the growth (**Figure 46.53**). Inverted papillomas can undergo malignant change. Full surgical resection is required and this can usually be performed endoscopically.

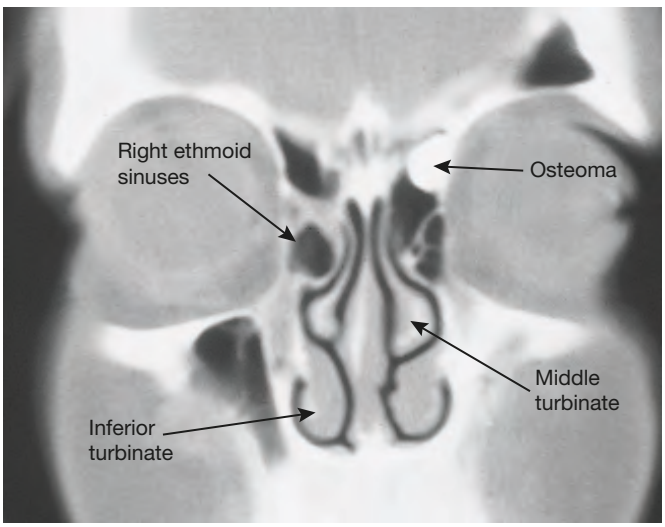

Figure 46.52 Coronal computed tomography scan showing a small osteoma in the left ethmoid sinus adjacent to the orbit.

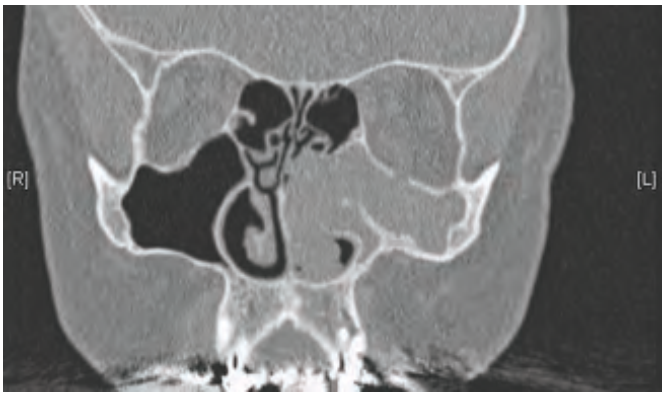

Figure 46.53 Coronal computed tomography scan showing extensive inverted papilloma involving the left maxillary antrum and ethmoid sinuses.

Malignant tumours

The most common malignant tumours to occur within the nasal cavity and paranasal sinuses are squamous cell carcinoma (**Figure 46.54**), adenoid cystic carcinoma and adenocarcinoma. Adenocarcinoma has been linked to exposure to hard wood dust in the furniture industry. Adenoid cystic carcinomas arise from minor salivary glands, which can be found in the nose. Suspicious signs of invasion of neighbouring tissues include diplopia, proptosis, loosening of the teeth (**Figure 46.55**), trismus, CN palsies and regional lymphadenopathy. **Figure 46.56** shows invasion of a left maxillary antral carcinoma into adjacent structures, including the orbit, on an MRI scan.

Patients with sinus or intranasal malignancy are best managed in a combined clinic where the expertise of ear, nose and throat (ENT) surgeons, maxillofacial surgeons and oncologists can be employed.

Summary box 46.16

Tumours of the nose and sinuses

- Unilateral nasal blockage, discharge and bleeding are often presenting symptoms in nasal or sinus tumours
- Osteomas are often asymptomatic
- Inverted papilloma is a benign tumour, which presents as a unilateral polyp that can undergo malignant change
- Squamous cell carcinoma is the most common malignant tumour
- Almost 50% of sinonasal cancers arise on the lateral nasal wall and 33% in the maxillary antrum
- Multidisciplinary management of malignant sinonasal tumours requires input from Ear, Nose and Throat surgeons, maxillofacial surgeons and oncologists

Chapter 47

Pharynx, larynx and neck

Learning objectives

To understand:

- The relevant anatomy, physiology, disease processes and investigations of the pharyngolarynx and neck
- The diagnosis and emergency treatment of airway obstruction
- The aetiology, natural history, management and prevention of squamous cell carcinoma of the upper aerodigestive tract

CLINICAL ANATOMY AND PHYSIOLOGY

The pharynx

The pharynx is a fibromuscular tube forming the upper part of the respiratory and digestive passages. It extends from the base of the skull to the level of the sixth cervical vertebra at the lower border of the cricoid cartilage where it becomes continuous with the oesophagus. It is divided into three parts: the nasopharynx, oropharynx and hypopharynx (**Figure 47.1**).

Nasopharynx

The nasopharynx lies anterior to the first cervical vertebra. The adenoids, which constitute the superior component of Waldeyer`s ring, are situated at the junction of the roof and posterior wall of the nasopharynx. Waldeyer`s ring is a ring of lymphoid tissue comprising, in addition to the adenoids, the palatine and lingual tonsils of the oropharynx. It is situated at the entry to the air and food passages and is constantly exposed to new inspired or ingested antigenic stimuli. Accordingly, it is an important part of the mucosa-associated lymphoid tissues (MALT), which process antigen and present it to T helper cells and B cells (**Figure 47.2**) thereby facilitating a first-line immune response mechanism, which is particularly important in childhood. The tissue of Waldeyer's ring undergoes physiological hypertrophy during early childhood as the child is exposed to increasing amounts of antigenic stimuli, and there is often a similar hypertrophy of the cervical lymph nodes.

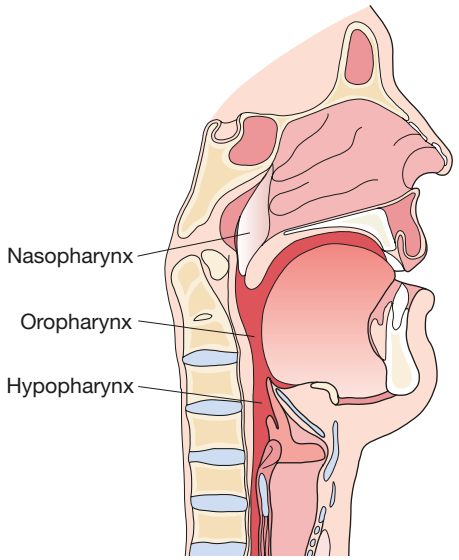

Figure 47.1 The component parts of the pharynx.

The Eustachian tubes, leading from the middle ear cleft, open into the postero-superior aspect of the lateral wall. Dorsal and superior to the openings, bounded anteriorly by a ridge formed by the salpingopharyngeus muscle, are the fossae of Rosenmüller, a common site for the development of nasopharyngeal carcinoma.

Bartolomeo Eustachio (Eustachius), ?1513–1574, appointed physician to the Pope in 1547, and Professor of Anatomy, Rome, Italy, in 1549.
Johann Christian Rosenmüller, 1771–1820, Professor of Anatomy and Surgery, Leipzig, Germany.

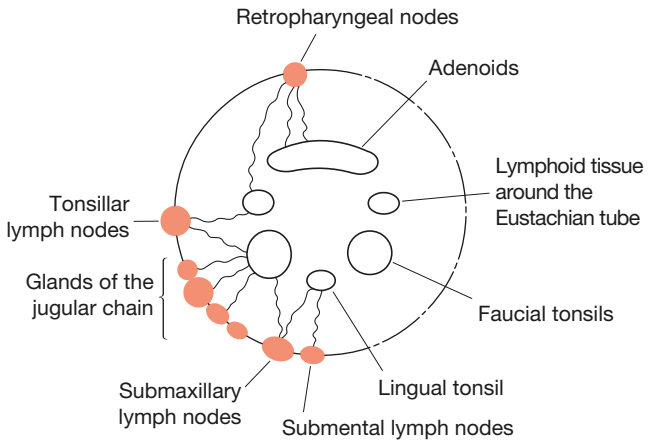

Figure 47.2 Waldeyer's ring.

Oropharynx

This is bounded superiorly by the soft palate, inferiorly by the upper surface of the epiglottis and anteriorly by the anterior faucial pillars and the vallate papillae of the tongue. The palatine tonsils are situated in the lateral wall between the anterior and posterior pillars of the fauces. The lateral wall, and in particular the tonsil, takes its blood supply from the facial artery, which may be closely related to the lower pole, and laterally a plexus of paratonsillar veins, which may be the source of serious venous bleeding following tonsillectomy.

Hypopharynx

The superior border of the hypopharynx is the level of the laryngeal inlet. Its inferior border is the lower border of the cricoid cartilage where it continues into the oesophagus. The hypopharynx is commonly divided into three areas: the right and left piriform fossae, the posterior pharyngeal wall and the postcricoid region. The mucosa of these areas is, however, continuous so disease processes, such as squamous cell carcinoma, often involve more than one area as a result of submucosal spread.

The multifaceted, complex process of swallowing is mediated via efferent fibres passing to the medulla oblongata through the second division of the trigeminal nerve (V), glossopharyngeal nerve (IX) and vagus nerve (X) (Figure 47.3). The afferent pathway is from the nucleus ambiguus and is mediated via the glossopharyngeal (IX), vagus (X) and hypoglossal (XII) nerves. Damage to these major cranial nerves at any point along their pathway, by trauma or disease, may cause dysphagia and/or aspiration.

Videofluoroscopy, in which the passage of a bolus of radiopaque liquid or solid from the point at which it enters the oral cavity down to its passage within the stomach is examined radiologically, is the investigation of choice when investigating swallowing (dys)function.

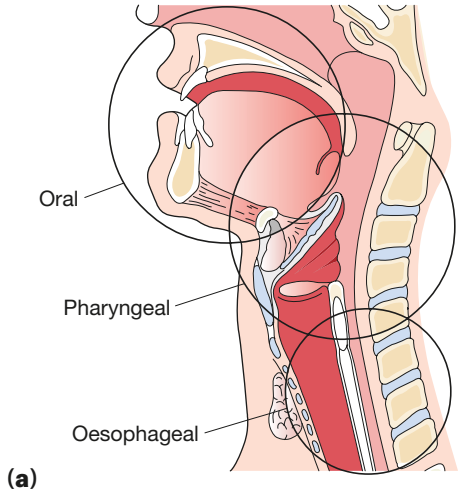
Anatomic relationships of the pharynx

Some of these are illustrated in Figure 47.4.

PARAPHARYNGEAL SPACE

This potential space lies lateral to the pharynx and extends from the base of the skull above to the superior mediastinum below. It is occupied by the carotid vessels, internal jugular vein, deep cervical lymph nodes, the last four cranial nerves and the cervical sympathetic trunk.

Infection and necrosis of the cervical lymph nodes in the parapharyngeal space most commonly occurs from infections



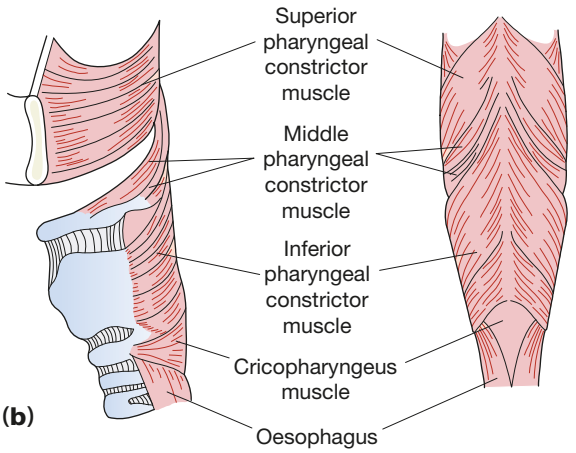


Figure 47.3 The three phases of swallowing (a) and the muscles (b).

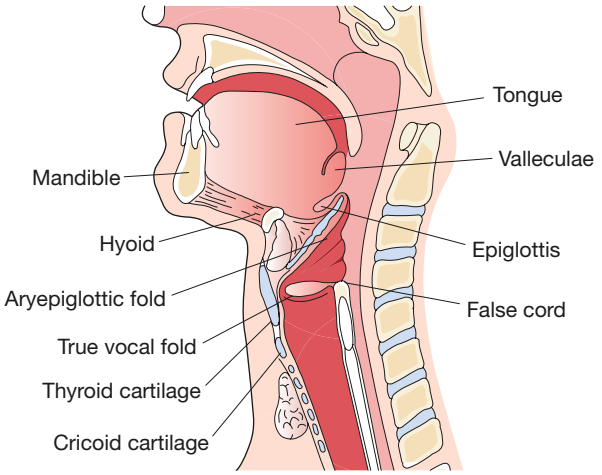

Figure 47.4 Sagittal diagram of the upper aerodigestive tract.

of the tonsils or teeth (particularly the third lower molar tooth). As the parapharyngeal space is not anatomically divided, infection may therefore spread from the skull base cranially to the superior mediastinum caudally and consequently often presents a surgical challenge.

RETROPHARYNGEAL SPACE

This potential space lies posterior to the pharynx, bounded anteriorly by the posterior pharyngeal wall and its covering buccopharyngeal fascia and posteriorly by the prevertebral musculature and its overlying prevertebral fascia. It contains the retropharyngeal lymph nodes, which are usually paired lateral nodes but which are separated by a tough midline fibrous condensation that connects the prevertebral and buccopharyngeal fascia.

As with the lymphoid tissue of Waldeyer`s ring, these nodes are more active in infancy and young children, and it is at this age that they are most likely to be involved in inflammatory processes, which, if severe, may affect swallowing and respiration as a consequence of gross swelling and suppuration of the retropharyngeal space.

Larynx

It is important to appreciate that the main function of the larynx is not the production of voice but the protection of the tracheobronchial airway and lungs. In order to achieve this, the larynx, together with the base of the tongue, forms the protective sphincter that closes off the airway during swallowing. It is only an evolutionary by-product that, in humans and some other mammals, the larynx is responsible for the production of sound.

The larynx comprises a cartilaginous framework (that may ossify in later life), which consists of the hyoid bone above, the thyroid and cricoid cartilages and the intricate arytenoid cartilages posteriorly.

The cricoid cartilage is the only complete ring in the entire airway and bounds the subglottis, which is the narrowest point of the airway. This is the most common site for damage from an endotracheal tube used for intensive care unit ventilation in seriously ill patients.

A purely anatomical description of the larynx divides it into the supraglottis, glottis and subglottis (**Figure 47.5**). The true vocal folds (often incorrectly called the vocal cords) are normally white in contrast to the pink mucosa of the rest of the larynx and airway. The true vocal folds meet anteriorly at the midlevel of the thyroid cartilage, whereas posteriorly they are separate and attached to an arytenoid cartilage. This arrangement produces the 'V' shape of the glottis (**Figure 47.6**).

Nerve supply

The sensory nerve supply to the larynx above the vocal folds is from the superior laryngeal nerve and below the vocal folds it is from the recurrent laryngeal nerve. Both these nerves are branches of the vagus nerve (X). The motor nerve supply to the larynx is from the recurrent laryngeal nerve, which supplies all intrinsic muscles. Only one of these intrinsic muscles,

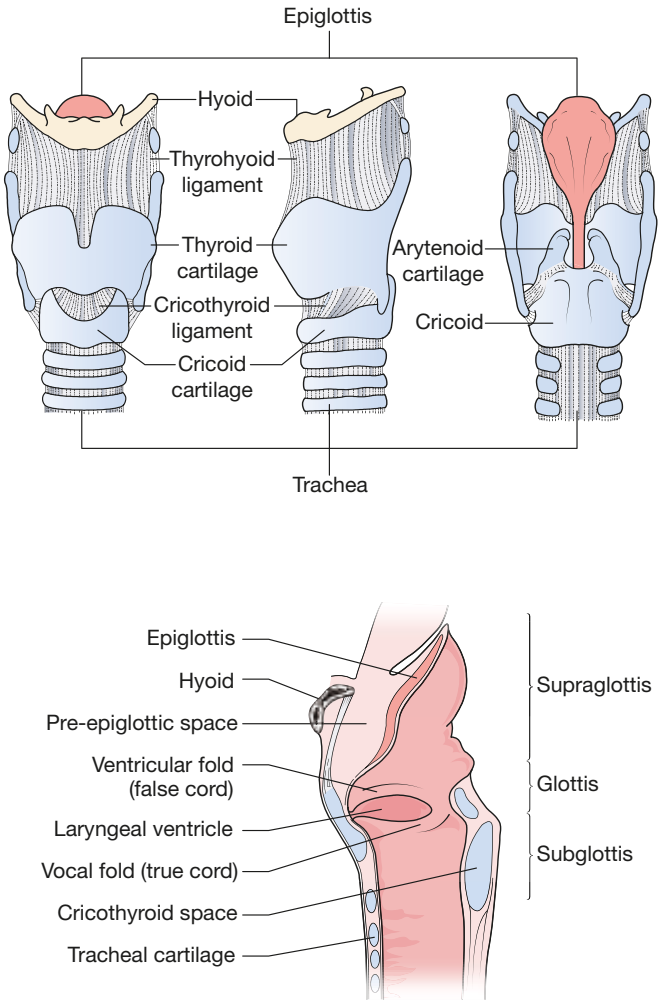

Figure 47.5 Anatomy of the larynx.

the posterior cricoarytenoid, abducts the vocal folds during respiration. All other intrinsic muscles adduct the cords. As all of the intrinsic muscles of the larynx are supplied by the recurrent laryngeal nerve, damage to this nerve, or to the vagus nerve above the recurrent laryngeal nerve branch, will cause paralysis of the vocal fold on the side of the damage.

Phonation/speech

The larynx functions by closing the vocal fold against the air being exhaled from the lungs, but the rise in subglottic pressure forces the vocal folds apart slightly for an instant of time, resulting in an accompanying sinusoidal wave-like vibration of the vocal fold epithelium. The opening and closing occurs in rapid sequence to produce a vibrating column of air, which is the source of sound that can be articulated by the structure of the oral cavity to produce speech.

Paralysis or disease of the vocal folds or closely associated laryngeal structures will give rise to disturbance of the sound, producing hoarseness.

The functions of the larynx are given in *Summary box 47.1*.

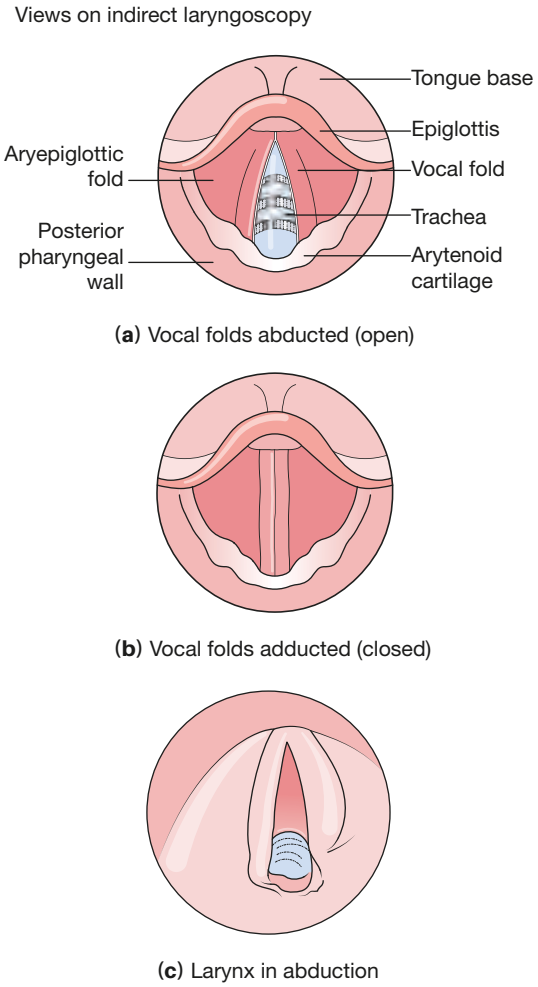

Figure 47.6 A view of the larynx on indirect laryngoscopy: **(a)** vocal folds abducted; **(b)** vocal folds adducted; **(c)** normal larynx in abduction.

Summary box 47.1

Functions of the larynx

Protection of the lower respiratory tract by

- Closure of the laryngeal inlet
- Closure of the false cords
- Closure of the glottis
- Cessation of respiration
- Cough reflex

Phonation

- Vocal folds produce sound by quasi-periodic vibration

Respiration

- Control of pressure

Fixation of chest

- Aids lifting, straining and climbing

Neck

The neck is divided into anterior and posterior triangles by the sternocleidomastoid muscle. The anterior triangle extends from the inferior border of the mandible to the sternum below, and is bounded by the midline and the sternocleidomastoid muscle. The posterior triangle extends backwards to the anterior border of the trapezius muscle and inferiorly to the clavicle. The upper part of the anterior triangle, above the hyoid bone, is commonly subdivided into the submandibular triangle above the digastric muscle and the submental triangle below. The lymphatic drainage of the head and neck is of considerable clinical importance (**Figure 47.7**). The most important chain of nodes are the jugular nodes (also called cervical), which run adjacent to the internal jugular vein. The other main groups are the submental, submandibular, pre- and postauricular, occipital and posterior triangle nodes.

A system of levels is used to describe the location of these neck nodes (**Figure 47.8**). Of particular note are

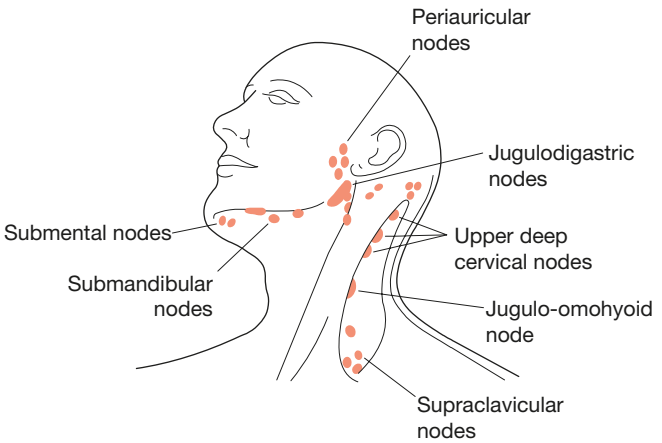

Figure 47.7 Distribution of cervical lymph nodes.

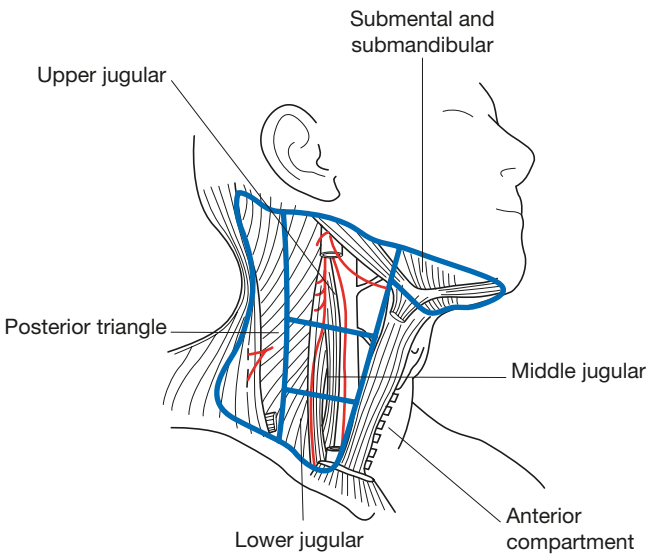

Figure 47.8 The level system for describing the location of lymph nodes in the neck. Level 1, submental and submandibular group; level II, upper jugular group; level III, middle jugular group; level IV, lower jugular group; level V, posterior triangle group; level VI, anterior compartment group.

the jugular nodal levels include levels II, III and IV, which relate to the upper, middle and inferior third of the carotid sheath, respectively. The level II nodes, which contain the large jugulodigastric node, drain the naso- and oropharynx, including the tonsils, posterolateral aspects of the oral cavity and the superior aspects of the larynx and piriform fossae. They are the most common sites of enlargement and may be palpated along the anterior border of the sternocleidomastoid muscle.

Metastatic spread of squamous cell carcinoma (80% of head and neck cancer) most commonly occurs with tumours of the nasopharynx, tongue base, tonsil, piriform fossae and supraglottic larynx. When an enlarged neck node is detected and malignant disease is suspected, these five primary sites must be carefully examined.

CLINICAL EXAMINATION

Pharynx and larynx

Before examination of the pharynx, the oral cavity should be examined with the aid of a good light and tongue depressors. Historically, a reflecting mirror on the head was used as a source of examination light. However, most practitioners in the resource-rich world now use a headband-mounted fibreoptic light source. Either option permits the use of both hands to hold instruments. Inspection should include the buccal mucosa and lips, the palate, the tongue and floor of the mouth, all surfaces of the teeth and gums, opening and closing of the mouth and dental occlusion. Patients should be asked to elevate the tongue to the roof of the mouth and protrude the tongue towards both the right and the left. Intraoral palpation may be required gently using one or two fingers to feel any swellings. Intraoral palpation may be combined with extraoral palpation of the submental and submandibular lymph nodes and salivary glands to aid the characterisation and/or localisation of any swelling detected.

Following examination of the oral cavity, the oropharynx is then inspected with the tongue depressor placed firmly onto the tongue base to depress it inferiorly. Care much be taken to, if possible, avoid provoking a gag reflex. The anterior and posterior faucial pillars, the tonsil, retromolar trigone and posterior pharyngeal wall should all be inspected for colour changes, ulceration, pus, foreign bodies and swellings. Pain and trismus as a consequence of pharyngolaryngeal or neck pathology may add to the difficulty of the examination, but are significant clinical findings in their own right.

While angled mirrors and a headlight may be used in expert hands, modern flexible fibreoptic endoscopes passed through the nose, with or without topical anaesthesia, allow high-quality examination of the entire nasopharynx, oropharynx, larynx and often the hypopharynx in almost every patient. Moreover, a camera attached to the endoscope permits the taking of high-quality photographs to record and present pertinent clinical findings. A rigid 0° fibreoptic endoscope (Hopkin`s rod) is often used in preference to inspect the nasal cavities and nasopharynx.

Neck

The patient should be examined in the sitting position with the whole neck exposed so that both clavicles are clearly seen. The neck is inspected from the front and the patient asked to swallow, preferably with the aid of a sip of water. Movements of the larynx and any swellings in the neck are noted. The patient should be asked to protrude the tongue if there is a midline neck swelling, as a thyroglossal duct cyst will move upwards with the tongue protrusion. The neck is then examined from behind with the chin flexed slightly downwards to remove any undue tension in the strap muscles, platysma and sternocleidomastoids.

On examining for a lump in the neck, it is often helpful to ask the patient to point to the lump first. Ask if the lump is tender. The neck is palpated bilaterally in a sequential manner comparing the two sides of the neck. All five palpable neck node levels (I–V) should be examined systematically.

If malignancy is suspected (hard, irregular or fixed to overlying skin or to deep structures), inspection of the nasopharynx, tonsils, tongue base, piriform fossae and supraglottic larynx is essential.

Summary box 47.2

Key points of history and examination

Mouth

- Adequate light source and two spatulas to examine the mouth
- Examine
  - Teeth, gums, gingival sulci
  - Buccal mucosa, opening of parotid duct
  - Floor of mouth
  - Hard and soft palate
  - Retromolar trigone region
  - Anterior and posterior faucial pillars, tonsils
  - Posterior pharyngeal wall
  - Tongue (observe full movements)
- Palpate
  - Salivary glands/ducts

Larynx, oropharynx and hypopharynx

- Indirect laryngoscopy
  - Mirror and headlight
- Direct flexible fibreoptic pharyngolaryngoscopy

Nasopharynx

- Rigid Hopkins' rod endoscopy
- Flexible fibreoptic nasendoscopy

Neck

- Inspection
  - Tongue protrusion
  - Observe swallowing
- Palpation
  - If a mass is palpable, evaluate for size, site, shape, consistency, superficial and deep fixation, fluctuation, transillumination, auscultation

INVESTIGATION OF THE PHARYNX, LARYNX AND NECK

Plain lateral radiographs

Plain lateral radiographs of the neck and cervical spine may show soft tissue abnormalities, although their sensitivity and specificity is low; of particular importance is the depth and outline of the prevertebral soft tissue shadow on sagittal section as an indication of retropharyngeal pathology. The outline of the laryngotracheal airway may be a useful guide to the presence of disease in the pharynx and larynx. There should be no air within the upper oesophagus. If air is seen, endoscopy is advised. Radiopaque foreign bodies may be seen impacted in the pharynx, larynx or upper oesophagus on these radiographs (**Figure 47.9**).

Figure 47.9 Plain lateral radiograph showing normal anatomy.

Barium swallow

Barium (or water-soluble contrast if a pharyngeal or oesophageal perforation is suspected) liquid video fluoroscopic studies record the movement of a small quantity of radiopaque liquid and allow detailed evaluation of the oral and pharyngeal phases of swallowing (**Figure 47.10**).

Computed tomography scanning

Computed tomography (CT) scanning provides high resolution imaging of disease in the pharynx, larynx and neck. Intravenous contrast given at the same time as the CT scan (dynamic scanning) further improves the demonstration of disease in these areas (**Figure 47.11**).

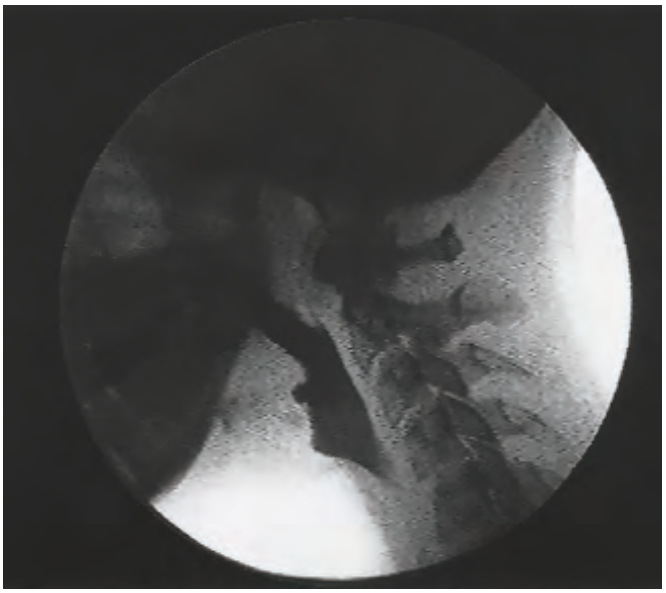

Figure 47.10 Videofluoroscopy image showing liquid barium in the upper pharynx in a normal swallow.

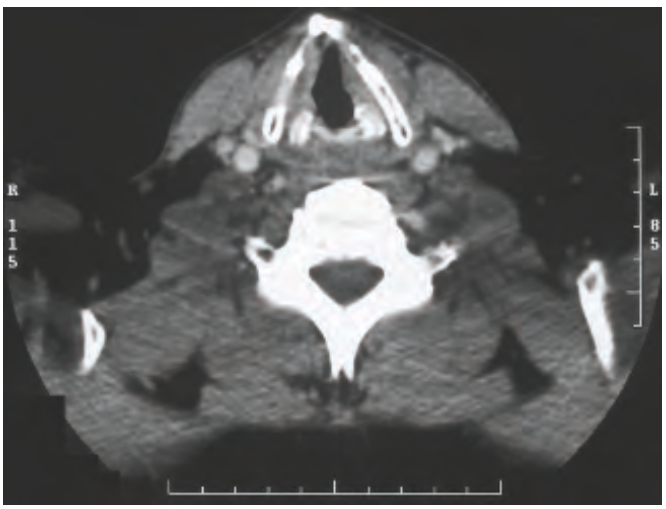

Figure 47.11 Axial computed tomography scan through the larynx at the level of the glottis.

Other imaging

Magnetic resonance imaging (MRI) may be used to give better soft tissue definition and is preferred for tumour staging in some centres. Drawbacks of this approach include a reduction in image quality due to movement artefact, poorer definition of bony and cartilaginous structures and upstaging of tumours due to oversensitivity (**Figure 47.12**). Ultrasound scanning can be useful in differentiating solid lesions (e.g. malignant lymph nodes from cystic lesions such as a branchial cyst) and is particularly helpful when attempting fine-needle aspiration.

If a head and neck malignancy is suspected, then CT imaging of the thorax should also be performed as the rate of synchronous primary bronchogenic tumours, while not particularly high (~5%), is significant and if detected, will change treatment options.

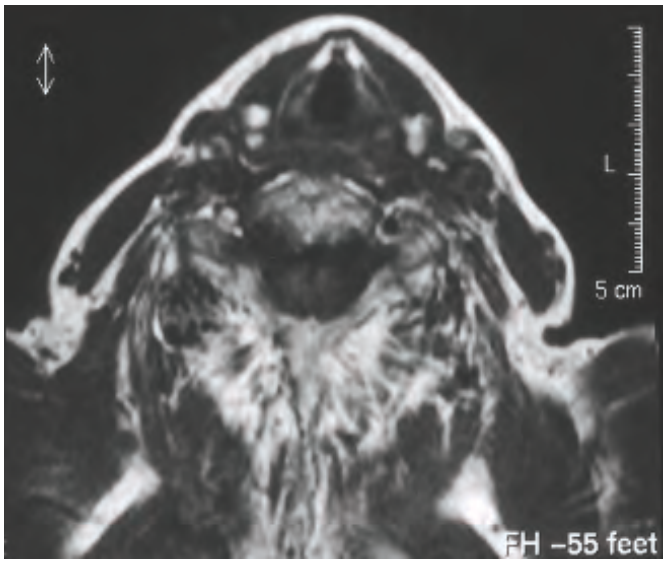

Figure 47.12 Axial magnetic resonance imaging scan at the same level as Fig. 47.11.

Fine-needle aspiration cytology

This is the investigation of choice when attempting to determine the nature of a neck or thyroid mass. Fine-needle aspiration cytology (FNAC) is considerably aided by ultrasound or CT guidance to the extent the ultrasound-guided FNAC is now routine in many units around the world. The technique is safe and well tolerated and has high diagnostic sensitivity and specificity, especially when diagnosing cervical lymph node enlargement and performed by a practitioner with a high volume practice.

Angiography or digital subtraction vascular imaging

These techniques may be indicated if a vascular lesion such as a carotid body tumour is suspected. Angiography may have a therapeutic role to play by facilitating embolisation of the lesion.

Direct pharyngoscopy and laryngoscopy

Examination of the pharynx, larynx and neck under general anaesthesia may be required if a primary head and neck malignancy is suspected or there are problems with the routine examination of patients, such as an inadequate view as a result of trismus from pain, poor patient compliance or large obstructive pharyngeal or laryngeal pathology. These examinations may be further aided by the use of an operating microscope or rigid straight and angled (30° and 70°) endoscopes (Hopkins' rods) (**Figure 47.13**).

The advantages and disadvantages of laryngeal examination techniques are given in *Summary box 47.3*.

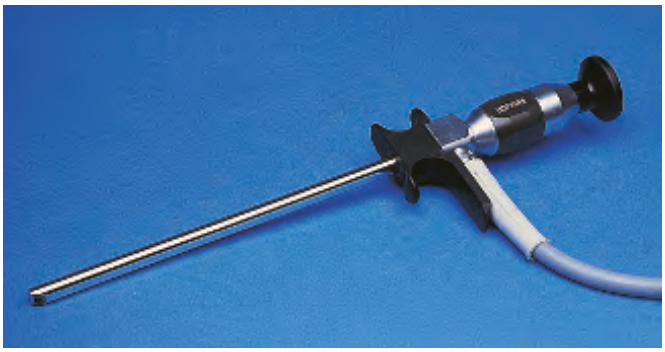

Figure 47.13 A rigid Hopkins' rod or endoscope.

Summary box 47.3

Advantages and disadvantages larynx and pharynx examination techniques

Flexible nasendoscopy

- Well tolerated examination
- Can also examine nasal passages and postnasal space
- Need fibreoptic light source

Rigid endoscopy

- Can be used with stroboscope for evaluation of voice
- High definition view
- Needs fibreoptic light source
- Bulky and difficult if prominent gag reflex present

Laryngeal mirror

- Does not need fibreoptic light source
- No record of exam, small image

Harold Horace Hopkins, 1918–1994, Professor of Applied Optics, The University of Reading, Reading, UK, invented the rigid rod endoscope (Hopkins' rod, 1954), and contributed to the development of the fibres for flexible endoscopes.

DISEASES OF THE PHARYNX

NASOPHARYNX

Enlarged adenoid

The most common cause of an enlarged adenoid (there is only one nasopharyngeal adenoid, despite the common use of the term 'adenoids') is physiological hypertrophy in childhood. The size of the adenoid alone is not an indication for removal. Of more importance is the consequences of hypertrophy (e.g. nasal obstruction). Adenoid hypertrophy is often associated with hypertrophy of the other lymphoid tissues of Waldeyer's ring. Of particular note, if excessive adenoidal hypertrophy causes blockage of the nasopharynx in association with tonsil hypertrophy, the upper airway may become compromised during sleep causing, obstructive sleep apnoea (OSA).

Obstructive sleep apnoea

This condition is becoming increasingly diagnosed in children and is important because it can cause sleep deprivation and secondary cardiac complications. It has been implicated in some cases of sudden infant death syndrome. The most common symptom is snoring, which is typically irregular, with the child actually ceasing respiration (apnoea) and then restarting with a loud inspiratory snort. The child is often restless and may take up strange sleep positions as he or she tries to improve the pharyngeal airway. Surgical removal of the tonsils and adenoid is curative, but it is important to avoid sedative premedications and opiate analgesics postoperatively because they may further depress the child's respiratory drive.

OSA may also occur in adults, where the obstruction may result from nasal deformity, a hypertrophic soft palate associated with an altered nasopharyngeal isthmus, obesity and general narrowing of the pharyngeal airway, or supraglottic laryngeal pathology. The initial investigation may include a sleep study, during which measurement of the patient's sleep pattern and arterial oxygenation are undertaken. Continuous positive airway pressure devices may ameliorate OSA by splinting the obstruction open. Surgery may also be indicated, depending on the level(s) of the obstruction.

Hypertrophy of adenoid tissue most commonly occurs between the ages of 4 and 10, but the adenoid tissue usually undergoes spontaneous atrophy during puberty, although some remnants may persist into adult life (**Figure 47.14**). The relationship of adenoid enlargement to recurrent secretory otitis media or recurrent acute otitis media is not entirely clear.

Adenoidectomy

Adenoid tissue can be removed alone or in conjunction with a tonsillectomy. The indications for adenoidectomy are:

- obstructive sleep apnoea associated with postnasal obstruction;
- recurrent acute otitis media or prolonged serous otitis media, usually longer than 3 months' duration;
- recurrent rhinosinusitis*;
- postnasal discharge*.

*Relative indications

Figure 47.14 Plain lateral radiograph showing a large pad of adenoid tissue (arrow) in the postnasal space.

Operative technique

With the patient placed in a prone position with the neck in a neutral position, the adenoid tissue is removed with a guarded curette pressed against the roof of the nasopharynx before sweeping downwards to deliver the excised adenoid into the oropharynx (**Figures 47.15 and 47.16**). A postnasal swab is placed into the nasopharynx until all haemorrhage

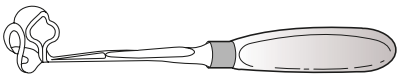

Figure 47.15 St Clair Thomson adenoid curette.

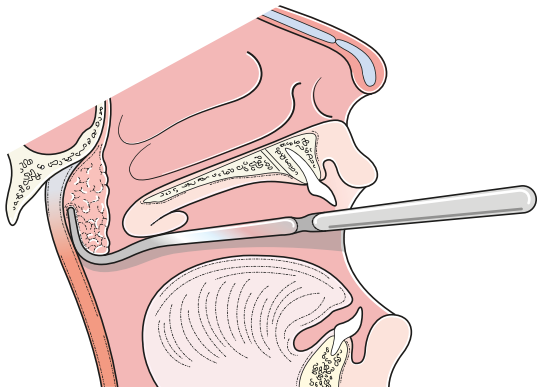

Figure 47.16 Curettage of the adenoid.

has ceased. A mirror can be used to guide the direction of the adenoid curette. Alternatively, suction monopolar diathermy may be used to remove adenoid tissue.

Reactionary or secondary haemorrhage during the recovery period may require a nasopharyngeal pack under a further anaesthetic. This can occasionally cause respiratory depression in children and adults, and strict observation is required while the pack is in place.

Tumours of the nasopharynx

Benign

There are two main types of benign tumour of the nasopharynx: the angiofibroma and the antrochoanal polyp. Both are rare.

ANGIOFIBROMA

This tumour is confined to young male patients most commonly between the ages of 8 and 20 years. It usually causes progressive nasal obstruction, recurrent severe epistaxis, purulent rhinorrhoea and occasionally loss of vision because of compression of the optic nerve by superior extension of the tumour through the skull base. Although the tumour is rare, these symptoms in a young male patient should always arouse suspicion. The tumour is more common in northern India, although the reasons for this are unknown. Clinical examination typically shows a mass in the nasal cavity or nasopharynx, but CT scanning best demonstrates the extent of the tumour and any associated bony erosion. MRI scanning defines the soft tissue extent and, with these two modern investigations, angiography is rarely indicated. Biopsy should be avoided unless clinical and radiological examinations are not diagnostic because of the risk of bleeding.

Surgical resection requires adequate exposure either through a midfacial approach or lateral rhinotomy (**Figures 47.17 and 47.18**). Both allow ligation of the feeding maxillary artery. More recently, endoscopic resection has been used for smaller lesions.

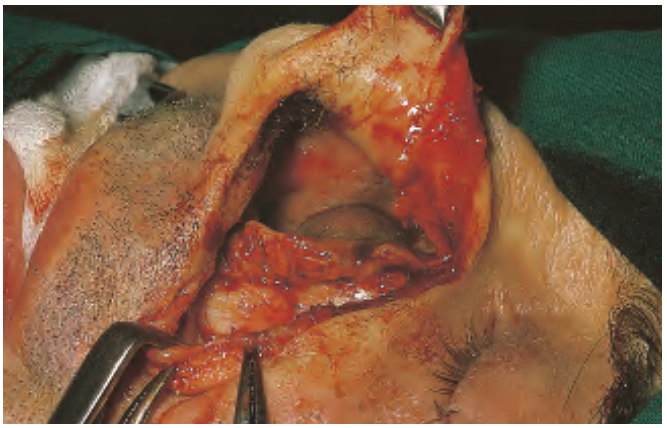

Figure 47.18 Intraoperative photograph showing an incision in lateral rhinotomy.

ANTROCHOANAL POLYP

This relatively uncommon lesion is a benign mucosal polyp that arises in the maxillary antrum and prolapses into the nasal cavity where it expands backwards into the nasopharynx and occasionally into the oropharynx (**Figures 47.19 and 47.20**). It may mimic an angiofibroma from which it is distinguished by its avascularity and pale colour, as well as its site of origin, which is determined on endoscopic examination and imaging. It requires complete removal via an endoscopic approach through the middle meatus of the maxillary sinus or, occasionally, via an open Caldwell–Luc approach.

Malignant

NASOPHARYNGEAL CARCINOMA

Nasopharyngeal carcinoma has a marked geographically variable incidence. In most parts of the world, the tumour

Figure 47.17 Intraoperative photograph showing exposure during a midfacial degloving approach.

Figure 47.19 Intraoral view showing a fleshy polyp hanging in the oropharynx.

George Walter Caldwell, 1834–1918, otolaryngologist, who practised successively in New York, San Francisco, and Los Angeles, USA, devised this operation for treating suppuration in the maxillary antrum in 1893.
Henri Luc, 1855–1925, otolaryngologist, Paris, France, described his operation in 1889.

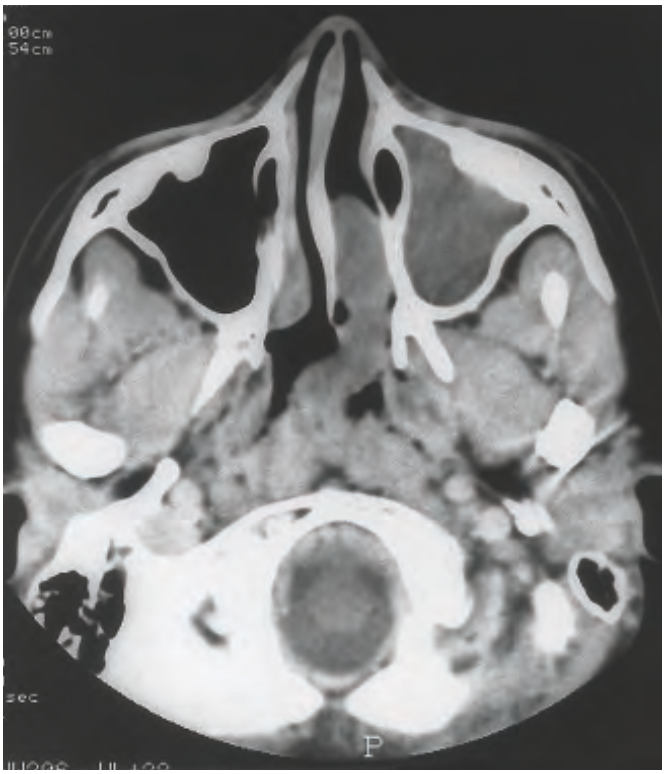

Figure 47.20 Axial computed tomogram of an antrochoanal polyp (as seen in Fig. 47.19), with opaque maxillary antrum and a mass in the nasal cavity and nasopharynx.

is rare with an annual incidence of 1 case per 100 000 population; however, among southern Chinese populations the rate is 30–50 cases per 100 000 population. The aetiology of nasopharyngeal carcinoma is multifactorial. Genetic susceptibility, early infection by the Epstein–Barr virus and consumption of traditional diets, particularly salted fish, are known to contribute.

Summary box 47.4

Aetiological factors in nasopharyngeal carcinoma

- Genetic (e.g. Cantonese)
- Infective (e.g. Epstein–Barr virus)
- Environmental (e.g. salted fish)

The majority of nasopharyngeal tumours are undifferentiated with a characteristic morphology, comprising over 90% of nasopharyngeal malignancy in endemic areas. Rare epithelial tumours are adenocarcinoma and adenoid cystic carcinoma, which arise from minor salivary glands. B- and T-cell lymphomas also occur in the nasopharynx and should not be confused with the more common undifferentiated carcinoma. Nasopharyngeal carcinoma has a bimodal distribution with an increased incidence in teenagers and young adults and then again in the 50–60 age group.

Clinical features Symptoms are closely related to the position of the tumour in the nasopharynx and the degree of regional and/or distant spread. Early symptoms are often minimal and may be ignored by both patient and doctor. Approximately 50% of patients will present with a malignant node or nodes in the neck, indicating an advanced tumour. While investigation of the lymph node will involve fine-needle aspiration or a biopsy, such a clinical presentation mandates an immediate thorough examination of the nasopharynx. In about 5% of patients, the nasopharynx may look normal or minimally asymmetrical but contains submucosal nasopharyngeal carcinoma. MRI or CT of the head and neck should be performed as part of the diagnostic work-up and even if a nasopharyngeal mass is not identified clinically or radiologically, a biopsy of the nasopharynx, targeting the fossa of Rosenmüller is essential if there is suspicion of nasopharyngeal malignancy. In contrast, nasal complaints (obstruction +/- rhinorrhoea) occur in one-third of patients and aural symptoms of unilateral deafness as a consequence of Eustachian tube obstruction and secretory otitis media occur in approximately 20%. Neurological complications with cranial nerve palsies as a result of disease in the skull base occur relatively late in the disease, but are a poor prognostic sign, as is trismus resulting from tumour involvement of the medial pterygoid.

Summary box 47.5

Nasopharyngeal carcinoma: main presenting complaints

Systemic

- Cervical lymphadenopathy

Local

- Unilateral serous otitis media, otalgia
- Nasal obstruction, bloody discharge, epistaxis
- Cranial nerve palsies, especially III–VI then IX–XII
- Trismus

Investigation This is by direct inspection with a flexible or rigid nasendoscope and biopsy under topical or general anaesthesia. Serological investigation for Epstein–Barr virus-associated antigenic markers in combination with the clinical and histological examination is valuable for the early detection of disease. Highly sensitive assays for antiviral antibodies together with virus-associated serological markers are useful in early detection and in post-treatment surveillance. Immunoglobulin (Ig) A antiviral capsid antigen antibody and

Michael Anthony Epstein, born 1921, formerly Professor of Pathology, The University of Bristol, Bristol, UK.
Yvonne Barr, 1931–2016, virologist who emigrated to Australia. Epstein and Barr discovered this virus in 1964.

early antigen antibody have been evaluated in mass surveys in southern China and have been found to be an excellent screening method for early detection of nasopharyngeal carcinoma in high-risk groups.

Imaging This is essential for staging and to determine the extent of disease. The imaging of choice is MRI with gadolinium and fat suppression. This allows for assessment of brain parenchyma, cavernous sinus and the closely associated cranial foramina. CT or positron emission tomography (PET)-CT of the head, neck and chest has a major role in planning radiotherapy and assessing the response to treatment, diagnosing recurrence and detecting complications.

Treatment The primary treatment of nasopharyngeal carcinoma, depending on the stage of disease, is with external beam or intensity modulated radiotherapy +/- cisplatin-based chemotherapy, as the majority of the tumours are chemoradiosensitive, undifferentiated squamous cell carcinomas. Surgery is usually reserved for regional recurrence in the neck. For early disease, 5-year disease-free survival rates of more than 75% are common; however, in advanced disease the results are less good, with 5-year disease-free survival rates of 30–50%.

OROPHARYNX

Acute tonsillitis

This common condition is characterised by a sore throat, fever, general malaise, dysphagia, enlarged upper cervical nodes and sometimes referred otalgia. Approximately half the cases are bacterial, the most common cause being a pyogenic group A streptococcus. The remainder are viral and a wide variety of viruses have been implicated, in particular infectious mononucleosis (glandular fever), which may be mistaken for bacterial tonsillitis.

On examination, the tonsils are swollen and erythematous, and yellow or white pustules may be seen on the palatine tonsils, hence the name 'follicular tonsillitis' (**Figure 47.21**). A throat swab should be taken at the time of examination as well as blood for Paul–Bunnell testing to confirm or refute the diagnosis of glandular fever.

Treatment

Paracetamol or similar analgesia may be administered to relieve pain and gargles of glycerol–thymol are soothing. The condition is frequently sensitive to benzyl- or phenyoxymethylpenicillin (penicillin V) and these are given until antibiotic sensitivities are established. Ampicillin is avoided as it may precipitate a rash in patients with infectious mononucleosis. Most cases resolve in a few days.

Figure 47.21 Acute follicular tonsillitis.

Quinsy

This is an abscess in the peritonsillar region that causes severe pain and trismus (**Figure 47.22**). The trismus caused by spasm induced in the pterygoid muscles may make examination difficult but may be overcome by instillation of local anaesthesia into the posterior nasal cavity (anaesthetising the sphenopalatine ganglion) and the oropharynx. Inspection reveals a diffuse swelling of the soft palate just superior or lateral to the involved tonsil, displacing the uvula medially. In more advanced cases, pus may be seen pointing underneath the thin mucosa.

Treatment

In the early stages, intravenous broad-spectrum antibiotics may produce resolution. However, if there is frank abscess formation, incision and drainage of the pus can be carried out under local anaesthesia. A small scalpel is best modified by winding a strip of adhesive tape around the blade so that only 1 cm of the blade projects. In teenagers and young adults, the

Figure 47.22 Quinsy (peritonsillar abscess).

John Rodman Paul, 1893–1971, Professor of Preventative Medicine, Yale University, New Haven, CT, USA.
Walls Willard Bunnell, 1902–1966, American physician. Paul and Bunnell described this test in 1932.

patient sits upright and an incision is made approximately midway between the base of the uvula and the third upper molar tooth (Figure 47.23). This may produce immediate release of pus, but, if not, a dressing forceps is pushed firmly through the incision and, on opening, pus may then be encountered. In small children, general anaesthesia is required.

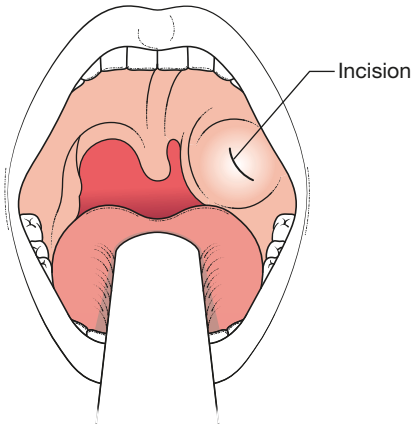

Figure 47.23 Site of incision in a peritonsillar abscess.

Chronic tonsillitis

Chronic tonsillitis usually results from repeated attacks of acute tonsillitis in which the tonsils become progressively damaged by inflammatory processes and provide a reservoir for infective organisms.

Tonsillectomy

Recurrent acute tonsillitis is the most common relative indication for tonsillectomy in children and adolescents, although it is important that these attacks are well documented, frequent and do not simply constitute a minor viral sore throat. Chronic tonsillitis more frequently affects young adults in whom it is important to establish that chronic mouth breathing secondary to nasal obstruction is not the main problem rather than the tonsils themselves. Absolute indications for tonsillectomy are when the size of the tonsils is contributing to airway obstruction or a malignancy of the tonsils is suspected (*Table 47.1*).

TABLE 47.1 Indications for tonsillectomy.

Absolute	Sleep apnoea, chronic respiratory tract obstruction, cor pulmonale
	Suspected tonsillar malignancy
Relative	Documented recurrent acute tonsillitis
	Chronic tonsillitis
	Peritonsillar abscess (quinsy)
	Tonsillar asymmetry
	Tonsillitis resulting in febrile convulsions
	Diphtheria carriers
	Systemic disease caused by β-haemolytic *Streptococcus* (nephritis, rheumatic fever)

Ideally, the procedure should be undertaken when the tonsils are not acutely infected, and it is important to discuss factors that may increase the tendency to bleed. Blood transfusion is rarely required, but it is normal practice to type and screen blood for cross-match in children under 15 kg in weight.

Dissection tonsillectomy is carried out under general anaesthesia. The mucosa of the anterior faucial pillar is incised and the tonsil capsule identified. Using blunt dissection, the tonsil is separated from its bed until only a small inferior pedicle is left (Figure 47.24). It is then separated from the lingual tonsil. A tonsil swab is placed in the tonsillar bed and pressure applied for some minutes, following which bleeding points may be controlled by ligature or by bipolar diathermy. (Coblation and laser dissection is commonly used in the resource-rich world in an attempt to reduce postoperative pain and bleeding.)

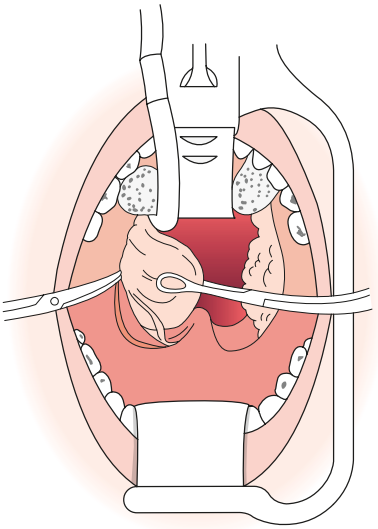

Figure 47.24 Removal of the tonsils.

Following surgery, the patient is kept under close observation for any systemic or local evidence of bleeding, with regular pulse and blood pressure measurements and observation to monitor whether the patient is swallowing excessively (Figure 47.25). Postoperatively, patients are encouraged to eat normally. Paracetamol is preferred to non-steroidal analgesics. Patients are allowed home on the same or following day and are warned that they may experience otalgia as a result of referred pain from the glossopharyngeal nerve and that secondary haemorrhage may occur up to 10 days following the surgery.

Haemorrhage is the most common complication in the immediate postoperative period. Local pressure may help in mild cases, but reactionary haemorrhage usually requires return to theatre for definitive treatment, particularly in younger patients. Under general anaesthesia, it may be possible to identify a bleeding spot, but often a more generalised ooze is observed and suturing of the tonsil bed combined with the application of haemostatic gauze and bipolar diathermy is often more successful than attempted placement of ligatures.

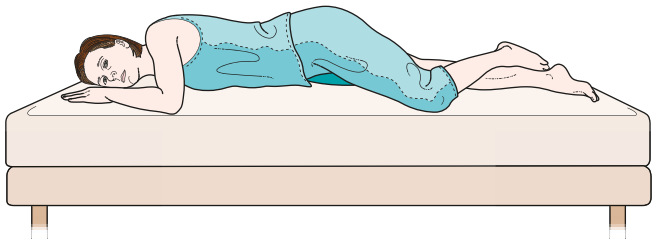

Figure 47.25 Positioning of the patient after tonsillectomy.

Late haemorrhage is sometimes secondary to infection and patients are usually started on broad-spectrum intravenous antibiotics. Any residual clot in the tonsil fossa should be removed and regular gargling with a dilute solution of hydrogen peroxide may be beneficial. Significant or persistent bleeding may require a further general anaesthetic and haemostasis, which may require diathermy and/or undersewing of the granulating, sloughy tonsil fossa. Postoperative tonsillar haemorrhage is still a serious and life-threatening complication and should not be underestimated, particularly in the younger patient.

Summary box 47.6

Complications of tonsillectomy

Anaesthetic

- Traumatic intubation
- Cardiopulmonary arrest
- Malignant hyperthermia

Surgical

- Haemorrhage (immediate or late)
- Infection
- Pain/otalgia
- Postoperative airway obstruction
- Velopharyngeal insufficiency

Parapharyngeal abscess

Parapharyngeal abscess may be confused with a peritonsillar abscess, but the maximal swelling is *behind* the posterior faucial pillar and there may be little oedema of the soft palate. The patient is usually a young child and there may be a severe general malaise and obvious neck swelling. In early cases, admission to hospital and the institution of fluid replacements coupled with intravenous antibiotics may produce resolution. In advanced cases, drainage and intravenous antibiotics are required. With an obvious abscess pointing into the oropharynx, drainage may be carried out with a blunt instrument or the glove finger, but general anaesthesia is frequently required and the expertise of a senior anaesthetist, good illumination and good suction are absolutely essential. A large parapharyngeal abscess may compromise both the airway and swallowing. MRI or CT scanning of the head and neck is often an invaluable aid to diagnosis and management as it allows assessment of the extent of the abscess and facilitates planning of the optimal surgical approach.

Acute retropharyngeal abscess

This is the result of suppuration of the retropharyngeal lymph nodes and, again, is most commonly seen in children, with most cases occurring under the age of 1 year. It is associated with infection of the upper aerodigestive tract, and is frequently accompanied by severe general malaise, neck rigidity, dysphagia, drooling, a croupy cough, an altered cry and marked dyspnoea.

Dyspnoea may be the prominent symptom and may also be accompanied by febrile convulsions and vomiting. These children should always be carefully examined by the most senior clinicians available. Inspection of the posterior wall of the pharynx may show gross swelling and an abscess pointing beneath the thinned mucosa.

In countries where diphtheria still occurs, an acute retropharyngeal abscess may be confused with this, but the presence of the greyish–green membrane aids differentiation. Occasionally, a foreign body, most commonly a fish bone which has perforated the posterior pharyngeal mucosa, will give rise to a retropharyngeal abscess in older children and young adults. Intravenous antibiotics are commenced immediately but surgical drainage of the abscess is often necessary. It requires experienced anaesthesia because, on induction, care must be taken to avoid rupturing the abscess. The airway is protected by placing the child in a head down position while a pair of dressing forceps, guided by the finger, may be thrust into an obvious abscess in the posterior wall and the contents evacuated. On other occasions, an approach anterior and medial to the carotid sheath via a cervical incision may be preferable.

Chronic retropharyngeal abscess

This condition is now rare and is most commonly the result of an extension of tuberculosis of the cervical spine, which has spread through the anterior longitudinal ligament to reach the retropharyngeal space. In addition to the retropharyngeal swelling seen intraorally, there may be fullness behind the sternocleidomastoid muscle on one side. In contrast to an acute retropharyngeal abscess, this condition occurs almost solely in adults. Radiology usually shows evidence of bone destruction and loss of the normal curvature of the cervical spine. The spine may be quite unstable and undue manipulation may precipitate a neurological event.

In contrast to an acute abscess, a chronic retropharyngeal abscess must not be opened into the mouth, as such a procedure may lead to secondary infection. Drainage of the abscess may not be necessary if suitable treatment of the underlying tuberculosis disease is instituted. If it is necessary, drainage should be carried out through a cervical incision anterior to the sternocleidomastoid muscle with an approach anterior and medial to the carotid sheath to enter the retropharyngeal space. The cavity is opened and suctioned dry after taking biopsy material. Occasionally, surgery is required to decompress or stabilise the spinal cord if there is a progressive neurological deficit.

Glandular fever (infectious mononucleosis)

This systemic condition is usually caused by the Epstein–Barr virus, but similar features can be caused by cytomegalovirus or toxoplasmosis. The tonsils are typically erythematous with a creamy grey exudate and appear almost confluent, usually symmetrical. In addition to the discomfort and dysphagia, patients may drool saliva and have respiratory difficulty, particularly on inspiration. They commonly have a high temperature and gross general malaise with marked cervical or generalised lymphadenopathy. Occasionally, an enlarged spleen or liver may be detected. The condition is most frequent in teenagers and young adults. The diagnosis can be confirmed by serological testing showing a positive Paul–Bunnell test, an absolute and relative lymphocytosis, and the presence of atypical monocytes in the peripheral blood.

Treatment

Analgesia and maintenance of fluid intake are important. A small number of patients require admission to hospital if the airway is compromised or if oral intake of fluids is not possible, and a short course of steroids may be helpful. Antibiotics are of little value and ampicillin is contraindicated because of the frequent appearance of a widespread skin rash. Rarely, if the airway is severely compromised, an elective tracheostomy under local anaesthesia is safer and less traumatic than an emergency intubation. Emergency tonsillectomy is contraindicated because of the generalised pharyngeal oedema and compromised airway.

Human immunodeficiency virus

Acquired immune deficiency syndrome (AIDS) can affect the ear, nose and throat (ENT) system at any point during the disease. The initial seroconversion may present with the symptoms of glandular fever, which is followed by an asymptomatic period of variable length. In the pre-AIDS period, before the full-blown symptoms of the AIDS-related complex, many patients have minor upper respiratory tract symptoms that are often overlooked, such as otitis externa, rhinosinusitis and a non-specific pharyngitis. As the patient moves into the full-blown AIDS-related complex, a persistent, generalised lymphadenopathy is frequently found affecting the cervical nodes, which is usually due to follicular hyperplasia. However, patients may also develop tumours such as Kaposi's sarcoma, sometimes seen in the oral cavity, and high-grade malignant B-cell lymphoma affecting the cervical lymph nodes and nasopharynx. In addition, multiple ulcers may be found in the oral cavity or pharynx associated with herpesvirus infection. Severe candida may affect the oral cavity, pharynx, oesophagus or even larynx, and a hairy leucoplakia may affect the tongue (**Figure 47.26**).

Figure 47.26 Intraoral view showing hairy tongue in a human immunodeficiency virus-positive patient.

The globus syndrome

A wide variety of patients experience the feeling of a lump in the throat (from the Latin *globus* = lump). The symptom most commonly affects adults between 30 and 60 years of age. This feeling is not true dysphagia as there is no difficulty in swallowing. Most patients notice the symptom more if they swallow their own saliva (i.e. a forced, dry swallow) rather than when they eat or drink.

The aetiology of this common symptom is unknown, but some patients may have gastro-oesophageal reflux or spasm of their cricopharyngeus muscle. Radiological and endoscopic investigation may be necessary to exclude an underlying cause and/or for patient reassurance.

Pharyngeal pouch

A pharyngeal pouch is a protrusion of mucosa though Killian's dehiscence, a weak area of the posterior pharyngeal wall between the oblique fibres of the thyropharyngeus and the transverse fibres of cricopharyngeus at the lower end of the inferior constrictor muscle (**Figure 47.27**). These fibres, along with the circular fibres of the upper oesophagus, form the physiological upper oesophageal sphincter mechanism. Why the pouch forms is not yet clear, even with modern videofluoroscopic and manometric studies. Many patients with pharyngeal pouches have been demonstrated to have normal relaxation of the upper oesophageal sphincter mechanism in relation to swallowing, but others have been shown to have incomplete pharyngeal relaxation, early cricopharyngeal contraction and abnormalities of the pharyngeal contraction wave. When enlarged, the pouch almost invariably deviates to the left hand side, why this is the case is also unclear.

Moritz Kaposi, 1837–1902, Professor of Dermatology, Vienna, Austria, described pigmented sarcoma of the skin in 1872.
Gustav Killian, 1860–1921, Professor of Laryngology at Freiburg, and later at Berlin, Germany.

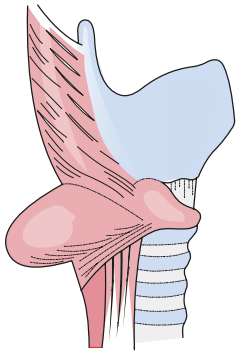

Figure 47.27 A pharyngeal pouch.

Clinical features

Patients suffering from this condition are commonly more than 60 years of age and it is more common in men than women. As the diverticulum enlarges, patients may experience regurgitation of undigested food, sometimes hours after a meal, particularly if they are bending down or turning over in bed at night. They sometimes wake at night with a feeling of tightness in the throat and a fit of coughing. Occasionally, they may present with recurrent, unexplained chest infections as a result of aspiration of the contents of the pouch. As the pouch increases in size, patients may notice gurgling noises from the neck on swallowing and the pouch may become large enough to form a visible swelling in the neck.

Radiological examination

A thin emulsion of barium is given to the patient as a barium swallow (**Figure 47.28**) or ideally as part of a videofluoroscopic swallowing study. Care should be exercised in patients who cough on swallowing, indicating they may have aspiration. A small volume of barium is sufficient to outline the pharynx, pouch and upper oesophagus. The videofluoroscopic study gives additional information about the pharyngeal contraction waves and the performance of the upper oesophageal sphincter.

Figure 47.28 Barium swallow showing a pharyngeal pouch.

Treatment

Surgery is indicated when the pouch is associated with progressive symptoms and particularly when a prominent cricopharyngeal bar of muscle associated with abnormality of the upper oesophageal sphincter mechanism causes considerable dysphagia. In elderly patients, a decision to operate may be influenced by their general condition. However, surgical intervention is mandated in all but the most poorly patients as, in most cases, it is the pouch that is contributing significantly to the underlying debilitation. Of particular importance is the risk of recurrent pneumonia from aspiration and overspill of pouch contents, as well as increasing dysphagia as the pouch opening becomes larger than the oesophageal opening and the enlarged pouch exerts extramural pressure on the oesophagus. Accordingly, preoperative chest physiotherapy and attention to the respiratory, cardiovascular and nutritional aspects of the patient are important.

The preferred surgical technique is endoscopic stapling of the diverticular wall. A double-bladed rigid endoscope is passed, with one blade in the diverticulum and one blade positioned in the oesophagus. Opening of the bivalve scope reveals the pathonmonic 'bar' formed by the cricopharyngeus muscle and overlying mucosa, which forms the boundary between the posterior wall of the oesophagus and the anterior wall of the pouch. At this stage the pouch should be emptied of food content and the mucosa should be inspected for the rare occurrence of carcinoma in the pouch. An endoscopic linear stapler is then introduced to sit astride of the 'bar'. One jaw of the stapler is placed in the oesophagus, the other in the pouch. The stapler is fired dividing the wall separating the two. The process should be repeated until the bottom of the pouch is reached. This has the effect of opening the pouch, incorporating it as part of the oesophageal wall and dividing the cricopharyngeus muscle. If the patient is symptom free after the procedure, they may start graded per-oral intake and early discharge. Division of the 'bar' using CO_2 laser, as an alternative to stapling, is gaining popularity in some centres.

Occasionally, usually because of inadequate endoscopic access, an open excision of the pouch becomes necessary. In the classic external operation, the opening to the pouch is first identified using a pharyngoscope and a nasogastric tube placed into the oesophageal lumen for postoperative nutrition. This initial endoscopy is often difficult because the normal oesophageal opening is small compared with the lumen of the pouch, but it may be better visualised using a Dohlman's rigid endoscope. The pouch may be packed with ribbon gauze to further aid identification of its neck.

A lower neck incision along the anterior border of the left sternocleidomastoid muscle, or a transverse crease incision, is used and the muscle and carotid sheath are retracted laterally and the trachea and larynx medially. The pouch is found medially behind the lower pharynx and is carefully isolated and dissected back to its origin at Killian's dehiscence. It is then excised and the pharynx closed in two layers or, if it

is small, the pouch may be invaginated into the pharyngeal lumen before closing the muscle layers. In all cases, a myotomy dividing the fibres of the cricopharyngeus muscle and the upper oesophageal circular muscle fibres must be performed. The wound is usually closed with drainage and the patient fed through a nasogastric tube for 3–7 days.

The average operating time with an endoscopic procedure is 20–30 minutes compared with 60–90 minutes with an external procedure. Inpatient stay is also decreased for patients undergoing an endoscopic procedure. The endoscopic technique is associated with a high symptomatic success rate and a low morbidity, which is particularly important in the elderly.

Complications

The classic operation has been associated with wound infection, mediastinitis, pharyngeal fistula formation, recurrent laryngeal nerve palsy and stenosis of the upper oesophagus. Endoscopic division is associated with the same risks but at much lower rates. The recurrence rates between the two procedures appears to be equal; longer-term follow up will establish this. Endoscopic stapling will also allow for safe reoperation if necessary.

In light of this risk–benefit difference, it is an option, if the main reason preventing endoscopic stapling is prominent incisors, to offer extraction of the upper incisors to facilitate access for stapling. If available, primary osseointegrated implants could be inserted at the time of stapling to allow dental restoration. This approach, despite the dental extractions, is still less risky than an open procedure.

Sideropenic dysphagia

Prolonged iron deficiency anaemia may lead to dysphagia, particularly in middle-aged women. In addition, they may have koilonychia, cheilosis and angular stomatitis together with lassitude and poor exercise tolerance. The dysphagia is caused by a postcricoid or upper oesophageal web and these patients have a higher incidence of postcricoid malignancy. The syndrome is associated with the names of Plummer and Vinson, Paterson and Brown Kelly.

Tumours of the oropharynx

Benign

Benign tumours of the oropharynx are rare, papillomas being the most common. These are usually incidental findings and are rarely of any importance.

Malignant

The most important epithelial tumour is squamous cell carcinoma, which constitutes approximately 90% of all epithelial tumours in the upper aerodigestive tract (**Figures 47.29 and 47.30**). In the oropharynx, the proportion is less (70%) because of the higher incidence of lymphoma (25%) and salivary gland tumours (5%). Because of the rich lymphatic drainage of the oropharynx, cervical node metastases are common. They may be the only presenting feature with an apparent occult primary tumour often being unsuspected and missed in the tonsil or tongue base.

AETIOLOGY

While it has been long established that oropharyngeal squamous cell carcinoma (OPSCC) is strongly associated with cigarette smoking and consumption of alcohol, over recent decades there has been a near epidemic increase in human papillomavirus-associated OPSCC (HPV+OPSCC) in the resource-rich world, with prevalences up to 70% being commonly reported in the USA, UK and Northern Europe. Why

Figure 47.29 Squamous cell carcinoma of the right tonsil.

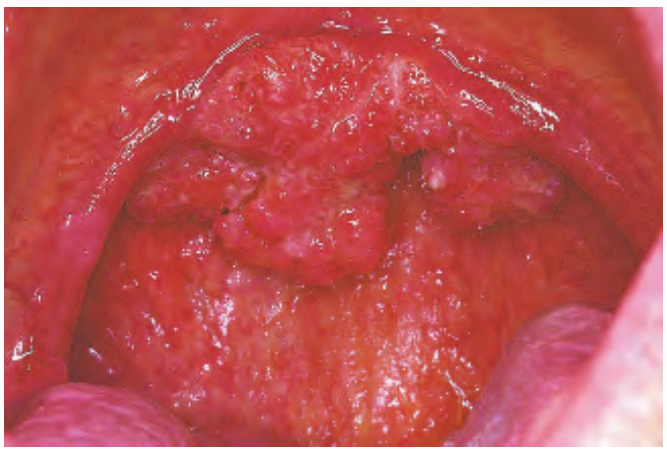

Figure 47.30 Squamous cell carcinoma of the soft palate.

Henry Stanley Plummer, 1874–1937, physician, The Mayo Clinic, Rochester, MN, USA, described this syndrome in 1912.
Porter Paisley Vinson, 1890–1959, physician, The Mayo Clinic, Rochester, MN, who later practised in Richmond, VA, USA.
Donald Rose Paterson, 1863–1939, surgeon, The Ear, Nose and Throat Department, The Royal Infirmary, Cardiff, UK.
Adam Brown Kelly, 1865–1941, surgeon, The Ear, Nose and Throat Department, The Royal Victoria Infirmary, Glasgow, UK.
Vinson, Paterson and Kelly all described this syndrome independently in 1919.

this increase has happened recently is unclear and is the subject of ongoing research. That HPV+OSCC constitutes a separate disease entity is undoubted. In contrast to patients presenting with HPV+OPSCC, those presenting with HPV-OPSCC are typically younger and fitter and smoke and drink less alcohol. Moreover, although the presenting features of HPV+OPSCC (multiple large cystic cervical lymph nodes with a high prevalence of extracapsular spread [ECS]) are usually associated with poor outcome, paradoxically, HPV+ tumours respond far better to treatment than their HPV- counterparts. Again, why this is the case is unclear and is the subject of much ongoing research.

TREATMENT

Treatment varies with facilities around the world, but early stage tumours may be cured by radiotherapy, laser excision or more conventional excision. Intermediate or late stage disease is usually managed with open surgery and reconstruction using myocutanous pedicles or free flaps, or concurrent chemoradiotherapy. Recurrent disease following radiotherapy +/- chemotherapy is a surgical challenge and usually requires open surgery and reconstruction. Neck dissection is required in most cases where surgery is the primary treatment modality and is also required for patients who have only partially responded following chemoradiotherapy. Postoperative dysphagia with aspiration as a result of interference in the complex neuromuscular control of the second phase of swallowing is a particular problem in these patients. The advent of HPV+OPSCC has created a clinical need to define novel de-intensified treatments that maintain current advantageous survival rates while reducing the late morbidity of treatment. Management of such tumours should be multidisciplinary and is best carried out in a major centre undertaking this work on a regular basis.

Lymphoma of the head and neck

Lymphomas of the head and neck may arise in nodal or extranodal sites and both Hodgkin's disease and non-Hodgkin's lymphoma commonly present as lymph node enlargement in the neck. Hodgkin's disease is rare in the oropharynx, but non-Hodgkin's lymphoma accounts for 15–20% of tumours at this site in some countries. Most are of the B-cell type and have features in common with other MALT tumours. Further evaluation with CT scanning of the thorax and abdomen and bone marrow evaluation are essential. FNAC of neck lymph nodes is now mandatory (although excision biopsy to improve tissue yield is still often required to establish a grading diagnosis) and flow cytometry of the aspirates has aided in diagnosis and classification of lymphomas.

Radiotherapy is the treatment of choice for localised non-Hodgkin's lymphoma and may give control rates as high as 75% at 5 years. For disseminated non-Hodgkin's lymphoma, systemic chemotherapy is preferred.

HYPOPHARYNX

Tumours of the hypopharynx

Benign

Benign tumours of the hypopharynx are very rare, the most common being the fibroma and the leiomyoma. They show a smooth, constant mass lying in the lumen of the hypopharynx or oesophagus.

Malignant

Malignant tumours of the hypopharynx are almost exclusively squamous cell carcinomas and typically behave aggressively. The tumours are usually classified according to their probable anatomical site of origin from the piriform fossa, postcricoid region or posterior pharyngeal wall. Marked differences in the incidence of these tumours occur globally because of factors such as iron-deficiency anaemia (see Sideropenic dysphagia, page 740). They may be associated with marked submucosal spread, which further complicates evaluation. Tumours arising from the piriform fossa and posterior pharyngeal wall may spread to upper or lower cervical nodes. Tumours arising in the postcricoid area typically metastasise to paratracheal and paraoesophageal nodes, which may not be palpable. As with other non-HPV head and neck cancers, alcohol and tobacco are two principal carcinogens. Postcricoid carcinoma, though rare, is more common in women than men.

The diagnosis of hypopharyngeal carcinoma should be considered in all patients presenting with dysphagia, hoarseness or referred otalgia, particularly if they have a history of smoking or significant alcohol consumption.

Fibreoptic endoscopic examination in the clinic may show only subtle signs such as oedema or pooling of saliva unilaterally in the piriform fossa. Note should also be made that this region is not well seen on flexible gastroscopy. The preferred investigation is with direct rigid pharyngoscopy and oesophagoscopy with biopsy under a general anaesthetic. All regions of the neck must be assessed in a systematic manner. Fine-needle aspirate is advocated for suspicious nodes.

RADIOLOGICAL EXAMINATION

As for other head and neck cancers, a suspected primary tumour requires an MRI or CT scan of the neck together with a CT scan of the thorax and upper abdomen.

TREATMENT

Squamous cell carcinoma of the hypopharynx commonly presents late and carries a poor prognosis. Early lesions may be treated with radiotherapy or transoral endoscopic carbon dioxide laser resection and a neck dissection plus postoperative radiotherapy. Non-surgical strategies for intermediate and late stage disease, designed to preserve function, rely on chemoradiotherapy. Major open excisional surgery is

Thomas Hodgkin, 1798–1866, Curator of the Museum and Demonstrator of Morbid Anatomy, Guy's Hospital, London, UK, described lymphadenoma in 1832.

generally used for recurrence after radiotherapy or as primary excision in advanced disease. Total laryngectomy and either partial or total pharyngectomy followed by pharyngeal reconstruction involving myocutaneous or free flap reconstruction (e.g. jejunum or anterolateral thigh) or gastric transposition is commonly required (Figure 47.31). Swallowing and voice rehabilitation are necessary to support patients after this major surgery if they are to adjust and maintain some quality of life.

Summary box 47.7

Tumours of the hypopharynx

- Variable symptoms – discomfort, pain, dysphagia, hoarseness
- Awareness increased by history of smoking and alcohol
- Expert examination with nasendoscopy
- Referral to multidisciplinary team for detailed assessment and treatment – radiotherapy +/- chemotherapy, transoral laser or extensive surgery

DISEASES OF THE LARYNX

EMERGENCIES

Stridor

Stridor means noisy breathing. It may be inspiratory or expiratory, or occur in both phases of respiration. Inspiratory stridor is usually due to an obstruction at or above the vocal folds and is most commonly the result of an inhaled foreign body or acute infections such as epiglottitis. Expiratory stridor is usually from the lower respiratory tract and gives rise to a prolonged expiratory wheeze. It is most commonly associated with acute asthma or acute infective tracheobronchitis. Biphasic stridor is usually due to obstruction or disease of the tracheobronchial airway and distal lungs.

Summary box 47.8

Stridor

Inspiratory

- Foreign body or epiglottitis

Expiratory

- Acute asthma or infective tracheobronchitis

Biphasic

- Obstruction, disease of tracheobronchial airway or distal lungs

Stridor in children

Infants and children presenting with stridor need careful assessment with a full history and examination as appropriate. If, on presentation, a child is cyanosed and severely unwell, the airway must be secured as soon as possible, but a brief history with important pointers can often be obtained from the parents.

History

In infants in the first year of life, it is important to establish if the stridor is associated with particular activities such as swallowing, crying or movement. These may suggest congenital laryngomalacia or subglottic stenosis. If the stridor is exacerbated by feeding, particularly in the first 4 weeks of life, this suggests a vascular ring compressing the oesophagus or tracheo-oesophageal fistula. If the cry is weak or abnormal, this suggests a vocal fold palsy. If the problem only occurs in association with an upper respiratory tract infection and, in particular, is biphasic, this would suggest congenital subglottic stenosis. In a young child, inspiratory stridor and drooling suggest acute epiglottitis, whereas biphasic stridor without drooling suggests laryngotracheobronchitis or croup.

Examination

It is important when possible to observe the child carefully at rest. Once a baby starts to cry, it may be impossible to study its resting respiratory pattern for some time. Ask the mother, not a nurse or a colleague, to move a baby or young child

Summary box 47.9

Acute paediatric stridor

Congenital

- Neurological
  - Vocal fold palsy
- Neoplasia
  - Benign laryngeal papillomatosis

into different positions, such as face down and supine, and watch for changes in respiratory pattern and level of distress. Observe any drooling and, with neonates and infants, always try to watch the child being fed, listening to the trachea and chest with a stethoscope if possible. Always examine the whole child, looking for any evidence of congenital abnormalities before attempting any examination of the throat.

If a child is stridulous and drooling, do not attempt to lay it down and do not attempt to look inside the mouth. These manoeuvres are potentially life-threatening as the child may aspirate a large quantity of thick saliva contained within the oral cavity. It is particularly important in acute epiglottitis as the aspiration of thick saliva may be associated with further laryngeal spasm and a respiratory arrest. Restlessness, increasing tachycardia and cyanosis are important signs of hypoxia. If the child is not distressed and drooling, and not markedly stridulous, he/she may be cooperative enough that it is possible to look inside the mouth and check the palate, tongue and oropharynx. In stridulous children, particularly neonates and infants, a transcutaneous oximeter is invaluable. A resuscitation trolley with the necessary equipment for emergency intubation or tracheostomy should be close at hand if at all possible before commencing examination.

Investigation

Plain lateral radiographs of the neck and a chest radiograph can be obtained but only if the child's condition permits. If a child is severely stridulous, they should *not* be sent to a radiography department without access to medical staff or resuscitation equipment.

Examination under anaesthesia is essential in all children whose diagnosis remains in doubt. This requires a high level of skill and appropriate rigid laryngoscopes, bronchoscopes, endoscopic Hopkins' rods and an operating microscope should be made available if possible. Equipment should be available at all times to undertake an urgent tracheostomy to establish or maintain an airway.

Acute epiglottitis

In children acute epiglottitis is of rapid onset. It tends to occur in children of 2 years of age and over. Stridor is usually associated with drooling of saliva. The condition is caused by *Haemophilus influenzae* infection, which initially causes a severe pharyngitis that extends to involve the laryngeal inlet, causing inflammation and oedema. Further progression involves the whole of the supraglottic larynx, with severe oedema of the aryepiglottic folds and epiglottis being the most notable component, hence the commonly used term 'acute epiglottitis'.

These children frequently require intensive management with emergency intubation or tracheostomy followed by oxygenation, humidification, continuous oximetry and antibiotics such as ampicillin or chloramphenicol. There may be associated septicaemia so blood cultures should be obtained. Attempted examination with a spatula into the mouth may precipitate a respiratory arrest and should be avoided. The incidence of acute epiglottitis has plummeted where *Haemophilus influenzae* vaccination programmes are in place.

Laryngotracheobronchitis (croup)

Croup is usually of slower onset than acute epiglottitis and occurs most commonly in children under 2 years of age. It is usually viral in origin and the cases often occur in clusters. The children have biphasic stridor, and are often hoarse with a typical barking cough. Airway intervention is required less often, but admission to hospital with oxygenation and humidification, coupled with antibiotics, may be necessary if there are signs of secondary infection.

Foreign bodies

Both children and adults may inhale foreign bodies. Young children will attempt to swallow a wide variety of objects, but coins, beads and parts of toys are particularly common. In adults, the aspiration is usually food, particularly inadequately chewed bones and meat. This is more common in elderly edentulous adults. Occasionally, portions of dentures may be inhaled, particularly in association with road traffic accidents.

Clinical features

The history is paramount and a history of foreign body ingestion or inhalation in a child, even though the pain, dysphagia, coughing, etc. may have settled, should always be taken seriously.

Adults usually have a clear recall, which facilitates diagnosis. Fish bones may lodge in the tonsils or base of tongue with minimal symptoms, but small fish bones may give rise to delayed para- and retropharyngeal abscess formation.

Examination

Examination may be prevented by trismus, pain and anxiety, but the presence of a foreign body may be suspected by a salivary pool within the piriform fossa or adjacent oedema and erythema of the pharyngolaryngeal mucosa.

Radiology

Radiology may be helpful but is not critical. Fish bones are often invisible on plain radiographs and a normal plain radiograph does not exclude a foreign body within the pharynx, larynx, oesophagus or lungs.

Specialised studies may help in cases of doubt, using a CT scan or a gastrografin swallow in the case of a suspected oesophageal foreign body.

Treatment

In the case of an inhaled foreign body causing severe stridor in a neonate or infant, it may be removed either by hooking it from the pharynx with a finger or by inverting the child carefully by the ankles and slapping his/her back. In a larger child, it may be more appropriate to bend the child over your knee with the child's head hanging down and again strike the child firmly between the shoulders. In the case of adults, an impacted laryngeal foreign body may be coughed out using a Heimlich manoeuvre. This involves standing behind the patient, clasping the arms around the lower thorax, such that the knuckles of the clasped hands come into contact with the patient's xiphisternum, and then a brief, firm compression of the lower thorax may aid instant expiration of the foreign body. If none of these immediate emergency measures removes the foreign body and the patient is cyanosed and severely stridulous, an immediate cricothyroidotomy or tracheostomy may be necessary. In less urgent cases, and when a foreign body is strongly suspected, endoscopy under general anaesthesia may be indicated.

Other causes of acute pharyngolaryngeal oedema

Angioneurotic oedema, radiotherapy, laryngeal trauma associated with road traffic accidents, corrosives, scalds and smoke ingestion may all cause significant pharyngolaryngeal oedema, in addition to the acute infective conditions mentioned above. Hoarseness is the predominant symptom along with dysphagia prior to the increase in dyspnoea. If flexible laryngoscopic examination is possible, marked oedema of the supraglottis and pharynx can be seen. Humidified oxygen, adrenaline nebulisers, systemic antihistamines and steroids may be valuable. Morphine should not be given as it may cause respiratory depression and respiratory arrest. If the dyspnoea progresses, intubation or tracheostomy will be necessary.

TRACHEOSTOMY AND OTHER EMERGENCY AIRWAY MEASURES

This procedure relieves airway obstruction or protects the airway by fashioning a direct entrance into the trachea through the skin of the neck. Tracheostomy may be carried out as an emergency for acute airway obstruction when the larynx cannot be intubated, but it is not always an easy procedure, particularly in an obese patient. An easier alternative for the inexperienced is insertion of a large intravenous cannula or a small tube into the cricothyroid membrane, which lies in the midline immediately below the thyroid cartilage. *The time to do a tracheostomy is when you first think it may be necessary*.

If time allows, the following should be undertaken:

- inspection and palpation of the neck to assess the laryngotracheal anatomy in the individual patient;
- indirect or direct laryngoscopy;
- assessment of pulmonary function by auscultation.

Whenever possible, the procedure should be adequately explained to the patient beforehand, with particular emphasis on the inability to speak immediately following the operation. Ample reassurance is required that they will not have 'lost' their voice permanently. The indications for tracheostomy are shown in Summary box 47.10.

Summary box 47.10

Indications for tracheostomy

Acute upper airway obstruction

- For example, an inhaled foreign body, a large pharyngolaryngeal tumour, or acute pharyngolaryngeal infections in children

Potential upper airway obstruction

- For example, after or prior to major surgery involving the oral cavity, pharynx, larynx or neck

Protection of the lower airway

- For example, protection against aspiration of saliva in unconscious patients as a consequence of head injuries, maxillofacial injuries, comas, bulbar poliomyelitis or tetanus

Patients requiring prolonged artificial respiration

- Best performed within 10 days of ventilation

Emergency tracheostomy

If a skilled anaesthetist is unavailable, local anaesthesia is employed, but in desperate cases when the patient is unconscious, none is required. In patients who have suffered severe head and neck trauma and who may have an unstable cervical spine fracture, cricothyroidotomy may be more suitable. If it is possible, the patient should be laid supine with padding placed under the shoulders and the extended neck kept as steady as possible in the midline. This aids palpation of the thyroid and cricoid cartilage between the thumb and index finger of the free hand. The movements of the fingers of the free hand are important in this technique. The operation is more difficult in small children and thick-necked adults as the landmarks are difficult to palpate (**Figures 47.32 and 47.33**).

A vertical midline incision is made from the inferior aspect of the thyroid cartilage to the suprasternal notch and

Henry Jay Heimlich, 1920–2016, thoracic surgeon, Xavier University, Cincinnati, OH, USA.

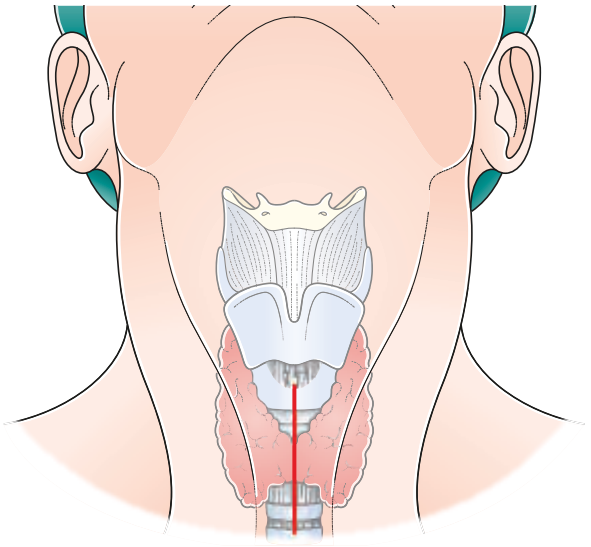

Figure 47.32 Position of the skin incision in an emergency tracheostomy.

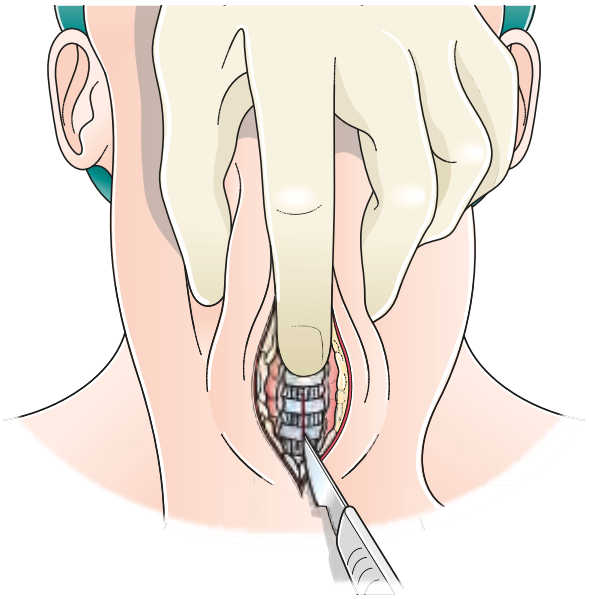

Figure 47.33 An incision in the trachea in an emergency tracheostomy.

continued down between the infrahyoid muscles. There may be heavy bleeding from the wound at this point, particularly if the neck is congested as a result of the patient's efforts to breathe around an acute upper airway obstruction. No steps should be taken to control this haemorrhage, although an assistant and suction are valuable. The operator should feel carefully for the cricoid cartilage using the index finger of the free hand while retracting the skin edges by pressure applied by the thumb and middle finger. If the situation is one of extreme urgency, a further vertical incision straight into the trachea at the level of the second, third and fourth ring should be made immediately without regard to the presence of the thyroid isthmus. The knife blade is rotated through 90°, thus opening the trachea. At this point the patient may cough violently as blood enters the airway. The operator should be aware of this possibility and avoid losing the position of the scalpel in the open trachea. Any form of available tube should be inserted into the trachea as soon as possible and blood and secretion sucked out. Once an airway has been established, haemostasis is then secured. With the emergency under control, the tracheostomy should be refashioned as soon as possible.

Should additional equipment and more time be available once the cricoid cartilage has been identified, blunt finger dissection inferiorly can be used to mobilise the thyroid isthmus, which should be clipped and divided, clearing the trachea before making a vertical incision through the second to the fourth rings. A tracheal dilator is inserted through the tracheal incision and the edges of the tracheal wound are separated gently. This is likely to induce coughing and so, particularly in cases where there is a suspected infection risk, as far as possible care should be taken to minimise the risk of contaminating the operator(s). A tracheostomy tube is inserted into the trachea and the dilator removed. It is important that the surgeon keeps a finger on the tube while the assistant ties the attached tapes around the patient's neck. Return the neck to a neutral position before tying the tapes firmly.

Elective tracheostomy

The advantage of an elective surgical procedure is that there is complete airway control at all times, unhurried dissection and careful placement of an appropriate tube. Close cooperation between the surgeon, anaesthetist and scrub nurse is essential, and attention to detail will markedly reduce possible complications and morbidity from the procedure.

Following induction of general anaesthesia and endotracheal intubation, the patient is positioned with a combination of head extension and placement of an appropriate sandbag under the shoulders (**Figure 47.34**). There should be no rotation of the head. Children's heads should not be overextended, as it is possible to enter the trachea in the fifth and sixth rings in these circumstances. A transverse incision may be used in the elective situation (**Figure 47.35**). The tracheal isthmus is divided carefully and oversewn and tension sutures placed either side of the tracheal fenestration in children (**Figure 47.36**). A Bjork flap may be used in adults (**Figures 47.37 and 47.38**).

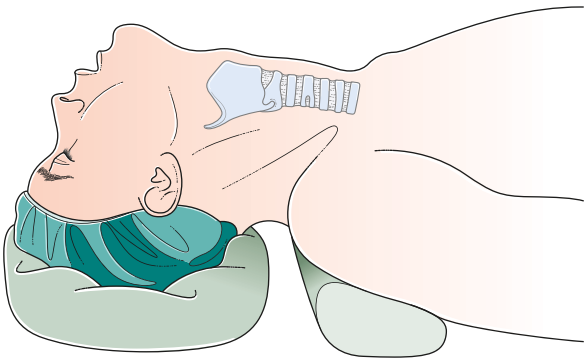

Figure 47.34 Position of the patient for elective tracheostomy.

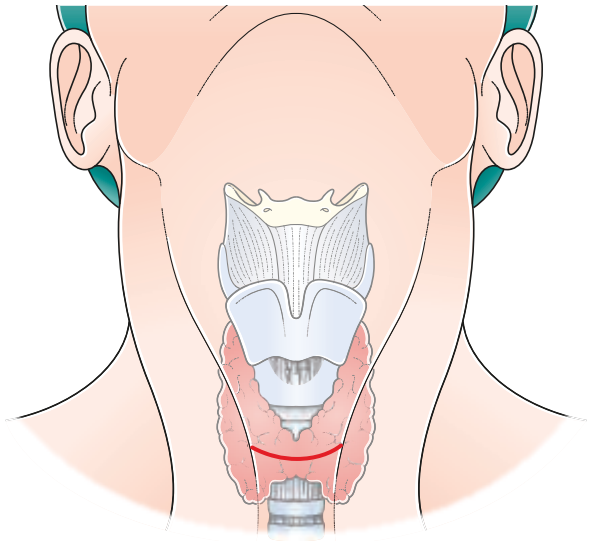

Figure 47.35 Position of the skin incision in an elective tracheostomy.

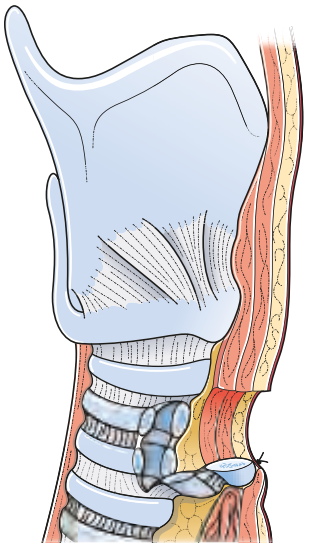

Figure 47.37 Bjork flap.

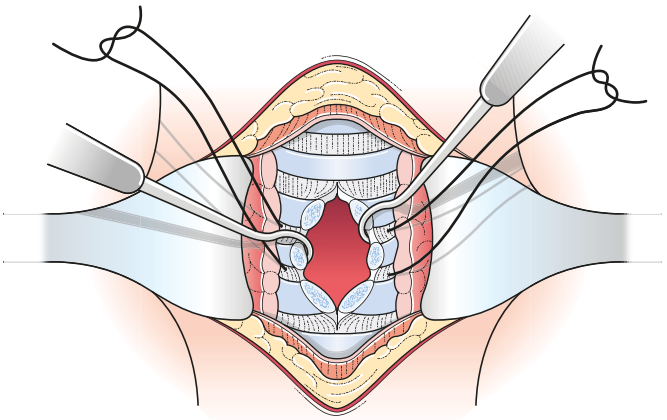

Figure 47.36 Tracheal fenestration in an elective tracheostomy.

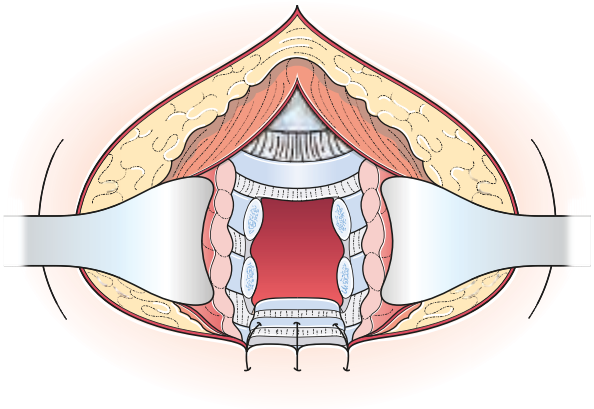

Figure 47.38 Fenestration in a Bjork flap.

The advantages of a Bjork flap outweigh the potential disadvantages, as performed correctly it is safe and allows reintroduction of a displaced tube with the minimum of difficulty, reducing the risk of replacing the displaced tube in a false track anterior to the trachea into the superior mediastinum.

The inferiorly based flap is created by starting with an incision into the trachea between the first and second or second and third tracheal rings. In order to reduce the risk of subglottic stenosis, damage to the first tracheal ring should be avoided at all costs. A stay suture is inserted around the cartilage at the free edge of the flap. Lateral incisions are made in a caudal direction extending through two tracheal rings to create the flap. One option is to leave the stay suture attached and taped to the chest wall to allow retraction of the flap to obliterate the pretracheal space when replacing a displaced tube. An alternative is to suture the free edge of the flap to the edge of the inferior transverse skin incision.

In a paediatric patient a vertical incision is made between the second and third tracheal rings. No tracheal tissue is removed. Prior to incision of the trachea, vertical stay sutures are placed lateral to the midline through the tracheal rings and left in place. These can provide traction for the trachea and allow for rapid tracheostomy tube reinsertion if accidental decannulation occurs prior to the establishment of the tract. Some surgeons will suture skin flaps to the trachea for additional safety. It is essential to stick to the midline during dissection as more lateral dissection risks a pneumothorax, as the cupula of the cervical pleura extends in to the neck on either side of the trachea.

Viking Olaf Bjork, 1918–2009, formerly cardiac surgeon, Karolinska Sjukset, Stockholm, Sweden.

Percutaneous tracheostomy

As an alternative to open tracheostomy, a percutaneous tracheostomy is commonly performed in the critical care setting. A transverse skin incision is made at the level of the first and second tracheal rings, blunt dissection of the midline is then performed. A 22-gauge needle is inserted between the second and third tracheal rings. When air is aspirated into the syringe, the guidewire is introduced. Sequentially larger dilators are then inserted over the guide wire to create a suitable sized tracheostome. Finally, the tracheotomy tube is introduced along the guidewire and dilator. The guidewire and dilator are removed, the cuff of the tracheotomy tube is inflated and the breathing circuit is connected. The endotracheal tube can then be removed.

Patients must have appropriate anatomy and no limitation of neck movement. If any doubt arises as to the suitability of a patient for percutaneous tracheostomy, a surgical approach should be adopted. Percutaneous tracheostomy is rarely performed in children.

Tracheostomy tubes

Most modern tracheostomy tubes are made of plastic (**Figure 47.39**). Tubes of various sizes with varying curves, angles, cuffs, inner tubes and speaking valves are available. After a newly fashioned tracheostomy is created, a cuffed tube is used initially to protect the airway from secretions or bleeding. This may be changed after 3–4 days to a non-cuffed tube. The pressure within the tube cuff should be carefully monitored and should be low enough so as not to occlude circulation in the mucosal capillaries, which promotes scar tissue formation and subglottic stenosis. When in position, the tube should retained by double tapes threaded through the flanges and passed around the patient's neck. It is important that the patient's head is flexed when the tapes are tied, otherwise they may become slack when the patient is moved from the position of extension, thereby resulting in a possible displacement of the tube if the patient coughs. Alternatively, the flanges of the plastic tube may be stitched directly to the underlying neck skin. A removable inner tube, which is easily cleaned, should always be used to prevent lumen occlusion by thickened, dried secretions from the trachea.

Figure 47.39 Modern plastic tracheostomy tube with introducer, low-pressure cuff and inner cannula.

All forms of tracheostomy and cricothyroidotomy bypass the upper airway and have the following advantages:

- the anatomical dead space is reduced by approximately 50%;
- the work of breathing is reduced;
- alveolar ventilation is increased;
- the level of sedation needed for patient comfort is decreased and, unlike endotracheal intubation, the patient may be able to talk and eat with a tube in place.

However, there are several disadvantages:

- loss of heat and moisture exchange in the upper respiratory tract;
- desiccation of tracheal epithelium, loss of ciliated cells and metaplasia;
- the presence of a foreign body in the trachea stimulates mucous production; where no cilia are present, the mucociliary stream is therefore impeded;
- the increased mucus is more viscid and thick crusts may form and block the tube;
- although many patients with a tracheostomy can feed satisfactorily, there is some splinting of the larynx, which may prevent normal swallowing and lead to aspiration; this aspiration may be silent.

Postoperative treatment is designed to counteract these effects and frequent suction and humidification are most important. A trolley must be placed by the bed containing a tracheal dilator, duplicate tubes and introducers, retractors and dressings. Oxygen is at hand and, in the initial period, a nurse must be in constant attendance. Humidification will render the secretions less viscid and a sucker with a catheter attached should be on hand to keep the tracheobronchial tree free from secretions.

Summary box 47.11

Tracheostomy: postoperative management

- Suction – efficient, sterile and as often as required
- Humidification (with or without oxygen)
- A warm, well-ventilated room
- Position of the tube and patient
- Spare tube, introducer, tapes, tracheal dilator
- Change of tube, inner tube, possible speaking valve
- Physiotherapy
- Initiation of local decannulation protocols where indicated

Complications of tracheostomy

The intraoperative, early and late postoperative complications of tracheostomy are listed in *Table 47.2*.

TABLE 47.2 Tracheostomy: complications.	
Intraoperative complications	Haemorrhage
	Injury to paratracheal structures, particularly the carotid artery, recurrent laryngeal nerve and oesophagus
	Damage to the trachea
Early postoperative complications	Apnoea caused by a fall in the PCO_2
	Haemorrhage
	Subcutaneous emphysema, pneumomediastinum and pneumothorax
	Accidental extubation, anterior displacement of the tube, obstruction of the tube lumen and tip occlusion against the tracheal wall
	Infection
	Swallowing dysfunction
Late postoperative complications	Difficult decannulation
	Tracheocutaneous fistula
	Tracheo-oesophageal fistula, tracheoinnominate artery fistula with severe haemorrhage
	Tracheal stenosis

OTHER EMERGENCY AIRWAY PROCEDURES

Fibreoptic endotracheal intubation

In most emergency situations, endotracheal intubation is the most direct and satisfactory method of securing the airway. Nasotracheal 'awake' intubation in expert hands is also a well-established technique and is particularly useful if the patient has trismus, severe mandibular injuries, cervical spine rigidity or an obstructing mass within the oral cavity. This is facilitated by passing a fibreoptic endoscope through the centre of an endotracheal tube, hence guiding it into the larynx and trachea under direct vision.

Figure 47.40 Laryngeal mask airway being inserted.

Laryngeal mask airway

The laryngeal mask airway (LMA) is a wide-bore airway with an inflatable cuff at the distal end, which forms a seal in the pharynx around the laryngeal inlet. Provided the laryngotracheal airway is clear, the LMA provides a clear and secure airway. The technique can easily be learnt by non-anaesthetists and secures an airway in most cases. It comes in a range of sizes covering infants to large adults. It is particularly useful in cases of difficult intubation where mouth opening is unimpeded (**Figure 47.40**).

Transtracheal ventilation

This technique is simple and effective and allows ventilation for periods in excess of 1 hour providing time to allow for more elective intubation. The cricothyroid membrane is located by palpation of the neck with the index finger, and a 14- or 16-gauge plastic sheathed intravascular needle and a 10 mL syringe containing a few millilitres of lidocaine are introduced in the midline and directed downwards and backwards into the tracheal lumen. The needle is advanced steadily and negative pressure is placed on the syringe until bubbles of air are clearly seen (**Figure 47.41**). The tissues of the neck may be infiltrated with the anaesthetic if desired and the tracheal mucosa likewise partly anaesthetised by the introduction of 1–2 mL after gaining the lumen. The needle is removed and the plastic sheath cannula remains in the tracheal lumen and must be carefully held and fixed in place by the operator so that it does not come out of the lumen into the soft tissues of the neck. It is attached by means of a Luer connection to the high-pressure oxygen supply. Ventilation may be undertaken in a controlled manner with a jetting device, with the chest being observed for appropriate movements.

If there is severe obstruction of the laryngopharynx by the foreign body or tumour, the exhaled outflow of gases can be

Luer was a German instrument maker who was working in Paris, France, at the end of the 19th century.

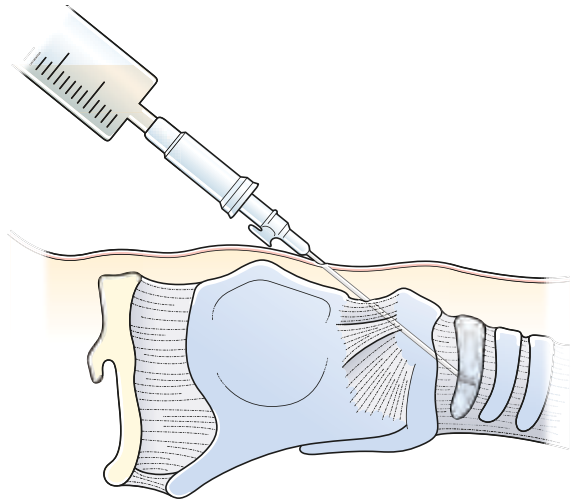

Figure 47.41 Transtracheal needle introduction.

aided by the placement of one or two further cannulas as exhalation ports. This procedure gains extremely rapid control of ventilation and requires a minimum of technical expertise. Its only notable complication is surgical emphysema of the neck tissues if the cannula dislodges from the tracheal lumen.

Cricothyroidotomy

Cricothyroidotomy has the advantages of speed and ease requiring minimal equipment and surgical expertise and has great value in the emergency setting when conditions are not optimal to perform a tracheostomy.

The patient's neck is extended and the area between the prominence of the thyroid cartilage and the cricoid cartilage below is palpated with the index finger of the free hand. In the emergency situation, a vertical skin incision is recommended with dissection rapidly carried down to the cricothyroid membrane. A 1 cm transverse incision is made through the membrane immediately above the cricoid cartilage and the scalpel twisted through a right angle to gain access to the airway. If available, an artery forceps, dilator or tracheal hook will improve the aperture and insertion of an available tube (**Figures 47.42 and 47.43**). As soon as practicably possible, the cricothyroidotomy should be converted to a tracheostomy. Although there is debate about the frequency of subglottic stenosis following this procedure, there is general agreement that it is much increased if any long-term ventilation is undertaken via even a modestly size tracheostomy tube through the cricothyroid membrane.

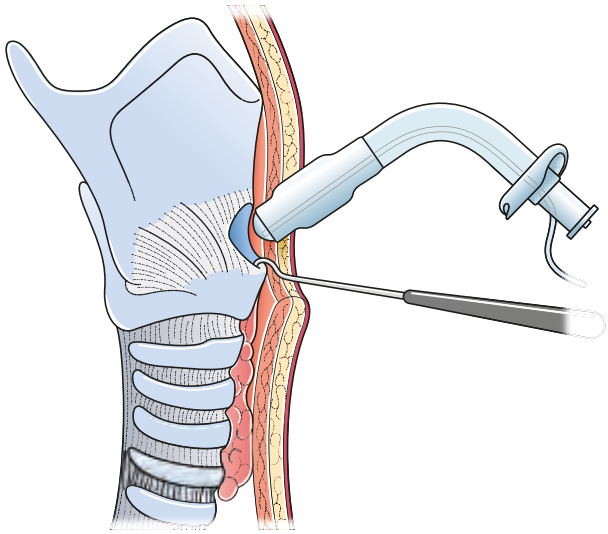

Figure 47.43 Insertion of a tube after cricothyroidotomy.

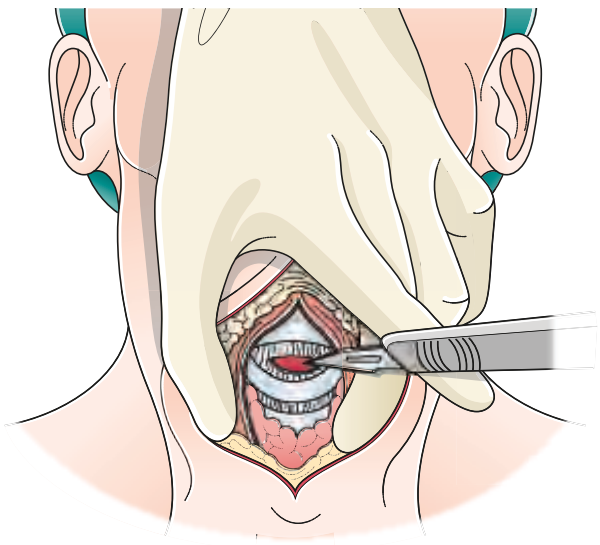

Figure 47.42 Incision in a cricothyroidotomy.

LARYNGEAL DISEASE CAUSING VOICE DISORDERS

Vocal nodules

These are fibrous thickenings of the vocal folds at the junction of the middle and anterior third (**Figure 47.44**) and result from vocal abuse; they are known as singers' nodules in adults and screamers' nodules in children. Speech therapy is therefore the preferred treatment and the lesions will resolve spontaneously in most cases. Occasionally, the nodules will need to be surgically removed using modern microlaryngoscopic dissection or laser techniques, but speech therapy will still be required for postoperative voice rehabilitation.

Vocal fold polyps

These are usually unilateral and may be associated with an acute infective episode, cigarette smoking or vocal abuse (**Figure 47.45**). Speech therapy is again indicated, but they do usually require removal by microdissection or laser surgery.

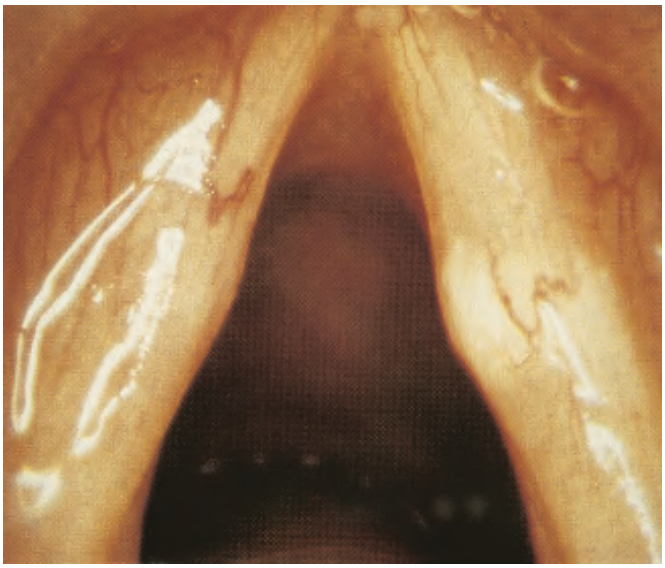

Figure 47.44 Vocal fold nodules.

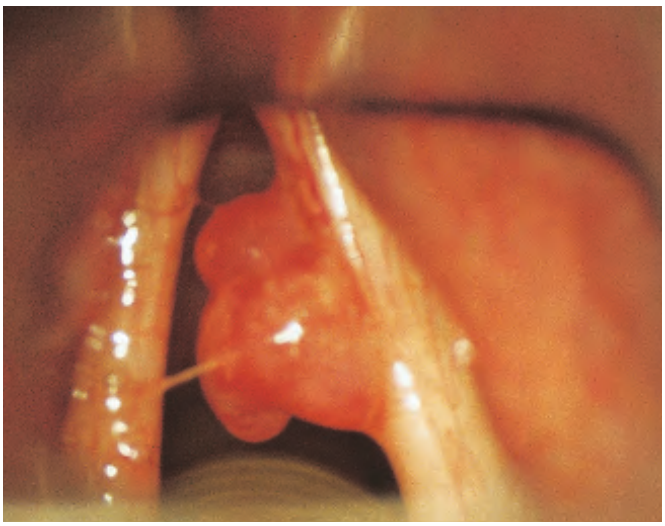

Figure 47.45 A vocal fold polyp.

Summary box 47.12

Causes of hoarseness

- Mucosal disease (e.g. vocal nodule, polyps or laryngeal papillomatosis, acute or chronic laryngitis)
- Neurological disease (e.g. vocal fold palsy)
- Neoplasia (e.g. laryngeal tumours)
- Non-specific voice disorders, functional dysphonia

Laryngeal papillomata

These are rare benign tumours occurring mainly in children, but can also present in adults. They are most commonly found on the vocal folds, but may spread throughout the larynx and tracheobronchial airway (although this is less likely in adults) (Figure 47.46). They are caused by papillomaviruses and need repeated removal by carbon dioxide laser or microsurgery to maintain a reasonable voice and airway. These patients are best managed in specialist centres, with the appropriate expertise. Antiviral treatment is of doubtful value. Papilloma vaccination is, to date, of unproven benefit.

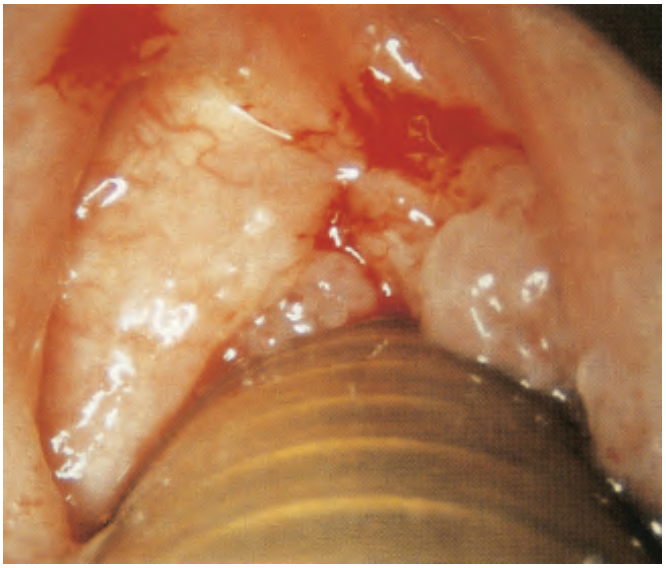

Figure 47.46 Laryngeal papillomata.

Acute laryngitis

This often occurs as part of an upper respiratory tract infection in association with a cough and pharyngitis. Usually viral, it may be localised to the larynx and it settles quickly if the voice is rested during the acute inflammation. Steam inhalations are soothing along with mild analgesia, but antibiotics are unnecessary.

Summary box 47.13

Warning

- Hoarseness lasting for 3–4 weeks should always be referred for an ENT opinion

Chronic laryngitis

Chronic laryngitis may be specific and can be caused by mycobacteria, syphilis and fungi. Treatment is directed towards the causative organism. Non-specific laryngitis is common, the main predisposing factors being smoking, chronic upper and lower respiratory sepsis and voice abuse. Gastro-oesophageal reflux has been implicated as a factor in laryngitis, vocal fold nodules and polyps, but the evidence is controversial. However, anti-reflux medication and proton pump inhibitors are commonly prescribed. Diagnosis of chronic laryngitis should not be made unless the larynx has been fully evaluated by a laryngologist.

Vocal fold palsy

This may be unilateral or bilateral (Figure 47.47). Unilateral cord palsy is most commonly idiopathic. In non-idiopathic cases, left vocal fold palsy is most common because of the long intrathoracic course of the left recurrent laryngeal nerve, which arches around the aorta and may be commonly involved in inflammatory and neoplastic conditions involving the left hilum or lung apex. Lung cancer should be considered the cause of a left vocal palsy until proved otherwise.

Tumours of the nasopharynx, larynx, thyroid gland or oesophagus may also cause vocal cord palsy. Bilateral vocal fold paralysis is uncommon and tends to occur after thyroid surgery or head injuries.

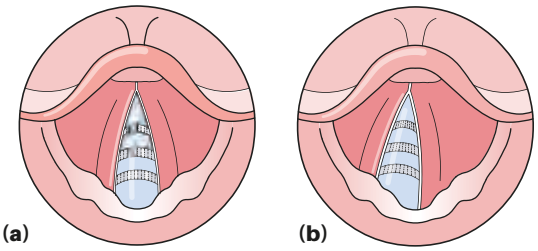

Figure 47.47 Vocal fold positions: **(a)** normal; **(b)** unilateral vocal fold palsy.

Summary box 47.14

Causes of vocal fold palsy

Congenital (infants)

Acquired

- Traumatic
  - Direct to neck
  - Post-surgical (e.g. thyroidectomy)
- Infective
  - Viral (rare)
- Neoplastic
  - Carcinoma of the lung involving the left hilum
  - Carcinoma of the nasopharynx, larynx, thyroid and oesophagus
- Vascular
  - Aortic aneurysm
- Neurological
  - Lower motor neurone disease

Clinical features

Unilateral recurrent laryngeal nerve palsy of sudden onset produces hoarseness, difficulty in swallowing liquids and a weakened cough. These symptoms may be short-lived and the voice may return to normal within a few weeks as the muscles in the opposite vocal fold compensate and move it across the midline to meet the paralysed vocal fold, which usually lies in the paramedian position. Bilateral recurrent laryngeal nerve palsy is an occasional and serious complication of total thyroidectomy. On anaesthetic reversal, acute dyspnoea occurs as a result of the paramedian position of both vocal folds, which reduce the airway to 2–3 mm and which tend to get sucked together on inspiration. In severe cases, tracheostomy or intubation is necessary immediately, otherwise death occurs from asphyxia.

Investigation of vocal fold paralysis is by a CT scan from the skull base (including posterior fossa) to the diaphragm. Approximately 20–25% of vocal fold paralysis occurs without known pathology and spontaneous recovery may occur. When compensation does not occur, a unilateral paralysed fold may be medialised by injection or external thyroplasty.

In bilateral vocal fold palsy, surgery may be carried out to remove a portion of the posterior aspect of one vocal fold or a portion of one arytenoid cartilage. These procedures are most easily performed endoscopically with a carbon dioxide laser. They increase the size of the posterior glottic airway, allowing the patient to be decannulated or even avoid an initial tracheostomy.

Tumours of the larynx

Benign tumours of the larynx are extremely rare. Squamous cell carcinoma is the most common malignant tumour, being responsible for more than 90% of tumours within the larynx. It is the second most common head and neck cancer (oral cavity is more common) and previously usually occurred in elderly male smokers. However, over the past decades, the incidence among women has risen as a consequence of increased smoking habits. The incidence of laryngeal cancer in the three compartments, supraglottis, glottis and subglottis, varies around the world. The glottis is generally the most common site for cancer in patients in the UK, followed by the supraglottis (Figure 47.48).

Clinical features

Patients typically present with voice change. If an early diagnosis can be made (i.e. confined to one vocal fold), treatment with radiotherapy or carbon dioxide laser excision is associated with a 5-year disease-free survival of approximately 90%. This rate drops dramatically once the lymphatically rich supraglottis or subglottis is involved because of spread to neck nodes. Tumour spread to just one neck gland reduces by half the overall prognosis for the patient.

Investigations

Direct laryngoscopy, preferably a microlaryngoscopy, together with angled (30° and 70°) Hopkins' rod examination, allows precise determination of the extent of the tumour and biopsy confirms the histology. CT and MRI give further details of the extent of larger tumours, demonstrating spread outside the larynx and suspicious nodal involvement within the neck, which may not be obvious clinically. The tumour–node–metastasis (TNM) classification of laryngeal cancer is given in *Table 47.3*.

Treatment

EARLY LARYNGEAL CANCER (T1 AND T2)

Early stage supraglottic and glottic tumours are optimally treated with either radiotherapy or endoscopic surgical

Figure 47.48 A total laryngectomy specimen with a transglottic tumour.

resection, with the aim of preservation of some function. Although both modalities are associated with similar survival rates, transoral laser resection is commonly used as it usually involves day case surgery and more therapeutic options are available for the small mumber of patients who suffer local recurrence.

ADVANCED LARYNGEAL CANCER (T3 AND T4)

Organ preservation should be a priority when treating T3 larynx cancer. The non-surgical standard of care is concurrent chemoradiotherapy, while a variety of open partial laryngectomy procedures are also available but these are best undertaken in specialist centres.

T4 disease is usually best treated with total laryngectomy and adjuvant postoperative radiotherapy or chemoradiotherapy.

After the larynx has been removed, the remaining trachea is brought out onto the lower neck as a permanent tracheal stoma and the hypopharynx, which is opened at the time of the operation, is closed to restore continuity for swallowing (Figure 47.49). Thus the upper aero- and digestive tracts are permanently disconnected. Part or all of the thyroid gland and associated parathyroid glands may also be removed, depending on the extent of the disease.

Vocal rehabilitation

The loss of the larynx as a generator of sound does not prevent patients speaking as long as an alternative source of sound can be created by vibration in the pharynx. This can be achieved in one of three ways:

1 A small one-way valve may be inserted through the back wall of the tracheal stoma into the pharynx (Figure 47.50). This allows air from the trachea to pass into

TABLE 47.3 Tumour–node–metastasis (TNM) classification of laryngeal carcinoma.

T – primary tumour

- TX Primary tumour cannot be assessed
- T0 No evidence of primary tumour
- Tis Carcinoma in situ
- Supraglottis
  - TI Tumour limited to one subsite of supraglottis, with normal vocal fold mobility
  - T2 Tumour invades more than one subsite of supraglottis, with normal vocal fold mobility
  - T3 Tumour limited to larynx with vocal fold fixation and/or invades post-cricoid area, medial wall of piriform sinus or pre-epiglottic tissues
  - T4 Tumour invades through cartilage and/or extends to other tissues beyond the larynx (e.g. to oropharynx, soft tissues of neck)
- Glottis
  - T1 Tumour limited to vocal fold(s) (may involve anterior or posterior commissures) with normal mobility
  - T1a Tumour limited to one vocal fold
  - T1b Tumour involves both vocal folds
  - T2 Tumour extends to supraglottis and/or subglottis, and/or with impaired vocal fold mobility
  - T3 Tumour limited to the larynx with vocal fold fixation
  - T4 Tumour invades through thyroid cartilage and/or extends to other tissues beyond the larynx (e.g. to oropharynx, soft tissues of the neck)
- Subglottis
  - T1 Tumour limited to the subglottis
  - T2 Tumour extends to vocal fold(s) with normal or impaired mobility
  - T3 Tumour limited to the larynx with vocal fixation
  - T4 Tumour invades through thyroid cartilage and/or extends to other tissues beyond the larynx (e.g. to oropharynx, soft tissues of the neck)

N – regional lymph nodes

- N0 No regional lymph node metastases
- N1 Metastasis in a single ipsilateral lymph node 3 cm or less in greatest diameter
- N2 Metastasis in a single ipsilateral lymph node more than 3 cm or in multiple ipsilateral nodes or in bilateral or contralateral nodes

M – distant metastasis

the pharynx, but does not allow food and liquid to pass into the airway. These valves must not be confused with tracheostomy tubes. Like all foreign bodies, the speaking valves are associated with minor complications, such as the formation of granulations, bleeding or leakage of pharyngeal contents, and have an ongoing financial cost due to the need for regular replacement.

2 An external battery-powered vibrating device when applied to the soft tissues of the neck produces sound, which is turned into speech by the vocal tract comprising the tongue, pharynx, oral cavity, lips, teeth and nasal sinuses.

3 Oesophageal speech when air is swallowed into the pharynx and upper oesophagus. On regurgitating the air, a segment of the pharyngo-oesophageal mucosa vibrates to produce sound, which is modified by the vocal tract into speech (Figure 47.51).

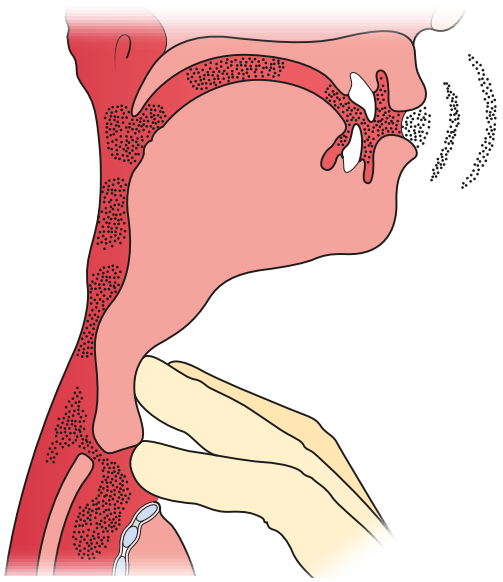

Figure 47.51 Production of oesophageal speech.

DISEASES OF THE NECK

LUMP IN THE NECK

On presentation, a careful history and examination is essential. The clinical signs of size, site, shape, consistency, fixation to skin or deep structures, pulsation, compressibility, transillumination or the presence of a bruit must be established and recorded.

Branchial cyst

A branchial cyst develops from the vestigial remnants of the second branchial cleft, is lined by squamous epithelium and contains thick, turbid fluid. The cyst usually presents in the upper neck in early or middle adulthood and is found at the junction of the upper third and middle third of the sternomastoid muscle at its anterior border. It is a fluctuant swelling that may transilluminate and is often soft in its early stages so that it may be difficult to palpate.

Summary box 47.15

Diagnosis of a lump in the neck

History

Physical signs

- Size
- Site
- Shape
- Surface
- Consistency
- Fixation: deep/superficial
- Pulsatility
- Compressibility
- Transillumination
- Bruit

If the cyst becomes infected, it becomes erythematous and tender and the differential diagnosis is broadened. Ultrasound and fine-needle aspiration both aid diagnosis and treatment is by complete excision, which is best undertaken when the lesion is quiescent. Although the anterior aspect of the cyst is easy to dissect, it may pass backwards and upwards through the bifurcation of the common carotid artery as far as the pharyngeal constrictors. It passes superficial to the hypoglossal and glossopharyngeal nerves, but deep to the posterior belly of the digastric. These structures and the spinal accessory nerve must be positively identified to avoid damage. In patients over 40 years of age, a high index of suspicion for a necrotic metastatic lymph should exists and malignancy should be excluded before excision.

Branchial fistula

A branchial fistula (**Figure 47.52**) may be unilateral or bilateral and is thought to represent a persistent second branchial cleft. The external orifice is nearly always situated in the lower third of the neck near the anterior border of the sternocleidomastoid, while the internal orifice is located on the anterior aspect of the posterior faucial pillar just behind the tonsil. The internal aspect of the tract may, however, end blindly at or close to the lateral pharyngeal wall, constituting a sinus rather than a fistula. The tract is lined by ciliated columnar epithelium and, as such, there may be a small amount of recurrent mucopurulent discharge onto the neck. The tract follows the same path as a branchial cyst and requires complete excision to avoid recurrence.

Cystic hygroma

Cystic hygromas (**Figure 47.53**) usually present in the neonate or in early infancy, and occasionally may present at birth and be so large as to obstruct labour. The cysts are filled with clear lymph and lined by a single layer of epithelium with a mosaic appearance. Swelling usually occurs in the neck and may involve the parotid, submandibular, tongue and floor of mouth areas. The swelling may be bilateral and is soft and partially compressible, visibly increasing in size when the child coughs or cries. The characteristic that distinguishes it from all other neck swellings is that it is brilliantly translucent. The cheek, axilla, groin and mediastinum are other less frequent sites for a cystic hygroma.

The behaviour of cystic hygromas during infancy is unpredictable. Sometimes the cyst expands rapidly and occasionally respiratory difficulty ensues, requiring immediate aspiration and even occasionally a tracheostomy. The cyst may become infected.

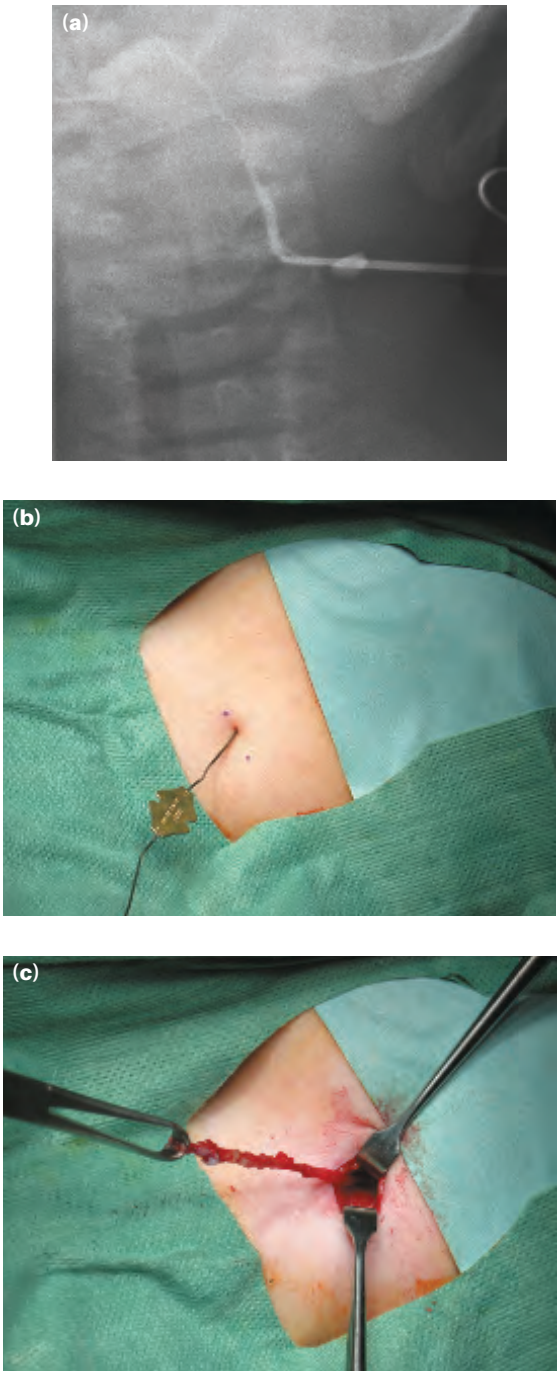

Figure 47.52 **(a)** Plain radiograph with radiopaque dye in the fistula tract. **(b)** Probing of the fistula tract. **(c)** Excision of the fistula tract.

Figure 47.53 Cystic hygroma.

Definitive treatment involving complete excision of the cyst at an early stage is best if possible. Injection of a sclerosing agent is an alternative strategy and may reduce the size of the cyst; however, they are commonly multicystic and therefore complete resolution is a challenge.

Thyroglossal duct cysts

Embryology

The thyroid gland descends early in fetal life from the base of the tongue towards its position in the lower neck with the isthmus lying over the second and third tracheal rings. At the time of its descent, the hyoid bone has not been formed and the track of the descent of the thyroid gland is variable, passing in front, through or behind the eventual position of the hyoid body. Thyroglossal duct cysts represent a persistence of this track and may therefore be found anywhere in or adjacent to the midline from the tongue base to the thyroid isthmus. Rarely, a thyroglossal cyst may contain the only functioning thyroid tissue in the body.

Clinical features

The cysts almost always arise in the midline but, when they are adjacent to the thyroid cartilage, they may lie slightly to one side of the midline. Classically, the cyst moves upwards on swallowing and with tongue protrusion, but this can also occur with other midline cysts such as dermoid cysts, as it merely indicates attachment to the hyoid bone.

Thyroglossal cysts may become infected and rupture onto the skin of the neck presenting as a discharging sinus. Although they often occur in children, they may also present in adults, even as late as the sixth or seventh decade of life (**Figure 47.54**).

Figure 47.54 A patient with a thyroglossal fistula from a cyst in the midline of the neck.

Treatment

Treatment must include excision of the whole thyroglossal tract, which involves removal of the body of the hyoid bone and the suprahyoid tract through the tongue base to the vallecula at the site of the primitive foramen caecum, together with a core of tissue on either side. This operation is known as Sistrunk's operation and prevents recurrence, most notably from small side branches of the thyroglossal tract.

TRAUMA TO THE NECK

Wounds above the hyoid bone

The cavity of the mouth or pharynx may have been entered and the epiglottis may be divided via the pre-epiglottic space. These wounds require repair with absorbable sutures on a formal basis under a general anaesthetic. If there is any degree of associated oedema or bleeding, particularly in relation to the tongue base or laryngeal inlet, it is advisable to perform a tracheostomy to avoid any subsequent respiratory distress.

Wounds of the thyroid and cricoid cartilage

Blunt crushing injuries or severe laceration injuries to the laryngeal skeleton can cause marked haematoma formation or swelling and rapid loss of the airway. There may be significant disruption of the laryngeal skeleton. These patients should not have an endotracheal intubation for any length of time, even if this is the initial emergency way of protecting the airway. The larynx is a delicate three-tiered sphincter and the presence of a foreign body in its lumen after severe disruption gives rise to major fibrosis and loss of laryngeal function. These injuries are frequently require a low tracheostomy, following

Walter Ellis Sistrunk, Jr., 1880–1933, Professor of Clinical Surgery, Baylor University College of Medicine, Dallas, TX, USA.

which the larynx can be carefully explored, damaged cartilages repositioned and sutured or plated, and the paraglottic space drained.

An indwelling stent of soft sponge shaped to fit the laryngeal lumen and held by a nylon retaining suture through the neck may be left in place for 5–10 days to minimise webbing. This stent can be removed endoscopically after cutting the retaining suture and, as the laryngeal damage heals, the patient may then be decannulated.

Division of the trachea

Wounds of the trachea are rare. They should all be formally explored and, in order to obtain adequate exposure, it is usually necessary to divide and ligate the thyroid isthmus. A small tracheostomy below the wound followed by repair of the trachea with a limited number of submucosal sutures is appropriate. In self-inflicted wounds, the recurrent laryngeal nerves, which lie protected in the tracheo-oesophageal grooves, are rarely injured. Primary repair of the nerve is rarely possible but may be undertaken at the time of formal exploration of a major neck wound.

Neurovascular injury

Penetrating wounds of the neck may involve the common carotid or the external or internal carotid arteries. Major haemorrhagic shock may occur. Venous air embolism may occur as a result of damage to one of the major veins, most commonly the internal jugular. Compression, resuscitation and exploration under general anaesthetic, with control of vessels above and below the injury and primary repair, should be undertaken. All cervical nerves are vulnerable to injury, particularly the vagus and recurrent laryngeal nerves and cervical sympathetic chain.

Thoracic duct injury

Wounds to the thoracic duct are usually iatrogenic and usually left sided, occurring when lymph node level IV is dissected during a neck dissection. When damage to the duct is not recognised at the time of operation, chyle may subsequently leak from the wound in amounts up to 2 litres per day with profound effects on nutrition.

Treatment

Should the damage be recognised during an operation, the proximal end of the duct must be ligated. Ligation of the duct is not harmful because there are a number of anastomotic channels between the lymphatic and venous system in the lower neck. If undetected, chyle usually starts to discharge from the neck wound within 24 hours of the operation. On occasion, firm pressure by a pad to the lower neck may stop the leakage, but frequently this is unsuccessful and the wound should be re-explored and the damaged duct ligated.

INFLAMMATORY CONDITIONS OF THE NECK

Ludwig's angina

Ludwig described a clinical entity characterised by a brawny swelling of the submandibular region combined with inflammatory oedema of the mouth. These clinical features, as well as accompanying putrid halitosis define the condition.

The infection is often caused by a virulent streptococcal infection associated with anaerobic organisms. There may also be an underlying oral cavity cancer. The infection tracks deep to the mylohyoid muscle causing oedema and inflammation such that the tongue is displaced upwards and backwards, giving rise to dysphagia and subsequently to painful obstruction of the airway. Unless treated, cellulitis may extend beneath the deep fascial layers of the neck to involve the larynx, causing glottic oedema and further airway compromise.

Antibiotic therapy should be instituted as soon as possible using intravenous broad-spectrum antibiotics, with anaerobic cover. If the swelling does not subside rapidly with such treatment, or in advanced cases where pus is evident, a curved submental incision may be used to drain both submandibular triangles. The mylohyoid muscle may be incised to decompress the floor of the mouth and corrugated drains placed in the wound, which is then lightly sutured. This operation may be conducted under local anaesthetic. Rarely, a tracheostomy may be necessary.

Cervical lymphadenitis

Cervical lymphadenitis is common due to infection or inflammation in the oral and nasal cavities, pharynx, larynx, ear, scalp and face.

Acute lymphadenitis

The affected lymph nodes are enlarged and tender, and there may be varying degrees of general constitutional disturbance such as pyrexia, anorexia and general malaise. The treatment in the first instance is directed to the primary focus of infection, for example tonsillitis or a dental abscess.

Chronic lymphadenitis

Chronic, painless lymphadenopathy may be caused by tuberculosis in young children or adults, or be secondary to malignant disease, most commonly from a squamous cell carcinoma in older individuals. Lymphoma and/or HIV infection may also present in the cervical nodes.

Wilhelm Friedrich von Ludwig, 1790–1865, Professor of Surgery and Midwifery, Tubingen, Germany

Summary box 47.16

Causes of cervical lymphadenopathy

Inflammatory
- Reactive hyperplasia

Infective
- Viral
  - For example, infectious mononucleosis, HIV
- Bacterial
  - *Streptococcus, Staphylococcus*
  - Actinomycosis
  - Tuberculosis
  - Brucellosis
- Protozoan
  - Toxoplasmosis

Neoplastic
- Malignant
  - Primary (e.g. lymphoma)
  - Secondary (e.g. squamous cell carcinoma)
    - Known primary
    - Occult primary

Tuberculous adenitis

This condition most commonly affects children or young adults, but can occur at any age. The deep upper cervical nodes are most commonly affected, but there may be a widespread cervical lymphadenitis with matted nodes. In most cases, the tubercular bacilli gain entrance through the ipsilateral tonsil. In approximately 80% of patients, the tuberculous process is limited to the clinically affected group of lymph nodes, but a primary focus in the lungs must always be suspected.

As renal and pulmonary tuberculosis (TB) occasionally co-exist, the urine should be examined carefully. Rarely, the patient may develop a natural resistance to the infection and the nodes may be detected at a later date as evidenced by calcification on radiography. This can also be seen after appropriate general treatment of tuberculosis adenitis. If treatment is not instituted, the caseated node may liquefy and break down with the formation of a cold abscess in the neck. The pus is initially confined by the deep cervical fascia, but after weeks or months, this may become eroded at one point and the pus flows through the small opening into the space beneath the superficial fascia. The process has now reached the well-known stage of a 'collar-stud' abscess. The superficial abscess enlarges steadily and, unless suitably treated, a discharging sinus results.

Investigation

Fine-needle aspirate taken from neck nodes with a suspicion of TB should be tested for presence of acid-fast bacilli. Systemic investigation should not be neglected, with chest x-ray and Mantoux testing useful first line investigations. Depending on country of origin, where TB is diagnosed or suspected, the co-existence of other infectious diseases such as HIV and malaria should not be overlooked.

Treatment

The patient should be treated using appropriate chemotherapy, dependent on the sensitivities derived from the abscess contents. If an abscess fails to resolve despite appropriate chemotherapy and general measures, occasionally excision of the abscess and its surrounding fibrous capsule is necessary, together with the relevant lymph nodes. If there is active tuberculosis of another system, for example pulmonary TB, then removal of tuberculous lymph nodes in the neck is inappropriate. The matted nodes are associated with significant fibrosis making surgery difficult to the extent that the sacrifice of adjacent structures such and the internal jugular vein or sternocleidomastoid muscle may be necessary. The resected nodes should be sent for both histology and microbiology.

PRIMARY TUMOURS OF THE NECK

Neurogenic tumours

Chemodectoma (carotid body tumour)

This is a rare tumour that has a higher incidence in areas where people live at high altitudes because of chronic hypoxia leading to carotid body hyperplasia. The tumours most commonly present in the fifth decade and approximately 10% of patients have a family history. There is an association with phaeochromocytoma. The tumours arise from the chemoreceptor cells on the medial side of the carotid bulb and, at this point, the tumour is adherent to the carotid wall. The cells of the chemodectoma are not hormonally active and the tumours are usually benign with only a small number of cases producing proven metastases (**Figure 47.55**).

CLINICAL FEATURES

There is often a long history of a slowly enlarging, painless lump at the carotid bifurcation. About one-third of patients present with a pharyngeal mass that pushes the tonsil medially and anteriorly. The mass is firm, rubbery, pulsatile, mobile from side to side but not up and down, and can sometimes be emptied by firm pressure, after which it slowly refills in a pulsatile manner. A bruit may also be present. Swellings in the parapharyngeal space, which often displace the tonsil medially, should not be biopsied from within the mouth.

INVESTIGATIONS

When a chemodectoma is suspected, a carotid angiogram can be carried out to demonstrate the carotid bifurcation, which is usually splayed, and a blush, which outlines the tumour vessels. MRI scanning also provides excellent detail in most cases. This tumour must not be biopsied and fine-needle aspiration is also contraindicated.

TREATMENT

Because these tumours rarely metastasise and their overall rate of growth is slow, the need for surgical removal must be considered carefully as complications of surgery are potentially serious. The operation is best avoided in elderly patients. Radiotherapy has no effect. In some cases it may be possible

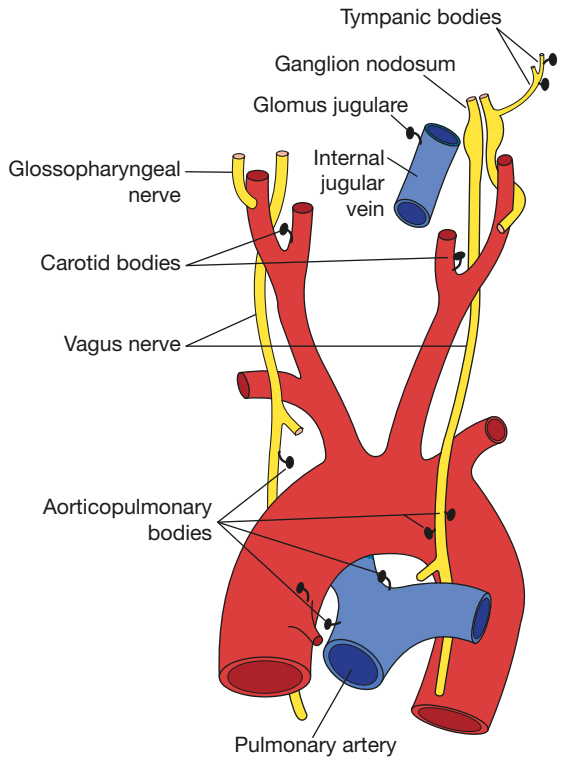

Figure 47.55 Sites for chemodectomas.

to dissect the tumour away from the carotid bifurcation but, at times, when the tumour is large, it may not be separable from the vessels and resection will be necessary, such that all appropriate facilities should be available to establish a bypass while a vein autograph is inserted to restore arterial continuity in the carotid system.

Vagal body tumours

Vagal paragangliomas arise from nests of paraganglionic tissue of the vagus nerve just below the base of the skull near the jugular foramen. They may also be found at various sites along the nerve down to the level of the carotid artery bifurcation. They also present as slowly growing and painless masses in the anterolateral aspect of the neck, and may also have a long history, commonly of 2–3 years, before diagnosis. They may spread into the cranial cavity. Diagnosis is confirmed by CT and MRI scanning and additional MR angiogram or arteriography if necessary. Treatment is surgical excision following appropriate consent of resulting hoarseness.

Peripheral nerve tumours

Schwannomas are solitary and encapsulated tumours attached to or surrounded by nerve, although paralysis of the associated nerve is unusual. The vagus nerve is the most common site. Neurofibromas also arise from the Schwann cell and may be part of von Recklinghausen's syndrome of multiple neurofibromatosis. Multiple neurofibromatosis is an autosomal dominant, hereditary disease and the neurofibromas may be present at birth and often multiple.

Diagnosis requires CT or MRI scanning to differentiate them from other parapharyngeal tumours but, on occasions, the diagnosis must wait until excision.

Secondary carcinoma

Metastatic spread of squamous cell carcinoma to the cervical lymph nodes is a common occurrence from head and neck primary cancers and may be the presenting feature of the disease. The nasopharynx, tonsil, tongue, piriform fossa and supraglottic larynx must be carefully examined by panendoscopy for the primary growth before considering biopsy or any surgery on the neck. Investigation is further assisted by ultrasound and fine needle aspirate of the neck node.

Management

The management of malignant cervical lymph nodes depends on the overall treatment regime:

- if surgery is being used to treat the primary disease and the cervical nodes are palpable and >3 cm, they may be excised with the primary lesion as part of a neck dissection;
- if radiotherapy or chemoradiotherapy is used initially with resolution of the primary tumour, but there is subsequent residual or recurrent nodal disease, then this situation will require cervical lymph node dissection.

Type of neck dissection

CLASSICAL RADICAL NECK DISSECTION (CRILE)

The classic operation involves resection of the cervical lymphatics and lymph nodes and those structures closely associated: the internal jugular vein, the accessory nerve, the submandibular gland and the sternocleidomastoid muscle. These structures are all removed *en bloc* and in continuity with the primary disease if possible. The main disability that follows the operation is weakness and drooping of the shoulder due to paralysis of the trapezius muscle as a consequence of excision of the accessory nerve.

Friedrich Theodor Schwann, 1810–1882, Professor of Anatomy and Physiology, successively at Louvain (1839–1848) and Liege (1848–1880), Belgium, described the neurilemma in 1839.
Friedrich Daniel von Recklinghausen, 1833–1910, Professor of Pathology, Strasbourg, France, described generalised neurofibromatosis in 1882.
George Washington Crile, 1864–1943, Professor of Surgery, The Western Reserve University, and one of the founders of the Cleveland Clinic, Cleveland, OH, USA.

MODIFIED RADICAL NECK DISSECTION

In selected cases, one or more of the three following structures are preserved: the accessory nerve, the sternocleidomastoid muscle or the internal jugular vein. Otherwise, all major lymph node groups and lymphatics are excised. Careful note should be made of whichever structures are preserved.

SELECTIVE NECK DISSECTION

In this type of dissection, one or more of the major lymph node groups is preserved along with the sternocleidomastoid muscle, accessory nerve and internal jugular vein. In these circumstances, the exact groups of nodes excised must be documented.

SUMMARY

The anatomical and physiological performance of the pharyngolarynx is involved in the important mechanisms of breathing, coughing, voice production and swallowing. A variety of congenital, traumatic, infectious and neoplastic conditions disturb these functions, giving rise to the common symptoms of pain, swelling, hoarseness, dyspnoea and dysphagia.

Squamous cell carcinomas are the most common malignancies, accounting for approximately 80% of all head and neck tumours. Their incidence and anatomical site vary around the world, but they are mainly caused by the preventable aetiological agents of smoking and alcohol, although nasopharyngeal and oropharyngeal squamous carcinomas have additional genetic and environmental factors. All head and neck cancers have a high morbidity and mortality, and require expert treatment.

Chapter 48

Oral cavity malignancy

Learning objectives

To understand:

- The relationship between oral (pre)malignancy and the use of alcohol and tobacco
- The cardinal features of premalignant and malignant lesions of the oral cavity
- The investigation and treatment of these patients

INTRODUCTION

Globally, oral cancer remains a relatively uncommon disease, accounting for only 1.5% of all malignant tumours; however, there remains wide diparities in the burden of disease in specific geographic areas, such as the Indian subcontinent. Current evidence suggests that the incidence of oral cavity cancer is increasing; however, these increases are overshadowed by the rapid change in oropharyngeal cancer incidence.

EPIDEMIOLOGY

The principal aetiological agents are tobacco and alcohol. In Europe and North America this is mainly through cigarette smoking combined with alcohol abuse. Synergism between alcohol abuse and tobacco use in the development of squamous cell carcinoma (SCC) of the head and neck is well established. While the human papillomavirus (HPV; specifically HPV16) is playing a significant role in the increasing incidence of oropharyngeal cancer in resource-rich nations, its role in the oral cavity appears to be limited (<5% of incident tumours being HPV positive) and without clear relevance to outcomes. Risk factors associated with cancer of the oral cavity are outlined in *Summary box 48.1*.

In the Indian subcontinent, the use of 'pan' (a combination of betel nut, areca nut, lime and tobacco) as well as reverse smoking (smoking a cheroot with the burning end inside the mouth) are responsible for the high incidence of oral cancer. Betel quid appears to be the major carcinogen, although there is also a relationship between slaked lime and the areca nut and cancer.

Summary box 48.1

Risk factors associated with cancer of the head and neck

- Tobacco
- Alcohol
- Areca nut/pan masala

Poor nutrition

- Inherited conditions (inc. Fanconi anaemia, Li-Fraumeni syndrome)
- Human papillomavirus

INCIDENCE

The estimated age standardised ratio (ASR) for oral cavity cancer is 2.7 per 100 000 in 2012, with the proportion of incident cancers being greater in men than in women (typically 2:1). Oral cancer predominantly effects people over the age of 65. Geographic variation is incidence is profound with the highest ASRs evident in Papua New Guinea and Southern Asia countries (notably Sri Lanka, Pakistan).

ANATOMY

The oral cavity extends from the skin–vermilion border of the lips anteriorly to the junction of the hard and soft palate

Guido Fanconi, 1892–1979, Swiss paediatrician, named several conditions including Fanconi anaemia, a rare genetic disorder of DNA repair leading to bone marrow failure and the development of haematological and solid malignancies typically within early life.
Frederick Pei Li (1940–2015), Boston, MA, USA, and **Joseph F Fraumeni, Jr.**, b.1933, NIH, MD, USA, described a familial syndrome of soft tisuue sacromas, breast cancer and other malignancies in 1969.

superiorly and the line of the circumvallate papillae on the junction of the posterior one-third third and anterior two-thirds of the tongue posteriorly. The anatomical sites that are frequently involved in mouth cancer include the floor of the mouth, the lateral border of the anterior tongue, buccal sulcus and the retromolar trigone (**Figure 48.1**). The retromolar trigone is defined as the attached mucosa overlying the ascending ramus of the mandible posterior to the last molar tooth and extending superiorly to the maxillary tuberosity. It is essential to appreciate the anatomical boundries of the oral cavity when defining tumour sites, particularly with respect to prognosis; the aetiological influence of HPV and its implication of improved outcomes is restricted to tumours of the oropharynx (in particular tonsillar and base of tongue subsites).

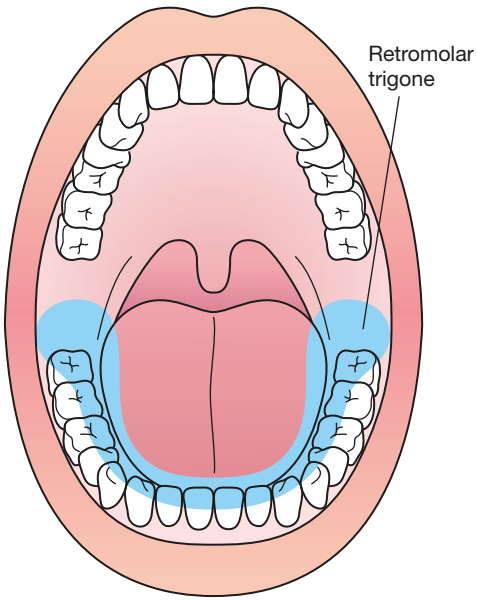

Figure 48.1 Common anatomical sites (blue) for oral squamous cell carcinoma.

PATHOLOGY

The anatomy of the oral cavity is complex and the course of the nerves, blood vessels, lymphatic pathways and fascial planes influences the spread of disease. The role that different anatomical sites play in prognosis is conflicted in the literature with both oral tongue and buccal cancer having been reported to carry worse outcomes. Whether this is a feature of anatomy or variation in biological aggression has yet to be demonstrated.

At a histological level, grade of malignancy, the presence of perineural invasion, the degree of cellular cohesion at the advancing front and angioinvasion all carry negative prognosic influence and correlate directly with regional and distant metastases. Evidence of extracapsular spread or extension (ECS or ECE) beyond the lymph node capsule in nodal metastases is a reliable predictor of poor outcome and has been included in the 8th edition of the *AJCC Cancer Staging Manual* (2017).

Histology

SCC is the predominant histology for tumours arising in the oral cavity. Tumours mainly arise from the mucosal epithelium, although malignant salivary gland tumours from the minor salivary glands are a rare but important group of lesions. Lymphomas, particularly around Waldeyer's ring (tonsils, tongue base, lingual tonsil regions, posterior one-third of the tongue), make up the last of the three principal pathological groups of oropharyngeal cancer.

Chronic exposure of the mucosal surface to carcinogenic substances (i.e. tobacco and alcohol) can produce multiple subclinical sites of carcinoma that can at any stage develop into malignant tumour. This pathological process supports the preventive measures of smoking cessation and alcohol rehabilitation in patients with both premalignant lesions and those with established head and neck cancer. This seeks to minimise the occurrence of disease progression in those with premalignant disease and, in those undergoing treatment for malignancy, it improves treatment efficacy (particulrly smoking cessation prior to radiotherapy) and to minimise synchronous and metachronous tumours development (see below).

Premalignant lesions

The majority of oral carcinomas are not preceded by or associated with clinically obvious premalignant lesions. There are, however, a group of oral pathological conditions in which an association with malignant transformation exists.

Clinical features

Leucoplakia

Leucoplakia is a clinical term used to describe any white patch or plaque that cannot be rubbed off or characterised clinically or pathologically as another disease. It is purely a descriptive term with no histological correlation. Leucoplakia varies from a small, well-circumscribed, homogenous white plaque to an extensive lesion involving large surface areas of the oral

Summary box 48.2

Conditions associated with malignant transformation

High-risk lesions

- Erythroplakia (homogenous or speckled)
- Proliferative verrucous leucoplakia
- Chronic hyperplastic candidiasis

Medium-risk lesions

- Oral submucous fibrosis
- Syphilitic glossitis

Low-risk/equivocal-risk lesions

- Oral lichen planus
- Discoid lupus erythematosus
- Discoid keratosis congenita

mucosa. It may be smooth or wrinkled, fissured and vary in white colouration depending on the thickness of the lesion. Approximately 2% of the general population have such lesions and the frequency with which dysplasia is present in the lesion varies up to approximately 20% in less homogenous lesions.

Speckled leucoplakia

This is a variation of leucoplakia arising on an erythematous base (**Figure 48.2**). It has the highest rate of malignant transformation.

Erythroplakia

Occurring less frequently than leucoplakia (0.02–0.5% in Asian population), erythroplakia is defined as a lesion of the oral mucosa that presents as a bright red velvety plaque that cannot be characterised clinically or pathologically as any other recognisable condition. The lesions may be irregular in outline and distinct from adjacent normal mucosa (**Figure 48.3**). The surfaces may be nodular or broadly atrophic in nature and frequently display contact bleeding. These lesions can coexist with leucoplakia. The risk of malignancy (or *in-situ* change) within erythroplakia is high and therefore biopsy is essential, after which surgical ablation is frequently necessary.

Figure 48.2 Speckled leucoplakia on the lateral border of the tongue. Histology confirmed carcinoma *in situ*.

FIELD CHANGE AND SECOND PRIMARY TUMOURS

The diffuse and chronic exposure of the mucosa of the upper aerodigestive tract to carcinogenic substances (e.g. tobacco and alcohol) causes widespread adverse changes in the mucosal epithelium. The consequence of the diffuse exposure is the development of separate tumours at different anatomical sites. These may present simultaneously, within 6 months (synchronous), or may be delayed (metachronous). Slaughter, in 1953, first proposed the concept of field change or 'cancerisation'. Separate primary tumours may not represent distinct genetic mutational events but rather the same clonal origin of cells, which migrate to separate sites in the upper aerodigestive tract. Nevertheless, minimising exposure of the mucosal surfaces to potential insults is the cornerstone of long-term management for patients with head and neck cancer.

Patients who develop a first tumour in the oral cavity and the oropharynx are more likely to develop a second primary tumour (approximately 15%, a third of which are in the head and neck). In total, 80% of these are metachronous tumours, of which 50% develop within the first 2 years of initial presentation (**Figure 48.4**). Synchronous second primary tumours in the head and neck are uncommon.

Potential for malignant change

The potential risk for malignant transformation includes:

- severity/grade of dysplasia;
- increases with increasing age of the patient;
- increases with increasing size of the lesion;
- may be higher in smokers (although contradictory evidence exists to suggest non-smokers are at higher risk);

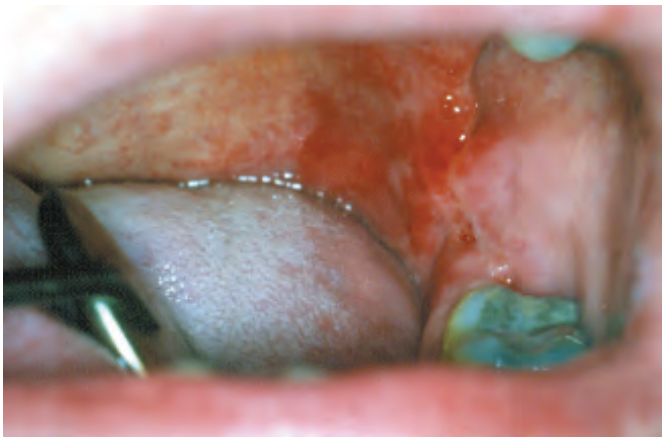

Figure 48.3 Erythroplakia of the left soft palate and lateral pharyngeal wall.

Figure 48.4 Metachronous tumour in the right mandibular alveolus after previous partial glossectomy and forearm flap reconstruction.

Danely P Slaughter, ?1911–2014, otolaryngologist, University of Illinois College of Medicine, Chicago, IL, USA.

- increases with alcohol consumption;
- depends on the anatomical site of the premalignant lesion;
- is particularly high for premalignant lesions on the lateral/ventral surface of the tongue, particularly in younger women, even in the absence of associated risk factors.

PREMALIGNANT CONDITIONS

Chronic hyperplastic candidiasis

Chronic hyperplastic candidiasis produces dense plaques of leucoplakia, particularly around the commissures of the mouth. The lesions occasionally extend on to the vermilion and even the facial skin (**Figure 48.5**). These lesions have a high incidence of malignant transformation, thought to be the result of invasion of the lesion by *Candida albicans*. A small percentage of patients have an associated immunological defect, which encourages the invasion of *C. albicans*, rendering the patient susceptible to malignant transformation. Specific management of chronic hyperplastic candidiasis includes prolonged (6 weeks) topical antifungal treatment or systemic antifungal treatment (2 weeks). If the lesions persist after medical therapy, particularly when dysplasia is evident on biopsy, surgical excision should be considered.

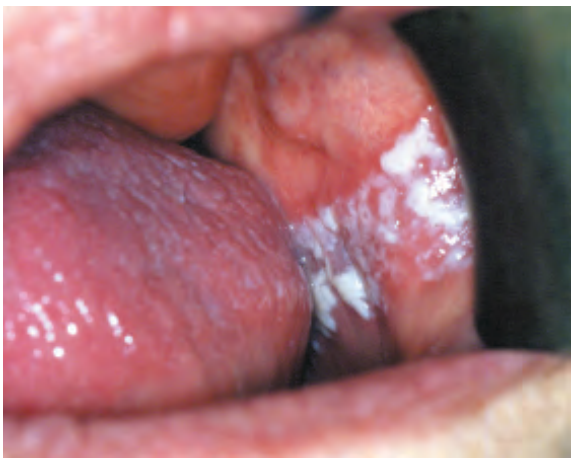

Figure 48.5 Chronic hyperplastic candidiasis of the left buccal mucosa.

Oral submucous fibrosis

Oral submucous fibrosis is a progressive disease in which fibrous bands form beneath the oral mucosa. Scarring produces contracture, resulting in limited mouth opening and restricted tongue movement. The condition is almost entirely confined to the Asian population and is characterised pathologically by epithelial fibrosis with associated atrophy and hyperplasia of the overlying epithelium (**Figure 48.6**). The epithelium also shows changes of epithelial dysplasia. Restricted mouth opening can be treated with intralesional steroids. Surgical excision/release and reconstruction may lead to short-term benefit only for fibrous bands to recur at the same site or progress at other sites.

Figure 48.6 Oral submucous fibrosis of the right buccal mucosa and soft palate.

Research strongly indicates that oral submucous fibrosis is significantly associated with the use of pan masala areca nut, with or without concurrent alcohol use. Cessation of usage may halt the process but not necessarily lead to improvement. Tobacco smoking alone is not associated with oral submucous fibrosis.

Proliferative verrucous leucoplakia

Proliferative verrucous leucoplakia is a rare progressive exophytic variant of leucoplakia, which is frequently multifocal and carries a high (>50%) risk of malignant tranformation. It is a rare, yet distinct entity, frequently arising in the absence of traditional risk factors for oral premalignancy. Diagnosis is made on the basis of combined clinical and histopathological grounds. It may be localised and typically affects the gingivae or, more commonly, as a widespread varient, affects several oral mucosal sites. There is controversy as to the best approach to management; however, long-term surveillance is essential given the condition's propensity to undergo malignant transformation.

Sideropenic dysphagia (Plummer–Vinson and Paterson–Kelly syndromes)

There is a well-known relationship between sideropenia (iron deficiency in the absence of anaemia) and the development of oral cancer. Sideropenia is common in Scandinavian women and leads to epithelial atrophy, which renders the oral mucosa vulnerable to irritation from topical carcinogens. Correction of the sideropenia with iron supplements reduces the epithelial atrophy and risk of malignant transformation.

Henry S Plummer, 1874–1936 physician, Mayo Clinic, Rochester MN, USA.
Porter P Vinson, 1890–1959, surgeon, Mayo Clinic, Rochester, MN, USA.
Donald Rose Paterson, 1863–1939, surgeon, Ear, Nose and Throat Department, The Royal Infirmary, Cardiff, UK.
Adam Brown Kelly, 1865–1941, surgeon, Ear, Nose and Throat Department, The Royal Victoria Infirmary, Glasgow, UK.

CLASSIFICATION AND STAGING

TNM staging

Staging of head and neck cancer is defined by the American Joint Committee on Cancer (AJCC) and follows the TNM system. The system also takes into account the pretreatment radiological findings (either on computed tomography (CT) or magnetic resonance imaging (MRI)) of the tumour. The T classification indicates the extent of the primary tumour and the N classification relates to the extent of regional neck metastases to the cervical lymph nodes. The recent publication of the 8th edition of the *AJCC Cancer Staging Manual* (2017) has introduced profound changes, firstly on the basis of tumour aetiology (with variation on the basis of HPV status in oropharyngeal cancer) and secondly, on depth of tumour invasion as well as on greatest dimensional size. Further, as noted above, ECS or ECE is recognised as a finding worthy of upstaging of nodal stage. The introduction of these changes into clinical practice has yet to be decided in many geographic regions. The original 7th Edition of the TNM staging for oral cavity cancer is outlined in *Table 48.1*.

The M classification relates to distant metastasis. The risk of distant metastasis is related more closely to the extent of nodal disease than to the size of the primary tumour. Tumours close to the midline are at a greater risk of developing bilateral or contralateral cervical node metastasis.

TABLE 48.1 The TNM staging system.

Primary tumour (T)			
TX	Primary tumour cannot be assessed		
T0	No evidence of primary tumour		
Tis	Carcinoma in situ		
T1	Tumour <2 cm in greatest dimension		
T2	Tumour >2 but <4 cm		
T3	Tumour >4 cm but <6 cm		
T4	Tumour invades adjacent structures (e.g. mandible, skin)		
Regional lymph nodes (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastasis in a single ipsilateral lymph node <3 cm in greatest dimension		
N2a	Metastasis in a single ipsilateral lymph node >3 cm but not more than 6 cm		
N2b	Metastasis in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension		
N2c	Metastasis in bilateral or contralateral lymph nodes, none greater than 6 cm in greatest dimension		
N3	Metastasis in any lymph node >6 cm		
Distant metastasis			
M0	No evidence of distant metastasis		
M1	Evidence of distant metastasis		
Stage			
0	Tis	N0	M0

III	T3	N0	M0
	T1, T2, T3	N1	M0
IV	T4	N0	M0
Any T	N2	M0	
Any T	N3	M0	
Any T	Any N	M1	

Patterns of lymph node metastasis

The cervical lymph nodes are divided into five principal levels, as outlined in **Figure 48.7**.

The spread of tumour from the primary site has been well described. SCC in the oral cavity and lips tends to metastasise to lymph nodes at levels I, II and, to a lesser extent, level III unless higher levels are also positive. However (albeit infrequently), for SCC of the oral tongue there is a risk of skip metastasis directly to lymph node levels III or IV, without the involvement of higher-level lymph node groups. Importantly, there is also a recognised risk of contralateral neck metastasis even in well lateralised tumours of the oral tongue. Tumours arising in the oropharynx commonly metastasise to lymph node levels II, III and IV, as well as retropharyngeal and contralateral nodal groups.

Distant metastases are relatively uncommon but sites involved include lung and, to a lesser extent, the brain, liver, bone and skin.

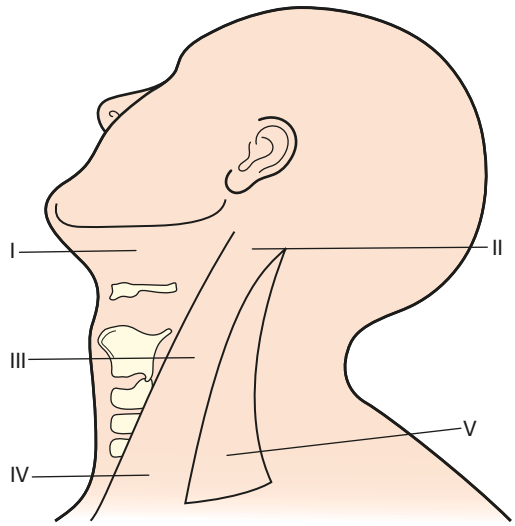

Figure 48.7 Cervical lymph nodes: (I) submandibular; (II) upper deep cervical; (III) mid-cervical; (IV) lower cervical; (V) posterior triangle.

CLINICAL FEATURES

Between 25% and 50% of patients with cancer of the oral cavity present late, particularly in regions of the resource-poor world and in areas of social deprevation in more affluent

nations. The reasons for delay in presentation are multifactorial and not easily generalisable when considered in a global context.

Lip cancer

Lip cancer presents early as it is readily visible to the patient. It usually arises as an ulcer on the vermilion border (Figure 48.8). In total, 95% of carcinomas of the lip arise on the lower lip and 15% arise in the central one-third and commissures, reflecting the aetiological influence of UV (sunlight) radiation on the more exposed lower lip. Tumours tend to spread laterally over the mucosal surface. Lymph node metastases, usually to the submental or submandibular nodes, occur in approximately 5% of cases and reflect aggressive disease behaviour when apparent.

Figure 48.8 Squamous cell carcinoma of the lower lip.

Oral cavity

Clinical presentation is markedly dependent on the anatomical site and state but classically involves mucosal ulceration with rolled margins, combinations of exophytic and endophytic neoplastic tissue, contact or spontaneous bleeding (Figure 48.9). Where involving tooth bearing areas, there may be loss of periodontal/bone support and subsequent mobility. Pain can be a feature and this may be at the site of the primary tumour or referred to adjacent structures in the case of otalgia stemming from tumours invading the lateral tongue. With advancing stage of disease comes increased risk of nutritional impairment as a result of pain and restricted oral intake. In contrast to oropharyngeal malignancy, awareness of nodal metastasis (lump in the neck) is less common in the absence of a known primary tumour.

The duration of symptoms is highly variable, from several weeks to many months.

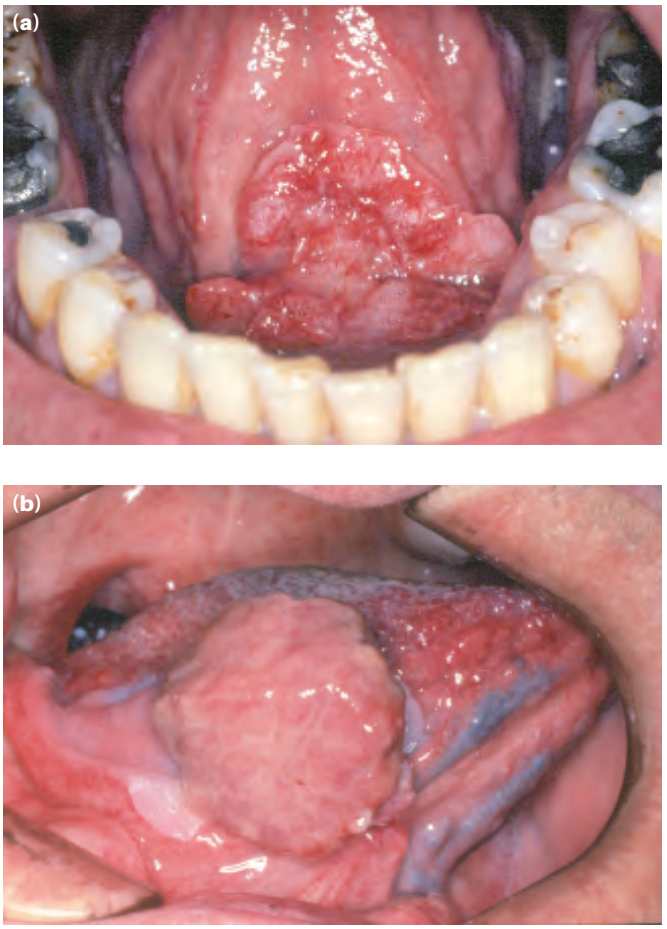

Figure 48.9 **(a)** Ulcerative squamous cell carcinoma of the anterior floor of the mouth. **(b)** Exophytic squamous cell carcinoma of the right lateral border of the tongue.

Summary box 48.3

Clinical features of oral cancer that warrent investigation

- Persistent oral swelling for >3 weeks
- Mouth ulceration for >3 weeks
- Sore tongue
- Difficulty swallowing
- Jaw or facial swelling
- Painless neck lump
- Unexplained tooth mobility
- Trismus

INVESTIGATIONS

When a clinical diagnosis of oral cancer is suspected, a comprehensive protocol of investigations should be instituted. A tissue diagnosis, typically by way of incisional biopsy, is essential. Formal examination under anaesthetic is desirable, particularly for advanced stage disease, not only to carry out the biopsy, but also to palpate and examine the extent of the tumour, which can be exquisitely tender in the conscious patient. Under the same anaesthetic, extraction of teeth with a dubious prognosis can be performed. The biopsy should be generous and include the most suspicious area of the lesion, as well as normal adjacent tissue. Areas of necrosis or gross infection should be avoided. In circumstances where the diagnosis

has already been made and where combined modality treatment proposed, consideration of insertion of a percutaneous endoscopic gastrostomy can be made at this stage.

Radiography

Plain radiography of the jaw is undertaken to facilitate adequate dental assessment rather than as a means to assessed for evidence of bone invasion.

Magnetic resonance imaging

The investigation of choice for cancer of the oral cavity, oropharynx and neck, will vary depending on institution protocol, resources and local expirtise. CT and MRI are both viable alternatives; however, MRI suffers less degredation by metallic dental restorations and provides excellent visualisation of soft-tissue infiltration of the tumour (**Figure 48.10**). Ideally it should be performed before diagnostic biopsy as biopsy frequently distorts the image of the primary tumour. The specificity and sensitivity of MRI in diagnosing cervical node metastasis are similar to that of CT. Patients who suffer with claustrophobia may have difficulty in tolerating the investigation. Contrast enhancement (in particular gadolinium), suppression techniques and variation in image sequence acquisition (e.g. Short Tau Inversion-Recovery; STIR) can aid interpretation. CT of the primary site and neck is an alternative favoured in some institutions.

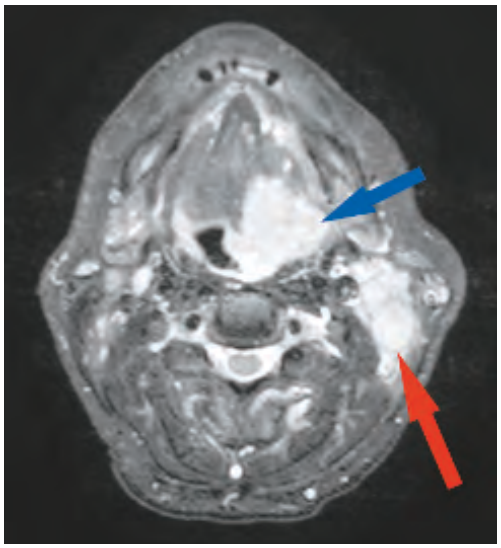

Figure 48.10 Magnetic resonance imaging of a primary tumour of the left tongue base (blue arrow) and neck node metastasis (red arrow).

Computed tomography

CT is much more widely available than MRI but its utility may be restricted by artifact degredation of images by dental restorative materials. It is useful when bony invasion is suspected. CT of the thorax is now indicated for all patients and not just those with proven cervical lymph node metastasis and large-volume disease.

Positron emmission tomography combined with CT

Positron esmission tomography combined with CT (PET-CT) of the whole body uses the anatomical capability of CT scanning in concert with radiolabelled tracers capable of localising to specific tissues. The most widely used tracer is 18 fluoro-dexoyglrucose (FDG), which is transported and trapped within hypermetabolic tissues (typically cancerous or inflammed tissues, or those that are predictably physiologically active). Evidence-based guidelines suggest targetted use of PET scanning in the work-up of patients with malignant cervical lymphadenopathy with an unknown primary. There is trial evidence for its use for surveillance following non-surgical treatment of oropharyngeal SCC and it shows promise for assessment of patients being investigated for recurrence.

Ultrasound

Ultrasound has become an integral part of head and neck services, particularly in association with one-stop clinics for the evaluation of undiagnosed neck lumps or presumed cervical metastasis. Used alongside fine-needle aspiration cytology (FNAC), ultrasound is capable of delineating and sampling cervical lymphadenopathy and both thyroid and salivary gland lesions/masses. The technique is operator dependent but benefits from exposing the patient to no ionising radiation or detrimental side-effects.

Fine-needle aspiration cytology

FNAC is useful for the assessment and pathological diagnosis of enlarged cervical lymph nodes. It involves the use of a fine-needle puncture into the mass and immediate aspiration for cytological examination. It has few complications and there is no evidence of tumour seeding along needle tracts. It requires no specialist equipment other than a 21G or 23G needle and a 10 mL syringe. Aspiration should be carried out only when the needle enters the swelling. If the specimen can be assessed immediately by an expert cytologist, then it can be sent without fixation. If there is delay in microscopic examination, then the specimen, smeared on a microscope slide, should be fixed before transfer to the laboratory. The positive yield from FNAC is dependent not only on the quality of the aspirate, but also on the skill of the cytologist.

Radionucleotide studies to assess bone invasion

A radioisotope bone scan of the facial skeleton adds little to the diagnosis and assessment of head and neck cancer, beyond that of clinical assessment, MRI and/or CT, and plain imaging. The scan is not specific and tends to show increased uptake wherever there is increased metabolic activity in bone. A false-positive diagnosis is common and 'overstaging' of the disease frequent.

TREATMENT

General principles

The management of head and neck cancer necessitates a multidisciplinary approach, integrating the combined skills and capabilities of surgeons, oncologists, radiologists, pathologists and allied health professionals to deliver an optimal treatment strategy seeking to maximise oncologic outcomes while mitigating, or restoring, loss of form and function.

Surgery remains the primary treatment modality for oral cavity cancer. Where adverse pathological features are apparent (based on resective pathology), postoperative radiotherapy or chemoradiotherapy are advocated. Given the critical normal functional demands of the oral cavity and associated structures, reconstruction of the ablated surgical defect is frequently necessary to restore (as best possible) form and function. Options for reconstruction will depend on the defect, relevant patient co-morbidities, the clinical environment/facilities and, importantly, the skill set of the treating surgeon.

In the clinically node-positive neck, a therapeutic neck dissection is normally performed at the time of pirmary resection. Management of the clinically node-negative neck in oral cavity cancer is more contentious, particularly in early stage (T1/2) disease. Recent randomised control evidence has demonstrated improved outcomes for elective neck dissection over a watch and wait policy for such patients. Sentinel lymph node biopsy as an additional staging tool in early oral cavity cancer does offer a means to avoid unnecessary elective neck dissection; however, it lacks clinical trials level evidence despite being included in some clinical guidelines.

Patient factors

Modern anaesthesia and postoperative critical care facilities have allowed major head and neck surgery to be carried out on patients with significant medical comorbidity. Advancing age is not considered to be a contraindication to major head and neck cancer surgery but may certainly influence the extent of adjuvant treatment (inclusion of chemotherapy to postoperative radiotherapy has little evidence of benefit to those over 70 years of age). Conversely, young patients should not be denied radiotherapy for fear of inducing a second malignancy (e.g. sarcoma) in later life.

Management of premalignant conditions

Elimination of associated aetiological factors is the initial basis of the management of premalignant oral mucosal lesions. Cessation of smoking, elimination of the areca nut/pan habit and reduction in alcohol consumption should be encouraged in all patients with premalignant lesions. A photographic record of the lesion is useful, particularly for long-term follow-up. All erythroplakia and speckled leucoplakia should undergo urgent incisional biopsy, as many will represent either *in-situ* or early oral cancer at presentation. Biopsy from more than one site provides a better representation of histological heterogeneity within a lesion.

Severe epithelial dysplasia and carcinoma in situ should be ablated by surgical excision where feasible. Laser vaporisation can be employed; however, it does not yeild a surgical specimen for histological examination, thus preventing assessment of resection margins and also detection of disease upstaging initially missed through sampling effects of incisional biopsies. Small lesions, particularly on the lateral border of the tongue or buccal mucosa, may be managed with surgical excision and primary closure by undermining the adjacent mucosa, or be left to granulate. Larger defects can be managed with laser excision and allowed to epithelialise spontaneously (**Figure 48.11**). Monitoring of less severe grades of dysplasia with elimination of causative agents is pragmatic but can be labour intensive. Use of primary care physcians/dentists can be helpful as part of a multidisciplinary follow-up regime.

Currently there are no successful chemoprevention agents; however, clinical trials are ongoing in the attractive area of clinical research with the ambition of reducing the risk of malignant transformation in high-risk oral premalignant lesions.

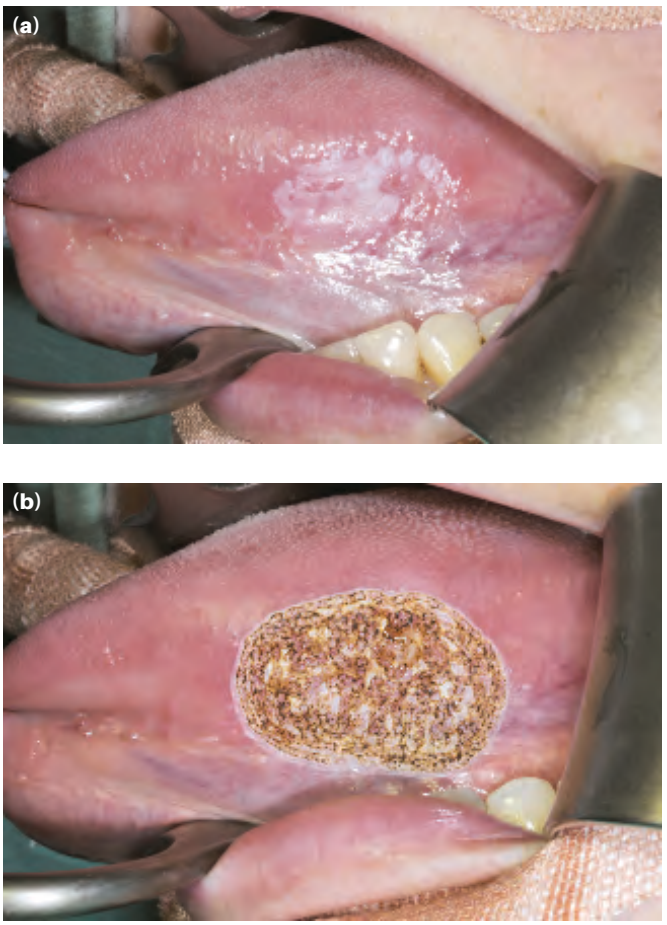

Figure 48.11 **(a)** Leucoplakia with severe dysplasia of the lateral border of the tongue. **(b)** Laser vaporisation.

LIP CANCER

Surgery and external beam radiotherapy are highly effective methods of treatment for lip cancer. The cure rate approaches 90% for either modality.

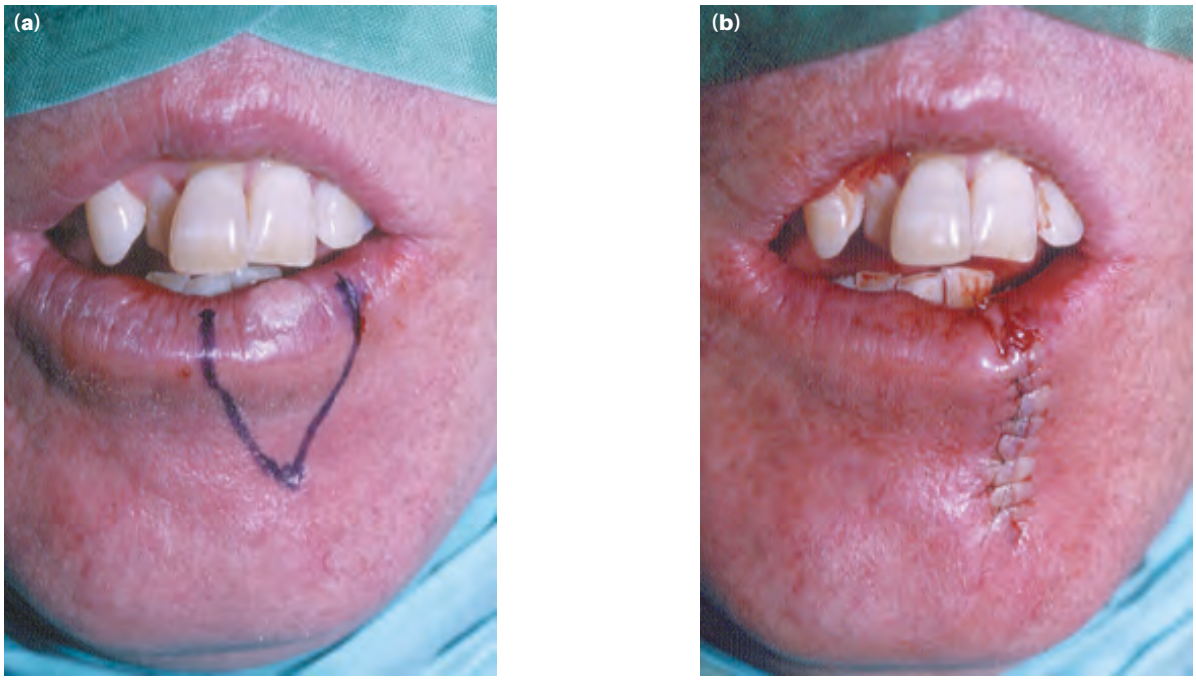

Figure 48.12 **(a)** Skin markings for wedge excision of the lower lip. **(b)** Primary closure.

Premalignant changes on the lower lip mucosa are frequently extensive and are best managed by a lower lip shave, in which the vermilion defect is closed by advancement of the lower labial mucosa.

Small tumours

Small tumours (<2 cm) of the lip can be managed with either a V- or W-shaped excision under local or general anaesthesia. The defect, which should be no larger than one-third of the total lip size, is closed in three layers – mucosa, muscle and skin – with particular attention paid to the correct alignment of the vermilion border (Figure 48.12).

Intermediate tumours

Larger tumours, which produce defects of between one-third and two-thirds the size of the lower lip, require local flaps for reconstruction. V or W excision will result in microstomia. Large central defects can be managed using local flaps such as the Johansen step technique (Figure 48.13). This allows closure of the defect by symmetrical advancement of soft-tissue flaps, utilising the excess skin in the labiomental

Figure 48.13 **(a)** Skin markings for Johansen step reconstruction. **(b)** Closure of lip and labiomental steps.

grooves. Alternative techniques include the Bernard or the Karapandzic advancement flaps.

Total lip reconstruction

Extensive tumours of the lower lip, which invade adjacent tissues (T4), have a high incidence of neck node metastasis. Patients with such advanced disease require surgery, which may include unilateral or bilateral selective neck dissection and total excision of the lower lip and chin, with or without adjacent mandibular resection (rim or segmental mandibulectomy). The lower lip soft-tissue defect can be reconstructed with a variety of free flaps including the radial forearm flap potentially suspended with palmaris longus tendon (**Figure 48.14**) or perforator flaps such as the anterolateral thigh (ALT) flap or the medial sural artery perforator (MSAP) free flap. The benefits of each vary in terms of tissue bulk, donor site morbidity and vascular pedicle length. Where segmental bony resection has been required, composite (bone including) free flaps are necessary to restore adequate mandibular continuity and soft-tissue form/function. The choice of flap will depend on the defect and the surgeons repertoire; however, the scapula free flap provides exceptional flexibility and tissue variability. Alternatives include the composite radial forearm flap, fibula free flap and perforator based osseocutaneous iliac crest free flap (DCIA; deep circumflex iliac artery free flap)

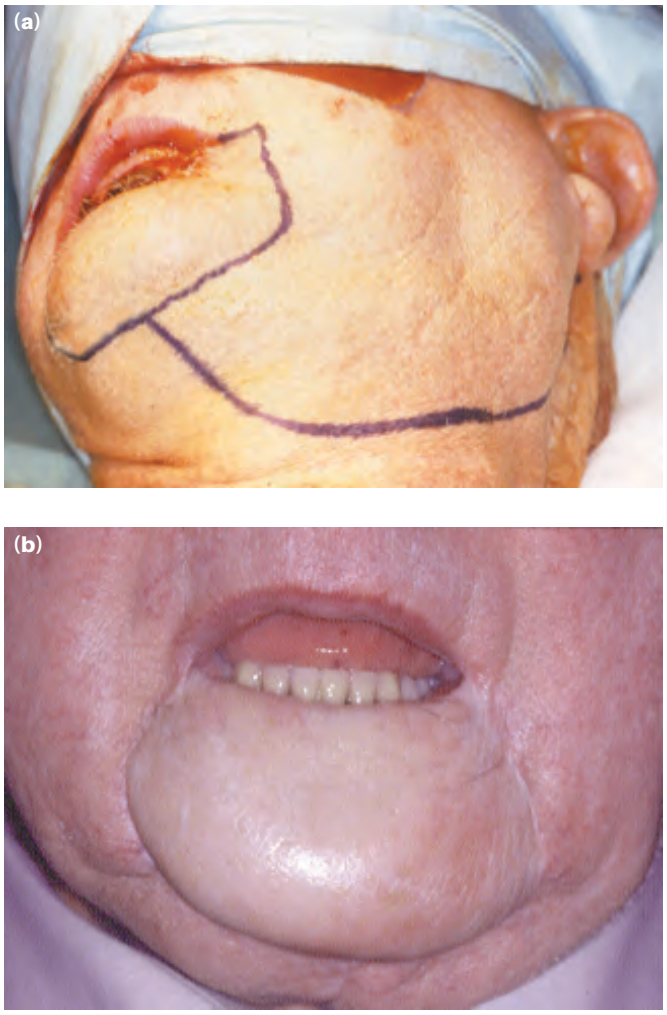

Figure 48.14 **(a)** Skin markings for total excision of the lower lip, chin and left selective neck dissection. **(b)** Postoperative view of the reconstructed lower lip using a radial artery forearm flap.

TONGUE CANCER

Management of the neck in early stage oral cavity cancer, including the oral tongue, has been discussed above; however, consideration for elective management of the node-negative neck should be made in all instances. When performing surgical excision of the primary tumour (**Figure 48.15**), a 1 cm margin in all planes should be attempted in seeking a complete excision with pathologically clear (>5 mm) margins. Resection resulting in partial or hemiglossectomy can be performed with either a cutting diathermy or laser if available. Advanced tumours (T3 and T4) often encroach upon the floor of the mouth and, occasionally, the mandible. In these circumstances a resection of the tongue and floor of the mouth and mandible is required. T4 tumours of the oral tongue may cross the midline, for which (sub)total glossectomy is the only option to achieve adequate tumour clearance. Decisions regarding elective neck dissections on the contralateral side will be dictated by radiological and clinical findings, in particular proximity of the tumour to the midline.

Access

Access for oral cancer is important to allow accurate assessment and clear visualisation to enable tumour clearance to be achieved. Access techniques include:

Figure 48.15 Ulcerative squamous cell carcinoma of the right lateral border of the tongue.

Camille Bernard, surgeon, presented a novel approach to the subtotal lower lip defect to the *Societé de Chirurgie de Paris* in 1852. von Burrow subsequently published his account of the flap (1855), claiming to have been using it in practice for some time. The flap is therefore referred to by some as the Bernard–von Burrow flap.
Miodrag Karapandzic, 1930–2016, maxillofacial surgeon, Professor of Plastic & Reconstructive Surgery, University of Belgrade, Yugoslavia.

- transoral – small –moderate sized anterior oral tumours;
- lip-split technique and paramedian or median mandibulotomy (**Figure 48.16**);
- visor incision (**Figure 48.17**) with or without drop down.

Reconstruction

Imparment of function (e.g. speech, swallowing) is related primarily to tumour size, site and reconstruction but is also influenced by patient factors (age, comorbidity, prior treatment). However, typically the more anterior the defect in the oral cavity, the greater the impact on speech, and the more posterior, the greater the detrimental impact will be on swallowing. Reconstruction of the surgical defect restores oral integrity to the neck and provides a bulk of non-dynamic tissue with an aim of restoring function benefit.

Small defects of the lateral tongue can be managed by primary closure or be allowed to heal by secondary intention

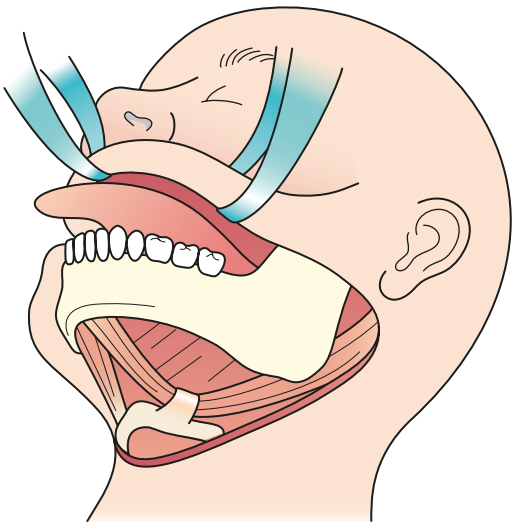

Figure 48.17 Visor approach to the anterior mandible/floor of the mouth and tongue.

with little or no functional impairment. Larger defects (e.g. T2, T3 and T4 resections) require formal reconstruction to encourage good speech and swallowing. Free tissue transfer of suitable tissue (e.g. a radial forearm flap [Figure 48.18], or ALT), utilising microvascular anastomosis in most instances, gives a good functional result. Large-volume defects, including total glossectomy, may require more bulky flaps such as the rectus abdominus free flap or ALT depending on patient body habitus. If feasible, the preservation of one or both hypoglossal nerves is useful to encourage floor of mouth function to help relearn swallowing.

The ablative surgeon should consider adequate access for the resection and consider adjunctive procedures to facilitate this where compromised (e.g. the visor procedure with drop down [see Figure 48.17]).

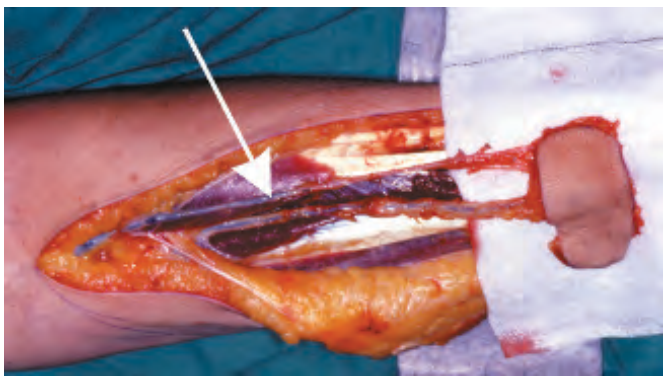

Figure 48.18 Radial artery forearm flap raised before division of a vascular pedicle and cephalic vein (arrow).

FLOOR OF MOUTH

Carcinoma of the floor of the mouth can spread to the ventral surface of the anterior tongue or encroach on the lower anterior alveolus. Surgical excision may include a partial anterior glossectomy and anterior mandibular resection. Only very small tumours of the floor of the mouth can be managed by simple excision. Management of the adjacent mandible/mandibular rim may be necessary where the tumour abuts the mandible; this may be by way of a rim resection or segmental mandibulectomy.

Reconstruction

Reconstruction will depend on the defect size (and its constituents) and ranges from healing by secondary intention to use of the thin, pilable radial forearm free flap for small defects, to ALT and composite flaps for larger resections.

Small tumours of the floor of the mouth excised with a laser frequently may avoid formal reconstruction. For larger defects, where the ventral tongue and labial mucosa are involved, reconstruction is needed to avoid severe difficulties with speech, swallowing and mastication. Smaller, simple soft-tissue defects of the anterior floor of mouth are best reconstructed with a radial artery forearm flap. If a patient is unfit for microvascular free-flap surgery or the facilities are limited, bilateral nasolabial flaps tunnelled into the mouth and interdigitated provide an acceptable alternative (Figure 48.19). Three weeks later their pedicles are divided and inset into the lateral floor of mouth defects. Large defects that involve rim resection of the anterior mandible may also be managed with soft-tissue reconstruction only. Full-thickness resection of the anterior mandible, however, requires immediate reconstruction to prevent severe functional defects or a cosmetic deformity. Vascularised bone with a soft-tissue component provides the most up-to-date method of reconstruction. A fibula flap or a vascularised iliac crest graft (DCIA) are two options in the management of anterior mandible defects with simultaneous floor of mouth defects.

Figure 48.19 (a) Skin markings for bilateral nasolabial flaps. **(b)** Transposition of bilateral nasolabial flaps into the anterior floor of the mouth.

BUCCAL MUCOSA

SCC of the buccal mucosa (Figure 48.20) should be excised widely, including the underlying buccinator muscle. Larger tumours occasionally extend onto the maxillary tuberosity, tonsillar fossa or mandibular alveolus. Facial skin involvement is rare but carries a poor prognosis. Management of the clinically negative neck should be no different for tumours of the buccal mucosa and as such, a simultaneous ipsilateral selective supraomohyoid neck dissection (levels I, II, III), or sentinel lymph node biopsy, is considered good practice.

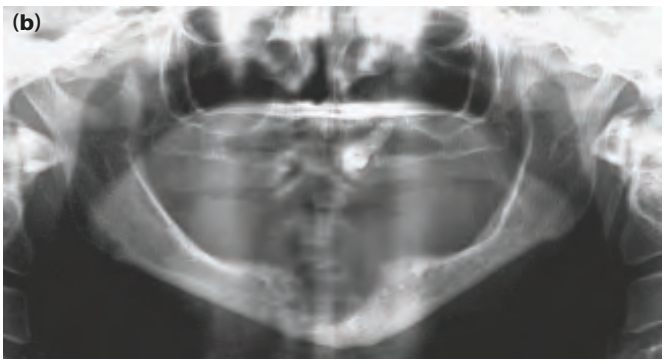
Access for buccal carcinoma can be achieved either transorally for smaller lesions (T1, T2) or using the lip-splitting technique for larger lesions (T3, T4).

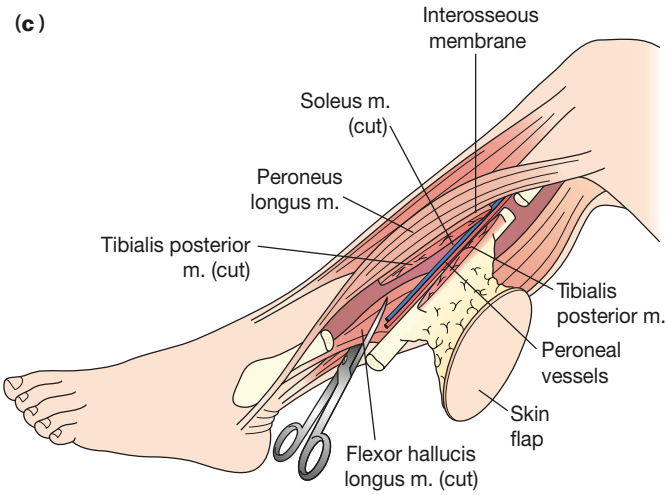
Reconstruction of the buccal mucosa prevents scarring and trismus. Options include the radial artery forearm flap or a temporalis muscle flap. Raw temporalis muscle inset into the buccal mucosal defect will epithelialise spontaneously over several weeks.

Figure 48.20 Exophytic squamous cell carcinoma of the right buccal mucosa.

LOWER ALVEOLUS

Tumours that involve the mandibular alveolus are similarly treated with surgery including (Figure 48.21a) ipsilateral selective neck dissections for lateral tumours and bilateral selective neck dissection for anterior tumours. Bone invasion (Figure 48.21b) demands segmental resection of the mandible and this may be in continuity with the neck dissection(s).





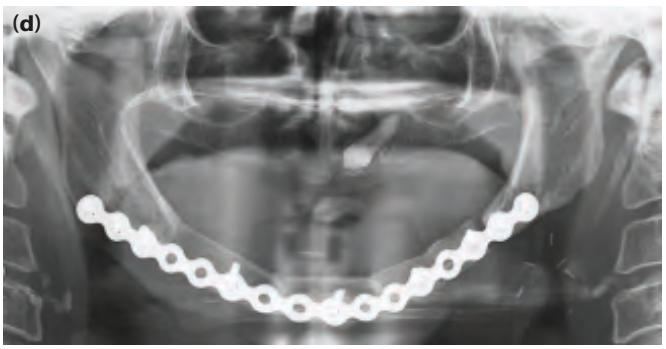


Figure 48.21 (a) Extensive squamous cell carcinoma of the anterior mandible involving the floor of the mouth. (b) Plain radiography (orthopantomogram) revealing bony destruction of the anterior mandible. (c) Osseocutaneous fibula flap. (d) Postoperative radiograph of the reconstructed mandible with fibula flap and reconstruction plate.

Primary or immediate reconstruction is preferred as the functional and cosmetic outcomes are superior to those of delayed reconstruction. Options for bony reconstruction are shown in *Table 48.2*. They include the fibula flap for the edentulous mandible (**Figures 48.21c, d**) and the iliac crest (DCIA) for patients with a dentate mandible (**Figure 48.22**). The vascularised iliac crest can be wrapped with internal oblique abdominal wall muscle, which epithelialises spontaneously. This intraoral epithelialisation provides an excellent surface for prosthetic replacement with or without osseointegrated implants.

Although non-vascularised bone grafts have been utilised for mandibular reconstruction, the long-term success is low as many patients receive postoperative radiotherapy and loss of the bone and dehiscence of the titanium tray or reconstruction plate can be expected sequelae.

TABLE 48.2 Mandibular reconstruction (reconstructive ladder).

Method	Technique
No reconstruction	Primary closure
Soft tissue only	Pectoralis major myocutaneous flap
Alloplastic material	2.4 mm reconstruction plate alone
Combination alloplastic/soft tissue	2.4 mm reconstruction plate and pectoralis major flap
Non-vascularised bone grafts	Titanium tray and cancellous chips (iliac crest)
Vascularised bone grafts	Fibula (edentulous and dentate); iliac crest (dentate); scapula (concomitant large soft-tissue defect)

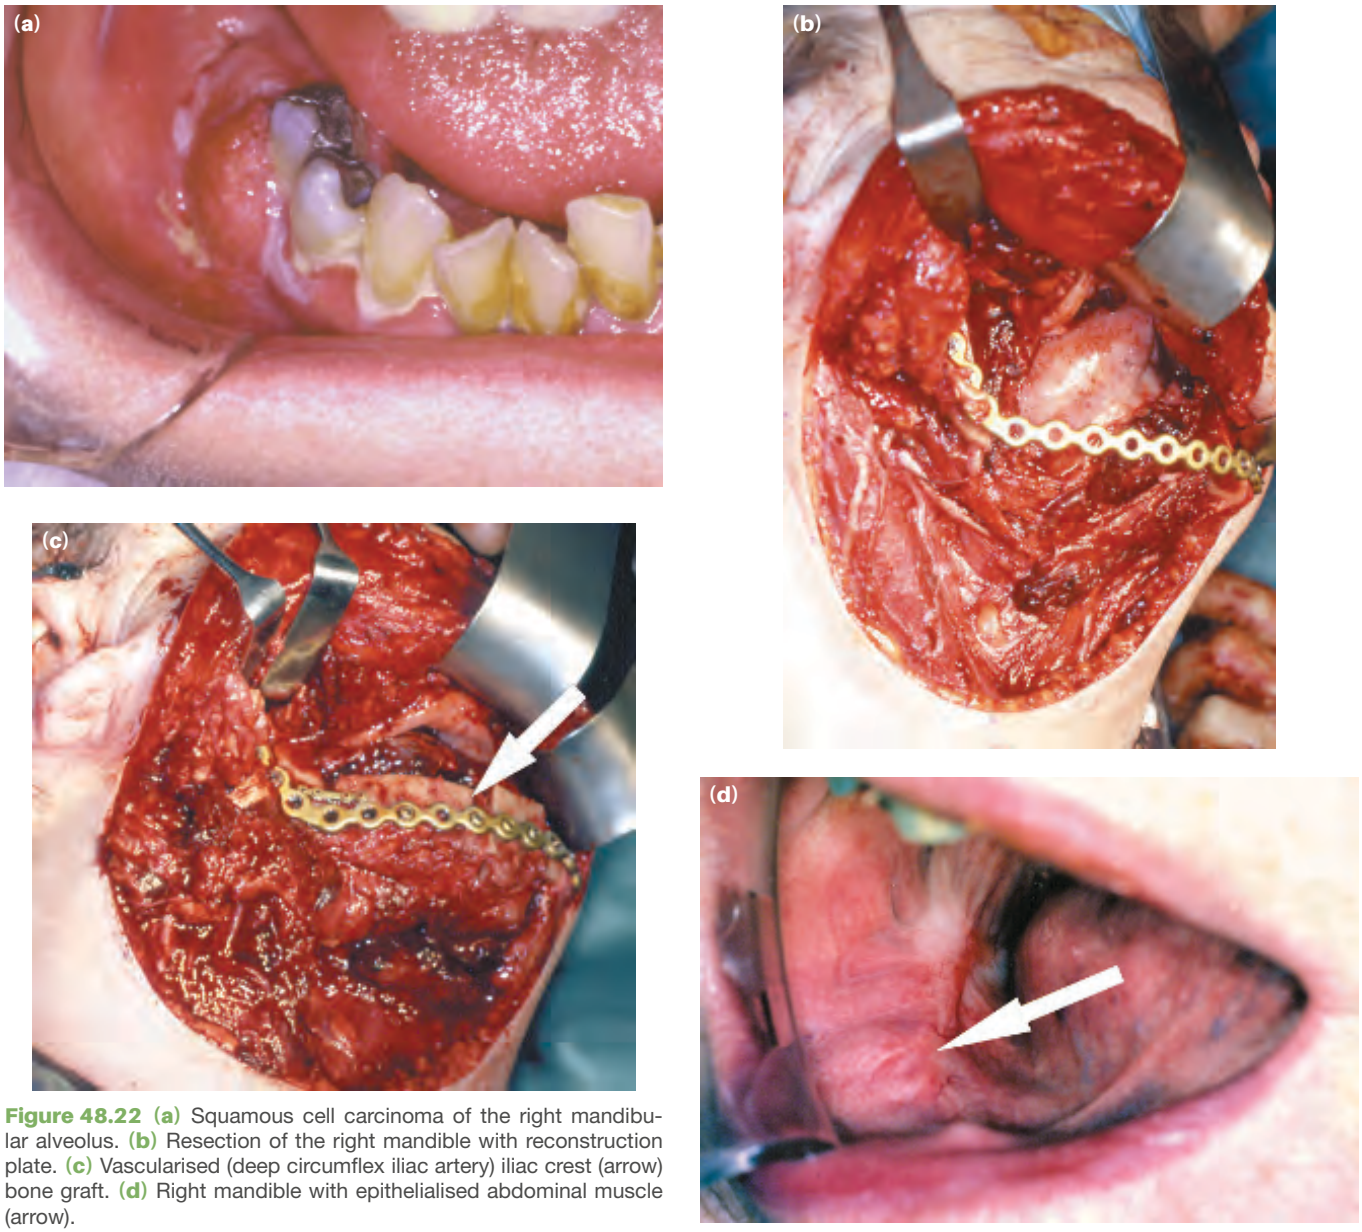

Figure 48.22 **(a)** Squamous cell carcinoma of the right mandibular alveolus. **(b)** Resection of the right mandible with reconstruction plate. **(c)** Vascularised (deep circumflex iliac artery) iliac crest (arrow) bone graft. **(d)** Right mandible with epithelialised abdominal muscle (arrow).

RETROMOLAR PAD

Tumours at this site frequently, but not always, invade the ascending ramus of the mandible. They also spread medially into the soft palate and the tonsillar fossa. Access for excision may necessitate additional access (e.g. a lip split and mandibulotomy [see **Figure 48.16**]). Small defects are managed ideally with a microvascular free flap, such as a radial artery forearm flap, or with a temporalis muscle flap where pedicled options are prefered. Segmental mandibular resections require vascularised bone to achieve adequate reconstruction; in such circumstances the scapula free flap provides a good source for restoration of bone continuity and abundant soft tissue capable of modification and flexible at inset, to suit larger defects.

HARD PALATE AND MAXILLARY ALVEOLUS

The maxillary alveolus and hard palate are relatively uncommon sites for SCC. A useful classification of the maxillectomy defect with suitable reconstructive options is provided by Brown *et al.* (see Further reading). A tumour arising in these areas may arise either from the oral mucosa *per se* or from the maxillary antrum penetrating the oral cavity. In the Indian subcontinent, carcinoma of the hard palate is more common and is particularly associated with reverse smoking. When they occur, malignant tumours of minor salivary glands typically present as swellings of the hard palate. Small tumours of the maxillary alveolus can be managed by transoral partial maxillectomy. More extensive tumours involving the floor of the maxillary sinus require wider access by a Weber–Fergusson incision (**Figure 48.23**). If the preoperative investigations demonstrate extension of the disease into the pterygoid space or the infratemporal fossa, the prognosis is poor as surgical clearance is difficult if not impossible. Tumour extending into the orbit requires simultaneous orbital exenteration or even a combined neurosurgical resection. The vascularised iliac crest graft is the method of choice for immediate maxillary reconstruction, although the fibula provides adequate bony replacement to maintain facial contour.

Microvascular free tissue transfer remains the method of choice for the management of defects in the oropharynx (*Table 48.3*). Free flaps are superior reconstructive options to pedicled or local flaps, which may be used for salvage procedures or recurrent disease. Each 'free' flap has a principal blood supply and a concomitant venous drainage. The flaps can be tailored to the defect to include skin, fascia, bone and muscle. The techniques of free tissue transfer demand specialist training and a microscope to connect blood vessels in the neck after neck dissection (e.g. facial artery to the prepared artery attached to the flap). The vascular anatomy of microvascular free flaps is summarised in *Table 48.4*.

TABLE 48.3 Primary reconstructive options in oral cancer.

Anatomical site	Primary reconstructive options	Alternative reconstruction
Floor of mouth	RFFF	Free flap – ALT, MSAP, lateral arm Pedicled/local flap – nasolabial flaps (bilateral), submental island flap
Lateral tongue	RFFF/ALT	Free flap – MSAP Pedicled/local flap – pectoralis major, platysma skin flap
Total tongue/glossectomy	ALT/rectus abdominus	Pedicled flap – pectoralis major
Buccal mucosa	RFFF	Free flap – ALT/MSAP Pedicled/local flap – pectoralis major
Mandible		
Dentate	Iliac crest (DCIA)	Free flap – fibula, composite radial, scapula or tip of scapula (angular branch of thoracodorsal A)
Edentulous	Fibula	Free flap – composite radial, scapula or tip of scapula (angular branch of thoracodorsal A) Pedicled/local flap – reconstruction plate and pectoralis major
Maxilla		
Low-level/hard palate	Obturation, RFFF/ALT	Pedicled/local flap – temporalis muscle Free flap – 'ZIP flap' - zygomatic implant retained prosthesis (perforating) RFFF/ALT
High	Iliac crest/scapula	Fibula
Soft palate/tonsil	Forearm/MSAP	Free flap – ALT for larger defects ± pharyngeal flap Pedicled/local flap – temporalis muscle, galeal flap
Tongue base	RFFF	Free flap – ALT for larger defects Pedicled/local flap – pectoralis major

ALT, anterolateral thigh; DCIA, deep circumflex iliac artery; MSAP, medial sural artery perforator; RFFF, radial forearm free flap.

Sir William Fergusson, 1808–1877, Scottish surgeon, described and published a modification of the original Weber incision to access the midface.

TABLE 48.4 Common microvascular 'free' flaps in oral cavity reconstruction.

Flap	Blood supply	Common variants
Forearm (RFFF)	Radial artery	Skin only; fascia only
Composite forearm	Radial artery	Skin and bone (radius)
Anterolateral thigh	Perforator vessels off descending (or transverse) branch of lateral circumflex femoral artery	Skin only; skin and muscle ± additional fascia (capacity for tubed reconstruction of pharynx)
Medial sural artery perforator (MSAP)	Medial sural artery	Fasciocutaneous flap
Lateral arm	Profunda brachii artery	Fasciocutaneous
Rectus abdominus	Deep inferior epigastric artery	Skin and muscle; muscle only
Fibula	Peroneal artery	Bone and skin; bone only; bone and fascia/fat
Iliac crest	Deep circumflex iliac artery	Bone only; bone and muscle; bone, muscle and skin, bone and skin as perforator flap
Scapula	Subscapular artery (+ optional angular branch of thoracodorsal artery)	Bone and skin; bone and multiple skin paddles, separate bone segments on circumflex scapula artery and angular branch of thoracodorsal artery

RFFF, radial forearm free flap.

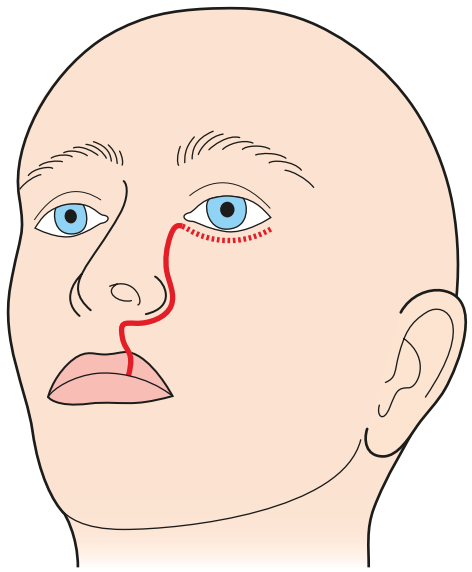

Figure 48.23 Weber–Ferguson incision for maxillectomy (lower eyelid extension may be required in extended maxillectomy).

POST-TREATMENT MANAGEMENT

As with the initial management of oral cavity cancer, the multidisciplinary team is essential for the ongoing management of oral cancer patients. For most patients, in particular those who have received combined modality treatment (surgery and (chemo)radiotherapy) medium to long-term sequelae can have a significant impact on quality of life. Speech and swallowing alteration is frequently encountered, as is the complication of osteoradionecrosis, in up to 10% of patients receiving adjuvant radiotherapy. While allied health professionals such as speech and language therapists are essential in the management of the former, surgical intervention, with its increased risks, is frequently required in the latter.

Surveillance for recurrence and, to a lesser extent, second primary tumours is necessary and development of local protocols for this can be helpful, although as a general rule recurrence reaches it peak within the first 12–24 months post treatment and therefore monitoring is most intensive in this period

Chapter 49

Disorders of the salivary glands

Learning objectives

To understand:

- The surgical anatomy of the salivary glands
- The presentation, pathology and investigation of salivary gland disease
- The medical and surgical treatment of stones, infections and tumours that affect salivary glands

INTRODUCTION

There are three paired major salivary glands, two parotid glands, two submandibular glands and two sublingual glands. In addition, there are multiple minor salivary glands.

MINOR SALIVARY GLANDS

Anatomy

The mucosa of the oral cavity contains approximately 800 minor salivary glands. They are distributed in the mucosa of the lips, cheeks, palate, floor of the mouth and retromolar area. These minor salivary glands also appear in other areas of the upper aerodigestive tract including the oropharynx, larynx and trachea as well as the sinuses. They have a histological structure similar to that of mucus-secreting major salivary glands. Overall, they contribute to 10% of the total salivary volume.

Summary box 49.1

Anatomy of salivary glands

- Two parotid glands
- Two submandibular glands
- Two sublingual glands
- Approximately ~800 minor salivary glands

Common disorders of minor salivary glands

Cysts

Cysts are common and arise from trauma to the glandular parenchyma or drainage system. The minor salivary glands have the distinction that they can secrete against pressure and most cysts are of the extravasation rather than retension variety. They arise in the loose mucosa of the lower lip and the floor of mouth where saliva can easily collect. The swelling is painless and usually, but not always, translucent (**Figure 49.1**). Some resolve spontaneously, but most require formal surgical excision. Recurrence is rare.

Tumours

Few tumours show more diversity in histological appearance and anatomical site than those that arise from mucous glands of the upper aerodigestive tract. Tumours of minor salivary glands are histologically similar to those of major glands; however, more minor salivary gland tumours are malignant and as are almost all tumours in the sublingual glands. Tumours of minor salivary gland origin occur anywhere in the upper aerodigestive tract; however, common sites for tumour formation include the palate, upper lip and retromolar regions. Less

Figure 49.1 Mucous retention cyst. A translucent swelling on the lower lip is typical.

common sites for minor salivary gland tumours include the nasal and pharyngeal cavities. These tumours arise in submucosal seromucous glands that are found throughout the upper aerodigestive tract. A well-defined rubbery lump is a salivary gland tumour until proven otherwise. Benign minor salivary gland tumours present as painless, firm, slow-growing swellings. Overlying ulceration is extremely rare. Minor salivary gland tumours are managed by excision to include the overlying mucosa, with primary closure (**Figure 49.2**).

Benign tumours of the palate, less than 1 cm in diameter, can be managed by excisional biopsy, and the defect left to heal by secondary intention (**Figure 49.3**). Where the tumours are greater than 1 cm in diameter, a 3 mm punch biopsy (dermatological punch) is recommended to establish a diagnosis prior to formal excision and to avoid the embarrasment of inadvertently encountering a low-grade malignant lesion.

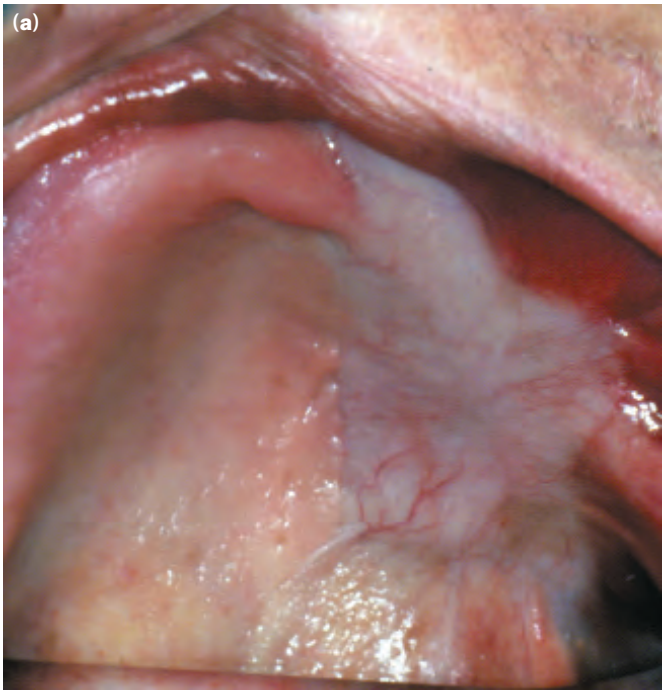
Figure 49.3 (*Continued*)

Malignant neoplasms

Malignant minor salivary gland tumours are rare (2 per million population). Most are low grade and present as apparently benign lumps. They have a firm consistency, and the overlying mucosa may have a varied discolouration from pink to blue or black (Figure 49.4). High-grade lesions usually become necrotic with ulceration as a late presentation.

Figure 49.4 Adenoid cystic carcinoma of the left maxillary alveolus.



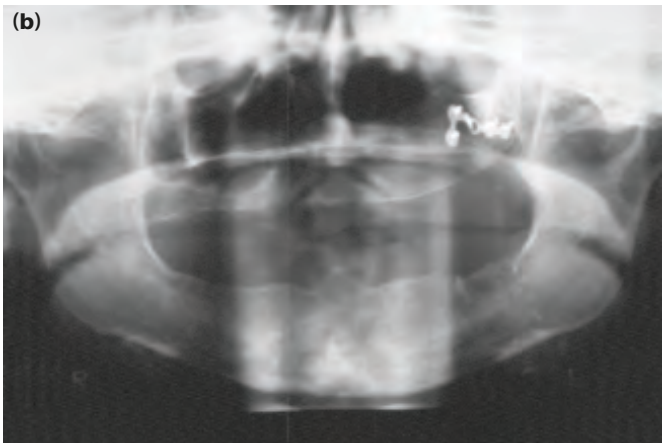


Figure 49.5 **(a)** Postoperative appearance following left maxillectomy and immediate reconstruction with a vascularised iliac crest graft and abdominal wall musculature (epithelialised). **(b)** Postoperative radiographic appearance of a reconstructed left maxilla with internal fixation.

Malignant minor salivary gland tumours of the palate that are low grade and early stage can be managed by wide excision with burring down of the underlying bone and then left to heal by secondary intention. Those that have perforated the palate may require partial or total maxillectomy. The subsequent defect can be managed by either prosthetic obturation or immediate reconstruction. Various microvascular flaps have been designed to reconstruct maxillectomy defects including radial forearm flap, fibular flap, rectus abdominus, latissimus dorsi and vascularised iliac crest graft (Figure 49.5).

Necrotising sialometaplasia

This is a well established but rare entity. Typically it occurs in the palate and mimics an aggressive cancer. It presents as a deep punched out ulcer with an indurated margin. It can not be distinguished from a neoplastic lesion except by biopsy. The diagnosis is sugested by rapid onset in a young person. The lesion resolves spontaniously with symptomatic treatment.

THE SUBLINGUAL GLANDS

Anatomy

The sublingual glands are a paired set of salivary glands lying in the anterior part of the floor of the mouth between the mucous membrane, the mylohyoid muscle and the body of the mandible close to the mental symphysis. The gland has a head portion that drains by numerous excretory ducts (Ducts

of Rivinus) directly into the oral cavity and the tail that drains into the submandibular duct or directly into the mouth.

Summary box 49.2

Sublingual glands

- Problems are rare
- Minor mucous retention cysts may need surgery
- Plunging ranula is a retention cyst that tunnels deep
- Nearly all tumours are malignant

Common disorders of the sublingual glands

Cysts

The term 'ranula' is applied to a mucous extravasation cyst that arises from the sublingual gland. It produces a characteristic translucent swelling that takes on the appearance of a 'frog's belly' (ranula) (**Figure 49.6**). A ranula can resolve spontaneously, but many also require active treatment. The traditional and effective way is to remove the sublingual gland, but it is not an easy operation and the morbidity can be significant. New less invasive techniques are now quite effective (85% success) in resolving ranulas while preserving the gland. Incision and drainage, however tempting, usually results in recurrence.

Ranula is derived from 'rana', the Latin for frog.

Figure 49.6 Large ranula affecting the floor of the mouth.

Plunging ranula

Plunging ranula is a rare form of mucous retention cyst that arises from the sublingual salivary glands. Mucus collects below the gland and perforates through the mylohyoid muscle diaphragm to enter the neck. Patients present with a dumb-bell-shaped swelling that is soft, fluctuant and painless in the submandibular or submental region of the neck (**Figure 49.7**). Diagnosis is made on ultrasound or magnetic resonance imaging (MRI) examination but clinched by aspirating thick yellow treacly fluid from the cyst. This distinguishes it from a lymphangioma. A cervical approach is now contraindicated. The cyst arises from the sublingual gland. All that is required is to remove the sublingual gland and aspirate the saliva out of the sac. The latter is formed of connective tissue not epithelium so melts away once the leak of saliva is resolved.

Figure 49.7 Plunging ranula in the left submandibular region.

Tumours

Tumours involving the sublingual gland are extremely rare and are usually (90%) malignant. They present as a rubbery painless swelling in the floor of the mouth. Pain or lingual nerve paresthesia indicate a high-grade tumour. All such lumps must have a formal punch biopsy prior to formulating a treatment plan. Treatment requires *en block* wide excision involving the overlying mucosa and the adjacent periosteum with simultaneous neck dissection depending on the stage of the disease. Immediate reconstruction of the intraoral defect is recommended, especially when communication with the neck has been established. Radial artery forearm free flap or anterolateral thigh flap is usually the reconstruction of choice for fit patients, otherwise a pedicled pectoralis major flap can be used. There is normally a low threshold for adjuvant radiotherapy except for low-grade and stage lesions.

Augustus Quirinus Rivinus, 1652–1723, German physician and botanist who studied the anatomy of salivary glands and also developed ways of classifying plants.

THE SUBMANDIBULAR GLANDS

Anatomy

The submandibular glands are paired salivary glands that lie below the mandible on either side. They consist of a larger superficial and a smaller deep lobe that are continuous around the posterior border of the mylohyoid muscle. Important anatomical relations include the anterior facial vein and artery running over the surface of the gland in close association with the ramus mandibularis (marginal mandibular) of the facial nerve. The deep part of the gland lies on the hyoglossus muscle closely related to the lingual nerve and inferior to the hypoglossal nerve. The gland is surrounded by a well-defined capsule that is derived from the deep cervical fascia which splits to enclose it. The gland is drained by a single submandibular duct (Wharton's duct) that emerges from its deep surface and runs in the space between the hyoglossus and mylohyoid muscles. It drains into the anterior floor of the mouth at the sublingual papilla. There are several lymph nodes immediately adjacent and sometimes within the superficial part of the gland.

Summary box 49.3

Important anatomical relationships of the submandibular glands

- Lingual nerve
- Hypoglossal nerve
- Anterior facial vein
- Facial artery
- Marginal mandibular branch of the facial nerve

Ectopic/aberrant salivary gland tissue

The most common ectopic salivary tissue is a Stafne bone cyst, the origin of which is uncertain. It presents as an asymptomatic, clearly demarcated radiolucency of the angle of the mandible, characteristically below the inferior dental neurovascular bundle (**Figure 49.8**). The cavity in the lingual plate houses part of the submandibular gland or ectopic salivary tissue, but the origin of the cavity is unclear and has been attributed to the pulse pressure from the facial artery. No treatment is required.

Inflammatory disorders of the submandibular gland

Inflammation of the submandibular gland is termed sialadenitis. Submandibular sialadenitis may be acute, chronic or acute on chronic.

Common causes are:

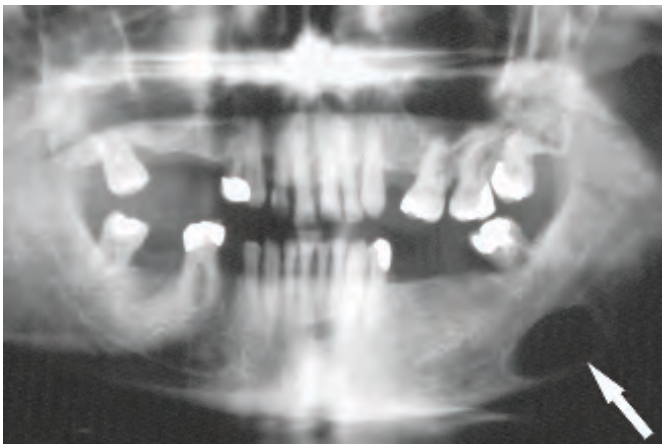

Figure 49.8 Plain radiographic appearance of a Stafne bone cyst.

- Acute submandibular sialadenitis
  - **Viral**. The paramyxovirus (mumps) is a viral illness of the salivary glands that usually produces parotitis. The submandibular glands are occasionally involved, causing painful tender swollen glands. Other viral infections of the submandibular gland are extremely rare.
  - **Bacterial**. Bacterial sialadenitis is more common than viral sialadenitis and occurs secondary to obstruction by stone. These stones can be reliably removed by minimally invasive techniques that preserve the gland.
- Chronic submandibular sialadenitis.

Obstruction and trauma

The most common cause of obstruction within the submandibular gland is stone formation (sialolithiasis) within the gland and its associated duct system. Eighty per cent of all salivary stones occur in the submandibular glands because their secretions are relatively viscous. Eighty per cent of submandibular stones are radio-opaque and can be identified on plain radiography (**Figure 49.9**). Stones are mainly composed of phosphate and oxalate salts.

The second most common cause of submandibular duct obstruction is stricture. The remaining 5–10% of cases are secondary to floor of mouth pathology or external pressure, particularly trauma to the floor of the mouth from an overextended flange on a lower denture that impinges on the sublingual papilla, causing inflammation and subsequent stricture.

Clinical symptoms

Patients usually present with acute painful swelling in the region of the submandibular gland, precipitated by eating (**Figure 49.10**). The swelling occurs rapidly and often resolves spontaneously over 1–2 hours after the meal is completed (meal-time syndrome). This classical picture occurs when the stone causes complete obstruction as it is washed forward and impacts in the lumen. The two most common sites of impaction are the hilum of the gland as the duct bends

Thomas Wharton, ?1616–1673, physician, St. Thomas's Hospital, London, UK, described the submandibular duct in 1656.
Edward C Stafne, 1894–1981, dental surgeon, The Mayo Clinic, Rochester, MN, USA, described these cysts in 1942.

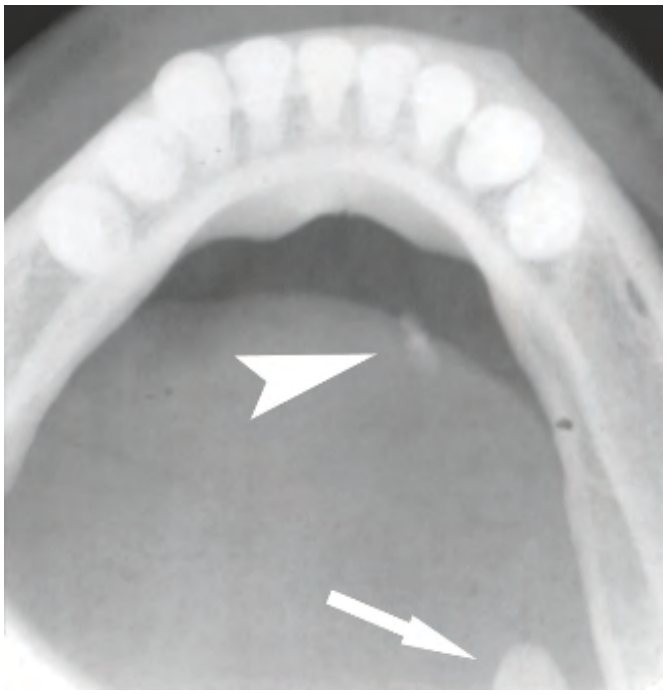

Figure 49.9 Lower occlusal X-ray highlighting a radio-opaque submandibular duct stone (arrowhead). Note the larger stone posteriorly located in the hilum of the gland (arrow).

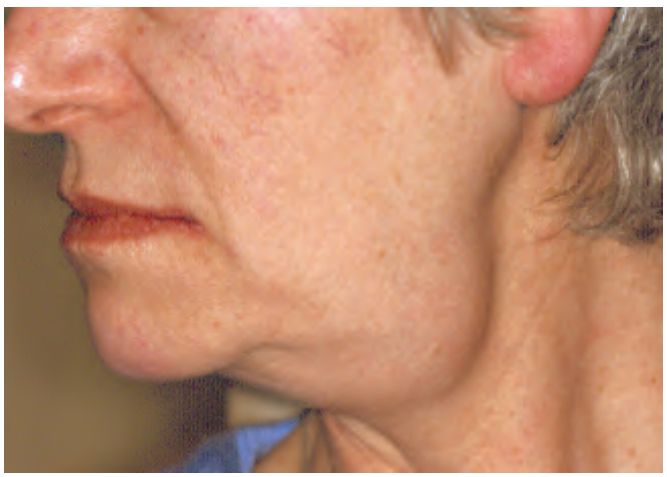

Figure 49.10 Acute left submandibular sialadenitis.

over the mylohyoid muscle and near the punctum. The symptoms are frequently intermittent as the stone can dislodge and allow the gush of saliva induced at meal times to pass. In such circumstances, symptoms are moderate with minimal discomfort and swelling. Clinical examination reveals an enlarged firm submandibular gland, tender on bimanual examination. Pus may be visible draining from the sublingual papilla or expressed by bimanual palpation of the gland (**Figure 49.11**).

Management

Small (less then 4 mm) mobile stones can be retrieved using a Dormia® basket. This minimally invasive procedure is usually performed under local anaestheisa either endoscopically (sialendoscopy) or under radiological control (ultrasonography). For larger stones, extracorporeal or intracorporeal lithotripsy can be employed to break the stone into smaller pieces using shock waves and the stone fragments can then removed with a basket. Recently, a pneumatic intraductal lithotripter (StoneBraker™) has been developed that can be advanced into the duct lumen under endoscopic control to fragment the stone. Results are promising, with 70% of stones being cleared in slected cases.

Figure 49.11 Acute suppurative submandibular sialadenitis. There is pus extruding from the left sublingual papilla.

If the stone is lying within the submandibular duct in the floor of the mouth anterior to the point at which the duct crosses the lingual nerve (second molar region), the stone can be removed under local anaesthetic but not by incising directly on to the duct. The latter runs under the sublingual gland and trauma to the head of the sublingual gland induces ranulae. Therefore, the incision has to run along the medial margin of the gland and the latter is then rotated laterally to expose the duct on its deep surface. Once the stone has been delivered via a single longitudinal incission along its surface, the duct should be closed by a resorbable suture and the incision in the floor of mouth closed.

Where the stone is proximal to the lingual nerve (i.e. at the hilum of the gland), stone retrieval via an intraoral approach can be performed quite reliably under general anaesthesia. The key is to choose cases in which the stone is palpable. This approach can be difficult and attendance on a suitable salivary course is recommended. Stone retrieval rates are excellent (95%). The risk to the lingual nerve is greatest with deep stones that are not palpable, as they lie outside the mouth below the mylohyoid. Traction injuries can occur in such circumstances. If stone retrieval fails, submandibular gland excision can be performed.

Submandibular gland excision

With the availability of more conservative techniques, submandibular gland excision is performed less frequently for benign disease as almost all benign conditions can be treated without gland removel. It is now the treatment of last rather than first resort. Submandibular gland incision is indicated for:

- sialadenitis, when minimally invasive methods have failed;
- salivary tumours.

Excision of the submandibular gland involves four distinct phases.

INCISION AND EXPOSURE OF GLAND

Surgery is usually performed under endotracheal general anaesthesia with moderate neck extension and the chin rotated to the opposite side. The incision should be marked at least 3–4 cm below the lower border of the mandible to avoid damage to the marginal mandibular branch of the facial nerve (**Figure 49.12a**). The incision should be sited within the nearest skin crease and should be approximately 4 cm long. Infiltration with lidocaine with adrenaline is optional. Sharp dissection is performed down to the platysma muscle, which should be clearly identified to facilitate later closure (**Figure 49.12b**). The muscle is incised and retracted. The underlying investing layer of deep cervical fascia is then divided, and the marginal mandibular branch of the facial nerve that normally runs on the deep surface of the platysma muscle is preserved. Posteriorly, the incision approaches the angular tract where the deep cervical fascia splits to form the investing layer around the sternomastoid muscle. Superficial veins, including the anterior facial vein, require ligation.

GLAND MOBILISATION

Deepening the incision divides the submandibular gland capsule. In inflammatory conditions, the submandibular gland is excised by intracapsular dissection, mobilising the gland by sharp dissection. For tumours of the submandibular gland it is imperative to know if the lesion is benign or malignant. This can be ascertained by Tru-Cut biopsy. This is important because if the wrong operation is undertaken on a malignant tumour, the survival rate of the patient is reduced by 20%. Malignant tumours require wide excission with neck dissection in selected cases. Benign tumours can be dealt with by extracapsular dissection and excision of the submandibular gland.

The superficial lobe of the submandibular gland is first mobilised. As dissection proceeds, the posterior belly and anterior belly of the digastric muscle are identified. Dissection posteriorly identifies the facial artery (**Figure 49.13**), which is divided to facilitate further mobilisation. The course of the facial artery is variable, sometimes penetrating the gland emerging on the upper border and sometimes lying in a groove on the deeper aspect of the gland. The gland is further mobilised by blunt and sharp dissection. A number of small arteries and veins are encountered, which require control with bipolar diathermy.

DISSECTION OF THE DEEP LOBE AND IDENTIFICATION OF THE LINGUAL NERVE

An important landmark in submandibular gland dissection is the posterior border of the mylohyoid muscle. Once identified, it can be retracted forwards to reveal the deep lobe of the gland. Several veins are usually encountered, which need to be controlled with diathermy. The gland is then retracted inferiorly, invariably attached to the lingual nerve through parasympathetic secretor motor fibres. In the presence of chronic infection and subsequent fibrosis, identification of the lingual nerve on the deep aspect of the gland is sometimes difficult. It is imperative that the lingual nerve is formally identified prior to division of the parasympathetic fibres. The gland is then pedicled entirely on the submandibular duct, which, once identified, is ligated. The gland is delivered and sent for histological examination. The hypoglossal nerves lie deep to the submandibular capsule and should not be damaged during intracapsular dissection (**Figure 49.14**).

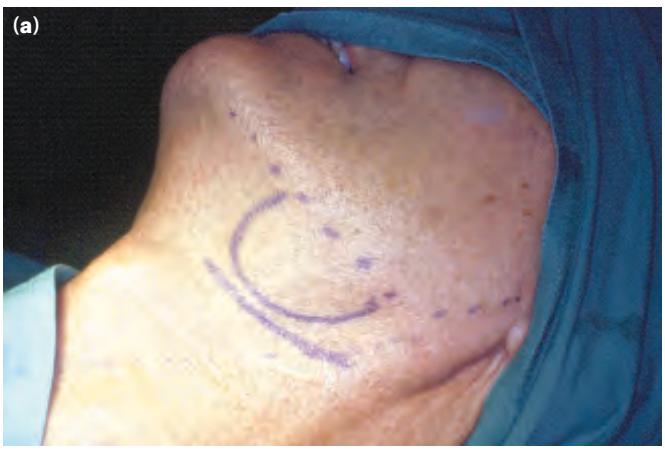

Figure 49.12 **(a)** Surface landmarks of submandibular gland excision. **(b)** Skin flaps elevated and platysma exposed.

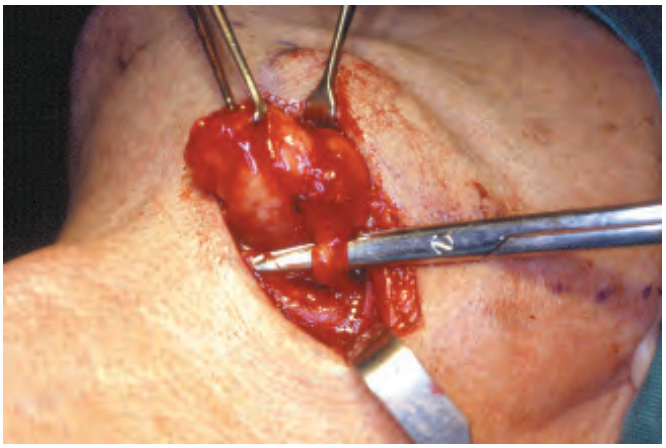

Figure 49.13 Submandibular gland mobilisation and exposure of the facial artery.

Figure 49.14 Bed of the submandibular triangle following submandibular gland removal, revealing the posterior edge of the mylohyoid muscle and the tendon of the digastric muscle.

Figure 49.15 Benign tumour of the right submandibular gland.

Three cranial nerves (CNs) are at risk during removal of the submandibular gland:

1 the marginal mandibular branch of the facial nerve;
2 the lingual nerve;
3 the hypoglossal nerve.

An adequate incision coupled with meticulous haemostasis allows the surgeon to identify these important structures during surgery.

WOUND CLOSURE

Haemostasis is confirmed and a vacuum suction drain inserted. The wound is closed using a continuous resorbable suture to the platysma muscle, as the platysma muscle has a direct contribution to the depressor activity of the corner of the mouth. The skin may be closed with a subcuticular non-resorbable suture, removed 7 days after surgery. The drain remains for 24 hours.

Complications of submandibular gland excision

Complications are:

- haematoma;
- wound infection;
- marginal mandibular nerve injury;
- lingual nerve injury;
- hypoglossal nerve injury;
- transection of the nerve to the mylohyoid muscle producing submental skin anaesthesia.

Tumours of the submandibular gland

Tumours of the submandibular gland are uncommon and usually present as a slow-growing, painless swelling within the submandibular triangle (**Figure 49.15**). About 60–70% of submandibular gland tumours are benign, in contrast to 80–90% of parotid gland tumours (*Table 49.1*). In many circumstances, the swelling cannot, on clinical examination, be differentiated from submandibular lymphadenopathy. This can be resolved definitively by ultrasound examination. Most salivary neoplasms, even malignant tumours, are often slow-growing, painless swellings. The difficulty is to always distinguish between benign and malignant lesions prior to excision, as in up to 30% referrals of submandibular gland cancers to regional cancer centres, patients have already had surgical excison of the gland, which was subsequently found to be malignant on histological examination. Pain is not a reliable indication of malignancy; however, rapid growth, facial nerve palsy, lymph node enlargement and skin tethering are signs of a high-grade malignant lesion. The most common malignant tumour is an adenocystic carcinoma (40%), which may masquerade as a benign lump.

TABLE 49.1 Salivary gland tumours – frequency and distribution.

Type	Location	Frequency	Malignant (%)
Major	Parotid Submandibular Sublingual	Common Uncommon Very rare	10–20 50 85
Minor	Upper aerodigestive tract	Rare	90

Clinical features of high-grade malignant salivary tumours

These include:

- facial nerve weakness;
- rapid enlargement of the swelling;
- induration and/or ulceration of the overlying skin;
- cervical node enlargement.

Investigation

The initial investigation of choice is ultrasound with fine-needle aspiration cytology (FNAC)/True-Cut biopsy. Once it is established that a tumour is present, computed tomography (CT) and MRI scanning are complimentary techniques for imaging tumours arising in the major salivary glands. The tumour is intrinsic to the gland. The scan will highlight the

relationship of the tumour to other anatomical structures, which is helpful in planning surgery.

Open surgical biopsy is contraindicated as this may seed the tumour into surrounding tissues, making it impossible to eradicate microscopic deposits of tumour cells. Fine-needle aspiration or Tru-Cut biopsy is a safe alternative as the risk of seeding tumour is remote. The combination of careful history and examination in conjunction fine-needle aspitation cytology can identify over 95% of malignant cases. The few malignant cases that are indistinguishable from benign disease by these methods and are only identified by histology are usually indolent and act as benign tumours.

Management of submandibular gland tumours

Benign tumours of the submandibular gland can be safely removed by meticulous dissection outside the submandibular capsule. No instrument should be applied to the gland as to do so may crush it. As long as the capsule of the gland is preserved intact, the risk of recurrence is 1–1.5% at 10 years. As with all salivary gland tumours, surgical excision with a cuff of normal tissue is the goal.

The management of malignant salivary gland tumours is governed by the stage and clinical grade of the lesion. The

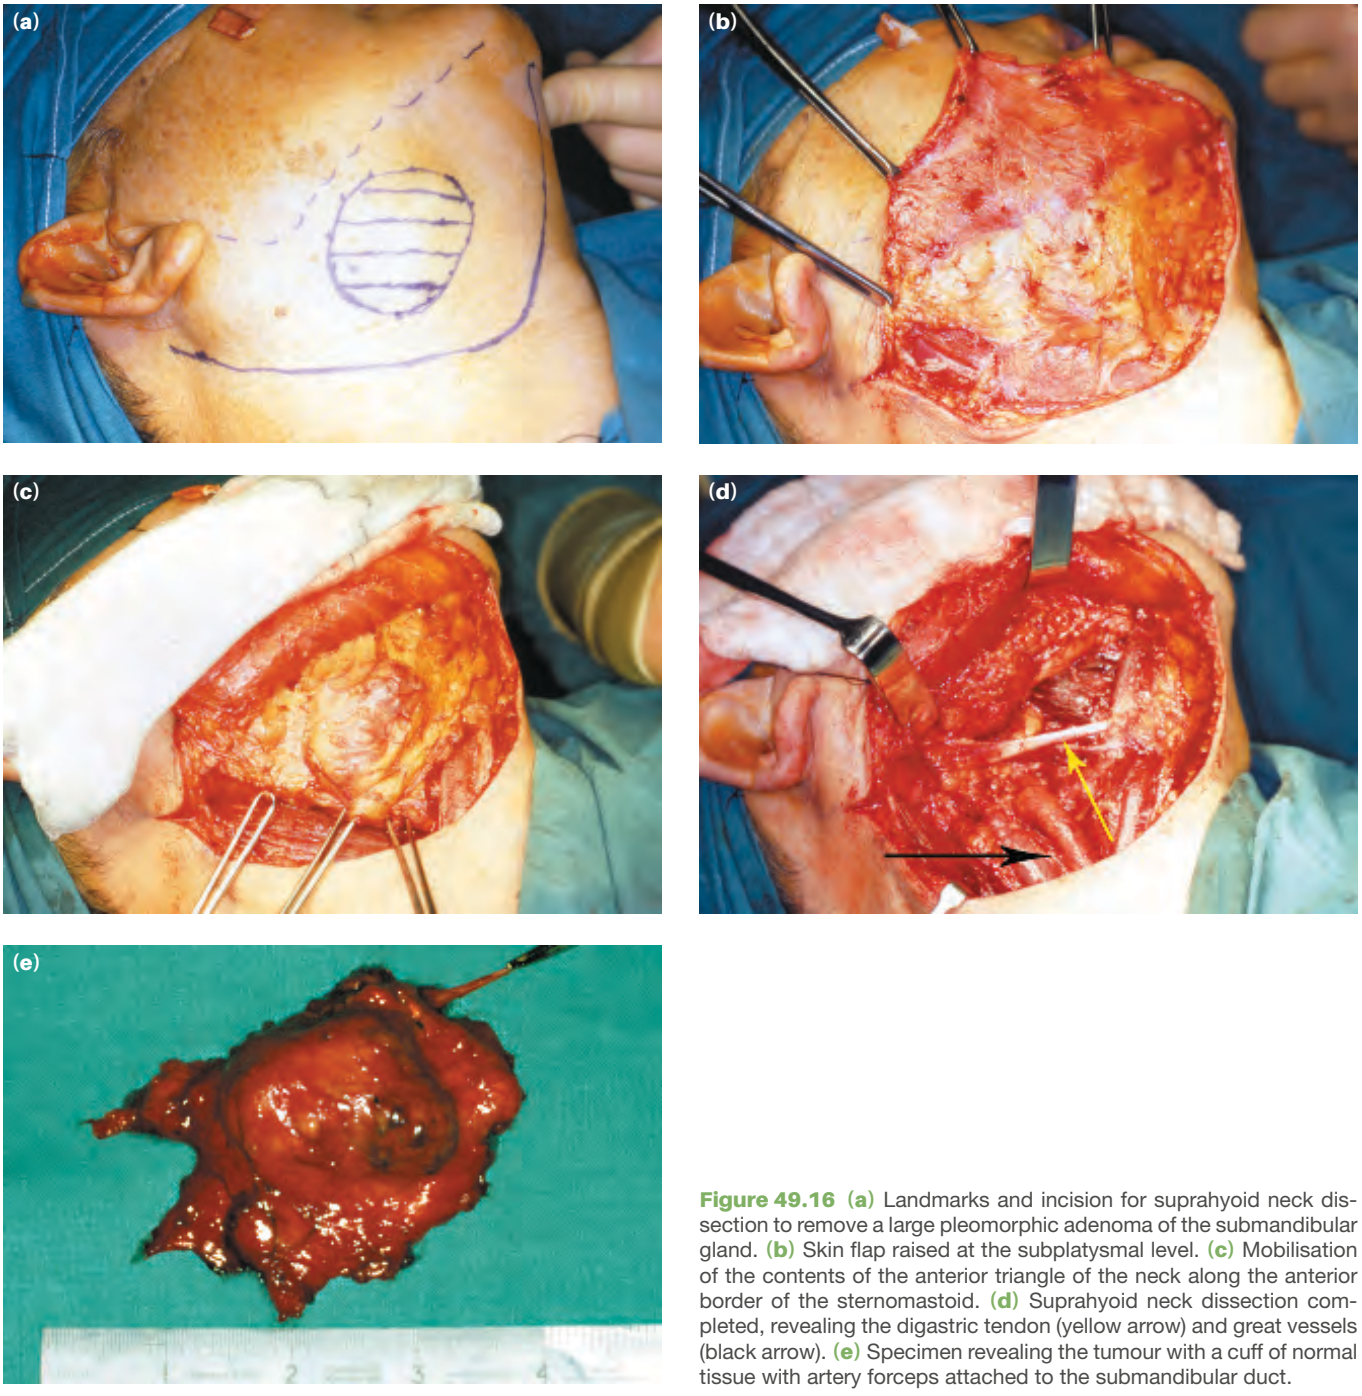

Figure 49.16 **(a)** Landmarks and incision for suprahyoid neck dissection to remove a large pleomorphic adenoma of the submandibular gland. **(b)** Skin flap raised at the subplatysmal level. **(c)** Mobilisation of the contents of the anterior triangle of the neck along the anterior border of the sternomastoid. **(d)** Suprahyoid neck dissection completed, revealing the digastric tendon (yellow arrow) and great vessels (black arrow). **(e)** Specimen revealing the tumour with a cuff of normal tissue with artery forceps attached to the submandibular duct.

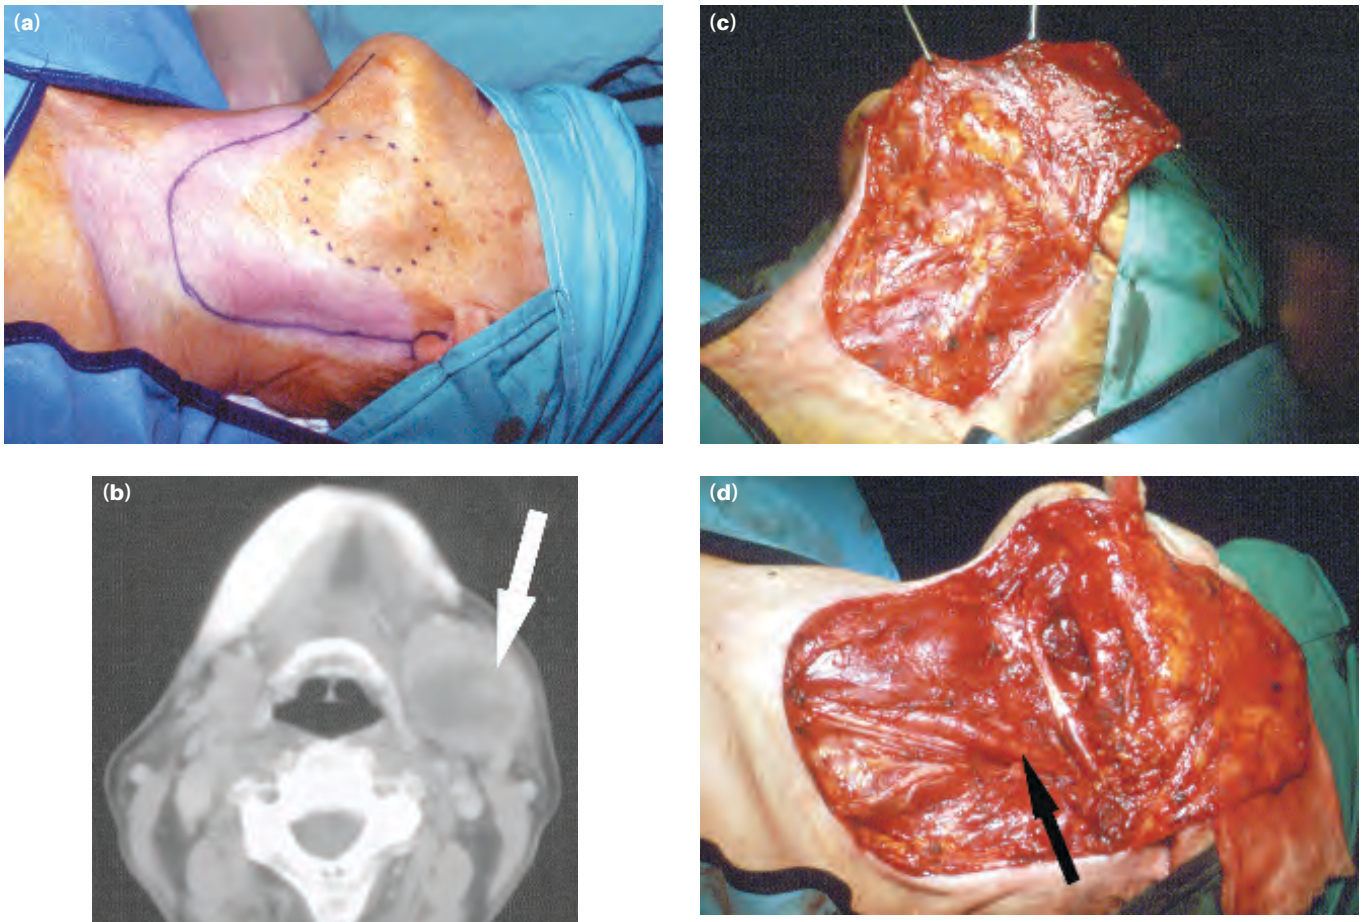

Figure 49.17 **(a)** Landmarks and incision for radical neck dissection for carcinoma of the left submandibular gland. **(b)** computed tomography scan revealing a large tumour of the left submandibular gland with central necrosis (arrow). **(c)** Skin flap developed for radical neck dissection. **(d)** Completion of radical neck dissection revealing the great vessels of the neck (arrow).

larger and more aggressive the lesion, the more radical is the surgery required. Each case has to be judged on its own merits, but wide clearance of the submandibular triangle with some form of neck dissection is normally the treatment of choice (Figure 49.16). This may neccessitate sacrifice of the lingual and hypoglossal nerves if the tumour is adherent to the deep bed of the gland (Figure 49.17). Adjuvant radiotherapy is usually dictated by pathological findings such as close margins and high-grade cancers. The prognostic cut off point for salivary cancers is 4 cm and most tumours larger than this need adjuvant therapy as will patients with adenoid cystic carcinoma if optimum results are to be achieved.

THE PAROTID GLAND

Anatomy

The parotid gland lies in a recess bounded by the ramus of the mandible, the base of the skull and the mastoid process. It lies on the carotid sheath and CNs XI and XII and extends forward over the masseter muscle. The gland is enclosed in a sheath of dense deep cervical fascia. Its upper pole extends just below the zygoma and its lower pole (tail) into the neck.

Several important structures run through the parotid gland. These include:

- the facial nerve trunk that divides into its major five branches;
- the terminal branch of the external carotid artery that divides into the maxillary artery and the superficial temporal artery;
- the retromandibular vein;
- intraparotid lymph nodes.

The gland is arbitrarily divided into deep and superficial lobes, separated by the facial nerve. Eighty per cent of the parotid gland lies superficial and 20% deep to the nerve. An accessory lobe is occasionally present lying anterior to the superficial lobe on the masseter muscle.

Developmental disorders

Developmental disorders such as agenesis, duct atresia and congenital fistula are extremely rare.

Inflammatory disorders

Viral infections

Mumps is the most common cause of acute painful parotid swelling and predominantly affects children. It is spread via airborne droplets of infected saliva. The disease starts with a prodromal period of 1–2 days, during which the patient experiences fever, nausea and headache. This is followed by pain and swelling in one or both parotid glands. Parotid pain can be very severe and exacerbated by eating and drinking. Symptoms resolve within 5–10 days. The diagnosis is based on history and clinical examination; recent contact with an infected patient with a painful parotid swelling is often sufficient to lead to a diagnosis. Atypical viral parotitis does occur and may present with predominantly unilateral swelling or even submandibular involvement. A single episode of infection confers lifelong immunity. Treatment of mumps is symptomatic with regular paracetamol and adequate oral fluid intake. Complications of orchitis, oophoritis, pancreatitis, sensorineural deafness and meningoencephalitis are rare, but are more likely to occur in adults.

Other viral agents that produce parotitis include Coxsackie A and B, parainfluenza 1 and 3, Echo and lymphocytic choriomeningitis.

Bacterial infections

Acute ascending bacterial sialadenitis is historically described in dehydrated elderly patients following major surgery. Reduced salivary flow secondary to dehydration results in ascending infection via the parotid duct into the parotid parenchyma. The more common picture today is an acute bacterial parotitis associated with a salivary calculus. The patient presents with a tender, painful parotid swelling that arises over several hours (**Figure 49.18**). There is generalised malaise, pyrexia and occasional cervical lymphadenopathy. The pain is exacerbated by eating or drinking. The parotid swelling may be diffuse, but often localises to the lower pole of the gland. Intraoral examination may reveal pus exuding from the parotid gland papilla. The infecting organism is usually *Staphylococcus aureus* or *Streptococcus viridans*, and treatment is with appropriate intravenous antibiotics. If the gland becomes fluctuant, ultrasound may identify abscess formation within the gland that may require aspiration with a large-bore needle or formal drainage under general anaesthesia. In the latter procedure, the skin incision should be made low to avoid damage to the lower branch of the facial nerve. Blunt dissection using sinus forceps is preferred, and the cavity is opened to facilitate drainage. A drain is inserted and left *in situ* for 24–72 hours. Sialography is contraindicated during acute infection. Chronic bacterial sialadenitis is rare in the parotid gland.

Figure 49.18 Acute left bacterial parotitis.

Recurrent parotitis of childhood

Recurrent parotitis of childhood is a distinct clinical entity of unknown aetiology and variable prognosis. It is characterised by rapid swelling of one or both parotid glands, in which the symptoms are made worse by chewing and eating. Systemic upset with fever and malaise is variable. The symptoms usually last from 3 to 7 days, and are then followed by a quiescent period of weeks to several months. Children usually present between the ages of 3 and 6 years, although symptoms have been reported in infants as young as 4 months. The diagnosis is based on the characteristic history and can be confirmed by sialography. This shows a characteristic punctate sialectasis likened to a 'snowstorm' (**Figure 49.19**). The condition is difficult to manage if it becomes established and so the initial treatment is important. The condition responds to regular endoscopic washouts and long courses of antibiotics. The suspicion is that in some cases the condition is caused by an incompetent punctum that leads to soiling of the parotid ducts with contaminated oral fluids.

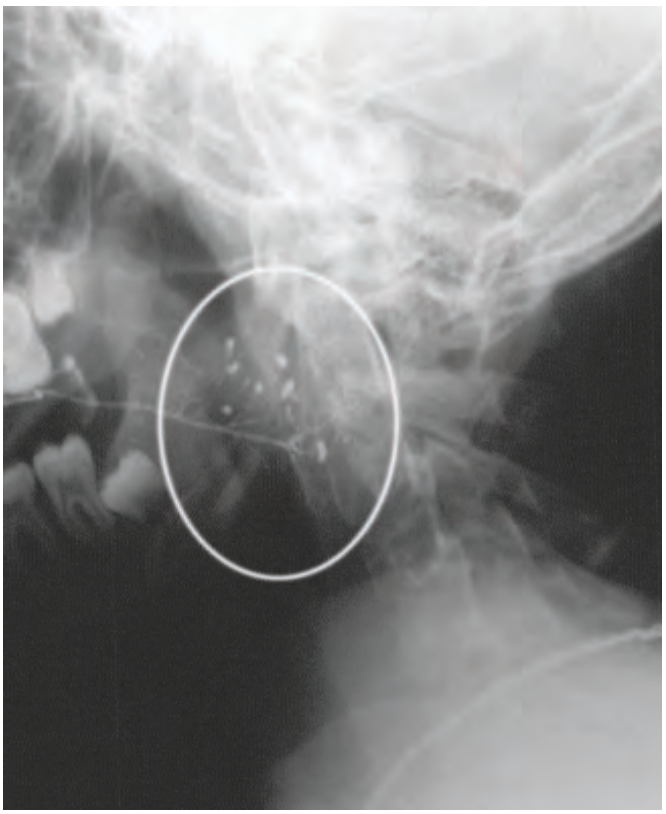

Figure 49.19 Characteristic 'snowstorm' appearance of recurrent parotitis of childhood (circled).

Human immunodeficiency virus-associated sialadenitis

Chronic parotitis in children may signify human immunodeficiency virus (HIV) infection. The presentation of HIV-associated sialadenitis is very similar to classical Sjögren's syndrome in adulthood. Although HIV-associated sialadenitis and Sjögren's syndrome are histologically similar, the former condition is usually associated with a negative autoantibody screen. Other presentations of salivary gland disease in HIV-positive patients include multiple parotid cysts, which cause gross parotid swelling and facial disfigurement. CT and MRI demonstrate the characteristic 'Swiss cheese' appearance of multiple large cystic lesions (**Figure 49.20**). The swollen glands are usually painless and may regress on the institution of antiviral therapy. Cysts can be aspirated.

Obstructive parotitis

There are several causes of obstructive parotitis, which produces intermittent painful swelling of the parotid gland, particularly at mealtimes.

Stone formation and strictures

Sialolithiasis is less common in the parotid gland (20%) than in the submandibular gland (80%). Parotid duct stones are usually radiolucent and rarely visible on plain radiography. They are frequently located at the confluence of the collecting ducts, at the point the duct courses over the masseter muscle or in the distal aspect of the parotid duct adjacent to the parotid papilla. The stones are easily demonstrated on ultrasound. The same rules for treatment apply to parotid stones as to submandibular duct stones. Small stones (~4 mm) can be retrieved by baskets, slightly larger stones up to 8 mm can be broken with lithotripsy and stones over 8 mm diameter should be removed by endoscopic assisted surgery while preserving the gland. Strictures are common in the parotid gland and are responsible for about 20% of obstructive cases. The symptom complex is a little different as the obstruction is due to mucus plugs. These form after periods of stagnation. Classically, the patient complains of a meal-time syndrome starting at breakfast and the saliva cannot seep past the mucus plug so the swelling persists. Massage eventually releases the plug with a gush of salty saliva. Infection is uncommon unless there is stone formation. Strictures respond to dilatation and endoscopic washouts with steroid solutions.

Figure 49.20 Magnetic resonance imaging scan. Giant bilateral parotid cysts in human immunodeficiency virus infection.

Papillary obstruction

Obstructive parotitis, can be caused by trauma to the parotid papilla. The subsequent inflammation and oedema obstructs salivary flow, particularly at mealtimes. This is a rare but real entity. The partial obstruction over a protracted period leads to dilation of the duct and an entity called 'mega-duct'. A large dilated duct is visible coursing over the patient's cheek. Drainage has to be re-established. This can be done by progressive dilatation of the punctum and the insertion of a stent that is kept in position for many weeks. Surgical attempts to refashion the punctum are unlikely to be successful. Papillotomy should not be performed as this often leads to stricture formation and a life time of problems. This is not the case with the submandibular gland.

Tumours of the parotid gland

The parotid gland is the most common site for salivary tumours. Most tumours arise in the superficial lobe and present as slow-growing, painless swellings below the ear (**Figure 49.21a**), in front of the ear (**Figure 49.21b**) or in the upper aspect of the neck. Less commonly, tumours may arise from the accessory lobe and present as persistent swellings within the cheek. Rarely, tumours may arise from the deep lobe of the gland and present as a parapharyngeal mass (**Figures 49.21c, d**). Symptoms include difficulty in swallowing and snoring. Clinical examination reveals a diffuse firm swelling in the soft palate and tonsil.

Some 80–90% of tumours of the parotid gland are benign, the most common being pleomorphic adenoma (*Table 49.2*).

Malignant salivary gland tumours are divided into two distinct sub-groups:

1 **Low-grade malignant tumours** (e.g. acinic cell carcinoma) are indistinguishable on clinical examination from benign neoplasms.

Henrik Samuel Conrad Sjögren, 1899–1986, Professor of Ophthalmology, Göthenburg, Sweden, described this condition in 1933.
A Swiss cheese is one with many holes in it.

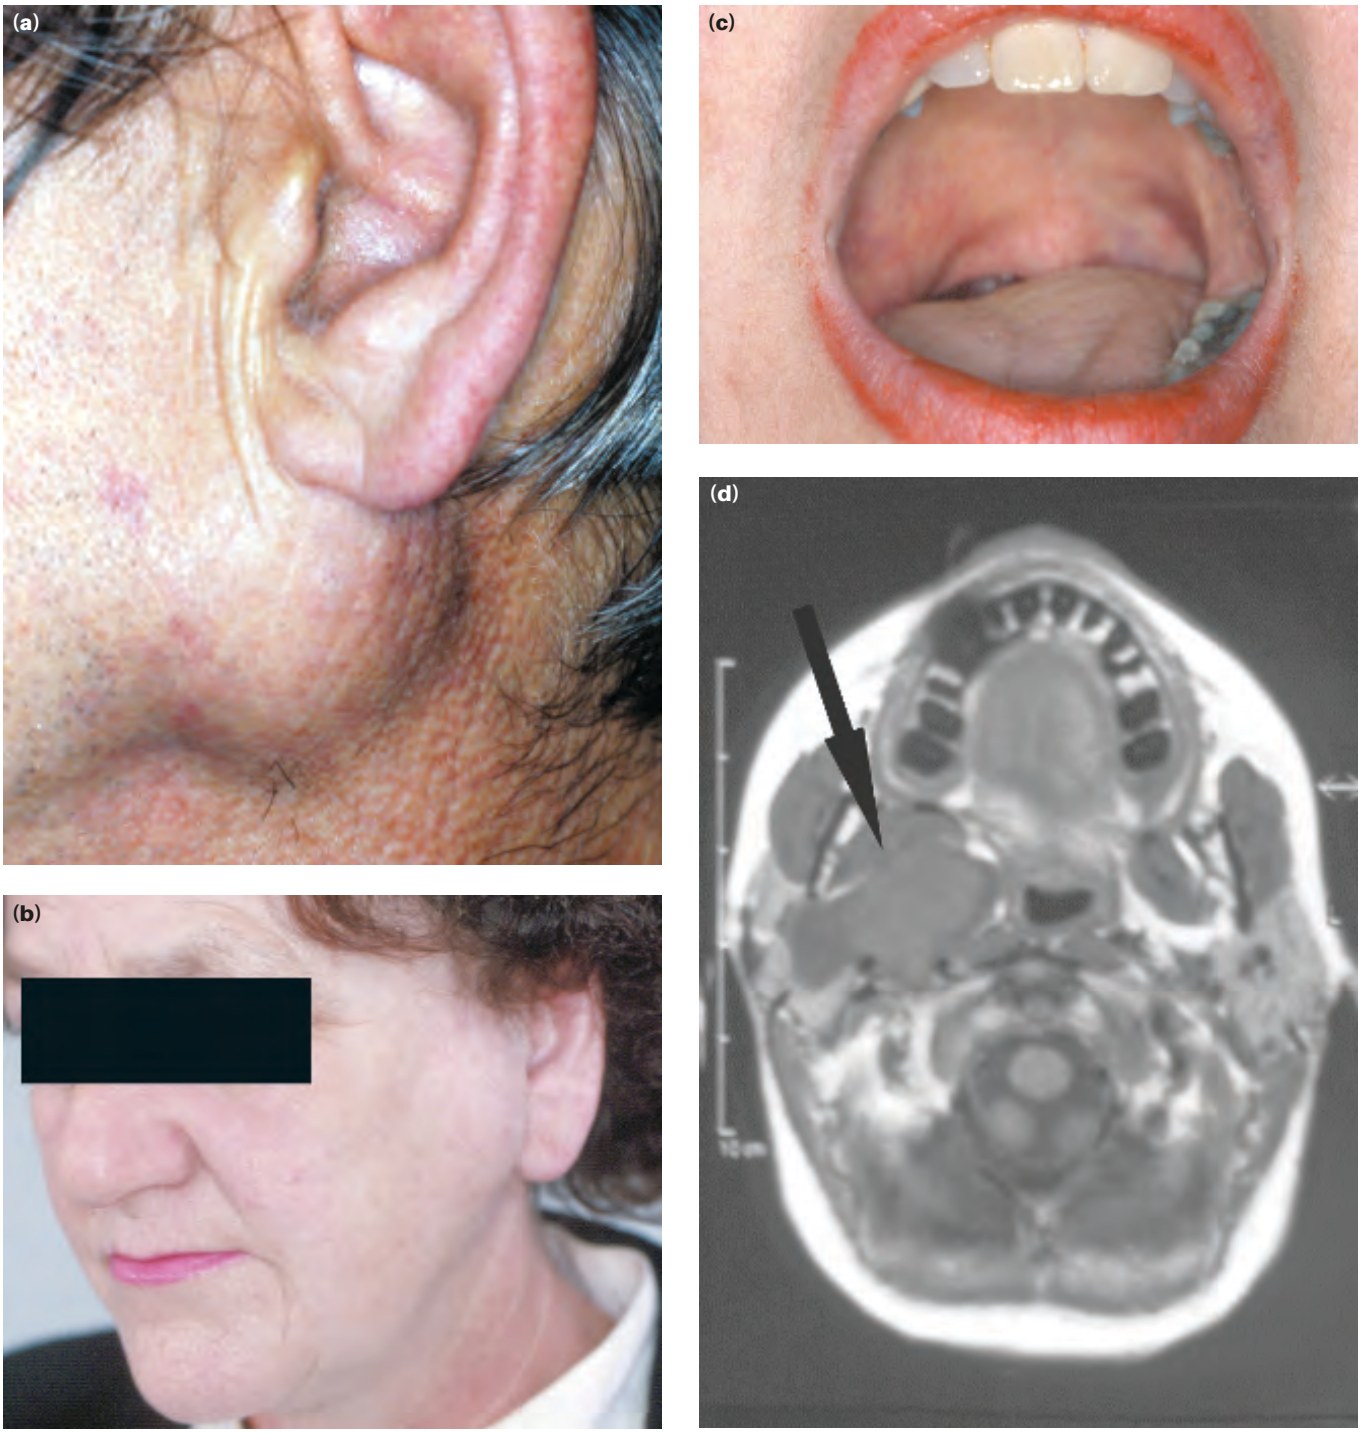

Figure 49.21 (a) Benign tumour of the left parotid gland producing characteristic deflection of the ear lobe. (b) Pleomorphic adenoma arising from the upper pole of the left parotid gland producing a preauricular swelling. (c) Deep lobe tumour of the right parotid presenting with a swelling of the right soft palate. (d) Magnetic resonance imaging scan revealing a large deep lobe tumour (arrow) of the right parotid gland, occupying the parapharyngeal space.

2 **High-grade malignant tumours** usually present as rapidly growing, often painless swellings in and around the parotid gland. The tumour presents as either a discrete mass with infiltration into the overlying skin (Figure 49.22) or a diffuse but hard swelling of the gland with no discrete mass. Presentation with advanced disease is common, and cervical lymph node metastases may be present.

Among primary parotid malignant tumours, mucoepidermoid carcinoma is the most common, followed by adenocystic carcinoma. The latter is notorious for its proclivity for perineural invasion and metastatic potential so surgery is normally supported by adjuvant radiotherapy to gain local control of the disease.

TABLE 49.2 Classification of salivary gland tumours (simplified).

Type	Subgroup	Common examples
I Adenoma	Pleomorphic Monomorphic	Pleomorphic adenoma Adenolymphoma (Warthin's tumour)
II Carcinoma	Low grade	Acinic cell carcinoma Adenoid cystic carcinoma Low-grade mucoepidermoid carcinoma
	High grade	Adenocarcinoma Squamous cell carcinoma High-grade mucoepidermoid carcinoma
III Non-epithelial tumours		Haemangioma, lymphangioma
IV Lymphomas	Primary lymphomas Secondary lymphomas	Non-Hodgkin's lymphomas Lymphomas in Sjögren's syndrome
V Secondary tumours	Local Distant	Tumours of the head and neck especially Skin and bronchus
VI Unclassified tumours		
VII Tumour-like lesions	Solid lesions	Benign lymphoepithelial lesion Adenomatoid hyperplasia
	Cystic lesions	Salivary gland cysts

Figure 49.22 Malignant tumour of the left parotid gland with invasion of the overlying skin.

Investigations

The initial imaging modality of choice is ultrasound as it demonstrates if the lump is intrinsic to the parotid or not. It also facilitates accurate sampling of the lesion by FNAC or True-Cut biopsy. Subsequently, CT and MRI are the most useful imaging techniques (**Figure 49.23**). Open surgical biopsy is contraindicated unless evidence of gross malignancy is present, and preoperative histological diagnosis is required as a prelude to radical parotidectomy.

Parotidectomy

The aim of superficial parotidectomy is to remove the tumour with a cuff of normal surrounding tissue. The most important structure traversing the parotid gland in the facial nerve. Parotid tumour excision techniques are classified based on the approach onto the facial nerve. Essentially the traditional parotidectomy is in reality a dissection of the facial nerve. A parotidectomy is conservative when the nerve is spared and radical when the nerve is excised *en bloc* with the tumour. A superficial parotidectomy is when the part of the gland superficial to the facial nerve is removed. A deep lobe parotidectomy is when the part of the gland beneath the nerve is removed and total parotidectomy is when both are dissected and removed. Superficial parotidectomy can be partial in relatively small tumours that are removed with a cuff of clinically normal parenchyma without removal of the entire superficial portion of the gland.

An alternative surgical approach is to focus on the tumour itself as the principal procedure and not facial nerve dissection. Extracapsular dissection is now an established alternative to parotidectomy. It does not require formal facial nerve dissection and is a less invasive technique with reduced morbidity. Temporary facial nerve injury rates are 7% compared with 25% for superficial parotidectomy.

Superficial parotidectomy

Superficial parotidectomy is the most common procedure for parotid gland pathology. Surgery is performed under endotracheal general anaesthesia, which may or may not be accompanied by hypotensive anaesthesia to facilitate dissection, improve the visual surgical field and reduce blood loss. The operation has several distinct phases.

INCISION AND DEVELOPMENT OF A SKIN FLAP

The most commonly used incision is the 'lazy S' pre-auricular–mastoid–cervical (**Figure 49.24a**). The incision is marked

Aldred Scott Warthin, 1866–1931, Professor of Pathology, University of Michigan, Ann Arbor, MI, USA.
Thomas Hodgkin, 1798–1866, curator of the museum, and demonstrator of Morbid Anatomy, Guy's Hospital, London, UK, described lymphadenoma in 1832.

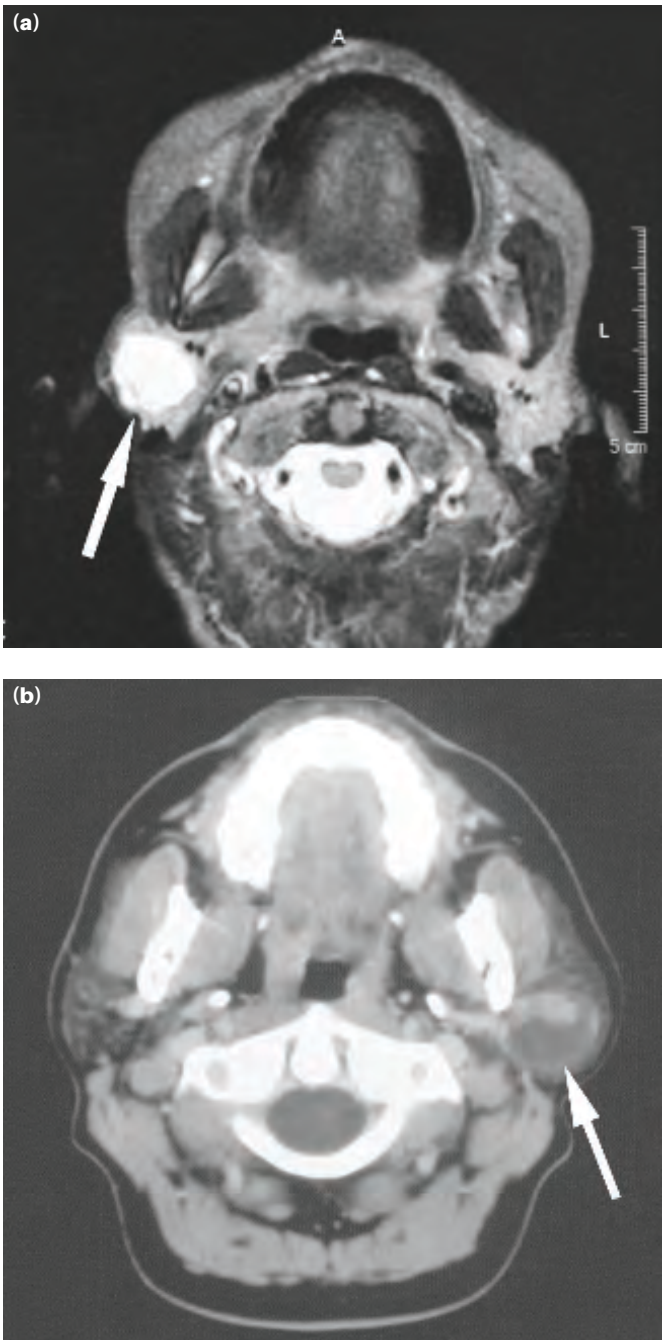

Figure 49.23 **(a)** Magnetic resonance imaging scan revealing a space-occupying lesion (arrow) in the right parotid gland; histology revealed pleomorphic adenoma. **(b)** Computed tomography scan of the left parotid gland revealing a cystic lesion (arrow). Histology revealed acinic cell carcinoma.

out and three points identified along its length to facilitate closure. Infiltration with local anaesthetic and adrenaline is optional, but does aid in the development of the skin flap, improves visibility and reduces blood loss in the initial phase. The skin flap is developed in an anterior direction by either scalpel or scissors dissection. The plane of dissection is well below the hair follicles, just above the parotid fascia. The skin flap is developed forwards to the anterior border of the gland. Posterior undermining of the incision in the cervical region facilitates access to the anterior border of the sternomastoid muscle.

MOBILISATION OF THE GLAND

This phase of the dissection aims to free the posterior margin of the gland, allowing identification of the facial nerve. Clips are applied along the fascia overlying the sternomastoid muscle, with the assistant applying traction anteriorly. By sharp dissection along the anterior border of the sternomastoid, an avascular plane is developed (**Figure 49.24b**), which requires elective transection of the great auricular nerve. At the lower end of the dissection, the external jugular vein is often encountered and ligated. The gland is gradually mobilised by sharp dissection up to and on to the anterior aspect of the mastoid process, identifying the posterior belly of the digastric muscle.

A second avascular plane is developed along the anterior border of the cartilaginous and bony external auditory meatus immediately anterior to the tragus. The two avascular planes are then connected by blunt and sharp dissection. By developing two broad avascular planes, identification of the facial nerve trunk is facilitated (**Figure 49.24c**). It is best achieved by scissors dissection in the line of the facial nerve trunk. Interoperative use of a facial nerve stimulator is recommended.

LOCATION OF THE FACIAL NERVE TRUNK

The main methods of facial nerve trunk localisation can be divided into antegrade and retrograde. The former utilises anatomical landmarks to identify the nerve trunk after its exit from the stylomastoid foramen, which is then traced distally. Landmarks commonly used are:

1. the inferior portion of the cartilaginous canal. This is termed Conley's pointer (tragal pointer) and indicates the position of the facial nerve, which lies 1 cm deep and inferior to its tip;
2. the upper border of the posterior belly of the digastric muscle. Identification of this muscle not only helps to mobilise the parotid gland, but also exposes an area immediately superior, in which the facial nerve is usually located;
3. the squamotympanic fissure;
4. the styloid process (the nerve is superficial to it);
5. the mastoid process can be drilled and the nerve identified more proximally.

Retrograde techniques rely on the identification of one of the nerve main branches (buccal in relation to the parotid duct, marginal mandibular in relation to the facial vessels, temporal branch), which is then traced proximally until the main trunk is identified. These techniques can be useful in revision cases where the anatomy is altered or postradiotherapy when significant fibrosis distorts the planes of dissection.

John J Conley, 1912–1999, otolaryngologist, St. Vincent's Hospital and Medical Center, USA, made important contributions in the treatment of head and neck cancer.

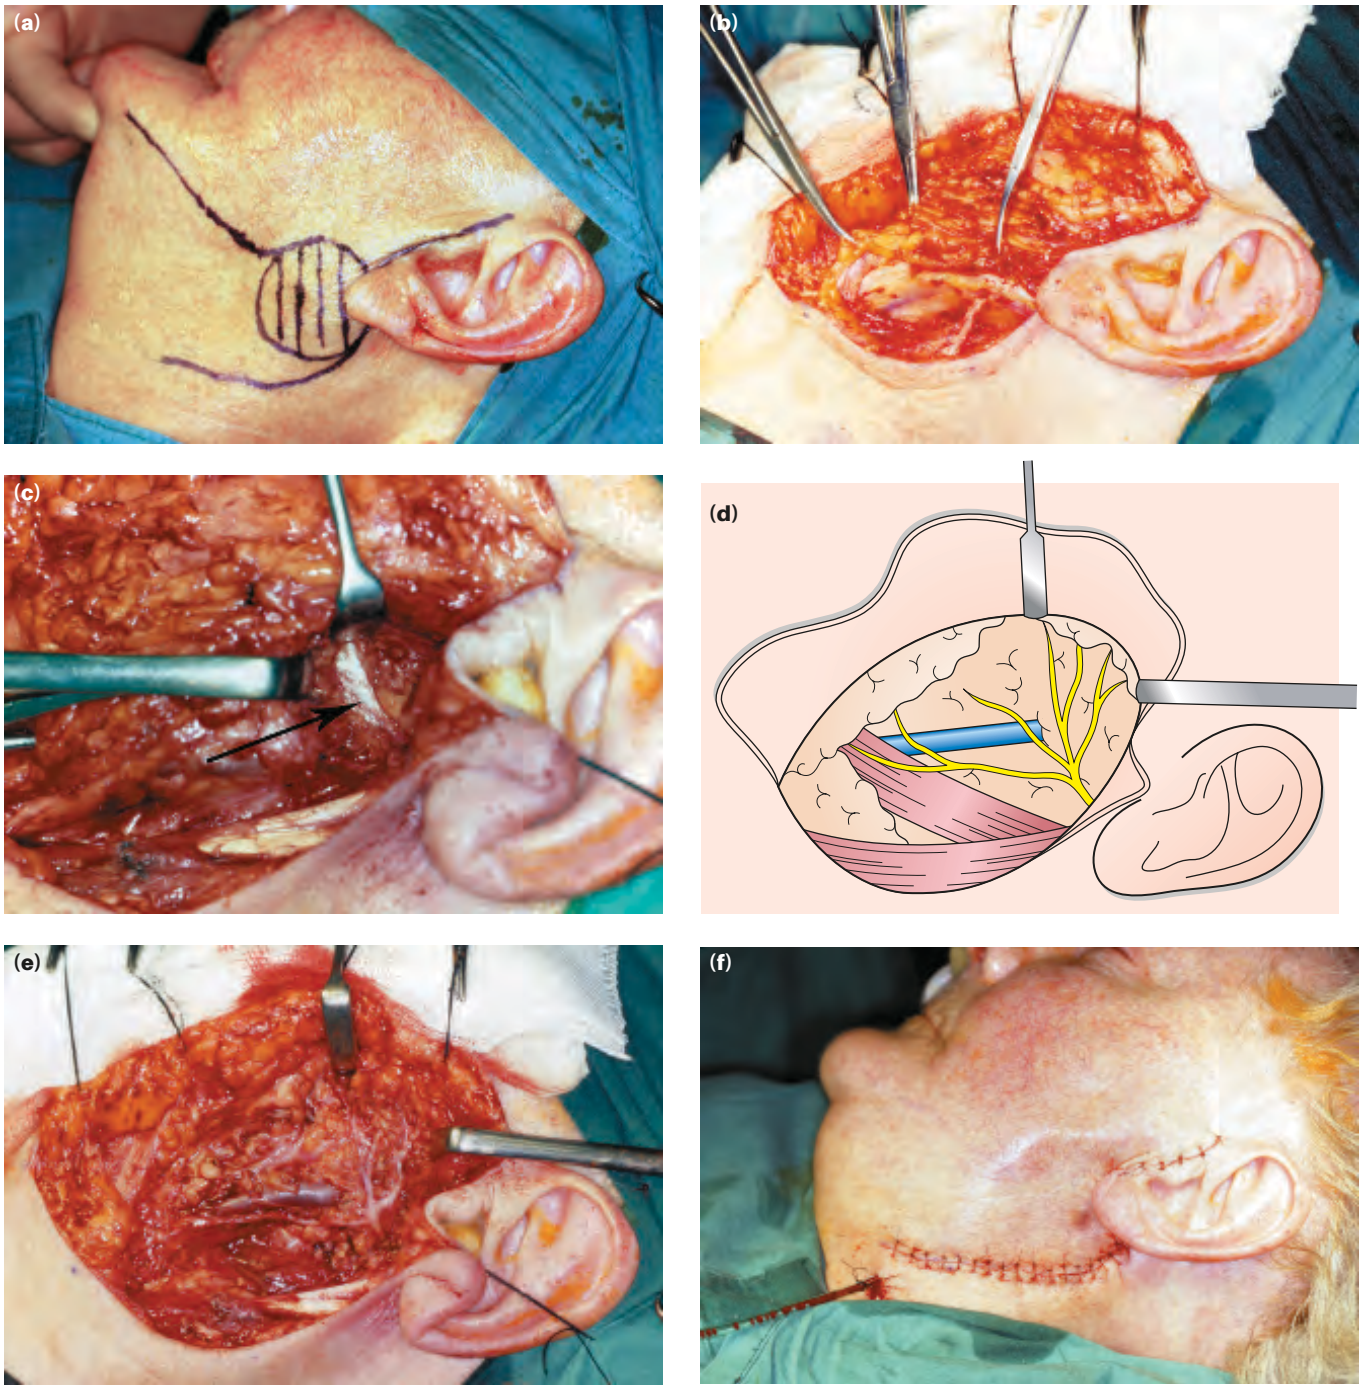

Figure 49.24 **(a)** Landmarks and cervical–mastoid preauricular incision for superficial parotidectomy. **(b)** Development of the avascular plane along the anterior border of the sternomastoid prior to sacrifice of the great auricular nerve. **(c)** Identification of the trunk of the facial nerve (arrow). **(d)** Diagram highlighting the anatomical landmarks of the parotid bed. **(e)** Branches of the facial nerve and retromandibular vein following delivery of the tumour. **(f)** Wound closure with a vacuum drain.

Once the facial nerve trunk has been identified, gentle traction anteriorly facilitates further mobilisation. Control of haemorrhage at this stage is vital as bleeding, no matter how minor, significantly impedes visibility for the surgeon. Haemostasis can be achieved with bipolar diathermy, although caution is necessary, particularly as the facial nerve is approached. Damage to the stylomastoid artery, which lies immediately lateral to the nerve, can result in troublesome bleeding immediately prior to identification. Pledget swabs soaked in adrenaline are sometimes helpful in reducing the ooze associated with this phase of the dissection.

DISSECTION OF THE GLAND OFF THE FACIAL NERVE

Once the facial nerve trunk is identified, further exposure of the branch of the facial nerve can be achieved by scissors dissection in the perineural plane immediately above the nerve.

The tunnel thus created is then laid open, and divisions and branches of the facial nerve are followed to the periphery in a sequential manner, usually beginning with the upper division. The upper division divides into a temporal and a zygomatic branch, and the lower division into mandibular and cervical branches. In this way, the superficial lobe and its associated tumour are mobilised in a superior to inferior direction (**Figures 49.24d, e**). The upper division of the nerve is frequently tortuous in its course and it can be damaged unless great care is taken during perineural dissection. It is often not necessary to dissect all branches of the facial nerve completely, as adequate tumour clearance can be achieved with a more conservative resection of the superficial lobe. When a branch of the facial nerve is adherent to the tumour or running through the tumour, it may require elective division. With the exception of the buccal branch, the transected nerve should be repaired immediately with a cable graft, harvested from the great auricular nerve.

CLOSURE

The patient is placed into a Trendelenburg position to identify any residual bleeding vessels. A suction drain is applied for a period of 24–48 hours and the wound closed in layers (**Figure 49.24f**).

Extracapsular dissection

Extracapsular dissection is an oncologically sound technique for benign parotid gland tumours. The recurrent rates of pleomorphic adenomas excision with extracapsular dissection compare favourably with traditional superficial parotidectomies (extracapsular dissection 1.3–1.5% vs superficial parotidectomy 2–2.4%) and complication rates are less (temporary facial nerve palsy 7% vs 25%: Frey's syndrome 0 vs 60%)

A preauricular incision is made, the length and position of which is adapted to the size and site of the tumour (**Figure 49.25a**). The dissection proceeds in the plane just immediately above the 'shining' parotid fascia (the SMAS or superficial muscular aponeurotic system layer) and continues in continuity with the platysma muscle. The skin flap should extend past the lump for at least 1 cm (**Figure 49.25b**).

The circumference of the tumour is marked with ink and a cruciate incision marked over the surface. The legs of the cruciate incision should extend 1 cm past the edge of the tumour. This is an essential part of the technique. Four small artery clips are then placed where the two lines bisect. The artery clips are used to tent up the parotid fascia, which is then divided along the cruciate lines (**Figure 49.25c**). Small rounded end scissors are then used to commence a dissection through the parotid gland. The dissection advances in a blunt fashion and only when the scissors blades are visible through the fascia may the tissue bridge be divided.

As the dissection proceeds around the tumour, the presence of a facial nerve is easy to discern (**Figures 49.25d, e**). It is prudent to use continuous facial monitoring during the operation, which helps alert the surgeon to the presence of a facial nerve. It is not difficult to recognise a branch of the nerve as long as the basic principle is adhered to that no parotid parenchyma is diathermised or cut unless one can see through the tissues. The key to the extracapsular dissection technique is to place traction on the artery clips, which pulls the parotid tissue away from the lump and normally reveals a plane through which the surgeon can work 2–3 mm away from the tumour. When a branch of the facial nerve is observed, it is not necessarily dissected unless in close vicinity to the tumour capsule. Retractors can be used on the normal parotid gland to improve exposure of the tumour, but direct pressure on the tumour should be avoided to minimise the risk of rupture. The tumour is removed (**Figure 49.25f**), leaving a parted but essentially intact parotid gland (**Figure 49.25g**). Depending on the depth of the tumour, a suction drain can be used at the surgeon's discretion.

The cruciate incision is re-approximated (**Figure 49.25h**) and the skin incision closed. It is advised that a mastoid-type pressure dressing is always applied at the end of the procedure otherwise sialoceles can occur. The pressure dressing is kept for about 48 hours.

Radical parotidectomy

Radical parotidectomy is performed for patients in whom there is clear histological evidence of a high-grade malignant tumour (e.g. squamous cell carcinoma) with invasion of facial nerve. Low-grade and low stage malignant tumours can usually be managed by standard superficial parotidectomy. Radical parotidectomy involves removal of all parotid gland tissue and elective division of the facial nerve, usually through the main trunk (**Figure 49.26**). The surgery inevitably removes the ipsilateral masseter muscle and may also require simultaneous neck dissection, particularly where there is clinical, radiological and cytological evidence of lymph node metastases in the ipsilateral neck. When indicated, facial nerve can be repaired using cable grafts (interpositional greater auricular or sural nerve grafts).

COMPLICATIONS OF PAROTID GLAND SURGERY

Complications of parotid gland surgery include:

- haematoma formation;
- infection;
- deformity: unsightly scar and retromandibular hollowing;
- temporary facial nerve weakness;
- transection of the facial nerve and permanent facial weakness;
- sialocele;
- facial numbness;
- permanent numbness of the ear lobe associated with great auricular nerve transection;
- Frey's syndrome.

Friedrich Trendelenburg, 1844–1924, successively Professor of Surgery at Rostock (1875–1882), Bonn (1822–1895) and Leipzig, (1895–1911), Germany. The Trendelenburg Position was first described in 1885.
Lucie Frey, 1896–1944, physician, The Neurological Clinic, Warsaw, Poland.

Frey's syndrome

Frey's syndrome (gustatory sweating) is now considered an inevitable consequence of parotidectomy unless preventive measures are taken (see below). It results from damage to the autonomic innervation of the salivary gland with inappropriate regeneration of the postganglionic parasympathetic nerve fibres of the auriculotemporal nerve that aberrantly stimulate the sweat glands of the overlying skin. The clinical features include sweating and erythema (flushing) over the region of surgical excision of the parotid gland as a consequence of autonomic stimulation of salivation by the smellor taste of food. The symptoms are entirely variable and are clinically

demonstrated by a starch iodine test. This involves painting the affected area with iodine, which is allowed to dry before applying dry starch, which turns blue on exposure to iodine in the presence of sweat. Sweating is stimulated by salivary stimulation. The management of Frey's syndrome involves the prevention as well as the management of established symptoms.

PREVENTION

The incidence of Frey's syndrome is minimal when extracapsular dissection is performed as the parotid fascia is primarily repaired and communication between denuded parotid parenchyma and subcutis sealed off.

There are a number of quite invasive techniques described to prevent Frey's syndrome following parotidectomy. These include:

- sternomastoid muscle flap;
- temporalis fascial flap;
- insertion of artificial membranes between the skin and the parotid bed.

All these methods replace the barrier between the skin and the parotid bed to minimise inappropriate regeneration of autonomic nerve fibres.

MANAGEMENT OF ESTABLISHED FREY'S SYNDROME

Methods of managing Frey's syndrome include:

- antiperspirants, usually containing aluminium chloride;
- denervation by tympanic neurectomy;
- the injection of botulinum toxin into the affected skin.

The last is the most effective and can be performed as an out-patient.

Granulomatous sialadenitis

This is a group of rare conditions that affect the salivary glands producing a variety of signs and symptoms, particularly painless swellings of the parotid and/or submandibular glands. Systemic upset is variable. These include the following:

- **Mycobacterial infection.** Tuberculosis and non-tuberculous sialadenitis typically present as a tumour-like swelling of the salivary gland. There is little pain and no fever. Preoperative investigations may be of some help, and the diagnosis is only confirmed when the swelling has been excised by either submandibular gland excision or formal parotidectomy.
- **Sarcoidosis.** Sarcoidosis can affect the salivary tissue and presents with persistent salivary gland swelling that may be associated with xerostomia. Occasionally, the patient will present with a localised tumour-like swelling in one salivary gland, more commonly the parotid – the so called sarcoid pseudotumour. In such circumstances, the diagnosis is only likely to be made following surgical excision for a presumed neoplasm. Heerfordt's syndrome is sarcoidosis that involves parotid swelling, anterior uveitis, facial palsy and fever.
- **Other.** These include cat scratch disease, toxoplasmosis, syphilis, deep mycoses and granulomatosis with polyangiitis (previously Wegener's granulomatosis), allergic sialadenitis and sialadenitis associated with radiotherapy of the head and neck.

Tumour-like lesions

There is a group of pathological conditions that affect the salivary glands and which do not fall into any particular classification or category and are often difficult to diagnose. These include such conditions as sialadenosis, adenomatoid hyperplasia and multifocal monomorphic adenomatosis.

SIALADENOSIS

Sialadenosis (sialosis) is used to describe non-inflammatory swelling particularly affecting the parotid gland. It usually occurs in association with a variety of conditions including diabetes mellitus, alcoholism, other endocrine diseases, pregnancy, drugs, bulimia and other eating disorders, and idiopathic diseases.

Most patients present between 40 and 70 years of age, and the salivary swellings are soft and often symmetrical (**Figure 49.27**). When the parotid glands are affected, patients may complain of a hamster-like appearance. Drug-induced sialosis

Figure 49.27 Sialosis of the parotid glands secondary to excess alcohol intake.

Christian Frederick Heerfordt, 1871–1953, Danish ophthalmologist, described this syndrome in 1909.
Friedrich Wegener, 1907–1990, Professor of Pathology, Lübeck, Germany, described this form of granulomatosis in 1939.

is particularly common with sympathomimetic drugs. In many patients, no underlying disorder can be identified. Severe and prolonged malnutrition, as seen in eating disorders, produces sialadenosis by a process of hypertrophy to compensate for swings in acid balance. The pathological mechanism of sialadenosis can be associated with a process of neuropathy, which interferes with salivary gland function and subsequent acinar cell atrophy. This may be the case in diabetes mellitus, where autonomic neuropathy is a recognised complication as well as drug-induced sialosis.

The treatment of sialosis is unsatisfactory, but treatment is aimed at correction of the underlying disorder. Drug-associated sialadenosis may regress when the drug responsible is withdrawn.

Degenerative conditions

Sjögren's syndrome

Sjögren's syndrome is an autoimmune condition causing progressive destruction of salivary and lacrimal glands. Primary Sjögren's syndrome differs from secondary Sjögren's syndrome in that xerostomia and keratoconjunctivitis sicca occur without an associated connective tissue disorder or other autoimmune condition (rhematoid arthritis, systemic lupous erythematosus, scleroderma, polymyositis, thyroiditis). However, the symptoms are often more severe, and the incidence of lymphomatous transformation (see below) in the primary group is higher than that in the secondary group (*Table 49.3*).

The incidence of Sjogren's syndrome is 0.5–2% of the population. Females are affected more than males in the ratio 10:1. Occasionally, there is enlargement of the salivary glands, more commonly the parotid rather than the submandibular glands. The glands are occasionally painful, and the patient rarely develops a bacterial sialadenitis due to ascending infection from the associated xerostomia.

The characteristic pathological feature of Sjögren's syndrome is progressive lymphocytic infiltration, acinar cell destruction and proliferation of duct epithelium in all salivary and lacrimal gland tissue. The diagnosis is based on the history as no single laboratory investigation is pathognomonic of either primary or secondary Sjögren's syndrome (**Figure 49.28**).

TABLE 49.3 Degenerative disorders.

Primary Sjögren's syndrome	More severe xerostomia
	Widespread exocrine gland dysfunction
	No connective tissue disorder
Secondary Sjögren's syndrome	M:F: 1:10
	Middle age
	Underlying connective tissue disorder
Benign lymphoepithelial lesion	20% develop lymphoma
	Diffuse parotid swelling 20% bilateral

Figure 49.28 Clinical appearance of primary biliary cirrhosis associated with Sjögren's syndrome.

MANAGEMENT

Management of Sjögren's syndrome remains symptomatic. No known treatment modifies or improves the xerostomia or keratoconjunctivitis sicca. An ophthalmological assessment is important, and artificial tears are essential to preserve corneal function. For dry mouth, various artificial salivary substitutes are available, but patients often consume large volumes of water, carrying a bottle of water with them at all times. In the dentate patient, the use of salivary substitutes with fluoride is important to counter the risk of accelerating dental caries. Other oral complications include oral candidosis and accelerated periodontal disease.

COMPLICATIONS OF SJÖGREN'S SYNDROME

There is an increased incidence of developing lymphoma (most commonly non-Hodgkin's B-cell lymphoma) in patients with Sjögren's syndrome. The risk is highest within the primary group, and the onset of lymphoma is heralded by immunological change within the blood. The incidence of lymphoma in patients with Sjogren's syndrome is 4.3% (18.9 times higher than in the general population). Enlarged and painful parotid glands raise the prospect of MALT (mucosa associated lymphoid tissue) lymphoma.

Xerostomia

Xerostomia is a common symptom in many aspects of medical practice. Normal salivary flows decrease with age in both men and women, although many patients with xerostomia are postmenopausal women who also complain of a burning tongue or mouth. Common causes of xerostomia are:

1 chronic anxiety states and depression;
2 dehydration;

3 anticholinergic drugs, especially antidepressants;
4 salivary gland disorders – Sjögren's syndrome. Ascending parotitis is an occasional complication of xerostomia and is managed with antibiotics and increased fluid intake;
5 radiotherapy to the head and neck.

Sialorrhoea

Certain drugs and oral infection produce a transient increase in salivary flow rates. In healthy individuals, excess salivation is rarely symptomatic as excess saliva is swallowed spontaneously. Uncontrolled drooling is usually seen in the presence of normal salivary production in children with mental and physical handicap, most notably cerebral palsy.

MANAGEMENT

Sialorrhoea can be managed medically with antisialogogues or with intraparenchymal botulinum toxin injection.

Uncontrollable drooling is managed surgically, and many operations are available. Surgical options include:

- bilateral submandibular duct repositioning and simultaneous sublingual gland excision;
- bilateral submandibular gland excision;
- transposition of the parotid ducts and simultaneous submandibular gland excision.

Most resting salivary gland flow arises from the submandibular glands, and surgery should be focused on this gland to control uncontrolled sialorrhoea.

Breast and endocrine

Chapter 50

The thyroid gland

Learning objectives

- To understand the development and anatomy of the thyroid gland
- To know the physiology and investigation of thyroid function
- To be able to select appropriate investigations for thyroid swellings
- To know when to operate on a thyroid swelling
- To describe thyroidectomy
- To know the risks and complications of thyroid surgery

EMBRYOLOGY

The embryology of the thyroid and parathyroid glands underlies the anatomical position, anatomical variations and congenital conditions of these structures and is therefore vital for surgery (**Figure 50.1**). The thyroglossal duct develops from the median bud of the pharynx. The foramen caecum at the junction of the anterior two-thirds and posterior one-third of the tongue is the vestigial remnant of the duct. This initially hollow structure migrates caudally and passes in close continuity with, and sometimes through, the developing hyoid cartilage. The parathyroid glands develop from the third and fourth pharyngeal pouches. The thymus also develops from the third pouch. As it descends, the thymus takes the associated parathyroid gland with it, which explains why the inferior parathyroid, which arises from the third pharyngeal pouch, normally lies inferior to the superior gland. However, the inferior parathyroid may be found anywhere along this line of descent (see also Chapter 51). The developing thyroid lobes amalgamate with the structures that arise in the fourth pharyngeal pouch, i.e. the superior parathyroid gland and the ultimobranchial body. Parafollicular cells (C cells) from the neural crest reach the thyroid via the ultimobranchial body.

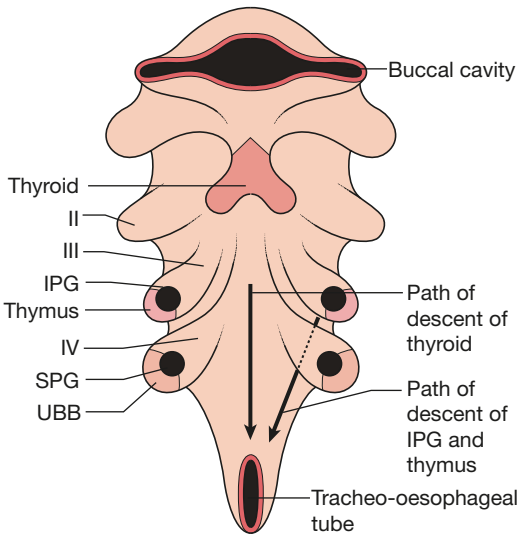

Figure 50.1 Embryology of thyroid and parathyroid. Diagram of an anterior view of the pharynx in a 4-week embryo showing the relationship of the third and fourth pharyngeal pouches to final position of the thyroid and parathyroid glands. IPG, inferior parathyroid; SPG, superior parathyroid; UBB, ultimobranchial body.

SURGICAL ANATOMY

The normal thyroid gland weighs 20–25 g. The functioning unit is the lobule supplied by a single arteriole and consists of 24–40 follicles lined with cuboidal epithelium. The follicle contains colloid in which thyroglobulin is stored (**Figure 50.2**). The arterial supply is rich, and extensive anastomoses occur between the main thyroid arteries and branches of the tracheal and oesophageal arteries (**Figure 50.3**). There is an extensive lymphatic network within and around the gland. Although some lymph channels pass directly to the deep cervical nodes, the subcapsular plexus drains principally to the central compartment juxtathyroid – 'Delphian' and paratracheal nodes

Delphi, a sacred site near the Gulf of Corinth in Greece, is the place where Phythia, the snake-woman oracle, resided. She sat on a tripod clutching the ribbons of the monolithic 'omphalos' of the world and after inhaling sulphurous fumes, would utter meaningless jargon which was interpreted equivocally by the attendent priests for those who came to consult her. Formerly the purpose of these lymph nodes was uncertain, and they were therefore called 'Delphic'.

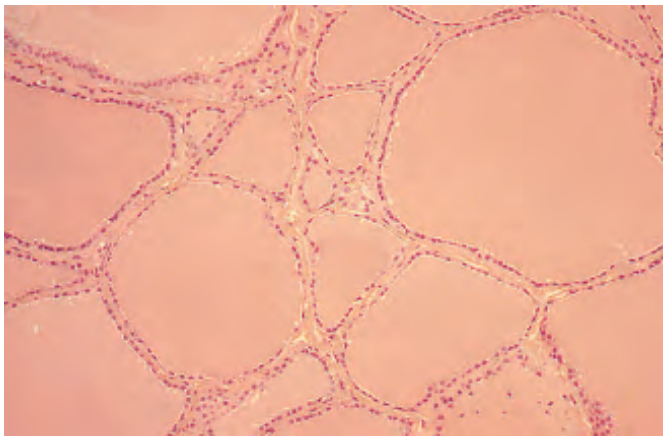

Figure 50.2 Histology of the normal thyroid.

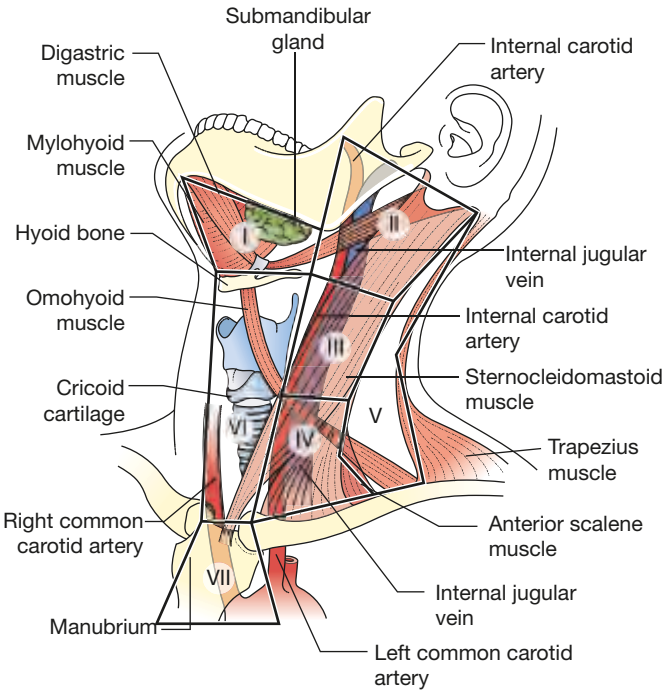

Figure 50.4 Cervical lymph node levels.

and nodes on the superior and inferior thyroid veins (level VI), and from there to the deep cervical (levels II, III, IV and V) and mediastinal groups of nodes (level VII) (Figure 50.4).

The relationship between the recurrent laryngeal nerve (RLN) and the thyroid is of supreme importance to the operating surgeon. A branch of the vagus, the nerve recurs round the arch of the aorta on the left and the subclavian artery on the right. The clinical significance of this is that on the left the nerve has more distance in which to reach the tracheoesophageal groove and therefore runs in a medial plane. On the right, there is less distance and the nerve runs more obliquely to reach the tracheoesophageal groove. Approximately 2% of nerves on the right are non-recurrent and will enter the larynx from above.

The nerve runs posterior to the thyroid and enters the larynx at the cricothyroid joint. This entry point is at

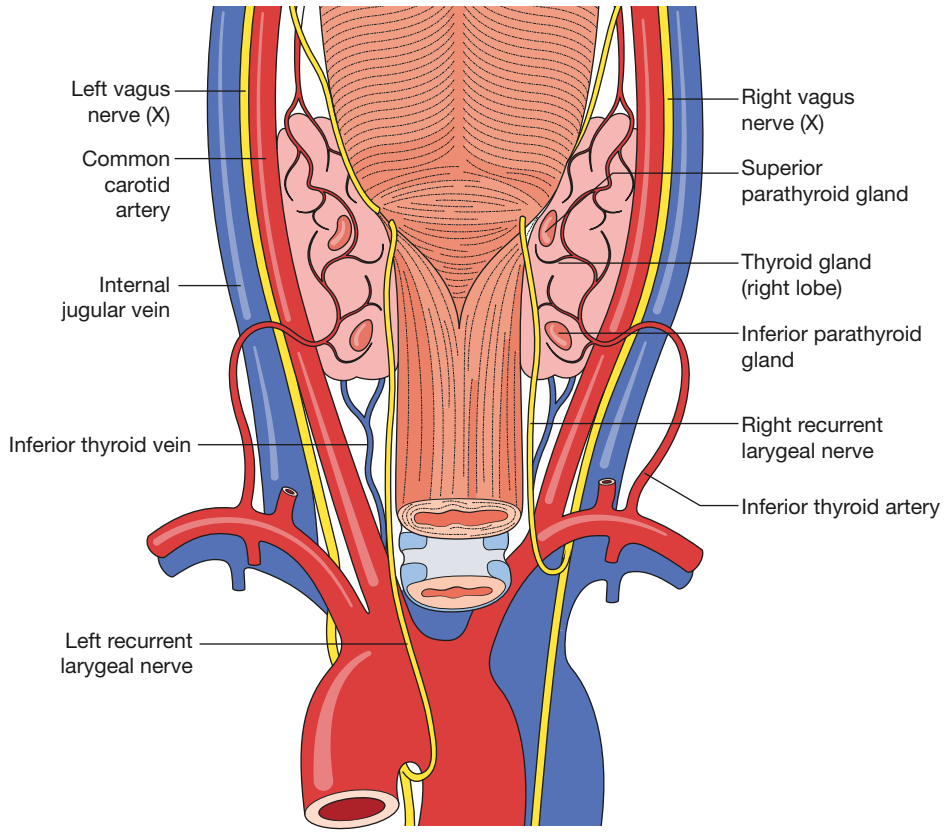

Figure 50.3 The thyroid gland from behind.

the level of Berry's ligament, a condensation of pretracheal fascia that binds the thyroid to the trachea. This is the point at which the nerve is at most risk of injury during surgery. In terms of surgical anatomy, the nerve can be located in the tracheosophageal groove where it forms one side of Beahrs' triangle (the other two sides are the carotid artery and the inferior thyroid artery) or at the cricothyroid joint. The nerve will normally be found as the thyroid lobe is mobilised laterally, lying under the most posterolateral portion of the gland called the tubercle of Zuckerkandl.

PHYSIOLOGY

Thyroxine

The hormones tri-iodothyronine (T_3) and l-thyroxine (T_4) are bound to thyroglobulin within the colloid. Synthesis within the thyroglobulin complex is controlled by several enzymes, in distinct steps:

- trapping of inorganic iodide from the blood;
- oxidation of iodide to iodine;
- binding of iodine with tyrosine to form iodotyrosine;
- coupling of monoiodotyrosines and di-iodotyrosines to form T_3 and T_4.

When hormones are required, the complex is resorbed into the cell and thyroglobulin is broken down. T_3 and T_4 are liberated and enter the blood, where they are bound to serum proteins: albumin, thyroxine-binding globulin (TBG) and thyroxine-binding prealbumin (TBPA). The small amount of hormone that remains free in the serum is biologically active.

The metabolic effects of the thyroid hormones are due to unbound free T_4 and T_3 (0.03% and 0.3% of the total circulating hormones, respectively). T_3 is the more important physiological hormone and is also produced in the periphery by conversion from T_4. T_3 is quick acting (within a few hours), whereas T_4 acts more slowly (4–14 days).

Calcitonin

The parafollicular C cells of the thyroid are of neuroendocrine origin and arrive in the thyroid via the ultimobranchial body (**Figure 50.1**). They produce calcitonin.

The pituitary–thyroid axis

Synthesis and release of thyroid hormones from the thyroid is controlled by thyroid-stimulating hormone (TSH) from the anterior pituitary. Secretion of TSH depends upon the level of circulating thyroid hormones and is modified in a negative feedback manner. In hyperthyroidism TSH production is suppressed, whereas in hypothyroidism it is stimulated. Regulation of TSH secretion also results from the action of thyrotrophin-releasing hormone (TRH) produced in the hypothalamus.

Thyroid-stimulating antibodies

A family of IgG immunoglobulins bind with TSH receptor sites (TRAbs) and activate TSH receptors on the follicular cell membrane. They have a more protracted action than TSH (16–24 versus 1.5–3 hours) and are responsible for virtually all cases of thyrotoxicosis not due to autonomous toxic nodules. Serum concentrations are very low but their measurement is not essential to make the diagnosis.

Serum thyroid hormones

Serum TSH

TSH levels can be measured accurately down to very low serum concentrations with an immunochemiluminometric assay. Interpretation of deranged TSH levels depends on knowledge of the T_3 and T_4 values. In the euthyroid state, T_3, T_4 and TSH levels will all be within the normal range. Florid thyroid failure results in depressed T_3 and T_4 levels, with gross elevation of TSH. Incipient or developing thyroid failure is characterised by low normal values of T_3 and T_4 and elevation of TSH. In toxic states, the TSH level is suppressed and undetectable (*Table 50.1*). T_3 toxicity (with a normal T_4) is a distinct entity and may only be diagnosed by measuring T_3, although a suppressed TSH in the presence of normal T_4 suggests the diagnosis.

Thyroid autoantibodies

Serum levels of antibodies against thyroid peroxidase (TPO) and thyroglobulin are useful in determining the cause of thyroid dysfunction and swellings. Autoimmune

TABLE 50.1 Results of thyroid function tests in normal and pathological states.

Thyroid functional state	TSH (0.3–3.3 mU/L)	Free T4 (10–30 nmol/L)	Free T3 (3.5–7.5 µmol/L)
Euthyroid	Normal	Normal	Normal
Thyrotoxic	Undetectable	High	High
Myxoedema	High	Low	Low
Suppressive T_4 therapy	Undetectable	High	High (often normal)
T_3 toxicity	Low/undetectable	Normal	High

Sir James Berry, 1860–1946, surgeon, Royal Free Hospital, London, UK.
Oliver H Beahrs, 1914–2006, surgeon, Mayo Clinic, MN, USA.
Emil Zuckerkandl, 1849–1901, Austro-Hungarian anatomist, brother of urologist Otto Zuckerkandl.
Myxoedema was first described in 1873 by Sir William Withey Gull, 1816–1890, physician, Guy's Hospital, London, UK.

thyroiditis may be associated with thyroid toxicity, failure or euthyroid goitre. Levels above 25 units/mL for TPO antibody and titres of greater than 1:100 for antithyroglobulin are considered significant, although a proportion of patients with histological evidence of lymphocytic (autoimmune) thyroiditis are seronegative. The presence of antithyroglobulin antibody interferes with assays of serum thyroglobulin, with implications for follow-up of thyroid cancers. TSH receptor antibodies (TSH-Rab or TRAB) are often present in Graves' disease. They are largely produced within the thyroid itself.

Summary box 50.1

Thyroid investigations

Essential

- Serum: TSH (T3 and T4 if abnormal); thyroid autoantibodies
- FNAC of palpable discrete swellings; ultrasound guidance may reduce the 'Thy1' rate

Optional

- Corrected serum calcium
- Serum calcitonin (carcinoembryonic antigen may be used as an alternative screening test for medullary cancer)
- Imaging: chest radiograph and thoracic inlet if tracheal deviation/retrosternal goitre; ultrasound, CT and MRI scan for known cancer, some reoperations and some retrosternal goitres; isotope scan if discrete swelling and toxicity coexist

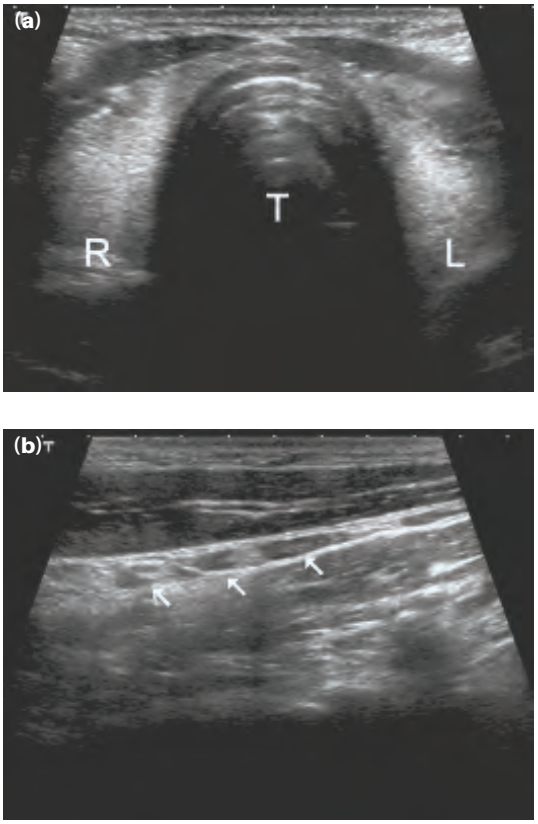

Figure 50.5 Ultrasound scanning. **(a)** Transverse scan of normal thyroid. R, right lobe; L, left lobe; T, trachea. **(b)** Longitudinal scan of normal jugular lymph nodes (white arrows).

Thyroid imaging

The workhorse investigation in thyroid disease for the surgeon is ultrasound. This modality allows assessment of the gland and the regional lymphatics. Not only can the characteristics of the gland substance be quantified, but critically the presence and features of thyroid nodules can be described. Number, size, shape, margins, vascularity and specific features such as the presence of microcalcifications can be used to predict the risk of malignancy within a specific nodule. Regional lymphatics, particularly in the lateral neck can be assessed accurately for the presence of metastatic deposits. During ultrasound, fine needle aspiration (FNA) can be performed more accurately than free-hand techniques allow.

Ultrasound has the advantages that it is not associated with ionising radiation and is non-invasive and cheap (**Figure 50.5**). Visualisation of the central neck nodes, in particular those behind the sternum, is however limited. For this reason, when metastatic disease is detected cross-sectional imaging is required to fully stage the disease. Retrosternal extension, which can often be predicted on plain chest x-ray (**Figure 50.6**), also requires more advanced techniques to determine the extent adequately prior to considering management. For most of these indications, the imaging modality of choice is computed tomography (CT). Rapid acquisition times minimise the artifact secondary to breathing and the lung fields can be accurately assessed simultaneously.

In the setting of an invasive primary thyroid cancer, both CT and magnetic resonance imaging (MRI) may have a role. Contrast enhanced CT is useful for determining the extent of airway invasion (**Figure 50.7**) and MRI is superior at determining the presence of prevertebral fascia invasion.

Positron emission tomography (PET) scans have limited application in thyroid disease. They may be considered in the setting of recurrent thyroid cancer. This is particularly useful when the disease does not concentrate iodine, at which point fluorodeoxyglucose (FDG) uptake increases and lesions become positive on PET scans.

Isotope scanning

The uptake by the thyroid of a low dose of either radiolabelled iodine (^{123}I) or the cheaper technetium (^{99m}Tc) will demonstrate the distribution of activity in the whole gland. Routine isotope scanning is unnecessary and inappropriate for distinguishing benign from malignant lesions because the majority (80%) of 'cold' swellings are benign and some (5%) functioning or 'warm' swellings will be malignant. Its principal value is in the toxic patient with a nodule or nodularity of the thyroid. Localisation of overactivity in the gland will differentiate between a toxic nodule with suppression of the remainder of the gland, and toxic multinodular goitre with several areas of increased uptake with important implications for therapy **(Figure 50.8)**.

Whole-body scanning is used to demonstrate metastases. However, the patient must have all normally functioning thyroid tissue ablated either by surgery or radioiodine before the scan is performed, because metastatic thyroid cancer tissue cannot compete with normal thyroid tissue in the uptake of iodine.

Fine-needle aspiration cytology

Fine-needle aspiration cytology (FNAC) is the investigation of choice in discrete thyroid swellings. FNAC has excellent patient compliance, is simple and quick to perform in the out-patient department and is readily repeated. This technique, developed in Scandinavia 40 years ago, is now routine throughout the world. FNAC results should be reported using standard terminology *(Table 50.2)*. As stated above there is a trend to

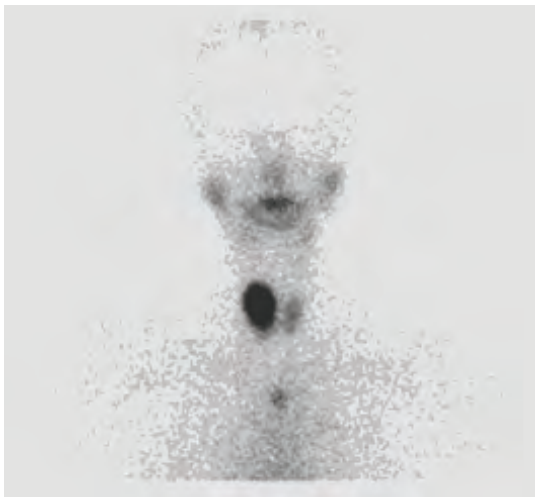

Figure 50.8 Technetium thyroid scan showing appearance of a 1-cm 'toxic' adenoma in the right thyroid lobe with suppression of uptake in the left lobe. The intense uptake gives a false impression of the size of the swelling.

TABLE 50.2 Classification of fine-needle aspiration cytology reports.

Thy5	Malignant

use ultrasound to guide the needle to achieve more accurate sampling and reduce the rate of unsatisfactory aspirates.

THYROID ENLARGEMENT

The normal thyroid gland is impalpable. The term goitre (from the Latin guttur = the throat) is used to describe generalised enlargement of the thyroid gland. A discrete swelling (nodule) in one lobe with no palpable abnormality elsewhere is termed an isolated (or solitary) swelling. Discrete swellings with evidence of abnormality elsewhere in the gland are termed dominant.

A scheme for classifying thyroid enlargement is given in *Table 50.3*.

TABLE 50.3 Classification of thyroid swellings.

Simple goitre (euthyroid)	Diffuse hyperplastic	Physiological Pubertal Pregnancy
	Multinodular goitre	
Toxic	Diffuse (Graves' disease)	
	Multinodular	
	Toxic adenoma	
Neoplastic	Benign

Thyroid swellings

- Know how to describe thyroid swellings
- Use appropriate investigations
- Know the indications for surgery
- Select the appropriate procedure
- Describe and manage postoperative complications

Simple goitre

Aetiology

Simple goitre may develop as a result of stimulation of the thyroid gland by TSH, either as a result of inappropriate secretion from a microadenoma in the anterior pituitary (which is rare), or in response to a chronically low level of circulating thyroid hormones. The most important factor in endemic goitre is dietary deficiency of iodine (see below), but defective hormone synthesis probably accounts for many sporadic goitres (see below).

TSH is not the only stimulus to thyroid follicular cell proliferation and other growth factors, including immunoglobulins, exert an influence. The heterogeneous structural and functional response in the thyroid resulting in characteristic nodularity may be due to the presence of clones of cells particularly sensitive to growth stimulation.

IODINE DEFICIENCY

The daily requirement of iodine is about 0.1–0.15mg. In nearly all districts where simple goitre is endemic, there is a very low iodide content in the water and food. Endemic areas are in the mountainous ranges, such as the Rocky Mountains, the Alps, the Andes and the Himalayas and in the UK areas of Derbyshire and Yorkshire. Endemic goitre is also found in lowland areas where the soil lacks iodide or the water supply comes from far away mountain ranges, e.g. the Great Lakes of North America, the plains of Lombardy, the Struma valley, the Nile valley and the Congo. Calcium is also goitrogenic and goitre is common in low-iodine areas on chalk or limestone, for example Derbyshire and Southern Ireland. Although iodides in food and water may be adequate, failure of intestinal absorption may produce iodine deficiency.

DYSHORMONOGENESIS

Enzyme deficiencies of varying severity may be responsible for many sporadic goitres, i.e. in non-endemic areas (**Figure 50.9**). There is often a family history, suggesting a genetic defect. Environmental factors may compensate in areas of high iodine intake; for example, goitre is almost unknown in Iceland where the fish diet is rich in iodine. Similarly, a low intake of iodine encourages goitre formation in those with a metabolic predisposition.

Hakaru Hashimoto, 1881–1934, Director of The Hashimoto Hospital, Mie, Japan, described chronic lymphocytic thyroiditis in 1912. The link to an autoimmune basis was defined by Roitt and his co-workers.

Struma. The River Struma arises in the mountains of Bulgaria and flows into the Aegean Sea. Along its banks and those of its tributaries dwell peoples of several nationalities among whom endemic goitre has long been prevalent. Struma is a European continental term for goitre.

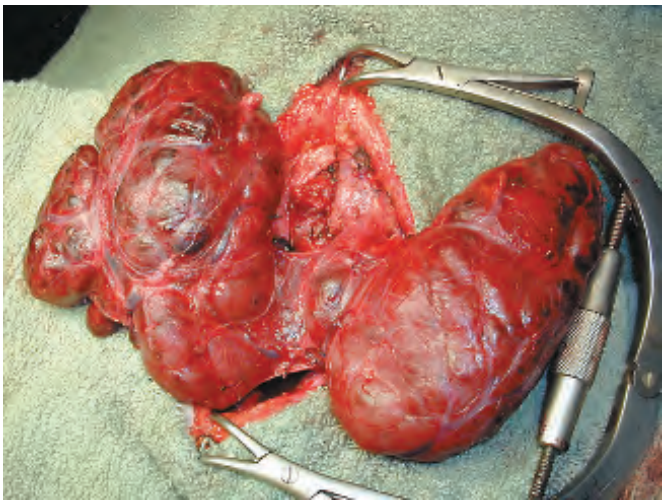

Figure 50.9 Total thyroidectomy for dyshormonogenetic goitre in a 14-year-old girl.

GOITROGENS

Well-known goitrogens are the vegetables of the brassica family (cabbage, kale and rape), which contain thiocyanate, drugs such as para-aminosalicylic acid (PAS) and the antithyroid drugs. Thiocyanates and perchlorates interfere with iodide trapping; carbimazole and thiouracil compounds interfere with the oxidation of iodide and the binding of iodine to tyrosine.

Surprisingly, iodides in large quantities are goitrogenic because they inhibit the organic binding of iodine and produce an iodide goitre. Excessive iodine intake may be associated with an increased incidence of autoimmune thyroid disease.

The natural history of simple goitre

Stages in goitre formation are:

- Persistent growth stimulation causes diffuse hyperplasia; all lobules are composed of active follicles and iodine uptake is uniform. This is a diffuse hyperplastic goitre, which may persist for a long time but is reversible if stimulation ceases.
- Later, as a result of fluctuating stimulation, a mixed pattern develops with areas of active lobules and areas of inactive lobules.
- Active lobules become more vascular and hyperplastic until haemorrhage occurs, causing central necrosis and leaving only a surrounding rind of active follicles.
- Necrotic lobules coalesce to form nodules filled either with iodine-free colloid or a mass of new but inactive follicles.
- Continual repetition of this process results in a nodular goitre. Most nodules are inactive, and active follicles are present only in the internodular tissue.

DIFFUSE HYPERPLASTIC GOITRE

Diffuse hyperplasia corresponds to the first stages of the natural history. The goitre appears in childhood in endemic areas but, in sporadic cases, it usually occurs at puberty when metabolic demands are high. If TSH stimulation ceases the goitre may regress, but tends to recur later at times of stress such as pregnancy. The goitre is soft, diffuse and may become large enough to cause discomfort. A colloid goitre is a late stage of diffuse hyperplasia, when TSH stimulation has fallen off and when many follicles are inactive and full of colloid (**Figure 50.10**).

NODULAR GOITRE

Nodules are usually multiple, forming a multinodular goitre (**Figure 50.11**). Occasionally, only one macroscopic nodule is found, but microscopic changes will be present throughout the gland; this is one form of a clinically solitary nodule. Nodules may be colloid or cellular, and cystic degeneration and haemorrhage are common, as is subsequent calcification. Nodules appear early in endemic goitre and later (between 20 and 30 years) in sporadic goitre, although the patient may be unaware of the goitre until his or her late 40s or 50s. All types of simple goitre are more common in the female than in the male owing to the presence of oestrogen receptors in thyroid tissue.

Figure 50.10 Colloid goitre.

Figure 50.11 Large multinodular goitre.

Diagnosis

Diagnosis is usually straightforward. The patient is euthyroid, the nodules are palpable and often visible; they are smooth, usually firm and not hard and the goitre is painless and moves freely on swallowing. Hardness and irregularity, due to calcification, may simulate carcinoma. A painful nodule, sudden appearance or rapid enlargement of a nodule raises suspicion of carcinoma but is usually due to haemorrhage into a simple nodule. Differential diagnosis from autoimmune thyroiditis may be difficult and the two conditions frequently coexist.

Investigations

Thyroid function should be assessed to exclude mild hyperthyroidism, and the presence of circulating thyroid antibodies tested to differentiate from autoimmune thyroiditis. Ultrasound is the gold standard assessment when undertaken by a suitably trained and experienced operator. FNAC is only required for a nodule within the goitre that demonstrates ultrasonic features of concern. This may or may not be the largest 'dominant' nodule. The biopsy should be performed under ultrasonic guidance to ensure the correct nodule is sampled. If there are swallowing or breathing symptoms then a CT scan of the thoracic inlet is the best modality to assess tracheal or oesophageal compression.

Complications

Tracheal obstruction may be due to gross lateral displacement or compression in a lateral or anteroposterior plane by retrosternal extension of the goitre (**Figure 50.7**). Acute respiratory obstruction may follow haemorrhage into a nodule impacted in the thoracic inlet.

SECONDARY THYROTOXICOSIS

Transient episodes of mild hyperthyroidism are common, occurring in up to 30% of patients.

CARCINOMA

An increased incidence of cancer (usually follicular) has been reported from endemic areas. Dominant or rapidly growing nodules in longstanding goitres should always be subjected to aspiration cytology.

Prevention and treatment of simple goitre

In endemic areas the incidence of goitre has been strikingly reduced by the introduction of iodised salt.

In the early stages, a hyperplastic goitre may regress if thyroxine is given in a dose of 0.15–0.2 mg daily for a few months.

Although the nodular stage of simple goitre is irreversible, more than half of benign nodules will regress in size over 10 years. Most patients with multinodular goitre are asymptomatic and do not require operation. Surgery is indicated for nodular goitres with features of underlying malignancy, for swallowing symptoms if other causes have been excluded or for cosmetic reasons if the patient finds the goitre unsightly. If the goitre is causing tracheal compression then surgery should be considered. Many such patients are found incidentally and are asymptomatic and often very elderly. As these goitres often grow very slowly the risks and benefits of surgery should be considered carefully, particularly if a sternal split may be required for access.

There is a choice of surgical treatment in multinodular goitre: **total thyroidectomy** with immediate and lifelong replacement of thyroxine or some form of partial resection to conserve sufficient functioning thyroid tissue to subserve normal function while reducing the risk of hypoparathyroidism that accompanies total thyroidectomy. **Subtotal thyroidectomy** involves partial resection of each lobe removing the bulk of the gland, leaving up to 8 g of relatively normal tissue in each remnant. The technique is essentially the same as described for toxic goitre, as are the postoperative complications. More often, however, the multinodular change is asymmetrical, with one lobe more significantly involved than the other. In these circumstances, particularly in older patients, **total lobectomy** on the more affected side is the appropriate management with either subtotal resection (Dunhill procedure) or no intervention on the less affected side. In many cases, the causative factors persist and recurrence is likely.

Reoperation for recurrent nodular goitre is more difficult and hazardous and, for this reason, an increasing number of thyroid surgeons favour **total thyroidectomy** in younger patients. However, when the first operation comprised unilateral lobectomy alone for asymmetric goitre, reoperation and completion total thyroidectomy is straightforward if required for progression of nodularity in the remaining lobe. Total lobectomy and total thyroidectomy have the additional advantage of being therapeutic for incidental carcinomas (see below).

After subtotal resection, it has been customary to give thyroxine to suppress TSH secretion, with the aim of preventing recurrence. Whether this is either necessary or effective is uncertain, although the evidence of benefit in endemic areas is better than elsewhere. There is some evidence that radioactive iodine may reduce the size of recurrent nodular goitre after previous subtotal resection and, in some circumstances, this may be a safer alternative than reoperation, particularly if there has been more than one previous thyroid procedure.

Clinically discrete swellings

Discrete thyroid swellings (thyroid nodules) are common and are palpable in 3–4% of the adult population in the UK and USA. They are three to four times more frequent in women than men.

Diagnosis

A discrete swelling in an otherwise impalpable gland is termed **isolated** or **solitary**, whereas the preferred term is **dominant** for a similar swelling in a gland with clinical evidence of generalised abnormality in the form of a palpable contralateral lobe or generalised mild nodularity. About 70% of discrete thyroid swellings are clinically isolated and about 30% are dominant. The true incidence of isolated swellings is

Sir Thomas Peel Dunhill, 1876–1957, surgeon, St Bartholomew's Hospital, London, UK.

somewhat less than the clinical estimate. Clinical classification is inevitably subjective and overestimates the frequency of truly isolated swellings. When such a gland is exposed at operation or examined by ultrasonography, CT or MRI, clinically impalpable nodules are often detected. The true frequency of thyroid nodularity compared with the clinical detection rate by palpation is shown in Figure 50.12.

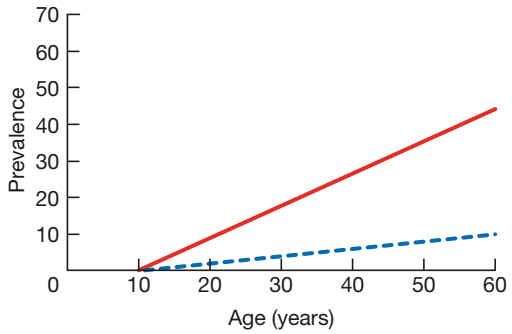

Figure 50.12 The prevalence of thyroid nodules detected on palpation (broken line) or by ultrasonography or postmortem examination (solid line) (after Mazzaferri).

Demonstrating the presence of impalpable nodules does not change the management of palpable discrete swellings and begs the question of the necessity of investigating incidentally found nodules. The importance of discrete swellings lies in the risk of neoplasia compared with other thyroid swellings. Some 15% of isolated swellings prove to be malignant and an additional 30–40% are follicular adenomas. The remainder are non-neoplastic, largely consisting of areas of colloid degeneration, thyroiditis or cysts. Although the incidence of malignancy or follicular adenoma in clinically dominant swellings is approximately half of that of truly isolated swellings, it is substantial and cannot be ignored (Figure 50.13).

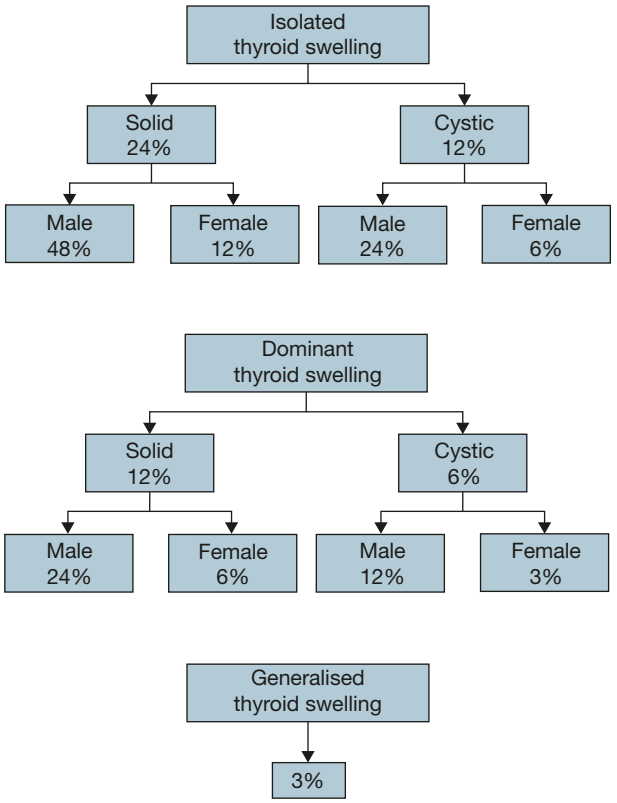

Figure 50.13 The risk of malignancy in thyroid swellings ('rule of twelve'). The risk of cancer in a thyroid swelling can be expressed as a factor of 12. The risk is greater in isolated versus dominant swellings, solid versus cystic swellings and in men versus women.

Investigation

THYROID FUNCTION

Serum TSH and thyroid hormone levels should be measured. If hyperthyroidism associated with a discrete swelling is confirmed biochemically, it indicates either a 'toxic adenoma' or a manifestation of toxic multinodular goitre. The combination of toxicity and nodularity is important and is an indication for isotope scanning to localise the area(s) of hyperfunction.

AUTOANTIBODY TITRES

The autoantibody status may determine whether a swelling is a manifestation of chronic lymphocytic thyroiditis. The presence of circulating antibodies increases the risk of thyroid failure after lobectomy.

ISOTOPE SCAN

Isotope scanning used to be the mainstay of investigation of discrete thyroid swellings but has been abandoned except when toxicity is associated with nodularity.

ULTRASONOGRAPHY

This is gold standard investigation to determine the physical characteristics of thyroid swellings. There are a number of ultrasonic features in a thyroid swelling associated with thyroid neoplasia, including microcalcification and increased vascularity, but only macroscopic capsular breach and nodal involvement are diagnostic of malignancy. Ultrasound should be used as the primary investigation of any thyroid nodule as a reassuring appearance mitigates the need for an FNAC (see below).

FINE-NEEDLE ASPIRATION CYTOLOGY

FNAC should be used, ideally under ultrasound guidance, on all nodules that do not fulfil a fully benign (U2) classification on ultrasound. FNAC is reliable in identifying papillary thyroid cancer but cannot distinguish between a benign follicular adenoma (Figure 50.14) and follicular carcinoma, as this distinction is dependent not on cytology but on histological criteria, which include capsular and vascular invasion.

FNAC is both highly specific and sensitive. Using ultrasound improves this further, particularly in part cystic, part solid nodules in which ultrasound allows targeting of the solid element for biopsy.

Ernest L Mazzaferri, 1936–2013, endocrinologist, Ohio State University School of Medicine, Columbus, OH, USA.

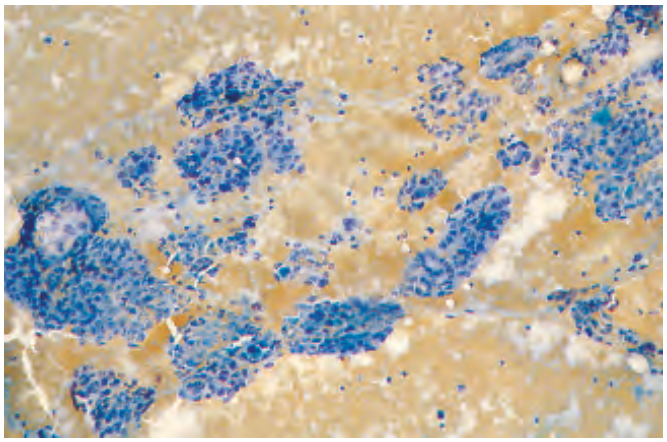

Figure 50.14 Thy3 aspiration cytology. Follicular neoplasm showing increased cellularity with a follicular pattern.

RADIOLOGY

Plain films have previously been used to assess tracheal compression and deviation, but the modality of choice now is CT scanning. CT scanning is also useful if ultrasound has identified metastatic disease in the neck as it can assist surgical planning and also assess the superior mediastinum and lungs.

LARYNGOSCOPY

Flexible laryngoscopy has rendered indirect laryngoscopy obsolete and is widely used preoperatively to determine the mobility of the vocal cords. The presence of a unilateral cord palsy coexisting with an ipsilateral thyroid nodule of concern is usually diagnostic of malignant disease.

CORE BIOPSY

Core biopsy is rarely indicated in thyroid masses due to the vascularity of the thyroid gland and the risk of postprocedure haemorrhage. It can be useful in the rapid diagnosis of widely invasive malignant disease, for example anaplastic carcinoma, or in the diagnosis of lymphadenopathy.

The main indication for operation is the risk of neoplasia, which includes follicular adenoma as well as malignant swellings. The reason for advocating the removal of all follicular neoplasms is that it is seldom possible to distinguish between a follicular adenoma and carcinoma cytologically. On this basis, some 50% of isolated swellings and 25% of dominant swellings should be removed on the grounds of neoplasia. Even when the cytology is negative, the age and sex of the patient and the size of the swelling may be relative indications for surgery, especially when a large swelling is responsible for symptoms. Some patients are happier to have a swelling removed even when cytology is negative.

There are useful clinical criteria to assist in selection for operation according to the risk of neoplasia and malignancy. Hard texture alone is not reliable as tense cystic swellings may be suspiciously hard but a hard, irregular swelling with any apparent fixity, which is unusual, is highly suspicious. Evidence of RLN paralysis, suggested by hoarseness and a non-occlusive cough and confirmed by laryngoscopy, is almost pathognomonic. Deep cervical lymphadenopathy along the internal jugular vein in association with a clinically suspicious swelling is almost diagnostic of papillary carcinoma. In most patients, however, such features are absent but there are risk factors associated with sex and age. The incidence of thyroid carcinoma in women is about three times that in men, but a discrete swelling in a male is much more likely to be malignant than in a female and it is seldom justifiable to avoid removing such a swelling in a man. The risk of carcinoma is increased at either end of the age range and a discrete swelling in a teenager of either sex must be provisionally diagnosed as carcinoma. The risk increases as age advances beyond 50 years, more so in males.

Thyroid cysts

Routine FNAC (or ultrasonography) shows that over 30% of clinically isolated swellings contain fluid and are cystic or partly cystic. Tense cysts may be hard and mimic carcinoma. Bleeding into a cyst often presents with a history of sudden painful swelling, which resolves to a variable extent over a period of weeks if untreated. Aspiration yields altered blood but reaccumulation is frequent. About 50% of cystic swellings are the result of colloid degeneration, or of uncertain aetiology because of an absence of epithelial cells in the lining. Although most of the remainder are the result of involution in follicular adenomas (**Figure 50.15**), some 10–15% of cystic follicular swellings are histologically malignant (30% in men and 10% in women). Papillary carcinoma is often associated with cyst formation (**Figure 50.16**).

Most patients with discrete swellings, however, are women, aged 20–40 years, in whom the risk of malignancy, although significant, is low and the indications for operation are not clear cut.

Ultrasound is the most useful tool for assessing cysts. If there is no discernable solid element then the cyst is almost certainly benign and does not need to be further investigated. If there is an associated solid element then consideration

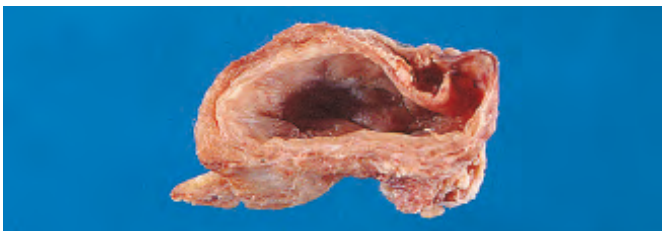

Figure 50.15 Apparently simple cystic thyroid swelling, the wall of which comprised follicular neoplastic tissue.

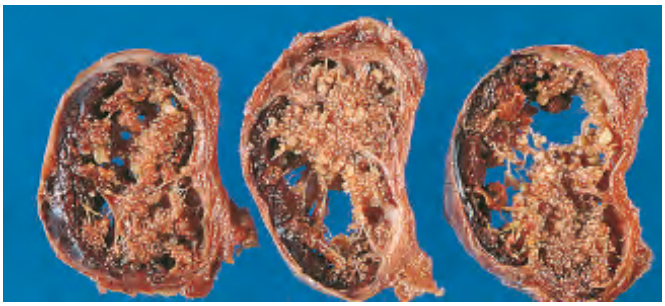

Figure 50.16 Cyst formation in a papillary carcinoma.

should be given to targeting that area with an ultrasound-guided FNAC.

The indications for operation in isolated or dominant thyroid swellings are listed in *Table 50.4*.

TABLE 50.4 Indications for operation in thyroid swellings.

	Clinical suspicion	Age
		Male sex
		Hard texture
		Fixity
		Recurrent laryngeal nerve palsy
		Lymphadenopathy
		Recurrent cyst
Toxic adenoma		
Pressure symptoms		
Cosmesis		
Patient's wishes		

Selection of thyroid procedure

The choice of thyroid operation depends on:

- diagnosis (if known preoperatively);
- risk of thyroid failure;
- risk of RLN injury;
- risk of recurrence;
- Graves' disease;
- multinodular goitre;
- differentiated thyroid cancer;
- risk of hypoparathyroidism.

Total and near-total thyroidectomy do not conserve sufficient thyroid tissue for normal thyroid function and thyroid replacement therapy is necessary. In most patients with negative antithyroid antibodies, one thyroid lobe will maintain normal function. In subtotal thyroidectomy, the volume of thyroid tissue preserved influences the risk of thyroid failure: larger remnants have a better chance of normal function but a higher risk of recurrence in Graves' disease.

Subtotal resections for colloid goitre run the risk of later growth of the remnant and, if a second operation is required years later, this greatly increases the risk to the RLN and parathyroid glands. In young patients, total thyroidectomy should be considered. It may be preferable to leave the least affected lobe untouched to permit a straightforward lobectomy in the future if required, rather than carry out subtotal resections.

In Graves' disease, preserving large remnants increases the risk of recurrence of the toxicity and, in these cases, it is better to err on the side of removing too much thyroid tissue rather than too little (*Table 50.5*). Thyroid failure should not be regarded as a failure of treatment, but recurrent toxicity is.

The relative merits of routine total versus selective total thyroidectomy in differentiated thyroid cancer are discussed below.

Summary box 50.3

Thyroid operations

All thyroid operations can be assembled from three basic elements:

1 Total lobectomy
2 Isthmusectomy
3 Subtotal lobectomy

Total thyroidectomy = 2 × total lobectomy + isthmusectomy

Subtotal thyroidectomy = 2 subtotal lobectomy + isthmusectomy

Near-total thyroidectomy = total lobectomy + isthmusectomy + subtotal lobectomy (Dunhill procedure)

Lobectomy = total lobectomy + isthmusectomy

Retrosternal goitre

Retrosternal goitre tends to arise from the slow growth of a multinodular gland down in to the mediastinum. As the gland enlarges within the thoracic inlet, pressure may lead to dysphagia, tracheal compression and eventually airway symptoms. The vast majority of patients have minimal symptoms. Patient should be considered for surgery if there is significant airway compression, if symptoms are present or in young patients in whom symptoms are likely to develop. In elderly patients with incidentally discovered retrosternal goitres, most surgeons would observe rather than treat

TABLE 50.5 Comparison of surgical options for Graves' disease.

	Total thyroidectomy	Subtotal thyroidectomy
Control of toxicity	Immediate	Immediate
Return to euthyroid state	Immediate	Variable – up to 12 months
Risk of recurrence	None	Lifelong – up to 5%[a]
Risk of thyroid failure	100%	Lifelong – up to 100% at 30 years[a]
Risk of permanent hypoparathyroidism	5%	1%
Need for follow-up	Minimal	Lifelong

[a]The risk of recurrence and late failure are a function of the size of the remnant as a proportion of the total gland weight. Large remnants in small glands have a higher risk of recurrence and a low risk of failure, and small remnants in large glands have a higher risk of thyroid failure but a low risk of recurrence.

prophylactically. Clearly a balance between risk and benefit must be made.

If a decision is made to proceed to surgery, assessment of the extent of disease is critical. The vast majority (>95%) of retrosternal goitres can be removed transcervically. Those at most risk of requiring conversion to an open sternotomy approach include malignant or revision cases, those which extend into the posterior mediastinum and those in which the diameter of the goitre exceeds that of the thoracic inlet. In such cases a joint case with thoracic surgery should be planned.

All cases should have cross-sectional imaging. Ideally this is performed in the surgical position and when interpreting CT chest scans, the surgeon should pay attention to the arm position. If the arms are up (as for standard CT chest) a great deal of thyroid movement will be achieved when the arms are down and the neck extended.

The approach to surgery is as described below. A longer incision is required. The surgeon may mobilise the sternomastoid muscle from the strap muscles to improve access. The ligamentous tissue between the sternal heads of the clavicles may be gently divided to increase the opening for gland delivery. Blunt dissection on the capsule of the gland allows mobilisation. Gentle traction is applied to deliver the gland into the neck. If the goitre has developed from a posteriorly positioned nodule there is a risk that the RLN may be displaced anteriorly, so great care must be taken in dividing apparent fascial bands that overlie the gland. The blood supply is from the neck, reducing the risk of catastrophic bleeding from the great vessels. Nonetheless, care should be taken in the region of the major blood vessels in the neck and chest.

If the gland is fixed and immobile or too large to deliver through a cervical approach, a midline sternotomy is performed and the gland can be dissected from below to achieve a safe total thyroidectomy.

HYPERTHYROIDISM

Thyrotoxicosis

The term thyrotoxicosis is retained because hyperthyroidism, i.e. symptoms due to a raised level of circulating thyroid hormones, is not responsible for all manifestations of the disease. Clinical types are:

- diffuse toxic goitre (Graves' disease);
- toxic nodular goitre;
- toxic nodule;
- hyperthyroidism due to rarer causes.

Diffuse toxic goitre

Graves' disease, a diffuse vascular goitre appearing at the same time as hyperthyroidism, usually occurs in younger women and is frequently associated with eye signs. The syndrome is that of primary thyrotoxicosis **(Figure 50.17)**; 50% of patients have a family history of autoimmune endocrine diseases. The

Figure 50.17 Graves' disease.

whole of the functioning thyroid tissue is involved, and the hypertrophy and hyperplasia are due to abnormal TSH-RAb that bind to TSH receptor sites and produce a disproportionate and prolonged effect.

Toxic nodular goitre

A simple nodular goitre is present for a long time before the hyperthyroidism, usually in the middle-aged or elderly, and very infrequently is associated with eye signs. The syndrome is that of secondary thyrotoxicosis.

In many cases of toxic nodular goitre, the nodules are inactive, and it is the internodular thyroid tissue that is overactive. However, in some toxic nodular goitres, one or more nodules are overactive and here the hyperthyroidism is due to autonomous thyroid tissue as in a toxic adenoma.

Toxic nodule

A toxic nodule is a solitary overactive nodule, which may be part of a generalised nodularity or a true toxic adenoma. It is autonomous and its hypertrophy and hyperplasia are not due to TSH-RAb. TSH secretion is suppressed by the high level of circulating thyroid hormones and the normal thyroid tissue surrounding the nodule is itself suppressed and inactive.

HISTOLOGY

The normal thyroid gland consists of acini lined with flattened cuboidal epithelium and filled with homogeneous colloid **(Figure 50.2)**. In hyperthyroidism **(Figure 50.18)**, there is hyperplasia of acini, which are lined by high columnar epithelium. Many of them are empty, and others contain vacuolated colloid with a characteristic 'scalloped' pattern adjacent to the thyrocytes.

Robert James Graves, 1796–1853, physician, Meath Hospital, Dublin, Ireland, published an account of exopthalmic goitre in 1835. He was President of the Royal College of Physicians of Ireland and elected Fellow of The Royal Society of London in 1849. There is a statue of him in the Royal College of Physicians in Ireland.

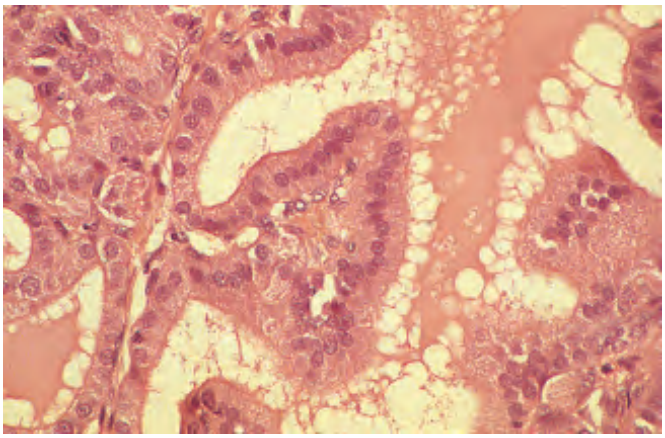

Figure 50.18 Histology of thyrotoxicosis.

Principles of treatment of thyrotoxicosis

Non-specific measures are rest and sedation and in established thyrotoxicosis should be used only in conjunction with specific measures, i.e. the use of antithyroid drugs, surgery and radioiodine.

ANTITHYROID DRUGS

Those in common use are carbimazole and propylthiouracil. Antithyroid drugs are used to restore the patient to a euthyroid state and to maintain this for a prolonged period in the hope that a permanent remission will occur, i.e. that production of thyroid-stimulating antibodies (TSH-RAb) will diminish or cease. Antithyroid drugs cannot cure a toxic nodule. The overactive thyroid tissue is autonomous and recurrence of the hyperthyroidism is certain when the drug is discontinued.

- **Advantages**. No surgery and no use of radioactive materials.
- **Disadvantages**. Treatment is prolonged and the failure rate is at least 50%. The duration of treatment may be tailored to the severity of the toxicity, with milder cases being treated for only 6 months and severe cases for 2 years before stopping therapy.

SURGERY

In diffuse toxic goitre and toxic nodular goitre with overactive internodular tissue, surgery cures by reducing the mass of overactive tissue by reducing the thyroid below a critical mass. After subtotal thyroidectomy the patient should return to a euthyroid state, albeit after a variable period of hypothyroidism. There are however, the long-term risks of recurrence and eventual thyroid failure. In contrast total/near total thyroidectomy accepts immediate thyroid failure and lifelong thyroxine replacement to eliminate the risk of recurrence and simplify follow-up. Operation may result in a reduction in TSH-RAb. In the autonomous toxic nodule, and in toxic nodular goitre with overactive autonomous toxic nodules, surgery cures by removing all the overactive thyroid tissue; this allows the suppressed normal tissue to function again.

- **Advantages**. The goitre is removed, the cure is rapid and the cure rate is high if surgery has been adequate.
- **Disadvantages**. Recurrence of thyrotoxicosis occurs in at least 5% of cases when subtotal thyroidectomy is carried out. There is a risk of permanent hypoparathyroidism and nerve injury. Young women tend to have a poorer cosmetic result from the scar.

Every operation carries a risk, but with suitable preparation and an experienced surgeon the mortality is negligible and the morbidity low.

RADIOIODINE

Radioiodine destroys thyroid cells and, as in thyroidectomy, reduces the mass of functioning thyroid tissue to below a critical level.

- **Advantages**. No surgery and no prolonged drug therapy.
- **Disadvantages**. Isotope facilities must be available. The patient must be quarantined while radiation levels are high and avoid pregnancy and close physical contact, particularly with children. Eye signs may be aggravated.

Choice of therapy

Each case must be considered individually. Below are listed guiding principles on the most satisfactory treatment for a particular toxic goitre at a particular age; these must, however, be modified according to the facilities available and the personality and wishes of the individual patient, business or family commitments and any other coexistent medical or surgical condition. Access to post-treatment care and availability of replacement thyroxine can be important considerations in resource-poor countries.

In advising treatment, compliance, influenced by social and intellectual factors, is important; many patients cannot be trusted to take drugs regularly if they feel well, and indefinite follow-up, which is essential after radioiodine or subtotal thyroidectomy is a burden for all.

DIFFUSE TOXIC GOITRE

Most patients have an initial course of antithyroid drugs with radioiodine for relapse. Exceptions are those who refuse radiation, have large goitres, progressive eye signs or are pregnant.

TOXIC NODULAR GOITRE

Toxic nodular goitre is often large and uncomfortable and enlarges still further with antithyroid drugs. A large goitre should be treated surgically because it does not respond as well or as rapidly to radioiodine or antithyroid drugs as does a diffuse toxic goitre.

TOXIC NODULE

Surgery or radioiodine treatment is appropriate. Resection is easy, certain and with a low risk of morbidity. Radioiodine is a good alternative for patients over the age of 45 years because the suppressed thyroid tissue does not take up iodine and thus there is minimal risk of delayed thyroid insufficiency.

FAILURE OF PREVIOUS TREATMENT WITH ANTITHYROID DRUGS OR RADIOIODINE

In this case, surgery or thyroid ablation with ^{123}I is appropriate.

Surgery for thyrotoxicosis

Preoperative preparation

Traditional preparation aims to make the patient biochemically euthyroid at operation. Preparation is as an out-patient and only rarely is admission to hospital necessary on account of severe symptoms at presentation, failure to control the hyperthyroidism or non-compliance with medication. Care should be coordinated with endocrinology input.

Carbimazole 30–40 mg per day is the drug of choice for preparation. When euthyroid (after 8–12 weeks), the dose may be reduced to 5 mg 8-hourly or a 'block and replace' regime used. In this case, the high dose of carbimazole is continued to inhibit T_3 and T_4 production and a maintenance dose of 0.1–0.15 mg of thyroxine is given daily. The last dose of carbimazole may be given on the evening before surgery. Iodides are not used alone because, if the patient needs preoperative treatment, a more effective drug should be given.

An alternative method of preparation is to abolish the clinical manifestations of the toxic state, using β-adrenergic blocking drugs. These act on the target organs and not on the gland itself. Propranolol also inhibits the peripheral conversion of T_4 to T_3. The appropriate dosages are propranolol 40 mg t.d.s. or the longer acting nadolol 160 mg once daily. Clinical response to β-blockade is rapid and the patient may be rendered clinically euthyroid and operation arranged in a few days rather than weeks. The dose of β-adrenergic blocking drug is increased to achieve the required clinical response and quite often larger doses (propranolol 80 mg t.d.s. or nadolol 320 mg once daily) are necessary.

β-adrenergic blocking drugs do not interfere with synthesis of thyroid hormones, and hormone levels remain high during treatment and for some days after thyroidectomy. It is, therefore, important to continue treatment for 7 days postoperatively.

Iodine may be given with carbimazole or a β-adrenergic blocking drug for 10 days before operation. Iodide alone produces a transient remission and may reduce vascularity, thereby marginally improving safety. The use of iodine preparations is not universal because of more effective alternatives. Iodine gives an additional measure of safety in case the early morning dose of β-adrenergic blocking drug is mistakenly omitted on the day of operation.

The extent of the resection depends on the size of the gland, the age of the patient, the experience of the surgeon, the need to minimise the risk of recurrent toxicity and the wish to avoid postoperative thyroid replacement (*Table 50.5*).

SURGICAL TECHNIQUE OF THYROIDECTOMY

Having made the decision to proceed to surgery, the first step is informed consent. Patients should understand the risk of scar, RLN damage, bleeding, hypocalcaemia and hypothyroidism.

Endotracheal intubation is performed, and if a nerve monitor is to be used its position should be confirmed once the patient is in the surgical position (see New technology in thyroidectomy, below).

The patient lies supine with the neck extended. Surgical preparation extends from the mandible on to the chest. A skin crease incision is placed around the level of the cricoid cartilage. Classically those patients with 'pendulous' breasts should have an incision placed more superiorly as it will tend to migrate inferiorly over years and a sternal wound is less attractive.

Subplatysmal flaps are raised to an extent that allows access to the goitre, often from thyroid notch to sternal notch. The midline is identified between the strap muscles. The plane is developed to dissect between the muscle layers, elevating sternohyoid laterally until ansa cervicalis is visualised. The sternothyroid muscle is then mobilised from the gland, taking great care with the delicate vasculature. If required, the strap muscles may be divided superiorly to afford greater exposure.

Attention is turned first to the superior pole. A plane between the larynx and superior pole is developed and the branching divisions of the superior vascular pedicle are dissected. As these insert onto the gland they are dissected, controlled with ties or bipolar diathermy and divided individually. Not only does this mobilise the superior pole, but preserves the blood supply to the superior parathyroid gland. In addition, this minimises risk to the superior laryngeal nerve, which can often be seen passing medially towards the cricothyroid muscle. Gradually the superior pole is mobilised taking care not to dissect below the cricoid cartilage, at which point the RLN is at risk.

By now, the fascia around the thyroid has been clearly identified. This plane is followed over the anterolateral aspect of the gland to the inferior pole. The tracheoesophageal groove should not be entered at this point as the RLN is yet to be identified. Inferiorly the trachea should be dissected in order to confirm the anatomical landmark.

At this point structures inferior and superior to the RLN have been identified and careful dissection toward the lateral aspect of the gland allows the gland to be rotated medially, displaying the tracheoesophageal groove. Careful dissection of this area proceeds being sure not to divide any structure that could be the nerve. The fascia from the thyroid is mobilised, being vigilant throughout. The RLN is identified and confirmed by the anatomical location, direction of travel and the nerve monitor, if in use. The nerve is then traced towards the larynx, allowing mobilisation of the lateral aspect of the gland.

During this part of the dissection the surgeon must prioritise identification of the nerve, preservation of the inferior parathyroid and its blood supply, as well as control of branches of the inferior thyroid artery. Again, these should be divided in a controlled manner as close as possible to gland in order to preserve parathyroid blood supply.

At this stage the nerve should be traced towards the cricothyroid joint as it enters the larynx. This point is the area where the nerve is most commonly damaged. The pretracheal fascia condenses into Berry's ligament at this stage. Small vessels within the ligament retract if not controlled with bipolar diathermy or ties, and the resulting bleeding can disorientate the surgeon placing the nerve at risk (**Figure 50.19**).

In order to avoid this, pre-emptive diathermy to the ligament and careful layer by layer dissection allows final mobilisation of the thyroid lobe. Some surgeons prefer to isolate the ligament and apply a careful tie to achieve haemostasis.

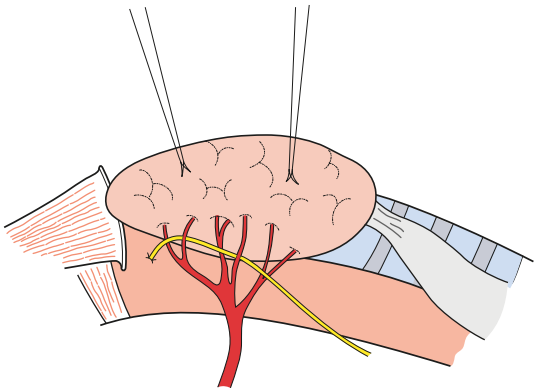

Figure 50.19 Identification of the recurrent laryngeal nerve. Note how rotating the gland medially anteriorly kinks the nerve that is normally intimately related to the terminal branches of the inferior thyroid artery.

Whichever method is preferred, great care must be taken at this point. The lobe is then mobilised medially and the nerve falls laterally.

If total thyroidectomy is indicated the procedure is repeated on the contralateral side. If, however, lobectomy alone is indicated, the isthmus should be divided between clamps and oversewn. The surgical bed is then inspected to confirm the integrity of the nerve and the state of the parathyroid glands. Consideration may be given to reimplantation of parathyroids to the sternomastoid muscle if they appear devascularised. Irrigation followed by meticulous haemostasis should follow and no bleeding is acceptable. Ideally this is performed with a Valsalva manouvre with the head down.

Following complete haemostasis the strap muscles are loosely reapproximated in order to avoid a water tight seal but to prevent adhesion between skin and trachea. The wound is then closed in layers with absorbable suture to platysma and skin closure. This may be with clips, non-absorbable sutures or subcuticular closure. It is important that those involved in postoperative care know how the wound was closed and how to perform a bedside reopening in the event of a life-threatening bleed.

The patient is then returned to the recovery room and the postoperative area for overnight monitoring. Not only is the wound regularly reviewed, but for total thyroidectomy patients postoperative calcium should be checked to identify hypocalcaemia.

NEW TECHNOLOGY IN THYROIDECTOMY

The major immediate risk following thyroidectomy is haemorrhage; conventionally, artery forceps, ligatures and sutures have been used to secure the meticulous haemostasis necessary to minimise the risk of this potentially life-threatening complication. Ultrasonic shears, enhanced bipolar diathermy and harmonic vessel sealing devices are increasingly used in thyroid surgery and may be advantageous in complex procedures.

Monitoring of the RLN and vagus nerve has become available over the last few years. By placing electrodes on the endotracheal tube between the vocal cords, movements can be detected when the nerve is stimulated. Such intermittent nerve monitoring is gaining in popularity. Advocates consider the monitor particularly useful in recurrent operations where scar tissue makes the nerve difficult to identify. In addition, some authors find operative time is reduced and that this is a valuable tool for training. There is also some support for the use of nerve monitoring during bilateral thyroid surgery, as the information provided can aid in the identification of a unilateral palsy to prevent bilateral palsy that can require tracheostomy. Those who do not support the use of the nerve monitor highlight the lack of evidence that any real difference in outcome associated with this practice. In addition, there is the expense of the base machine and the electrodes.

In contrast to intermittent nerve monitoring that allows identification of a damaged nerve, continuous nerve monitoring has now been developed. In theory, this provides the opportunity to identify a nerve when function is threatened (by excessive traction for example). This technique, although theoretically advantageous, requires an electrode placed on the vagus nerve and has not gained widespread acceptance (**Figure 50.20**).

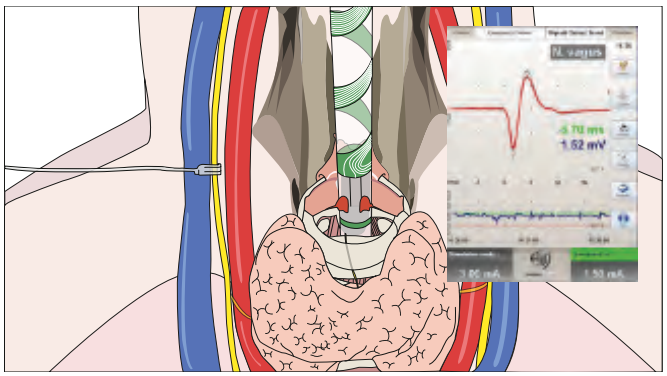

Figure 50.20 Diagram of continuous monitoring of the vagus nerve (adapted from an image provided by Inomed UK Ltd).

ALTERNATIVE SURGICAL TECHNIQUES

Over the past two decades, increasing experience has been gained in alternative approaches to thyroid surgery. Minimally invasive video assisted techniques have been developed, which allow surgeons to operate through an incision <2 cm in length. With appropriately modified dissectors, experienced operators and advanced haemostatic electrosurgical devices, such procedures offer reduced scar length. However, they are only appropriate for small volume disease and as such are not suitable for many thyroid cases.

Robots have found a role in many aspects of modern surgical practice. In the Far East, a neck scar is found to be socially unacceptable. Robotic techniques have been developed that allow access to the thyroid via an axillary incision. Such 'maximally invasive' techniques require extended dissection over the chest wall and again are most suitable for small volume disease. Experienced centres continue to expand the indications for these techniques. However, they are associated with great cost and significant time, which currently limits their application to thyroid surgical practice.

POSTOPERATIVE COMPLICATIONS

Haemorrhage Haemorrhage is the most frequent life-threatening complication of thyroidectomy. Around 1 in 50 patients will develop a haematoma, and in almost all cases this will develop in the first 24 hours. If an arterial bleed occurs, the tension in the central compartment pressure can rise until it exceeds venous pressure. Venous oedema of the larynx can then develop and cause airway obstruction leading to death. Although improvements in understanding of the blood supply to the larynx and technical developments in terms of haemostatic technologies have been made, this complication has not been eliminated. Although many surgeons worldwide practice day case thyroidectomy, bleeding is the reason that, in the UK, thyroidectomy remains an inpatient procedure.

Intraoperative attention to detail in terms of haemostasis is critical. When closing the wound, avoiding a watertight closure of the strap muscles may allow a haematoma to escape into the subcutaneous tissues. Wound drains have not been shown to have a protective effect. Close monitoring of the wound is advised postoperatively. If a haematoma develops, clinical staff should know to remove skin sutures in order to release some pressure and seek senior advice immediately. Endotracheal intubation should be used to secure the airway while the haematoma is evacuated and the bleeding point controlled.

Recurrent laryngeal nerve paralysis and voice change RLN injury may be unilateral or bilateral, transient or permanent. Early routine postoperative laryngoscopy reveals a much higher incidence of transient cord paralysis than is detectable by simple assessment of the integrity of the voice and cough. Such temporary dysfunction is not clinically important however, but voice and cord function should be assessed at first follow-up 4 weeks postoperatively. The British Association of Endocrine Surgeons audit revealed a RLN palsy rate of 1.8% at 1 month, declining to 0.5% at 3 months for first time operations. Permanent paralysis is rare if the nerve has been identified at operation.

If a RLN is injured during surgery and the transected ends are identified, they should be reanastomosed. In the event that a length of nerve is excised (due to invasion by malignancy for example), anastomosis of the ansa cervicalis may be considered. This does not return mobility of the vocal cord but maintains neurological input to the muscles of the larynx. By avoiding denervation and related muscle atrophy, the vocal quality is improved. Permanent vocal cord paralysis should be treated conservatively with speech therapy. If voice quality is unacceptable, medialisation procedures can be performed. Nerve grafting has shown promise but experience is limited.

Injury to the external branch of the superior laryngeal nerve is more common because of its proximity to the superior thyroid artery. This leads to loss of tension in the vocal cord with diminished power and range in the voice. Patients, particularly those who use their voice professionally, must be advised that any thyroid operation will result in change to the voice even in the absence of nerve trauma. Fortunately, for most patients the changes are subtle and only demonstrable on formal voice assessment.

Thyroid insufficiency Following total thyroidectomy, clearly thyroxine replacement will be required. Around one in three patients who has a lobectomy will require supplementation; rates are higher in those with thyroid autoantibodies. Subtotal thyroidectomy was at one time performed with the aim of leaving sufficient tissue to maintain thyroid function. However, this is difficult to judge and over years, the benign process that necessitated primary surgery may recur, requiring difficult revision procedures. For this reason, the practice of subtotal thyroidectomy has been more or less abandoned outside of environments where exogenous thyroxine is not available.

Parathyroid insufficiency This is due to removal of the parathyroid glands or infarction through damage to the parathyroid end arteries; often both factors occur together. Vascular injury is probably far more important than inadvertent removal. The incidence of permanent hypoparathyroidism should be less than 1% and most cases present dramatically 2–5 days after operation but, very rarely, the onset is delayed for 2–3 weeks or a patient with marked hypocalcaemia may be asymptomatic. The complication is limited to total thyroidectomy, as when lobectomy is performed the contralateral parathyroid glands are sufficient to maintain calcium levels. In particular, total thyroidectomy with central neck dissection places the parathyroid glands and their vascular supply at great risk and should only be performed when there is evidence of metastatic disease or high risk of occult disease in the regional lymph nodes.

Thyrotoxic crisis (storm) This is an acute exacerbation of hyperthyroidism. It occurs if a thyrotoxic patient has been inadequately prepared for thyroidectomy and is now extremely rare. Very rarely, a thyrotoxic patient presents in a crisis and this may follow an unrelated operation. Symptomatic and supportive treatment is for dehydration, hyperpyrexia and restlessness. This requires the administration of intravenous fluids, cooling the patient with ice packs, administration of oxygen, diuretics for cardiac failure, digoxin for uncontrolled atrial fibrillation, sedation and intravenous hydrocortisone. Specific treatment is by carbimazole 10–20 mg 6-hourly, Lugol's iodine 10 drops 8-hourly by mouth or sodium iodide 1g i.v. Propranolol intravenously (1–2 mg) or orally (40 mg 6-hourly) will block β-adrenergic effects.

Wound infection Cellulitis requiring prescription of antibiotics, often by the general practitioner, is more common than most surgeons appreciate. A significant subcutaneous or deep cervical abscess is exceptionally rare and should be drained.

Hypertrophic or keloid scar This is more likely to form if the incision overlies the sternum and in dark skinned individuals. Intradermal injections of corticosteroid should be given at once and repeated monthly if necessary. Scar revision rarely results in significant long-term improvement.

Stitch granuloma This may occur with or without sinus formation and is seen after the use of non-absorbable, particularly silk, suture material. Absorbable ligatures and sutures

should be used throughout thyroid surgery. Some surgeons use a subcuticular absorbable skin suture rather than the traditional skin clips or staples.

POSTOPERATIVE CARE

Following surgery, the patient should be returned to the recovery room and nursed overnight on the ward. Wound care should include vigilance for signs of a haematoma. Following total thyroidectomy, calcium levels should be checked postoperatively. Not all patients develop immediate hypocalcaemia and they should be educated about the signs (parasthesia of the fingers and toes or round the mouth). Serial calcium monitoring should be recommended for those at highest risk. Those patients who had a total thyroidectomy require thyroxine replacement, which should start day 1 postoperatively. On clinic review, in addition to checking the histology report, the wound should be inspected and the larynx examined for vocal cord function. Biochemical assessment of thyroid function and calcium, if required, should be arranged.

NEOPLASMS OF THE THYROID

Classification of thyroid neoplasms is presented in *Table 50.6* and the relative incidence of malignancies in *Table 50.7*.

TABLE 50.6 Classification of thyroid neoplasms.

Benign	Follicular adenoma		
Malignant	Primary	Follicular epithelium – differentiated	Follicular Papillary
		Follicular epithelium – poorly differentiated	Anaplastic
		Parafollicular cells	Medullary
		Lymphoid cells	Lymphoma
	Secondary	Metastatic	
		Local infiltration	

TABLE 50.7 Relative incidence of primary malignant tumours of the thyroid gland.

Malignancy	Relative incidence
Papillary carcinoma	80%
Follicular carcinoma	10%
Poorly differentiated/anaplastic carcinoma	5%
Medullary carcinoma	2.5%
Lymphoma	2.5%

Benign tumours

Follicular adenomas present as clinically solitary nodules **(Figure 50.21)** and the distinction between a follicular carcinoma and an adenoma can only be made by histological examination; in the adenoma there is no invasion of the capsule or of pericapsular blood vessels. For this reason, FNA, which provides cytologic detail but not tissue architecture, cannot differentiate between benign and malignant follicular lesions. Diagnosis and treatment is therefore, by wide excision, i.e. total lobectomy. The remaining thyroid tissue is normal so that prolonged follow-up is unnecessary.

Figure 50.21 Isolated swelling in the upper pole of the right thyroid lobe.

Malignant tumours

The vast majority of primary malignancies are carcinomas derived from the follicular cells *(Table 50.6)*. Such tumors were thought of as differentiated (papillary, follicular and Hürthle cell) and undifferentiated (anaplastic). However, now an intermediate class of 'poorly differentiated carcinoma' is recognised, which is likely to represent a state of dedifferentiated, between classic differentiated and undifferentiated diseases. The parafollicular C cells can undergo malignant transformation into medullary carcinoma, and thyroid lymphoma is another primary thyroid malignancy. In addition, the thyroid can be involved by direct spread from surrounding structures (larynx and oesophagus) or metastases (most commonly from renal cell carcinoma). Lymph node and blood-borne metastases of thyroid cancer occur primarily to bone and lung and may be the mode of presentation **(Figure 50.22)**.

Aetiology of malignant thyroid tumours

The great majority of thyroid cancers have no known aetiological factor. The most important identifiable aetiological factor in differentiated thyroid carcinoma (particularly papillary) is irradiation of the thyroid under 5 years of age. In the town of Gomel, Ukraine, the incidence of childhood thyroid cancer rose from <1 per million to 96 per million following the Chernobyl nuclear disaster.

Short latency aggressive papillary cancer is associated with the ret/PTC3 oncogene and later developing, possibly less aggressive, cancers with ret/PTC1. The incidence of follicular carcinoma is high in endemic goitrous areas, possibly due to TSH stimulation. Malignant lymphomas sometimes develop in autoimmune thyroiditis, and the lymphocytic infiltration in the autoimmune process may be an aetiological factor.

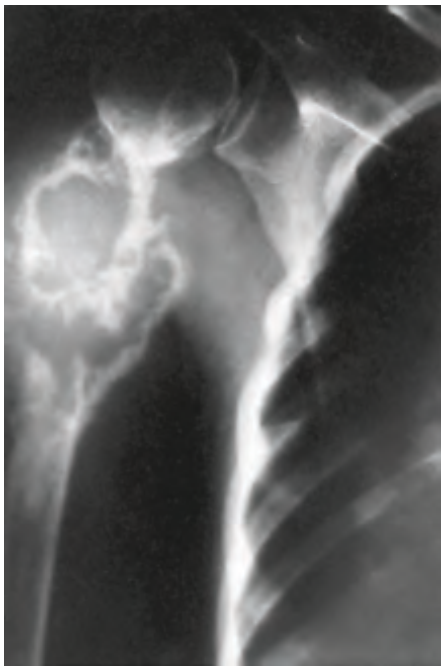

Figure 50.22 Metastasis in the humerus from thyroid carcinoma (courtesy of DS Devadatta, Vellore, India).

Clinical features of thyroid cancers

The annual incidence is about 0.6 per million of the population and the sex ratio is three females to one male. However, the incidence of papillary thyroid cancer is increasing rapidly across the world. This is mostly due to increased rates of imaging detecting previously occult disease. For that reason, although the incidence is increasing, the mortality rates remain static at over 80% 5-year survival for all groups. In particular, anaplastic carcinoma predicts poor outcome with differentiated carcinomas generally having excellent outcomes. The most common presenting symptom is a thyroid swelling (**Figures 50.21 and 50.23**). Enlarged cervical lymph nodes may be the presentation of papillary carcinoma (PTC). RLN paralysis is very suggestive of locally advanced disease.

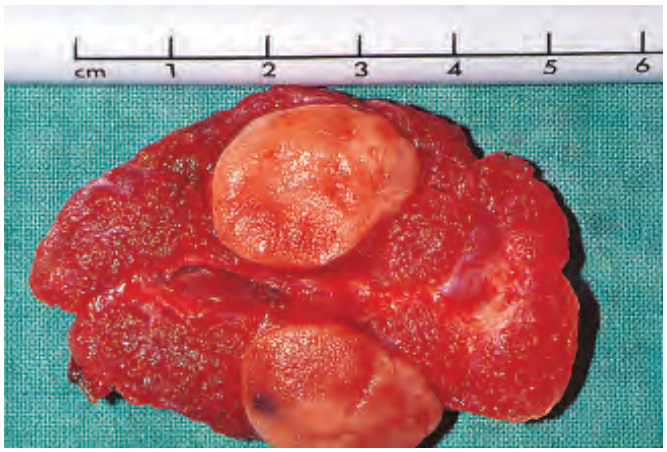

Figure 50.23 Follicular neoplasm of the thyroid presenting as an isolated swelling.

Anaplastic growths are usually hard, irregular and infiltrating. A differentiated carcinoma may be suspiciously firm and irregular, but is often indistinguishable from a benign swelling. Small papillary tumours may be impalpable, even when lymphatic metastases are present. Pain, often referred to the ear, is suggestive of nerve involvement from infiltrating tumours.

Diagnosis of thyroid neoplasms

Clinical history and examination continue to be the cornerstone of diagnosis of thyroid neoplasms. As previously mentioned, radiation exposure and family history should be discussed. Examination of the central neck and regional lymphatics should be combined with assessment of vocal cord function. Biochemical assessment of thyroid function should also be considered in this first encounter, if not already performed.

Following initial assessment, the next step is ultrasound. This non-invasive investigation is most accurate at assessing thyroid swellings. Not only can a judgement be made on the presence, size and number of thyroid nodules present, but an estimate of risk of malignancy can be made depending on these findings.

Following ultrasound, lesions can be categorised as benign, indeterminate or malignant. Benign lesions require no further assessment unless surgery is considered for compressive symptoms. Indeterminate or malignant lesions should be investigated with FNAC.

Occasionally, the surgeon will encounter a thyrotoxic patient. Such cases are one of the few indications for a radioiodine uptake scan. This allows assessment of the function of a nodule. Hot nodules are very rarely malignant. Cold nodules will require assessment as for all other thyroid neoplasms.

Following clinical, ultrasound and cytological assessment, the vast majority of lesions will be characterised as benign, malignant or indeterminate. Further treatment will be planned accordingly.

Certain situations require specific consideration. For patients with widespread nodal disease or suspicion of locally invasive disease affecting the airway, contrast enhanced imaging should be considered. This should cover the neck and chest. Not only does this allow accurate assessment of any visceral invasion, but is superior to ultrasound at defining disease in the mediastinum and thorax. Concerns over the impact of iodine-containing contrast on delays to radioactive iodine therapy have been overplayed, and it is more critical that the surgeon has an accurate assessment of disease extent prior to surgery.

Patients with a rapidly growing thyroid mass, particularly if solid and fixed, should be considered at risk of anaplastic carcinoma. However, this diagnosis can be difficult to differentiate from thyroid lymphoma or occasionally thyroiditis. Despite the difficulty, an accurate diagnosis is critical as anaplastic carcinoma is rapidly fatal and palliative measure are general recommended, whereas confounding disease processes may respond to therapy. In this setting, core or even open biopsy may be required to make a confident diagnosis.

Papillary carcinoma

Papillary carcinoma is the most common thyroid malignancy. Interestingly, up to 30% of patients who die of non-thyroid disease have deposits of PTC in autopsy studies, suggesting that many patients live with this disease undetected. Nonetheless, when papillary cancer is diagnosed most patients will be offered treatment. The disease is known for its propensity for lymph node metastases. These are more common in younger patients, in whom they do not affect the otherwise excellent survival. This finding is in contrast to most malignances, where the finding of metastatic disease confers a poor outcome. One contentious finding in patients with PTC is a high rate of occult micrometastases (as high as 40% of N0 patients in the central neck). Despite the presence of metastases, few patients progress to have clinically meaningful disease and the role of elective nodal surgery is in question. Distant metastases are uncommon in PTC.

Recently, increasing interest has focused on 'papillary microcarcinoma'. This term is used to describe PTC that is <10 mm in size. These lesions are common (detected in about 10% of benign thyroid resections) and not associated with adverse outcomes, including recurrence or non-survival. As such, management and follow-up of patients with these lesions of doubtful clinical significance is controversial. In Korea, for example, national screening has led to a significant increase in these cases. In Japan groups are opting for an observational approach without surgery. These studies have shown that at least two-thirds never progress. In the USA some groups are attempting non-surgical management with ablation techniques using ethanol or radiofrequency. In most of the world however, groups try to avoid diagnosing these small, insignificant lesions by limiting biopsies to >10 mm lesions and being conservative in the management of lesions following their diagnosis.

Follicular carcinoma

Follicular carcinoma can normally only be differentiated from follicular adenoma by the architecture on histology. For this reason, follicular lesions on FNA are unable to be diagnosed as malignant in the absence of clinical features such as metastases (**Figure 50.24**). Multiple foci of follicular carcinoma are seldom seen and lymph node involvement is much less common than in papillary carcinoma. Blood-borne metastases are more common and the eventual mortality rate, although still low, is twice that of papillary cancer (**Figure 50.25**).

Hürthle cell tumours are a rare variant of follicular neoplasm in which oxyphil (Hürthle, Askanazy) cells predominate histologically. Hürthle cell cancers are associated with a poorer prognosis.

Prognosis in differentiated thyroid carcinoma

The prognosis in differentiated thyroid cancers is generally excellent. In terms of survival, older patients, those with large tumors or extrathyroid extension or distant metastases have worse outcomes. A system of risk stratification can be used to predict the risk on an individual basis. In a young patient with a low-risk tumour, the risk of death following appropriate treatment is almost zero. In an older patient with a high-risk tumour (extrathyroid extension or distant metastases), the risk is as high as 50% at 5 years. Older patients with low-risk tumours and younger patients with high-risk tumours are an intermediate risk group. Nodal metastases deserve special mention. In younger patients they predict for recurrence but not for death. This is because recurrent neck disease in young

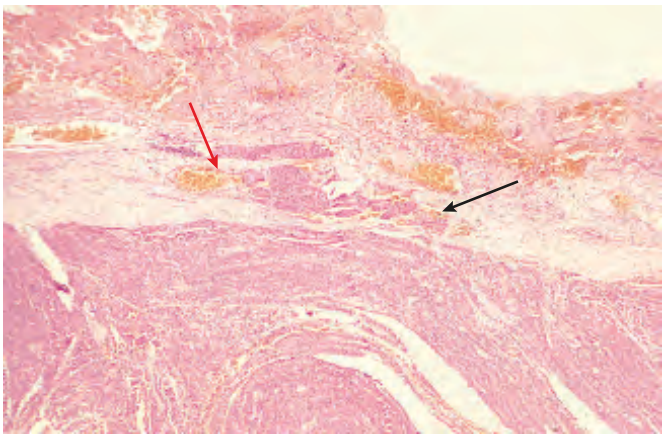

Figure 50.24 Histology of follicular thyroid carcinoma showing vascular (red arrow) and capsular (black arrow) invasion (courtesy of Dr SWB Ewen, Aberdeen, UK).

Figure 50.25 Follicular carcinoma of thyroid with skull secondaries.

Karl Hürthle, 1866–1945, German histopathologist, first drew attention to these cells.
Max Askanazy, 1865–1940, described these cells while working at the Pathological Anatomy Institute, Tübingen, Germany.

patients can almost always be successfully salvaged. In contrast, for older patients neck metastases (particularly in the lateral neck) are a marker of distant metastases in some, and therefore carry a negative prognostic implication for both recurrence and death.

The AJCC staging system is in the process of modification. However, the current edition stages all patients <45 years as stage I unless they have distant metastases, when they are stage II. Older T1N0M0 patients are stage I and T2N0M0 are stage II. The presence of nodal disease in the central neck nodes (N1a) upstages older patients to stage III, as does T3 disease. All older patients with lateral neck disease (N1b), locally invasive primary disease (T4) or distant metastases are stage IV.

The AJCC 8th edition will raise the age cut-off to 55 years. It will also formally recognise that extrathyroid extension is less significant if identified microscopically but not evident during surgery. The extent of nodal involvement will also be included, with small numbers of low-volume nodes being considered less significant than multiple large-volume nodes.

Surgical treatment for differentiated thyroid cancer

This subject has many contentious aspects. For the vast majority of patients, outcome is excellent irrespective of the extent of surgery. The low number of recurrences and death has made prospective trials difficult and, as such, very few exist.

The aim of surgery is to rid the patient of macroscopic disease and minimise the chance of recurrence and death. An additional aim is to minimise surgical morbidity. Achieving a balance between these aims is critical. In addition, the surgeon must consider whether radioactive iodine is to be recommended. In low-risk cases this is rarely indicated, whereas in high-risk patients it is used almost universally. Risk stratification is therefore critical.

In high-risk patients with nodal or distant metastases, total thyroidectomy will be performed to eradicate disease in the thyroid and prepare the patient for radioactive iodine. For low-risk patients with a single focus of disease limited to the thyroid, a thyroid lobectomy can be offered. This has the significant advantage of protecting the contralateral RLN and parathyroid glands. This approach is now considered appropriate unless there are high-risk features of disease.

In terms of the neck, when metastatic disease is present, a therapeutic compartment-orientated neck dissection should be performed to remove disease from the central or lateral neck, depending on the site of involvement. The role of elective neck surgery, when no disease in the nodes is detected preoperatively, is far more controversial. Lateral neck dissection carries significant morbidity and despite high rates of occult metastases in papillary carcinoma, has been abandoned. The reason is that even in patients who are thought to have occult metastases, very few progress to clinically meaningful disease. In contrast, the morbidity of central neck dissection is lower, and the compartment has to be opened during a thyroidectomy. In addition, salvage surgery in the central neck carries a high risk to the RLN and parathyroid glands. For these reasons elective central neck dissection has been popular in the last few decades. However, increased recognition that performing such surgery in all patients with PTC leads to high rates of morbidity and the lack of evidence that outcomes improve due to more aggressive surgery, has led to a move away from this practice. At this point, patients who are considered at highest risk of having occult metastases in the central neck (those with extrathyroid extension for example) are considered most likely to see benefit from elective surgery and it is not recommended routinely in low-risk patients.

Many patients will only be diagnosed with their thyroid cancer following a diagnostic lobectomy. In this setting, risk assessment is again critical. If the patient is considered low risk, further surgery is unlikely to be beneficial. If, however, patient or tumour features are considered high risk, radioactive iodine may be recommended, in which case completion thyroidectomy may be required.

Given the complexity of decision making in thyroid cancer and the different groups involved (surgeons, endocrinologists, radiologists, cytologists, pathologists and nuclear medicine physicians), all cases should be discussed in a multidisciplinary setting.

Thyroxine

Following surgery, thyroid cells (both normal and malignant) can be suppressed using high doses of thyroxine. This was once considered routine for all differentiated thyroid cancers during follow-up. Again, risk stratification has modified our approach to these patients. Following surgery, patients can be considered high or low risk. For those patients at high risk from disease, thyroxine will be prescribed at levels which suppress TSH without making the patient biochemically hyperthyroid. In contrast, low-risk patients may be considered for thyroxine replacement at physiological levels. In this patient group, a balance of benefit (remember these patients have extremely low rates of recurrence or death) versus risk must be made. In particular, long-term TSH suppression can result in cardiac arrhythmia and osteoporosis. As such the treating team should consider all risks during follow-up to strike this balance.

Low-risk patients who have had lobectomy alone may require no thyroxine at all. Patients who had a total thyroidectomy will clearly require replacement and those considered high risk should be managed with suppression, in order to minimise the chance of disease recurrence.

Radioiodine

Thyroid tissue concentrates iodine. For this reason, ^{131}I can be given in order to deliver tumoricidal doses of radioactivity directly to thyroid tissue, both benign and malignant. In the setting of thyroid cancer, all normal tissue should be removed (total thyroidectomy) along with any gross neck disease (neck dissection) in order for any residual microscopic disease or distant metastases to receive an optimal dose. Radioiodine treatment is not an alternative to surgical resection for gross resectable disease.

As with many aspects of differentiated thyroid cancer management, indications for radioiodine treatment are controversial. Again, low-risk patients have little to gain and

may be safely managed without adjuvant therapy. High- risk patients, however, remain candidates.

In order to effectively drive the radioiodine into cells, high levels of TSH are required. This can be achieved by rendering the patient hypothyroid (off thyroxine) or by using recombinant TSH, which is injected prior to radioiodine administration.

Following radioiodine administration, an uptake scan is performed. This demonstrates areas of iodine uptake in the whole body and can be used to identify any metastatic disease not recognised on initial imaging. This information is useful in the ongoing process of risk stratification of patients following initial therapy.

Outside the setting of primary treatment, radioiodine treatment may be considered in cases of recurrence, particularly if not used initially. Multiple doses can be used in order to treat unresectable disease, distant metastases or even a rising thyroglobulin in the absence of structural disease.

Most differentiated thyroid cancers will concentrate iodine. However, with advancing patient age and particularly if disease is multiply recurrent the tumour will lose its iodine avidity. This is called radioiodine refractory disease. Such cases may be considered for external beam radiotherapy, although this is uncommon.

Thyroglobulin

Thyroglobulin is a tumour marker produced by normal thyroid cells and most differentiated thyroid cancer. As such, this offers an extremely accurate method of following patients postoperatively. If a lobectomy has been performed the level will not be undetectable, but trends can be used to monitor for recurrence. Following total thyroidectomy, the aim is to have an undetectable thyroglobulin. Patients who achieve this point are at extremely low risk of recurrence. Serial thyroglobulin measurement (6–12 monthly) combined with ultrasound assessment of the neck can then be used to monitor patients during follow-up.

If an undetectable level is not achieved, the thyroglobulin can be followed. If it increases, imaging should be performed to look for gross recurrent disease. Resectable disease should be addressed surgically and normally further radioactive iodine (RAI) would be indicated. The role of RAI in a rising thyroglobulin without structural disease is controversial.

Undifferentiated (anaplastic) carcinoma

This is one of the most aggressive malignancies in humans. Thankfully it is rare. It may develop *de novo*, or present as dedifferentiation of a papillary or poorly differentiated carcinoma. The disease is characterised by rapid growth, visceral invasion and distant metastases. The surgeon's role in this disease is crucial. Thyroid lymphoma can be incorrectly diagnosed as anaplastic cancer and so biopsy is critical. This can be done using a core or open technique.

Management is controversial. Almost all patients will be dead within 6 months. Radiotherapy and chemotherapy have not been shown to improve survival. Occasional patients may present with disease limited to the neck, which appears resectable on imaging. Such patients seem to have a slightly better outcome if treated with aggressive surgery and postoperative adjuvant therapy (radiotherapy +/- chemotherapy). However, solid evidence is lacking and the majority of patients will not be considered for curative treatment.

Those patients who have a known diagnosis and develop airway symptoms are generally better managed without tracheostomy, despite the potentially distressing mode of death. In patients who present with airway signs and without a diagnosis, a tracheostomy may be required to buy time to confirm the diagnosis and in order to allow a few more days for patients to 'get their affairs in order'.

Medullary carcinoma

These are tumours of the parafollicular (C cells) derived from the neural crest. rather than the cells of the thyroid follicle as are other primary thyroid carcinomas. The cells are not unlike those of a carcinoid tumour and on histological analysis a characteristic amyloid stroma is seen (**Figure 50.26**). High levels of serum calcitonin and carcinoembryonic antigen are produced by many medullary tumours, which should be tested for in suspected cases. Calcitonin levels fall after resection and rise again with recurrence, making it a valuable tumour marker in the follow-up of patients with this disease. Diarrhoea is a feature in 30% of cases and this may be due to 5-hydroxytryptamine or prostaglandins produced by the tumour cells.

Some tumours are familial and account for 10–20% of all cases. Medullary carcinoma may occur in combination with adrenal phaeochromocytoma and hyperparathyroidism (HPT) (usually due to hyperplasia) in the syndrome known as multiple endocrine neoplasia type 2A (MEN-2A). The familial form of the disease frequently affects children and young adults, whereas the sporadic cases occur at any age with no sex predominance. When the familial form is associated with prominent mucosal neuromas involving the lips, tongue and inner aspect of the eyelids, with a Marfanoid habitus, the syndrome is referred to as MEN type 2B (see Chapter 52).

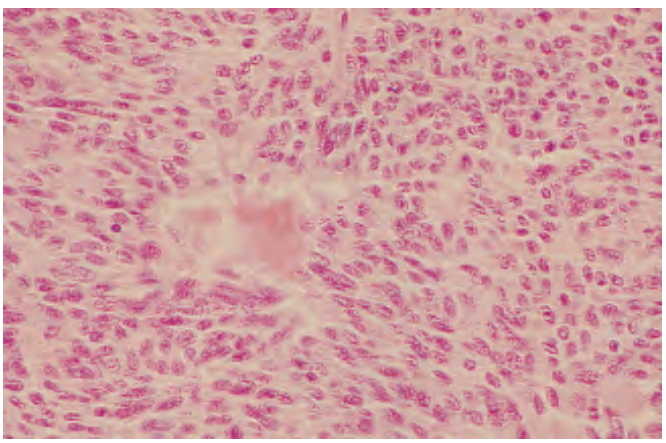

Figure 50.26 Histology of medullary carcinoma showing characteristic 'cell balls' and amyloid (courtesy of Dr SWB Ewen, Aberdeen, UK).

Involvement of lymph nodes occurs in 50–60% of cases of medullary carcinoma and blood-borne metastases are common. As would be expected, tumours are not TSH dependent and do not take up radioactive iodine. The prognosis is variable and depends on the stage at diagnosis. Any nodal involvement virtually eliminates the prospect of cure and, unfortunately, even small tumours confined to the thyroid gland may have spread by the time of diagnosis, particularly in familial cancers. In common with many endocrine tumours the progression of disease may be very slow, with a characteristically indolent course and long survival, even in the absence of cure.

In familial cases of medullary thyroid cancer, genetic screening of relatives should be recommended. This is a complex subject but individuals identified can be risk stratified dependent on the genetic abnormality. This information can be used to make recommendations concerning prophylactic thyroidectomy. Some relatives may be monitored into adulthood with serial calcitonin monitoring. In contrast, the highest-risk mutations are associated with early-onset disease and total thyroidectomy is recommended during infancy.

Treatment

When medullary carcinoma is diagnosed, staging of the neck and chest should be performed. For those patients with disease confined to the thyroid, total thyroidectomy is recommended to remove all C cells. In addition, elective dissection of the central neck nodes is also performed to optimise the chance of cure. If there is evidence of nodal metastases, cure is unlikely. In this setting, gross disease should be excised but the surgeon should be mindful of morbidity. Such patients are highly likely to recur and a pragmatic approach should be adopted.

Malignant lymphoma

In the past, many malignant lymphomas were diagnosed as small round-cell anaplastic carcinomas. Response to irradiation is dramatic **(Figure 50.27)** and radical surgery is unnecessary once the diagnosis is established by biopsy. In patients with tracheal compression, isthmusectomy is the most appropriate form of biopsy although the response to therapy is so rapid that this should rarely be necessary unless there has been difficulty in making a histological diagnosis. The prognosis is good, particularly if there is no involvement of cervical lymph nodes. Rarely, the tumour is part of widespread malignant lymphoma disease and the prognosis in these cases is worse. Most lymphomas occur against a background of lymphocytic thyroiditis.

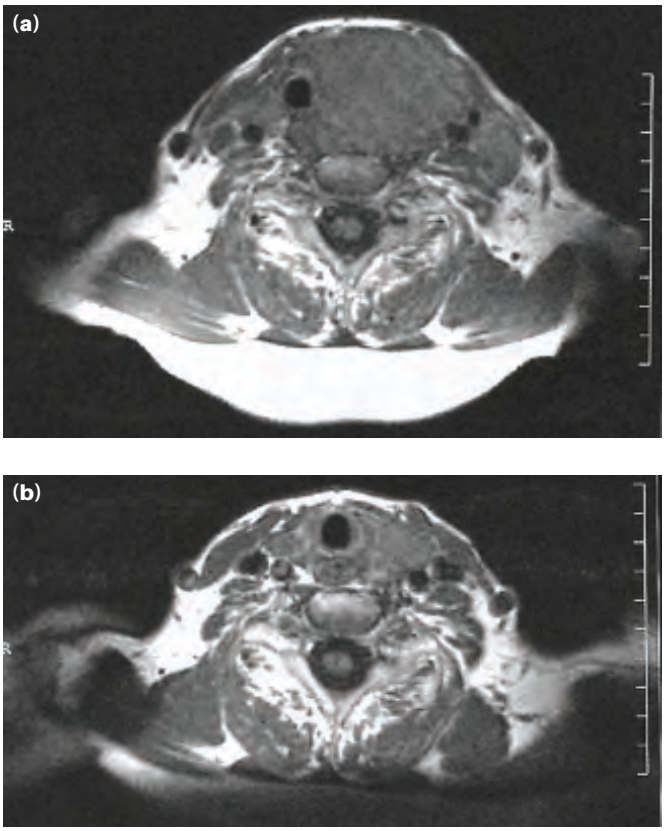

Figure 50.27 Magnetic resonance imaging scans of extensive malignant lymphoma **(a)** before and **(b)** after 7 days of external beam radiotherapy (courtesy of Dr FW Smith, Aberdeen, UK).

THYROIDITIS

Chronic lymphocytic (autoimmune) thyroiditis

This common condition is usually associated with raised titres of thyroid antibodies. It commonly presents as a goitre, which may be diffuse or nodular with a characteristic 'bosselated' feel or with established or subclinical thyroid failure. The diagnosis often follows investigation of a discrete swelling. Features of chronic lymphocytic (focal) thyroiditis are commonly present on histological examination in association with other thyroid disease, notably toxic goitre **(Figure 50.28)**. Primary

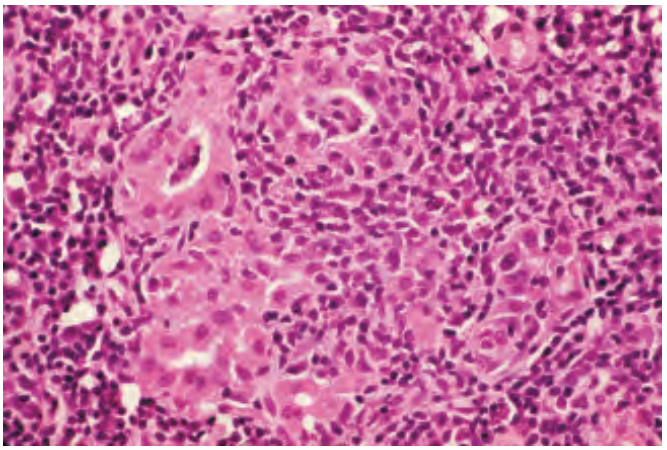

Figure 50.28 Autoimmune thyroiditis (Hashimoto's disease; struma lymphomatosa). Intense lymphocytic-plasma cell infiltration, acinar destruction and fibrosis.

Friedrich Joseph de Quervain, 1868–1940, Professor of Surgery, Berne, Switzerland, described this form of thyroiditis in 1902.

myxoedema without detectable thyroid enlargement represents the end stage of the pathological process.

Granulomatous thyroiditis (subacute thyroiditis, de Quervain's thyroiditis)

This may follow a viral infection. In a typical subacute presentation, there is pain in the neck, fever, malaise and a firm, irregular enlargement of one or both thyroid lobes. There are raised inflammatory markers, absent thyroid antibodies, the serum T_4 is high normal or slightly raised, and the ^{123}I uptake of the gland is low. The condition is self-limiting and, in a few months, the goitre subsides and there may be a period of months of hypothyroidism before eventual recovery. In 10% of cases the onset is acute, the goitre very painful and tender and there may be symptoms of hyperthyroidism. One-third of cases are asymptomatic but for the presence of the goitre. If diagnosis is in doubt, it may be confirmed by FNAC, radioactive iodine uptake and by a rapid symptomatic response to prednisone. The specific treatment for the acute case with severe pain is to give prednisone l0–20 mg daily for 7 days and the dose is then gradually reduced over the next month. If thyroid failure is prominent, treatment with thyroxine may be required until function recovers.

Riedel's thyroiditis

This is very rare, accounting for 0.5% of goitres. Thyroid tissue is replaced by cellular fibrous tissue, which infiltrates through the capsule into muscles and adjacent structures, including parathyroids, recurrent nerves and carotid sheath. It may occur in association with retroperitoneal and mediastinal fibrosis and is most probably a collagen disease. The goitre may be unilateral or bilateral and is very hard and fixed. The differential diagnosis from anaplastic carcinoma can be made with certainty only by biopsy, when a wedge of the isthmus should also be removed to free the trachea. If unilateral, the other lobe is usually involved later and subsequent hypothyroidism is common. Treatment is with high-dose steroid, tamoxifen and thyroxine replacement. Reduction in the size of the goitre and long-term improvement in symptoms are to be expected if treatment is commenced early.

Chapter 51

The parathyroid glands

Learning objectives

To understand:

- The anatomy of the parathyroid glands
- The physiology of calcium regulation
- The underlying causes of hypercalcaemia and appropriate emergency management
- The aetiology, presentation, investigation and management of primary hyperparathyroidism and associated special cases
- The aetiology, presentation, investigation and management of secondary and tertiary hyperparathyroidism
- The aetiology and management of parathyroid carcinoma

INTRODUCTION

The parathyroid glands were first described by Sir Richard Owen in a neck dissection of an Indian rhinoceros at the London Zoological Gardens in 1850. Credit for recognition of the 'glandulae parathyreoidae' goes, however, to Sandström who published a monograph in 1887 on dissection of the parathyroid glands and their blood supply in animals and human cadavers. Unfortunately, Sandström committed suicide at the age of 37 and it was not until the 1890s that his work was rediscovered by Gley, who associated tetany following thyroid surgery with removal of the parathyroid glands. In 1905, MacCallum found that he could relieve postoperative tetany by the injection of parathyroid extract. While the association between parathyroid enlargement and bone disease was reported in 1907, it was not until 1925 that the first parathyroidectomy was performed by Mandl in Vienna on Albert Gahne, a tram conductor with severe primary hyperparathyroidism (PHPT) and osteitis fibrosa cystica.

ANATOMY OF THE PARATHYROID GLANDS

The developmental embryology and surgical anatomy of the parathyroid glands are intimately linked, and knowledge of both is essential for successful surgical treatment of parathyroid disease.

The parathyroid glands, of which there are four, develop from the third and fourth pharyngeal pouches between the fifth and twelfth week of gestation. They are typically described as 'Portland brick' (yellow/brown) in colour and weigh approximately 30 mg. Approximately 13% of the population have abnormal parathyroid tissue, with 5% having a true supernumerary gland. The blood supply of both the superior and inferior parathyroid glands arises from the inferior thyroidal artery. While the location of the individual glands may vary significantly, there appears to be a degree of symmetry between opposite sides that can be helpful during surgical dissection.

The inferior parathyroid gland and the thymus arise from the third pharyngeal pouch. As a result of the longer normal embryological descent, there is correspondingly more variation in their anatomical position. However, in more than 50% of cases they are located at the inferior pole of the thyroid gland, on the anterior, lateral or posterior surface. The gland itself is freely mobile within a globule of fat adjacent to the lower pole **(Figure 51.1a)**.

The superior parathyroid glands arise from the dorsal portion of the fourth pharyngeal pouch. As a result of their more limited embryological descent they are more constant in

position. In more than 80% of patients, the superior parathyroid glands are located at the posterior aspect of the thyroid lobe in an area 2 cm in diameter, centred 1 cm around the junction of the inferior thyroid artery and the recurrent laryngeal nerve in strict proximity to the cricothyroid junction (Figure 51.1b). The parathyroid glands are closely associated with, but contained within, a halo of fat that is freely mobile over the thyroid capsule.

CALCIUM AND PARATHYROID HORMONE REGULATION

The parathyroid glands play a central role in the regulation of serum calcium levels through the production of the active 84 amino-acid peptide, parathyroid hormone (PTH). PTH is secreted in response to low serum calcium or high serum magnesium levels. It is initially cleaved in the liver yielding

an inactive C-terminal that is cleared by the kidneys. The N-terminal fragment is responsible for the biological activity of PTH on peripheral tissues. The active circulating molecule has a half life of approximately 3–5 minutes in patients with normal renal function.

PTH acts directly on the kidneys, bone and the gastrointestinal tract to activate intracellular second messengers, including cyclic AMP and calcium. In the kidneys, PTH increases serum calcium levels by increasing resorption of calcium from the renal tubules and increasing the hydroxylation of 25-hydroxyvitamin D to the biologically active 1,25-dihydroxyvitamin D. Active vitamin D increases both the resorption of phosphorus in the kidneys and the absorption of calcium from the gastrointestinal tract. In the bone, PTH acts on osteoblasts and osteoclasts to increase bone turnover, thereby increasing the amount of calcium in the extracellular space **(Figure 51.2)**.

Calcitonin, which is synthesised by the parafollicular C cells of the thyroid gland, acts as the physiological antagonist to PTH. Calcitonin decreases serum calcium by decreasing bone turnover.

PRIMARY HYPERPARATHYROIDISM

The early descriptions of patients with PHPT were dominated by those with osteitis fibrosa cystica. Brown tumours of the long bones and associated subperiostal bone reabsorption, distal tapering of the clavicles and the classical 'salt and pepper' erosions of the skull were typical findings. Over 80% of patients had associated renal stones, significant neuromuscular dysfunction and muscle weakness. This led to the traditional mnemonic that patients with PHPT presented with 'bones, stones, abdominal groans and psychiatric overtones'. The introduction of the automated serum chemical autoanalyser in the 1970s as well as radioimmune assay to accurately measure circulating PTH levels radically improved early diagnosis of PHPT, such that the majority of patients are now identified incidentally on routine biochemical investigations and are asymptomatic. The current controversies therefore, centre on the indications for intervention, either surgically or medically.

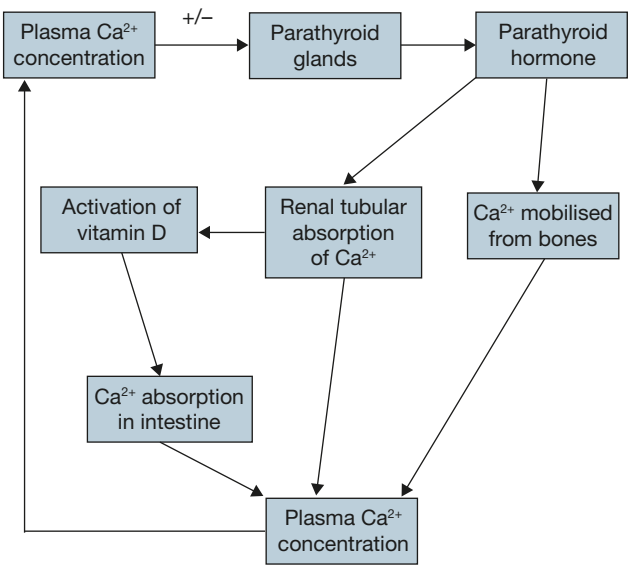

Figure 51.2 Schematic diagram of actions of parathyroid hormone.

Presentation

PHPT is defined as hypercalcaemia in the presence of an unsuppressed and therefore relatively, or absolutely, elevated PTH level. Prevalence of the disease is reported to be 0.2–0.5% with approximately 100 000 new cases per year in the USA. The majority of PHPT is sporadic in nature. Familial disease can occur in multiple endocrine neoplasia (MEN) type 1 or type 2A or as a familial cluster. Patients usually present in the 5th or 6th decades and there is a female predominance with a ratio of 3:1.

Patients are typically identified incidentally with an elevated total calcium or following routine assessment of bone densitometry (DEXA scan). Most patients will, however, have some vague constitutional symptoms, such as fatigue, muscle weakness, depression or some mild memory impairment on questioning. The presence of kidney stones remains the most common clinical manifestation of symptomatic PHPT. Between 15% and 20% of patients will have nephrolithiasis and over 40% of patients will have hypercalciuria. Increasingly, postmenopausal women present with significant osteopenia or osteoporosis in the distal one-third of the radius with a minimal reduction in the lumbar spine, which prompts further investigation. This distribution arises as PTH appears to be catabolic at cortical sites (distal one-third of the radius) and anabolic at cancellous sites (lumbar spine).

PHPT may present with pancreatitis, although it is rarely seen in patients with milder forms of the disease. Common epidemiologically linked disorders, such as hypertension and peptic ulcer disease, are often encountered. Clinical examination is usually normal. Band keratopathy, pathognomonic of the disease and due to deposition of calcium phosphate crystals in the cornea, is now rarely identified.

The differential diagnosis of PHPT includes other causes of hypercalcaemia, which are usually readily distinguishable *(Table 51.1)*. It is important to exclude the presence of a widespread malignancy, in which patients will typically have other symptoms. The exception to this rule is multiple myeloma, in which hypercalcaemia can be the presenting complaint. Improvements in the immuno-radiometric and immunochemiluminometric assays for PTH can help to distinguish these conditions, as in malignancy PTH levels are typically suppressed.

Hypercalcaemic crisis: presentation and management

Hypercalcaemia is documented in 0.5% of the general population and in up to 5% of hospitalised patients. The vast majority are asymptomatic with a mild to moderate elevation of serum calcium (<3 mmol/L and 3–3.5 mmol/L, respectively) and respond to treatment of the underlying aetiology with associated dietary modification. A small proportion of

TABLE 51.1 Causes of hypercalcaemia.

Endocrine	Primary hyperparathyroidism Thyrotoxicosis Phaeochromocytoma
Renal failure	Secondary hyperparathyroidism Tertiary hyperparathyroidism
Malignant disease	Skeletal metastatic disease Multiple myeloma, lymphoma, leukaemia Solid tumours (PTH-related peptide mediated): lung, renal, squamous cell carcinoma of the head and neck, oesophagus, genital tract
Nutritional	Excessive vitamin D ingestion Vitamin A intoxication Milk-alkali syndrome Aluminium intoxication
Granulomatous	Sarcoidosis Tuberculosis
Inherited disease	Hypercalciuric hypercalcaemia
Immobilisation	
Paget's disease	
Drug related	Lithium

patients will present symptomatically with a total calcium of >3.5 mmol/L. This is referred to as a hypercalcaemic crisis and requires aggressive medical management.

Although symptoms can be varied, the typical presentation is of acute confusion, abdominal pain, vomiting, dehydration and anuria. Prolongation of the P–R interval with a shortened Q–T interval can be identified on an electrocardiogram (ECG) prior to potentially lethal cardiac arrhythmias. Where the calcium is >4.5 mmol/L, coma and cardiac arrest can occur.

Treatment revolves around increasing renal excretion of calcium, reducing skeletal release of calcium and treatment of the underlying cause. Aggressive rehydration plays a pivotal role. Typically, 200–500 mL/h of normal saline is given to maintain a urine output >100 mL/h, with the caveat that this may be modified to account for associated patient comorbidities. Once intravascular volume has been adequately restored, loop diuretics, such as furosemide, can be used to enhanced the renal excretion of calcium. The majority of patients will have normalisation of their calcium with these simple measures.

In patients with advanced malignancy and a serum calcium level >3 mmol/L, agents that blunt the release of calcium from skeletal stores may be required. First-line treatment includes administration of bisphosphonates. These are pyrophosphate analogues that inhibit osteoclast activity in areas of high bone turnover. In the acute setting, these are given intravenously due to poor absorption in the gastrointestinal tract. Calcitonin can be used to both decrease osteoclastic activity and increase renal excretion of calcium. It has a short duration of action and is usually used as a bridge to reduce calcium until the sustained action of the bisphosphonates is seen. Finally, glucocorticoids (prednisolone) can be used to enhance the action of calcitonin. They increase calciuresis and decrease intestinal absorption of calcium. As a result, they may also play a role in diseases associated with vitamin D excess.

Pathology

The underlying aetiology of PHPT is usually a solitary parathyroid adenoma; however, in a small number of patients (2–4%) there are double adenomas. It may occur in a sporadic fashion or it can be familial (MEN type 1 or type 2A, hyperparathyroidism-jaw tumour syndrome (HPT-JT)) in nature. The only known risk factor for the development of PHPT is a history of prior neck irradiation. The underlying molecular basis of PHPT is heterogeneous; however, upregulation of cyclin D may lead to a clonal proliferation within the parathyroid glands. This does not alter the set point of calcium but the hyperplasic nature of the parathyroid cells themselves causes excessive secretion of PTH.

Multigland disease is less common, occurring in approximately 15% of patients. No clinical features differentiate single from multigland disease, although multigland disease is more commonly associated with familial syndromes such as MEN types 1 and 2A, as well as the chronic ingestion of lithium.

Diagnosis

PHPT is a biochemical diagnosis. Only when the disease has been confirmed biochemically should localisation studies be undertaken. Positive imaging does not confirm the diagnosis and negative findings cannot rule it out.

PHPT is defined as an elevated total, or more specifically ionised, calcium, in the presence of an inappropriately elevated or unsuppressed PTH. It is associated with a low serum phosphate in the setting of normal creatinine and vitamin D levels; 24-hour urinary excretion of calcium may be normal or elevated. It is important to perform a 24-hour urinary collection to rule out the presence of the rare familial hypocalciuric hypercalcaemia. Alkaline phosphatase may be elevated in patients in whom there is concomitant bone disease. This is important to recognise preoperatively, as the surgeon should anticipate significant postoperative hypocalcaemia due to the development of hungry bone syndrome.

Localisation studies

> "In my opinion, the only localising study required in a patient with untreated primary hyperparathyroidism is to localise an experienced parathyroid surgeon."
>
> John Doppman, 1986

Historically, preoperative localisation studies for PHPT were considered less important than identifying an experienced surgeon. However, with a shift away from the traditional four-

John L Doppman, 1928–2000, radiologist, National Institutes of Health, USA, developed the technique of selective venous sampling for parathyroid localisation.

gland (cervical neck) exploration to more minimally invasive procedures, accurate preoperative identification is critically important to guide surgical strategy.

There are a variety of both non-invasive and invasive studies commonly is use. Non-invasive radiology includes nuclear medicine-based studies, ultrasonography and 4D computed tomography (CT) scanning. Invasive imaging is largely reserved for reoperative surgery and includes ultrasound or CT-guided fine-needle aspiration with concomitant PTH assays, parathyroid angiography or selective venous sampling for the PTH gradient.

Nuclear medicine-based studies (sestamibi scanning)

The use of sestamibi (2-methoxy-2-methylpropylisonitrile (MIBI)) for parathyroid localisation was first described in 1989 and is now regarded as the most accurate and reliable method for imaging the parathyroid glands. It is safe and reproducible and while it has a sensitivity and specificity similar to ultrasound, it may image glands in ectopic positions better **(Figure 51.3a)**.

Sestamibi accumulates in mitochondria and therefore washes out at differential rates depending on the number of mitochondria within individual tissues. Parathyroid adenomas often have a high concentration of oxyphilic cells with high mitochondrial content. These retain tracer and adenomas are therefore associated with a slow washout when compared with the thyroid gland. There are three different protocols for sestamibi scanning: single-isotope dual-phase scan, dual isotope subtraction imaging and single-photon emission computed tomography (SPECT). The sensitivity and specificity of sestamibi, regardless of the protocol used, are 79% and 90%, respectively. False positives are rare but may arise from some solid thyroid nodules, such as Hürthle cell nodules, that are associated with high oxyphilic content. These can be reduced by the addition of a thyroid-specific radioactive tracer, such as ^{99}Tc-pertechnetate and subsequent subtraction images.

Ultrasonography

Ultrasonography is a non-invasive, inexpensive method of imaging the parathyroid glands **(Figure 51.3b)**. Parathyroid adenomas are typically oval or elongated, bi- or multilobed

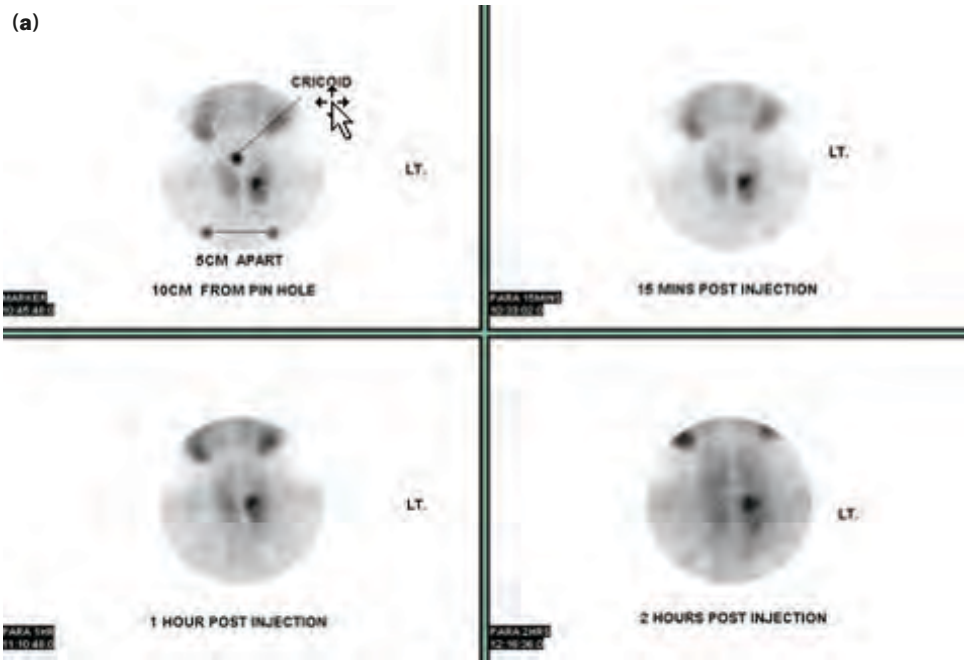

Figure 51.3 Sestamibi scan **(a)** demonstrating right inferior adenoma, with concordant ultrasound **(b)**.

Karl Hürthle, 1866–1945, histopathologist, Breslau, Germany.

hypoechoic structures. Rarely, adenomas may be cystic or heterogeneous in nature. Giant adenomas are described as those over 3 cm in size. Ultrasound is not associated with any radiation exposure and has the advantage of being able to identify and facilitate biopsy of any concomitant thyroid pathology. However, ultrasonography is operator, lesion size and location dependent. Critically, ultrasound may miss adenomas located in retro-oesophageal, retrosternal or retrotracheal areas. It can also be difficult to differentiate between a small parathyroid gland and a normal appearing lymph node. A recent meta-analysis of preoperative localisation techniques in PHPT demonstrated that ultrasound and sestamibi-SPECT have comparable accuracy, with pooled sensitivities of 76.1% and 78.9% respectively, and positive predictive values (PPVs) of 93.2% and 90.7% respectively (Krakauer *et al.*, 2016).

4D Computed tomography scanning

Multiphase CT imaging (4D-CT) has become widely utilised to localise disease (**Figure 51.4**). It gives both anatomical as well as functional information about the parathyroid glands. Using precontrast, postcontrast and delayed images, it demonstrates not only detailed anatomic localisation but, combined with rapid uptake and wash-out, allows hyperfunctioning glands to be differentiated from lymph nodes, which demonstrate a progressive enhancement pattern. The potential disadvantage of 4D-CT scanning is the higher radiation dose when compared with traditional imaging modalities. Modification of the protocol now allows fewer phases to be obtained without compromising outcomes. The initial study in 2006 reported a sensitivity of 88% for lateralisation and 70% for localisation of parathyroid adenomas (Rodgers *et al.*, 2006). A more recent meta-analysis, although limited by the small number of studies, demonstrated a sensitivity and PPV of 89.4% and 93.5% respectively, when 4D-CT was used as the primary imaging modality. This was reduced to 71.8% and 74.9% respectively in cases of negative or inconclusive prior imaging (Cheung *et al.*, 2012).

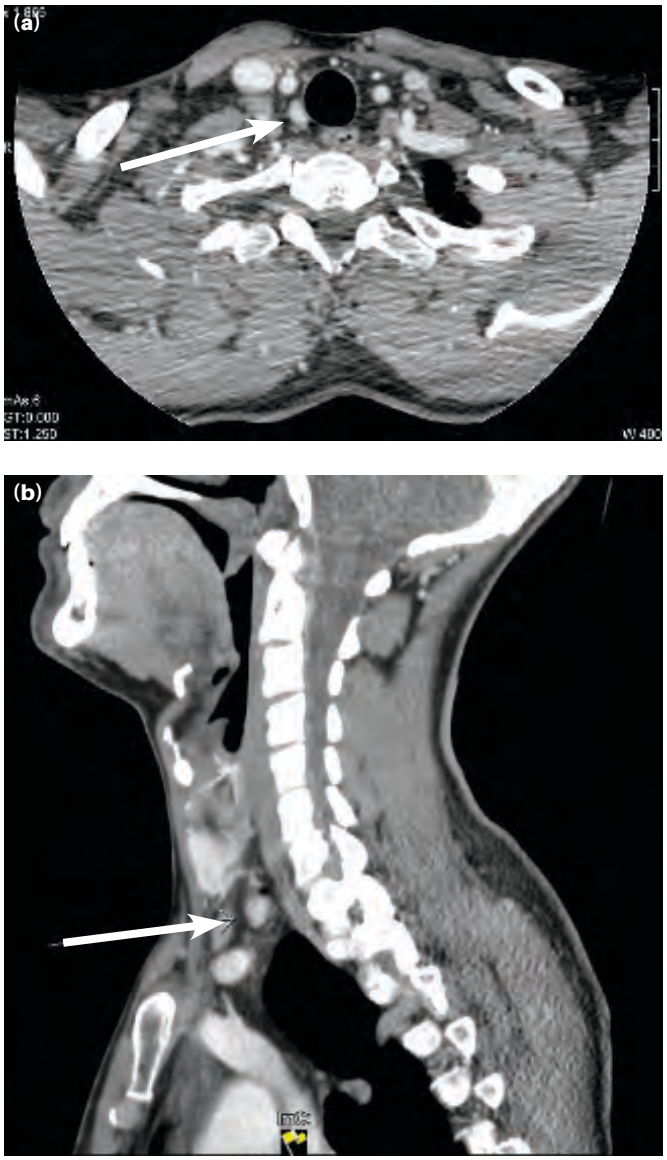

Figure 51.4 (a, b) 4D Computed tomography scanning demonstrating a right inferior parathyroid adenoma (arrows).

Magnetic resonance imaging

Magnetic resonance imaging (MRI) is not commonly used to image the parathyroid glands. However, on T2-weighted images, enlarged parathyroid glands demonstrate significantly increased intensity. In reoperative cases or where the adenoma is located in the mediastinum, MRI may be beneficial, with higher reported sensitivities (50–88%). While the sensitivity of MRI is slightly better than CT (64–88%) in primary disease, it has significant limitations. It is expensive, patients can be poorly compliant due to claustrophobia and the resolution for normal glands or adenomas <5 mm is poor. Similarly, it can be difficult to localise superior glands due to their posterior location, which allows them to be obscured by the thyroid gland.

Parathyroid angiography and venous sampling for PTH

Parathyroid angiography is reserved for reoperative cases and is now rarely required due to improvements in non-invasive imaging modalities. It involves examination of both thyrocervical trunks, both internal mammary arteries and carotids, with occasional selective superior thyroid artery catheterisation. Vascular parathyroid adenomas appear as a persistent oval or round 'stain' on angiography. Serious complications such as contrast-induced renal failure, embolisation and neurological damage have limited its utility.

Selective venous sampling for PTH can allow accurate localisation of adenomas but an experienced interventional radiologist is vital for success. The venous drainage of the lesion is established when there is a two-fold drop in the PTH between the sampled blood and the serum PTH. The sensitivity is reported to be 80% and is equally effective in localising cervical and mediastinal adenomas. However, the false-positive rate of between 6% and 18% limits its utility to reoperative cases.

Management strategies

Surgical management

The mainstay of treatment for PHPT is surgery, addressing the underlying aetiology and allowing not only resolution of biochemical abnormalities but also sustained improvements in end-organ damage. Traditionally a bilateral cervical exploration was performed with reported cure rates of 95–98%. With improvements in preoperative radiological localisation, a more minimally invasive approach has been developed and widely adopted (**Figure 51.5**).

All symptomatic patients should be offered surgery. An expert panel recently published recommendations on which asymptomatic patients should be considered for surgical intervention (*Table 51.2*) (Bilezikian *et al.*, 2014). When criteria have been met and where a single adenoma has been confidently identified by radiological means, a minimally invasive parathyroidectomy may be offered. Conversely, where there is discordant imaging or where imaging fails to identify any parathyroid abnormalities, then a bilateral neck exploration and three and a half-gland parathyroidectomy or a four-gland parathyroidectomy and autotransplantation should be performed.

Consent for a parathyroidectomy must include the possibility of recurrent laryngeal nerve damage (risk <1%), permanent hypoparathyroidism (requiring lifelong calcium and vitamin D supplementation, risk 0.5%), and persistent (5%) or recurrent hyperparathyroidism. Persistent disease is defined as an elevated serum calcium within 6 weeks of surgical intervention and recurrent disease is defined as an increase in calcium levels after 6 months but with an intervening period of normocalcaemia.

MINIMALLY INVASIVE (FOCUSED) PARATHYROIDECTOMY

Minimally invasive approaches are based on the principle that over 80% of individuals with PHPT have a single adenoma. Although there is no strict definition of the procedure, it commonly refers to the removal of a localised abnormal parathyroid gland through an incision less than 3 cm in length (**Figure 51.6**). The term encompasses open approaches (central and lateral incisions), video-assisted and radio-guided parathyroidectomies. A number of randomised studies have shown that the focused approach has similar cure rates to a cervical exploration but with reduced rates of postoperative hypocalcaemia, shorter operating times, potentially less pain and better cosmesis.

The need to convert from a focused to a cervical exploration may be guided by the use of intraoperative PTH measurements. Routine use is, however, controversial due to high false-positive and false-negative rates. The basic concept is that the half life of circulating PTH is 3–5 minutes and there should therefore be a significant drop detected in the plasma PTH following resection of a single adenoma. If no such drop is detected, then

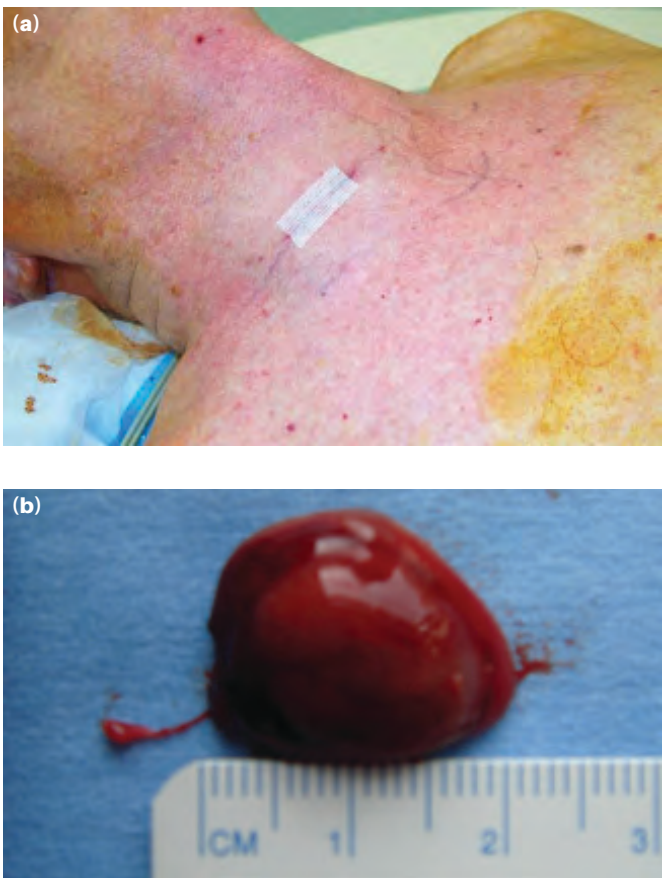

Figure 51.6 **(a)** Minimally invasive parathyroidectomy through a lateral approach; **(b)** the excised parathyroid adenoma.

multigland disease may be suspected and conversion to a bilateral neck exploration should be considered. The Miami criteria were developed to determine the extent of resection. A drop in the PTH into the normal range and to less than half the maximum preoperative PTH at 10 minutes appears to accurately predict single-gland disease (Figure 51.7).

BILATERAL NECK EXPLORATION

A traditional cervical neck exploration is required where imaging is negative or discordant, in MEN (type 1 or type 2A) or in lithium-induced PHPT. A transverse collar (Kocher's) incision is made and the subplatysmal plane developed. The deep cervical fascia is divided between the strap muscles and these are retracted. The thyroid lobes are mobilised and the middle thyroid vein may be divided when present.

Identification of the recurrent laryngeal nerve and the middle thyroid artery allows a starting point for a systematic exploration. All four glands are identified. Three and a half glands are resected, with half of a vascularised parathyroid left *in situ*. The other half of the gland should be sent for frozen section to confirm the presence of parathyroid tissue (Figure 51.8). Ideally the most normal appearing parathyroid is left *in situ*. With this caveat in mind, where possible an inferior gland should be left. It is marked with a non-absorbable suture to aid identification in the presence of recurrent disease, where resection can be achieved without increasing the risk of damage to the recurrent laryngeal nerve. Alternatively, all four glands can be resected and a forearm autotransplant created. Small pieces of parathyroid are sutured into pockets created in the brachioradialis muscle. Cure rates, persistent and recurrent disease appear to be similar, regardless of the type of procedure use. However, in recurrent disease it can be difficult to identify the location of the recurrent tissue when an autotransplant is performed.

THYMECTOMY AND RESECTION OF MEDIASTINAL ADENOMAS

The incidence of clinically significant supernumerary glands is increased in patients with multigland disease or those with hereditary syndromes. A thymectomy should be routinely undertaken for patients with MEN 1-associated PHPT or in secondary hyperparathyroidism. A cervical thymectomy is performed by dissecting close to the thymic capsule, exploring the cervical part of the gland. The mediastinal part of the gland can be removed by gentle upwards traction, with ligation of the veins draining into the innominate vein. The end of the gland is tapered and rarely requires formal ligation. A median sternotomy is not required where a prophylactic thymectomy is being performed.

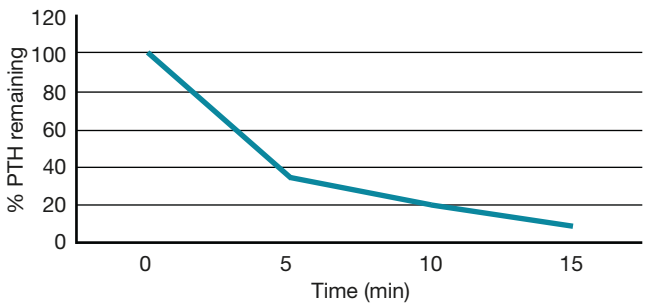

Figure 51.7 Miami criteria for intraoperative parathyroid hormone (PTH) measurement. Drop of PTH into the normal range and less than half the maximum value at 10 min postresection.

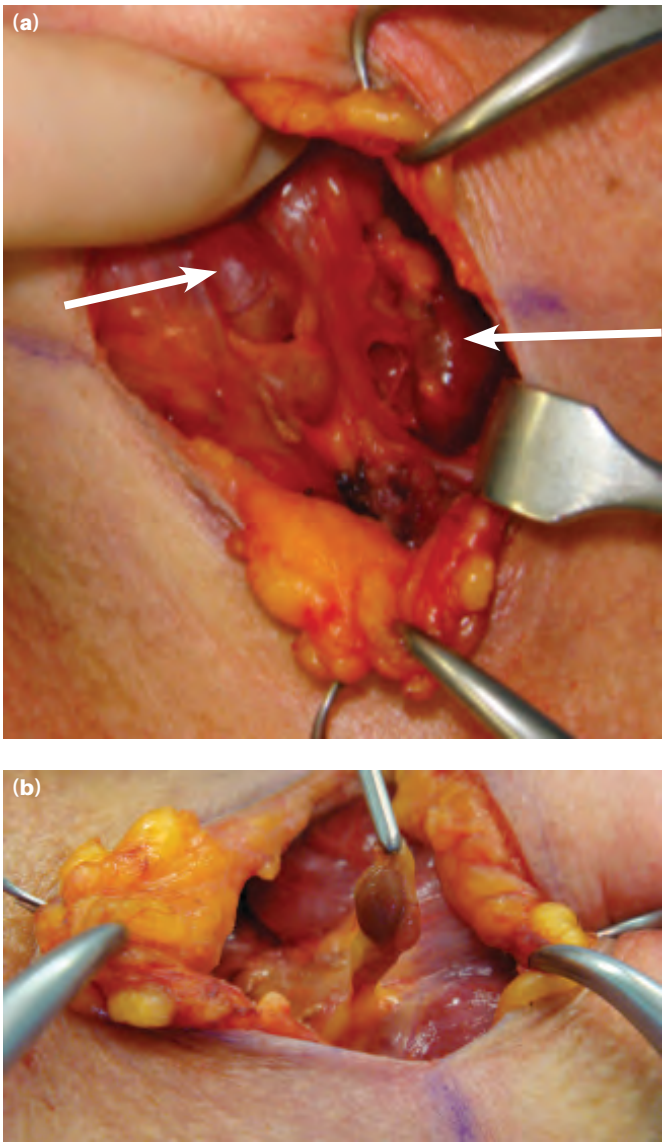

Figure 51.8 Parathyroidectomy with exposure of the left superior and inferior parathyroid glands (white arrows) *in situ* **(a)** and left superior gland mobilised on its vascular pedicle **(b)**.

Mediastinal adenomas are rare, accounting for less than 1% of all parathyroid adenoma. They will be typically identified on preoperative imaging. Resection can either be achieved by an open sternotomy or increasingly by a thoracoscopic approach. A minimally invasive approach can be particularly effective where the abnormal gland lies immediately deep to the mediastinal pleura. It can confer significant advantages in length of hospital stay and complication rates.

Permanent hypoparathyroidism

Permanent hypoparathyroidism is defined as the continuing need for calcium and/or vitamin D replacement at 1 year

postoperatively. It is a rare complication when surgery is undertaken for PHPT (0.5%), but in secondary hyperparathyroidism it can range from 4% to 12%. Symptoms and signs relate to serum calcium levels. Symptoms include mild circumoral or digital numbness and paraesthesia, carpopedal or laryngeal spasms and cardiac arrhythmias. Chvostek's and Trousseau's signs may be elicited. Chvostek's sign refers to contraction of the ipsilateral facial muscles on percussion of the facial nerve below the zygoma. Trousseau's sign refers to the development of carpopedal spasm secondary to occlusion of the arm (usually with a blood pressure cuff).

Biochemical investigations include total and ionised calcium levels as well as serum magnesium levels. An ECG may demonstrate a prolonged QT interval or QRS complex changes. Mild hypocalcaemia can be treated with oral calcium and vitamin D supplementation. Acute symptomatic hypocalcaemia is an emergency and should be corrected with intravenous as well as oral calcium and vitamin D replacement. Traditionally, 10 mL of 10% calcium gluconate is administered slowly intravenously. Supplemental magnesium may also be required, due to the synergistic action of transporters for calcium and magnesium.

Medical management

Medical management is warranted in patients who are deemed unfit or who have contraindications to surgical intervention, in patients with failed surgical intervention or in the long-term management of parathyroid carcinoma. The aims are to prevent skeletal complications (improve bone mineral density and reduce fracture risk) and to stabilise biochemical parameters. There are only limited data on the long-term efficacy of such an approach as surgery is known to provide durable responses.

BISPHOSPHONATES

Bisphosphonates are pyrophosphate analogues that are concentrated in areas of high bone turnover. They inhibit osteoclast activity and apoptosis, thereby increasing bone mineralisation and reducing bone turnover. Studies looking at the management of PHTP utilising bisphosphonates are limited by small numbers and short follow-up. However, use does appear to stabilise bone mineral density without markedly altering the underlying serum biochemistry.

HORMONE REPLACEMENT THERAPY AND SELECTIVE OESTROGEN RECEPTOR ANTAGONISTS

Hormone replacement therapy (HRT) has been shown to improve bone mineral density and reduce the associated fracture risk in postmenopausal women by reducing bone turnover. Two non-randomised controlled trials have shown a durable and similar response to surgery for PHTP at 4 years, with improvements in bone mineral density but without any improvement in the underlying serum biochemistry. The rational for the use of selective oestrogen receptor antagonists (SERMs) is that they should confer the benefits of HRT but without the potential adverse vascular and breast effects. The effect on the bone mineral, however, appears to be less significant than that of HRT.

CALCIMIMETICS

The extracellular calcium sensing receptor (CaR) on the parathyroid cell surface negatively regulates secretion of PTH. Activation of the receptor decreases secretion of PTH, thereby decreasing bone turnover. Calcimimetics, such as cinacalcet, amplify the sensitivity of the CaR to extracellular calcium, altering the set point and thereby decreasing PTH production. The use of calcimimetics has gained widespread acceptance in secondary hyperparathyroidism, but use in PHTP is largely limited to patients unfit for surgery. Despite this, a number of small studies have shown normalisation of PTH levels and a reduction in bone remodelling, with durable results at 2 years, with the use of cinacalcet. Drug tolerance, especially gastrointestinal side effects, can be problematic and may limit the duration of usage.

SPECIAL CASES

Lithium-induced hyperparathyroidism

Lithium-induced hyperparathyroidism occurs in 10–15% of patients treated with long-term lithium. It is generally associated with a mild elevation in calcium with failure to suppress PTH. The underlying aetiology can be either gland hyperplasia, with lithium originally thought to stimulate all parathyroid tissue, or a single adenoma which has been shown to occur in 33–49% of cases. It has recently been suggested that the hyperparathyroidism may be caused by interference with the parathyroid kinase C signal transduction system and the Wnt pathway. Biochemical abnormalities may resolve with discontinuation of lithium. Surgery is indicated where ongoing treatment with lithium is required or where abnormalities persist following withdrawal of lithium. Minimally invasive surgery is relatively contraindicated in these patients due to the high incidence of multigland disease. Excision, however, should be limited to those glands that are obviously enlarged at exploration rather than a formal three and a half-gland excision.

Familial syndromes

Familial hyperparathyroidism can be part of a well-recognised endocrine disorder, but it may also occur in isolation in a non-syndromic form. PHPT occurs as a central facet in multiple MEN 1, MEN 2A, HPT-JT and familial hypocalciuric hypercalcaemia (FHH).

Familial isolated hyperparathyroidism

Isolated familial hyperparathyroidism occurs when patients have PHPT without any other associated endocrinopathies.

Frantisek Chvostek, 1835–1884, physician, The Jasefsacademie, Vienna, Austria.
Armand Trousseau, 1801–1867, physician, Hôtel Dieu, Paris, France.

The underlying genetic abnormality has yet to be fully elucidated, but the syndrome has been linked to known mutations in the *MEN 1* gene, the *HRPT2* gene as well as the calcium-sensing receptor gene. A significant proportion of patients will belong to the MEN 1 family, with documented recognised mutations but without expression of other endocrinopathies. Hyperparathyroidism should be treated with a formal bilateral neck exploration and management as per patients with MEN.

MEN 1-associated hyperparathyroidism

MEN 1 is a rare autosomal dominant syndrome consisting of tumours of the parathyroids, endocrine pancreas–duodenum and the pituitary (the three Ps). It occurs in approximately 1 per 30 000 individuals. It can also be associated with adrenal adenomas or carcinoma, foregut carcinoids and lipomas. Mutations, of which there are over 1000 identified in different families, occur in the *MEN 1* gene, which encodes the protein menin. Menin acts as a tumour suppressor. Patients typically present with young onset (20–30 years of age) of symptomatic hyperparathyroidism and over 95% of patients will have PHPT before the age of 40 years.

Surgical intervention in MEN aims to obtain and maintain normocalcaemia for the longest time possible. In general, it is associated with the presence of multigland parathyroid disease and as such has mandated a bilateral cervical exploration with at least a subtotal parathyroidectomy and cervical thymectomy. A total parathyroidectomy and forearm autotransplantation is an acceptable alternative. Half of the most normal appearing parathyroid should be left *in situ* with a marking stitch to facilitate reoperative intervention. Detailed intraoperative notes, including diagrams, should be kept. Despite meticulous and extensive surgery, the rates of both persistent and recurrent disease remain high in this group of patients (up to 62%) regardless of the type of surgery performed. Unfortunately, the rates of postoperative permanent hypocalcaemia are also high, with published rates up to 47%.

MEN 2A-associated hyperparathyroidism

MEN 2A consists of medullary thyroid carcinoma, unilateral or bilateral phaeochromocytomas and PHPT. PHPT occurs in approximately 20% of patients and is associated with mutations in codon 634 in the *RET* proto-oncogene. The majority of patients will be asymptomatic, with a mild elevation in calcium and asymmetrically enlarged parathyroid glands. It is extremely important that the presence of a phaeochromocytoma is excluded prior to surgical intervention. Surgery is usually performed for medullary thyroid carcinoma (MTC), with the parathyroid enlargement often being a coincidental intraoperative finding. In this setting, with extensive surgery for MTC, the primary aim of treatment is to avoid hypoparathyroidism. A conservative stance is adopted with resection of grossly enlarged glands, but with preservation of parathyroid tissue where possible and identification with a marking stitch in the neck.

Hyperparathyroid-jaw tumour syndrome

HPT-JT is a rare cause of PHPT. It arises due to inactivating mutations in the *HRPT2* gene on chromosome 1 q21-32, encoding parafibromin. It classically presents with early-onset PHPT (mean age of 32 years), the aetiology of which can be either single- or multiple-gland disease but is predominantly cystic in nature. It presents with severe hypercalcaemia and is associated with an increased risk of an underlying parathyroid carcinoma. Approximately 40% of patients will have the pathognomonic ossifying jaw fibromas of the maxilla or mandible. Other associated abnormalities include renal pathology (hamartomas, polycystic kidney disease and adult Wilms' tumours) and female patients may have uterine malignancies. Surgical intervention involves removal of all enlarged parathyroid glands.

Where there is concern for a parathyroid carcinoma, great care must be taken to avoid tumour spillage. Whether or not an *en bloc* resection of the enlarged suspicious parathyroid and the adjacent thyroid lobectomy is required remains controversial.

Familial hypocalciuric hypercalcaemia

FHH is not a surgical disease and therefore preoperative diagnosis is imperative for the surgeon. FHH arises as a result of heterozygous mutations in the calcium receptor gene (*CASR*) on chromosome 3. Benign familial hypocalciuric hypercalcaemia typically presents with mild hypercalcaemia in young (<10 years of age) asymptomatic patients. Patients with FHH have a normal or slightly elevated PTH level, increased serum magnesium levels and hypocalciuria. A low urinary calcium/creatinine clearance ratio is used to discriminate between FHH and mild PHPT. Patients rarely require intervention and surgical intervention is not indicated.

Summary box 51.1

Primary hyperparathyroidism

- Presentation is now typically asymptomatic rather than the classical 'bones, stones, abdominal groans and psychiatric overtones'
- The diagnosis of primary hyperparathyroidism is a biochemical one
- Presence of an elevated ionised calcium with an inappropriately elevated/not suppressed PTH level confirms the diagnosis
- Sestimibi and focused neck ultrasound are the first-line radiological investigations
- 85% of cases are due to a single adenoma
- Minimally invasive parathyroidectomy is a safe and acceptable alternative to a four-gland exploration in the presence of localised disease
- Familial syndromes and disease that is not localised require a formal four gland exploration and three and a half gland parathyroidectomy

Max Wilms, 1867–1918, Professor of Surgery, University of Heidelberg, Germany.

SECONDARY HYPERPARATHYROIDISM

Secondary hyperparathyroidism is defined as a derangement in calcium homeostasis, which leads to a compensatory increase in PTH secretion. It occurs primarily as a result of chronic kidney disease and is therefore sometimes referred to as renal hyperparathyroidism. Other underlying causes include gastrointestinal malabsorption, vitamin D deficiency, liver disease or chronic lithium usage.

The pathogenesis of secondary hyperparathyroidism is related to renal dysfunction. Abnormalities in the renal tubular absorption of phosphate lead to hyperphosphataemia. This acts directly on the parathyroid cells and stimulates PTH secretion. More recent translational research has identified a novel phosphaturia hormone, fibroblast growth factor 23 (FGF 23). This is progressively secreted from osteocytes to compensate for chronic phosphate retention that in turn leads to a reduction in 1,25-dihydroxyvitamin D, which by reducing the intestinal absorption of calcium, also acts to increase secretion of PTH. Previous studies in patients with chronic renal disease have shown that there is a reduction in the expression of the vitamin D receptor and the CaR, with associated skeletal resistance to PTH. These factors interact to form the complex pattern leading to progressive secondary hyperparathyroidism in the setting of chronic renal disease.

The pathological characteristics associated with secondary hyperparathyroidism include hyperplasia, asymmetrical glandular enlargement or nodularity. This differentiation is important, as when the parathyroid gland becomes nodular it loses expression of the vitamin D and Ca receptors. It has been proposed that nodular parathyroid glands may be resistant to calcimimetics and therefore be refractory to medical management.

Diagnosis

The classical symptoms associated with secondary hyperparathyroidism are seen less commonly now, with greater awareness of the disease and the resultant earlier medical intervention. However progressive bone disease, especially bone pain, can occur with associated soft tissue calcium deposits **(Figure 51.9)**.

The diagnosis of secondary hyperparathyroidism is characterised by hypocalcaemia or normocalcaemia with an elevated PTH. Patients have a high serum phosphate and a low vitamin D. Traditional plain x-rays now rarely demonstrate the pathognomonic osteitis fibrosa cystica. However, bone densitometry (DEXA scan) typically demonstrates osteopenia or osteoporosis.

The diagnosis of secondary hyperparathyroidism is a biochemical one. In general, localisation studies are not undertaken as minimally invasive surgery is not indicated. However, a neck ultrasound can be performed to identify patients with nodular hyperplasia who may be refractory to medical management. Localisation studies are helpful in patients with recurrent disease, in order to identify ectopic parathyroid tissue, especially in the mediastinum. In cases of recurrent disease, when there is no evidence of active disease in the neck, and a previous allograft has been used to the forearm, then selective venous sampling for PTH in the neck and the brachial vein on the side of the graft can be useful. This is known as the Casanova test and to prove that the recurrent disease is located in the grafted arm (graft hyperplasia) the ratio must be greater than 20:1.

Figure 51.9 Secondary hyperparathyroidism. X-ray showing ectopic calcification.

Calciphylaxis

Calciphylaxis (calcific uraemic arteriolopathy) is a syndrome of disseminated calcification resulting in both vascular calcification and skin necrosis. It accounts for approximately 4% of patients undergoing surgical intervention for secondary hyperparathyroidism. It presents with expanding painful cutaneous purpuritic lesions, predominantly on the extremities, although it can also be seen on the lower abdomen. The underlying tissue calcification within the arteriolar and small vascular walls leads to ischaemic necrosis and the development of gangrene, which in turn leads to overwhelming

Daniel Casanova, contemporary, University of Cantabria, Santander, Spain.

sepsis and death. The majority of these patients will have an elevated calcium × phosphate product but it is not usually associated with an extremely high PTH level. The underlying aetiology remains unclear but a number of potential factors have been postulated. A reduction in the serum levels of a calcification inhibitory protein, α-2-Heremans–Schmid glycoprotein, and abnormalities in smooth muscle cell biology in uraemic patients may play a role in the development of the syndrome. Prognosis for these patients is extremely poor, with a mortality of up to 87%. An urgent parathyroidectomy has been shown to decrease pain, improve wound healing and reduce the risk of amputation in these patients. It has also been associated with an increase in median survival.

Management

Renal transplantation remains the only definite treatment for secondary hyperparathyroidism. Other therapies are a bridge to this or aim to provide symptom relief. Standard management includes replacement of calcium and vitamin D and the reduction of phosphate levels by the use of phosphate binders. Treatment of this disease changed radically with the introduction of calcimimetic drugs, such as cinacalcet. Calcimimetics alter the set point of the CaR, thereby reducing the constant stimulation of the parathyroid glands and lowering the PTH level. This obviously does not address the underlying renal disease. It remains controversial as to which patients may benefit from the use of calcimimetics and which patients may benefit from earlier surgical intervention. Indications for pursing medical management include those patients who are deemed non-surgical candidates by reason of medical comorbidities. Similarly, where there is persistent or recurrent disease, the origin of which cannot be clearly elucidated, surgical management should be avoided. However, there are definite indications for surgical intervention in secondary hyperparathyroidism (*Table 51.3*) although these have been modified to reflect the current use, where available, of calcimimetics (*Table 51.4*).

TABLE 51.3 Indications for surgical intervention in secondary hyperparathyroidism.

Essential components
1. Persistently high serum level of intact PTH >500 pg/mL 2. Hyperphosphataemia (serum P >6 mg/dL) or hypercalcaemia (serum Ca >2.5 mmol/L or 10 mg/dL) which is refractory to medical management 3. Estimated volume of the largest gland >300–500 mm^3 or long axis >1 cm
Clinical findings
If patients have one of these symptoms, parathyroidectomy should be recommended: Severe osteitis fibrosa with associated high bone turnover Subjective symptoms (bone and joint pain, arthralgia, muscle weakness, irritability, puritis, depression) Progressive ectopic calcification Calciphylaxis Progressive reduction in bone mineral content Anaemia resistant to erythropoietin stimulating agent (ESA) Dilated cardiomyopathy/cardiac failure

TABLE 51.4 Proposed indications for surgical management of secondary hyperparathyroidism (SHPT) in the era of calcimimetics.

When SHPT is refractory to vitamin D replacement or vitamin D analogues and prolonged survival is anticipated
Severely impaired quality of life due to either SHPT or intolerance to calcimimetics
When sufficient reduction in parathyroid hormone cannot be achieved with use of calcimimetics
Thyroid surgery is also required (thyroid carcinoma)

There are a wide variety of operations that can be utilised for the management of secondary hyperparathyroidism, none of which appears significantly superior in terms of clinical outcomes (persistent or recurrent disease). These include a subtotal parathyroidectomy, a total parathyroidectomy with autograft or a total parathyroidectomy without autograft. Cryopreservation of resected tissue, where available, should be performed in case of significant postoperative hypocalcaemia. The first two procedures are most widely accepted and the type of operation performed depends upon the surgeon.

A subtotal parathyroidectomy is where three and a half parathyroid glands are excised, with the remnant being marked with a non-absorbable stitch to facilitate identification in the event of recurrent disease. A biopsy of the final gland that is to be left *in situ* is mandatory to confirm the presence of residual parathyroid tissue. Ideally an inferior gland is left *in situ* to facilitate reoperative surgery and minimise potential damage to the recurrent laryngeal nerve in that setting (**Figure 51.10**). A total parathyroidectomy with a forearm autograft involves removal of all parathyroid tissue in the neck, with reimplantation of a small amount of morcellated tissue within a pocket formed in the brachoradialis muscle. Overall, regardless of the operative approach utilised the cure rate ranges between 90% and 96%, with similar complication rates. A randomised study looking at 40 patients who either underwent a subtotal or total parathyroidectomy with autotransplant demonstrated no significant difference between the two operations in terms of efficacy and recurrence rate (Rothmund *et al.*, 1991).

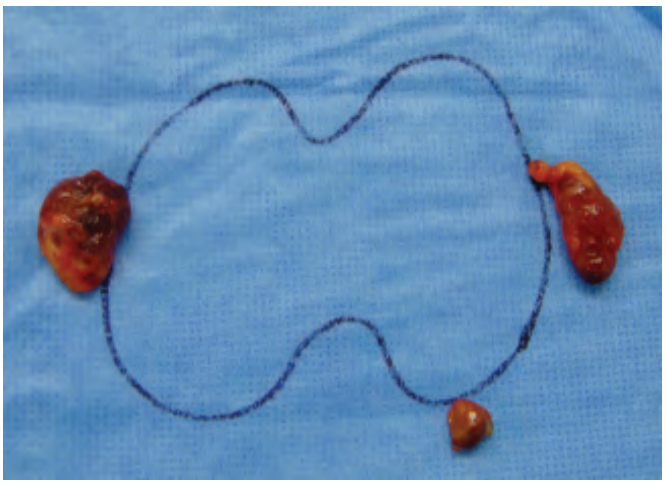

Figure 51.10 Subtotal parathyroidectomy for parathyroid hyperplasia. Right inferior gland biopsied and half left *in situ*.

The response to surgical intervention is often dramatic. The biochemical parameters may resolve almost immediately and appear to be sustained for up to 3 years postoperatively. Patients subjectively report improvements in the symptoms of secondary hyperparathyroidism including bone pain, pruritus, fatigue and depression. Finally, bone metabolism is improved with an approximate 10% increase in trabecular bone, with almost immediate suppression of bone resorption and acceleration of new bone formation.

Summary box 51.2

Secondary hyperparathyroidism

- Primarily due to underlying chronic kidney disease
- Associated with parathyroid hyperplasia
- Diagnosis is made biochemically with a low or normal calcium and an elevated PTH. High phosphate levels and low vitamin D levels are seen
- No localisation studies are required
- Mainstay of treatment is renal transplantation. Medical management with calcium and vitamin D replacements and phosphate binders is a bridge to transplantation
- Use of calcimimetics has reduced the requirement for surgical intervention
- Subtotal parathyroidectomy remains the surgical intervention of choice when indicated

TERTIARY HYPERPARATHYROIDISM

Tertiary hyperparathyroidism is a persistent autonomous hypercalcaemic hyperparathyroidism occurring after kidney transplantation. A number of proposed factors may prevent involution of the hyperplastic parathyroid glands following resolution of the underlying renal impairment. These include impaired graft function, non-suppressible PTH secretion, slow involution of enlarged glands or insufficient calcitriol conversion by the transplanted kidney.

The biochemical diagnosis is confirmed by an elevated total or ionised calcium, with an associated elevated or unsuppressed PTH and a reduced phosphate occurring at least 1-year post renal transplantation. Differentiation from PHPT can be difficult. Fewer than 1% of patients with tertiary hyperparathyroidism will require surgical intervention (*Table 51.5*). The only new evidence for intervention is the presence of nodular hyperplasia of the glands themselves. Traditionally, localisation studies or imaging of the neck was not indicated in tertiary hyperparathyroidism. However, increasing knowledge of the clonal nature of gland hyperplasia suggests that where there is a nodule within the parathyroid with a volume of tissue greater than 500 mm^3, then resolution of electrolyte abnormalities is unlikely.

TABLE 51.5 Indications for surgical intervention in tertiary hyperparathyroidism.

Subacute severe hypercalcaemia (>3 mmol/L)
Impaired graft function
Nodular hyperplasia of the parathyroid gland(s)
Progressive symptoms (>2 years following transplantation)
Worsening bone disease (pain, fractures, bone loss)
Renal stones/nephrocalcinosis
Soft tissue or vascular calcifications

The use of calcimimetics in tertiary hyperparathyroidism remains controversial and has not been approved for this indication. However, isolated reports have documented control of hypercalcaemia with minimal side effects in individual patients. Surgical intervention remains the definitive management strategy. Subtotal parathyroidectomy or total parathyroidectomy with autotransplantation are acceptable surgical options. The majority of endocrine surgeons will opt for a subtotal parathyroidectomy in this setting, leaving a gland approximately four times normal in volume to minimise postoperative complications. Total parathyroidectomy without an autograft is not a treatment option due to the postoperative and persistent difficulties in managing the associated hypocalcaemia.

Summary box 51.3

Tertiary hyperparathyroidism

- Persistent autonomous hypercalcaemic hyperparathyroidism occurring after kidney transplantation
- Diagnosis is made by demonstrating an elevated total or ionised calcium with an associated elevated or unsuppressed PTH and a reduced phosphate occurring at least 1-year post renal transplantation
- Localisation studies are not required but a focused neck ultrasound may confirm the presence of nodular enlargement
- Surgical intervention remains the mainstay of treatment and involves a subtotal parathyroidectomy

PARATHYROID CARCINOMA

Parathyroid carcinoma is a rare malignancy occurring in approximately 1% of cases of PHPT, with an estimated prevalence of 0.005% of all cancers. While the aetiology remains unclear, recent advances in molecular biology suggest that there may be an underlying genetic basis. Currently, a history of previous neck irradiation remains the only known environmental risk factor. However, given that it can arise in patients with end-stage renal disease as well as in those with MEN type 1, malignant transformation in hyperplastic glands may also occur.

A significant proportion of patients (>10%) with a parathyroid carcinoma will have HPT-JT. The underlying mutation is in the *HRPT2* gene at 1q25-32, a tumour suppressor gene that encodes the protein parafibromin. Parafibromin is involved in the regulation of cellular transcription and histone modification. *HRPT2* mutations, leading to inactivation of parafibromin, are therefore an important contributor to the pathogenesis of parathyroid carcinoma.

Parathyroid carcinoma remains difficult to diagnose preoperatively as it biochemically resembles PHPT. There are, however, a number of suggestive features. Firstly, the diagnosis is typically made a decade earlier, with an equal gender preponderance (female:male 1:1) when compared to PHPT.

Secondly, a greater proportion of these patients will be symptomatic at presentation. A palpable neck mass is found in 36–52% of patients with parathyroid carcinomas but rarely (<5%) in cases of PHPT. Finally, the biochemical abnormalities tend to be exaggerated with an average total calcium of between 3.75 and 3.97 mmol/L and a PTH level 5–10 times the normal range.

The leading cause of morbidity and mortality from parathyroid carcinoma is hypercalcaemia, due to inappropriate PTH secretion. Treatment is focused on controlling hypercalcaemia and removal of the carcinoma where possible. Surgery remains the mainstay of treatment for primary presentations and locally recurrent disease. Complete resection of the tumour avoiding spillage is vital in preventing seeding and thus recurrent disease. *En bloc* resection of the tumour, associated thyroid lobectomy and central neck dissection remains controversial. Traditionally, complete R0 resection was thought to provide the only means of a cure. However, a number of recent studies have failed to demonstrate an improvement in local recurrence rates with such comprehensive resection. Adjuvant chemotherapy has not been shown to confer a disease-free or overall survival benefit. Use of external beam radiotherapy should be considered on an individual basis. Traditionally, it has not been deemed effective, but more recent single institution case series appear to challenge this assumption. It may be considered where it is difficult to achieve a complete surgical resection or in patients with multifocal recurrent soft tissue deposits.

Histological confirmation of a parathyroid carcinoma remains difficult. The classical description included trabecular architecture, mitotic figures, thick fibrous bands and capsular and vascular invasion. However, these findings can be non-significant and new molecular markers may aid the diagnosis and stratify patients for more intensive follow-up (Figure 51.11). Immunohistochemical evidence of down-regulation of parafibromin has a sensitivity of 67% and a specificity of 100% for detecting parathyroid carcinoma and the protein gene product 9.5 (PGP 9.5). Parafibromin immunohistochemistry may be used with immunohistochemistry for PGP 9.5. This is a protein encoded by *ubiquitin carboxyl-terminal esterase L1*. It is upregulated in parathyroid carcinoma and has a sensitivity of 78% and a specificity of 100%

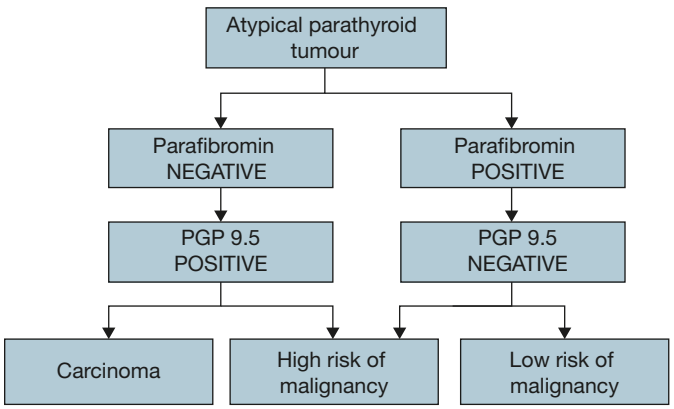

Figure 51.11 Proposed decision tree for atypical parathyroid tumours using parafibromin and PGP 9.5 immunostaining.

(Figure 51.11). All parafibromin-negative and PGP 9.5-positive tumours should be considered for genetic screening.

Parathyroid carcinoma is an indolent but progressive disease. Metastatic spread can occur to the lungs, liver and bones. Recurrence rates range from 33% to 80% and it typically occurs in the first 3 years. Overall survival is reported to be 85–90% at 5 years and 49–77% at 10 years.

Summary box 51.4

Parathyroid carcinoma

- Accounts for approximately 1% of all cases of primary hyperparathyroidism
- A history of previous neck irradiation remains the only known environmental risk factor
- The tumours remain difficult to diagnose preoperatively as they biochemically resemble primary hyperparathyroidism
- Treatment is focused on controlling hypercalcaemia and removal of the carcinoma where possible
- Surgery remains the mainstay of treatment for primary presentations and locally recurrent disease. Complete resection of the tumour avoiding spillage is vital in preventing seeding and thus recurrent disease

PERSISTENT HYPERPARATHYROIDISM

Persistent hyperparathyroidism is defined as an elevated calcium within 6 weeks of surgical intervention. For all parathyroid operations (minimally invasive parathyroidectomy (MIP) and bilateral exploration) the rate of persistent hypercalcaemia is approximately 6% in sporadic disease and between 16% and 20% in hereditary disease. It usually arises as a result of a technical error during the first operation, either due to a missed adenoma or asymmetrical disease. When this occurs all preoperative biochemistry, radiological imaging, intraoperative findings and pathology must be carefully reviewed. If reoperation is appropriate, repeat imaging of the neck and mediastinum is required (sestamibi, ultrasound and 4D-CT scanning). Surgical intervention can be straightforward where there are intact tissue planes, such as following a minimally invasive parathyroidectomy. Complications, including recurrent laryngeal nerve damage and permanent hypocalcaemia, are increased when extensive previous dissection has occurred and the patient must be consented appropriately.

RECURRENT HYPERPARATHYROIDISM

Recurrent hyperparathyroidism is defined as hypercalcaemia occurring 6 months after surgery but with an intervening period of normocalcaemia. Common causes include missed pathology at the first operation; hyperplasia in remaining or autotransplanted tissue; parathyromatosis or, very rarely, the development of a second parathyroid adenoma. Parathyromatosis refers to disseminated parathyroid tissue within the soft

tissues of the neck and superior mediastinum due to rupture of the parathyroid gland during the primary surgery. A definitive indication for surgical intervention must be present prior to embarking on localisation studies. Surgical intervention will be guided by the radiological imaging. Complication rates of recurrent laryngeal nerve damage and permanent hypocalcaemia are higher in reoperative surgery.

Chapter 52

The adrenal glands and other abdominal endocrine disorders

Learning objectives

To understand:

- The anatomy and function of the adrenal and other abdominal endocrine glands
- The diagnosis and management of these endocrine disorders
- The role of surgery in the management of these endocrine disorders

ADRENAL GLANDS

Anatomy

The weight of a normal adrenal gland is approximately 4 g. There are two distinct components to the gland: the inner adrenal medulla and the outer adrenal cortex (Figure 52.1). The adrenal glands are situated near the upper poles of the kidneys, in the retroperitoneum, within Gerota's capsule. The right adrenal gland is located between the right liver lobe and the diaphragm, close to and partly behind the inferior vena cava (IVC). The left adrenal gland lies close to the upper pole of the left kidney and the renal pedicle. It is covered by the pancreatic tail and the spleen (Figure 52.2). The adrenal glands are well supplied by blood vessels. The arterial blood supply branches from the aorta and the diaphragmatic and renal arteries and varies considerably. A usually single large adrenal vein drains on the right side into the vena cava and on the left side into the renal vein.

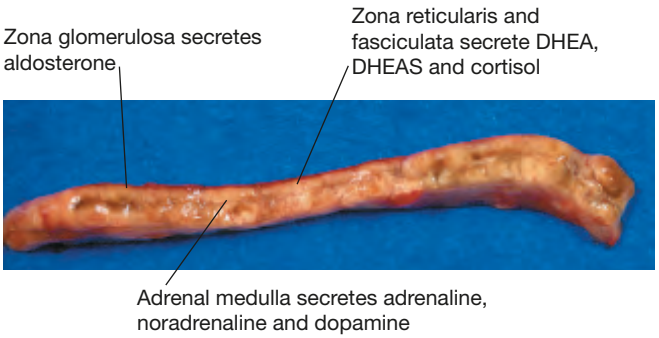

Figure 52.1 Cross-section of a normal adrenal gland. The inner, very thin layer between the two dark lines (zona reticularis) is the adrenal medulla. (DHEA, dehydroepiandrosterone; DHEAS, dehydroepiandrosterone sulphate.)

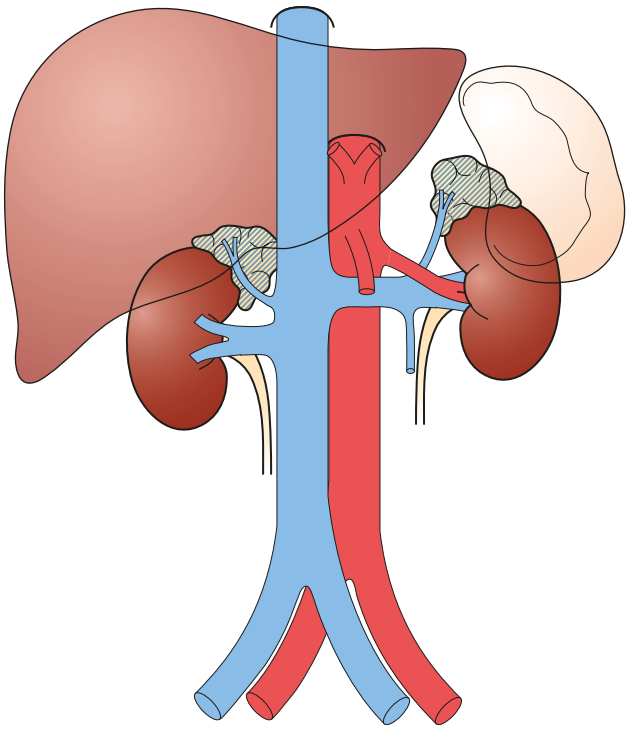

Figure 52.2 Position of the adrenal glands (hatched) in the retroperitoneum.

Dumitru Gerota, 1867–1939, Professor of Surgery, Bucharest, Romania.

Embryology

The two functional parts, the cortex and the medulla, arise from different blastodermic layers: mesodermal cells form the adrenal cortex and neuroectodermal cells migrate to the cortex from the neural crest during embryogenesis and form the adrenal medulla.

Histology

The adrenal cortex is arranged in a zonal configuration. The outer zona glomerulosa contains small, compact cells. The central zona fasciculata can be identified by larger, lipoid-rich cells, which are arranged in radial columns. Compact and pigmented cells characterise the inner zona reticularis. The adrenal medulla consists of a thin layer of large chromaffin cells, which synthesise, store and secrete catecholamine.

Function of the adrenal glands

The adrenal glands play a pivotal role in the response to stress. Catecholamines are secreted by the adrenal medulla and corticosteroids, aldosterone and cortisol are synthesised in the adrenal cortex (**Figure 52.1**). Cells of the adrenal medulla synthesise mainly adrenaline (epinephrine) but also noradrenaline (norepinephrine) and dopamine. These catecholamines act as hormones as they are secreted directly into the circulation. Their effects, which are mediated through α and β receptors on target organs, include the cardiovascular system, resulting in an increase in blood pressure and heart rate; vasoconstriction of vessels in the splanchnic system and vasodilatation of vessels in the muscles; bronchodilatation; and increased glycogenolysis in liver and muscles, all necessary for the flight/fight response. Cells of the zona glomerulosa produce aldosterone, which regulates sodium–potassium homeostasis. The target organs of aldosterone are the kidneys, the sweat and salivary glands and the intestinal mucosa. Aldosterone promotes sodium retention and potassium excretion. The most important regulators of aldosterone secretion are the renin–angiotensin system and the serum potassium concentration. Renin produced by the juxtaglomerular cells in the kidneys acts on its substrate angiotensinogen to generate angiotensin I. Angiotensin I is converted by angiotensin-converting enzyme (ACE) to the octapeptide angiotensin II, which is modified to angiotensin III. Both stimulate the secretion of aldosterone from the adrenal cortex. A decrease in renal blood flow (haemorrhage, dehydration, salt depletion, orthostasis, renal artery stenosis) or hyponatraemia increases renin secretion and leads to sodium retention, potassium excretion and an increase of plasma volume.

Cells of the zona fasciculata and zona reticularis synthesise cortisol and the adrenal androgens dehydroepiandrosterone (DHEA) and its sulphate DHEAS. DHEA and DHEAS are precursors of androgens and are converted in peripheral tissues such as fat. Cortisol secretion is regulated by adrenocorticotrophic hormone (ACTH), which is produced by the anterior pituitary gland. The hypothalamus controls ACTH secretion by secreting corticotrophin-releasing hormone (CRH). The serum cortisol level inhibits the release of CRH and ACTH via a closed-loop system (negative feedback loop).

Cortisol has numerous metabolic and immunological effects. It increases gluconeogenesis and lipolysis, decreases peripheral glucose utilisation, inhibits immunological response and, in time, reduces muscular mass. It affects fat distribution, wound healing and bone mineralisation; and alters mood (euphoria or, rarely, depression) and brain cortical activity and alertness.

DISORDERS OF THE ADRENAL CORTEX

Incidentaloma

Definition

An incidentaloma is an adrenal mass, detected incidentally by imaging studies conducted for other reasons, not known previously to have been present or causing symptoms.

Incidence

The prevalence of adrenal masses in autopsy studies ranges from 1.4% to 8.7% and increases with age. Incidentalomas may be detected on imaging studies in 1% of patients. More than 75% are non-functioning adenomas but Cushing's adenomas, phaeochromocytomas, metastases, adrenocortical carcinomas and Conn's tumours can all be found this way (*Table 52.1*).

Diagnosis

When an incidentaloma is identified, a complete history and clinical examination is required. Occasionally a previously occult endocrine disturbance will come to light. A biochemical work-up for hormone excess and sometimes additional imaging studies are also needed. The main goal is to exclude a functioning or malignant adrenal tumour.

TABLE 52.1 Prevalence of non-functioning and functioning tumours in patients with incidentalomas.

Tumour	Prevalence (%)
Non-functioning adenoma	78
Cushing's adenoma	7
Adrenocortical carcinoma	4
Phaeochromocytoma	4
Myelolipoma	2
Cyst	2
Metastases	2
Conn's adenoma	1

Harvey Williams Cushing, 1869–1939, Professor of Surgery, Harvard University Medical School, Boston, MA, USA.

Hormonal evaluation includes:

- morning and midnight plasma cortisol measurements;
- a 1-mg overnight dexamethasone suppression test;
- 24-hour urinary cortisol excretion;
- 12- or 24-hour urinary excretion of metanephrines or plasma-free metanephrines;
- serum potassium, plasma aldosterone and plasma renin activity;
- serum DHEAS, testosterone or 17-hydroxyestradiol (virilising or feminising tumour).

Cross-sectional imaging such as computed tomography (CT) or magnetic resonance imaging (MRI) should be performed in all patients with adrenal masses. The likelihood of an adrenal mass being an adrenocortical carcinoma increases with the size of the mass (25% >4 cm). Adrenal metastases are likely in patients with a history of cancer elsewhere and the sole indication for biopsy of an adrenal mass is to confirm a suspected metastasis from a distant primary site.

Summary box 52.1

Adrenal gland biopsy

- Never biopsy an adrenal mass until phaeochromocytoma has been biochemically excluded
- The indication for adrenal gland biopsy is to confirm a suspected adrenal gland metastasis

Treatment

The treatment of functional adrenal tumours is described below. Any non-functioning adrenal tumour greater than 4 cm in diameter and smaller tumours that increase in size over time should undergo surgical resection. Non-functioning tumours smaller than 4 cm should be followed-up after 6, 12 and 24 months by imaging (MRI) and hormonal evaluation. If the tumour remains non-functioning and stable in size, surveillance can be discontinued. Repeated frequent imaging using ionising radiation can lead to dangerous exposure to radiation and should be avoided.

Primary hyperaldosteronism – Conn's syndrome

Incidence

Primary hyperaldosteronism (PHA) is defined by hypertension, as a result of hypersecretion of aldosterone. In PHA, plasma renin activity is suppressed. Among patients with hypertension the incidence of PHA is approximately 2%. Recent studies have revealed that up to 12% of hypertensive patients have PHA with normal potassium levels, thus potassium levels are an inconsistent diagnostic feature of this disease, and cannot be relied on to confirm or exclude it.

Pathology

The most frequent cause of PHA with hypokalaemia is a unilateral adrenocortical adenoma (**Figure 52.3**). In 20–40% of cases, bilateral micronodular hyperplasia is present. Rare causes of PHA are bilateral macronodular hyperplasia, glucocorticoid-suppressible hyperaldosteronism or adrenocortical carcinoma. In the subset of patients with normokalaemic PHA, 70% have hyperplasia and 30% unilateral adenoma. Somatic mutations at the *KCNJ5* gene coding for the potassium channel Kir3.4 are present in aldosterone-producing adenomas and a germline *KCNJ5* mutation can cause a very rare autosomal dominant and early-onset form of PHA, characterized by bilateral adrenal hyperplasia.

Clinical features

Most patients are between 30 and 50 years of age with a female predominance. Apart from hypertension, patients complain of non-specific symptoms: headache, muscle weakness, cramps, neurological events, polyuria, polydypsia and nocturia.

Diagnosis

The key feature of the biochemical diagnosis is the assessment of the aldosterone to plasma renin activity ratio. Hypokalaemia may be present. Antihypertensive and diuretic therapy, which cause hypokalaemia and influence the renin–angiotensin–aldosterone system, have to be discontinued. Once the biochemical diagnosis is confirmed, MRI or CT should be performed to distinguish unilateral from bilateral disease. Conn's adenomas usually measure between 1 and 2 cm and are detected by CT with a sensitivity of 80–90% (**Figure 52.4**). Micronodular changes and small adenomas are often underdiagnosed. An apparent unilateral mass could be a non-functioning tumour in a patient with bilateral micronodular hyperplasia. Selective adrenal vein catheterisation can help before a decision on non-surgical or surgical treatment is

Figure 52.3 A Conn's adenoma (arrow) of the left adrenal gland; note the V-shaped normal adrenal tissue.

Jerome William Conn, 1907–1981, Professor of Internal Medicine, The University of Michigan, Michigan, MI, USA.

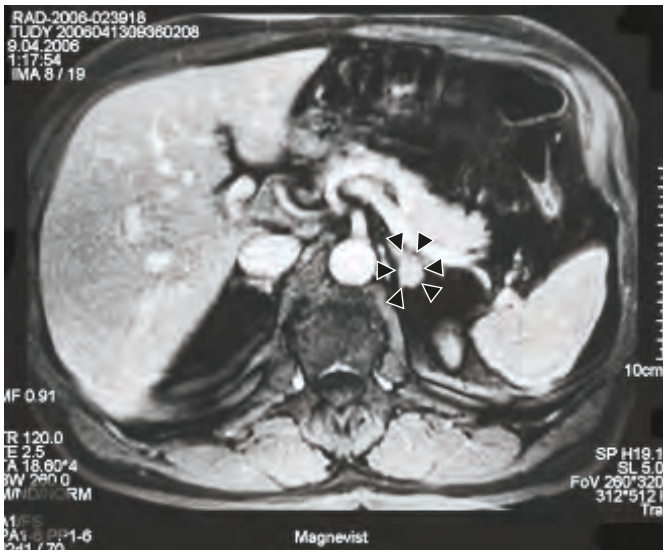

Figure 52.4 Computed tomography scan of a Conn's adenoma of the left adrenal gland (arrowheads).

made. During selective adrenal vein catheterisation, samples are obtained from the vena cava and from both adrenal veins and the aldosterone to cortisol ratio (ACR) is determined in each sample. A significant difference in the ACR ratio on one side indicates unilateral disease. In patients under age 40 with a biochemical diagnosis of Conns syndrome, a unilateral adrenal mass almost invariably represents the cause and selective adrenal vein sampling can be avoided in such cases.

Treatment

The first-line therapy for PHA with bilateral hyperplasia is medical treatment with spironolactone. In most cases supplemental antihypertensive medication is necessary to achieve satisfactory control of blood pressure.

Unilateral laparoscopic adrenalectomy is an effective therapy in patients with clear evidence of unilateral or asymmetrical bilateral disease. A subtotal adrenal resection can be considered in the case of a typical single Conn's adenoma. In 10–30% of patients who undergo an adrenalectomy, hypertension persists despite adequate diagnostic work-up and treatment, allbeit at a lower level and requiring fewer medications to control it.

Cushing's syndrome

Definition

Hypersecretion of cortisol caused by endogenous production of corticosteroids is known as Cushing's syndrome. It can be either ACTH-dependent or ACTH-independent in origin. The most common cause (85%) of ACTH-dependent Cushing's syndrome is Cushing's disease resulting from a pituitary adenoma that secretes an excessive amount of ACTH. Ectopic ACTH-producing tumours (small cell lung cancer, foregut carcinoid) and CRH-producing tumours (medullary thyroid carcinoma, neuroendocrine pancreatic tumour) are more infrequent causes of ACTH-dependent Cushing's syndrome. Excessive or prolonged administration of cortisol-like drugs will produce the same clinical picture.

In about 15% of patients, an ACTH-independent Cushing's syndrome (low ACTH levels) is caused by a unilateral adrenocortical adenoma. Adrenocortical carcinoma and bilateral macronodular or micronodular hyperplasia represent rare causes of hypercortisolism.

Clinical symptoms

The clinical features of Cushing's syndrome are shown in *Summary box 52.2*. The typical patient is characterised by a facial plethora, a buffalo hump and a moon face in combination with hypertension, diabetes and central obesity (**Figures 52.5 and 52.6**). However, clinical signs can be minimal or absent in patients with subclinical Cushing's syndrome.

Figure 52.5 A 34-year-old patient with Cushing's syndrome whose symptoms included thickening of the face, weight gain and acne. Today patients with Cushing's syndrome rarely have the full-blown appearance as shown in older textbooks.

Figure 52.6 Discrete central obesity, ecchymosis and fragile skin in a patient with Cushing's syndrome.

Summary box 52.2

Clinical features of Cushing's syndrome

- Weight gain/central obesity
- Diabetes
- Hirsutism
- Hypertension
- Skin changes (abdominal striae, facial plethora, ecchymosis, acne)
- Muscle weakness
- Menstrual irregularity/impotence
- Depression/mania
- Osteoporosis
- Hypokalaemia

Diagnosis

- Morning and midnight plasma cortisol levels are elevated, usually with loss of diurnal rhythm.
- Dexamethasone fails to suppress 24-hour urinary cortisol excretion.
- Serum ACTH levels discriminate ACTH-dependent from ACTH-independent disease.

Elevated or normal ACTH levels provide evidence for an ACTH-producing pituitary tumour (85%) or ectopic ACTH production. Therefore, in patients with elevated ACTH, MRI of the pituitary gland must be performed. If MRI is negative and additional venous sampling from the inferior petrosal sinus has excluded a pituitary microadenoma, a CT scan of the chest and abdomen is warranted to detect an ectopic ACTH-producing tumour. In patients with suppressed ACTH levels, a CT or MRI scan is performed to assess the adrenal glands.

Subclinical Cushing's syndrome is diagnosed if clinical symptoms are absent in the face of abnormal cortisol secretion.

Treatment

Medical therapy with metyrapone or ketoconazole reduces steroid synthesis and secretion and can be used to prepare patients with severe hypercortisolism preoperatively or if surgery is not possible. ACTH-producing pituitary tumours are treated by trans-sphenoidal resection or radiotherapy. If an ectopic ACTH source is localised, resection will correct hypercortisolism.

A unilateral adenoma is treated by adrenalectomy. In cases of bilateral ACTH-independent disease (**Figure 52.7**), bilateral adrenalectomy is the primary treatment. Patients with an ectopic ACTH-dependent Cushing's syndrome and an irresectable or unlocalised primary tumour should be considered for bilateral adrenalectomy as this controls hormone excess. Subclinical Cushing's syndrome caused by unilateral adenoma can be treated by unilateral adrenalectomy.

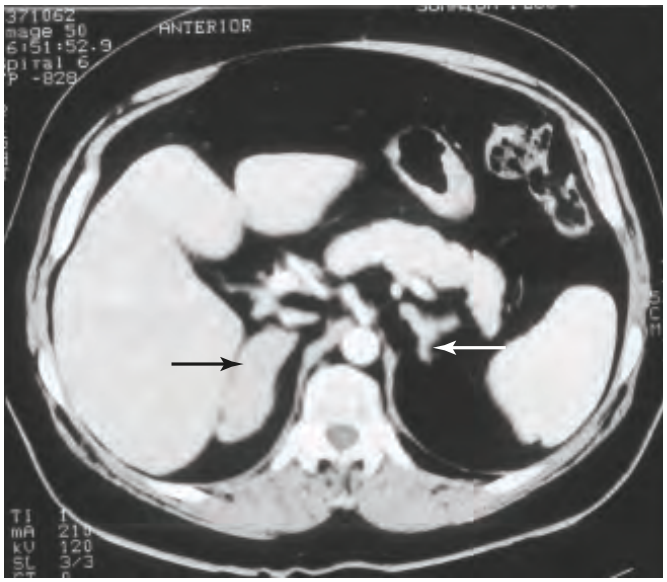

Figure 52.7 Bilateral asymmetrical hyperplasia of the adrenal glands (arrows) in a patient with Cushing's syndrome.

Preoperative management

Patients with Cushing's syndrome are at an increased risk of hospital-acquired infection, thromboembolic and myocardial complications. Therefore, prophylactic anticoagulation and the use of prophylactic antibiotics are essential. Cushing-associated diseases (diabetes, hypertension) must be controlled by medical therapy preoperatively.

Postoperative management

After unilateral adrenalectomy supplemental cortisol should be given postoperatively because the contralateral gland will be suppressed. In total, 15 mg/h is required parenterally for the first 12 hours followed by a daily dose of 100 mg for 3 days, which is gradually reduced thereafter. After unilateral adrenalectomy, the contralateral suppressed gland needs up to 1 year to recover adequate function. A synacthen test to evaluate adrenal fuction prior to stopping cortisol supplements is advised. In 10% of patients with Cushing's disease who undergo a bilateral adrenalectomy after failed pituitary surgery, the pituitary adenoma causes Nelson's syndrome due to continued ACTH secretion at high levels, causing hyperpigmentation as a result of chemical synergies between ACTH and melanocyte-stimulating hormone.

Adrenal metastases

Adrenal metastases are discovered at autopsy in one-third of patients with malignant disease (less frequently during life). In declining frequency, the most common primary tumours are breast, lung, renal, gastric, pancreatic, ovarian and colorectal cancer. In selected circumstances an adrenalectomy is appropriate, for example if it is the sole site of metastatic disease.

Don H Nelson, 1925–2010, Professor of Medicine, The University of Utah, Salt Lake City, UT, USA.

Adrenocortical carcinoma

Incidence

Adrenocortical carcinoma (ACC) is a rare malignancy with an incidence of 1–2 cases per 1 000 000 population per year and a variable but generally poor prognosis. A slight female predominance is observed (1.5:1). The age distribution is bimodal with a first peak in childhood and a second between the fourth and fifth decades.

Pathology

The differentiation between benign and malignant adrenal tumours is challenging, even in the hands of an experienced pathologist. Criteria for malignancy are tumour size, the presence of necrosis or haemorrhage and microscopic features such as capsular or vascular invasion. These should be assessed in terms of a microscopic diagnostic score. Additional information is provided by immunohistochemistry. The macroscopic features are commonly multinodularity and heterogeneous structure (**Figure 52.8**) with haemorrhage and necrosis.

Clinical presentation

Approximately 60% of patients present with evidence of cortisol excess (Cushing's syndrome). Patients with non-functioning tumours frequently complain of abdominal discomfort or back pain caused by large tumours. However, with increasing use of abdominal imaging, a growing number of adrenocortical carcinomas are detected incidentally. Adrenal tumours secreting more than one hormone in excess, or feminising/masculanising steroids are likely to be malignant.

Diagnosis

The diagnostic work-up should include measurements of DHEAS, cortisol and catecholamines to exclude a phaeochromocytoma and a dexamethasone suppression test. MRI and CT are equally effective in imaging ACC (**Figure 52.9**). MRI angiography is useful to exclude tumour thrombus in the vena cava. As distant metastases are frequently present, a preoperative staging CT scan is recommended. The World Health Organization classification of 2004 is based on the McFarlane classification and defines four stages: tumours <5 cm (stage I) or >5 cm (stage II), locally invasive tumours (III) or tumours with distant metastases (IV). Functioning tumours tend to do worse than non-functioning, but have the advantage of a serum marker that can be used for follow-up and disease monitoring.

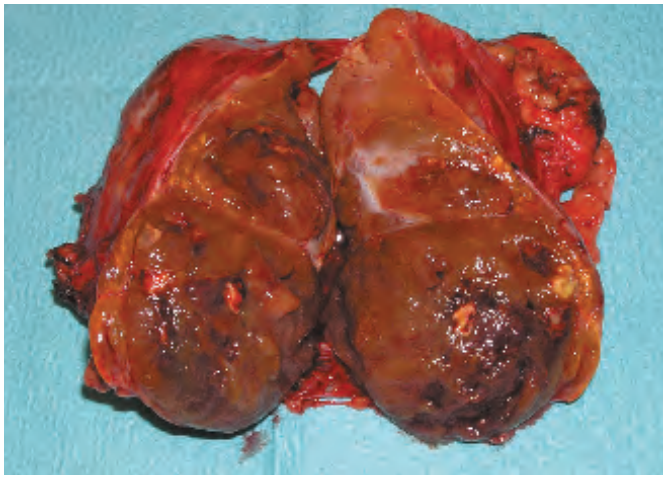

Figure 52.8 Adrenocortical carcinoma that caused Cushing's syndrome and virilisation in a female patient.

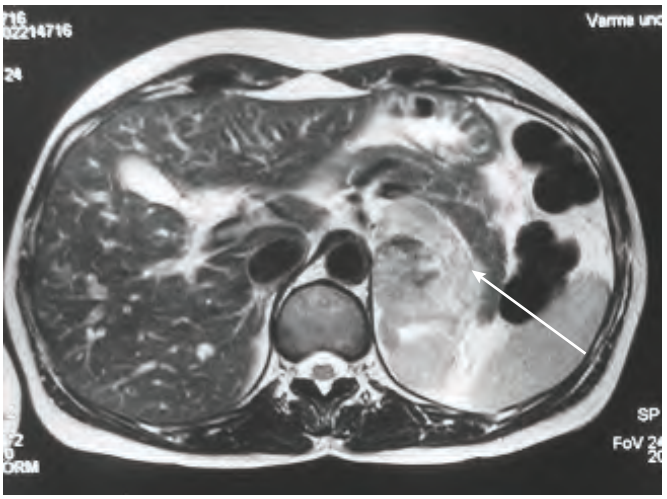

Figure 52.9 Magnetic resonance imaging of adrenocortical carcinoma (arrow) in a patient with cortisol and testosterone excess.

Treatment

Complete tumour resection (R0) is associated with favourable survival and should be attempted whenever possible. In order to prevent tumour spillage and implantation metastases, the capsule must not be damaged. *En bloc* resection with removal of locally involved organs is often required and in case of tumour thrombus in the vena cava, thrombectomy is needed. Laparoscopic adrenalectomy is associated with a high incidence of local recurrence and cannot be recommended. Tumour debulking plays a role in functioning tumours to control hormone excess.

Patients can be treated postoperatively with mitotane alone or in combination with etoposide, doxorubicin and cisplatin. Adjuvant radiotherapy may reduce the rate of local recurrence. After surgery, restaging every 3 months is required as the risk of tumour relapse is high. Prognosis depends on the stage of disease and complete removal of the tumour. Patients with stage I or II disease have a 5-year survival rate of 25%, whereas patients with stage III and stage IV disease have 5-year survival rates of 6% and 0% respectively. Recently, genetic sequencing of adrenocortical tumours has identified two distinct molecular subgroups that characterise aggressive and indolent ACCs and provide robust prognostic information in addition to pathological and MacFarlane staging.

en bloc is French for 'in a block'.

Congenital adrenal hyperplasia (adrenogenital syndrome)

Virilisation and adrenal insufficiency in children are pathognomonic of congenital adrenal hyperplasia (CAH). This is an autosomal recessive disorder caused by a variety of enzymatic defects in the synthetic pathway of cortisol and other steroids from cholesterol. The most frequent defect (95%) is the 21-hydroxylase deficiency, which has an incidence of 1 in 5000 live births. Excessive ACTH secretion is caused by the loss of cortisol and this leads to an increase in androgenic cortisol precursors and to CAH. CAH may present in girls at birth with ambiguous genitalia or as late-onset disease at puberty. Hypertension and short stature, caused by the premature epiphyseal plate closure, are common signs. Affected patients are treated by replacement of cortisol and with fludrocortisone. Large hyperplastic adrenals may need to be removed if symptomatic.

Adrenal insufficiency

Primary adrenal insufficiency is caused by the loss of function of the adrenal cortex. It was first described by Thomas Addison in 1855. An early diagnosis is a clinical challenge, even today. Symptoms are only evident when about 90% of the adrenal cortex is destroyed. Secondary adrenal insufficiency is caused by a deficiency of pituitary ACTH secretion. Tertiary adrenal deficiency is provoked by a loss of hypothalamic CRH secretion and is caused by therapeutic glucocorticoid administration, brain tumour, trauma or irradiation.

Summary box 52.3

Diseases associated with adrenal insufficiency

- Polyglandular autoimmune syndrome
- Tuberculosis
- After bilateral adrenalectomy
- Haemorrhage
- Metastases
- Systemic diseases (Boeck's disease, amyloidosis, Wilson's disease)
- Hereditary diseases (e.g. adrenoleukodystrophia, adrenogenital syndrome)
- Human immunodeficiency virus infection

Acute adrenal insufficiency

Acute adrenal insufficiency usually presents as shock in combination with fever, nausea, vomiting, abdominal pain, hypoglycaemia and electrolyte imbalance. Waterhouse–Friderichsen syndrome is a bilateral adrenal infarction associated with meningococcal sepsis and is rapidly fatal unless immediately treated. Because of intestinal symptoms and fever, the so-called Addisonian crisis is often misdiagnosed as an acute abdominal condition.

Chronic adrenal insufficiency

When symptoms develop over time, patients present with anorexia, weakness and nausea. As a result of negative feedback, ACTH and pro-opiomelanocortin (POMC) levels increase and cause hyperpigmentation of the skin and oral mucosa. Hypotension, hyponatraemia, hyperkalaemia and hypoglycaemia are commonly observed. The diagnosis of adrenal insufficiency is made using the ACTH stimulation test. Basal ACTH levels are found to be high with cortisol levels decreased. There is no rise in cortisol levels following the exogenous administration of ACTH (synacthen test).

Treatment

If a patient displays features of adrenal insufficiency, treatment must immediately be commenced, before awaiting the biochemical diagnosis. Initial blood samples can be used for later determinations of ACTH and cortisol levels. In addition to intravenous administration of hydrocortisone 100 mg every 6 hours, 3 litres of saline is given in 6 hours under careful cardiovascular monitoring. Concomitant infections, which are frequently present, require treatment.

Chronic adrenal insufficiency is treated by replacement therapy with daily oral hydrocortisone (10 mg/m^2 body surface area) and fludrocortisone (0.1 mg). Patients must be advised about the need to take lifelong glucocorticoid and mineralocorticoid replacement therapy. To prevent an Addisonian crisis, patients must be aware of the need to increase the dose in case of illness or stress. If patients with adrenal insufficiency are scheduled for surgery, appropriate steroid cover must be administrated.

DISORDERS OF THE ADRENAL MEDULLA AND NEURAL CREST-DERIVED TISSUE

Phaeochromocytoma and paraganglioma

Definition

These are tumours of the adrenal medulla and sympathetic ganglia that are derived from chromaffin cells and most commonly produce supraphysiological levels of circulating catecholamines.

Aetiology

The prevalence of phaeochromocytoma in patients with hypertension is 0.1–0.6% with an overall prevalence of 0.05% in autopsy series. In total, 4% of incidentalomas are

Thomas Addison, 1795–1860, physician, Guy's Hospital, London, England, described the effects of disease of the suprarenal capsules in 1852.
Caesar Peter Moller Boeck, 1845–1917, Professor of Medicine, The University of Oslo, Norway.
Samuel Alexander Kinnier Wilson, 1878–1936, Professor of Neurology, King's College Hospital, London, UK, described this condition in 1912.
Rupert Waterhouse, 1873–1958, physician, The Royal United Hospital, Bath, UK, described this syndrome in 1911.
Carl Friderichsen, 1886–1979, Medical Superintendent, Sundby Hospital, Copenhagen, Denmark, gave his account of the syndrome in 1918.

phaeochromocytomas. Sporadic phaeochromocytomas occur around the fourth decade, whereas patients with hereditary forms are diagnosed earlier. Phaeochromocytoma is known as the '10% tumour' as 10% of tumours are inherited, 10% are extra-adrenal, 10% are malignant, 10% are bilateral and 10% occur in children. With the recent advent of detailed genetic predisposition tests, however, the incidence of hereditary phaeochromocytomas has been shown to be higher.

Hereditary phaeochromocytomas occur in several tumour syndromes:

- **Multiple endocrine neoplasia type 2 (MEN 2)**: an autosomal dominant inherited disorder that is caused by activating germline mutations of the *RET* proto-oncogene.
- **Familial paraganglioma (PG) syndrome**: glomus tumours of the carotid body and extra-adrenal paraganglioma are characteristic in this hereditary tumour syndrome, which is caused by germline mutations within the succinate dehydrogenase complex subunit B (*SDHB*) *SDHD* and *SDHC* genes.
- **von Hippel–Lindau (VHL) syndrome**: those affected can develop early-onset bilateral kidney tumours, phaeochromocytomas, cerebellar and spinal haemangioblastomas and pancreatic tumours. Patients have a germline mutation in the *VHL* gene.
- **Neurofibromatosis (NF) type 1**: phaeochromocytomas in combination with fibromas on the skin and mucosae ('café-au-lait' skin spots) are indicative of a germline mutation in the *NF1* gene.

Pathology

Phaeochromocytomas are greyish-pink on the cut surface and are usually highly vascularised. Areas of haemorrhage or necrosis are often observed (**Figure 52.10**). Microscopically, tumour cells are polygonal but the configuration varies considerably. The differentiation between malignant and benign tumours is difficult, except when metastases are present. An increased PASS (**p**haeochromocytoma of the **a**drenal gland **s**cale **s**core), a high number of Ki-67-positive cells, vascular invasion or a breached capsule all lean more towards malignant rather than benign.

Phaeochromocytomas may also produce calcitonin, ACTH, vasoactive intestinal polypeptide (VIP) and parathyroid hormone-related protein (PTHrP). In patients with MEN 2, the onset of phaeochromocytoma is preceded by adrenomedullary hyperplasia, sometimes bilateral. Phaeochromocytoma is rarely malignant in MEN 2.

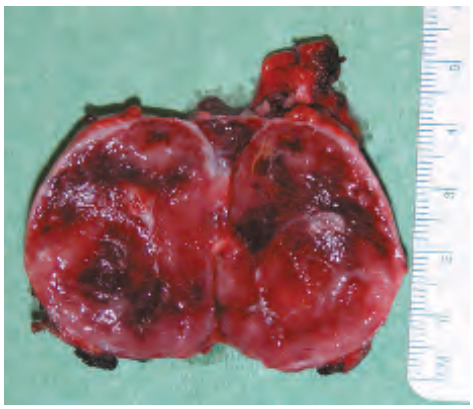

Figure 52.10 Gross appearance of a phaeochromocytoma.

Clinical features

Symptoms and signs are caused by catecholamine excess and are typically intermittent (*Table 52.2*). In total, 90% of patients with the combination of headache, palpitations and sweating in the presence of an adrenal tumour have a phaeochromocytoma. Paroxysms may be precipitated by physical training, induction of general anaesthesia and numerous drugs and agents (contrast media, tricyclic antidepressive drugs, metoclopramide and opiates). Hypertension may occur continuously, be intermittent or absent. A subset of patients are asymptomatic. More than 25% of apparently sporadic phaeochromocytomas are caused by germline mutations in the *RET, SDHB*, *SDHC*, *SDHD* and *NF1* genes; genetic testing for these and other genes is therefore recommended, particularly in those patients aged under 50 years.

Diagnosis

The first step in the diagnosis of a phaeochromocytoma is the confirmation of excessive catecholamine levels in the patient either by the measurement of adrenaline and noradrenaline breakdown products, metanephrine and normetanephrine level, in a 12 or 24-hour urine collection, (levels that exceed the normal range by 2–40 times will be found in affected patients) or by determination of plasma-free metanephrine and normetanephrine levels. Biochemical tests should be performed at least twice. The biochemical diagnosis is then followed by localisation of the phaeochromocytoma. MRI is preferred because contrast media used for CT scans can provoke paroxysms. Classically, phaeochromocytomas show

TABLE 52.2 Clinical signs of phaeochromocytoma.

Symptoms	Prevalence (%)
Hypertension	80–90
Paroxysmal	50–60
Continuous	30
Headache	60–90
Sweating	50–70
Palpitation	50–70
Pallor	40–45
Weight loss	20–40
Hyperglycaemia	40
Nausea	20–40
Psychological effects	20–40

Eugen von Hippel, 1867–1939, Professor of Ophthalmology, Göttingen, Germany.
Arvid Lindau, 1892–1958, Professor of Pathology, Lund, Sweden.

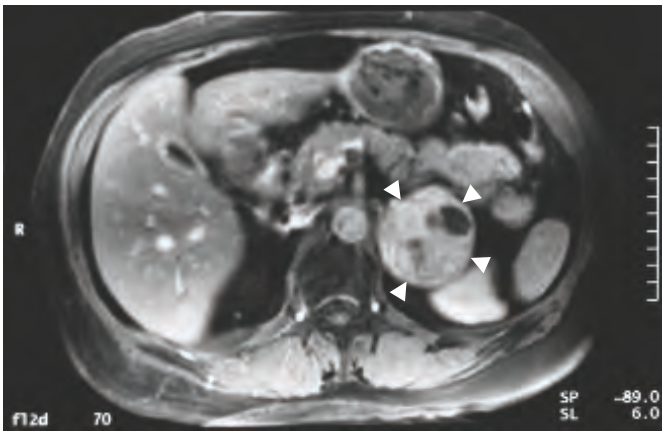

Figure 52.11 Magnetic resonance imaging of a sporadic phaeochromocytoma of the left adrenal gland (arrowheads).

a 'Swiss cheese' configuration (**Figure 52.11**). ^{123}I-MIBG (metaiodobenzylguanidine) single-photon emission computed tomography (SPECT) will identify about 90% of primary tumours and is essential for the detection of multiple extra-adrenal tumours and metastases (**Figure 52.12**). Positron emission tomography (PET) scanning using fluorodeoxyglucose (FDG) or dihydroxyphenylalanine (DOPA) is yet more sensitive in detecting metastatic foci.

Treatment

Laparoscopic resection is now routine in the treatment of phaeochromocytoma. If the tumour is larger than 8–10 cm or radiological signs of malignancy are detected, an open approach should be considered.

PREOPERATIVE

Once a phaeochromocytoma has been diagnosed, an α-adrenoreceptor blocker (phenoxybenzamine) is used to block the effects of catecholamine excess and its consequences during surgery. With adequate medical pretreatment, the perioperative mortality rate has decreased from 20–45% to less than 3%. A dose of 20 mg of phenoxybenzamine initially should be increased daily by 10 mg until a daily dose of 100–160 mg is achieved and the patient reports symptomatic postural hypotension. Additional β-blockade is required if tachycardia or arrhythmias develop; this should not be introduced until the patient is α-blocked.

With adequate α-blockade preoperatively, anaesthesia should not be more hazardous than in patients with a non-functioning adrenal tumour; however, in some patients, dramatic changes in heart rate and blood pressure may occur and require sudden administration of pressor or vasodilator agents. A central venous catheter and invasive arterial monitoring are used. Special attention is required when the adrenal vein is ligated as a sudden drop in blood pressure may occur. The infusion of large volumes of fluid or administration of noradrenaline can be necessary to correct postoperative hypotension in the presence of unopposed α-blockade.

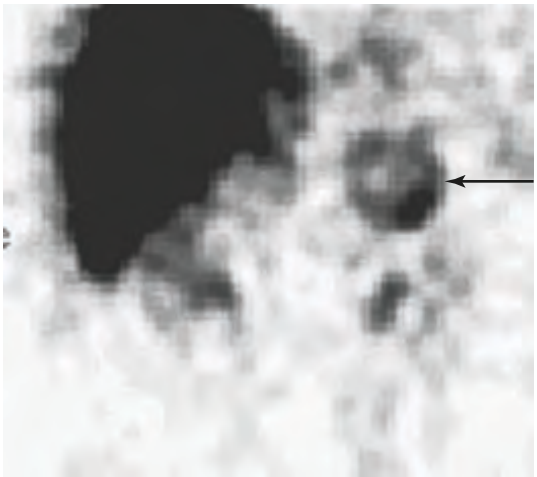

Figure 52.12 Meta-iodobenzylguanidine (MIBG) single-photon emission computed tomography scan of a phaeochromocytoma of the left adrenal gland (arrow) in the same patient as in Figure 52.11.

POSTOPERATIVE

Patients should be observed for 24 hours in the intensive care (ICU) or high dependancy unit as hypovolaemia and hypoglycaemia may occur. Lifelong yearly biochemical tests should be performed to identify recurrent, metastatic or metachronous phaeochromocytoma.

Summary box 52.4

Phaeochromocytoma

- Obtain a secure biochemical diagnosis
- Evaluate family history, refer to genetics if <50 years old
- Diagnosis confirmed, treat with α-blockers
- Plan surgical excision
- Yearly lifelong follow-up

Malignant phaeochromocytoma

Definition

Approximately 10% of phaeochromocytomas are malignant. This rate is higher in extra-adrenal tumours (paragangliomas). The diagnosis of malignancy implies metastases of chromaffin tissue, most commonly to lymph nodes, bone and liver.

Treatment

Surgical excision is the only chance for cure. Even in patients with metastatic disease, tumour debulking can be considered to reduce the tumour burden and to control the catecholamine excess. Symptomatic treatment can be obtained with α-blockers. Mitotane should be started as adjuvant or palliative treatment. Treatment with ^{131}I-MIBG or combination chemotherapy has resulted in a partial response in 30% and an improvement of symptoms in 80% of patients. The natural history is highly variable with a 5-year survival rate of less than 50%.

Phaeochromocytoma in pregnancy

Phaeochromocytomas in pregnancy may be silent and present as a hypertensive emergency, may mimic an amnion infection

syndrome or pre-eclampsia. Without adequate α-blockade, mother and unborn child are threatened by hypertensive crisis during delivery. In the first and second trimesters the patient should be scheduled for laparoscopic adrenalectomy after adequate α-blockade; the risk of a miscarriage during surgery is high. In the third trimester, elective caesarean with delayed **consecutive** adrenalectomy 6 weeks later should be performed. The maternal mortality rate is 50% when a phaeochromocytoma remains undiagnosed.

Neuroblastoma

Definition

A neuroblastoma is a malignant tumour that is derived from the sympathetic nervous system in the adrenal medulla (38%) or from any site along the sympathetic chain in the paravertebral sites of the abdomen (30%), chest (20%) and, rarely, the neck or pelvis.

Pathology

Neuroblastomas have a pale and grey surface, are encapsulated and show areas with calcification. With increased tumour size, necrosis and haemorrhage may be detected. They are characterised by the presence of immature cells derived from the neuroectoderm of the sympathetic nervous system. Mature cells are found only in ganglioneuroblastomas.

Clinical features

Predominantly newborn infants and young children (<5 years of age) are affected. Symptoms are caused by tumour growth or by bone metastases. Patients present with a mass in the abdomen, neck or chest, proptosis, bone pain, painless bluish skin metastases, weakness or paralysis. Metastatic disease is present in 70% of patients at presentation.

Diagnosis

Biochemical evaluation should include urinary excretion (24-hour urine) of vanillylmandelic acid (VMA), homovanillic acid (HVA), dopamine and noradenaline, as increased levels are present in about 80% of patients. Accurate staging requires CT/MRI of the chest and abdomen, a bone scan, bone marrow aspiration and core biopsies as well as an MIBG scan. Staging is established according to the International Neuroblastoma Staging System (INSS).

Treatment

Prognosis can be predicted by the tumour stage and the age at diagnosis. Patients are classified as low, intermediate or high risk. Low-risk patients are treated by surgery alone (the addition of 6–12 weeks of chemotherapy is optional) whereas intermediate-risk patients are treated by surgery with adjuvant multiagent chemotherapy (carboplatin, cyclophosphamide, etoposide, doxorubicin). High-risk patients receive high-dose multiagent chemotherapy followed by surgical resection in responding tumours and myeloablative stem cell rescue. Patients assigned to the low-risk, intermediate-risk and high-risk groups have overall 3-year survival rates of 90%, 70–90% and 30%, respectively.

Ganglioneuroma

Definition

A ganglioneuroma is a benign neoplasm that arises from neural crest tissue. Ganglioneuromas can occur in the adrenal medulla and are characterised by mature sympathetic ganglion cells and Schwann cells in a fibrous stroma.

Clinical features

Ganglioneuroma is found in all age groups but is more common before the age of 60. Ganglioneuromas occur anywhere along the paravertebral sympathetic plexus and in the adrenal medulla (30%). Most often they are identified incidentally by CT or MRI performed for other indications.

Treatment

Treatment is by surgical excision, laparoscopic when adrenalectomy is indicated.

SURGERY OF THE ADRENAL GLANDS

Since its introduction in the 1990s, laparoscopic or retroperitoneoscopic adrenalectomy has become the 'gold standard' in the resection of adrenal tumours, except for tumours with signs of malignancy. The more popular approach is the laparoscopic transperitoneal approach, which offers a better view of the adrenal region than open surgery. The advantage of the retroperitoneoscopic approach is the minimal dissection required by this extra-abdominal procedure. In the case of small, bilateral tumours or in patients with hereditary tumour syndromes a subtotal resection is warranted, to avoid steroid dependence. The mortality rate ranges from 0% to 2% in specialised centres.

An open approach should be considered if radiological signs, distant metastases, large tumours (>8–10 cm) or a distinct hormonal pattern suggest malignancy.

Laparoscopic adrenalectomy

Knowledge of the anatomy of the adrenal region is essential as anatomical landmarks guide the surgeon during operation. If these landmarks are respected, injury to the vena cava or renal vein, the pancreatic tail or the spleen can be avoided. Careful haemostasis is essential as small amounts of blood can impair the surgeon's view. To prevent tumour spillage, direct grasping of the adrenal tissue/tumour has to be avoided.

Theodor Schwann, 1810–1882, Professor of Anatomy, Louvain (1839–1848), and later at Liège (1852–1880), described the neurilemma in 1839.

Right adrenalectomy

The patient is positioned right side up, with table brake. Three ports are used to start. The dissection starts at the level of the periadrenal fat using careful coagulation and the peritoneum should be divided 2 cm below the edge of the liver from medial (IVC) to the lateral abdominal wall. This flap of peritoneum can then be used to retract the liver up and off the adrenal. A fourth port may be useful to hold the liver up. The gland is identified and mobilised gently, and the vein is secured with a clip or using one of the available energy devices; the gland is removed in a plastic catch bag (**Figure 52.13**).

Left adrenalectomy

With the patient positioned left side up, mobilisation of the spleen will displace it and the pancreatic tail medially. The incision of Gerota's fascia is followed by identification of the adrenal vein, which runs into the renal vein in the space between the medial aspect of the kidney and the posterior aspect of the pancreatic tail. The resection is completed by mobilising the adrenal gland at the level of the periadrenal fat. Remove the gland in a bag and close the 3 port sites after infiltrating each with local anaesthesia.

Retroperitoneoscopic adrenalectomy

The first port is placed at the distal end of the 12th rib with the patient in the prone position. After a digital dissection into the retroperitoneum, Gerota's fascia is displaced ventrally. The right adrenal vein is covered by the retrocaval posterior aspect of the adrenal gland. The left adrenal vein is usually located at the medial inferior pole of the adrenal gland. High inflation pressures allow bloodless dissection, effectively tamponading the veins. Being outside the abdominal cavity affords an excellent view.

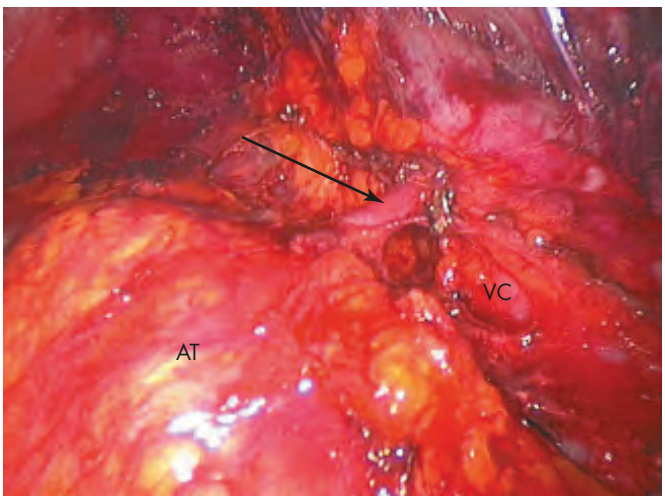

Figure 52.13 Laparoscopic view during a right adrenalectomy. Arrow indicates the adrenal vein. AT, adrenal tumour; VC, vena cava.

Open adrenalectomy

An open adrenalectomy is almost exclusively performed when a malignant adrenal tumour is suspected. On the right side the hepatic flexure of the colon is mobilised and the right liver lobe is cranially retracted to achieve an optimal exposure of the IVC and the adrenal gland. On the left side the adrenal gland can be exposed after mobilisation of the splenic flexure of the colon, through the transverse mesocolon or through the gastrocolic ligament. The remaining dissection is the same as in laparoscopic adrenalectomy. A resection of regional lymph nodes is recommended in malignant adrenal tumours and should include resection of the tissue between the renal pedicle and the diaphragm.

PANCREATIC ENDOCRINE TUMOURS

Introduction

Pancreatic endocrine tumours (PETs) represent an important subset of pancreatic neoplasms. They account for 5% of all clinically detected pancreatic tumours. They consist of single or multiple, benign or malignant neoplasms and are associated in 10–20% of cases with multiple endocrine neoplasia type 1 (MEN 1). PETs present as either functional tumours, causing specific hormonal syndromes, or non-functional tumours, with symptoms similar to those in patients with pancreatic adenocarcinoma. This section focuses on insulinomas, gastrinomas and non-functioning tumours because they represent 90% of all PETs (*Table 52.3*).

Function of the endocrine pancreas

The endocrine cells of the pancreas are grouped in the islets of Langerhans, which constitute approximately 1–2% of the mass of the pancreas (**Figure 52.14**). There are about one million islets in a healthy adult human pancreas and their combined weight is 1–1.5 g. There are four main types of cell in the islets of Langerhans, which can be classified according to their secretions:

- beta cells producing insulin (65–80% of the islet cells);
- alpha cells producing glucagon (15–20%);
- delta cells producing somatostatin (3–10%);
- pancreatic polypeptide (PP) cells containing polypeptide (1%).

Insulinoma

Definition

This is an insulin-producing tumour of the pancreas causing the clinical scenario know as Whipple's triad, i.e. symptoms of hypoglycaemia after fasting or exercise, plasma glucose levels <2.8 mmol/L and relief of symptoms on intravenous administration of glucose.

Paul Langerhans, 1847–1888, Professor of Pathological Anatomy, Freiberg, Germany.
George Hoyt Whipple, 1878–1976, Professor of Pathology, The University of Rochester, Rochester, NY, USA, described this disease in 1907. He shared the 1934 Nobel Prize for Physiology or Medicine with George Richards Minot and William Parry Murphy 'for their discoveries concerning liver therapy against anaemias'.

TABLE 52.3 Neuroendocrine tumours of the pancreas.

Tumour (syndrome)	Incidence (%)	Presentation	Malignancy (%)
Insulinoma	70–80	Weakness, sweating, tremor, tachycardia, anxiety, fatigue, dizziness, disorientation, seizures	<10
Gastrinoma	20–25	Intractable or recurrent peptic ulcer disease (haemorrhage, perforation), complications of peptic ulcer, diarrhoea	60–80
Non-functional tumours	30–50	Obstructive jaundice, pancreatitis, epigastric pain, duodenal obstruction, weight loss, fatigue	60–90
VIPoma	4	Profuse watery diarrhoea, hypotension, abdominal pain	80
Glucagonoma	4	Migratory necrolytic skin rash, glossitis, stomatitis, angular cheilitis, diabetes, severe weight loss, diarrhoea	80
Somatostatinoma	<5	Cholelithiasis, diarrhoea, neurofibromatosis	50
Carcinoid	<1	Flushing, sweating, diarrhoea, oedema	90
ACTHoma	<1	Cushing's syndrome	>90
GRFoma	<1	Acromegaly	30

ACTH, adrenocorticotrophic hormone; GRF, growth hormone-releasing factor; VIP, vasoactive intestinal polypeptide.

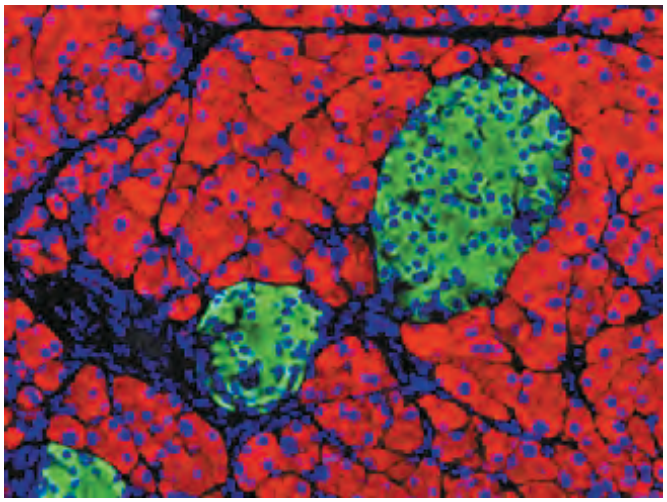

Figure 52.14 Immunofluorescent labelling of endocrine (insulin (green)) and exocrine (amylase (red)) pancreatic cells and the nuclear marker DAPI (blue) (courtesy of Dr Esni, Department of Surgery, University of Pittsburgh, USA).

Incidence

Insulinomas are the most frequent of all the functioning PETs with a reported incidence of 2–4 cases per million population per year. Insulinomas have been diagnosed in all age groups, with the highest incidence found in the fourth to the sixth decades. Women seem to be slightly more frequently affected.

Pathology

The aetiology and pathogenesis of insulinomas are unknown. No risk factors have been associated with these tumours. Virtually all insulinomas are located in the pancreas and tumours are equally distributed within the gland. Approximately 90% are solitary and about 10% are multiple and associated with MEN 1 syndrome.

Prognosis and predictive factors

No markers are available that reliably predict the biological behaviour of an insulinoma. Approximately 10% are malignant. Insulinomas of <2 cm in diameter without signs of vascular invasion or metastases are considered benign.

Clinical features

Insulinomas are characterised by fasting hypoglycaemia and neuroglycopenic symptoms. The episodic nature of the hypoglycaemic attacks is caused by intermittent insulin secretion by the tumour. This leads to central nervous system symptoms such as diplopia, blurred vision, confusion, abnormal behaviour and amnesia. Some patients develop loss of consciousness and coma. The release of catecholamines produces symptoms such as sweating, weakness, hunger, tremor, nausea, anxiety and palpitations.

Biochemical diagnosis

A fasting test that may last for up to 72 hours is regarded as the most sensitive test. Usually, insulin, proinsulin, C-peptide and blood glucose are measured in 1- to 2-hour intervals to demonstrate inappropriately high secretion of insulin in relation to blood glucose. About 80% of insulinomas are diagnosed by this test, most of them in the first 24 hours. Elevated C-peptide levels demonstrate the endogenous secretion of insulin and exclude factitious hypoglycaemia caused by insulin injection.

Differential diagnosis

The differential diagnosis of hypoglycaemia includes hormonal deficiencies, hepatic insufficiency, medication, drugs and enzyme defects. Occasionally, differentiating insulinoma from other causes of hypoglycaemia can be difficult. Nesidioblastosis is a rare disorder, mainly encountered in children, which is characterised by replacement of normal pancreatic islets by diffuse hyperplasia of islet cells.

Medical treatment of insulinoma

Medical management is reserved only for patients who are unable or unwilling to undergo surgical treatment or for unresectable metastatic disease. Diazoxide suppresses insulin secretion by direct action on the beta cells and offers reasonably good control of hypoglycaemia in approximately 50%

of patients. When surgical options to treat malignant insulinomas cannot be applied, chemotherapeutic options include doxorubicin and streptozotocin.

Surgical treatment of insulinoma

INDICATIONS FOR OPERATION

After a positive fasting test and exclusion of diffuse abdominal metastases by ultrasound or CT scan, all patients should be advised to undergo surgical excision of insulinoma.

PREOPERATIVE LOCALISATION STUDIES

Intraoperative exploration of the pancreas is the best method to use for localisation of insulinoma yet the operating surgeon will need preoperative localisation. Insulinomas are detected in about 65% of cases by endoscopic ultrasound (EUS), 33% of cases by CT scan and abdominal ultrasound and 15% of cases by magnetic resonance tomography. Intraoperative ultrasound (IOUS) of the pancreas is a vital tool after mobilisation of the gland. For preoperative localisation of an insulinoma, EUS has the highest sensitivity and should be used if laparoscopic resection is considered. If no lesion is identified and one can rely on the biochemical tests for diagnosis, laparotomy should follow, using IOUS.

BENIGN INSULINOMA

Surgical cure rates in patients with the biochemical diagnosis of insulinoma range from 90% to 100%. At open surgery an extended Kocher manoeuvre and mobilisation of the head and then the distal pancreas is performed to explore the whole gland. IOUS should then be used to confirm the presence of a tumour, to find non-palpable lesions and also to identify the relation of the tumour to the pancreatic duct (**Figure 52.15a**). Tumour enucleation is the technique of choice (**Figure 52.15b**). For superficial tumours, laparoscopic enucleation is undertaken (**Figure 52.16**). Tumours located deep in the body or tail of the pancreas and those in close proximity to the pancreatic duct require distal pancreatectomy. Postoperatively, blood sugar levels begin to rise in most patients within the first few hours after removal of the tumour. To preserve pancreatic function and reduce the risk of iatrogenic diabetes mellitus, patients in whom tumour localisation is not successful at operation should not undergo blind resection.

MALIGNANT INSULINOMA

Aggressive attempts at resection are recommended as these tumours are much less virulent than adenocarcinomas.

Gastrinoma (Zollinger–Ellison syndrome)

Definition

Zollinger–Ellison syndrome (ZES) is a condition that includes: (1) fulminating ulcer diathesis in the stomach, duodenum or atypical sites; (2) recurrent ulceration despite 'adequate' therapy; and (3) non-beta islet cell tumours of the pancreas (gastrinoma).

Theodor Kocher, 1841–1917, Professor of Surgery, Berne, Switzerland, awarded the Nobel Prize for Physiology or Medicine in 1909, 'for his work on the physiology, pathology, and surgery of the thyroid gland.'
Robert Milton Zollinger, 1903–1992, Professor of Surgery, The Ohio State University, Columbus, OH, USA.
Edwin Homer Ellison, 1918–1970, Professor of Surgery, Marquette University, WI, USA. Zollinger and Ellison described this condition in a joint paper in 1955 when they were both working at The Ohio State University.

Incidence

Gastrinomas account for about 20% of PET. Approximately 0.1% of patients with duodenal ulcers have evidence of ZES. The reported incidence is between 0.5 and 4 cases per million population per year. ZES is more common in males than in females. The mean age at the onset of symptoms is 38 years, and the range 7–83 years.

Pathology

The aetiology and pathogenesis of sporadic gastrinomas are unknown. At the time of diagnosis more than 60% of tumours are malignant. Pancreatic gastrinomas are mainly found in sporadic disease; most are found in the head of the pancreas. More than 70% of the gastrinomas in MEN 1 syndrome and most sporadic gastrinomas are located in the first and second part of the duodenum. Therefore, the anatomical area comprising the head of the pancreas, the superior and descending portion of the duodenum and the relevant lymph nodes has been called the 'gastrinoma triangle' because it harbours the vast majority of these tumours **(Figure 52.17)**. All patients with gastrinomas should be tested for MEN 1 syndrome.

Prognosis and predictive factors

In general, the progression of gastrinomas is relatively slow with a 5-year survival rate of 65% and a 10-year survival rate of 51%. Patients with complete tumour resection have excellent 5- and 10-year survival rates (90–100%). Patients with pancreatic tumours have a worse prognosis than those with primary tumours in the duodenum. There is no established marker to predict the biological behaviour of gastrinoma.

Clinical and biochemical features

Over 90% of patients with gastrinomas have peptic ulcer disease, often multiple or in unusual sites. Diarrhoea is another common symptom, caused by the large volume of gastric acid secretion. Abdominal pain from either peptic ulcer disease or gastro-oesophageal reflux disease (GORD) remains the most common symptom, occurring in more than 75% of patients.

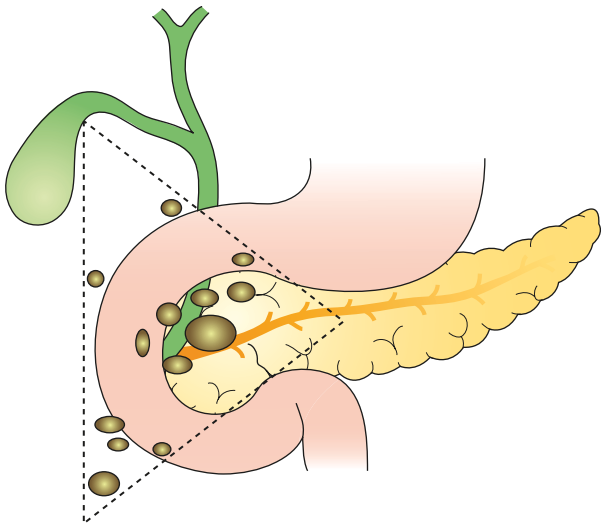

Figure 52.17 The gastrinoma triangle.

Biochemical diagnosis

If the patient presents with a gastric pH below 2.5 and a serum gastrin concentration above 1000 pg/mL (normal <100 pg/mL) then the diagnosis of ZES is confirmed. Unfortunately, the majority of patients have serum gastrin concentrations between 100 and 500 pg/mL and in these patients a secretin test should be performed. The secretin test is considered positive if an increase in serum gastrin of >200 pg/mL over the pretreatment value is obtained; this also rules out other causes of hypergastrinaemia (e.g. atrophic gastritis).

Differential diagnosis

The most common misdiagnoses are idiopathic peptic ulcer disease, chronic idiopathic diarrhoea and GORD. Other reasons for hypergastrinaemia are chronic atrophic gastritis, gastric outlet stenosis and retained antrum after gastric resection.

Medical treatment of gastrinoma

In most patients with ZES, gastric hypersecretion can be treated effectively with proton pump inhibitors. Octreotide can also help to control acid hypersecretion. Systemic chemotherapy is utilised in patients with diffuse metastatic gastrinomas. Streptozotocin in combination with 5-fluorouracil or doxorubicin is the first-line treatment.

Surgical treatment of gastrinoma

INDICATIONS FOR OPERATION

Surgical exploration should be performed in all patients without diffuse metastases, to remove known malignant gastrinomas or benign ones.

PREOPERATIVE LOCALISATION STUDIES

Pancreatic gastrinomas are often larger than 1 cm in diameter, whereas gastrinomas of the duodenum are usually smaller. Therefore, it is nearly impossible to identify duodenal gastrinomas by preoperative imaging. Pancreatic gastrinomas are detected by endoscopic ultrasound in about 80–90% of cases, by CT in 39% of cases and by MRI in 46% of cases. In approximately one-third of patients the results of conventional imaging studies are negative. On the basis of recent studies, either endoscopic ultrasound or CT and somatostatin receptor scintigraphy (SRS) scan should be performed preoperatively for staging.

PANCREATIC GASTRINOMAS

Most pancreatic gastrinomas are solitary, located in the head of the gland or uncinate process, and can be identified at operation. Enucleation with peripancreatic lymph node dissection is the procedure of choice. Rarely, tumours are situated in the body or tail and should be treated by enucleation or distal resection. Even if a tumour is found in the pancreas, duodenotomy is recommended to detect additional tumours, if the patient has MEN 1.

DUODENAL GASTRINOMAS

The duodenum should be opened with a longitudinal incision and the posterior and anterior walls palpated separately **(Figure 52.18)**. Duodenal tumours smaller than 5 mm can

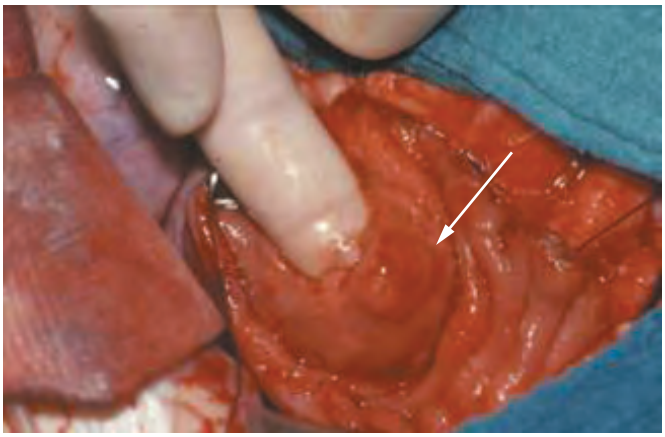

Figure 52.18 Palpation of a duodenal gastrinoma (arrow) after duodenotomy.

be enucleated with the overlying mucosa; larger tumours are excised with full-thickness excision of the duodenal wall.

Non-functional endocrine pancreatic tumours

Definition

PETs are clinically classified as non-functioning (NF-PETs) when they do not cause a clinical syndrome.

Incidence

NF-PETs account for 30–50% of all PETs. They are most often diagnosed in the fifth to sixth decades of life.

Pathology

NF-PETs cannot be differentiated from functional tumours by immunocytochemistry because they may also express hormones such as gastrin, insulin, etc. They usually stain positively for chromogranin A and synaptophysin. The tumours are usually large (>5 cm) and unifocal except in MEN 1 syndrome. They are distributed throughout the pancreas with a head to body to tail ratio of 7:1:1.5.

Prognosis and predictive factors

About 70% of all NF-PETs are malignant. Overall 5- and 10-year survival rates of 65% and 49% respectively have been described. When comparing NF-PETs with functioning PETs, the NF-PETs have a worse prognosis.

Clinical features

Patients usually present late because of the lack of a clinical/hormonal marker of tumour activity. Therefore, in contrast to functioning PETs, patients with NF-PETs present with various non-specific symptoms, including jaundice, abdominal pain, weight loss and pancreatitis. In some cases liver metastases are the first presentation.

Biochemical diagnosis

Increased levels of chromogranin A have been reported in 50–80% of NF-PETs; the level of chromogranin A sometimes correlates with the tumour burden. The combination of elevated chromogranin A and PP measurements increases the sensitivity of diagnosis from 84% to 96% in NF-PETs.

TABLE 52.4 Differences between pancreatic cancer and non-functioning endocrine pancreatic tumours (NF-PETs).

	Pancreatic cancer	NF-PETs
Tumour size	<5 cm	>5 cm
CT scan	Hypodensity	Hyperdensity
	No calcifications	Calcifications possible
Chromogranin A in blood	Negative	Positive
Somatostatin receptor scintigraphy	Negative	Positive

CT, computed tomography.

Differential diagnosis

Differentiation from the more aggressive pancreatic adenocarcinoma is extremely important (*Table 52.4*). Recognition of NF-PETs is imperative because of their resectability and excellent long-term survival compared with their exocrine counterparts.

Medical treatment of non-functioning islet cell tumours

When surgical excision is not possible, chemotherapeutic options include streptozotocin, octreotide and interferon.

Surgical treatment of non-functioning islet cell tumours

INDICATIONS FOR OPERATION

An aggressive surgical approach should be considered in malignant NF-PETs, even in the presence of distant metastases.

PREOPERATIVE LOCALISATION STUDIES

Preoperative ultrasound or CT scan are the procedures of choice as these tumours are relatively large. Also, SRS should be performed to differentiate endocrine from non-endocrine pancreatic tumours.

OPERATIVE PROCEDURES

The major goal is a potentially curative resection. This may require partial pancreaticoduodenectomy as well as the synchronous or metachronous resection of liver metastases. Using an aggressive approach, curative resections are possible in up to 62% of cases and overall 5-year survival rates of around 65% can be achieved. Repeated resections for resectable recurrences or metastases are justified to improve survival.

NEUROENDOCRINE TUMOURS OF THE STOMACH AND SMALL BOWEL

Definition and physiology

Neuroendocrine tumours (NET) of the gut and the pancreas arise from the diffuse neuroendocrine cell system, which can

be found as single or clustered cells in the mucosa of the bronchi, stomach, gut, biliary tree, urogenital system and in the pancreas (see Chapters 72 and 73 for NET of the appendix and rectum respectively). This cell system was first recognised as the 'clear cell system' by Feyrter in the 1930s and is identical to the APUD (amine precursor uptake and decarboxylation) system described by Pearse in 1970. All cells of the system secrete different neuroendocrine markers, such as synaptophysin, chromogranin A and neurone-specific enolase (NSE), and produce peptide hormones that are stored in granules, e.g. serotonin, somatostatin, PP or gastrin. In clinical practice chromogranin A is utilised as a tumour marker. The main functional test for NET of the jejunum and ileum (the NET that are most often encountered) is the measurement of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in urine.

Pathology

Neuroendocrine cells can form hyperplasias or tumours. Oberndorfer coined the term 'carcinoids' for tumours arising from these cells in 1907. Although the term carcinoid continues to be used in clinical practice, these tumours do not always grow in a well-differentiated pattern reflecting the rather benign 'carcinoma-like', i.e. 'carcinoid' tumour. They can show different growth patterns, from benign tumours to high-grade undifferentiated carcinomas having a poor prognosis (neuroendocrine carcinomas). Therefore, they should always be addressed as NET, including a description of their histological pattern (benign, low- or high-grade malignant) and their anatomical site (e.g. stomach, ileum) according to the World Health Organization (WHO) classification (2000). The relative distribution of NET in different organs is given in *Table 52.5*. Another classification based on embryological principles classifies NET as foregut (lung, stomach, pancreas), midgut (small bowel and appendix) and hindgut (colon and rectum) tumours.

TABLE 52.5 Relative distribution of neuroendocrine tumours in different organs.

Site	Distribution (%)
Lung	10
Stomach	5
Duodenum	2
Small bowel	25
Appendix	40
Colon	6
Rectum	15

Neuroendocrine tumours of the stomach

These tumours are rare. They comprise about 5% of all NET of the gastrointestinal tract and have an incidence of approximately 0.2 cases per 100 000 population per year. There are four different types of gastric NET (*Table 52.6*). Types 1 and 2 are small benign tumours that arise from the enterochromaffin-like (ECL) cells in the gastric mucosa and grow in either a linear or a nodular pattern **(Figure 52.19)**. Hypergastrinaemia may cause symptoms and the treatment of choice is

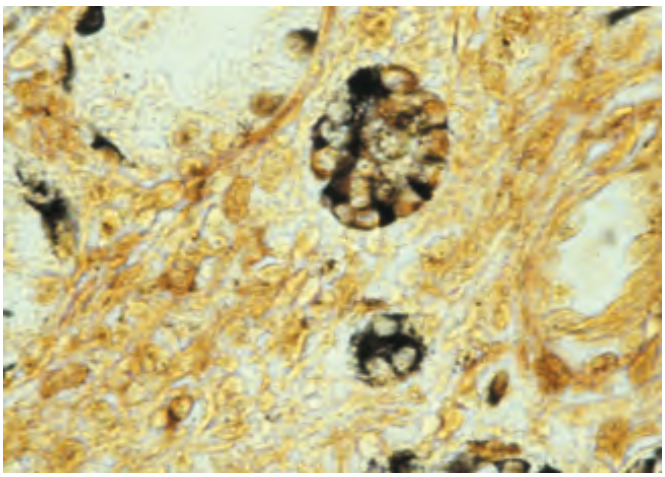

Figure 52.19 Immunostaining of chromogranin in micronodular hyperplasia of enterochromaffin-like (ECL) cells of the stomach, associated with chronic atrophic gastritis.

TABLE 52.6 Classification of gastric neuroendocrine tumours.

Type	Histological pattern	Size and location	Causative factor and prognosis
1	Benign, non-functional, well differentiated	Gastric corpus; <1 cm; mucosa/submucosa	ECLomas in chronic atrophic gastritis, hypergastrinaemia
2	Benign or low-grade malignant, differentiated	1–2 cm; angioinvasion; mucosa/submucosa	ECLomas with hypergastrinaemia as a result of gastrinoma in MEN 1
3	Low-grade malignant, differentiated	2 cm; invasion beyond submucosa	Sporadic ECLomas not related to hypergastrinaemia
4	Intermediate or small cell type, high-grade malignant (neuroendocrine carcinoma)	Different sizes	Causative factor unknown; prognosis poor

ECL, enterochromaffin-like; MEN, multiple endocrine neoplasia.

Anthony Guy Everson Pearse, 1916–2003, Professor of Histochemistry, The Royal Postgraduate Medical School, Hammersmith, London, UK.

endoscopic resection. Types 3 and 4 are almost always malignant and surgical resection should be undertaken if possible.

Pathogenesis, diagnosis and treatment

Type 1 tumours (ECLomas) are the most frequent NET of the stomach (approximately 80%); they occur mostly in elderly women. Chronic hypergastrinaemia is the result of chronic atrophic gastritis and achlorhydria, the alkaline pH being the stimulus for hypersecretion of gastrin. They do not cause symptoms and are usually detected during gastroscopy for other reasons. Endoscopic resection is the treatment of choice. Antrectomy and resection of ECLomas should be undertaken only if there is recurrent disease and multiple (more than six) tumours, with at least one measuring >1 cm and infiltration of at least one into the submucosa.

The pathogenesis, diagnosis and treatment of type 2 tumours is similar to that of type 1. The only difference is the cause of the hypergastrinaemia, which in type 2 tumours is the result of MEN 1 syndrome, with multiple gastrinomas in the duodenum or, rarely, in the pancreas.

Type 3 tumours are rare, sporadic and solitary tumours of unknown origin. Serum gastrin is normal; upper gastrointestinal bleeding is the usual symptom that leads to endoscopy. Type 3 tumours are usually larger than 2 cm and often have lymph node and liver metastases at the time of diagnosis. Gastrectomy and lymph node dissection and resection of liver metastases is the treatment of choice. Liver metastases can also be treated by chemoembolisation.

Type 4 tumours present as large ulcerating malignancies similar to adenocarcinomas and should be treated accordingly. The prognosis of types 3 and 4 is poor (*Table 52.6*).

Neuroendocrine tumours of the small bowel

Introduction

These are the tumours that are most commonly referred to as 'carcinoid' tumours, as most NET of the gastrointestinal tract are found in the small bowel. They are also called 'midgut' tumours (together with NET of the appendix and the right colon). These tumours produce serotonin and cause the 'carcinoid' syndrome, but only in patients who have a large volume of liver metastases or if there is advanced local tumour growth draining into the IVC and thereby bypassing the liver. NET of the duodenum (gastrinomas in MEN 1 syndrome, somatostatinomas and others) are very rare and are not discussed further.

Pathology

NET of the jejunum and ileum arise from a subgroup of cells of the diffuse neuroendocrine system, the enterochromaffin (EC) cells, which secrete serotonin and substance P. They are either solitary or more often multiple, are almost always malignant and metastasise early to the regional lymph nodes and the liver depending on the location of the primary tumour(s) (**Figure 52.20**).

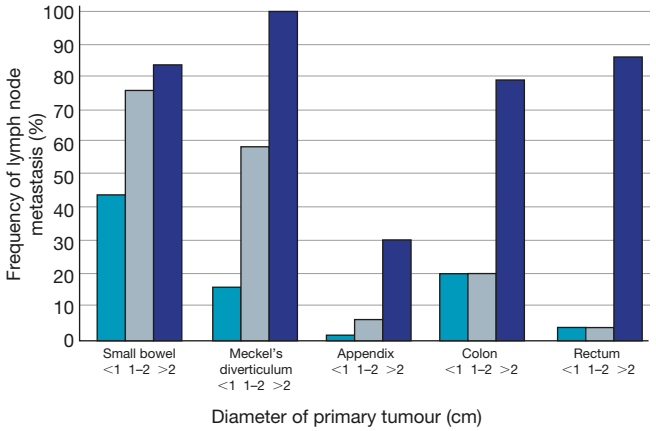

Figure 52.20 Relation of site and diameter of neuroendocrine tumours of the gut to frequency of lymph node metastasis.

Clinical symptoms

Symptoms that lead to the diagnosis are caused by either the primary tumour or its lymph node metastases. Acute or chronic, recurrent or persistent abdominal pain, ileus or, rarely, lower gastrointestinal bleeding may occur. Symptoms may be due to liver metastases, such as sudden painful reddening of the face and chest ('flushing'), diarrhoea or bronchospasm. These symptoms constitute 'carcinoid' syndrome. About 60% of patients eventually develop cardiac symptoms because of stenosis and insufficiency of the pulmonary and, more rarely, the tricuspid valve, with enlargement and thickening of the wall of the right atrium. The aetiology is unknown but local effects of serotonin and kinins may contribute.

Abdominal symptoms are caused either by obstruction of the appendix by an appendiceal NET (leading to appendectomy) or by obstruction of the mesentery or the bowel lumen by growth of lymph node metastases in the mesentery near the bowel. Pain is caused by chronic ischaemia of the bowel (**Figure 52.21**), resulting not only from mesenteric lymph

Figure 52.21 Chronic ischaemia of the small bowel caused by desmoplastic reaction and narrowing of vessels in the mesentery in a neuroendocrine tumour of the ileum.

Johann Friedrich Meckel (The Younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany.

node metastases but also from constriction of mesenteric arteries and fibrosis of the mesentery by a so-called desmoplastic reaction.

Primary tumours in the jejunum and ileum rarely cause symptoms such as bleeding or intussusception as they usually only measure from a few millimetres up to 1 cm or at the most 2 cm in diameter (Figure 52.22). A polypoid NET of the terminal ileum may, however, cause ileocaecal intussusception.

Diagnosis

The diagnosis of NET of the small bowel is made by history, physical examination of the abdomen, imaging and an assessment of 5-HIAA in a 24-hour urine sample. It is positive in larger tumours only if metastases are present. Cross-sectional imaging, sonography, CT scan and MRI may show the primary tumour, mesenteric lymph node and liver metastases.

The best method for staging of NET is an octreotide (SRS) scan. This will show all tumour deposits provided that they are large enough and have a high somatostatin receptor density (Figure 52.23).

Surgical procedure

Surgery should be undertaken as soon as the diagnosis is made, even in the presence of liver metastases. The main goal is resection of the bowel primary tumour(s) and mesenteric lymph node metastases. This may entail resection of large amounts of bowel (100 cm or more), particularly if stage III or IV lymph node masses are found in the mesentery (Figure 52.24). In the presence of liver metastases, extrahepatic disease should be resected whenever possible. Metastatic disease in the mesenteric root will lead to long-term pain in the abdomen or back and to a poor quality of life, whereas liver metastases can be treated by chemotherapy or embolisation.

Somatostatin and its analogues provide symptomatic treatment of the 'carcinoid' syndrome caused by a large volume of liver metastases. These drugs may also have an antiproliferative effect. Surgery to remove liver metastases is possible in approximately 10% of patients. In others, embolisation, chemoembolisation, SRS using radioactively labelled octreotide, chemotherapy, biotherapy and also liver transplantation can be performed.

Figure 52.22 Multiple neuroendocrine tumours in the small bowel causing large lymph node metastases in the mesentery.

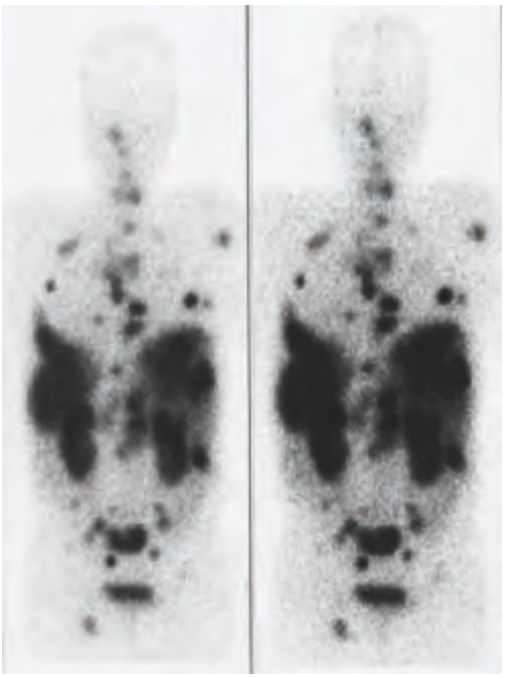

Figure 52.23 Octreotide scan of a patient with neuroendocrine tumour of the gut and diffuse metastases in different organs.

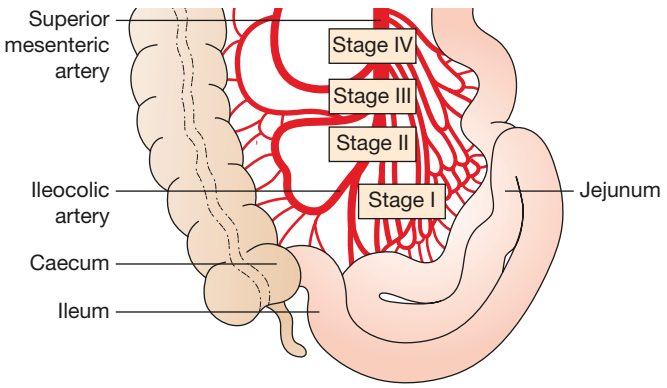

Figure 52.24 Bulky lymph node metastases can occur at different levels in the mesentery. To resect them completely, long segments of bowel must be resected, the closer to the mesenteric root the metastases are situated (adapted from Akerström G, Hellman P, Öhrvall U. Midgut and hindgut carcinoid tumours. In: Doherty GM, Skogseid B (eds.). *Surgical endocrinology*. Philadelphia, PA: Lippincott Williams & Wilkins, 2001, by kind permission.).

MULTIPLE ENDOCRINE NEOPLASIAS

Introduction

Multiple endocrine neoplasias (MEN) are inherited syndromes characterised by a combination of benign and malignant tumours in different endocrine glands. There are two main types, type 1 (MEN 1) and type 2 (MEN 2). The mode of inheritance is autosomal dominant in both.

MEN 1 is characterised by the triad of tumours in the anterior pituitary gland, mostly presenting as prolactinomas or non-functioning tumours, hyperplasia of the parathyroids causing primary hyperparathyroidism (pHPT) and pancreaticoduodenal endocrine tumours (PETs). The syndrome was first described by Wermer in 1954 and is therefore also called Wermer's syndrome. It is caused by germline mutations in the *menin* gene, located on chromosome 11.

MEN 2 is divided into three subtypes: familial medullary thyroid carcinoma (FMTC), MEN 2A and MEN 2B. Medullary thyroid carcinoma (MTC) plays the key role in all subtypes. MEN 2 is caused by germline mutations in the *RET* proto-oncogene, located on chromosome 10. MEN 2A is characterised by the combination of MTC, pHPT and mostly bilateral phaeochromocytomas. MTC combined with phaeochromocytoma alone is called Sipple's syndrome. FMTC is characterised by distinct mutations in *RET* and MTC alone as the clinical manifestation. MEN 2B comprises MTC, phaeochromocytoma and characteristic facial and oral mucosal neurinomas (**Figure 52.25**) and intestinal ganglioneuromatosis, accompanied by a Marfanoid habitus.

Figure 52.25 Neurinomas of the tongue in a patient with multiple endocrine neoplasia type 2B.

The most important difference between MEN 1 and MEN 2, besides the different clinical pictures, is that MEN 2 is characterised by a well-understood genotype–phenotype correlation. This means that depending on the particular mutation in the *RET* proto-oncogene, the phenotypic appearance and the onset of endocrine tumours will be different and can be predicted from the type of mutation. This is not the case in MEN 1 syndrome.

Multiple endocrine neoplasia type 1

Epidemiology

The prevalence of the syndrome is estimated to be around 0.04–0.2 cases per 1000 population per year. The penetrance is high with almost 100% of mutation carriers developing the syndrome. The disease is equally distributed between men and women.

Clinical presentation

The clinical presentation depends on the affected organs. Tumours can occur synchronously (*Table 52.7*). Most of the mutation carriers identified in screening programmes are asymptomatic.

TABLE 52.7 Affected organs in multiple endocrine neoplasia type 1.

Endocrine gland affected	Frequency (%)	Hormone	Clinical syndrome
Parathyroids	90	PTH	pHPT
Pancreas, duodenum (mostly multiple)	50–80		
Gastrinoma		Gastrin	Zollinger–Ellison syndrome
Insulinoma		Insulin	Hypoglycaemia syndrome
Non-functioning tumours		PP	–
VIPoma		VIP	Verner–Morrison syndrome
Glucagonoma		Glucagon	Glucagonoma syndrome
Anterior pituitary gland	30–60		
Prolactinoma		Prolactin	Galactorrhea
Non-functioning adenoma		–	Non-specific
Other manifestations			
Adrenals	40–50 Cortisol?	Mostly non-functioning	
NET in lung, thymus, stomach	3–10	–	–
Lipoma	5–10	–	–

NET, neuroendocrine tumours; pHPT, primary hyperparathyroidism; PP, pancreatic polypeptide; PTH, parathyroid hormone; VIP, vasoactive intestinal polypeptide.

Paul Wermer, 1898–1975, physician, The Presbyterian Hospital, New York, NY, USA, described this condition in 1954.
John H Sipple, b.1930, physician, The State University of New York, New York, NY, USA.
John V Verner, b.1927 and **Ashton B Morrison**, 1922–2008, at Duke University, USA, described the features of watery diarrhoea and hypokalaemia in 1958 and subsequently linked their observations with hyperplasia of non-beta islet cells of the pancreas in 1974.

PARATHYROIDS

In total, 90–100% of patients suffering from MEN 1 develop pHPT and it is usually the first manifestation of the disease. MEN 1 pHPT is characterised by multiglandular disease so that all four parathyroids become hyperplastic in the course of the disease. The clinical presentation of MEN 1 pHPT is similar to that of the sporadic disease. Few patients have asymptomatic disease; most common in symptomatic disease is nephrolithiasis. Diagnosis is established by determination of parathyroid hormone (PTH) and calcium in serum and urine.

ENDOCRINE PANCREAS

PETs occur in around 50–60% of MEN 1 patients. In such patients taking part in screening programmes, 70–90% are found to have non-functioning and functioning PETs. This high rate of detection of PETs is the result of the improvement in diagnostic procedures in the last decade, including EUS. MEN 1 PETs are the most common syndrome-associated cause of death. They are mostly multiple and often recur after surgery. Although most patients have multiple tumours, one hormone syndrome is usually dominant. The most common functional tumour is gastrinoma followed by insulinoma. VIPomas, glucagonomas and somatostatinomas are extremely rare. Non-functioning tumours can be asymptomatic for many years.

The diagnostic work-up is similar to that for sporadic PETs and includes hormone measurements, e.g. gastrin, insulin, PP, etc. and imaging.

ANTERIOR PITUITARY GLAND

Tumours of the anterior pituitary gland are found in 30–60% of patients with MEN 1. These are mostly microadenomas that present as prolactinomas or non-functioning tumours. Most prolactinomas can be treated with medication, thus avoiding operation.

ADRENAL TUMOURS AND OTHER ORGAN MANIFESTATIONS

Adrenal involvement is common in MEN 1 patients and affects nearly 40–50% of patients. Mostly non-functioning adenomas are found. Very rarely, adrenocortical carcinomas or phaeochromocytomas may develop.

Although very rare, manifestations of MEN 1 include NET of the lung, thymus, stomach, duodenum and small bowel. It is important to check for NETs of the thymus, as they are mostly malignant.

Genetic screening

Identification of the MEN 1 (*menin*) gene in 1997 formed the basis for direct mutational analysis of the gene and for family screening. After genetic counselling of the index patient, family members can be screened. Mutation carriers can then be included in screening programmes that make early detection of endocrine tumours possible. Screening programmes should follow the consensus guidelines published by Brandi *et al.* in 2001. In cases of apparently sporadic endocrine tumours in patients younger than 40 years, genetic testing for MEN 1 is advised.

Operative therapy

PARATHYROIDS

The indications for surgery in MEN 1 pHPT follow the same criteria as in sporadic disease but the choice of procedure is different. As multiglandular disease is present in all cases, resection follows the same rules as in secondary HPT. Therefore, the most common procedures are total parathyroidectomy, including cervical thymectomy or 31/2-gland resection, leaving approximately 50 mg of parathyroid tissue behind, and cervical thymectomy. Selective resection of enlarged glands is obsolete because of the high rates of recurrence (see Chapter 51).

ENDOCRINE PANCREAS

Indications for surgery and its extent are controversial. Most experts agree that MEN 1 gastrinoma and insulinoma have to be operated on to prevent liver metastases and to control hormonal excess, provided that diffuse liver metastases are not present. MEN 1 gastrinomas are more often located in the duodenum as multiple small tumours than in the pancreas. For gastrinomas located in the duodenum or pancreatic head (gastrinoma triangle, **Figure 52.17**), pylorus-preserving partial pancreaticoduodenectomy is recommended. In rare cases the gastrinoma is located in the body or tail of the pancreas. In such cases distal pancreatectomy with excision of tumours in the pancreatic head is the procedure of choice. In MEN 1 insulinoma the standard operative procedure is distal pancreatectomy with enucleation of tumours in the pancreatic head. Non-functioning PETs are operated on if they reach a size of 1 cm. Careful palpation and IOUS are essential in every pancreatic procedure for MEN 1 PETs.

ANTERIOR PITUITARY GLAND

The indications for surgery in tumours of the anterior pituitary gland are the presence of symptomatic non-functional tumours or if medical therapy of prolactinoma fails. Most procedures can be performed through a trans-sphenoidal approach.

ADRENAL TUMOURS

Functional adrenal tumours in MEN 1 are rare and have to be operated on. Non-functioning tumours should be resected if they reach a size of 4 cm. Pre- and perioperative management follow the same rules as in sporadic adrenal tumours; therefore, phaeochromocytoma has to be ruled out in every patient. In most cases a laparoscopic or retroperitoneoscopic approach can be used. If there is evidence for a malignant tumour, open surgery is preferred.

Multiple endocrine neoplasia type 2

In most patients with MEN 2A, the disease is caused by mutations of the *RET* proto-oncogene in codon 634. MTC is almost always the first manifestation of the syndrome. If phaeochromocytoma and pHPT do not occur, one must suspect the presence of the FMTC subtype. Patients with MEN 2B do not develop pHPT and in 95% of cases mutations in codon 918 of the *RET* proto-oncogene are causative (*Table 52.8*).

TABLE 52.8 Frequency of diseases in multiple endocrine neoplasia type 2 related to mutation in different codons.

Syndrome	Frequently affected codons in *RET*	MTC (%)	pHPT (%)	PCC (%)
FMTC	533, 630, 768, 844	90–100	–	–
MEN 2A	609, 634, 790, 804	90–100	20–30	10–50
MEN 2B	883, 918	100	–	10–50

FMTC, familial medullary thyroid cancer; MEN 2A, multiple endocrine neoplasia type 2A; MEN 2B, multiple endocrine neoplasia type 2B; MTC, medullary thyroid cancer; PCC, phaeochromocytoma; pHPT, primary hyperparathyroidism; *RET, RET* proto-oncogene (*RET* = rearranged during transfection).

Medullary thyroid carcinoma

MTC is characterised by multicentricity and is often accompanied by C-cell hyperplasia. These characteristics should lead to molecular diagnostic work-up (mutational analysis of the *RET* proto-oncogene) in patients with apparently 'sporadic' MTC. In contrast to sporadic MTC, the diagnosis in families with known mutation of the *RET* gene is mostly made much earlier, possibly as the result of mutational screening and calcitonin measurements. MTC is most aggressive in MEN 2B. It occurs in early childhood, much earlier than in MEN 2A, with lymph node metastases present in the early stages. Preventative surgery is advised around the age of 1 year.

Primary hyperparathyroidism

pHPT in MEN 2A is less common and has a milder clinical course than MEN 1 pHPT. It occurs in about 20–30% of patients with MEN 2A. Most patients are asymptomatic but all parathyroid glands can become hyperplastic, mostly metachronously. The disease develops after the third decade of life typically.

Phaeochromocytoma

The frequency of phaeochromocytoma in MEN 2 is around 10–50% and tumours can be bilateral. This can occur synchronously or metachronously. The tumours are almost always benign. Diagnostic work-up includes measurement of urinary catecholamines, abdominal CT or MRI and 131I-MIBG scintigraphy (see above).

Operative therapy

MEDULLARY THYROID CARCINOMA

Operative therapy for MEN 2 MTC in patients detected by genetic screening is a good example of efficient prophylactic surgery, as the likelihood of developing MTC is 100% for most mutations. The mutation carriers can be operated on with no evidence of tumour in the thyroid, protecting them from MTC for the rest of their lives. Different *RET* mutations are associated with early or late onset of the disease. Risk groups have been defined to determine the appropriate age for thyroidectomy (*Table 52.9*).

PHAEOCHROMOCYTOMA

The operative approach is laparoscopy or retroperitoneoscopy. Unilateral or bilateral subtotal resection may be feasible, which retains the healthy part of the gland and prevents postoperative dependence on cortisol and mineralocorticoid supplementation (see above) (**Figure 52.26**). Further phaeochromocytomas can develop in the remnants that are left, so continued surveillance is required.

PRIMARY HYPERPARATHYROIDISM

The clinical situation in MEN 2 pHPT is even more difficult than in MEN 1 pHPT because of the association with MTC in MEN 2. During neck surgery for MTC in a eucalcaemic patient, enlarged parathyroid glands should be removed. In cases in which neck surgery has already been performed for MTC, the surgical approach to MEN 2A pHPT should be more tailored to the individual patient. For example, in an older patient after thyroidectomy for MTC with mild asymptomatic hypercalcaemia, localisation procedures and a targeted approach may be appropriate.

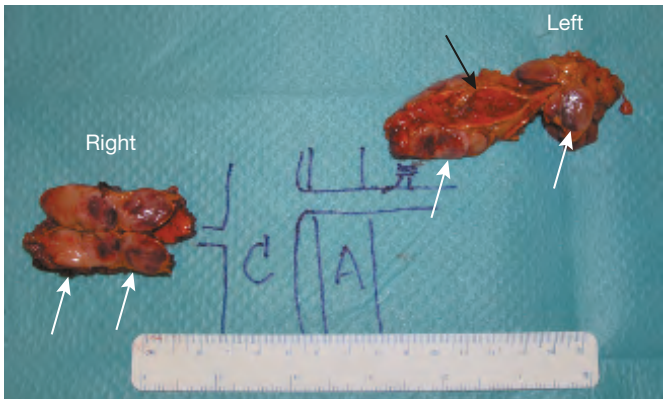

Figure 52.26 Bilateral multiple phaeochromocytomas in a patient with multiple endocrine neoplasia type 2A. A, aorta; C, vena cava; white arrows, tumours; black arrow, normal adrenal.

TABLE 52.9 Prophylactic thyroidectomy for medullary thyroid cancer depending on the site of mutation of the *RET* proto-oncogene in multiple endocrine neoplasia type 2 patients with normal calcitonin levels.

	Risk group		
	High	Medium	Low
Codon	883, 918, 922	609, 611, 618, 620, 634	768, 790, 791, 804, 891
Thyroidectomy at age (years)	<1	6	<20

Chapter 53

The breast

Learning objectives

To understand:

- Appropriate investigation of breast disease
- Breast anomalies and the complexity of benign breast disease
- The modern management of breast cancer

COMPARATIVE AND SURGICAL ANATOMY

The protuberant part of the human breast is generally described as overlying the second to the sixth ribs and extending from the lateral border of the sternum to the anterior axillary line. Actually, a thin layer of mammary tissue extends considerably further, from the clavicle above to the seventh or eighth ribs below, and from the midline to the edge of the latissimus dorsi posteriorly. This fact is important when performing a mastectomy, the aim of which is to remove the whole breast. The anatomy of the breast is illustrated in Figure 53.1.

The **axillary tail** of the breast is of surgical importance. In some normal subjects it is palpable and, in a few, it can be seen premenstrually or during lactation. A well-developed axillary tail is sometimes mistaken for a mass of enlarged lymph nodes or a lipoma.

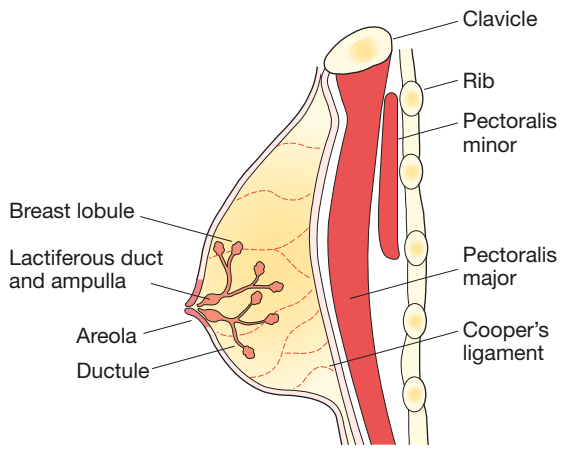

Figure 53.1 Cross-sectional anatomy of the breast.

The **lobule** is the basic structural unit of the mammary gland. The number and size of the lobules vary enormously: they are most numerous in young women. From 10 to over 100 lobules empty via ductules into a lactiferous duct, of which there are 15–20. Each lactiferous duct is lined with a spiral arrangement of contractile myoepithelial cells and is provided with a terminal ampulla, a reservoir for milk or abnormal discharges.

The **ligaments of Cooper** are hollow conical projections of fibrous tissue filled with breast tissue; the apices of the cones are attached firmly to the superficial fascia and thereby to the skin overlying the breast. These ligaments account for the dimpling of the skin overlying a carcinoma.

The **areola** contains involuntary muscle arranged in concentric rings as well as radially in the subcutaneous tissue. The areolar epithelium contains numerous sweat glands and sebaceous glands, the latter of which enlarge during pregnancy and serve to lubricate the nipple during lactation (Montgomery's tubercles).

The **nipple** is covered by thick skin with corrugations. Near its apex lie the orifices of the lactiferous ducts. The nipple contains smooth muscle fibres arranged concentrically and longitudinally; thus, it is an erectile structure, which points outwards.

The **lymphatics** of the breast drain predominantly into the axillary and internal mammary lymph nodes. The axillary nodes receive approximately 85% of the drainage and are arranged in the following groups:

- **lateral**, along the axillary vein;

Sir Astley Paston Cooper, 1768–1841, surgeon, Guy's Hospital, London, UK, described these ligaments in 1845.
William Fetherston Montgomery, 1797–1859, obstetrician, Dublin, Ireland, described these tubercles in 1837.

- **anterior**, along the lateral thoracic vessels;
- **posterior**, along the subscapular vessels;
- **central**, embedded in fat in the centre of the axilla;
- **interpectoral**, a few nodes lying between the pectoralis major and minor muscles;
- **apical**, which lie above the level of the pectoralis minor tendon in continuity with the lateral nodes and which receive the efferents of all the other groups.

The apical nodes are also in continuity with the supraclavicular nodes and drain into the subclavian lymph trunk, which enters the great veins directly or via the thoracic duct or jugular trunk. The **sentinel node** is defined as the first lymph node draining the tumour-bearing area of the breast. The importance of the sentinel node is described later.

The internal mammary nodes are fewer in number. They lie along the internal mammary vessels deep to the plane of the costal cartilages, drain the posterior third of the breast and are not routinely dissected, although they were at one time biopsied for staging.

INVESTIGATION OF BREAST SYMPTOMS

Although an accurate history and clinical examination are important methods of detecting breast disease, there are a number of investigations that can assist in the diagnosis. Examination precedes palpation and requires careful observation of the patient both with the arms at rest and also elevated to lift the breast. Small lesions may betray their presence by dimpling or minor distortions when the patient moves.

Mammography

Soft tissue radiographs are taken by placing the breast in direct contact with ultrasensitive film and exposing it to low-voltage, high-amperage x-rays (**Figure 53.2**). The dose of radiation is approximately 0.1 cGy and, therefore, mammography is a very safe investigation. The sensitivity of this investigation increases with age as the breast becomes less dense. In total, 5% of breast cancers are missed by population-based mammographic screening programmes; even in retrospect, such carcinomas are not apparent. Thus, a normal mammogram does not exclude the presence of carcinoma. Digital mammography is being introduced, which allows manipulation of the images and computer-aided diagnosis. Tomo-mammography is also being assessed as a more sensitive diagnostic modality.

Ultrasound

Ultrasound is particularly useful in young women with dense breasts in whom mammograms are difficult to interpret, and in distinguishing cysts from solid lesions (**Figures 53.3 and 53.4**). It can also be used to localise impalpable areas of breast

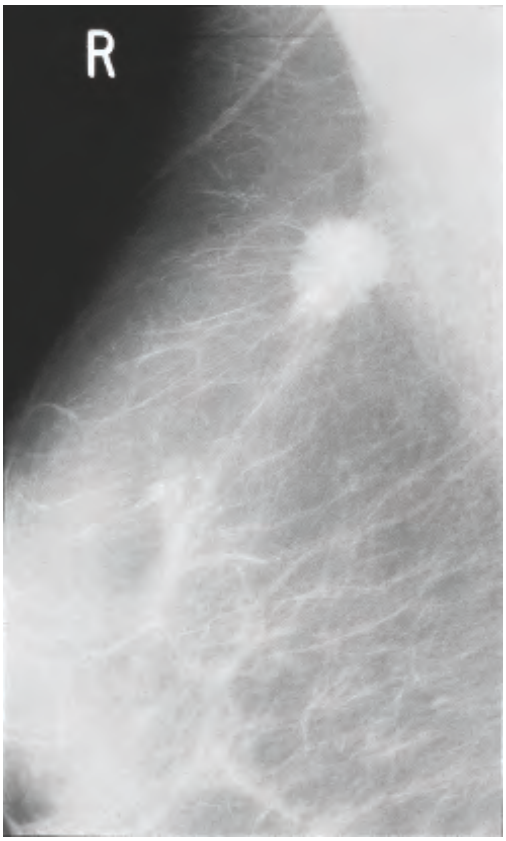

Figure 53.2 Mammogram showing a carcinoma.

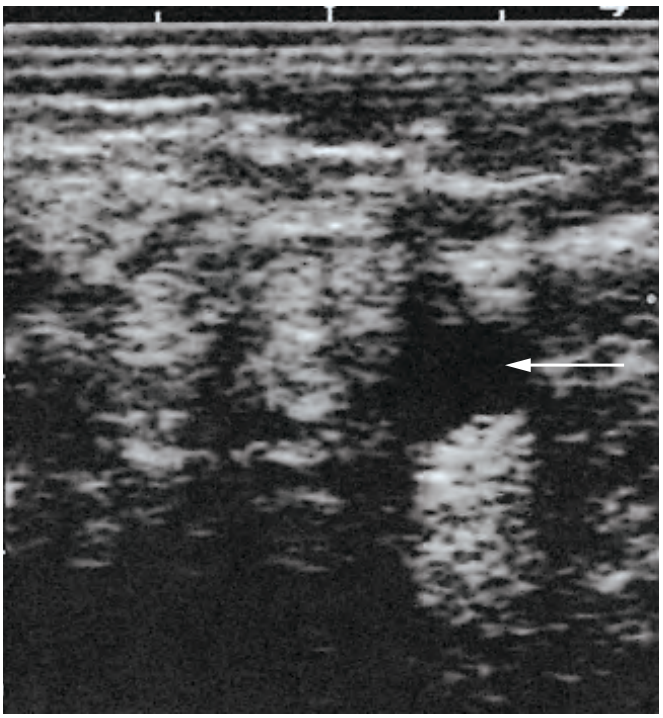

Figure 53.3 Ultrasound of the breast showing a cyst (arrow).

Gy is short for Gray, the SI unit for the absorbed dose of ionising radiation.
Louis Harold Gray, 1905–1965, Director, The British Empire Cancer Campaign Research Unit in Radiobiology, Mount Vernon Hospital, Northwood, Middlesex, UK.

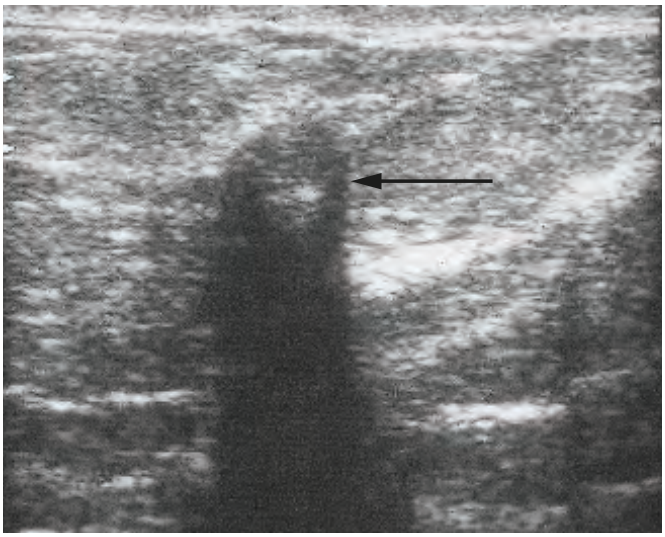

Figure 53.4 Ultrasound of the breast showing a carcinoma (arrow).

pathology. It is not useful as a screening tool and remains operator dependent. Increasingly, ultrasound of the axilla is performed when a cancer is diagnosed, with guided percutaneous biopsy of any suspicious glands.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) (Figure 53.5) of the breast is useful in a number of settings:

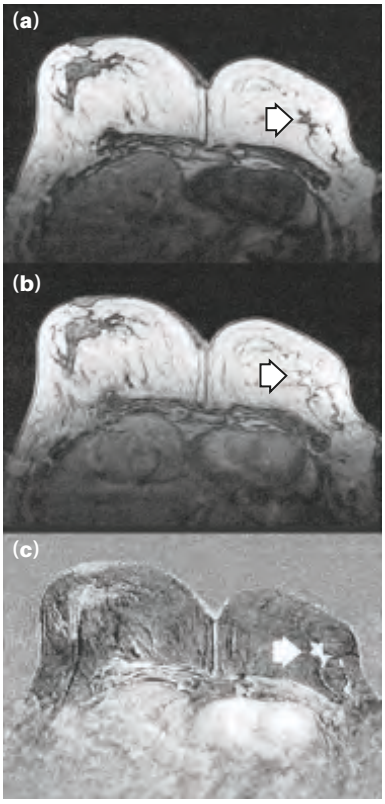

Figure 53.5 Magnetic resonance imaging scan of the breasts showing carcinoma of the left breast (arrows). **(a)** Precontrast; **(b)** post-gadolinium contrast; **(c)** subtraction image.

- to distinguish scar from recurrence in women who have had previous breast conservation therapy for cancer (although it is less accurate within 9 months of radiotherapy because of abnormal enhancement);
- to assess multifocality and multicentricity in lobular cancer and to assess the extent of high-grade ductal carcinoma *in situ* (DCIS). It is less useful in low-grade DCIS;
- it is the best imaging modality for the breasts of women with implants;
- as a screening tool in high-risk women (because of family history).

Although biopsies can be performed with MRI guidance, this is complicated by the configuration of the imaging system. With improved ultrasound equipment, an MRI-detected lesion can often be found on a second-look ultrasound and biopsied using this modality.

Needle biopsy/cytology

Histology can be obtained under local anaesthesia using a springloaded core needle biopsy device (Figure 53.6). Cytology is obtained using a 21G or 23G needle and 10-mL syringe with multiple passes through the lump with negative pressure in the syringe. The aspirate is then smeared on to a slide, which is air dried or fixed (Figure 53.7). Fine-needle

Figure 53.6 Corecut biopsy of breast.

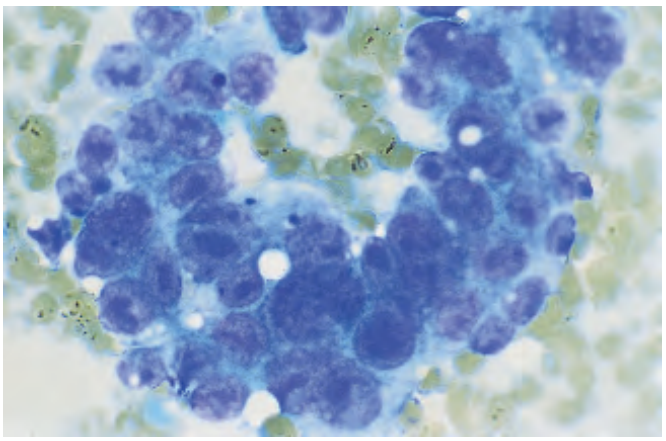

Figure 53.7 Fine-needle aspiration cytology showing grade III ductal carcinoma cells.

aspiration cytology (FNAC) is the least invasive technique of obtaining a cellular diagnosis and is rapid and very accurate if both operator and cytologist are experienced. However, false negatives do occur, mainly through sampling error, and invasive cancer cannot be distinguished from *in situ* disease. A histological specimen taken by core biopsy allows a definitive preoperative diagnosis, differentiates between DCIS and invasive disease and also allows the tumour to be stained for receptor status. This is important before commencing neoadjuvant therapy.

Large-needle biopsy with vacuum systems

The sampling error decreases as the biopsy volume increases and using 8G or 11G needles allows more extensive biopsies to be taken. This is useful in the management of microcalcifications or in the complete excision of benign lesions such as fibroadenomas.

Triple assessment

In any patient who presents with a breast lump or other symptoms suspicious of carcinoma, the diagnosis should be made by a combination of clinical assessment, radiological imaging and a tissue sample taken for either cytological or histological analysis **(Figure 53.8)**, the so-called triple assessment. The positive predictive value (PPV) of this combination should exceed 99.9%.

THE NIPPLE

Absence of the nipple is rare and is usually associated with amazia (congenital absence of the breast).

Supernumerary nipples are not uncommon and occur along a line extending from the anterior fold of the axilla to the fold of the groin **(Figure 53.9)**. This constitutes the milk line of lower mammals. Rarely, there is duplication of the nipple on a normal areola.

Nipple retraction

This may occur at puberty or later in life. Retraction occurring at puberty, also known as **simple nipple inversion**, is of unknown aetiology (benign horizontal inversion). In about 25% of cases it is bilateral. It may cause problems with breast-feeding and infection can occur because of retention of secretions, especially during lactation. Recent retraction of the nipple may be of considerable pathological significance. A slit-like retraction of the nipple may be caused by duct ectasia and chronic periductal mastitis **(Figure 53.10a)**, but circumferential retraction, with or without an underlying lump, may well indicate an underlying carcinoma **(Figure 53.10b)**.

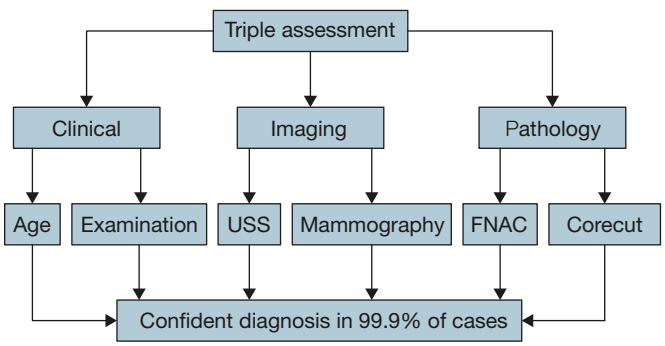

Figure 53.8 Triple assessment of breast symptoms. FNAC, fine-needle aspiration cytology; USS, ultrasound scan.

Figure 53.9 Accessory nipple with congenital retraction of the normal nipple.

Treatment

Treatment is usually unnecessary and the condition may spontaneously resolve during pregnancy or lactation.

Simple cosmetic surgery can produce an adequate correction but has the drawback of dividing the underlying ducts. Mechanical suction devices have been used to evert the nipple, with some effect.

Cracked nipple

This may occur during lactation and be the forerunner of acute infective mastitis. If the nipple becomes cracked during lactation, it should be rested for 24–48 hours and the breast should be emptied with a breast pump. Feeding should be resumed as soon as possible.

Papilloma of the nipple

Papilloma of the nipple has the same features as any cutaneous papilloma and should be excised with a tiny disc of skin. Alternatively, the base may be tied with a ligature and the papilloma will spontaneously fall off.

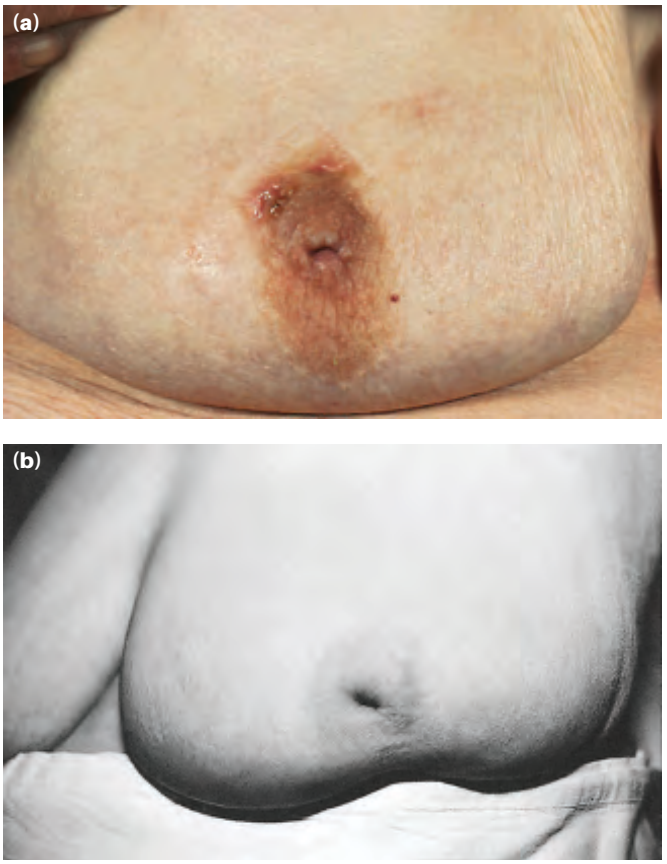

Figure 53.10 Recent nipple retraction. **(a)** Slit-like retraction of duct ectasia with mammary duct fistula. **(b)** Circumferential retraction with underlying carcinoma.

Retention cyst of a gland of Montgomery

These glands, situated in the areola, secrete sebum and if they become blocked a sebaceous cyst forms.

Eczema

Eczema of the nipples is a rare condition and is often bilateral; it is usually associated with eczema elsewhere on the body. It is treated with 0.5% hydrocortisone (not a stronger steroid preparation).

Paget's disease

Paget's disease of the nipple must be distinguished from eczema. The former is caused by malignant cells in the subdermal layer and is usually associated with a carcinoma within the breast. Eczema tends to occur in younger people who have signs of eczema elsewhere (look at the antecubital fossae).

Discharges from the nipple

Discharge can occur from one or more lactiferous ducts. Management depends on the presence of a lump (which should always be given priority in diagnosis and treatment) and the presence of blood in the discharge or discharge from a single duct. Mammography is rarely useful except to exclude an underlying impalpable mass. Cytology may reveal malignant cells but a negative result does not exclude a carcinoma or *in situ* disease.

A **clear, serous discharge** may be 'physiological' in a parous woman or may be associated with a duct papilloma or mammary dysplasia. Multiduct, multicoloured discharge is physiological and the patient may be reassured.

- A **blood-stained discharge** may be caused by duct ectasia, a duct papilloma or carcinoma. A duct papilloma is usually single and situated in one of the larger lactiferous ducts; it is sometimes associated with a cystic swelling beneath the areola.
- A **black or green discharge** is usually the result of duct ectasia and its complications.

Summary box 53.1

Discharges from the nipple (the principal causes are in bold)

Discharge from the surface
- Paget's disease
- Skin diseases (eczema, psoriasis)
- Rare causes (e.g. chancre)

Discharge from a single duct

Blood-stained:
- **Intraduct papilloma**
- **Intraduct carcinoma**
- Duct ectasia

Serous (any colour):
- **Fibrocystic disease**
- **Duct ectasia**
- Carcinoma

Discharge from more than one duct

Blood-stained:
- **Carcinoma**
- Ectasia
- Fibrocystic disease

Black or green:
- **Duct ectasia**

Purulent:
- **Infection**

Serous:
- **Fibrocystic disease**
- Duct ectasia
- Carcinoma

Milk:
- **Lactation**
- Rare causes (hypothyroidism, pituitary tumour)

Sir James Paget, 1814–1899, surgeon, St. Bartholomew's Hospital, London, UK, described this disease of the nipple in 1874.

Treatment

Treatment must firstly be to exclude a carcinoma by occult blood test and cytology. Simple reassurance may then be sufficient but, if the discharge is proving intolerable, an operation to remove the affected duct or ducts can be performed (microdochectomy).

MICRODOCHECTOMY

It is important not to express the blood before the operation as it may then be difficult to identify the duct in theatre. A lacrimal probe or length of stiff nylon suture is inserted into the duct from which the discharge is emerging. A tennis racquet incision can be made to encompass the entire duct or a periareolar incision used and the nipple flap dissected to reach the duct. The duct is then excised. A papilloma is nearly always situated within 4–5 cm of the nipple orifice.

Ductoscopy (inspection of the internal structure of the duct system) using microendoscopes is technically feasible but generally disappointing. The affected duct may not be visualised and biopsy systems are currently rudimentary.

CONE EXCISION OF THE MAJOR DUCTS (AFTER HADFIELD) (SUBAREOLAR RESECTION)

When the duct of origin of nipple bleeding is uncertain or when there is bleeding or discharge from multiple ducts, the entire major duct system can be excised for histological examination without sacrifice of the breast form. A periareolar incision is made and a cone of tissue is removed with its apex just deep to the surface of the nipple and its base on the pectoral fascia. The resulting defect may be obliterated by a series of purse-string sutures, although a temporary suction drain will reduce the chance of long-term deformity. It is vital to warn the patient that she will be unable to breast-feed after this and may experience altered nipple sensation.

BENIGN BREAST DISEASE

This is the most common cause of breast problems; up to 30% of women will suffer from a benign breast disorder requiring treatment at some time in their lives. The most common symptoms are pain, lumpiness or a lump. The aim of treatment is to exclude cancer and, once this has been done, to treat any remaining symptoms.

Congenital abnormalities

Amazia

Congenital absence of the breast may occur on one (**Figure 53.11**) or both sides. It is sometimes associated with absence of the sternal portion of the pectoralis major (Poland's syndrome). It is more common in males.

Polymazia

Accessory breasts (**Figure 53.12**) have been recorded in the axilla (the most frequent site), groin, buttock and thigh. They have been known to function during lactation.

Figure 53.11 Congenital absence of the left breast.

Figure 53.12 Bilateral accessory breasts.

Mastitis of infants

Mastitis of infants is at least as common in boys as in girls. On the third or fourth day of life, if the breast of an infant is pressed lightly, a drop of colourless fluid can be expressed; a few days later, there is often a slight milky secretion, which disappears during the third week. This is popularly known as 'witch's milk' and is seen only in full-term infants. It is caused by stimulation of the fetal breast by prolactin in response to the drop in maternal oestrogens and is essentially physiological. True mastitis is uncommon and is predominately caused by *Staphylococcus aureus*.

Diffuse hypertrophy

Diffuse hypertrophy of the breasts occurs sporadically in otherwise healthy girls at puberty (benign virginal hypertrophy) and, much less often, during the first pregnancy. The condition is rarely unilateral. This tremendous overgrowth is apparently caused by an alteration in the normal sensitivity of the breast to oestrogenic hormones and some success in treating it with antioestrogens has been reported. Treatment is otherwise by reduction mammoplasty.

Geoffrey John Hadfield, 1923–2006, surgeon, Stoke Mandeville Hospital, Aylesbury, Buckinghamshire, UK.
Alfred Poland, 1822–1872, surgeon, Guy's Hospital, London, UK, described this condition in 1841.

Injuries of the breast

Haematoma

Haematoma, particularly a resolving haematoma, gives rise to a lump, which, in the absence of overlying bruising, is difficult to diagnose correctly unless it is biopsied.

Traumatic fat necrosis

Traumatic fat necrosis may be acute or chronic and usually occurs in stout, middle-aged women. Following a blow, or even indirect violence (e.g. contraction of the pectoralis major), a lump, often painless, appears. This may mimic a carcinoma, even displaying skin tethering and nipple retraction, and biopsy is required for diagnosis. A history of trauma is not diagnostic as this may merely have drawn the patient's attention to a pre-existing lump. A seatbelt may transect or avulse the breast with a sudden deceleration injury, as in a road traffic accident.

Acute and subacute inflammations of the breast

Bacterial mastitis

Bacterial mastitis is the most common variety of mastitis and is associated with lactation in the majority of cases.

AETIOLOGY

Lactational mastitis is seen far less frequently than in former years. Most are caused by *S. aureus* and, if hospital acquired, are likely to be penicillin resistant. The intermediary is usually the infant; after the second day of life, 50% of infants harbour staphylococci in the nasopharynx.

Although ascending infection from a sore and cracked nipple may initiate the mastitis, in many cases the lactiferous ducts will first become blocked by epithelial debris leading to stasis; this theory is supported by the relatively high incidence of mastitis in women with a retracted nipple. Once within the ampulla of the duct, staphylococci cause clotting of milk and, within this clot, organisms multiply.

CLINICAL FEATURES

The affected breast, or more usually a segment of it, presents the classical signs of acute inflammation. Early on this is a generalised cellulitis but later an abscess will form.

TREATMENT

During the cellulitic stage, the patient should be treated with an appropriate antibiotic, such as flucloxacillin or co-amoxiclav. Feeding from the affected side may continue if the patient can manage. Support of the breast, local heat and analgesia will help to relieve pain.

If an antibiotic is used in the presence of undrained pus, an 'antibioma' may form. This is a large, sterile, brawny oedematous swelling that takes many weeks to resolve.

It used to be recommended that the breast should be incised and drained if the infection did not resolve within 48 hours or if after being emptied of milk there was an area of tense induration or other evidence of an underlying abscess. This advice has been replaced with the recommendation that repeated aspirations under antibiotic cover (if necessary using ultrasound for localisation) be performed. This often allows resolution without the need for an incision and will also allow the patient to continue breast-feeding.

The presence of pus can be confirmed with needle aspiration, and the pus should be sent for bacteriological culture. In contrast to the majority of localised infections, fluctuation is a late sign. Usually, the area of induration is sector shaped and, in early cases, about one-quarter of the breast is involved (**Figure 53.13**); in many late cases the area is more extensive (**Figure 53.14**). When in doubt, an ultrasound scan may clearly define an area suitable for drainage.

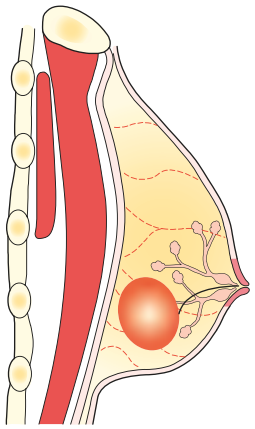

Figure 53.13 Intramammary breast abscess.

Figure 53.14 Large breast abscess.

Operative drainage of a breast abscess

This is less commonly needed as prompt commencement of antibiotics and repeated aspiration is usually successful. Incision of a lactational abscess is necessary if there is marked skin thinning and can usually be performed under local anaesthesia if an analgesic cream such as EMLA (lidocaine) is applied 30 minutes before surgery.

The usual incision is sited in a radial direction over the affected segment, although if a circumareolar incision will allow adequate access to the affected area this is preferred because it gives a better cosmetic result. The incision passes

through the skin and the superficial fascia. A long artery forceps is then inserted into the abscess cavity. Every part of the abscess is palpated against the point of the artery forceps and its jaws are opened. All loculi that can be felt are entered.

Finally, the artery forceps having been withdrawn, a finger is introduced and any remaining septa are disrupted. The wound may then be lightly packed with ribbon gauze or a drain inserted to allow dependent drainage.

Chronic intramammary abscess

A chronic intramammary abscess, which may follow inadequate drainage or injudicious antibiotic treatment, is often a very difficult condition to diagnose. When encapsulated within a thick wall of fibrous tissue the condition cannot be distinguished from a carcinoma without the histological evidence from a biopsy.

Tuberculosis of the breast

Tuberculosis of the breast, which is comparatively rare, is usually associated with active pulmonary tuberculosis or tuberculous cervical adenitis.

Tuberculosis of the breast occurs more often in parous women and usually presents with multiple chronic abscesses and sinuses and a typical bluish, attenuated appearance of the surrounding skin. The diagnosis rests on bacteriological and histological examination. Treatment is with antituberculous chemotherapy. Healing is usual, although often delayed, and mastectomy should be restricted to patients with persistent residual infection.

Actinomycosis

Actinomycosis of the breast is rarer still. The lesions present the essential characteristics of faciocervical actinomycosis.

Mondor's disease

Mondor's disease is thrombophlebitis of the superficial veins of the breast and anterior chest wall, although it may also occur in the arm.

In the absence of injury or infection, the cause of thrombophlebitis (like that of spontaneous thrombophlebitis in other sites) is obscure. The pathognomonic feature is a thrombosed subcutaneous cord, usually attached to the skin. When the skin over the breast is stretched by raising the arm, a narrow, shallow, subcutaneous groove alongside the cord becomes apparent (**Figure 53.15**). The differential diagnosis is lymphatic permeation from an occult carcinoma of the breast. The only treatment required is to restrict arm movements. The condition usually subsides within a few months without recurrence, complications or deformity. There are case reports of Mondor's disease being associated with subsequent development of malignancy, although coincidental malignancy is more likely.

Figure 53.15 Mondor's disease evident in the lateral aspect of the right breast.

Duct ectasia/periductal mastitis

PATHOLOGY

This is a dilatation of the breast ducts, which is often associated with periductal inflammation. The pathogenesis is obscure and almost certainly not uniform in all cases, although the disease is much more common in smokers.

The classical description of the pathogenesis of duct ectasia asserts that the first stage in the disorder is a dilatation in one or more of the larger lactiferous ducts, which fill with a stagnant brown or green secretion. This may discharge. These fluids then set up an irritant reaction in surrounding tissue, leading to periductal mastitis or even abscess and fistula formation (**Figures 53.16 and 53.17**). In some cases, a chronic indurated mass forms beneath the areola, which mimics a carcinoma. Fibrosis eventually develops, which may cause slit-like nipple retraction.

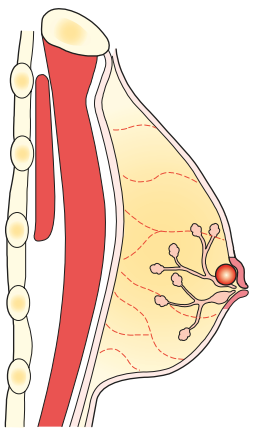

Figure 53.16 Subareolar abscess in duct ectasia.

Henri Mondor, 1885–1962, Professor of Surgery, Paris, France.

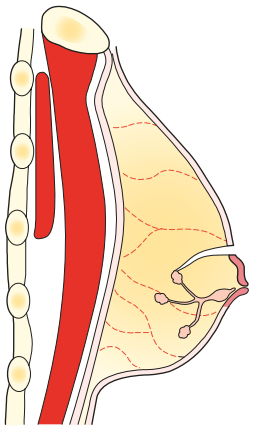

Figure 53.17 Mammary fistula originating in a chronic subareolar abscess.

An alternative theory suggests that periductal inflammation is the primary condition and, indeed, anaerobic bacterial infection is found in some cases. A marked association between recurrent periductal inflammation and smoking has been demonstrated. This was thought by some to indicate that arteriopathy is a contributing factor in its aetiology, although others believe that smoking increases the virulence of the commensal bacteria. It is certainly clear that cessation of smoking increases the chance of a long-term cure.

CLINICAL FEATURES

Nipple discharge (of any colour), a subareolar mass, abscess, mammary duct fistula and/or nipple retraction are the most common symptoms.

TREATMENT

In the case of a mass or nipple retraction, a carcinoma must be excluded by obtaining a mammogram and negative cytology or histology. If any suspicion remains the mass should be excised.

Antibiotic therapy may be tried, the most appropriate agents being co-amoxiclav or flucloxacillin and metronidazole. However, surgery is often the only option likely to bring about cure of this notoriously difficult condition; this consists of excision of all of the major ducts (Hadfield's operation). It is particularly important to shave the back of the nipple to ensure that all terminal ducts are removed. Failure to do so will lead to recurrence.

Aberrations of normal development and involution

Nomenclature

The nomenclature of benign breast disease is confusing. This is because over the last century a variety of clinicians and pathologists have chosen to describe a mixture of physiological changes and disease processes according to a variety of clinical, pathological and aetiological terminology. As well as leading to confusion, patients were often unduly alarmed or overtreated by ascribing a pathological name to a variant of physiological development. To address this confusion, a concept (Aberrations of Normal Development and Involution (ANDI)) has been developed and described by the Cardiff Breast Clinic.

Aetiology

The breast is a dynamic structure that undergoes changes throughout a woman's reproductive life and, superimposed upon this, cyclical changes throughout the menstrual cycle. (This is illustrated in **Figure 53.18**). The pathogenesis of ANDI involves disturbances in the breast physiology extending from a perturbation of normality to well-defined disease processes. There is often little correlation between the histological appearance of the breast tissue and the symptoms.

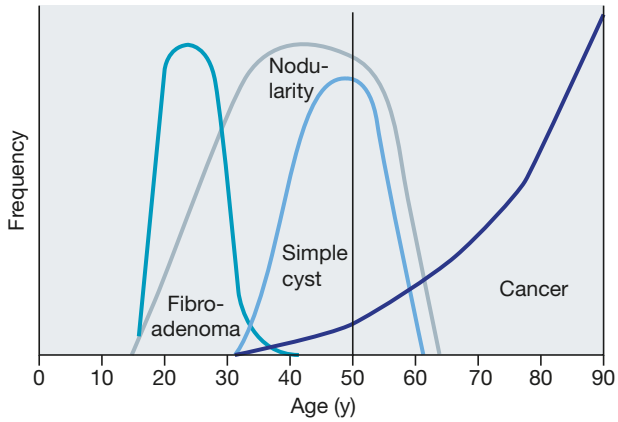

Figure 53.18 Normal breast changes throughout life. UK National Health Service Breast Screening Programme data.

Pathology

The disease consists essentially of four features that may vary in extent and degree in any one breast.

- **Cyst formation**. Cysts are almost inevitable and very variable in size.
- **Fibrosis**. Fat and elastic tissues disappear and are replaced with dense white fibrous trabeculae. The interstitial tissue is infiltrated with chronic inflammatory cells.
- **Hyperplasia** of epithelium in the lining of the ducts and acini may occur, with or without atypia.
- **Papillomatosis**. The epithelial hyperplasia may be so extensive that it results in papillomatous overgrowth within the ducts.

Clinical features

The symptoms of ANDI are many as the term is used to encompass a wide range of benign conditions, but often include an area of lumpiness (seldom discrete) and/or breast pain (mastalgia).

- A benign discrete lump in the breast is commonly a cyst or fibroadenoma. True lipomas occur rarely.
- Lumpiness may be bilateral, commonly in the upper outer quadrant or, less commonly, confined to one quadrant of one breast. The changes may be cyclical, with an increase in both lumpiness and often tenderness before a menstrual period.

- Non-cyclical mastalgia is more common in perimenopausal than postmenopausal women. It may be associated with ANDI or with periductal mastitis. It should be distinguished from referred pain, for example a musculoskeletal disorder. 'Breast' pain in postmenopausal women not taking hormonereplacement therapy (HRT) is usually derived from the chest wall, back or neck.

About 5% of breast cancers exhibit pain at presentation, but rarely as the sole presenting feature.

TREATMENT OF LUMPY BREASTS

If the clinician is confident that he or she is not dealing with a discrete abnormality (and clinical confidence is supported by mammography and/or ultrasound scanning if considered appropriate), the woman can initially be offered firm reassurance. It is perhaps worthwhile reviewing the patient at a different point in the menstrual cycle, for example 6 weeks after the initial visit as often the clinical signs will have resolved by that time. There is a tendency for women with lumpy breasts to be rendered unnecessarily anxious and to be submitted to multiple random biopsies because the clinician lacks the courage of his or her convictions. Rapid referral into the secondary health care sytem often means patients are assessed without an intervening menstrual cycle and this may lead to additional concerns.

TREATMENT OF MASTALGIA

Pronounced cyclical mastalgia may become a significant clinical problem if the pain and tenderness interfere with the woman's life, disturb her sleep and impair sexual activity. Initially, firm reassurance that the symptoms are not associated with cancer will help the majority of women. Acknowledgement that this is a real symptom, a non-dismissive attitude and an explanation of the aetiology are all helpful in managing this condition.

In the first instance, an appropriately fitting and supportive bra should be worn throughout the day and a soft bra (such as a sports bra) worn at night. Avoiding caffeine drinks is said to help, although the author remains unconvinced.

A patient symptom diary will help her to chart the pattern of pain throughout the month and thus determine whether this is cyclical mastalgia. This allows the majority of patients to adjust to the concept of a cyclical nature of their problem but, if reassurance is inadequate, then a planned escalation of treatment (*Table 53.1*) could be advised. Oil of evening primrose, in adequate doses given over 3 months, will help more than half of these women. It appears to achieve higher response rates in those over 40 years of age rather than younger women. For those with intractable symptoms, an antigonadotrophin, such as danazol, or a prolactin inhibitor, such as bromocriptine, may be tried. Very rarely it is necessary to prescribe an antioestrogen, for example tamoxifen, or a luteinising hormone-releasing hormone (LHRH) agonist to deprive the breast epithelium of oestrogenic drive.

For non-cyclical mastalgia it is important to exclude extramammary causes such as chest wall pain (Tietze syndrome). This is common in postmenopausal women who are not taking HRT, and the neck and shoulders are common sights of referred pain. It is seldom necessary these days to carry out a biopsy on a very localised tender area that might be harbouring a subclinical cancer as imaging is so much better. Treatment may be with non-steroidal analgesics or by injection with local anaesthetic on a 'trigger spot'.

Breast cysts

These occur most commonly in the last decade of reproductive life as a result of a non-integrated involution of stroma and epithelium. They are often multiple, may be bilateral and can mimic malignancy. Diagnosis can be confirmed by aspiration and/or ultrasound. They typically present suddenly and cause great alarm; prompt diagnosis and drainage provides immediate relief.

Treatment

A solitary cyst or small collection of cysts can be aspirated. If they resolve completely, and if the fluid is not blood-stained, no further treatment is required. However, 30% will recur and require reaspiration. Cytological examination of cyst fluid is no longer practised routinely. If there is a residual lump or if the fluid is blood-stained, a core biopsy or local excision for histological diagnosis is advisable, which is also the case if the cyst reforms repeatedly. This will exclude cystadenocarcinoma, which is more common in elderly women.

Galactocele

Galactocele is rare and usually presents as a solitary, subareolar cyst and always dates from lactation. It contains milk and in long-standing cases its walls tend to calcify.

TABLE 53.1 Treatment of breast pain.

Exclude cancer	
Reassure	Use pain chart if unsure if cyclical or non-cyclical. Also allows time for reassurance to become active!
Adequate support	Firm bra during the day and a softer bra at night
Exclude caffeine	Works for some although not very efficacious in author's practice
Consider medication	
Evening primrose oil (GLA)	Better effect in women over 40 years old than in younger women
Danazol, 100 mg three times a day	Start at 100 mg per day and increase (seldom used these days)
Tamoxifen	Not licensed for this indication but occasionally very helpful

Fibroadenoma

These usually arise in the fully developed breast between the ages of 15 and 25 years, although occasionally they occur in much older women. They arise from hyperplasia of a single lobule and usually grow up to 2–3 cm in size. They are surrounded by a well-marked capsule and can thus be enucleated through a cosmetically appropriate incision. A fibroadenoma does not require excision unless associated with suspicious cytology, it becomes very large or the patient expressly desires the lump to be removed. Alternatives to surgery include cryoablation, heating with high-frequency ultrasound (echotherapy) or removal with a large core vacuum biopsy system. Even if clinically obvious, a biopsy should be obtained if the patient is over 25 or there are any atypical features on ultrasound.

Giant fibroadenomas occasionally occur during puberty. They are over 5 cm in diameter and are often rapidly growing but, in other respects, are similar to smaller fibroadenomas and can be enucleated through a submammary incision. They are more common in the Afro-Caribbean population.

Phyllodes tumour

These benign tumours, previously sometimes known as serocystic disease of Brodie or cystosarcoma phyllodes, usually occur in women over the age of 40 years but can appear in younger women. They present as a large, sometimes massive, tumour with an unevenly bosselated surface (**Figure 53.19**). Occasionally, ulceration of overlying skin occurs because of pressure necrosis. Despite their size, phyllodes tumours remain mobile on the chest wall. Histologically, there is a wide variation in their appearance, with some of low malignant potential resembling a fibroadenoma and others having a higher mitotic index, which are histologically worrying. The latter may recur locally but, despite the name of cystosarcoma phyllodes, they are rarely cystic and only very rarely develop features of a sarcomatous tumour. These may metastasise via the bloodstream.

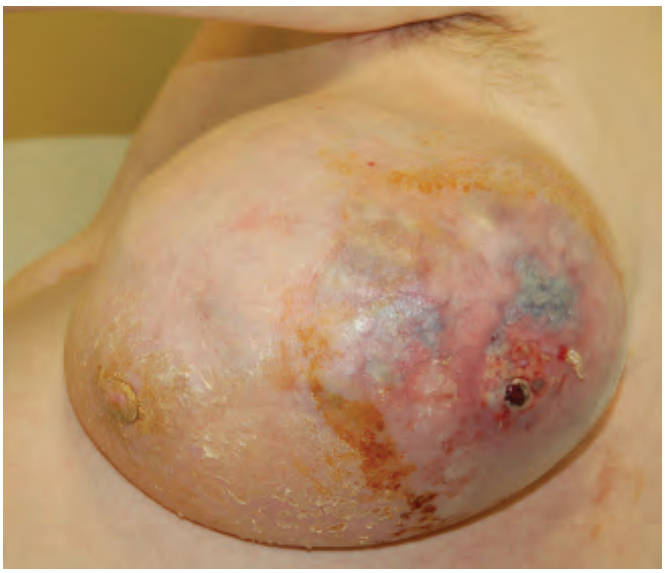

Figure 53.19 Phyllodes tumour (courtesy of Professor Mike Dixon).

Treatment

Treatment for the benign type is enucleation in young women or wide local excision. Massive tumours, recurrent tumours and those of the malignant type will require mastectomy.

Summary box 53.2

Benign breast disorder classification

Congenital disorders

- Inverted nipple
- Supernumerary breasts/nipples
- Non-breast disorders including Tietze's disease (costochondritis)
- Sebaceous cysts and other skin conditions

Injury

Inflammation/infection

- ANDI (aberations of normal differentiation and involution):
  - Cyclical nodularity and mastalgia
  - Cysts
  - Fibroadenoma
  - Duct ectasia/periductal mastitis
- Pregnancy-related:
  - Galactocele
  - Lactational abscess

When the diagnosis of carcinoma is in doubt

There will always be situations in which the clinician cannot be sure whether a particular lump in the breast is an area of mammary dysplasia, a benign tumour or an early carcinoma.

If there is doubt on clinical, cytological or radiological examination, it is essential to obtain a tissue diagnosis. This is often possible by needle biopsy. In the event of a negative result, open biopsy of the mass or large guage vacuum biopsy is necessary. Because of the possibility of reporting errors and because the histology is likely to be more difficult (if a diagnosis has not already been made), the author suggests that frozen-section reporting should be used rarely and certainly should not form the basis for a decision to undertake a mastectomy. *Table 53.2* gives an algorithm for investigating any breast lump.

Sir Benjamin Collins Brodie, 1783–1862, surgeon, St. George's Hospital, London, UK, described serocystic disease of the breast in 1840.
Alexander Tietze, 1864–1927, Professor of Surgery, Breslau, Germany (now Wroclaw, Poland), described this condition in 1921.

TABLE 53.2 Investigation of a breast lump (after imaging performed) using fine-needle aspiration cytology.

Cystic	Lump disappears; clear fluid (many colours)	Discharge patient
	Residual thickening; blood-stained fluid	Investigate – ?core biopsy
Solid	Benign	Offer excision or observe
	Atypical	Investigate – ?core biopsy
	Malignant	Treat for cancer

Risk of malignancy developing in association with benign breast pathology

The relative risks of malignancy developing according to different histological features found at biopsy are illustrated in *Table 53.3*.

These were elucidated 30 years ago but remain pertinent and a recent single-centre review reinforces the conclusion that the histological classification of the benign lesion in combination with a family history of breast cancer are important predictors of risk.

CARCINOMA OF THE BREAST

Breast cancer is the most common cause of death in middle-aged women in western countries. In England and Wales, 1 in 12 women will develop the disease during their lifetime. The incidence is expected to continue rising as the population ages, although more slowly than previously thought as the use of HRT has reduced in the USA and UK.

TABLE 53.3 Relative risk of invasive breast carcinoma based on pathological examination of benign breast tissue (American College of Pathologists Consensus Statement).[a]

No increased risk	Adenosis, sclerosing or florid
	Apocrine metaplasia
	Cysts, macro and/or micro
	Duct ectasia
	Fibroadenoma
	Fibrosis
	Hyperplasia
	Mastitis (inflammation)
	Periductal mastitis
	Squamous metaplasia
Slightly increased risk (1.5–2 times)	Hyperplasia, moderate or florid, solid or papillary
	Papilloma with a fibrovascular core
Moderately increased risk (5 times)	Atypical hyperplasia (ductal or lobular)
Insufficient data to assign a risk	Solitary papilloma of lactiferous sinus
	Radial scar lesion

After Page and Dupont (1978) by kind permission of the *Journal of the National Cancer Institute*, USA.

[a] A combination with positive family history significantly increases the risks shown above.

Aetiological factors

Geographical

Carcinoma of the breast occurs commonly in the western world, accounting for 3–5% of all deaths in women. In resource-poor countries it accounts for 1–3% of deaths.

Age

Carcinoma of the breast is extremely rare before the age of 20 years but, thereafter, the incidence steadily rises so that by the age of 90 years nearly 20% of women are affected.

Gender

Less than 0.5% of patients with breast cancer are male.

Genetic

Breast cancer occurs more commonly in women with a family history of breast cancer than in the general population. Breast cancer related to a specific mutation accounts for about 5% of breast cancers, yet has far-reaching repercussions in terms of counselling and tumour prevention in these women. This will be discussed more fully in a subsequent section.

Diet

Because breast cancer so commonly affects women in the 'developed' world, dietary factors may play a part in its causation. There is some evidence that there is a link with diets low in phytoestrogens. Alcohol consumption is associated with an increased risk.

Endocrine

Breast cancer is more common in nulliparous women and breast-feeding in particular appears to be protective. Also protective is having a first child at an early age, especially if associated with late menarche and early menopause. It is known that in postmenopausal women, breast cancer is more common in the obese. This is thought to be because of an increased conversion of steroid hormones to oestradiol in the body fat. Recent studies have clarified the role of exogenous hormones, in particular the oral contraceptive pill and HRT, in the development of breast cancer. For most women the benefits of these treatments will far outweigh the small putative risk; however, long-term exposure to the combined preparation of HRT does significantly increase the risk of developing breast cancer. The recent fall in use of HRT in USA and UK has seen a reduction in the incidence of breast cancer in the 50–60-year-old cohort.

Previous radiation

This was considered to be of historical interest, as the majority of women exposed to the atomic bombs at Hiroshima and Nagasaki have now died. It was, however, also a problem in women who had been treated with mantle radiotherapy as

part of the management of Hodgkin's disease, in which significant doses of radiation to the breast were received. The risk appeared about a decade after treatment and was higher if radiotherapy occurred during breast development. A surveillance programme was organised in the UK with MRI and mammographic screening. This type of radiotherapy is now no longer used and the cohort of patients at risk is now small.

Pathology

Breast cancer may arise from the epithelium of the duct system anywhere from the nipple end of the major lactiferous ducts to the terminal duct unit, which is in the breast lobule. The disease may be entirely *in situ*, an increasingly common finding with the advent of breast cancer screening, or may be invasive cancer. The degree of differentiation of the tumour is usually described using three grades: well differentiated, moderately differentiated or poorly differentiated. Commonly, a numerical grading system based on the scoring of three individual factors (nuclear pleomorphism, tubule formation and mitotic rate) is used, with grade III cancers roughly equating to the poorly differentiated group.

Previously, descriptive terms were used to classify breast cancer ('scirrhous', meaning woody, or 'medullary', meaning brain-like). More recently, histological descriptions have been used. These have been shown to have clinical correlations in the way that the tumour behaves. However, with the increasing application of molecular markers, there is a change in the way that breast cancers are classified and it is likely that much more information about an individual tumour will be routinely reported, such as its likelihood of metastasis and to which therapeutic agents it will be susceptible. Gene array analysis of breast cancers has identified five major subtypes (luminal A and luminal B, triple negative, Her-2 receptor positive and a miscellaneous group.) Some of these correlate with known markers such as oestrogen receptor status. There are specific gene signatures that correlate with response to chemotherapy or poor prognosis. A commercial test is now available to patients with oestrogen-positive tumours to assess their risk of recurrence. This is based on analysis of 21 genes and may allow selection of patients in whom more aggressive therapy is indicated.

Current nomenclature

Ductal carcinoma is the most common variant with **lobular carcinoma** occurring in up to 15% of cases. There are subtypes of lobular cancer, including the classical type, that carry a better prognosis than the pleomorphic type. Occasionally, the picture may be mixed with both ductal and lobular features. There are different patterns of spread depending on histological type. If there is doubt whether a tumour is predominantly lobular in type, immunohistochemical analysis using the e-cadherin antibody, which reacts positively in lobular cancer, will help in diagnosis.

Rarer histological variants, usually carrying a better prognosis, include **colloid** or **mucinous carcinoma**, whose cells produce abundant mucin, **medullary carcinoma**, with solid sheets of large cells often associated with a marked lymphocytic reaction and **tubular carcinoma**. Invasive lobular carcinoma is commonly multifocal and/or bilateral, hence the increasing use of MRI for assessment. Cases detected via the screening programme are often smaller and better differentiated than those presenting to the symptomatic service and are of a special type.

Inflammatory carcinoma is a fortunately rare, highly aggressive cancer that presents as a painful, swollen breast, which is warm with cutaneous oedema. This is the result of blockage of the subdermal lymphatics with carcinoma cells. Inflammatory cancer usually involves at least one-third of the breast and may mimic a breast abscess. A biopsy will confirm the diagnosis and show undifferentiated carcinoma cells. It used to be rapidly fatal but with aggressive chemotherapy and radiotherapy and with salvage surgery the prognosis has improved considerably.

***In situ* carcinoma** is preinvasive cancer that has not breached the epithelial basement membrane. This was previously a rare, usually asymptomatic, finding in breast biopsy specimens but is becoming increasingly common because of the advent of mammographic screening; it now accounts for over 20% of cancers detected by screening in the UK. *In situ* carcinoma may be ductal (DCIS) or lobular (LCIS), the latter often being multifocal and bilateral. Both are markers for the later development of invasive cancer, which will develop in at least 20% of patients. Although mastectomy is curative, this constitutes overtreatment in many cases. The best treatment for *in situ* carcinoma is the subject of a number of on-going clinical trials. DCIS may be classified using the Van Nuys system, which combines the patient's age, type of DCIS and presence of microcalcification, extent of resection margin and size of disease. Patients with a high score benefit from radiotherapy after excision, whereas those of low grade, whose tumour is completely excised, need no further treatment.

Staining for oestrogen and progesterone receptors is now routine, as their presence will indicate the use of adjuvant hormonal therapy with tamoxifen or an aromatase inhibitor (AI) (Figure 53.20). Tumours are also stained for Her-2 or

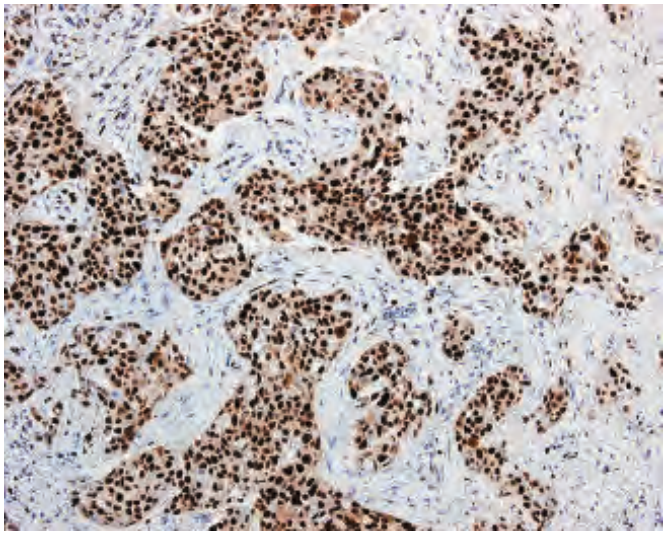

Figure 53.20 Immunohistochemical staining for oestrogen receptors.

Thomas Hodgkin, 1798–1866, Curator of the Museum, and Demonstrator of Morbid Anatomy, Guy's Hospital, London, UK.

c-erbB2 (a growth factor receptor) as patients who are positive can be treated with the monoclonal antibody trastuzumab (Herceptin®), either in the adjuvant or relapse setting.

The pathologist is an important member of the breast cancer team and will increasingly help decide which adjuvant therapies will be appropriate.

Paget's disease of the nipple

Paget's disease of the nipple (Figure 53.21) is a superficial manifestation of an underlying breast carcinoma. It presents as an eczema-like condition of the nipple and areola, which persists despite local treatment. The nipple is eroded slowly and eventually disappears. If left, the underlying carcinoma will sooner or later become clinically evident. Nipple eczema should be biopsied if there is any doubt about its cause. Microscopically, Paget's disease is characterised by the presence of large, ovoid cells with abundant, clear, pale-staining cytoplasm in the Malpighian layer of the epidermis.

The spread of breast cancer

Local spread

The tumour increases in size and invades other portions of the breast. It tends to involve the skin and to penetrate the pectoral muscles and even the chest wall if diagnosed late.

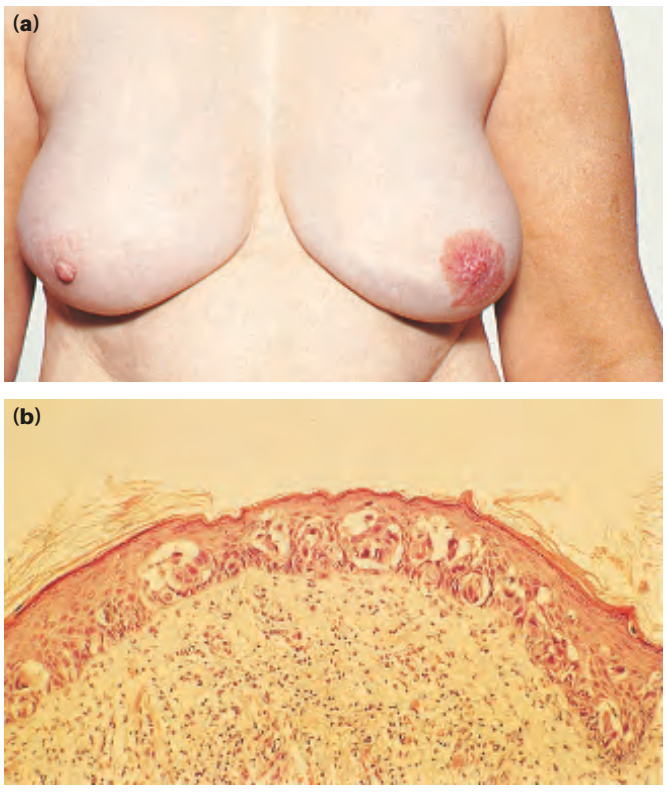

Figure 53.21 **(a)** Paget's disease of the nipple. **(b)** Histological appearance of Paget's disease.

Lymphatic metastasis

Lymphatic metastasis occurs primarily to the axillary and the internal mammary lymph nodes. Tumours in the posterior one-third of the breast are more likely to drain to the internal mammary nodes. The involvement of lymph nodes has both biological and chronological significance. It represents not only an evolutional event in the spread of the carcinoma but is also a marker for the metastatic potential of that tumour. Involvement of supraclavicular nodes and of any contralateral lymph nodes represents advanced disease.

Spread by the bloodstream

It is by this route that skeletal metastases occur, although the initial spread may be via the lymphatic system. In order of frequency the lumbar vertebrae, femur, thoracic vertebrae, rib and skull are affected and these deposits are generally osteolytic. Metastases may also commonly occur in the liver, lungs and brain and, occasionally, the adrenal glands and ovaries; they have, in fact, been described in most body sites. Analysis of peripheral blood samples for circulating tumour deoxyribonucleic acid (DNA) has shown prognostic significance and can be used to monitor response.

Clinical presentation

Although any portion of the breast, including the axillary tail, may be involved, breast cancer is found most frequently in the upper outer quadrant (Figures 53.22 and 53.23). Most breast cancers will present as a hard lump, which may be associated with indrawing of the nipple or overlying skin. As the disease advances locally there may be skin involvement with peau d'orange (Figure 53.24) or frank ulceration and fixation to the chest wall (Figure 53.25). This is described as cancer-en-cuirasse when the disease progresses around the

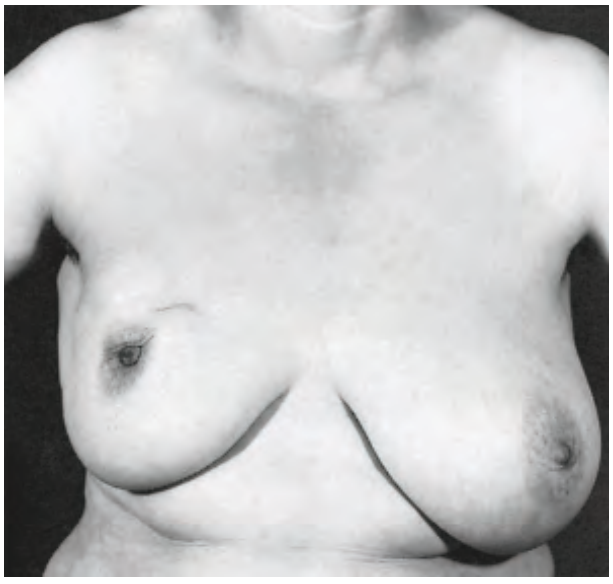

Figure 53.22 Invasive carcinoma of the right breast. Note the shrinking and elevation of the breast with nipple retraction.

Figure 53.25 Ulcerated carcinoma of the right breast.

chest wall. About 5% of breast cancers in the UK will present with either locally advanced disease or symptoms of metastatic disease. This figure is much higher in resource-poor countries. These patients must then undergo a staging evaluation so that the full extent of their disease can be ascertained. This will include a careful clinical examination, chest radiograph, computed tomography (CT) of the chest and abdomen and a bone scan (either using isotopes or MRI) (**Figure 53.26**). This is important for both prognosis and treatment; a patient with widespread visceral metastases may obtain an increased length and quality of survival from systemic hormone therapy or chemotherapy, but is unlikely to benefit from surgery as she will die from her metastases before local disease becomes a problem. In contrast, patients with relatively small tumours (<2 cm in diameter) confined to the breast with negative ipsilateral lymph nodes rarely need staging beyond a good clinical examination as the pick-up rate for distant metastases is so low. Currently, there are no tests recommended for screening of patients with early-stage breast cancer.

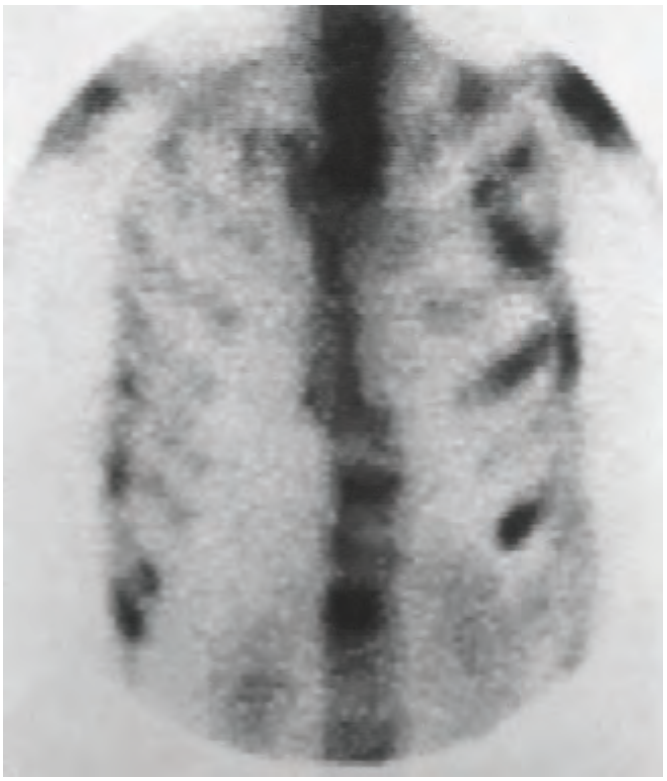

Figure 53.26 Skeletal isotope bone scan showing multiple 'hotspots' due to metastases.

Staging of breast cancer

Classical staging of breast cancer by means of the TNM (tumour–node–metastasis) or UICC (Union Internationale Contre le Cancer) criteria is used less often with increased knowledge of the biological variables that affect prognosis. It is becoming clear that these factors (discussed in more detail below) rather than anatomical mapping that influence outcome and treatment. Perhaps a more pragmatic approach would be to classify patients according to the treatment that they require (*Table 53.4*). Treatment recommendations are summarised in consensus statements such as those from the American Society of Clinical Oncology (ASCO) and the St Gallen Conference.

TABLE 53.4 A pragmatic classification of breast cancer.

Group	Approximate 5-year survival rate (%)	Example	Treatment
'Very low-risk' primary breast cancer	>90	Screen-detected DCIS, tubular or special types	Local
'Low-risk' primary breast cancer	70–90	Node negative with favourable histology	Locoregional with/without systemic
'High-risk' primary breast cancer	<70	Node positive or unfavourable histology	Locoregional with systemic
Locally advanced	<30	Large primary or inflammatory	Primary systemic
Metastatic	–	–	Primary systemic

DCIS, duct carcinoma *in situ*.

Prognosis of breast cancer

The best indicators of likely prognosis in breast cancer remain tumour size, grade and lymph node status; however, it is realised that some large tumours will remain confined to the breast for decades, whereas some very small tumours are incurable at diagnosis. Hence, the prognosis of a cancer depends not on its chronological age but on its invasive and metastatic potential. In an attempt to define which tumours will behave aggressively, and thus require early systemic treatment, a host of prognostic factors have been described. These include the histological grade of the tumour, hormone receptor status, measures of tumour proliferation such as Ki-67, growth factor analysis and oncogene or oncogene product measurements. Many others are under investigation but have proved of little practical value in patient management. Prognostic indices (such as the Nottingham prognostic index) have combined these factors to allow subdivision of patients into discrete prognostic groups. More recently, computer-aided programs (adjuvant online; www.adjuvantonline.com or in the UK Predict; www.predict.nhs.uk) have been developed, which incorporate the putative benefits of treatment allowing oncologist and patient to visualise the benefits of therapy.

Summary box 53.3

Algorithm for management of operable breast cancer

- Achieve local control
- Appropriate surgery
  - Wide local excision (clear margins) and radiotherapy, *or*
  - Mastectomy ± radiotherapy (offer reconstruction – immediate or delayed)
  - Combined with axillary procedure (see text)
  - Await final pathology and receptor measurements
  - Use risk assessment tool; stage if appropriate
- Treat risk of systemic disease
  - Offer chemotherapy if prognostic factors poor; include Herceptin if Her-2 positive
  - Radiotherapy as decided above
  - Hormone therapy if oestrogen receptor or progesterone receptor positive

Treatment of cancer of the breast

The two basic principles of treatment are to reduce the chance of local recurrence and the risk of metastatic spread. Treatment of early breast cancer will usually involve surgery with or without radiotherapy. Systemic therapy such as chemotherapy or hormone therapy is added if there are adverse prognostic factors such as lymph node involvement, indicating a high likelihood of metastatic relapse. At the other end of the spectrum, locally advanced or metastatic disease is usually treated by systemic therapy to palliate symptoms, with surgery playing a much smaller role. An algorithm for the management of breast cancer is shown in *Summary box 53.3*.

The multidisciplinary team approach

As in all branches of medicine, good doctor–patient communication plays a vital role in helping to alleviate patient anxiety. Participation of the patient in treatment decisions is of particular importance in breast cancer when there may be uncertainty as to the best therapeutic option and the desire to treat the patient within the protocol of a controlled clinical trial. As part of the preoperative and postoperative management of the patient it is often useful to employ the skills of a trained breast counsellor and also to have available advice on breast prostheses, psychological support and physiotherapy, when appropriate.

In many specialist centres the care of breast cancer patients is undertaken as a joint venture between the surgeon, medical oncologist, radiotherapist and allied health professionals such as the clinical nurse specialist. This has been shown to be good for the patient, to lead to higher trial entry and to improve the mental health of the professionals in the breast team. There are published guidelines for the optimal management of patients with breast cancer such as SIGN 84 (Scottish Intercollegiate Guidelines Network, (www.sign.ac.uk/guidelines/fulltext/84/).

Local treatment of early breast cancer

Local control is achieved through surgery and/or radiotherapy.

SURGERY

Surgery still has a central role to play in the management of breast cancer but there has been a gradual shift towards more conservative techniques, backed up by clinical trials that have

Summary box 53.4

Treatment of early breast cancer

The aims of treatment are:

- 'Cure': likely in some patients but late recurrence is possible
- Control of local disease in the breast and axilla
- Conservation of local form and function
- Prevention or delay of the occurrence of distant metastases

shown equal efficacy between mastectomy and local excision followed by radiotherapy.

It was initially hoped that avoiding mastectomy would help to alleviate the considerable psychological morbidity associated with breast cancer, but recent studies have shown that over 30% of women develop significant anxiety and depression following both radical and conservative surgery. After mastectomy women tend to worry about the effect of the operation on their appearance and relationships, whereas after conservative surgery they may remain fearful of a recurrence.

Mastectomy is indicated for large tumours (in relation to the size of the breast), central tumours beneath or involving the nipple, multifocal disease, local recurrence or patient preference. The radical Halsted mastectomy, which included excision of the breast, axillary lymph nodes and pectoralis major and minor muscles, is no longer indicated as it causes excessive morbidity with no survival benefit. The modified radical (Patey) mastectomy is more commonly performed and is thus described below. Simple mastectomy involves removal of only the breast with no dissection of the axilla, except for the region of the axillary tail of the breast, which usually has attached to it a few nodes low in the anterior group.

Patey mastectomy The breast and associated structures are dissected *en bloc* (Figure 53.27) and the excised mass is composed of:

- the whole breast;
- a large portion of skin, the centre of which overlies the tumour but which always includes the nipple;
- all of the fat, fascia and lymph nodes of the axilla.

The pectoralis minor muscle is either divided or retracted to gain access to the upper two-thirds of the axilla. The axillary vein and nerves to the serratus anterior and latissimus dorsi (the thoracodorsal trunk) should be preserved. The intercostal brachial nerves are usually divided in this operation and the patient should be warned about sensation changes postoperatively.

The wound is drained using a wide-bore suction tube. Early mobilisation of the arm is encouraged and physiotherapy helps normal function to return very quickly; most patients are able to resume light work within a few weeks.

Conservative breast cancer surgery This is aimed at removing the tumour plus a margin of normal breast tissue. This is commonly referred to as a wide local excision. The term lumpectomy should be reserved for an operation in which a benign tumour is excised and in which a large amount of normal breast tissue is not resected. A quadrantectomy involves removing the entire segment of the breast that contains the tumour. Both of these operations are usually combined with axillary surgery, usually via a separate incision in the axilla. There are various options that can be used to deal with the axilla, including sentinel node biopsy, sampling, removal of the nodes behind and lateral to the pectoralis minor (level II) or a full axillary dissection (level III). The width of the

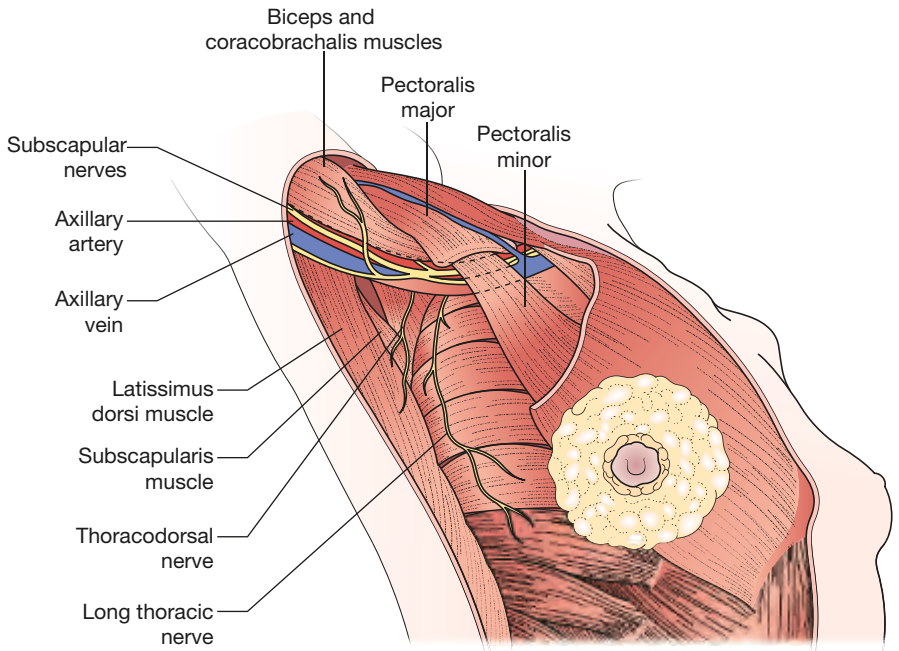

Figure 53.27 Radical mastectomy with pectoralis removed; the modified radical approach leaves the pectoralis major muscle intact.

William Stewart Halsted, 1852–1922, Professor of Surgery, Johns Hopkins Medical School, Baltimore, MD, USA.
David Howard Patey, 1899–1976, surgeon, The Middlesex Hospital, London, UK.

margin has attracted much controversy, with some units adopting a 1-cm margin and others 1 mm. A recent consensus meeting has suggested that no tumour at the inked margin is sufficient, although the trials upon which this is based have been challenged and many still regard 1 mm as a safer margin. There is no need for wider margins than this.

There is a somewhat higher rate of local recurrence following conservative surgery, even if combined with radiotherapy, but the long-term outlook in terms of survival is unaffected. Local recurrence is more common in younger women and in those with high-grade tumours and involved resection margins. Patients whose margins are involved should have a further local excision (or a mastectomy) before going on to radiotherapy. Local excision of a breast cancer without radiotherapy is associated with an unacceptably high local recurrence rate.

The role of axillary surgery is to stage the patient and to treat the axilla. The presence of metastatic disease within the axillary lymph nodes remains the best single marker for prognosis; however, treatment of the axilla does not affect long-term survival, suggesting that the axillary nodes act not as a 'reservoir' for disease but as a marker for metastatic potential. It used to be accepted that only premenopausal women should have their axilla staged by operation as there was a good case for giving chemotherapy to lymph node-positive patients; however, it is now clear that postmenopausal women also benefit from chemotherapy and so all patients require axillary staging. In postmenopausal patients, tamoxifen was once given regardless of axillary lymph node status, but it is now known that only hormone receptor-positive patients, irrespective of age, benefit from this. Axillary surgery should not be combined with radiotherapy to the axilla because of excess morbidity. Removal of the internal mammary lymph nodes is unnecessary.

Sentinel node biopsy This technique has become the standard of care in the management of the axilla in patients with clinically node-negative disease. An axillary ultrasound is now routinely performed along with the ultrasound of the breast cancer. Any suspicious nodes can be biopsied by either cytology or core biopsy The sentinel node is localised perioperatively by the injection of patent blue dye (**Figure 53.28**) and radioisotope-labelled albumin in the breast. The recommended site of injection is in the subdermal plexus around the nipple, although some still inject on the axillary side of the cancer. The marker passes to the primary node draining the area and is detected visually and with a hand-held gamma camera. Peropererative diagnosis allows completion axillary clearance if nodal disease is detected. This may be achieved with frozen-section analysis, touch imprint cytology (TIC) or by molecular methods. These involve homogenising the node and detection of a gene such as cytokeratin 19 or mammoglobin. In some cases there are only subcapsular micrometastases that are missed at frozen section. In patients in whom there is no tumour involvement of the sentinel node, further axillary dissection can be avoided. The utility of intraoperative diagnosis is increasingly questioned. It is time-consuming and with increasing use and experience of axillary ultrasound the rate of unexpectedly positive nodes is low. Moreover, there is increasing adoption of no further surgery even if a positive sentinel node is encountered. A nomogram outlining the chances of further axillary node positivity has been developed by the group at Memorial Sloan Kettering Hospital, New York, and is available on their website (www.mskcc.org/mskcc/html/15938.cfm). Recent trial results have called into question the utility of completion axillary clearance after a positive sentinel node has been detected but at present this remains controversial.

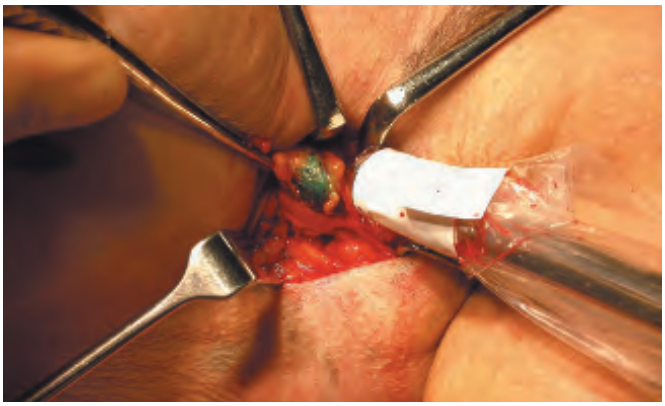

Figure 53.28 Sentinel node biopsy.

RADIOTHERAPY

Radiotherapy to the chest wall after mastectomy is indicated in selected patients in whom the risks of local recurrence are high. This includes patients with large tumours and those with large numbers of positive nodes or extensive lymphovascular invasion. There is some evidence that postoperative chest wall radiotherapy improves survival in women with node-positive breast cancer.

It is conventional to combine conservative surgery with radiotherapy to the remaining breast tissue. Recurrence rates are too high for treatment by local excision alone except in special cases (small node-negative tumours of a special type). Trials are under way to investigate whether radiotherapy can be given intraoperatively at one sitting or as an accelerated postoperative course. This would have considerable advantages in making conservative surgery available in areas where radiotherapy is not currently used. It would also relieve the burden of the current demand for radiotherapy, which accounts for up to 40% of activity in some departments.

Extrapolation from the Oxford overviews of systemic therapy (carried out every 5 years) suggests that for every four local recurrences avoided, one additional life will be spared at 15 years. This figure has recently been challenged but it does highlight the importance of getting the initial treatment right and avoiding local recurrence.

Adjuvant systemic therapy

Over the last 25 years there has been a revolution in understanding of the biological nature of carcinoma of the breast. It is now widely accepted that the outcomes of treatment are predetermined by the extent of micrometastatic disease at the time of diagnosis. Variations in the radical extent of local therapy might influence local relapse but probably do not alter long-term mortality from the disease. However, systemic therapy targeted at these putative micrometastases might be expected to delay relapse and prolong survival. As a result of

many international clinical trials and recent world overview analyses it can be stated with statistical confidence that the appropriate use of adjuvant chemotherapy or hormone therapy will improve relapse-free survival by approximately 30%, which ultimately translates into an absolute improvement in survival of the order of 10% at 15 years. Bearing in mind how common breast cancer is in Northern Europe and the USA, these figures are of major public health importance.

Who to treat and with what are still questions for which absolute answers have yet to found, but the data from overviews of recent trials show that lymph node-positive and many higher-risk node-negative women should be advised to have adjuvant combined chemotherapy. Women with hormone receptor-positive tumours will obtain a worthwhile benefit from at least 5 years of endocrine therapy, either 20 mg daily of tamoxifen if premenopausal or the AIs (anastrozole, letrozole and exemestane) if postmenopausal. It is no longer appropriate to give hormone therapy to women who do not have oestrogen or progesterone receptor-positive disease. Recent trials have shown that longer durations of endocrine therapy provide a small extra benefit but with increased toxicity.

HORMONE THERAPY

Tamoxifen has been the most widely used 'hormonal' treatment in breast cancer. Its efficacy as an adjuvant therapy was first reported in 1983 and it has now been shown to reduce the annual rate of recurrence by 25%, with a 17% reduction in the annual rate of death. Beneficial effects of tamoxifen in reducing the risk of tumours in the contralateral breast have also been observed, as has its role as a preventative agent (IBIS-I and NSABP-P1 trials). Trials studying the optimal duration of treatment suggest that 5 years of treatment is preferable to 2 years.

Other hormonal agents that are also beneficial as adjuvant therapy have been developed. These include the LHRH agonists, which induce reversible ovarian suppression and thus have the same beneficial effects as surgical or radiation-induced ovarian ablation in premenopausal receptor-positive women, and the oral AIs for postmenopausal women. AIs are now licensed for treatment of all stages of disease and have been shown to be superior to tamoxifen. A large trial comparing anastrazole to tamoxifen in the adjuvant setting has shown beneficial effect for the AI in terms of relapse-free survival, although no benefit for overall survival. There is an additional reduction in contralateral disease, which makes this drug suitable for a study of prevention, and the side-effect profile is different from that of tamoxifen. AIs are more expensive than tamoxifen but are coming off patent protection and generic copies may allow more widespread use. There is an increase in bone density loss with patients taking an AI and a bone density scan is advised prior to commencement with treatment of underlying osptepaenia or osteporosis.

CHEMOTHERAPY

Chemotherapy using a first-generation regime such as a 6-monthly cycle of cyclophosphamide, methotrexate and 5-fluorouracil (CMF) will achieve a 25% reduction in the risk of relapse over a 10–15-year period. It is important to understand that this 25% reduction refers to the likelihood of an event happening. For example, a woman with a 96% chance of survival at, for example, 5 years only has a 4% chance of death over this time and the absolute benefit from chemotherapy would be an increase in survival rate of 1%, to 97%. This would not be a sufficient gain to offset the side effects of this potentially toxic therapy. However, for a woman with a 60% chance of dying (40% survival rate) a 25% reduction in risk would increase her likelihood of survival to 55% and thus treatment would be worthwhile. CMF is no longer considered adequate adjuvant chemotherapy and modern second- and third-generation regimes include an anthracycline (doxorubicin or epirubicin) and the newer agents such as the taxanes.

Chemotherapy used to be prescribed only to premenopausal women with a poor prognosis (in whom its effects are likely to be the result, in part, of a chemical castration effect) but it is now also offered to postmenopausal women with poor prognosis disease. Chemotherapy may be considered in node-negative patients if other prognostic factors, such as tumour grade, imply a high risk of recurrence. The effect of combining hormone and chemotherapy is additive, although hormone therapy is started after completion of chemotherapy to reduce side effects.

High-dose chemotherapy with stem cell rescue for patients with heavy lymph node involvement has now been shown in controlled trials to offer no advantage and has been abandoned.

Primary chemotherapy (neoadjuvant) is being used in many centres for large but operable tumours that would traditionally require a mastectomy (and almost certainly postoperative adjuvant chemotherapy). The aim of this treatment is to reduce tumour volume to enable breast-conserving surgery to be performed. This approach is successful in up to 80% of cases, but is not associated with improvements in survival compared with conventionally timed chemotherapy. Patients who achieve a complete pathological response have increased survival rates. Patients with Her-2-positive disease will receive Herceptin as part of their management and have high complete response rates. It is important that tumours have a metallic clip placed into them at the onset of therapy as otherwise there will be uncertainty about which area to resect once chemotherapy has been completed. There is debate about the safety and utility of sentinel node biopsy preinduction of chemotherapy; however, it can be safely performed after completion of chemotherapy. Neoadjuvant therapy is also used in the triple negative cohort of patients (Er, PR and Her-2 negative). In patients with breast cancer strongly positive for hormone receptors, a similar effect can be seen following 3 months of endocrine treatment.

Newer 'biological' agents will be used more frequently as molecular targets are identified – the first of these, trastuzamab (Herceptin®), is active against tumours containing the growth factor receptor c-erbB2. Other agents currently available are lapitinab, an oral combined tyrosine kinase inhibitor (TKI). Other TKIs are in development such as, pertuzumab. T-DM1 is a drug used in Her- 2-positive disease where a chemotherapy agent, emestane, is bound to an anti-Her-2 agent to allow targeted delivery of the chemotherapy to Her-2-positive cells. The antivascular growth factor bevacizumab initially showed promise but is now no longer routinely used for adjuvant therapy.

It is unclear how and when these agents will be used, whether in combination or instead of standard chemotherapy agents. They are very expensive and unaffordable in many countries. Other agents likely to be used in the next few years include CK4/CDK6 inhibitors for metastatic ER-positive cancer.

Follow-up of breast cancer

Patients with breast cancer used to be followed for life to detect recurrence and dissemination. This led to large clinics with little value for either patient or doctor. It is current practice to arrange yearly or 2-yearly mammography of the treated and contralateral breast. There is a move to return the patient early to the care of the general practitioner with fast-track access back to the breast clinic if suspicious symptoms appear. There is currently no routine role for repeated measurements of tumour markers or imaging other than mammography.

Phenomena resulting from lymphatic obstruction in advanced breast cancer

Peau d'orange

Peau d'orange is caused by cutaneous lymphatic oedema (**Figure 53.24**). Where the infiltrated skin is tethered by the sweat ducts it cannot swell, leading to an appearance like orange skin. Occasionally, the same phenomenon is seen over a chronic abscess.

Lymphoedema

Lymphoedema of the arm is a troublesome complication of breast cancer treatment, fortunately seen less often now that radical axillary dissection and radiotherapy are rarely combined. However, it does still occur occasionally after either mode of treatment alone and appears at any time from months to years after treatment. There is usually no precipitating cause but recurrent tumour should be excluded because neoplastic infiltration of the axilla can cause arm swelling as a result of both lymphatic and venous blockage. This neoplastic infiltration is often painful because of brachial plexus nerve involvement.

An oedematous limb is susceptible to bacterial infection following quite minor trauma and this requires vigorous antibiotic treatment. Antibiotics may need to be given for much longer than is normal and patients at risk of infection should have antibiotics readily available to enable treatment to be started promptly. Treatment of late oedema is difficult but limb elevation, elastic arm stockings and pneumatic compression devices can be useful.

Cancer-en-cuirasse

The skin of the chest is infiltrated with carcinoma and has been likened to a coat. It may be associated with a grossly swollen arm. This usually occurs in cases with local recurrence after mastectomy and is occasionally seen to follow the distribution of irradiation to the chest wall. The condition may respond to palliative systemic treatment but prognosis in terms of survival is poor.

Lymphangiosarcoma

Lymphangiosarcoma is a rare complication of lymphoedema with an onset many years after the original treatment. It takes the form of multiple subcutaneous nodules in the upper limb and must be distinguished from recurrent carcinoma of the breast. The prognosis is poor but some cases respond to cytotoxic therapy or irradiation. Interscapulothoracic (forequarter) amputation is rarely indicated.

Breast reconstruction

Despite an increasing trend towards conservative surgery, up to 40% of women still require, or want, a mastectomy. These women can now be offered immediate or delayed reconstruction of the breast. Few contraindications to breast reconstruction exist. Even those with a limited life expectancy may benefit from the improved quality of life; however, patients do require counselling before this procedure so that their expectations of cosmetic outcome are not unrealistic.

The increasing use of oncoplastic techniques such as volume displacement and volume replacement have opened up the options for increasing conservation rates. Specialist training is required and close cooperation with established plastic surgeons allows optimal selection of patients.

The easiest type of reconstruction is using a silicone gel implant under the pectoralis major muscle. The lateral portion of the implant, which was traditionally left in the subcutaneous plane, is now increasingly covered by an acellular dermal matrix (ADM). This gives a superior cosmetic result. Prior tissue expansion using an expandable saline prosthesis first (or a combined device), creates some ptosis of the new breast. If the skin at the mastectomy site is poor (e.g. following radiotherapy) or if a larger volume of tissue is required, a musculocutaneous flap can be constructed either from the latissimus dorsi muscle (an LD flap) (**Figure 53.29**) or using the transversus abdominis muscle (a TRAM flap as shown in **Figure 53.30**). The latter gives an excellent cosmetic result in experienced hands but is a lengthy procedure and requires careful patient selection. It is now usually performed as a free transfer using microvascular anastomosis, although the pedicled TRAM from the contralateral side is still used. Variations on the TRAM flap requiring less muscle harvesting, such as the DIEP flap (based on deep inferior epigastric vessels), are increasingly being used.

The timing of reconstruction may be difficult. Impediments to immediate reconstruction include insufficient theatre time and a lack of experienced reconstructive surgeons. In addition, if a patient is likely to need postoperative radiotherapy then a delayed reconstruction using a flap often gives a better result. Radiotherapy onto a prosthesis often leads to a high incidence of capsular contracture and unacceptable results.

Nipple reconstruction is a relatively simple procedure that can be performed under a local anaesthetic. Many different types of nipple reconstruction are described but the majority lose height with time. Tattooing of the reconstructed nipple is often required. Alternatively, the patient can be fitted with a prosthetic nipple. To achieve symmetry the opposite

Figure 53.29 Reconstruction with latissimus dorsi flap.

Figure 53.30 Transversus abdominus muscle flap.

breast may require a cosmetic procedure such as reduction or augmentation mammoplasty, or mastopexy. A breast reconstructive service can be offered by a suitably trained breast surgeon, a plastic surgeon or, ideally, using a combined oncoplastic approach. The patient needs to be warned that breast reconstruction is seldom, if ever, one operation.

External breast prostheses that fit within the bra are the most common method of restoring volume fill and should be available for all women who do not have an immediate reconstruction.

Screening for breast cancer

Because the prognosis of breast cancer is closely related to stage at diagnosis it would seem reasonable to hope that a population screening programme that could detect tumours before they come to the patient's notice might reduce mortality from breast cancer. Indeed, a number of studies have shown that breast screening by mammography in women over the age of 50 years will reduce cause-specific mortality by up to 30%. Following the publication in 1987 of the Forrest report, the National Health Service in the UK launched a programme of 3-yearly mammographic screening for women between the ages of 50 and 64 years (now increased to 70 years). The introduction of this programme has undoubtedly improved the quality of breast cancer services but a number of questions remain unanswered, including the value of screening women under 50 years and the ideal interval between screenings. The psychological consequences of false alarms or false reassurances still need to be addressed and self-examination programmes that have failed to show any benefit for the population in terms of earlier detection of or decreased mortality from breast cancer remain controversial. The opponents of screening rightly point out that some women will have disease detected and treated that might never harm them in their lifetime. However, this group of women cannot as yet be reliably seperated from those in whom prompt diagnosis and treatment will be benficial.

MRI is used to screen those at very high risk or where radiation might be hazardous (Li-Fraumeni syndrome). There is no place for thermography as a secreening (or diagnostic) tool.

Familial breast cancer

Recent developments in molecular genetics and the identification of a number of breast cancer predisposition genes (*BRCA1*, *BRCA2* and *p53*) have done much to stimulate interest in this area. Yet women whose breast cancer is due to an inherited genetic change actually account for less than 5% of all cases of breast cancer, that is about 1250 cases per year in the UK and 9000 cases in the USA. A much larger number of women will have a risk that is elevated above normal because of an as yet unspecified familial inheritance. These women have a risk of developing breast cancer that is 2–10 times above baseline. The risks associated with family history are summarised in *Table 53.5*. There are computer programs available to assist the clinician in assessing family history risk.

The *BRCA1* gene has been associated with an increased incidence of breast (and ovarian) cancer and is located on the long arm of chromosome 17 (17q). The gene frequency in the population is approximately 0.0006. It does, however, occur with greater frequency in certain populations such as Ashkenazi Jews, in whom there is often a common (founder) mutation. *BRCA2* is located on chromosome 13q and there is an association with male breast cancer.

Frederick Pei Li, 1940 – 2015, Dana-Farber Cancer Institute, Boston, MA USA and **Joseph F Fraumeni, Jr.** (b.1933), National Institutes of Health, Washington DC, USA, in 1969 identified four families with increased susceptibility to cancer. This led to the discovery of mutation in the tumour suppressor gene p53.
Sir Andrew Patrick McEwen Forrest, Regius Professor of Clinical Surgery, The University of Edinburgh, Edinburgh, UK.
Ashkenazi Jews are Jews of Eastern or Central European descent.

TABLE 53.5 Likelihood of genetic mutation with family history.

2	4	3
3	17	13
4	41	33
5	55	44

[a] *BRCA1* is also associated with ovarian and, to a lesser extent, colorectal and prostate cancer.

[b] *BRCA2* is associated with familial male breast cancer.

Women who are thought to be gene carriers may be offered breast screening (and ovarian screening in the case of *BRCA1*, which is known to impart a 50% lifetime risk of ovarian cancer), usually as part of a research programme, or genetic counselling and mutation analysis. Those who prove to be 'gene positive' have a 50–80% risk of developing breast cancer, predominantly while premenopausal. Many will opt for prophylactic mastectomy. Although this does not completely eliminate the risk, it does reduce it considerably. This work should be carried out in specialist centres.

For the great majority of women with a positive family history, who are unlikely to be carriers of a breast cancer gene, there are no currently proven breast cancer screening manoeuvres, although this is under investigation. Tamoxifen given for 5 years appears to reduce the risk of breast cancer by 30–50% as does the AI, anastrozole. Thus, these women are best served by being assessed and followed-up, preferably in a properly organised family history clinic.

Pregnancy

The effects of pregnancy on breast cancer are increasingly understood and it is thought that breast cancer presenting during pregnancy or lactation tends to be at a later stage, presumably because the symptoms are masked by the pregnancy; however, in other respects it behaves in a similar way to breast cancer in a non-pregnant young woman and should be treated accordingly. Thus, treatment is similar with some provisos: radiotherapy should be avoided during pregnancy, making mastectomy a more frequent option than breast conservation surgery; chemotherapy should be avoided during the first trimester but appears safe subsequently; most tumours are hormone receptor negative and so hormone treatment, which is potentially teratogenic, is not required. Becoming pregnant subsequent to a diagnosis of breast cancer appears not to alter the likely outcome, but women are usually advised to wait at least 2 years as it is within this time that recurrence most often occurs. The risk of developing breast cancer with oral contraceptive use is only slight, and disappears 10 years after stopping the oral contraceptive pill.

Hormone replacement therapy

HRT increases the risk of developing breast cancer if taken for prolonged periods and in certain high-risk groups. HRT may also prolong symptoms of benign breast disorders such as cysts and mastalgia and make mammographic appearances more difficult to interpret.

Patients who develop breast cancer while on HRT appear to have a more favourable prognosis. The consequences in terms of recurrence in women using HRT following breast cancer are unknown.

Treatment of advanced breast cancer

Breast cancer may occasionally present as metastatic disease without evidence of a primary tumour (that is with an occult primary). The diagnosis is made partly by exclusion of another site for the primary tumour and may be confirmed by histology with special immunohistological stains of the metastatic lesions. Management should be aimed at palliation of the symptoms and treatment of the breast cancer, usually by endocrine manipulation with or without radiotherapy.

Locally advanced inoperable breast cancer

Locally advanced inoperable breast cancer, including inflammatory breast cancer, is usually treated with systemic therapy, either chemotherapy or hormone therapy.

Occasionally, 'toilet mastectomy' or radiotherapy is required to control a fungating tumour but often incision through microscopically permeated tissues results in a worse outcome.

Metastatic carcinoma of the breast

Metastatic carcinoma of the breast will also require palliative systemic therapy to alleviate symptoms. Hormone manipulation is often the first-line treatment because of its minimal side effects. It is particularly useful for bony metastases. However, only about 30% of these tumours will be hormone responsive and, unfortunately, in time even these will become resistant to treatment. First-line hormone therapy for postmenopausal women is now anastrazole or one of the other third-generation AIs. Tamoxifen, ovarian suppression by surgery (for premenopausal women), radiotherapy and medical treatment are all in common use. When resistance to these has developed, other hormonal agents can prove useful, with about one-half of the response rate seen in the first-line therapy. The newer agents such as antiprogestins, pure antioestrogens and growth factor TKIs are all candidates for this role.

Cytotoxic therapy is used particularly in younger women or those with visceral metastases and rapidly growing tumours. A variety of regimes is available and, although none prolongs survival, contrary to expectations, quality of life and symptom control is often better with more aggressive treatments, with responses being seen in up to 70% of patients.

Local treatment may also prove useful for some metastatic disease, such as radiotherapy for painful bony deposits and internal fixation of pathological fractures.

Gynaecomastia

Idiopathic

Hypertrophy of the male breast may be unilateral or bilateral. The breasts enlarge at puberty and sometimes present the characteristics of female breasts.

Hormonal

Enlargement of the breasts often accompanied stilbestrol therapy for prostate cancer, now rarely used. It may also occur as a result of a teratoma of the testis, in anorchism and after castration. Rarely, it may be a feature of ectopic hormonal production in bronchial carcinoma and in adrenal and pituitary disease. Body builders may use steroids to improve their physique, which may cause gynaecomastia. Some even go so far as to take tamoxifen to mask this symptom.

Associated with leprosy

Gynaecomastia is very common in men suffering from leprosy. This is possibly because of bilateral testicular atrophy, which is a frequent accompaniment of leprosy.

Associated with liver failure

Gynaecomastia sometimes occurs in patients with cirrhosis as a result of failure of the liver to metabolise oestrogens. It is associated with drugs that interfere with the hepatic metabolism of oestrogens. It is also seen with certain drugs such as cimetidine, digitalis and spironolactone.

Associated with Klinefelter's syndrome

Gynaecomastia may occur in patients with Klinefelter's syndrome, a sex chromosome anomaly having 47XXY trisomy.

TREATMENT

Provided that the patient is healthy and comparatively young, reassurance may be sufficient. If not, mastectomy with preservation of the areola and nipple can be performed. The patient must be warned about the side effects of this procedure, which are common and a cause of many medico-legal complaints in the UK.

Carcinoma of the male breast

Carcinoma of the male breast **(Figure 53.31)** accounts for less than 0.5% of all cases of breast cancer. The known predisposing causes include gynaecomastia and excess endogenous or exogenous oestrogen. As in the female it tends to present as a lump and is most commonly an infiltrating ductal carcinoma.

Treatment

Stage for stage the treatment is the same as for carcinoma in the female breast and prognosis depends upon stage at presentation. Adequate local excision, because of the small size of the breast, should always be with a 'mastectomy'.

Figure 53.31 Carcinoma of the male left breast (courtesy of Professor Mike Dixon).

OTHER TUMOURS OF THE BREAST

Lipoma

A true lipoma is very rare.

Sarcoma of the breast

Sarcoma of the breast is usually of the spindle-cell variety and accounts for 0.5% of malignant tumours of the breast. Some of these growths arise in an intracanalicular fibroadenoma or may follow previous radiotherapy, e.g. for Hodgkin's lymphoma, many years previously. It may be impossible to distinguish clinically a sarcoma of the breast from a medullary carcinoma, but areas of cystic degeneration suggest a sarcoma and on incising the neoplasm it is pale and friable. Sarcoma tends to occur in younger women between the ages of 30 and 40 years. Treatment is by simple mastectomy followed by radiotherapy. The prognosis depends on the stage and histological type.

Metastases

On rare occasions cancer elsewhere may present with a metastasis in the breast. The breast is also occasionally infiltrated by Hodgkin's disease and other lymphomas.

PART 9

Cardiothoracic

Chapter 54

Cardiac surgery

Learning objectives

To understand:

- The important role of surgery in cardiac disease
- The role of investigation in planning surgery
- The management of coronary heart disease
- The role of surgery in valvular heart disease
- The special role of surgery in congenital heart disease
- The management of aortic vascular and pericardial disease

INTRODUCTION

In 1925 Sir Henry Souttar reported the first mitral commissurotomy in the *British Medical Journal*. He wrote that the heart should be as amenable to surgery as any other organ. He saw the main problem as being maintenance of blood flow, particularly to the brain, while surgery was being performed.

The first real advances occurred in the late 1940s and early 1950s, driven by surgeons who had gained confidence and experience under the pressures and opportunities provided by war, followed by the development of cardiopulmonary bypass in the mid-1950s. Recently, the well-being and lifespan of patients with congenital, valvular and degenerative heart disease has improved drastically due to the advances in the range, complexity and technical expertise in cardiac surgery.

Summary box 54.1

Alternative uses of cardiopulmonary bypass (CPB)

- Rewarming from profound hypothermia
- Resuscitation in severe respiratory failure
- As an adjunct in pulmonary embolectomy
- In single- and double-lung transplantation
- In cardiopulmonary trauma
- In certain non-cardiac surgical procedures (e.g. resection of highly vascular tumours and tumours invading large blood vessels)

CARDIOPULMONARY BYPASS

Cardiopulmonary bypass (CPB) was first used successfully in 1953 by Gibbon and has since revolutionised cardiac surgery. It can be employed in any procedure in which the heart and lungs need to be stopped temporarily and their function replaced artificially. Before Gibbon's work, valve surgery under direct vision would not have been possible, nor would the precise reconstructions needed to treat extensive coronary artery disease (CAD). Much of the success of modern CPB is attributable to the development of new biomaterials and sophisticated oxygenating devices, as well as a greater understanding of the pathophysiological consequences of CPB.

Surgical approach to the heart

The heart is approached mainly by a median sternotomy. An incision is made from the suprasternal notch to the lower end of the xiphisternum. The sternum is divided and retracted to expose the thymus superiorly and the pericardium inferiorly. The thymus, although atrophic in adults, often remains relatively vascular. The thymus and pleurae are dissected from the pericardium and the pericardium is opened. Before cannulation for CPB, the patient is fully heparinised. Other incisions that can be used include left or right anterolateral thoracotomy for minimally invasive operations or for specific operations on the descending aorta.

Initiating cardiopulmonary bypass

Arterial cannulation

Conventionally, the great vessels are exposed and an aortic perfusion cannula is inserted into the ascending aorta, held in place by the purse-string suture. Air is excluded and the cannula connected to the bypass circuit. Alternatively, when it is inadvisable (aortic dissection), impractical (aortic root surgery) or impossible (severe adhesions) to cannulate the aorta, alternative arterial cannulation sites can be used, such as the

Sir Henry Sessions Souttar, 1875–1964, surgeon, The London Hospital, London, UK.
John Heysham Gibbon, 1903–1973, worked at Jefferson University, Philadelphia, PA, USA.

femoral artery or the axillary artery. The latter has recently been gaining more popularity, as it provides antegrade flow and can be utilised to provide selective cerebral perfusion in complex aortic operations; axillary cannulation has the theoretical advantage of reducing thromboembolic events when compared to femoral cannulation.

Venous cannulation

A purse-string suture is placed around the right atrial appendage and a single 'two-stage' venous cannula is placed to establish venous drainage. The venous pipe has end holes that sit in the inferior vena cava and side holes that sit in the right atrium (to take drainage from the superior vena cava). Alternatively, the superior and inferior vena cavae may be cannulated separately to gain better control over the venous return and to facilitate surgery within the right atrium. Venous drainage from the femoral vein can offer an alternative, particularly during thoracic aortic or minimally invasive procedures.

Cardio pulmonary bypass circuit

Once the circuit is connected (**Figure 54.1**) the CPB machine (the 'pump') gradually takes over the processes of circulation and ventilation. Once full flow is established (the required cardiac output depends on the body surface area of the patient), the ventilator is stopped and the heart can be isolated from the rest of the circulation. Blood is drained from the heart to the venous reservoir using the siphon effect by gravity, as it is usually placed 50–70 cm below the level of the heart and oxygenated using an oxygenator that allows gas exchange across its membrane. Blood is then pumped to the body by the bypass machine via the aortic cannula.

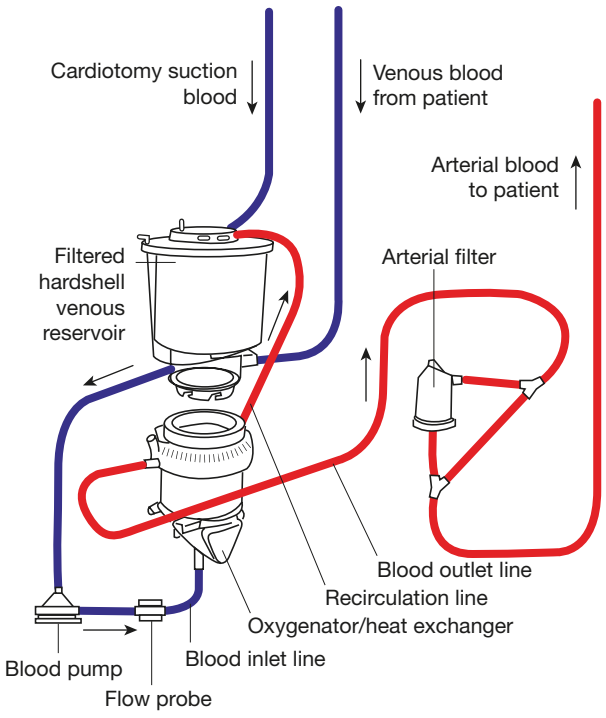

Figure 54.1 Components of the cardiopulmonary bypass (CPB) circuit. (Reproduced from Abraham JK. Cardiopulmonary bypass. *Surgery* 2000; **18**: 11, with permission from The Medical Publishing Company.)

The core systemic temperature can be lowered by passing the returning blood through a heat exchanger that can reduce the metabolic demands of the tissues. The degree of cooling is managed according to the severity and complexity of the surgical procedure, as well as the surgeon's preference.

The blood is also filtered to remove particulate emboli and returned to the systemic arterial circulation via a pump. Suction pumps can be employed to keep the area around the heart clear of blood and to decompress the heart when used as vents.

Myocardial protection

Once CPB has been established the ascending aorta is usually cross-clamped to obtain a bloodless operative field. The heart ceases to eject and becomes anoxic due to inhibition of coronary blood flow. Permanent myocardial damage can develop within 15–20 minutes, therefore most cardiac operations require some form of myocardial protection. Techniques of myocardial protection and the operative management of the myocardium have had a significant impact on the complexity of cardiac surgery. The methods of myocardial protection include intracoronary infusion of a cardioplegic solution (antegrade), infusion via the coronary sinus (retrograde), intermittent cross-clamp fibrillation and total circulatory arrest.

Cardioplegic solutions vary in terms of temperature, pH, arresting agent, osmolality and the presence of red cells and other factors. Most solutions contain potassium as the arresting agent. Potassium arrests the heart in diastole by depolarisation of the myocyte cellular membrane. Cold (4–10°C) isotonic crystalloid or blood solutions aid myocardial protection by reducing metabolic requirements through local hypothermia. Warm cardioplegic solutions, on the other hand, may facilitate better myocardial repair recovery postoperatively by aiding activation of intramyocardial enzymes.

Intermittent cross-clamp fibrillation is a technique in which intermittent ventricular fibrillation is induced by a small electrical charge. The heart does not eject and is relatively still but not bloodless. The aorta is cross-clamped to render the heart ischaemic. The heart can tolerate short periods (10–20 min) of ischaemia, provided the heart is reperfused when the cross-clamp is released and allowed to beat following cardioversion for short periods during the operation.

Total circulatory arrest becomes necessary when visibility and clarity of the operative area is crucial, as in paediatric surgery or in surgery of the ascending aorta and arch of the aorta. CPB is instituted and the core body temperature reduced to 15–18°C (profound hypothermia). The metabolic rate of all organs of the body is reduced by 50% with every 7°C drop in temperature. Using this technique, circulatory arrest can be tolerated for up to 20–30 min. Additional cerebral protection can be provided with ice packs placed around the head, pharmacological agents and cerebral perfusion techniques.

Discontinuing cardiopulmonary bypass

At the end of the procedure, air must be meticulously excluded from the cardiac chambers. Once perfusion is restored to the coronary arteries (by removing the cross-clamp) the heart

may beat spontaneously. If ventricular fibrillation is present, cardioversion may be required. Epicardial pacing wires may be placed to treat postoperative bradycardia or heart block. The patient is rewarmed, acidosis and hypokalaemia are corrected and ventilation is restarted. The heart gradually takes over the circulation while the arterial flow from the CPB machine is reduced. When the blood pressure is acceptable and the surgeon is confident that the heart function is adequate, CPB is discontinued. The cannulae are removed and the anticoagulation is reversed by administering protamine.

Complications of CPB

CPB is a complex technique and requires careful interaction and communication between surgeon, anaesthetist and perfusionist to ensure that the patient remains safe. Difficulties can occur during cannulation (aortic dissection or atrial injury), at the start of CPB (oxygenator failure) and at the end of CPB (coagulopathy). Many complications can occur following blood exposure to the non-physiological surface of the CPB circuit. This leads to the activation of inflammatory cascades giving rise to a post-CPB systematic inflammatory response syndrome (SIRS) that can ultimately lead to multi-organ failure.

Recent understanding of the impact of CPB on the coagulation cascade and the patient's inflammatory response (SIRS) has resulted in the development of smaller 'mini' CPB, which has demonstrated some advantages in terms of post-CPB inflammatory responses and blood transfusion requirement. Alternative methods include surgery on beating heart 'off-pump', although despite some advantages, use remains restricted to coronory artery bypass grafting (CABG) and long-term outcomes are still a matter of debate.

CORONARY ARTERY BYPASS SURGERY

Introduction

Before the 1950s, surgical attempts to treat CAD through augmentation of non-coronary flow to the myocardium was via the creation of pericardial or omental adhesions, which had limited success. From the 1960s onwards, the importance of aortocoronary saphenous vein grafts and the value of the internal mammary (internal thoracic artery) were increasingly recognised. The outcomes of CABG surgery were carefully monitored from the beginning and by the 1970s, multiple large, prospectively randomised, multicentre trials were conducted. All these trials showed that a subset of patients had improved survival after surgery, compared with other treatments. With the advent of percutaneous coronary intervention (PCI) in the 1980s, the patient population undergoing CABG has changed, becoming progressively sicker but often with the most to gain. Over the last decade there have been major advances in PCI including the use of bare metal stents and the development of different generations of drug-eluting stents, as well as biodegradable stents, in an effort to reduce restenosis. Although the role of CABG in the treatment of ischaemic heart disease has been questioned, a recent large multicentre randomised trial carried out comparing CABG to PCI with drug-eluting stents has clearly shown that CABG is still the gold standard operation in certain groups of patients. Other more recent trials have confirmed these findings mainly in diabetic and high-risk patients.

Summary box 54.2

Potential complications of CPB

- Bleeding disorders
- Infection
- Air embolism
- Intestinal ischaemia/infarction
- Microembolisation
- Myocardial depression
- Neurological dysfunction
- Pancreatitis
- Postcardiotomy syndrome
- Pulmonary injury
- Systemic organ dysfunction
- Vascular injury

Coronary artery anatomy

The coronary arteries are branches of the ascending aorta, arising from ostia in the aortic sinuses above the aortic valve, the right from the anterior sinus and the left from the left posterior sinus (**Figure 54.2**).

Summary box 54.3

Coronary artery surgery

- Randomised controlled trials have confirmed improvement in survival following CABG for certain groups of patients

Left coronary artery

The left main coronary artery, which arises from the aortic root, can be the site of significant stenosis ('left main stem disease') and carries the worst prognosis in terms of survival without surgery. The artery is inaccessible at its origin and therefore grafts are anastomosed to its branches, the left anterior descending artery (LAD) or anterior interventricular artery and obtuse/marginal (OM) branches of the circumflex artery. The LAD is the most frequently diseased coronary artery and most often bypassed during CABG surgery.

Right coronary artery

The right coronary artery (RCA) passes from its origin anteriorly between the right atrial appendage and the pulmonary trunk and courses in the atrioventricular groove around the margin of the right ventricle. It usually forms an anastomosis with the circumflex artery at the junction of the right and left atria and the interventricular septum (the crux). It continues as the posterior descending artery or interventricular artery. Common sites of stenosis of the RCA are in its proximal

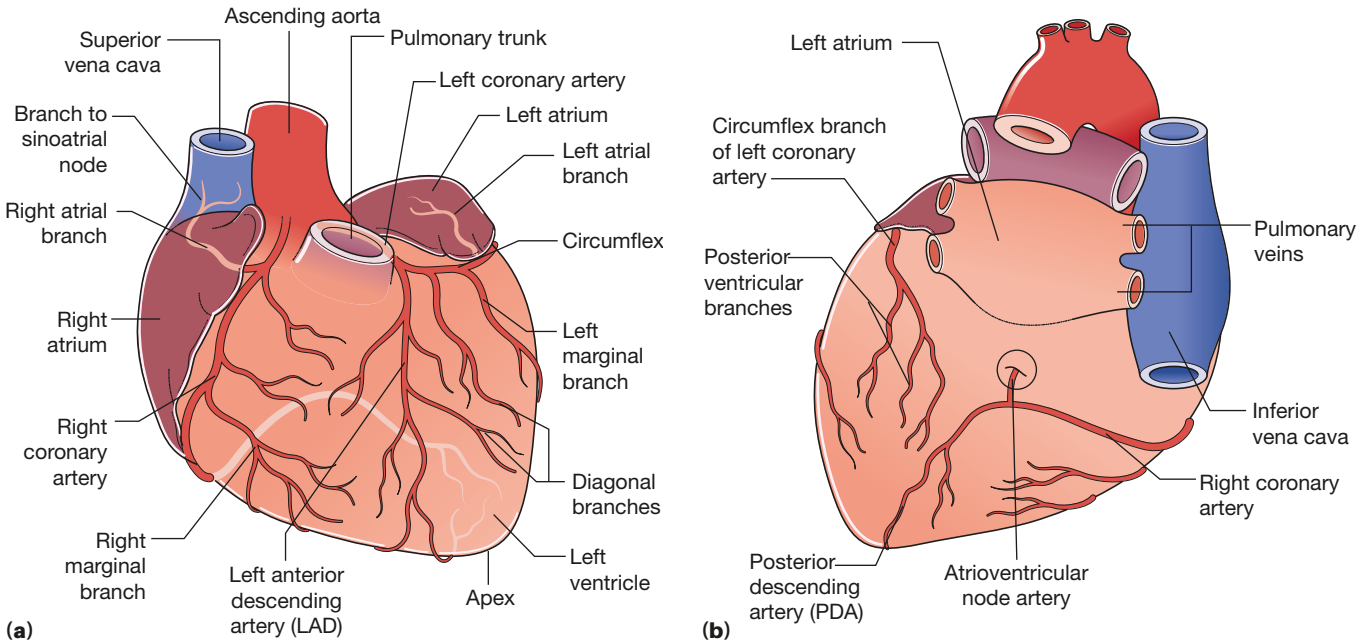

Figure 54.2 The heart, showing the distribution the of the left and right coronary arteries. **(a)** Anterior surface of the heart; **(b)** base and diaphragmatic surface of the heart.

portion or at the bifurcation or crux. In the presence of disease at the bifurcation, a graft can be placed distally to the posterior descending artery.

The question of anatomical dominance is determined by the artery that supplies the posterior descending artery. In approximately 90% of cases the posterior descending artery arises from the RCA, a pattern referred to as right dominance. The posterior descending artery can also arise from the circumflex artery, a pattern referred to as left dominance, which occurs in approximately 10% of cases. A balanced pattern is one in which two posterior descending arteries, one arising from the right coronary artery and one from the circumflex artery, can exist (**Figure 54.2**).

Ischaemic heart disease

Ischaemic heart disease (IHD) is a major cause of morbidity and mortality in resource-rich countries. The underlying pathology is mainly atherosclerosis of the coronary arteries.

Pathophysiology

Atherosclerosis is the process underlying the formation of focal obstructions or plaques in large- and medium-sized arteries. It is accepted that atherosclerosis is a chronic inflammatory process resulting from interactions between plasma lipoproteins, leukocytes (monocyte/macrophages, T lymphocytes), vascular endothelial cells and smooth muscle cells. Atherosclerotic lesions can histologically be found at different stages in blood vessels including:

- **The fatty streak**. The first evidence of atherosclerosis can be found in children 10–14 years of age. This appears as a yellow streak running along the major arteries. The streak consists of smooth muscle cells, which are filled with cholesterol, and foam cells.
- **Fibrous plaque**. A fibrous plaque consists of large numbers of smooth muscle cells, foam cells, and leukocytes. As the fibrous plaque grows, it projects into vessels leading to lumen narrowing that, in turn, can lead to ischaemia or infarction.
- **Complicated lesion**. This occurs when the fibrous plaque ruptures provoking activation of the coagulation cascade and the formation of thrombus

Clinical manifestations

The principal symptoms of IHD are chest pain or angina, breathlessness, fatigue, swelling, palpitations and syncope. Severity of symptoms and the extent to which the symptoms interfere with everyday activities form a significant part of the clinical history. An assessment of risk factors should be included. Clinical examination follows and, although often normal, any evidence of myocardial ischaemia or stigmata of associated disease, such as diabetes or peripheral vascular disease, should be noted.

Summary box 54.4

Risk factors for ischaemic heart disease (IHD)

- Advancing age
- Male gender
- Hyperlipidaemia
- Diabetes mellitus
- Hypertension
- Smoking
- Family history of IHD
- Obesity
- Reduced physical activity

Investigations

Non-invasive methods of diagnosis

RESTING ELECTROCARDIOGRAPHY

As a baseline test, a 12-lead resting electrocardiogram (ECG) often provides the first indication of ischaemic cardiac disease and is essential in the acute clinical setting. However, it is not necessarily abnormal even in the presence of severe multivessel coronary disease. Evidence of previous myocardial infarction (MI) is seen commonly, as Q waves and/or non-specific ST and T-wave changes.

TROPONIN AND CARDIAC ISOENZYMES

These are useful in assessing patients with an acute coronary syndrome (ACS) when the diagnosis is in doubt. Standard enzyme measurement such as troponin, creatine kinase MB (CKMB) and lactate dehydrogenase (LDH) can aid diagnosis, as well as having prognostic implications.

EXERCISE TOLERANCE TESTING

Exercise tolerance testing (ETT) is a valuable technique for assessing myocardial ischaemia, both for diagnostic purposes and as a prognostic tool. However, an abnormal exercise test must be interpreted in the light of the probability of CAD and the physiological response to exercise as measured by the percentage of the maximum predicted heart rate achieved. A positive test with evidence of ischaemia on the ECG (ST depression of ≤2 mm) does not always indicate IHD, and a negative test does not always exclude its presence.

ECHOCARDIOGRAPHY

Performed either through a transthoracic or transoesophageal approach, echocardiography is valuable for the evaluation of ventricular function and regional wall motion abnormalities, as well as valvular lesions.

Stress echocardiography can detect regional wall motion abnormalities brought on by exercise or the use of dobutamine or dipyridamole. It is a reliable method of identifying viable myocardium. Impaired but recoverable myocardium possesses a functional reserve that allows it to be temporarily recruited into action, whereas scar tissue does not. The development of real time 3-dimensional echocardiography (RT3DE) with the ability to carry out valve reconstruction from different aspects has recently revolutionised preoperative surgical planning in patients with complex valvular lesions.

RADIONUCLIDE STUDIES AND CARDIAC MAGNETIC RESONANCE IMAGING

The main type of radionuclide study used is myocardial perfusion scanning using specific radioiosotopes (such as thallium 201) to assess the significance of coronary disease and viability of the myocardium.

Cardiac magnetic resonance imaging (MRI) can be performed to evaluate the ischaemic burden of coronary disease (using pharmacological agents to stress the heart) and to provide details of tissue viability when using gadolinium as a contrast agent.

MRI is also very useful in assessing cardiac tumours, pericarditis and other structural heart diseases.

POSITRON EMISSION TOMOGRAPHY

Positron emission tomography (PET) provides information on myocardial perfusion, metabolism and cell membrane function. Positron-emitting isotopes are used to label physiological substances, which can measure the regional distribution of these substances. PET is valuable in the diagnosis of CAD, particularly when the more widely available imaging modalities are inconclusive. It can identify injured but viable myocardium that is potentially salvageable by revascularisation.

COMPUTED TOMOGRAPHY

With the development of the latest computed tomography (CT) scanners, which have the ability to correct for respiratory and cardiac movements, multislice high-resolution CT scanning may become an alternative to coronary angiography. It allows assessment of coronary disease, particularly proximal CAD, and gives some information about the degree of coronary artery calcification (calcium score) that is very helpful when stratifying patients to determine which ones will benefit from the more invasive coronary angiography.

Invasive methods of diagnosis

CORONARY ANGIOGRAPHY

Selective coronary angiography provides the means of accurately diagnosing the presence and extent of CAD and remains the 'gold standard' diagnostic technique (**Figure 54.3**). In spite of the availability of newer imaging techniques such as cardiac MRI, selective coronary angiography provides high image quality, demonstrating the extent, severity and location of coronary artery stenoses and the quality and size of the distal coronary arteries. Any stenosis in an artery of >70% of the diameter (90% reduction

Figure 54.3 Coronary angiogram demonstrating severe stenosis in the left main stem prior to bifurcation of the left anterior descending and circumflex arteries.

of cross-sectional area) is considered 'severe'. In addition, angiography can assess ventricular function and provide the cardiac surgeon with information to determine operability, operative risk and probability of the operative result. Coronary angiography only outlines the coronary anatomy, does not demonstrate ischaemia and carries an overall complication rate of less than 1%. However, flow measurement across a stenotic area, using techniques such as fractional flow reserve (FFR), has been effective in predicting patients who are likely to benefit from revascularisation. Moreover, intravascular ultrasound (IVUS) can provide more detailed information regarding the degree of stenosis, especially in left main stem disease.

Summary box 54.5

Coronary angiography

- 'Gold standard' for imaging of anatomy
- Demonstrates extent, severity and location of stenoses
- Reduction in diameter of >70% is considered severe (90% reduction in cross-sectional area)
- Demonstrates quality and size of distal arterial tree
- Aids diagnosis of ischaemia
- Evaluates suitability for surgery
- Aids in prognostic assessment

Indications for surgery

The decision to offer CABG is based on the balance between the expected benefit and the potential risks to the patient. The two issues to be addressed when deciding if a patient is suitable to have surgery are the appropriateness of revascularisation and the relative merits of CABG versus PCI. Current best evidence shows that revascularisation can be readily justified on symptomatic grounds in patients with persistent limiting symptoms (angina or angina equivalent) despite optimal medical therapy and/or on prognostic grounds in certain anatomical patterns of disease.

Recent guidelines concerning myocardial revascularisation released by the Task Force on Myocardial Revascularization of the European Society of Cardiology (ESC) and the European Association for Cardio-Thoracic Surgery (EACTS), are useful in identifying patients with certain angiographic features who can benefit from surgery.

Summary box 54.6

Indication for surgery

- >50% stenosis of the left main stem ('critical left main stem disease')
- >50% stenosis of the proximal left anterior interventricular artery
- Two or three main coronary arteries diseased ('triple-vessel disease')
- Poor ventricular function associated with multivessel disease

Chronic stable angina

Although PCI is increasingly being used for the treatment of stable angina, CABG is still indicated in the presence of certain angiographic features. Angina can be relieved by surgical revascularisation in most patients and symptomatic improvement can be expected for over 10 years.

Acute coronary syndromes

A recently published meta-analysis showed substantial benefit with an early invasive strategy mainly in high-risk patients. An invasive strategy always starts with angiography. After defining the anatomy and its associated risk features, a decision about the type and extent of intervention can be made. The angiography in combination with ECG changes often identifies the culprit lesion and PCI, if desirable, can be recommended to treat it. Angiography should be performed urgently for diagnostic purposes in patients at high risk and in whom the differential diagnosis of other acute clinical situations is unclear. In patients stabilised after an episode of ACS, the indications for CABG are similar to those for patients with stable chronic disease.

The optimal timing of revascularisation is different for PCI and for CABG. While the benefit from PCI in patients with non-ST segment elevation acute coronary syndrome (NSTE-ACS) is related to its early performance, the benefit from CABG is greatest when patients can undergo surgery after several days of medical stabilisation.

Surgery for the complications of myocardial infarction

Myocardial infarction (MI) leads to myocyte necrosis, which may heal to form scar tissue or rupture if the ventricular wall gives way. Free rupture of the ventricle is usually fatal despite treatment. **Ventricular septal rupture** typically presents 3–7 days after infarction with pulmonary oedema, a pansystolic murmur and haemodynamic instability. The diagnosis is usually confirmed with echocardiography. Repair is with a pericardial or artificial Dacron patch. Mitral valve **papillary muscle necrosis** causes acute mitral regurgitation, a pansystolic murmur and pulmonary oedema. Diagnosis is made by echocardiography and right heart catheterisation (showing large V waves). Mitral valve replacement is usually necessary, but the mortality rate is higher than in valve replacement for non-ischaemic valvular diseases. Ventricular aneurysm occurs following partial-thickness necrosis of the ventricular wall if the free wall is replaced with noncontractile fibrous tissue. Left ventricular function is affected because the fibrous wall balloons out during systole and reduces the actual stroke volume. Repair is undertaken using CPB, and CABG is undertaken at the same time if necessary combined with valve replacement if needed.

Acute failure of percutaneous coronary angioplasty

Since the advent of intracoronary stents, the need for emergency CABG following complications of PCI is low at <1%. The mortality rate in this group is significantly higher than for elective CABG.

Preparation for surgery

Clinical assessment

Before CABG, the severity and stability of the patient's IHD, the presence of significant valvular disease and the status of left ventricular function should be properly evaluated. Any comorbid risk factors for IHD should be documented and, in particular, the state of coexisting diseases assessed. Attention is paid to the presence of carotid artery disease, peripheral vascular disease, respiratory status, preoperative diabetic control and presence of associated diabetic complications, significant renal dysfunction or coagulopathy. All medications taken by the patient are noted. Ideally, some should be stopped before surgery, in particular antiplatelet agents, including aspirin, anticoagulants and oral hypoglycaemics. Other drugs, such as diuretics and angiotensin-converting enzyme (ACE) inhibitors, are stopped at the discretion of the surgeon. However, apart from the exceptions noted, as a general rule all cardiac and antihypertensive medications should be taken preoperatively.

Risk assessment

Myocardial revascularisation is appropriate when the expected benefits, in terms of survival or health outcomes, exceed the expected negative consequences of the procedure. Therefore, risk assessment is an important aspect of contemporary clinical practice, being of value to clinicians and patients. Over the long term, it allows quality control and the assessment of health economics. Numerous different models have been developed for risk stratification in cardiac surgery including the EuroSCORE II and STS score.

EuroSCORE II is the system commonly used to predict risk for patients in the UK and can be an independent predictor of major adverse cardiac events (MACEs). Therefore, it can be used to determine the risk of revascularisation irrespective of, and even before, the selection of treatment strategy. However, it is important to acknowledge that no risk score can accurately predict events in an individual patient. Moreover, limitations exist with all databases used to build risk models, and differences in definitions and variable content can affect the performance of risk scores when they are applied across different populations. Ultimately risk stratification should be used as a guide, while clinical judgement and multidisciplinary discussion (Heart Team) remain essential.

Selection of conduit

Venous grafts

The long saphenous vein is the most common vein used as a conduit as it is straightforward to harvest, provides good length and is easy to handle. Historical studies showed limited long-term patency rate for long saphenous vein grafts (50–60% at 10 years). However, recent studies suggest that the early use of lipid-lowering agents and antiplatelet agents such as low-dose aspirin can improve vein graft long-term patency. In assessing the patient preoperatively, the legs should be checked for varicose veins. Alternative vein conduits include the short saphenous vein or upper limb veins such as the cephalic vein; however, these grafts are associated with poorer long-term patency rates.

Arterial grafts

The left internal mammary artery (LIMA), or internal thoracic artery, has become the conduit of choice for the LAD. Since the mid-1980s, long-term patency rates of >98% have been reported, with improved long-term survival and fewer reoperations. As LIMA–LAD anastomosis avoids the late complication of vein graft atherosclerosis, particular interest has focused on the use of bilateral internal mammary artery (BIMA) grafts. However, there is ongoing debate regarding the appropriateness in certain subgroups of patients, such as the obese diabetic, in whom sternal wound complications appear higher.

The use of the radial artery as a second or alternative arterial bypass graft has enjoyed a revival in recent times. This has been driven to some extent by the developing concept of total arterial revascularisation and the belief that this will help improve long-term results of coronary surgery. Different randomised controlled studies have demonstrated excellent patency rates at 1 and 5 years. In assessing a patient in whom a radial artery harvest is planned, an Allen's test should be performed. Alternative arterial bypass grafts include the gastroepiploic artery and the inferior epigastric artery.

Summary box 54.7

Allen's test

- The patient makes a tight fist while the surgeon compresses both distal and ulnar arteries digitally; this squeezes blood from the hand
- The hand is then relaxed and compression of the ulnar artery is released; the speed of returning colour to the hand is assessed
- If colour returns in 5–7 s, patency and collateral flow from the ulnar artery is confirmed

The operation

Intraoperative monitoring includes monitoring of continuous central venous pressure and blood pressure (via a central line in the internal jugular or subclavian vein and radial artery line, respectively), urine output via a urinary catheter, temperature using a nasopharyngeal probe and continuous ECG monitoring.

The operation commences with harvesting of the conduits (long saphenous vein from the leg (**Figure 54.4**), and/or radial artery) while the chest is opened via a median sternotomy and the LIMA is dissected from the chest wall (**Figure 54.5**). The patient is typically placed on CPB after heparinisation, the aorta is cross-clamped and the heart arrested with

Edgar van Nuys Allen, 1900–1961, Professor of Medicine, The Mayo Clinic, Rochester, MN, USA.

cardioplegia. The grafts are anastomosed to coronary arteries distal to the stenosis (Figure 54.6).

The aortic cross-clamp is removed and the heart is reperfused with oxygenated blood. A side-biting clamp is applied to the ascending aorta and the proximal anastomoses are completed. Occasionally, the surgeon may opt to carry out the whole operation while the cross-clamp is applied, to reduce the risks associated with aortic manipulation. The patient is warmed and weaned from CPB. The heparin is reversed and the patient is returned to the intensive care unit (ICU).

Figure 54.4 The long saphenous vein is exposed at the ankle, anterior to the medial malleolus, as far as the saphenofemoral junction (if required). The side branches are tied carefully and divided and the vein is excised. Gentle distension of the vein through a cannula at its distal end allows inspection for leaks.

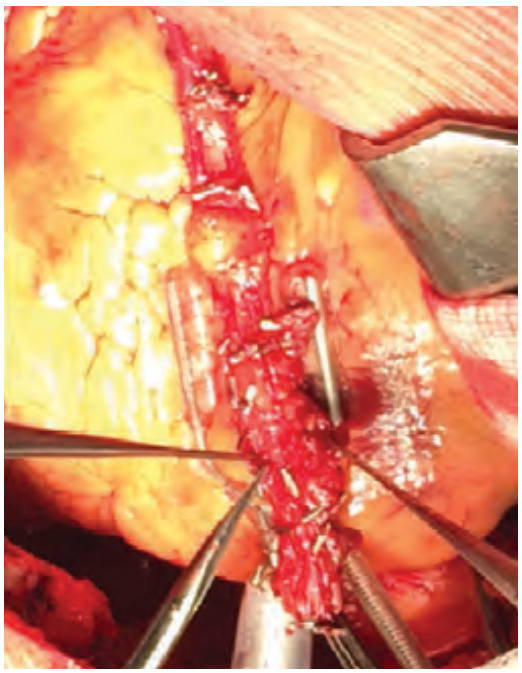

Figure 54.5 A pedicled left internal mammary artery is dissected off the chest wall and divided distally after systemic heparinisation. It is left attached to the subclavian artery proximally.

Postoperative recovery

The majority of patients are extubated a few hours after returning from surgery and remain in the ICU for 24 hours or so. In some centres, 'fast tracking' appropriate patients allows earlier transfer to a recovery area or high-dependency unit (HDU). Discharge is routinely 4–8 days after surgery.

Postoperative complications

Bleeding

Significant bleeding occurs in approximately 2–3% of patients. Rarely, acute cardiac tamponade or profound hypotension may occur in the early postoperative period and requires emergency resternotomy.

Arrhythmias

The most common postoperative arrhythmia is sinus tachycardia, closely followed by atrial fibrillation (AF). It occurs in around 30% of patients undergoing CABG and often spontaneously reverts to sinus rhythm. Treatment includes correction of potassium (>4.5 mmol/L), the use of β-blockers, amiodarone or digoxin and, if necessary, cardioversion. Bradycardia is seldom seen, but temporary pacing via epicardial pacing wires inserted intraoperatively may be required in the postoperative period.

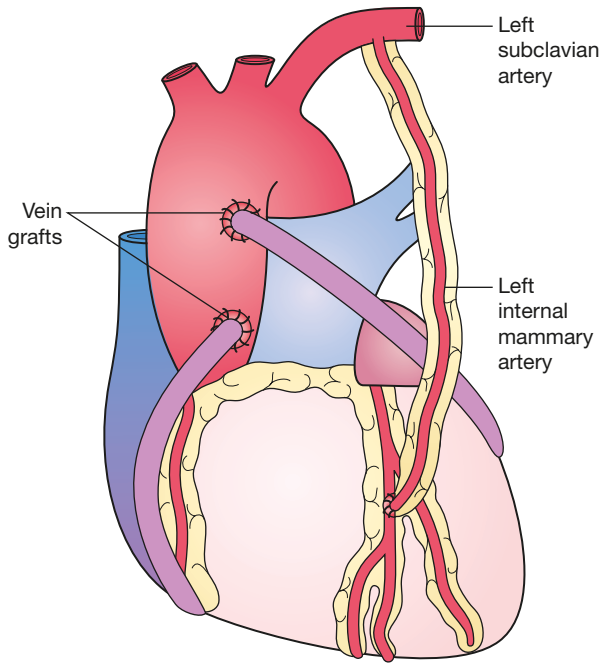

Figure 54.6 Completed coronary artery bypass grafts.

Poor cardiac output state

Myocardial function typically declines in the first few hours following cardiac surgery, presumably in response to an ischaemia/reperfusion-type injury. Inotropic agents are often required at this time to support the heart function and maintain the circulation. Occasionally, the patient develops a persistent low cardiac output state. The clinical manifestations include poor peripheral perfusion, low urine output, a developing metabolic acidosis and low blood pressure.

There are several mechanisms that account for this complication in the early postoperative period, including depressed myocardial contractility, reduced preload, increased afterload and a disturbance in heart rate or rhythm.

Treatment is aimed at the underlying cause but generally includes oxygenation, optimising preload, reducing afterload, managing any rhythm disturbances and improving contractility. If the low cardiac output state persists, the heart may require pharmacological or mechanical support.

PHARMACOLOGICAL SUPPORT

Inotropic drugs act in a variety of ways to alter the systemic vascular resistance, increase the heart rate and increase the force of myocardial contractility. Commonly used inotropes include dopamine, dobutamine, adrenaline (epinephrine) and noradrenaline (norepinephrine). These compounds are often used in conjunction with vasodilating agents that decrease the afterload.

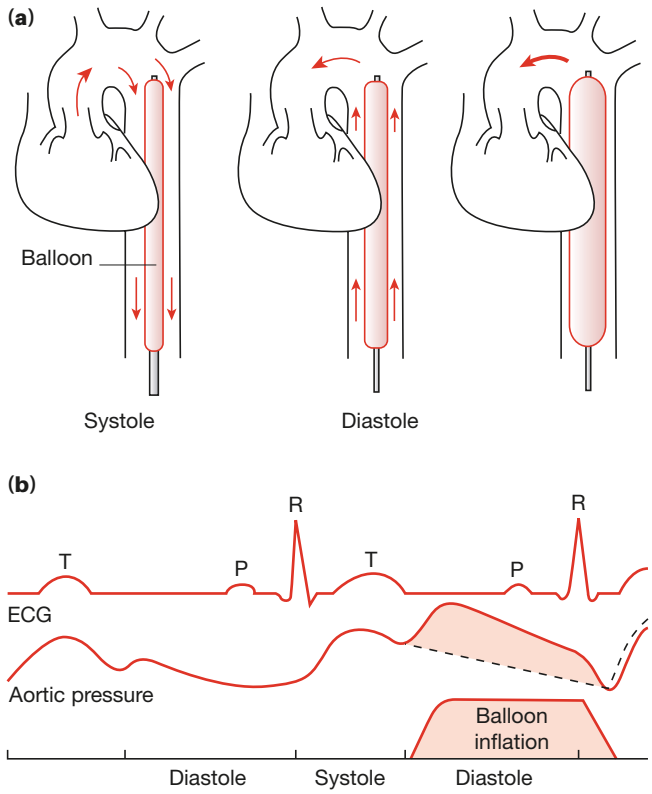

Figure 54.7 Intra-aortic balloon pump counterpulsation. **(a)** The balloon deflates during systole and thereby lowers systemic resistance. It inflates during diastole and increases coronary perfusion in addition to augmenting the systemic blood pressure. **(b)** The pressure changes and phases of the electrocardiogram (ECG) are shown.

MECHANICAL SUPPORT

If low cardiac output persists despite inotropic support, the heart may require mechanical support while it recovers its function. Mechanical support can be achieved using intra-aortic balloon pump (IABP), ventricular assist device (VAD) or extracorporeal membrane oxygenation (ECMO).

IABP is a device that is inserted, either percutaneously or under direct vision, into the common femoral artery. It is threaded into the aorta until its tip lies just distal to the arch vessels (**Figure 54.7**). The balloon is triggered by the ECG, deflating during ventricular systole (thus reducing afterload) and inflating in diastole (displacing blood that perfuses the coronary arteries retrogradely). When the heart has recovered sufficiently, the balloon is removed.

VAD is a mechanical circulatory supporting device used to replace the function of a failing heart partially or completely. It can be used as a short-term measure typically for patients recovering from heart attacks or heart surgery (bridge), or as a long-term support for patients suffering from congestive heart failure (destination). Current VAD devices are all continuous flow, based on a large trial that proved the superiority of continuous flow compared to pulsatile. Blood is exposed in these devices to a non-biological surface that can activate proinflammatory and coagulation cascades, leading to strokes and bleeding. Another important complication associated with VAD is infection.

ECMO is another circulatory support device that is similar to CPB; however ECMO can be established using venous access only (called VV-ECMO) or venous and arterial access (VA-ECMO). This mechanical support is mainly used for neonates and adults with potentially reversible respiratory failure, postcardiac surgery or as a temporary stabilisation method for patient who may need VAD (bridge therapy) as it can be easy to establish in unstable patients.

Neurological dysfunction

Stroke leading to a focal neurological deficit occurs in approximately 2% of patients following CABG. Embolisation, probably originating from the aortic arch or heart chambers, is the most common mechanism for territorial infarcts, with hypoperfusion leading to watershed infarcts. Diffuse neurological injury may occur leading to subtle cognitive abnormalities in memory, concentration and attention.

Wound infection

Significant deep wound infection resulting in sternal dehiscence and mediastinitis occurs in around 0.5–2% of patients. This can be associated with significant morbidity, with a prolonged hospital stay and further surgical interventions for debridement and/or rewiring of the sternum. It still has a significant mortality rate as high as 40%. Wound infections are more common in diabetics, dialysis patients and the obese.

Mortality

In the UK, the overall mortality rate for patients undergoing CABG is 1–3%. Multiple factors have been demonstrated to affect mortality after CABG, including age, gender, left ventricular function, use of LIMA and complete revascularisation.

Surgical outcome

Relief of symptoms

If revascularisation is complete, CABG alleviates or improves anginal symptoms in more than 90% of patients at 1 year; this falls to 80% at 5 years and 60% at 10 years. This symptomatic deterioration usually reflects progression of atherosclerotic disease in vein grafts and native coronary arteries.

Survival

Early surgical versus medical studies have reported survival rates to be >95% at 1 year, 90% at 5 years, 75% at 10 years and 60% at 15 years. Through changes in surgical practice, such as an increased use of arterial conduits and the widespread use of dual antiplatelet therapy, β-blockers and lipid-lowering agents, post-CABG survival may well improve in the future.

Summary box 54.8

Coronary artery bypass surgery outcome

Mortality

- 1–3%

Peroperative infarct

- 2–3%

Angina

- Better in >90% at 1 year
- 80% at 5 years
- 60% at 10 years

Survival

- >95% at 1 year
- 90% at 5 years
- 75% at 10 years
- 60% at 15 years

Off-pump coronary artery surgery

CABG without the use of CPB is a well-established and increasingly popular method that may be combined with a minimally invasive approach or carried out through a conventional sternotomy. It offers the advantages that it avoids the physiological stress associated with CPB and, to some extent, the aortic manipulation that can lead to neurological injury through atherosclerotic embolisation. Since the introduction of cardiac stabilising devices such as the Octopus® (**Figure 54.8**), off-pump coronary artery bypass (OPCAB) grafting has become widespread. One of the concerns, however, is related to the quality of anastomosis carried out on a beating heart and bloody field that can limit the surgeon's vision. The advantages of off-pump surgery over on-pump has recently been questioned, especially with the development of mini-bypass pumps, which offer a closed circuit and minimal

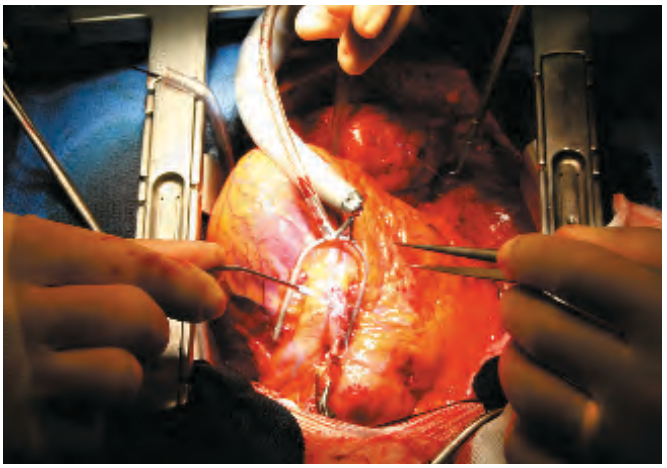

Figure 54.8 Off-pump coronary artery bypass using an Octopus® stabiliser to perform the distal anastomosis.

unphysiological surface area. This reduces proinflammatory activation but at the same time allows the surgeon to operate on a still, bloodless heart. However, there is still no evidence to support the superiority of any of the above mentioned techniques and the final decision is usually based on the surgeon's skills and the required operation.

Minimal access surgery

Minimally invasive direct coronary artery bypass (MIDCAB) grafting is performed through a strategically placed minimal access incision and so avoids all invasive aspects of conventional CABG. Through an anterior submammary incision the LIMA can be dissected down with the aid of a thoracoscope and grafted to the LAD. More lateral MIDCAB incisions allow access to other coronary vessels, including branches of the circumflex artery. Patient selection remains, at least at present, a restriction to the ever-increasing minimally invasive methods being developed. Although not yet critically evaluated, one particular approach is to combine MIDCAB (typically LIMA to LAD) with PCI to other less accessible coronary arteries ('hybrid' coronary revascularisation).

VALVULAR HEART DISEASE

Introduction

Early surgical management of valvular heart disease concentrated on valvular repair. The heroic early procedures for valve stenosis were closed and therefore 'blind' commissurotomies. They were replaced by open procedures with full visualisation, allowing precise repair and replacement. The first prosthetic valve replacement was performed by Harken in 1960 replacing the aortic valve, followed by a mitral valve replacement by Starr a year later. Continued improvements in perioperative care, myocardial protection and, in particular,

Dwight Emary Harken, 1910–1993, formerly Chief of Thoracic Surgery, The Peter Bent Brigham Hospital, Boston, MA, USA. Innovator in heart surgery, he introduced the concept of intensive care unit and opened the first intensive care unit in 1951. Served as Chief of Thoracic Surgery at Harvard University for 22 years.
Albert Starr, b.1926, formerly Professor of Surgery, The University of Oregon, Portland, OR, USA. Medical Director, Providence Heart and Vascular Institute, Portland. Inventor of the world's first durable artificial mitral valve; winner of Lasker award in 2007 – an award given by the Lasker Foundation in the United States to a person (or persons) who has made major contributions to medical science or who has performed public service on behalf of medicine.

TABLE 54.1 Comparing options for heart valve surgery.

	Advantages	Disadvantages
Valve repair	Preservation of integral structures Improved haemodynamics Avoids long-term anticoagulation	Technical difficulties Variable failure rate
Valve replacement		
Mechanical	Readily available Extensive experience of use	Needs lifelong anticoagulation Susceptibility to infection
	Used in any age group	
	Durability, lifelong	
Biological		
Stented	Readily available	Limited lifespan
	Short period of anticoagulation	
Stentless	Readily available	Limited lifespan
	Probably better haemodynamics with less outflow tract obstruction	More difficult to insert
	Short period of anticoagulation	
Homograft	No anticoagulation Improved haemodynamics Long-term outcome uncertain	Not readily available Technical difficulties

(Adapted from Sharpe DAC, Das SR. Heart valve surgery. *Surgery* 2000; **18**: 265–9.)

the development of prosthetic heart valves have improved long-term haemodynamic results, provided symptom relief and prolonged survival. The majority of valvular operations involve surgery on the aortic or mitral valve; tricuspid and pulmonary valve surgery is rarely undertaken in isolation.

Surgical anatomy

Heart valves function to maintain pressure gradients between cardiac chambers and so ensure unidirectional flow of blood without reflux through the heart. The aortic valve is tricuspid, with semilunar leaflets attached to the aortic wall at the annulus with the aortic sinuses being above the base of each leaflet, two of which form the origin or ostium of the coronary arteries. The intrinsic shape of the aortic semilunar valve allows blood to leave the ventricle during systole and prevents regurgitation during diastole. If disease leads to disruption of the leaflets or the annulus, valve function will be affected.

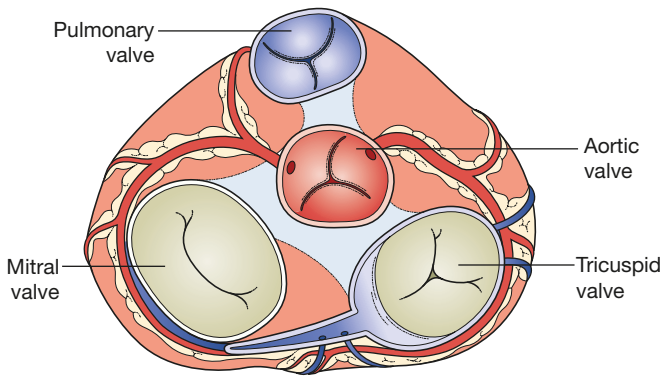

Figure 54.9 Four valves of the heart.

The mitral valve is bicuspid; the more anterior cusp is larger in area and lies between the orifices of the mitral and aortic valves. The leaflets, like those of the aortic valve, are attached to an annulus. The leaflets join at two commissures and are supported by a subvalvular apparatus, consisting of chordae tendinae and papillary muscles. The papillary muscles contract in ventricular systole, pulling the cusps towards the atrioventricular orifice and holding blood within the ventricle. The proper functioning of the mitral valve depends on the integrity of the annulus, leaflets, chordae and papillary muscles. If surgical correction is required, emphasis is on the preservation of these structures when possible (**Figure 54.9**).

Surgical options for heart valve disease

The decision of whether to repair or replace the diseased valve depends on the underlying pathology, the severity of disease and quality and/or involvement of the surrounding supporting structures. Generally, repair is increasingly favoured when possible in mitral valve disease, particularly in degenerative mitral regurgitation, in which it has been shown to have good long-term outcomes. Repair is the operation of choice in tricuspid valve disease, but aortic valve surgery generally involves replacing the diseased valve (*Table 54.1*).

Important factors in selecting the type of procedure and prosthesis include the patient's choice, age, existing comorbidities and the need for anticoagulation. Because of uncertainties about its lifespan, there is debate about when a bioprosthetic valve should be used, with most accepting its use in those over 60 years. The need for anticoagulation may have an impact on choice of valve, particularly in women of childbearing age, the elderly, the presence of congenital or

acquired bleeding diathesis and when there is the need for further major surgery.

Types of prosthetic valves

Mechanical valves

Mechanical valves can be used in any age group to replace any valve (Figure 54.10). They are extremely durable but the components of the valve are thrombogenic and, therefore, the patient requires systemic anticoagulation, usually with warfarin. This subjects the patient to a lifetime of blood tests, medication and the constant threat of haemorrhagic (intracerebral, epistaxis, gastrointestinal bleed) or thrombotic (cerebral infarction) complications.

Biological valves

Biological valves include **homograft** (or **allograft**) valves, removed from cadavers; **autografts**, a patient's own valve; and, most commonly, **heterografts** (or **xenografts**) prepared from animal tissues. All share the basic design of three semilunar leaflets with central flow, so decreasing pressure gradients and minimising turbulence (Figure 54.11). Heterograft 'tissue' valves are the most commonly used valves and can be stented with a limited durability of 10–15 years, whereas stentless (or frameless) valves are expected to have less late calcific degeneration but are more technically difficult to insert.

Figure 54.10 Bileaflet mechanical valve.

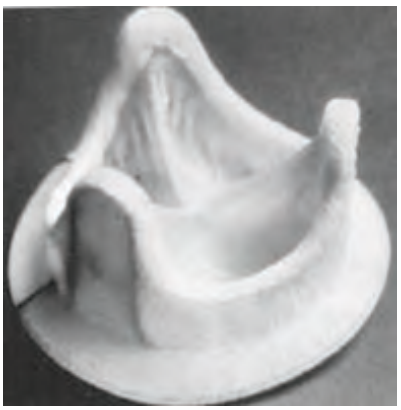

Figure 54.11 Porcine heterograft stented valve.

Prosthetic valve dysfunction and complications

Structural valve failure

Bioprosthetic valves are vulnerable to degenerative changes. Structural failure rates for biological valves, although rare in those over 70 years of age, can reach 60% after 15 years. However, newer biological valves have a reoperative rate of <10% at 20 years. Structural failure of a mechanical valve is generally uncommon.

Paravalvular leak

Early-onset paravalvular leaks usually result from technical difficulties at insertion. Late-onset leaks can occur and may be related to an episode of endocarditis or, in the presence of bioprostheses, leaflet degeneration. The leak can cause haemolytic anaemia or haemodynamic compromise and the valve may need replacement.

Thrombosis and thromboembolism

Thrombus formation on a prosthetic valve remains the most common complication of mechanical and biological valves (Figure 54.12). The risk of thromboembolism is greater with a valve in the mitral position (mechanical or biological) than with one in the aortic position. Improved haemodynamic function lowers the probability of thromboembolism. The incidence of thromboembolism in current mechanical valves is 0.5–3% per patient-year.

Prosthetic valve endocarditis

The incidence of prosthetic valve endocarditis (PVE) is 2–4%. The risk is lifelong and is at its greatest in the 3 months after surgery. The incidence of PVE is higher with mechanical and bioprosthetic valves and lowest with homograft and autograft valves. The diagnosis is suspected following symptoms of

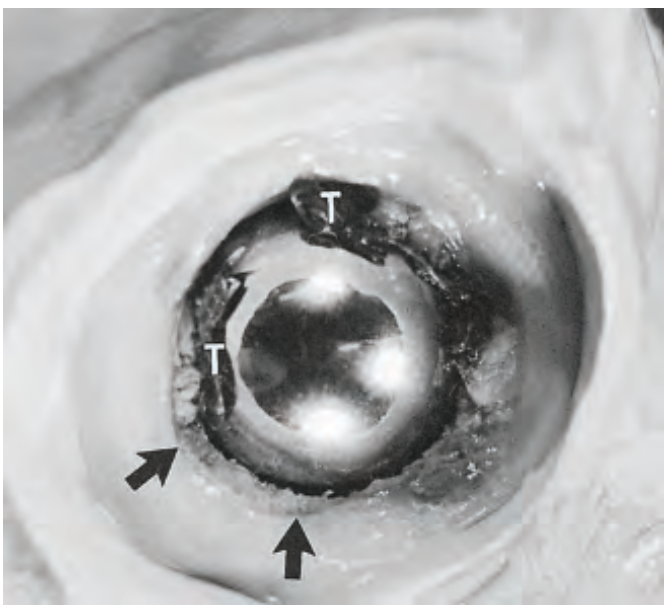

Figure 54.12 Thrombus (marked T and illustrated with the arrows) on the moving components of a ball-and-cage valve.

septicaemia, appearance of a new murmur or a septic embolus. It is confirmed with echocardiography, which may show vegetations and even abscess formation. A high index of suspicion is required and early multiple blood cultures are needed to confirm the diagnosis, identify the infective organism and choose appropriate antibiotic therapy. The most common organisms that can lead to PVE are the *Staphylococcus* species, particularly *S. epidermidis* in early PVE and *S. aureus* (at least 50% of cases); the *Streptococcus* species, usually *S. viridans* but also *S. pneumoniae*; and, less commonly, gram-negative bacilli, as well as fungal organisms.

The treatment of choice is early aggressive intravenous antibiotic therapy. Serial echocardiography to assess extent of infection into surrounding myocardial tissue, as well as functional assessment of the infected valve may help in optimising decisions on timing of surgical intervention. The prognosis of PVE remains poor, with an overall mortality rate of over 20%.

Postoperative management

Antibiotic prophylaxis

Currently; the National Institute for Health and Care Excellence (NICE) recommends that prophylactic antibiotics are not required for patients with prothetic valves undergoing dental procedures. Other leading European bodies have recently supported the above recommendation as the is no strong evidence to the contrary.

Antithrombotic therapy

All patients with mechanical valves require warfarin, usually started on the first or second postoperative day. The use of anticoagulation or antiplatelet therapy with biological valves is variable and depends on the patient's underlying rhythm postoperatively and surgeons' preference.

Mitral valve disease

Mitral regurgitation

Any pathological process affecting the mitral valve apparatus may lead to mitral regurgitation. As such, there are many causes of regurgitation and they can be broadly classified into four headings.

PATHOPHYSIOLOGY

There is an important distinction between acute and chronic mitral regurgitation. The former is usually the result of ischaemic papillary muscle rupture or following infective endocarditis, whereas the latter is the result of myxomatous degeneration or fibroelastic changes in the leaflets.

In acute mitral regurgitation, the left ventricle ejects blood back into a small, poorly compliant left atrium, imposing a sudden volume load on the left atrium during ventricular systole. This leads to an abrupt rise in left atrial pressure followed by a rise in pulmonary venous pressure and pulmonary oedema.

Summary box 54.9

Causes of mitral regurgitation and likely pathology

Degenerative

- Myxomatous degeneration of the valve and subvalvular apparatus (Barlow's disease)
- Fibroelastic deficiency (in elderly patients)
- Senile calcification: calcified annulus
- Connective tissue disorders (e.g. Marfan syndrome, Ehlers–Danlos syndrome): disruption of mitral valve apparatus

Ischaemic

- Papillary muscle rupture: following myocardial infarction
- Dynamic mitral regurgitation: as a result of transient ischaemia
- Poor left ventricular function: most common 'functional' cause secondary to myocardial ischaemia

Rheumatic

- Previous acute rheumatic fever: stiffened leaflets unable to coapt

Infective

- Endocarditis: leaflet destruction and perforation

(Adapted from Hall R. Mitral valve disease. *Medicine* 1997; **25**: 27.)

In chronic mitral regurgitation, the process is sufficiently slow to allow compensatory left ventricular dilatation and hypertrophy, and dilatation of the left atrium without any significant increase in pressure, so protecting the pulmonary circulation. As the disease advances and left atrial dilatation can no longer accomodate, left atrial pressure begins to rise, leading to a rise in pulmonary venous pressure and progressive pulmonary congestion, with eventual congestive cardiac failure.

CLINICAL FEATURES

In acute mitral regurgitation, the patient is usually unwell, presenting with clinical and radiological evidence of acute pulmonary oedema and a loud apical pansystolic murmur. Patients with mild chronic mitral regurgitation are usually asymptomatic. With progressive pulmonary congestion and left ventricular failure, the patient develops fatigue, dyspnoea on exertion and orthopnoea. The development of AF with left atrial dilatation is common. The enlarged left ventricle leads to a heaving apical impulse and a pansystolic murmur.

INVESTIGATIONS

- **ECG** may show left atrial hypertrophy (bifid P waves), left ventricular hypertrophy and atrial fibrillation.
- **Chest radiography**. There may be cardiomegaly with prominent pulmonary vasculature.
- **Echocardiography**. This is often combined with colour flow Doppler imaging, which shows the severity of the regurgitant jet of mitral regurgitation.

John Brereton Barlow, 1924–2008, South African cardiologist.
Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler Principle' in 1842.

- **Coronary angiography**. In patients >40 years of age to investigate the coronary arteries.
- **Cardiac MRI**. Increasingly popular as it can give detailed information on structure and function

INDICATIONS FOR SURGERY

Indications for surgery for patients with primary mitral regurgitation include severe mitral regurgitation in symptomatic patients or severe regurgitation associated with changes in left ventricular function or dimension (such as left ventricular end-systolic diameter), as evidence suggests that any changes in ventricular function in the setting of primary mitral regurgitation is usually associated with significant mortality if not corrected (**Figure 54.13**). It is also recommended to address severe mitral disease in the same setting if a patient is undergoing cardiac surgery for a different reason.

The treatment of mitral regurgitation secondary to ischaemic heart disease remains controversial and current evidence suggests that patients with severe ischaemic regurgitation may benefit from mitral valve replacement, while patients with moderate regurgitation should usually undergo repair along with CABG if indicated.

Mitral stenosis

The most common cause of mitral stenosis worldwide remains rheumatic fever, despite the fact that the incidence of overt rheumatic fever in resource-rich countries has decreased. During the healing phase of acute rheumatic fever, the valve leaflets become adherent to each other at their free border so that the commissures become obliterated and the valve orifice narrows. Symptoms of mitral stenosis usually develop more than 10 years after the acute attack.

PATHOPHYSIOLOGY

Mitral stenosis slows ventricular filling during diastole and the pressure in the left atrium rises to maintain cardiac output. This leads to atrial hypertrophy and dilatation. Pulmonary congestion results from the rise in left atrial pressure but, with time, the lungs are protected against pulmonary oedema by constriction of the pulmonary vessels. However, this adaptive response, along with the passive 'back pressure' generated by the rise in left atrial pressure, leads to pulmonary hypertension. This leads to an increased demand on the right ventricle with eventual right heart failure and tricuspid regurgitation. The development of AF is common and can lead to a significant reduction in cardiac output. AF predisposes to thrombi forming in the left atrium, which may embolise to the systemic circulation.

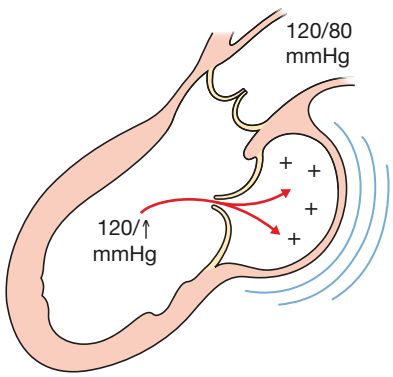

Figure 54.13 Features and pathophysiology of mitral regurgitation. There is a loud parasystolic murmur and the left atrium enlarges. The left ventricle enlarges as a consequence of volume overload.

Summary box 54.10

Causes of mitral valve disease

Stenosis
- Rheumatic heart disease (common)
- Calcification of valve or chordae
- Congenital (rare)

Regurgitation
- Rheumatic heart disease
- Valve prolapse
- Left ventricular dilatation or hypertrophy
- Ischaemia
- Bacterial endocarditis

CLINICAL FEATURES

Patients may remain asymptomatic for years and then present with symptoms when the heart is stressed by an event such as pregnancy, fever, chest infection or with the onset of AF. The common symptoms are fatigue and dyspnoea on exertion, which result from the combination of reduced forward flow and increased back pressure. The resulting pulmonary congestion adds to breathlessness and may produce a cough or haemoptysis. If mitral stenosis is advanced, there may also be a right ventricular heave due to right ventricular hypertrophy in response to pulmonary hypertension. Auscultation reveals an opening snap soon after the second heart sound, as the diseased valve is opened forcibly by the high pressure in the left atrium. The reverse happens when the valve closes and there is a loud 'tapping' first heart sound. In addition, a rumbling mid-diastolic murmur can be heard. The duration of the murmur is related to the severity of the mitral stenosis, increasing in length as the stenosis becomes more severe.

INVESTIGATIONS

- **ECG** may show left atrial enlargement (P-mitrale) or AF. Right axis deviation and other ECG signs of right ventricular hypertrophy (tall QRS complexes in the right ventricular leads $V_{1–3}$) may also be present.
- **Chest radiography**. There is a small aortic outline and a prominent pulmonary artery. The left atrium is enlarged (sometimes to an enormous degree) along with upper lobe diversion as a result of the raised pulmonary venous pressure. The right ventricle also appears enlarged (**Figure 54.14**).

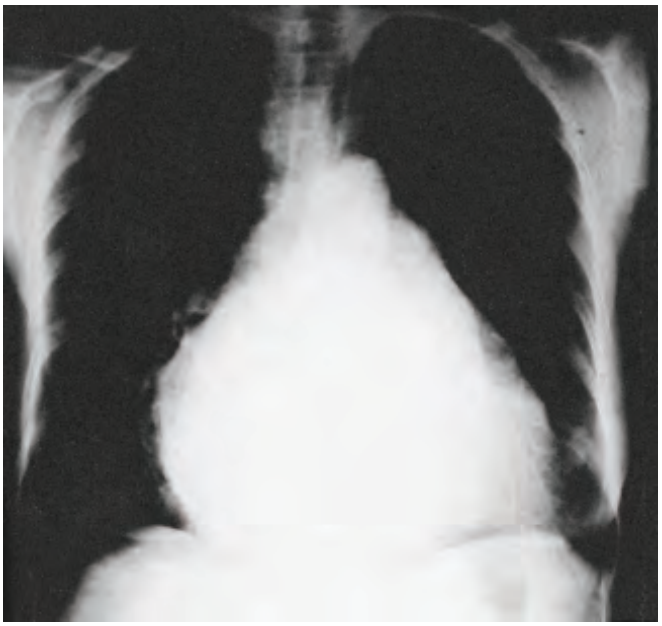

Figure 54.14 Chest radiograph of long-standing mitral stenosis, showing a massive left atrium.

- **Echocardiography**, in combination with colour flow Doppler imaging, allows assessment of the flow across the valve and, therefore, the degree of stenosis. Transoesophageal echocardiography (TOE) may be better at assessing valve morphology in detail and excluding the presence of an atrial thrombus.
- **Coronary angiography**. To investigate the coronary arteries.
- **Cardiac MRI**.
- **Right heart catheterisation**.

INDICATIONS FOR SURGERY

Medical management includes use of anticoagulation in patients with AF or left atrial enlargement. Tachyarrhythmias, including fast AF, that may lead to decompensation and cardiac failure, should be treated. Rate-controlling agents are the mainstay of treatment. Diuretics may provide some benefit. The principal invasive intervention is percutaneous mitral balloon valvuloplasty (PMBV); surgery is indicated for severely symptomatic patients who have failed or who are unsuitable for PMBV. The prognosis is determined by the severity of the stenosis, the size of the atrium, the onset of AF, rising pulmonary artery pressure and the unpredictable risk of embolism from a large, fibrillating atrium (**Figure 54.15**). Surgical options include mitral valve repair or mitral valve replacement. Formerly common surgical procedures such as closed or open commissurotomy are now rarely performed.

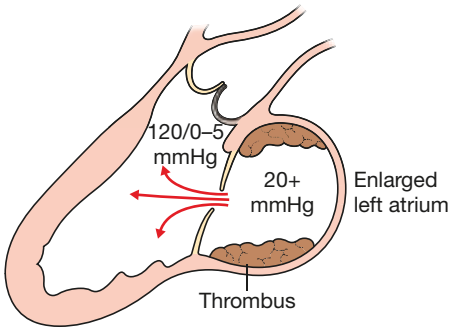

Figure 54.15 Features and pathophysiology of mitral stenosis. The aorta and left ventricle are relatively small because of chronically reduced cardiac output. The atrium is enlarged and may fibrillate, become stagnant and contain a thrombus. The ventricle fills with a turbulent jet that may be detected as a diastolic murmur or a thrill at the apex.

Mitral valve operations

Depending on the type of procedure and approach to the mitral valve, a median sternotomy or, occasionally, a right thoracotomy is performed. The mitral valve can be approached directly through the left atrium in the interatrial groove, through the right atrium and then the interatrial septum, or through the left atrial appendage.

MITRAL VALVE REPAIR

The restoration of normal valve function and preservation of the mitral apparatus is preferable to replacement in specific groups of pathology, as it can be associated with improved long-term ventricular remodelling and function. This approach reduces the bleeding complications associated with anticoagulants. The functional classification system developed by Carpentier serves as a guideline in valve reconstruction. It allows classification of any mitral insufficiency into one of three groups according to the amplitude of the leaflet motion and provides a useful framework for the mechanisms of failure of the mitral valve. As a rule, several valvular lesions or abnormalities are involved in a functional abnormality, with specific techniques developed to correct each lesion.

At surgery, the anatomy of the valvular apparatus and subvalvular structures have to be carefully inspected. In particular, the extent of annular dilatation, leaflet prolapse and chordal dysfunction are assessed. The mitral valve reconstruction is completed using various techniques, including insertion of a prosthetic ring annuloplasty (**Figure 54.16**); triangular or quadrangular resection of the leaflet; use of a sliding plasty; chordal shortening; chordal transposition and neochordea implantation.

There are many different techniques, which indicates that no one technique addresses all the issues that can occur with mitral regurgitation. Valve repair, however, offers better preservation of ventricular function and avoids the need for prolonged anticoagulation, as well as valve-related complications such as PVE or structural dysfunction. Recent advances in surgical techniques and the development of different types of rings has led to increased use of mitral valve repair with excellent results, making it the standard operation. The operative mortality is 1–3%. One of the major issues related to mitral repair is the incidence of regurgitation recurrence, which varies between series but can be up to 30% at 5 years. It seems that this is related to which leaflet is repaired and the amount of foreign material used in the repair (patch).

Figure 54.16 Operative view of the completed repair of a mitral valve using a Carpentier–Edwards annuloplasty ring (courtesy of A Murday, FRCS).

MITRAL VALVE REPLACEMENT

When valve repair is not feasible, mitral valve replacement is necessary. This usually involves a median sternotomy and access to the left atrium on CPB. The diseased valve is exposed, excised and a suitably sized mechanical or bioprosthetic valve is implanted. The atriotomy is closed following de-airing of the left heart. Intraoperative TOE can be used to assess adequate valve function.

The operative mortality rate for elective mitral valve replacement is approximately 5–6%. This depends largely on the state of the myocardium and the general condition (including age) of the patient. Common serious in-hospital complications include stroke (<4%) and renal failure (3%), although any complication of heart surgery is possible. The longer-term prognosis for patients following mitral valve replacement is generally good in comparison with the natural history of mitral valve disease. Indeed, more recent evidence suggests the patients with ischaemic severe mitral regurgitation can benefit more from valve replacement when compared to repair.

PERCUTANEOUS MITRAL VALVE REPAIR (MITRACLIP®)

The MitraClip® is a device used to reduce mitral valve regurgitation. The method involves suturing of the leaflets of the mitral valve together so that regurgitation into the left atrium is prevented. The valve continues to open through the sides of the suture and therefore blood continues to flow into the left ventricle. Although this method is less invasive, associated with rapid recovery and reduced in-hospital stay, it is however technically demanding and long-term durability of the results of the device is unknown.

Recent data suggest that Mitraclip® may be suitable for a small subset of high-risk patients or patients with chronic heart failure, but not for the vast majority, who are better served by surgery that leaves them with substantially less mitral regurgitation.

Aortic valve disease

Approximately two-thirds of all valve surgery performed in the UK is for aortic valve disease, which remains common despite a reduction in the incidence of rheumatic fever in resource-rich countries.

Aortic stenosis

Aortic stenosis, as opposed to aortic sclerosis, occurs when a pressure gradient can be demonstrated across the aortic valve. The difference is not absolute, as sclerosis can progress to stenosis. The common cause of aortic stenosis in adults is an acquired, degenerative, calcific process that results in immobile aortic valve cusps. Progressive fibrosis and calcification of a congenitally abnormal valve can mimic this degenerative process. The usual congenital abnormality is commissural fusion leading to a bicuspid aortic valve, which occurs in approximately 1% of the population (**Figure 54.17**).

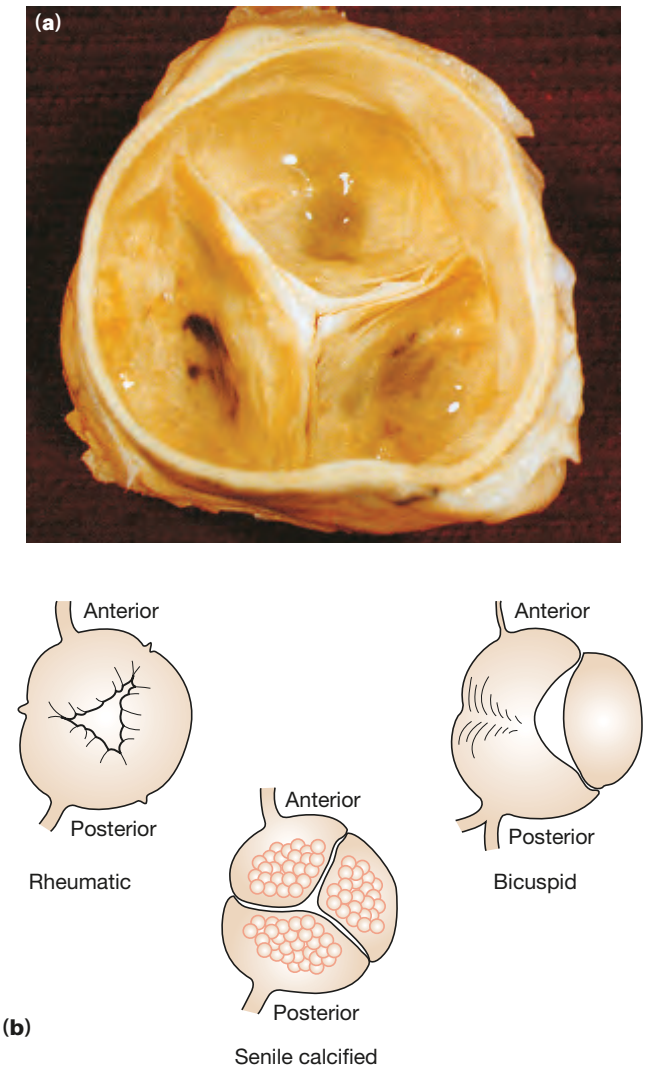

Figure 54.17 **(a)** Formaldehyde-treated aortic valve (normal tricuspid configuration). **(b)** Aortic stenosis, different pathologies.

Alain Carpentier, cardiothoracic surgeon, Hôpital European Georges Pompidou, Paris, France.

PATHOPHYSIOLOGY

A pressure gradient develops between the left ventricle and the aorta, with the left ventricle adapting to this systolic pressure overload by an increase in left ventricular wall thickness or hypertrophy. This adaptive response is an attempt to normalise left ventricular wall stress in the face of increased left ventricular systolic pressure and may maintain a normal cardiac output, prevent left ventricular dilatation and avoid significant symptoms for a number of years. Eventually, myocardial function is affected and, together with insufficient left ventricular hypertrophy to normalise wall stress (load mismatch), ventricular contractility is reduced.

When aortic stenosis is severe and cardiac output is normal, a >50 mmHg gradient between peak systolic left ventricular and aortic pressure exists. As aortic stenosis worsens, cardiac output cannot increase with exertion and eventually becomes insufficient at rest. The reduction in ventricular contractility leads to an irreversible decline in left ventricular function, with dilatation and a rise in left ventricular end-diastolic pressure, to the point of overt left heart failure.

CLINICAL FEATURES

Patients are often asymptomatic until decompensation occurs, typically presenting with dyspnoea and angina, which is due to increased oxygen needs of the hypertrophied left ventricle, reduced coronary filling and inadequate cardiac output during exertion. Patients often describe a feeling of light-headedness or 'near' syncope on effort. Cardiac arrhythmias can also occur. Auscultation of the heart demonstrates a murmur that is typically harsh, ejection in nature and best heard over the aortic area with radiation to the carotids. With critical aortic stenosis and a fall in cardiac output, the murmur may become quieter. The apex beat may be displaced in late disease along with signs of cardiac congestion (**Figure 54.18**).

INVESTIGATIONS

- **ECG**. There is left ventricular hypertrophy with tall R waves in the lateral leads and sometimes a 'strain pattern' (S–T depression with inverted T waves in the lateral leads).

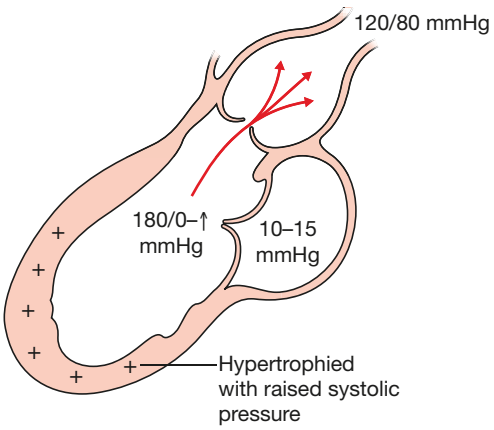

Figure 54.18 Features and pathophysiology of aortic stenosis. Haemodynamic changes in aortic stenosis. Aorta with poststenotic dilatation.

Figure 54.19 Chest radiograph in aortic stenosis.

- **Chest radiography**. May be normal. Cardiomegaly and pulmonary congestion can be seen in the presence of left ventricular failure. Poststenotic dilatation of the aorta is occasionally seen (**Figure 54.19**).
- **Echocardiography** confirms the diagnosis and, together with colour flow Doppler imaging, allows assessment of the aortic valve gradient, calculation of valve area and evaluation of left ventricular dimensions and wall thickness.
- **Coronary angiography**. To investigate the coronary arteries in patients >40 years of age.

INDICATIONS FOR SURGERY

Medical management focuses on the avoidance of systemic hypotension and arterial vasodilatation, which may reduce myocardial perfusion pressure and therefore provoke ischaemia.

The natural history of symptomatic patients with aortic stenosis is dismal, with a 10-year mortality rate of 80–90%. The patient is at risk of sudden death related to the severity of the stenosis. Severe symptomatic aortic stenosis (mean gradient >40 mmHg, velocity >4 m/s and effective orifice area <1 cm^2 are indications for surgery.

Surgery is indicated in asymptomatic patients with severe stenosis, impaired left ventricular function or when the patient is undergoing surgery for a different reason such as CABG. An abnormal blood pressure response to exercise (low blood pressure) is also a sign that there is limited reserve in asymptomatic patients.

Aortic regurgitation

The causes of aortic regurgitation can be classified according to the speed of development of the regurgitant jet (acute or chronic) or according to the anatomical location of pathology (valve leaflet or aortic wall). The causes of acute aortic

regurgitation include infective endocarditis, aortic dissection and trauma. The common causes of chronic aortic regurgitation include degeneration leading to aortic root and/or annular dilatation, congenital bicuspid valve and previous rheumatic fever or endocarditis.

Summary box 54.11

Causes of aortic regurgitation according to predominant anatomical location of pathology

Valve leaflet disease

- Congenital, e.g. bicuspid valve leading to degenerative changes, occasionally with ventricular septal defect
- Rheumatic heart disease
- Infective endocarditis

Aortic wall pathology

- Inflammatory, e.g. connective tissue disorders such as ankylosing spondylitis, systemic lupus erythematosus, rheumatoid arthritis
- Systemic disease, e.g. tertiary syphilis
- Degenerative, e.g. Marfan syndrome, aortic root dissection, senile aortopathy, leading to aortic root/annular dilatation

(Adapted from Petch M. Aortic valve disease. *Medicine* 1997; 25: 31.

PATHOPHYSIOLOGY

Acute aortic regurgitation imposes a volume load on the left ventricle because of backflow. It causes a sharp rise in left ventricular end-diastolic pressure, premature closure of the mitral valve and inadequate forward left ventricular filling. The result is sudden haemodynamic deterioration and acute respiratory compromise.

In chronic aortic regurgitation, volume load and left ventricular end-diastolic pressure increase gradually, leading to compensatory left ventricular dilatation and eccentric hypertrophy to maintain adequate cardiac output. Systolic and diastolic function is abnormal, and sudden deterioration can occur.

CLINICAL FEATURES

Longstanding aortic regurgitation is usually asymptomatic until the left ventricle begins to fail, when exertional dyspnoea may be the only symptom. Angina can also develop. A wide pulse pressure due to a reduction in diastolic pressure and collapsing pulse (waterhammer pulse) are commonly seen. Other manifestations of the wide pulse pressure include visible capillary pulsation of the nail bed (Quincke's sign), pulsatile head bobbing (de Musset's sign), visible arterial pulsation in the neck (Corrigan's sign), a 'pistolshot' sound on auscultating over the femoral artery (Traube's sign) and uvular pulsation (Müller's sign). The apex is displaced laterally, often visible and hyperdynamic or 'thrusting' in nature because of the left ventricular hypertrophy. Auscultation reveals a high-pitched early diastolic murmur best heard at the left sternal edge (**Figure 54.20**).

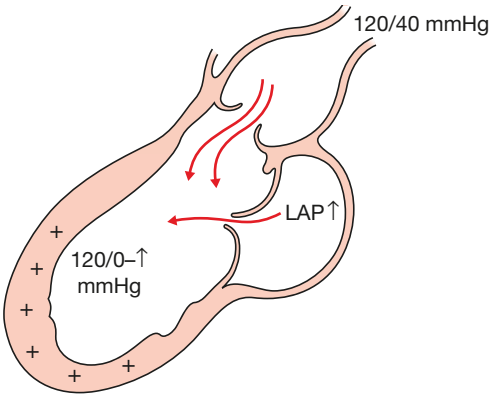

Figure 54.20 Haemodynamic consequences of aortic regurgitation. The left ventricle dilates and hypertrophies and there is a diastolic murmur. LAP, left atrial pressure.

INVESTIGATIONS

- **ECG**. There is left ventricular hypertrophy and sometimes a 'strain pattern'.
- **Chest radiography**. Cardiomegaly can be seen if the left ventricle is dilating; sometimes, the aortic shadow may also indicate dilatation.
- **Echocardiography**. This allows assessment of the underlying cause and severity of aortic regurgitation and enables the diameter of the aortic root as well as left ventricular dimensions to be determined. Colour flow Doppler imaging quantifies the size of the regurgitant jet.
- **Coronary angiography**. To investigate the coronary arteries in patients >40 years of age.

INDICATIONS FOR SURGERY

Medical therapy with vasodilator drugs for relief of dyspnoea or angina is designed to improve forward stroke volume and reduce regurgitant volume. However, symptomatic relief does not alter the need for valve surgery.

The indications for surgery include severe regurgitation in symptomatic patients. Asymptomatic patients with severe aortic regurgitation and left ventricular dysfunction should be offered surgery. Valve replacement should also be considered in asymptomatic patients with severe regurgitation if they are undergoing cardiac surgery for any other reason, or when there is evidence of progressive left ventricular dilatation

Bernard Jean Antonin Marfan, 1858–1942, physician L'Hôpital des Enfants-Malades, Paris, France, described this syndrome in 1896.
Heinrich Irenaeus Quincke, 1842–1922, Professor of Medicine, Kiel, Germany.
Louis Charles Alfred de Musset, 1810–1857, French poet and playwright in whom the sign, traditionally, was first noticed.
Sir Dominic John Corrigan, 1802–1880, physician, Jervis Street Hospital, Dublin, Ireland.
Ludwig Traube, 1818–1876, physician, The Charité, Berlin, Germany.
Friedrich von Müller, 1858–1941, physician, Munich, Germany.

Summary box 54.12

Causes of aortic valve disease

Stenosis

- Congenital
- Rheumatic heart disease
- Acquired calcification and fibrosis of valve or chordae tendineae with age

Regurgitation

- Rheumatic heart disease
- Infective endocarditis
- Congenital
- Inflammatory:
  - Systemic lupus erythematosus
  - Rheumatic ankylosing spondylitis
- Dilatation of aortic root:
  - Marfan syndrome
  - Dissection
- Systemic disease:
  - Syphilis
  - Ulcerative colitis

(left ventricular end-systolic diameter >50 mm). Aortic valve replacement is recommended if there is a decrease in systolic function.

Aortic valve surgery

Unlike mitral valve surgery, there are few occasions when the aortic valve can be repaired and usually the valve requires replacement. However, in neonates and children, aortic valve repair or valvotomy is well established. Percutaneous aortic balloon valvotomy has a role in children, but appears to only result in temporary benefit in adult aortic valve disease.

AORTIC VALVE REPLACEMENT

Aortic valve replacement (AVR) is performed through a median sternotomy on CPB. The aorta is cross-clamped and opened proximally to reveal the diseased valve. Cardioplegic solution is infused into the coronary arteries to arrest the heart in diastole. The valve is then excised leaving the annulus *in situ* but removing as much calcific debris as possible. The annulus is sized and the mechanical or biological valve is then sutured into position at the level of the native annulus and the aortotomy is closed.

The operative mortality rate for elective aortic valve surgery is 2–3%, but is higher in emergency surgery, in surgery for endocarditis and in older patients.

Major complications include stroke (2%), perioperative MI (2%) and heart block requiring a permanent pacemaker (<1%). The major determinant of late survival after aortic valve surgery is preoperative left ventricular function. The 5-year survival rate is approximately 75–85%, with the majority of late deaths related to myocardial factors.

TRANSCATHETER AORTIC VALVE IMPLANTATION

Although AVR is still the gold standard treatment, a significant number of patients affected by severe aortic stenosis requiring AVR do not undergo surgery because they are considered too old or too frail for such an invasive procedure, or because they are affected by concomitant comorbidities that noticeably increase the operative risk. In such patients transcatheter aortic valve implantation (TAVI) is an attractive alternative to standard AVR. Other indications include: heavily calcified ascending aorta ('porcelain' aorta) and the presence of a severe congenital thoracic distortion.

There are different approaches for valve implantation; the most commonly used are transapical (antegrade), and transluminal (retrograde).

- **Transapical approach**. The main advantage of performing transapical procedures is that the feasibility does not rely on the absence of a concomitant peripheral vascular disease or previous aortic surgery. This approach reduces the risk of calcium dislodgment due to the passage of a stiff transluminal device into a diseased aortic arch. In transapical TAVI, the cardiac apex is prepared through a small left anterolateral mini-thoracotomy using a purse-string or a crossing suture reinforced by pledgets and, after the procedure, a chest tube is routinely inserted into the left pleura.
- **Transluminal approach.** This can be carried out via the femoral or subclavian artery. This is a useful technique for patient with previous cardiac surgery; however, the presence of peripheral vascular disease, small vessel diameters, tortuous vessels, aortic disease or previous aortic surgery contraindicates this approach.

Whichever approach is used, a balloon catheter is advanced into the left ventricle over a guidewire and positioned at the opening of the aortic valve. The existing aortic valve is dilated in order to make room for the prosthetic valve. Rapid right ventricular pacing is used to interrupt cardiac output through the existing aortic valve and to reduce movement during implantation. The new valve, mounted on a metal stent, is manipulated into position and is either self-expanding or deployed using balloon inflation. Deployment leads to obliteration of the existing aortic valve.

Complications associated with TAVI include, mortality (5–18% at 30 days), mild-to-moderate aortic regurgitation (30–50%), stroke (3–9%), perioperative open conversion (9–12%), vascular complications (10–15%) and atrioventricular block (4–8%). A recent MI (<3 months), severe pulmonary dysfunction and the presence of an apical thrombus are contraindications for transapical TAVI. Interestingly, most recent multicentre trials have demonstrated that the role of TAVI can be expanded to include intermediate-risk patients, with satisfactory 2-year outcomes.

CONGENITAL HEART DISEASE

Introduction

Congenital heart diseases are abnormalities of cardiac structure that are present from birth. Such abnormalities in the development of the heart typically arise in the third to eighth week of gestation. The first operation for congenital heart

disease was the ligation of a patent ductus arteriosus (PDA) by Gross in 1938. With the development of neonatal CPB, improved methods of myocardial protection and microsurgical techniques, an increasing number of corrective and palliative operations are possible.

Development of the heart and fetal circulation and circulatory changes at birth

By 12 weeks of fetal life the primitive vascular tube is fully developed. The fetal circulation differs from that of the adult in that the right and left ventricles pump blood in parallel rather than in series. Such an arrangement allows the heart and head to receive more highly oxygenated blood. In the fetus this is possible because of the presence of three structural shunts: the ductus venosus, the foramen ovale and the ductus arteriosus **(Figure 54.21)**.

Soon after birth, pulmonary vascular resistance falls because of the action of breathing and the resulting pulmonary vasodilatation. In addition, within 30 minutes of delivery, the ductus arteriosus constricts in response to an increase in blood oxygen levels. The result is a reversal of the pulmonary–systemic pressure gradient and termination of blood flow from the pulmonary artery into the aorta.

After birth, the act of cutting and tying the umbilical cord stops venous blood flow from the placenta. This lowers the pressure in the inferior vena cava and, with the fall in pulmonary vascular resistance, right atrial pressure falls. The result is closure of the foramen ovale. The abolition of venous return from the placenta also causes the ductus venosus to close.

The closure of the fetal circulatory shunts in the few hours following birth is functional, with complete structural closure typically taking several months. In 20% of adults the structural closure of the foramen ovale remains incomplete, but is of no cardiovascular significance.

Abnormalities of cardiac structure may arise from the persistence of normal fetal channels (PDA, patent foramen ovale), failure of septation (atrial septal defect (ASD), ventricular septal defect (VSD), tetralogy of Fallot), stenosis (intracardiac–supravalvular, valvular, infravalvular or extracardiac coarctation of the aorta), atresia or abnormal connections (transposition of the great vessels (TGV), total anomalous venous drainage). Fetal echocardiography is now sufficiently sensitive to detect intracardiac lesions in the second trimester.

Incidence

Congenital heart disease is the most common congenital abnormality in the UK; the incidence of significant cardiac abnormalities is 8 cases per 1000 live births. Many spontaneous abortions or stillbirths have cardiac malformations or chromosomal abnormalities associated with structural heart defects. In neonates and children with congenital heart disease, 15% will have more than one cardiac abnormality and 15% will have another extracardiac abnormality.

Aetiology

There is often no obvious aetiology; most abnormalities appear to be multifactorial with both genetic and environmental influences. There are well-recognised associations.

Summary box 54.13

Recognised associations with congenital heart disease

Maternal (environmental) factors

- Infection: rubella
- Disease: systemic lupus erythematosus, diabetes mellitus
- Drugs/medications: alcohol abuse, warfarin, phenytoin, lithium

Genetic factors

- Single gene defects: Marfan, Noonan and Holt–Oram syndromes
- Chromosomal defects: trisomy 21 (Down syndrome), trisomy 18 (Edwards syndrome), trisomy 13 (Patau syndrome), Turner syndrome
- Deletions: DiGeorge and Williams syndromes

Diagnosis

Occasionally an antenatal diagnosis is possible, with severe congenital heart disease detected *in utero* at 16–18 weeks. If an infant is suspected of having a congenital heart disease, a diagnostic evaluation begins with an accurate history from the parents and specific questions about maternal health and drug intake during pregnancy. A detailed family history is important because some defects are familial. Clinical examination may reveal a murmur, evidence of heart failure, failure to thrive and cyanosis. In addition, congenital heart disease can present with hypertension, an arrhythmia, evidence of polycythaemia or a thromboembolic event. Investigation is much the same as for the adult patient and, with fetal echocardiography available, cardiac catheterisation is now avoided whenever possible.

Robert E Gross, 1905–1988, Surgeon-in-chief, Cardiovascular Surgery, Children's Hospital, Boston, USA.
Etienne Arthur Louis Fallot, 1850–1911, Professor of Medicine, Marseilles, France.
Jacqueline Anne Noonan, b.1921, pediatric cardiologist, The University of Kentucky College of Medicine, Lexington, KY, USA, described this condition in 1963.
Mary Clayton Holt, 1924–1993, cardiologist, The London Hospital for Women and Children, London, UK.
Samuel Oram, 1913–1991, cardiologist, King's College Hospital, London, UK. Holt and Oram described this syndrome in a joint paper in 1960.
John Hilton Edwards, 1928–2007, Professor of Genetics, The University of Oxford, Oxford, UK.
Klaus Patau, 1908–1975, German-born American geneticist, University of Wisconsin–Madison, USA.
Angelo M. DiGeorge, 1921–2009, Professor of Pediatrics, Temple University, Philadelphia, PA, USA.
John CP Williams, b.1922, New Zealand born cardiologist, described the condition in 1961.

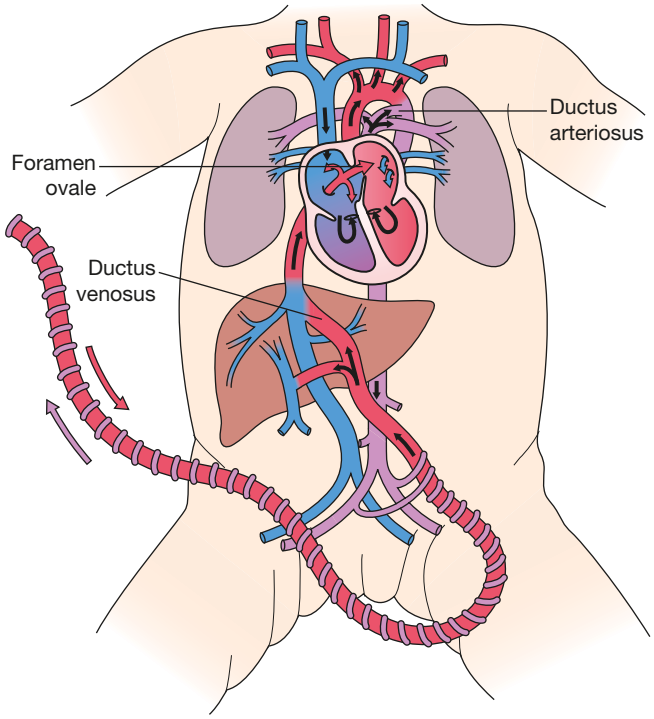

Figure 54.21 Fetal circulation.

Classification

Congenital heart disease can be broadly classified according to the presence or absence of cyanosis, although the distinction is not always clear-cut. The presence of central cyanosis, blueness of the trunk and mucous membranes, results from levels of deoxygenated haemoglobin of >3–5 g/dL in the arterial circulation.

Cyanotic congenital heart diseases make up one-third of cases and are usually more complex, although they do include simple defects. Cyanotic congenital cardiac lesions can involve:

- A right-to-left shunt resulting in decreased pulmonary blood flow. Many of these lesions consist of a septal defect in conjunction with a right-sided obstructive lesion, producing an obligatory right-to-left shunt. The most common cause of this is tetralogy of Fallot.
- Parallel systemic and pulmonary blood flow rather than in series. If there is no mixing this is incompatible with life, so typically neonates have a patent foramen ovale or VSD that allows some mixing of the two circulations at this level. The most common example of this is TGV.
- Defects in the connections of the heart in which there is mixing of the systemic and pulmonary flows. An example of such a complex lesion is total anomalous pulmonary venous drainage.

Acyanotic congenital heart diseases represent the other two-thirds of cases and are usually less complex. Such defects result in an increase in the work imposed on the heart because of either:

- A left-to-right shunt with increased pulmonary blood flow, which causes an increase in volume work of the heart. Examples include PDA, ASD and VSD.
- Obstruction of the blood flow across a heart valve on the left side of the heart, such as aortic stenosis, or in the aorta itself, as occurs with coarctation of the aorta, leading to an increase in pressure and work of the heart.

Typically, acyanotic congenital heart disease presents as heart failure in infancy because of pulmonary congestion caused by increased pulmonary blood flow, or increased pulmonary venous blood pressure resulting from an obstructive lesion. The common acyanotic cardiac defects can also present as a murmur in infancy or later.

Cyanotic congenital heart disease

Tetralogy of Fallot

This is the most common cyanotic congenital heart disease found in children surviving to 1 year and accounts for about 4–6% of all congenital heart diseases. The four intracardiac lesions originally described (**Figure 54.22**) were:

- VSD;
- overriding aorta;
- pulmonary (typically infundibular or subpulmonary) stenosis;
- right ventricular hypertrophy.

Clinically, there may be no signs initially but, as pulmonary stenosis progresses, cyanosis typically develops within the first year of life. Squatting is an adaptation by the child to hypoxic spells. This increases systemic vascular resistance and the venous return to the heart, and consequently blood is diverted into the pulmonary circulation with increased oxygenation. Lethargy and tiredness are also common. Classically

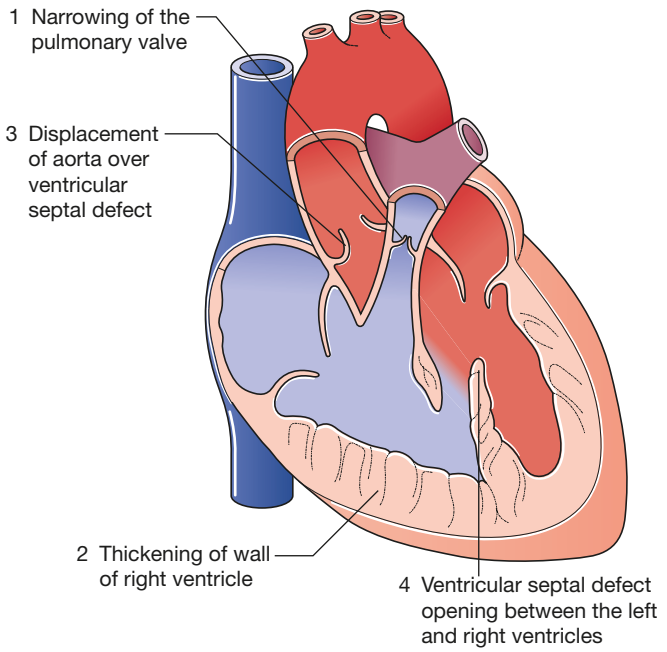

Figure 54.22 Fallot's tetralogy. Four abnormalities that result in insufficienctly oxygentated blood being pumped to the body.

the chest radiograph demonstrates a 'boot-shaped' heart with poorly developed lung vasculature. The diagnosis is confirmed with echocardiography. Surgery to correct the tetralogy is the mainstay of treatment and is usually carried out at 4–6 months of age, when possible. The repair is achieved using a patch to close the VSD and resection of the obstructing section of the infundibular septum. The results of surgery are good, with a late survival rate of 95% at 5–10 years following correction of tetralogy, an operative mortality rate for a repair of between 5% and 10%, and an incidence of reoperation following tetralogy repair of 5–10%.

Transposition of the great vessels

The condition, first described by Morgagni, is the second most common cyanotic congenital heart disease and is the most common cause of cyanosis from a congenital cardiac defect discovered in the newborn period. TGV results from abnormal development, and typically occurs when the aorta arises from the right ventricle and the pulmonary artery from the left ventricle (**Figure 54.23**). The resulting transposition causes the pulmonary and systemic circulations to run in parallel rather than in series, so that oxygenated pulmonary venous blood returns to the lungs and desaturated systemic venous blood is pumped around the body. The situation is incompatible with life and mixing of the blood must occur through associated shunts, such as a patent foramen ovale or associated VSD.

The most obvious presentation is severe central cyanosis occurring in the first 48 hours of life. However, if there is a large ASD or VSD there may be minimal cyanosis initially. Typically, progress is poor and, as pulmonary vascular resistance declines in the neonatal period, high pulmonary flow develops, with cardiac enlargement and left ventricular failure.

The chest radiograph shows pulmonary plethora, with the heart having an 'egg on its side' appearance, with a small pedicle (aorta in front of pulmonary artery). Cardiac echocardiography is sufficient to confirm the diagnosis and delineate the anatomy.

Many infants will die without treatment within 1 month of birth. Initial stabilisation can be achieved by performing percutanous balloon septostomy to increase the systemic arterial oxygen saturation. Alternatively, intravenous prostaglandins can be administered to keep the PDA open and increase systemic–pulmonary shunting. Arterial switch repair is currently the standard operation and is typically carried out within the first few weeks of birth. Long-term outcomes of the operation are excellent and many patients achieve good exercise tolerance; however, some patients will require reoperation for neopulmonary stenosis.

Total anomalous pulmonary venous drainage

Total anomalous pulmonary venous drainage (TAPVD) accounts for only l–2% of congenital heart disease. In this condition, the pulmonary venous drainage has become disconnected from the left atrium and drains into the systemic venous circulation at some other point (inferior vena cava, superior vena cava, coronary sinus or right atrium). Typically, TAPVD presents after the first week of life with cyanosis that is mild to moderate depending on pulmonary flow. Infants with high pulmonary flow develop cardiac failure, recurrent chest infections, failure to thrive and feeding difficulties. If high pulmonary flow is associated with a large ASD, cyanosis is often minimal and the lesion is tolerated well. If there is additional venous obstruction, cyanosis presents at birth with dyspnoea and pulmonary oedema. Echocardiography and cardiac (pulmonary) angiography are necessary to confirm the diagnosis and establish the location of the anomalous drainage.

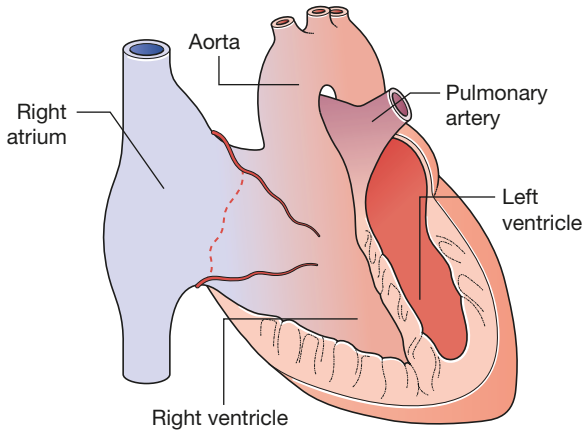

Figure 54.23 Transposition of the great vessels.

The surgical principle is to re-establish the pulmonary venous drainage into the left atrium. The exact operative technique depends on the anatomy and type of TAPVD. The long-term results for survivors of the operation are generally good. Late death following repair is uncommon but, when it occurs, it is often caused by intimal fibroplasia of the pulmonary veins away from the anastomosis.

Eisenmenger syndrome

Eisenmenger syndrome is becoming less common as corrective surgery is undertaken increasingly early and fewer patients develop a fixed increase in their pulmonary vascular resistance. It occurs following the reversal of a left-to-right shunt across a previous left-to-right shunt, such as with an ASD or VSD. These congenital anomalies cause an increase in flow and higher right-sided pressures, which lead to compensatory right ventricular hypertrophy and a subsequent rise in pulmonary artery pressure. Increasing pulmonary hypertension leads to equalisation of pressures either side of the shunt but, at some point, the right-sided pressures will exceed those on the left side, resulting in shunt reversal and desaturated blood entering the left side of the circulation. Cyanosis

Giovanni Battista Morgagni, 1682–1771, anatomist, Padua, Italy.
Victor Eisenmenger, 1864–1932, Austrian physician who described this condition in 1897, but the term 'Eisenmenger syndrome' was introduced in 1958 by an Australian cardiologist, **Paul Hamilton Wood** (1907–1962).

and dyspnoea are the most common clinical features. Closure of the shunt is contraindicated if pulmonary hypertension is irreversible because the right-to-left shunt now serves to decompress the pulmonary circulation.

Acyanotic congenital heart disease

Patent ductus arteriosus

The ductus arteriosus, a normal fetal communication, facilitates the transfer of oxygenated blood from the pulmonary artery to the aorta, shunting blood away from the lungs. Normally, functional closure of the ductus occurs within a few hours of birth; it is abnormal if it persists beyond the neonatal period. The ductus closes in response to an increase in peripheral oxygen saturation and a drop in the resistance of the pulmonary circulation as the lungs expand; this causes the ductal tissue to contract through a prostaglandin inhibition mechanism. A cyclo-oxygenase inhibitor (e.g. indomethacin) may be used therapeutically to close the ductus in the first few weeks of life. In premature babies the ductus is more likely to remain patent for longer or permanently. In the isolated case of PDA, there is a left-to-right shunt of blood, resulting in a high pulmonary blood flow. Small shunts usually cause few symptoms and signs apart from the continuous machinery murmur in the left second intercostal space. Larger ducts cause cardiac failure and can uncommonly lead to shunt reversal with cyanosis and clubbing. The diagnosis is best confirmed by echocardiography with colour flow Doppler imaging.

After 6 months of age, spontaneous closure of a PDA is rare. Most should be closed by preschool age, regardless of the absence of symptoms, if the risks of infective endocarditis, developing left ventricular failure or, rarely, Eisenmenger syndrome are to be avoided. In the adult, surgical treatment is indicated if there is a persistent left-to-right shunt, even in the presence of reversible pulmonary hypertension. In the premature infant, if medical treatment to close the ductus is unsuccessful, the PDA may be treated by interventional cardiology using an umbrella or coil duct occlusion device inserted percutaneously. If the PDA is very large or the patient very small, surgical closure via a left thoracotomy is preferred. This can be accomplished by either ligation or division of the PDA. The operative mortality rate is low and outcome generally very good.

Coarctation of the aorta

This accounts for 6–7% of congenital heart disease and is defined as a haemodynamically significant narrowing of the aorta, usually in the descending aorta just distal to the left subclavian artery, around the area of the ductus arteriosus (**Figure 54.24**). The coarctation typically puts a pressure load on the left ventricle, which can ultimately fail. The upper body is well perfused but the lower body, including the kidneys, is poorly perfused, leading to fluid overload, excess renin secretion and acidosis. Coarctation usually affects boys and, if it occurs in girls, is suggestive of Turner syndrome.

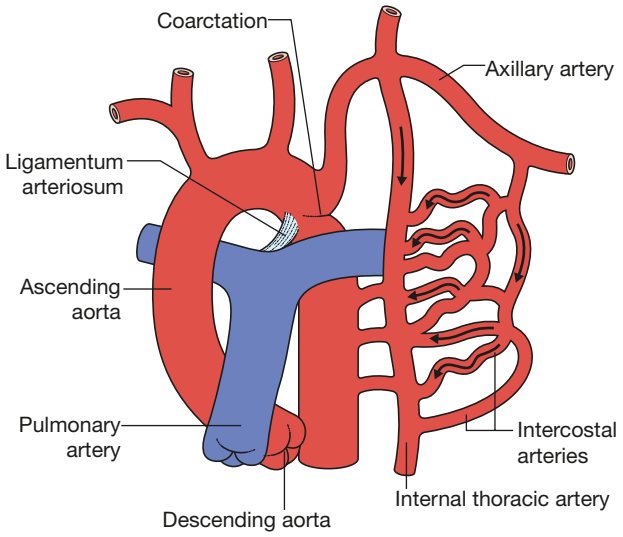

Figure 54.24 Coarctation of the aorta. Coarctation causes severe obstruction of blood flow in the descending thoracic aorta. The descending aorta and its branches are perfused by collateral channels from the axillary and internal thoracic arteries through the intercostal arteries (arrows).

In the neonatal period, coarctation, often referred to as 'infantile' or preductal coarctation, presents with symptoms of heart failure. The child may appear well in the first few days of life because the coarctation is bypassed by the ductus arteriosus and oxygenated blood reaches the entire systemic circulation. As the ductus closes, the child becomes progressively more unwell. In adult-type coarctation, which is often juxtaductal or slightly postductal, obstruction is gradual with complications developing in adolescence or early adulthood. Hypertension is a common presenting problem in older children, often upper body hypertension only with development of enormous collateral vessels that may cause rib-notching and flow murmurs over the scapula. Other symptoms include prominent pulsation in the neck, tired legs or intermittent claudication on exercise. Clinical examination of the pulses may demonstrate a radio-femoral delay and a murmur that is continuous and heard best over the thoracic spine or below the left clavicle.

The chest radiograph classically demonstrates rib-notching because of dilated posterior intercostal vessels. The heart is usually of normal size in the older child and shows a classical 'three sign' replacing the typical aortic knuckle. The upper part of the three sign is the dilated left subclavian, the middle part is the narrowing at the coarctation site and the lower part is the poststenotic dilatation of the descending aorta. Echocardiography is diagnostic. Infant coarctation typically presents with cardiac failure, often requiring vigorous medical treatment, including the administration of prostaglandin to reopen the ductus and general resuscitation, before corrective

Henry Hubert Turner, 1892–1970, Professor of Medicine, The University of Oklahoma, Oklahoma City, OK, USA.

surgery. Definitive treatment is usually surgical repair via a left thoracotomy. Coarctation presenting in the child or later typically requires surgical repair, as most patients die before the age of 40 years because of the associated complications. Percutaneous stenting is currently the standard treatment for adults with isolated coarctation. Without correction, the majority of deaths are caused by heart failure, infective endocarditis, rupture of the aorta or haemorrhagic stroke. The preoperative hypertension may not resolve despite surgical repair.

Atrial septal defects

An ASD is a defect in the septum between the left and right atria leading to a left-to-right shunt, the significance of which is determined by the size of the defect and the relative compliance of the ventricles. The development of the atrial septum is complex and abnormalities of development lead to three commonly recognised ASDs (Figure 54.25).

The most common type is an ostium secundum ASD. The anomaly is caused by failure of the septum primum to develop, leading to incomplete coverage of the ostium secundum. These defects are usually asymptomatic in childhood, with symptoms developing insidiously, typically presenting in middle age with congestive cardiac failure secondary to pulmonary hypertension or with atrial arrhythmias.

In ostium primum ASD, the anomaly is a form of partial atrioventricular canal defect or endocardial cushion defect. The abnormalities are confined to the atrial septum and are caused by the endocardial cushions failing to develop and so close the ostium primum part of the interatrial septum. The defect is associated with abnormalities of the mitral valve, leading to mitral regurgitation. There is a relatively high incidence of this abnormality in trisomy 21 (Down syndrome). Typically, the primum defect presents earlier than ostium secundum in childhood, with dyspnoea, recurrent chest infections and, if pulmonary hypertension develops, cyanosis.

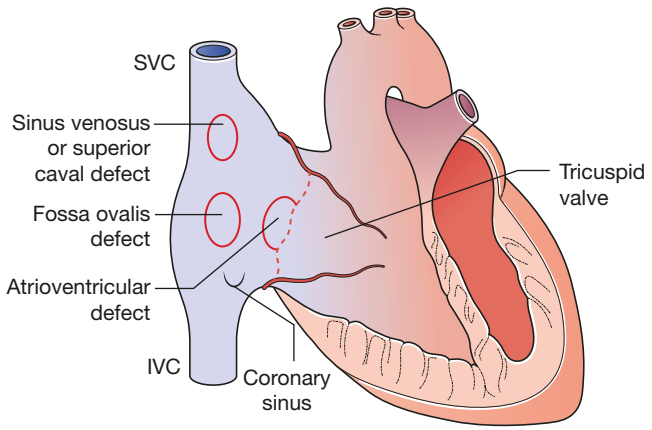

Figure 54.25 Atrial septum viewed from the right. The fossa ovalis is a useful reference point; the most common defect is in this area and is called a fossa ovalis (or ostium secundum) defect. A defect near the atrioventricular junction may be part of the spectrum of atrioventricular septal defects; if the defect is near the entry of the superior vena cava (SVC) it is commonly associated with anomalies of venous drainage into the atria. IVC, inferior vena cava.

A sinus venosus ASD is a rare defect and is the result of failure of partition of the pulmonary and systemic venous circulations. These defects are most commonly located high in the atrial septum at the junction of the superior vena cava and the right atrium. They are frequently associated with anomalous pulmonary venous drainage, with right superior pulmonary veins draining into the superior vena cava or right atrium directly.

Summary box 54.14

Atrial septal defects (ASDs)

Common defects

- Ostium secundum: fossa ovalis defect (approximately 70% of ASDs)
- Ostium primum: atrioventricular septal defect (approximately 20% of ASDs)
- Sinus venosus defect: often associated with anomalous pulmonary venous drainage (approximately 10% of ASDs)
- Patent foramen ovale: common in isolation, usually no left-to-right shunt (not strictly an ASD)

Rarer defects

- Inferior vena cava defects: a low sinus venosus defect and may allow shunting of blood into the left atrium
- Coronary sinus septal defect: also known as unroofed coronary sinus, with the left superior vena cava draining to the left atrium as part of a more complex lesion

Closure is performed during the first decade of life, even in the absence of symptoms, to avoid late-onset right ventricular failure, endocarditis and paradoxical emboli. In adults, closure is still appropriate for symptomatic improvement and avoidance of complications. The traditional method of closure involves open-heart surgery with CPB and closure of the defect, either directly with sutures, as with most secundum defects, or, if the defect is large, using a pericardial or synthetic patch. Closure of small to moderate ASDs using percutaneous catheter-delivered devices in the cardiology catheter laboratory is increasingly common. Primum atrioventricular defect repairs may require additional mitral valve repair. The operative mortality rate for isolated atrioventricular defect repairs is <1%, with an excellent prognosis. Surgical correction of complete atrioventricular canal defects, with closure of the ASD and ventricular septal components and mitral valve repair, is possible, but with a higher surgical mortality rate.

Ventricular septal defects

A VSD is a defect in the interventricular septum that allows a left-to-right shunting of blood. VSDs account for 20–30% of congenital heart disease and affect approximately 2 in 1000 live births. They may occur in isolation or as part of a more complex set of cardiac abnormalities (e.g. tetralogy of Fallot, complete atrioventricular canal defect). Four major anatomical types of VSD are described, based on the anatomical subsections of the interventricular septum (Figure 54.26).

John Langdon Haydon Down (sometimes given as Langdon-Down), 1828–1896, physician, The London Hospital, London, UK.

Summary box 54.15

Types of ventricular septal defects (VSD)

Perimembranous defect

- Also called conoventricular VSD; the most common defect (70–80%), usually located within the membranous septum and may extend to the tricuspid valve annulus or base of the aortic valve

Muscular defect

- Also called trabecular VSD; occurs in 10% of cases and is located within the membranous septum and often multiple

Atrioventricular defect

- Also called atrioventricular canal-type or inlet defect; occurs in 5% of cases and is located in the atrioventricular canal beneath the tricuspid valve

Subarterial defect

- Also called outlet or subarterial VSD; occurs in 5–10% of cases and lies within the conal septum immediately beneath the pulmonary valve annulus.

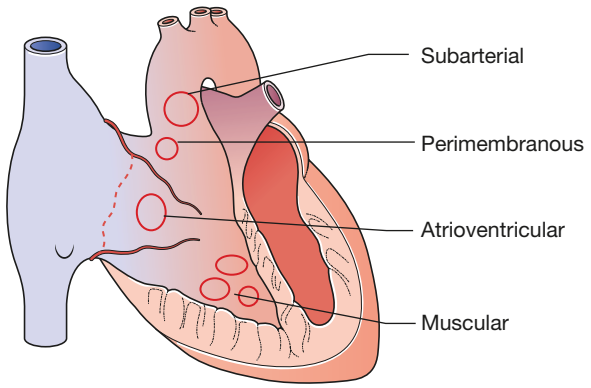

Figure 54.26 Ventricular septum viewed from the right, showing the characteristic sites of ventricular septal defects.

The VSD permits a left-to-right shunt at the ventricular level, with subsequent right ventricular volume overload and increased pulmonary blood flow. This may lead to progressive pulmonary oedema and congestive cardiac failure. Persistently elevated pulmonary blood flow and pulmonary vascular resistance also lead to irreversible pulmonary hypertension. They may eventually result in reversal of flow across the defect and Eisenmenger syndrome. The clinical presentation reflects the magnitude of the left-to-right shunt, which, in turn, depends on the size of the VSD and the pulmonary and systemic vascular resistances. Small defects may close or cause little systemic disturbance (maladie de Roger); infants are asymptomatic with normal development. In the first 5 years, up to 30–50% of VSDs close spontaneously. Clinically, a loud pansystolic murmur can be detected at the left sternal border because of high pressure flow between the ventricles. Large defects typically present with congestive cardiac failure in the first 2 months of life. Because of the size of the VSD, ventricular pressures are equalised and often only a soft systolic murmur is detected. If left untreated, pulmonary hypertensive changes start from about 1 year of age. Eisenmenger syndrome, secondary to shunt reversal in such cases, may become evident in the second decade of life.

Echocardiography confirms the diagnosis and can estimate the degree of shunting across the defect. Cardiac catheterisation can quantify the various pressures within the cardiac chambers and so assess the degree of pulmonary hypertension, as well as demonstrating a step-up in oxygen saturation between left and right ventricles. Generally, surgical closure is indicated for large defects; when there is failure to respond to medical therapy; for left-to-right shunts of >2:1; when there are signs of increasing pulmonary vascular resistance; and in the presence of complications of VSD. These include: (1) aortic regurgitation, which occurs in about 5% of defects; (2) infundibular stenosis, which tends to be progressive and leads to shunt reversal; and (3) infective endocarditis, often presenting with pneumonia or pleurisy as the infected 'emboli' in a VSD with a typical left-to-right shunt flows into the pulmonary circulation.

THE THORACIC AORTA

The most common pathologies affecting the thoracic aorta are aneurysm formation and aortic dissection.

Thoracic aortic aneurysms

A true aneurysm is a localised dilatation of a blood vessel involving all layers of the vessel, whereas a false aneurysm has compressed supporting tissue as its wall, and is usually the result of a defect in the vessel intima (from trauma, dissection or previous surgery). Aneurysms are described as fusiform when the whole circumference is affected or saccular when only part of the circumference is involved.

Aortic aneurysms can develop anywhere along its length, but thoracic aortic aneurysms, including those that extend into the upper abdomen (thoracoabdominal aneurysms) account for 25%, typically occurring in men in the fifth to seventh decade or younger in those with connective tissue disorders.

Aetiology

The most common aetiology is atherosclerosis, but connective tissue disorders account for many aneurysms in the aortic root and ascending aorta now that tertiary syphilis is rare. Marfan syndrome is associated with cystic medial degeneration involving the vessel wall and causes widening of the proximal aorta and aortic root, leading to aortic valve insufficiency. Other disorders associated with aneurysm formation and dissection include Ehlers–Danlos syndrome and osteogenesis imperfecta.

Henri Louis Roger, 1809–1891, physician, Hôpital Sainte-Eugene, Paris, France.
Edward Ehlers, 1863–1937, Professor of Clinical Dermatology, Copenhagen, Denmark.
Henri Alexandre Danlos, 1844–1912, dermatologist, Hôpital St. Louis, Paris, France, gave his account of this condition in 1908.

Trauma, typically following blunt chest injury, can lead to aneurysm formation, usually involving the descending aorta. However, these are usually false aneurysms containing haematoma from injury to the aortic vessel wall.

Clinical features

Many aneurysms are asymptomatic and are discovered incidentally on routine chest radiographs. Others present as a space occupying lesion in the thorax with pain caused by pressure on adjacent structures (vertebra), hoarseness (left recurrent laryngeal nerve), dysphagia (oesophagus) and respiratory symptoms (left main bronchus). Aortic root aneurysms may lead to dilatation of the aortic root annulus and aortic regurgitation.

Rupture can lead to cardiac tamponade or haemorrhage into the left pleural space, leading to dyspnoea and, if the tracheobronchial airway or oesophagus is involved, haemoptysis or haematemesis, respectively.

Investigations

The diagnosis is confirmed by CT or MRI. Arteriography is not necessary for diagnosis but is often required to demonstrate the relation of the arch vessels to the aneurysm.

Indications for surgery

Without treatment the aneurysm is likely to expand and ultimately rupture. Important factors to consider when planning treatment are age, comorbidity and coexisting coronary disease.

In ascending aneurysms, the presence of progressive aortic valve insufficiency is an important indication for surgery. Other indications in this group, including Marfan-related aneurysms, are a diameter of 4.5–5 cm and the presence of symptoms. In descending aneurysms, indications for surgery include symptoms, acute enlargement and a diameter of approximately 6 cm.

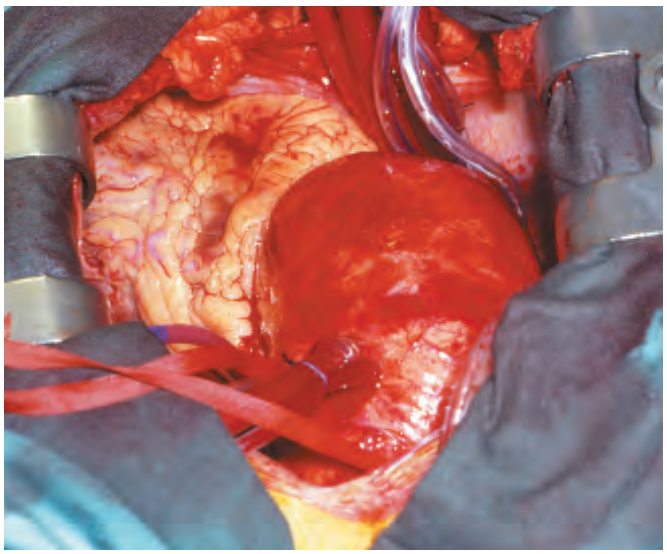

Figure 54.27 A large thoracic aortic aneurysm.

Surgical options

The approach adopted for surgical treatment depends on the location of the aneurysm, but typically involves a median sternotomy, CPB and cooling the patient to 18°C before cross-clamping the aorta above the aneurysm (**Figure 54.27**). If the aortic root is involved, the aorta, together with its annulus and valve, is resected and a composite graft is sutured to the aortic root. The circulation is arrested and, after removal of the aortic cross-clamp, the distal anastomosis is completed. The coronary ostia require reimplantation into the graft (Bentall's operation). If the ascending aorta is involved, it is resected and replaced with a tube graft. For aortic arch aneurysms, surgery on this section of the aorta is a formidable undertaking because the cerebral and subclavian vessels have to be anastomosed to the graft, either separately or *en bloc*. Typically, it involves a period of circulatory arrest and some form of cerebral protection. Excision of a descending aortic aneurysm is with graft replacement under CPB, with exposure via a left thoracotomy or with a heparin-bonded shunt. Increasingly, thoracic aneurysms at the aortic arch or more distal are repaired using a percutaneous approach via the femoral artery, with insertion of an endovascular stent under radiological guidance. The most recent guidelines support the use of endovascualr techniques over open surgical operations.

Surgical outcome

The operative mortality rate is variable depending on the location and type of repair required, but electively is between 5% and 15%. An emergency repair has a considerably higher operative mortality rate. Long-term survival depends on underlying pathology but, for ascending aneurysm repairs, the 5-year survival rate is approximately 65%. The major complications of descending aneurysm repairs include paraplegia, renal failure and ventricular dysfunction.

Aortic dissection

This occurs when a defect or flap occurs in the intima of the aorta, resulting in blood tracking into the aortic tissues splitting the medial layer and creating a false lumen. It most commonly occurs in the ascending aorta or, less often, just

Summary box 54.16

Predisposing factors for aortic dissection

- Age
- Hypertension
- Marfan syndrome
- Pregnancy
- Other connective tissue disorders, for example Ehlers–Danlos syndrome, giant cell arteritis, systemic lupus erythematosus
- Coarctation of the aorta
- Turner or Noonan syndromes
- Aortic cannulation site (iatrogenic)

Hugh Henry Bentall, 1920–2012, formerly Professor of Cardiac Surgery, The Royal Postgraduate Hospital, Hammersmith, London, UK.

distal to the left subclavian artery. It is also more common in men, typically those aged 50–70 years, and in Afro-Caribbean patients.

Aetiology

It usually occurs as a spontaneous or sporadic event, although very often a history of hypertension is noted. Other important associations include Marfan syndrome and pregnancy.

Clinical features

The presentation is often a tearing intrascapular pain not unlike the pain of myocardial ischaemia, and it may be difficult to distinguish between the two. The extent of arterial dissection may produce widespread symptoms and signs.

The dissection can extend distally down the aorta to involve:

- the renal arteries (renal pain and renal failure);
- the mesenteric arteries (abdominal pain and bowel ischaemia);
- the spinal arteries (paraplegia);
- the iliac arteries (leg pain, pallor, loss or reduced pulses and limb ischaemia).

The dissection may track proximally to involve:

- the head and neck vessels (symptoms and signs of a stroke or transient ischaemic attack);
- the coronary vessels (MI);
- the aortic root (aortic regurgitation).

The dissection may also result in aortic wall rupture into the pericardium (cardiac tamponade) or mediastinum (left haemothorax).

Classification

There are two classifications, both of which are limited in their application but widely used. The DeBakey classification is based on the pattern of dissection, whereas the Stanford classification is based on whether the ascending aorta is involved (**Figure 54.28**).

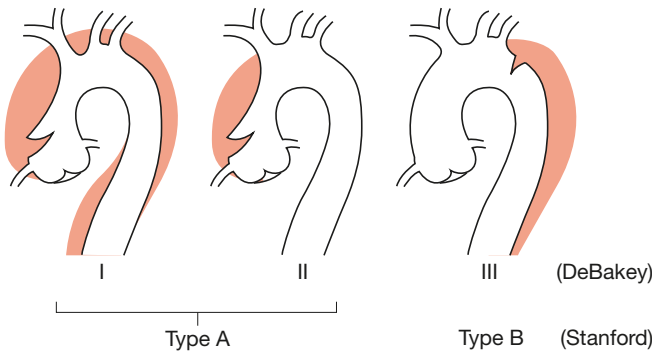

Figure 54.28 Stanford classification of aortic dissections according to whether the ascending aorta is involved (type A) or not (type B). This is simpler than the DeBakey classification (types I, II and III).

Investigations

The diagnosis is suspected based on the clinical presentation and careful history taking. Diagnosis is confirmed by CT, which is accepted as the standard method for diagnosis. Other imaging modalities such as TOE or MRI can be utilised in cases when the CT is equivocal (**Figure 54.29**).

Management

Intitial management of all types of aortic dissection includes blood pressure (which is usually high at presentation) control and strict pain management, followed by prompt referral for specialist management.

Surgical options

TYPE A (OR TYPE I AND II) DISSECTIONS

Those involving the ascending aorta usually require surgical intervention. The chest is opened through a median sternotomy and CPB is started, with core cooling down to 18°C. The aorta is cross-clamped as high as possible and opened. Cardioplegic solution is infused into the coronary ostia to arrest the heart in diastole. If the intimal tear is present and localised, the ascending aorta is excised with the tear and replaced with a synthetic graft. The distal anastomosis is performed with circulatory arrest. There has recently been attempts to carry out endovascular stenting of type A dissection with variable degrees of success.

TYPE B (OR TYPE III) DISSECTIONS

Initially, these are best managed medically with antihypertensive drugs. Intervention is indicated in complicated cases if the pain increases (signalling impending rupture) or when dissection is associated with evidence of malperfusion, such as organ, limb or neurological symptoms. The use of percutaneously placed endovascular stents is currently the standard

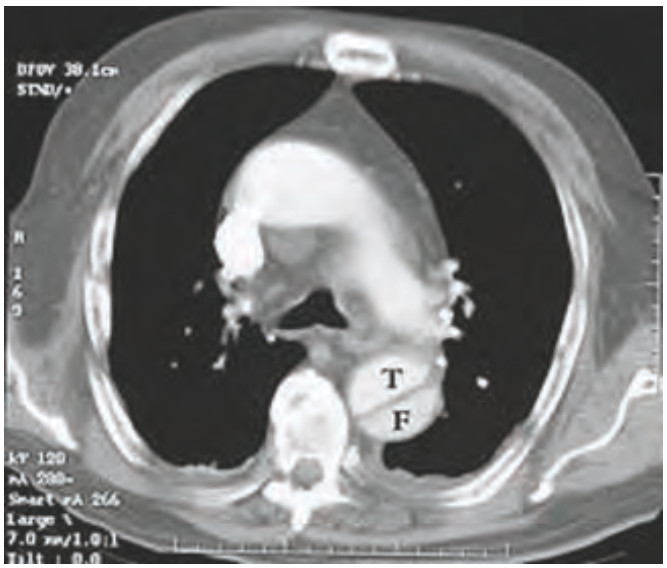

Figure 54.29 Computed tomography scan showing acute dissection of the descending thoracic aorta. F, false lumen; T, true lumen.

Michael Ellis DeBakey, 1908–2008, American cardiac surgeon, Baylor College of Medicine, Houston, Texas, USA.

intervention of choice in patients with complicated type B dissection, and surgery is only preserved for the rare cases which is not suitable for stenting.

Outcomes

If type A dissection is untreated, the mortality rate is 50% within 48 hours and 75% within 1–2 weeks, whereas patients with type B dissections have a better prognosis. The surgical mortality rate is variable but is around 20–25% for proximal aortic dissection. The overall survival rate for patients leaving hospital, regardless of the type of dissection, is around 80% at 5 years and 40% at 10 years.

PERICARDIAL DISEASES

There is a fibrous envelope covering the heart and separating it from the mediastinal structures. This fibrous structure includes a parietal layer and allows the heart to move with each beat. It is not essential for life because it can be left wide open after cardiac surgery without any ill-effects; however, there are a number of conditions affecting the pericardium that may present to the surgeon.

Pericardial effusion

There is continuous production and resorption of pericardial fluid. If a disease process disturbs this balance a pericardial effusion may develop. If the pressure exceeds the pressure in the atria, compression will occur, venous return will fall and the circulation will be compromised. This state of affairs is called 'tamponade'. A gradual build-up of fluid (e.g. malignant infiltration) may be well tolerated for a long period before tamponade occurs, and the pericardial cavity may contain 2 litres of fluid. Acute tamponade (from penetrating trauma, during coronary angiography or postoperatively) may occur in minutes with small volumes of blood. The clinical features are low blood pressure with a raised jugular venous pressure and paradoxical pulse. Kussmaul's sign is a characteristic pattern that is seen when the jugular venous pressure rises with inspiration as a result of the impaired venous return to the heart.

Emergency treatment of pericardial tamponade is aspiration of the pericardial space. A wide-bore needle is inserted under local anaesthesia to the left of the xiphisternum, between the angle of the xiphisternum and the ribcage (Figure 54.30). The needle is advanced towards the tip of the scapula into the pericardial space. An ECG electrode attached to the needle will indicate when the heart has been touched. This will relieve the situation temporarily until the cause of the tamponade is established. Penetrating wounds of the heart usually require exploration through a median sternotomy. Emergency room thoracotomy is rarely required. Chronic tamponade is usually a result of malignant infiltration of the pericardium (usually secondary carcinoma from breast or bronchus) or, very occasionally, uraemia or connective tissue disease. Treatment sometimes requires a pericardial window between the pericardial space and the pleural or peritoneal space.

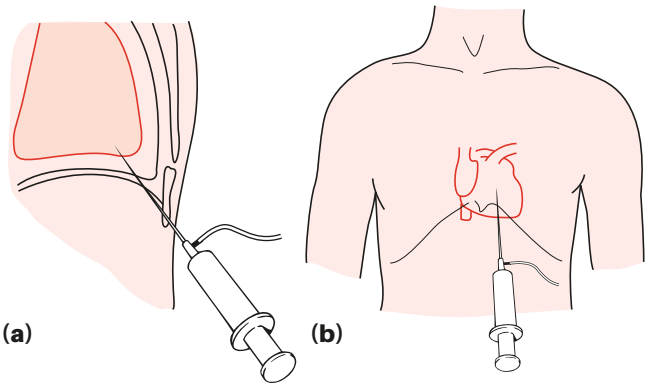

Figure 54.30 (a) Pericardial aspiration through the subxiphoid region. **(b)** Site of needle insertion for pericardial aspiration.

Pericarditis

Infection and inflammation may also affect the pericardium. Acute pericarditis usually occurs following a viral illness. Treatment is with non-steroidal anti-inflammatory drugs and bed rest (in case there is an underlying myocarditis). Acute purulent pericarditis is uncommon but requires urgent drainage and intravenous antibiotics, with attention to the underlying cause.

Chronic pericarditis is an uncommon condition in which the pericardium becomes thickened and non-compliant. The heart cannot move freely and the stroke volume is reduced by the constrictive process. The central venous pressure is raised and the liver becomes congested. Peripheral oedema and ascites are also a feature. Treatment is surgical and is aimed at relieving the constriction.

CARDIAC MASSES

Cardiac masses can be either thrombus (blood clots) or tumours. Thrombus can be found in patients with poor left ventricular function or long standing AF, as well as in patients with proximal pulmonary embolus, either in the ventricles or the left atrium.

Cardiac tumours can either be benign or malignant, which in turn can be secondary (from lung, esophagus, breast etc.) or primary.

Atrial myxoma

This is the most common benign cardiac mass in adult. Myxomas are neoplasm of endocardial origin and often appear as an ovid pedunculated mass most commonly seen in the left atrium (75%) or the right atrium (20%) and, rarely, in the ventricles (Figure 54.31). Myxomas are associated with congenital disorder (Carney complex) in 5% of cases. They usually present

J. Aidan Carney, b.1934, Co Roscommon, Ireland, pathologist at the Mayo Clinic, described a syndrome of myxomas, spotty pigmentation and endocrine overactivity in 1985.

Figure 54.31 Transthoracic echocardiography view of left atrial (LA) myoma (arrow). RA, right atrium.

with symptoms related to blood flow obstruction through heart valves or systemic embolisation. Treatment is by surgical excision and recurrence rates are usually <5%.

Rhabdomyoma

This is the most common benign cardiac tumour in childern. It usually presents with symptoms related to valve dysfuction or arrhythmias. There are usually multicentric pedunculated masses in either or both ventricles. Rhabdomyoma is associated with tuberus sclerosis in >50% of the cases. Treatment is usually by surgical excision.

Primary malignant cardiac tumours

These are extremely rare and less common than secondary malignencies. They include angiosarcoma, rhabdomyosarcoma and leiomyosarcoma. Patients usually have advanced disease when they are discovered, and they are associated with poor outcomes even with multimodality treatment (surgery and chemoradiation).

MANAGEMENT OF CARDIAC ARREST AFTER CARDIAC SURGERY

Introduction

The incidence of cardiac arrest after cardiac surgery is around 0.7–2.9%, with 17–79% survival rates. Ventricular fibrillation (VF), tamponade and major bleeding account for most of arrests. Multiple variables may dictate differences in the management of cardiac arrest after cardiac surgery when compared to other situations. Therefore, EACTS published guidelines for resuscitation of cardiac arrest postcardiac surgery, which are summarised below.

Cardiac arrest with 'non-shockable' rhythm

Cardiac surgical patients who have a non-VF/ventricular tachycardia (VT) arrest may have tamponade, tension pneumothorax or severe hypovolaemia. Prompt treatment is associated with an excellent outcome. Resternotomy should be peformed promptly if connecting the pacemaker and administrating atropine fail to resolve the arrest, especially if prolonged period of CPR is needed, which will be better performed by internal massage.

Emergency resternotomy for ventricular fibrillation or pulseless ventricular tachycardia

A precordial thump may be performed if within 10 s of the onset of VF or pulseless VT; however, this should not delay cardioversion by defibrillation. In VF or pulseless VT, emergency resternotomy should be performed after three failed attempts at defibrillation.

Emergency resternotomy

After the identification of cardiac arrest, basic life support according to the Advanced Life Support (ALS) guidelines should be initiated while preparing for emergency resternotomy. Emergency resternotomy may be required in 0.8–2.7% of all patients undergoing cardiac surgery. Emergency resternotomy is a multipractitioner procedure, which should be rapidly performed with full aseptic technique.

Preparation for emergency resternotomy

- A gown and gloves should be donned in a sterile fashion.
- The thoracic drape is applied, ensuring that the whole bed is covered (if an all-in-one sterile drape is used then there is no need to prepare the skin with antiseptic).
- The scalpel is used to cut the sternotomy incision, including all sutures deeply down to the sternal wires.
- All the sternal wires are cut with the wire cutters. The sternal edges will separate a little, which may relieve tamponade.
- Suction is used to clear excessive blood or clot.
- The retractor is placed between the sternal edges and the sternum opened.
- If cardiac output is restored expert assistance should then be summoned. If there is no cardiac output, the position of any grafts should be carefully identified and internal cardiac massage and internal defibrillation performed, if required.

Internal cardiac massage

This is a potentially dangerous procedure. Risks include avulsion of a bypass graft, with the left internal mammary artery being at particular risk, and right ventricular rupture, especially if it is thin or distended. Therefore, it is important to

carefully remove any clot and identify structures at risk such as grafts before placing hands around the heart.

There are several methods of internal massage; however, the two-hand technique is the safest.

TWO-HAND TECHNIQUE

The heart should be inspected to locate the internal mammary and any other grafts if present, followed by removing any blood clots. The right hand is passed over the apex of the heart and then advanced round the apex to the back of the heart, palm up and hand flat. The left hand is then placed flat onto the anterior surface of the heart and the two hands squeezed together at a rate of 100 per minute. Flat palms and straight fingers are important to avoid an unequal distribution of pressure onto the heart, thereby minimising the chance of trauma. If there is a mitral valve replacement or repair, care should be taken not to lift the apex by the right hand, as this can cause a posterior ventricular rupture.

Chapter 55

The thorax

Learning objectives

To understand:

- The anatomy and physiology of the thorax
- Investigation of chest pathology
- The role of surgery in pleural disease
- The assessment of patients requiring lung surgery
- Surgical oncology as applied to chest surgery

INTRODUCTION

Anatomical development of the lungs

The lungs are derived from an outpouching of the primitive foregut during the fourth week of intrauterine life. This bud becomes a two-lobed structure, the ends of which ultimately become the lungs. The lobar arrangement is defined early and is fairly constant but anomalies of fissures and segments leading to anatomical variation in the adult are common.

The primitive lungs drain into the cardinal veins, which ultimately become the pulmonary veins draining into the left atrium. Variability in venous drainage is very common and is usually of little functional significance. At the most severe end of the spectrum is total anomalous drainage, which presents in early infant life because oxygenated blood is all directed back to the right heart.

Anatomy of the lungs

The left lung is divided by the oblique fissure, which lies nearer to the vertical than horizontal, so the upper and lower lobes could also be called anterior and posterior. On the right, the equivalent of the left upper lobe is further divided to give the middle lobe. Each lobe is composed of segments, with anatomically defined and named bronchial, pulmonary arterial and venous connections (Figure 55.1).

The right main bronchus (RMB) is shorter, wider and nearly vertical compared with the left main bronchus (LMB). As a consequence, inhaled foreign bodies are more likely to enter the right main bronchus than the left (Figure 55.2). The trachea and bronchi have a systemic arterial blood supply delivered by the bronchial arteries, which arise directly from the nearby thoracic aorta.

Lymphatic drainage tends to follow the bronchi. Lymph nodes are both named and identified by numbered 'stations'

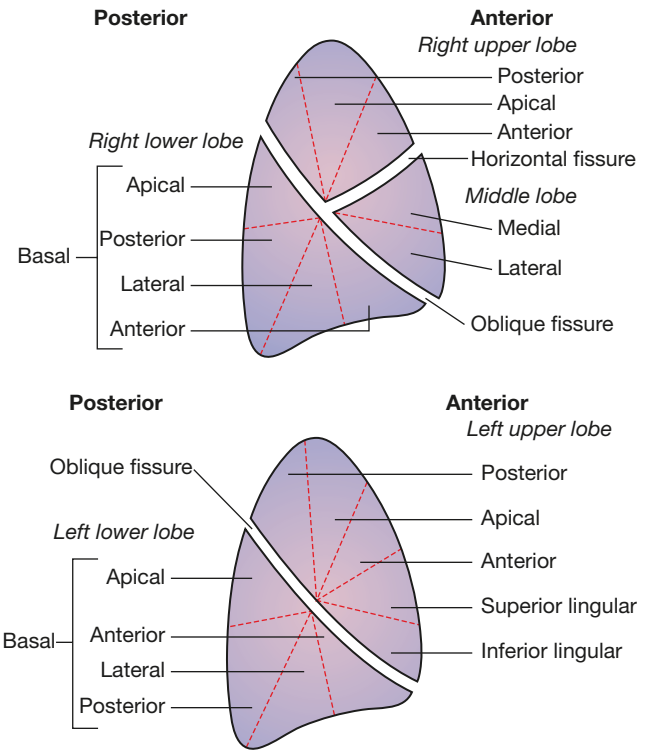

Figure 55.1 The lobar and segmental divisions of the lungs, right lung above and left lung below as if viewed from the side.

and more recently into zones, which are of importance in staging of lung cancer (Figure 55.3).

Mechanics of breathing

The intercostal muscles contract, causing the ribs to move upwards and outwards, thereby increasing the transverse and anteroposterior dimensions of the chest wall. The diaphragm contracts simultaneously and flattens, increasing the vertical

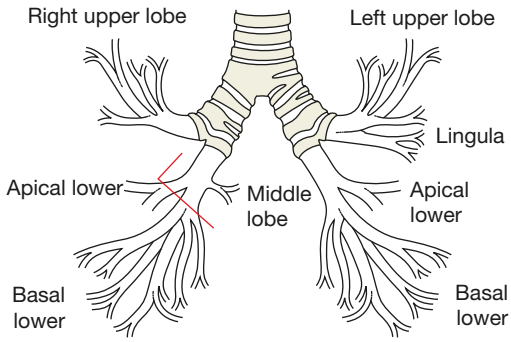

Figure 55.2 Surgical anatomy of the bronchial tree. To surgically remove the right lower lobe and conserve the middle lobe, the surgeon must be prepared to dissect and separately divide the apical bronchial segment (red line).

dimension of the chest cavity. As the volume increases, the intrathoracic pressure falls and air flows in until the alveolar pressure is the same as the atmospheric pressure. The only force used in normal expiration is the elastic recoil of the lung.

Coughing to clear sputum is an essential part of recovery from surgery. In a vigorous cough, probably the only muscle in the body that is relaxed is the diaphragm; as the abdomen and chest wall muscles contract, the limbs are braced and the sphincters are tightened. When the intrathoracic and abdominal pressure is built up, the glottis is opened and the diaphragm is forced up as a piston, or like the plunger of a syringe, to expel air at high velocity.

ASSESSMENT OF FITNESS FOR MAJOR THORACIC SURGERY

The British Thoracic Society (BTS) recommends a tripartite risk assessment model for patients undergoing lung resection, considering the risk of operative mortality, risk of perioperative myocardial events and risk of postoperative dyspnoea (**Figure 55.4**). (See also Chapter 17).

Risk of operative mortality

The Thoracoscore is the most widely used model to assess risk of operative mortality in thoracic patients. Risk is calculated based on nine variables – age, sex, American Society of Anesthesiologists (ASA) score, performance status, dyspnoea score, priority of surgery, extent of surgery, malignant diagnosis and composite comorbidity score. It is currently the most robust model available to estimate the risk of death when considering patients for thoracic surgery.

Risk of perioperative myocardial event

History, physical examination and resting electrocardiogram (ECG) form the basics of assessing perioperative cardiovascular risk. Patients who are found to have an active cardiac condition should be evaluated by a cardiologist and optimised (medical, revascularistion or cardiac surgery) before thoracic surgery. Surgery should be avoided within 30 days of myocardial infarction.

Supraclavicular zone

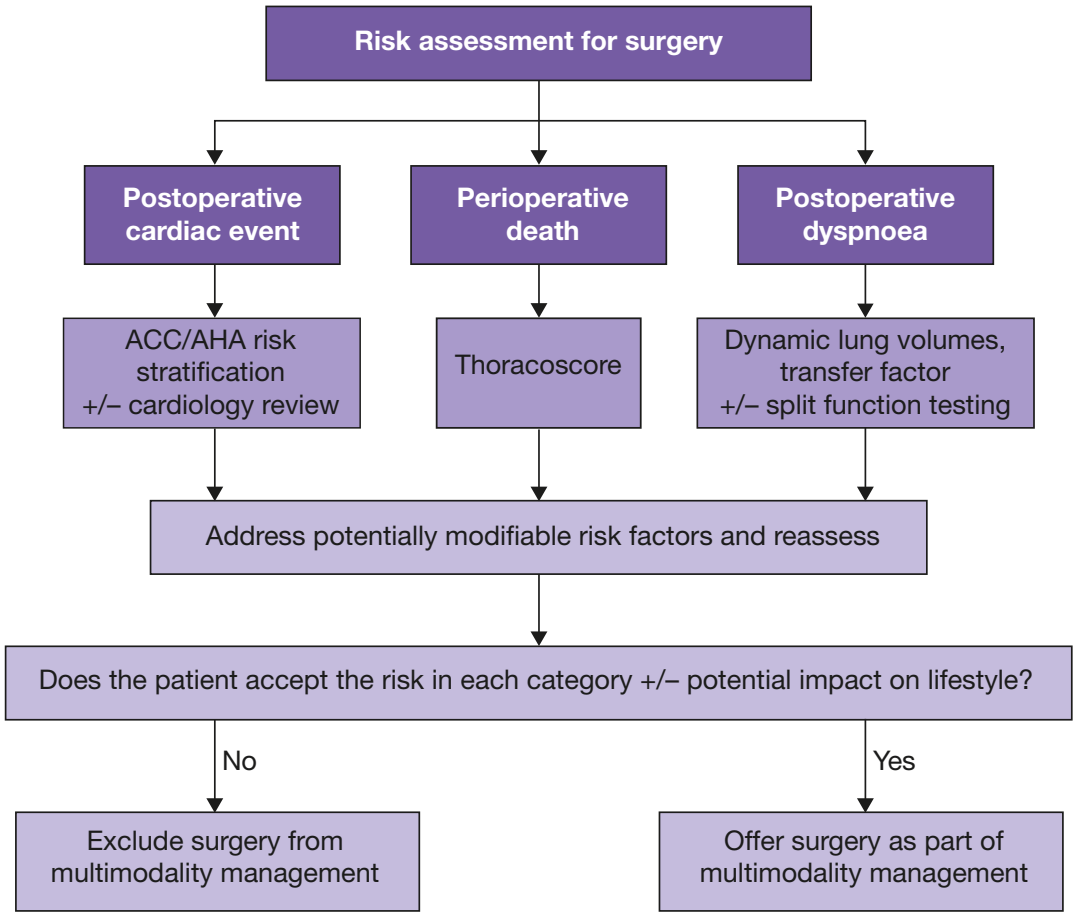

Figure 55.4 Tripartite risk assessment. ACC, American College of Cardiology; AHA, American Heart Association.

Risk of postoperative dyspnoea

Any patient undergoing general anaesthesia requires some assessment of respiratory function. This may be a clinical appraisal of fitness but more detail is necessary for patients who are undergoing lung resection.

Investigation of the respiratory system

Pulmonary function tests (PFTs) are useful in determining the functional capacity of the patient and the severity of pulmonary disease, and in predicting the response to various treatments. The tests range from simple clinic or bedside measurements to those only available in specialist centres. Spirometry is the most commonly performed PFT and measures specifically the amount (volume) and/or speed (flow rate) of air that can be inhaled or exhaled. It is reported in both absolute values and as a predicted percentage of normal. Normal values vary, depending on gender, race, age and height. The most common parameters measured in spirometry are defined below and illustrated in Figure 55.5.

Peak expiratory flow rate

Peak expiratory flow rate (PEFR) is measured by a Wright peak flow meter or a peak flow gauge. This is the maximum airflow velocity achieved during an expiration delivered with maximal force from the total lung capacity. It is a reliable and reproducible test but has the disadvantage of being effort dependent, and it may therefore be affected by abdominal or thoracic wound pain. PEFR measurements are often used in managing asthma, but there are many other causes of low PEFR such as a problem with large airway patency.

Forced expiratory volume in 1 second

The forced expiratory volume in 1 s (FEV_1) is the amount of air forcibly expired in 1 s. It is low in obstructive lung disease and may be normal in patients with poor gas exchange.

Basil Martin Wright, 1912–2001, member of the scientific staff of the Medical Research Council Research Centre, Northwick Park Hospital, Harrow, Middlesex, UK.

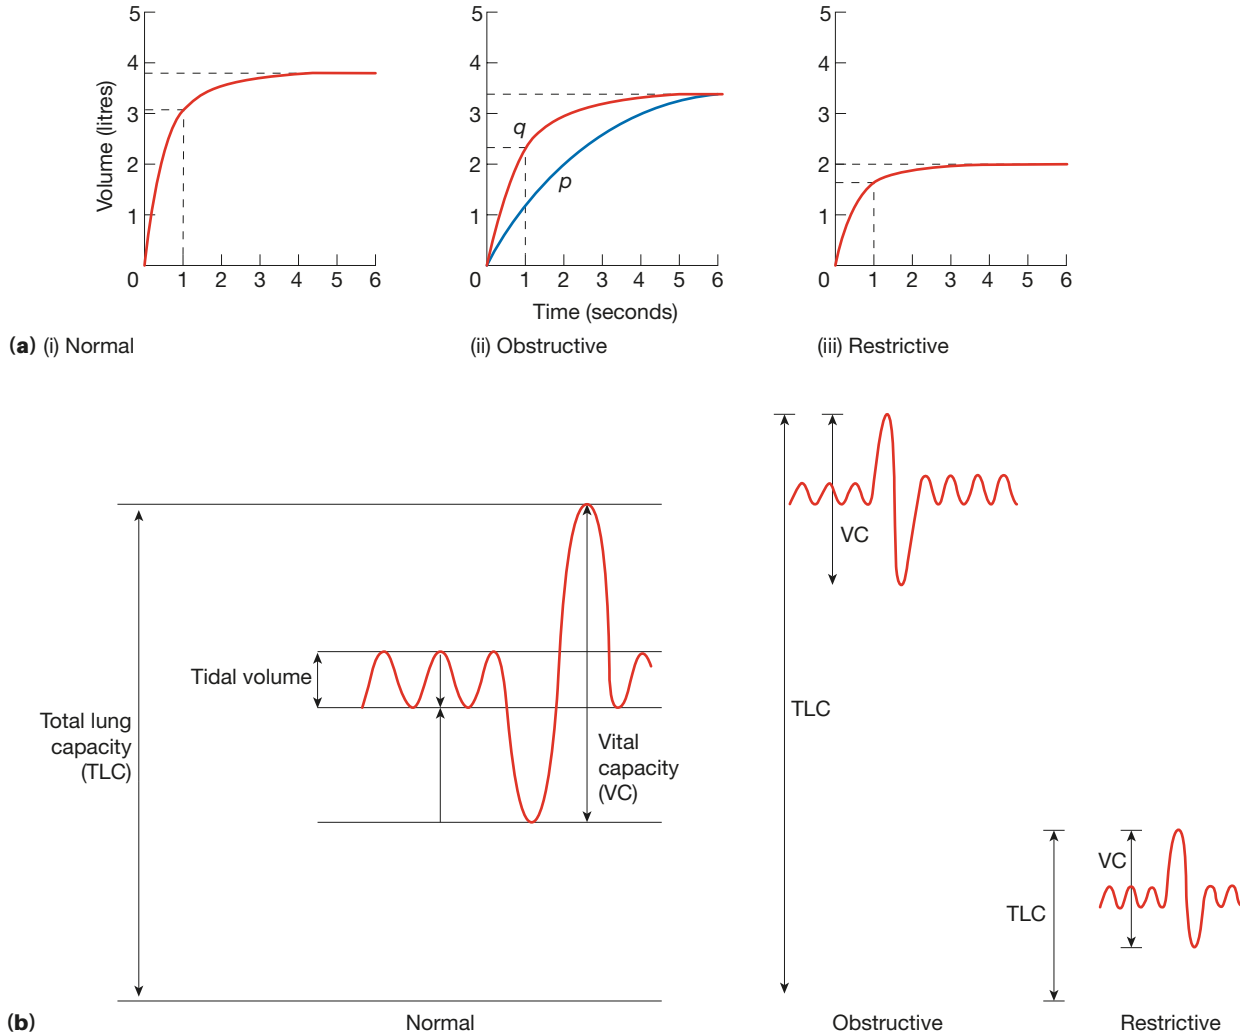

Figure 55.5 Spirometry. **(a)** Spirogram tracings obtained from a Vitallograph: **(i)** normal forced expiratory volume in 1 s (FEV_1) 3.1 litres, forced vital capacity (FVC) 3.8 litres, FEV_1/FVC 82%; (ii) obstructive defect, reversible asthma, *p* before a bronchodilator, FEV_1 1.4 litres, FVC 3.5 litres, FEV_1/FVC 40%; *q* after a bronchodilator, FEV_1 2.5 litres, FVC 3.5 litres, FEV_1/FVC 71%; (iii) restrictive defect, fibrosing alveolitis, FEV_1 1.8 litres, FVC 2.0 litres, FEV_1/FVC 90%. No change with bronchodilators. **(b)** Changes in lung volume in obstructive and restrictive lung disease. (Reproduced from Gray HH. Pulmonary embolism. *Medicine International* 1993; **21**: 477, by kind permission of the Medicine Group (Journals) Ltd.)

Forced vital capacity

The forced vital capacity (FVC) is the volume of air forcibly displaced following maximal inspiration to maximal expiration. The FEV_1 and the FVC can be measured using a Vitallograph, and a ratio (FEV_1/FVC) can be calculated (**Figure 55.5**). A low ratio indicates obstruction and the test should be repeated after bronchodilators. A normal ratio (FVC and FEV_1 reduced to the same extent) indicates a restrictive pathology.

There are two physiological categories of lung disease: obstructive and restrictive (*Table 55.1*). In obstructive conditions such as asthma or emphysema, the flow of air in and out of the lungs is impaired. In restrictive disrease, such as lung fibrosis, the lungs have lost size or elasticity, becoming 'stiff' so that they do not fill or expand properly.

TABLE 55.1 Spirometry values in obstructive and restrictive lung diseases.

	Obstructive pattern	Restrictive pattern
PEFR	↓↓	Normal or ↓
FEV_1	↓↓	Normal or ↓
FVC	Normal or ↓	↓↓
FEV_1/FVC	<70	>80

FEV_1, forced expiratory volume in 1 s; FVC, forced vital capacity; PEFR, peak expiratory flow rate.

Diffusion capacity

The diffusion capacity (DLCO) is a measurement of the lung's ability to transfer gases and is often referred to as the 'transfer factor'. It cannot be performed at the bedside, requires the patient's current haemoglobin level and is a test of the integrity of the lung's alveolar–capillary surface area for gas exchange. In lung diseases that damage the alveolar walls, such as emphysema, or that thicken the alveolar membrane, such as lung fibrosis, it may be reduced. In patients who require surgery to remove part of their lung, for example for lung cancer, measurement of DLCO is an important determinant of 'fitness' for surgery and it should be measured formally as part of a lung function test.

Oxygen saturation

Oxygen saturation (SpO_2) refers to the degree of oxygen molecules (O_2) carried in the blood attached to haemoglobin molecules (Hb). It is a measure of how much oxygen the blood is carrying as a percentage of the maximum it could carry. The common method of monitoring the oxygenation of a patient's haemoglobin is through a pulse oximeter.

Blood gases

The SpO_2 measured non-invasively with a pulse oximeter measures only oxygenation, not ventilation, and provides no information regarding a patient's carbon dioxide or bicarbonate levels, blood pH or base deficit. This requires arterial blood sampling or 'blood gases' (*Table 55.2*).

TABLE 55.2 Arterial blood gases: 'normal values'.

pH 7.35–7.45
$PaCO_2$ 4.5–6 kPa (35–50 mmHg)
PaO_2 11–14 kPa (83–105 mmHg)
Standard bicarbonate 22–28 mmol/L
Anion gap 10–16 mmol/L
Chloride 98–107 mmol/L

The FEV_1 and DLCO are often used to predict the risk of postoperative dyspnoea after lung resection. The predicted postoperative values can be calculated by considering the volume of lung, more specifically the number of bronchopulmonary segments, expected to be removed at surgery. For example if five segments of the left upper lobe are to be removed, the postoperative predicted FEV_1 in a patient with a preoperative FEV_1 of 2.5 litres (85% predicted) is (19 – 5)/19 × 2.5 = 1.84 litres, and (19 – 5)/19 × 85% = 62.6% predicted. This assumes that all bronchopulmonary segments are functioning (e.g. not collapsed) and contribute equally to lung function. Although an optimum cut-off of postoperative predicted FEV_1 of 40% is widely cited, there are currently limited data to provide guidance on this figure to help predict an acceptable degree of postoperative dyspnoea and quality of life. Patients should still be offered surgical resection if the predicted risk of postoperative dyspnoea is moderate or high, as long as they are aware of and accept the risks of dyspnoea and associated complications.

Other functional assessments, including the shuttle walk test, 6-minute walk test, as well as cardiopulmonary exercise testing, could be considered for patients at moderate or high risk of postoperative dyspnoea.

The pleura

The key to many aspects of practical chest surgery is an understanding of the pleura and of the mechanics of breathing. Management of the essentially healthy pleural space is logical and simple and needs minimal technology. On the other hand, when pleural disease is advanced, for example when there is gross pleural sepsis surrounding a leaking and trapped lung, management is difficult and the patient may require prolonged care with repeated interventions.

The physiology of pleural fluid

The turnover of fluid in the human pleural space is about 1–2 litres in 24 hours, with only 5–10 ml of fluid present at any one time as a film, about 20 micrometres thick, between the visceral and parietal pleura.

The mechanisms and equations given are simplifications but serve to explain the clinical conditions encountered. The fluid is produced from the capillaries of the parietal pleura as a transudate, according to the Starling capillary loop pressures. However, there is a further negative force in the pleura. The elastic content of the lung causes it to recoil and collapse if not held open by the negative pressure in the pleura. This elastic recoil exerts about 4 mmHg of negative pressure and favours accumulation of fluid. The secreting forces add up to about 11 mmHg in health. Pleural fluid is mainly reabsorbed (about 90%) by the visceral pleura, whose capillaries are part of the pulmonary circulation. The principal force in absorption of pleural fluid is oncotic pressure (approximately 25 mmHg) minus the difference in mean capillary hydrostatic pressure of the pulmonary capillary (8 mmHg). Thus, the overall absorbing pressure is 25 – 8 = 17 mmHg, producing a net drying effect (17 – 11) of about 6 mmHg (**Figure 55.6**).

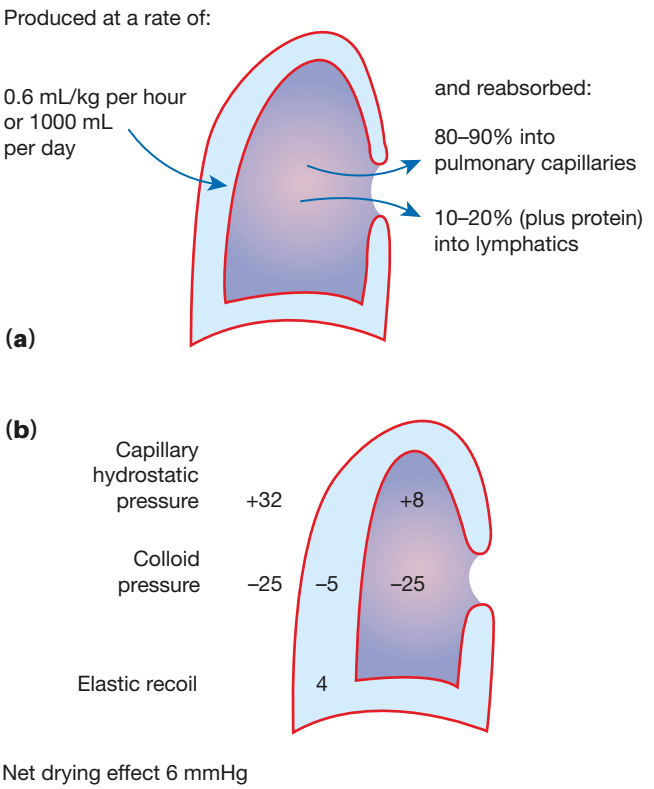

Figure 55.6 **(a)** Production and absorption of pleural fluid. **(b)** Normal pleural physiology. (See the text for an explanation of this simplistic physiological model.)

Ernest Henry Starling, 1866–1927, Professor of Physiology, University College, London, UK.

Gas in the pleural space

There is normally no free gas in the pleural space because the same physiological mechanism that absorbs air from a pneumothorax prevents any gas accumulating.

The partial pressures (water as saturated vapour pressure) of the gases in venous/end-capillary blood are:

- PO_2 40 mmHg 5.3 kPa
- PCO_2 46 mmHg 6.1 kPa
- PN_2 573 mmHg 76.4 kPa
- PH_2O 47 mmHg 6.3 kPa

These partial pressures add up to less than atmospheric pressure (760 mmHg). Free gas is therefore absorbed into the blood and lost to the atmosphere through the lungs, with the gases moving in relation to their solubility (carbon dioxide quickest and nitrogen slowest) and relative concentrations in the pleural space and the blood. This does not favour nitrogen, which constitutes about 80% of atmospheric air. Breathing oxygen accelerates nitrogen removal by reducing the content of nitrogen in the blood and increasing the gradient for its absorption. Nitrous oxide anaesthesia is dangerous in the presence of a pneumothorax; nitrous oxide is very soluble and, although not normally present in the pleural space, it will be rapidly transported into the space if the patient is given nitrous oxide to breathe.

DISORDERS OF THE PLEURA

Pneumothorax

Pneumothorax is the presence of air outside the lung, within the pleural space. It must be distinguished from bullae or air cysts within the lung. Bullae can be the cause of an air leak from the lung and can therefore coexist with pneumothorax.

Spontaneous pneumothorax occurs when the visceral pleura ruptures without an external traumatic or iatrogenic cause. Cases are divided into primary spontaneous pneumothorax (PSP) and secondary spontaneous pneumothorax (SSP). Pneumothorax can also occur following trauma or iatrogenic injury such as insertion of a central line. Tension pneumothorax is when (independent of aetiology) there is a build up of positive pressure within the hemithorax, to the extent that the lung is completely collapsed, the diaphragm is flattened, the mediastinum is distorted and, eventually, the venous return to the heart is compromised. Any pleural breach is inherently valve-like because air will find its way out through the alveoli but cannot be drawn back in because the lung tissue collapses around the hole in the pleura. Patients being mechanically ventilated following trauma are at particular risk.

Surgical emphysema is the presence of air in the tissues. It requires a breach of an air-containing viscus in communication with soft tissues, and the generation of positive pressure to push the air along tissue planes. The most serious cause is a ruptured oesophagus. Mediastinal surgical emphysema can also occur with asthma or barotrauma from positive pressure ventilation. A poorly managed chest drain with intermittent build up of pressure allows air to track into the chest wall through the point where the drain breaches the parietal pleura.

Primary spontaneous pneumothorax

This is a common condition characteristically seen in young people from their mid-teens to late 20s. About 75% of cases are in young men who tend to be tall and have a family history of the condition. It is due to leaks from small blebs, vesicles or bullae, which may become pedunculated, typically at the apex of the upper lobe or on the upper border of the lower or middle lobes.

Secondary spontaneous pneumothorax

This occurs when the visceral pleura leaks as part of an underlying lung disease; any disease that involves the pleura may cause pneumothorax, including tuberculosis, any degenerative or cavitating lung disease and necrosing tumours. As such it tends to occur in older patients, often with a history of underlying lung disease such as emphysema. The pneumothorax may be less well tolerated.

Usually, pneumothorax presents with sharp pleuritic pain and breathlessness. The pleura is exquisitely sensitive and the movement of the lung on and off the parietal pleura causes severe discomfort. As a result mild cases are more painful, whereas complete collapse is usually painless but causes more breathlessness. Bleeding and tension pneumothorax can occur. They are usually self-limiting; careful observation is wiser than too-ready resort to a chest drain. If the patient is not in respiratory distress or hypoxic there is no urgency. Tension pneumothorax should be immediately relieved by inserting a cannula into the hemithorax in as safe a position as possible (**Figure 55.7**).

The risk of recurrent pneumothorax is increased after the first episode. The best estimates of recurrence rates are:

- of patients who experience a first event, only about one-third experience recurrence;
- of those who have a second episode, about one-half go on to experience a third episode;
- those who have had three episodes will probably go on to have repeated recurrences.

Current recommendations from the BTS are that, in cases of persistent air leak following drain insertion or failure of the lung to re-expand, an early (3–5 days) thoracic surgical opinion should be sought. Other indications for thoracic surgical referral are given.

Summary box 55.1

Indications for surgical intervention for pneumothorax include:

- Second ipsilateral pneumothorax
- First contralateral pneumothorax
- Bilateral spontaneous pneumothorax
- Pneumothorax fails to settle despite chest drainage
- Spontaneous haemothorax: professions at risk (e.g. pilots, divers)
- Pregnancy

Current recommendations focus on the use of small bore (10–14 Fr) chest drains, usually of a Seldinger type, inserted ideally under ultrasound guidance. However, knowledge of the role of the 'surgical' chest drain and how to insert it safely is still required.

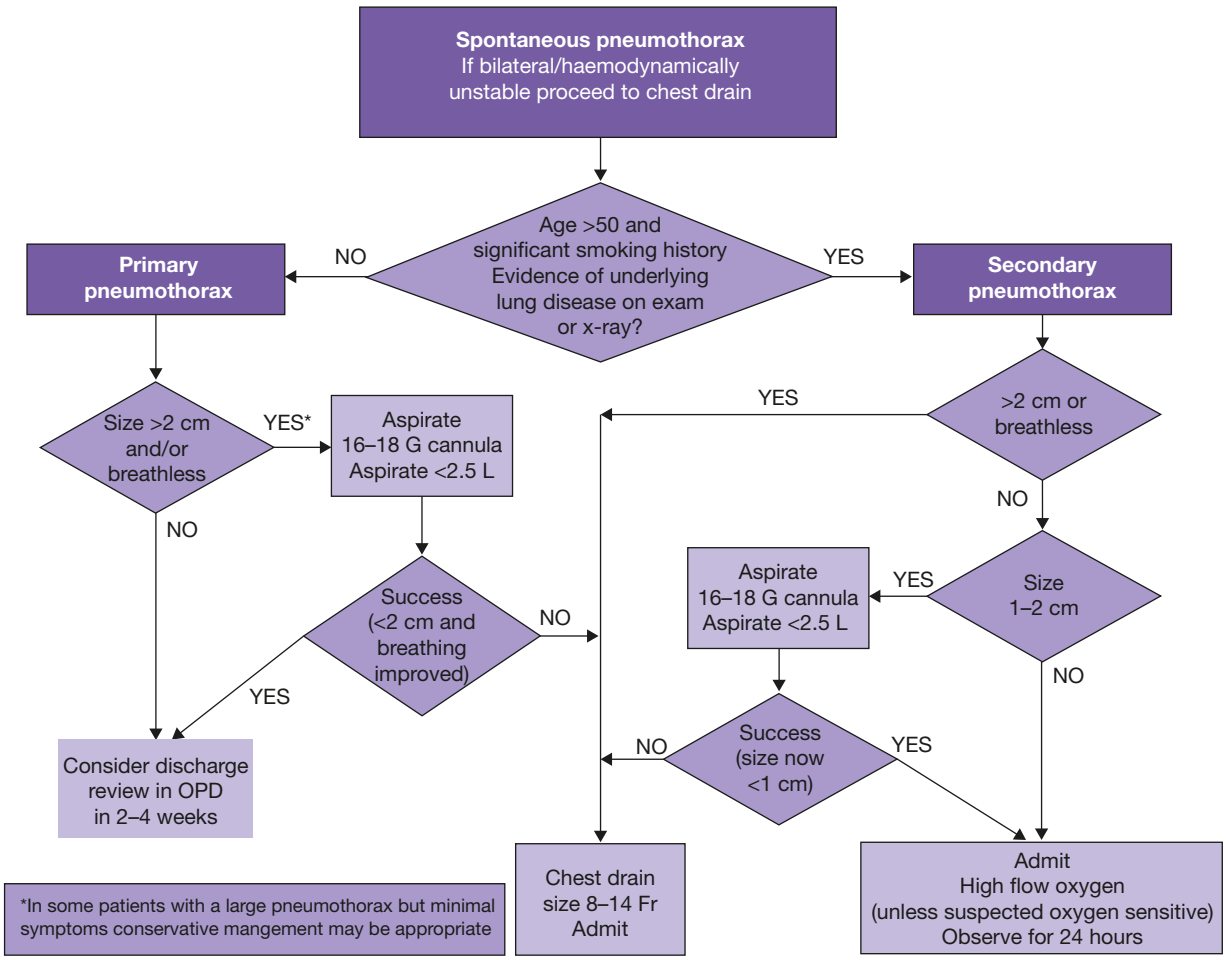

Figure 55.7 British Thoracic Society (BTS) guidelines on management of spontaneous pneumothorax (2010) (adapted from www.bts.org.uk). OPD, outpatient department.

Inserting and managing a chest drain

An intercostal tube connected to an underwater seal is central to the management of chest disease; however, the management of the pleura and of chest drains can be troublesome, even in experienced hands.

The safest site for insertion of a drain (**Figure 55.8**) is in the triangle that lies:

- anterior to the mid-axillary line;
- above the level of the nipple;
- below and lateral to the pectoralis major muscle.

This will ideally find the fifth space. The technique includes the following.

- Meticulous attention to sterility throughout.
- Adequate local anaesthesia to include the pleura.
- Sharp dissection to cut only the skin.
- Blunt dissection with artery forceps down through the muscle layers; these should only be the serratus anterior and the intercostals.
- An oblique tract, so that the skin incision and the hole in the parietal pleura do not overlie each other and the drain is in a short tunnel, which reduces the chance of entraining air.
- A drain for pneumothorax and haemothorax should aim towards the apex of the lung. A drain for pleural effusion or empyema should be nearer the base. The drain should pass over the upper edge of the rib to avoid the neurovascular bundle that lies beneath the rib.
- The retaining stitch should be secure but should not obliterate the drain.
- A vertical mattress suture is inserted for later wound closure. This is vital for pneumothorax management but should be omitted if the drain is for empyema (provided there is adherence of the pleura) because that tract should lie open.
- Connect the drain to an underwater seal device which functions as a one-way valve.
- After completion, check that the drain has achieved its objective by taking a chest radiograph.

It is preferable not to apply suction to the drain or clamp it. The danger is that the clamp may be applied for transport and forgotten. Dangers of disconnection and siphoning are small or best averted in other ways apart from clamping. A bubbling drain should (almost) never be clamped. Remove the drain when it no longer has a function.

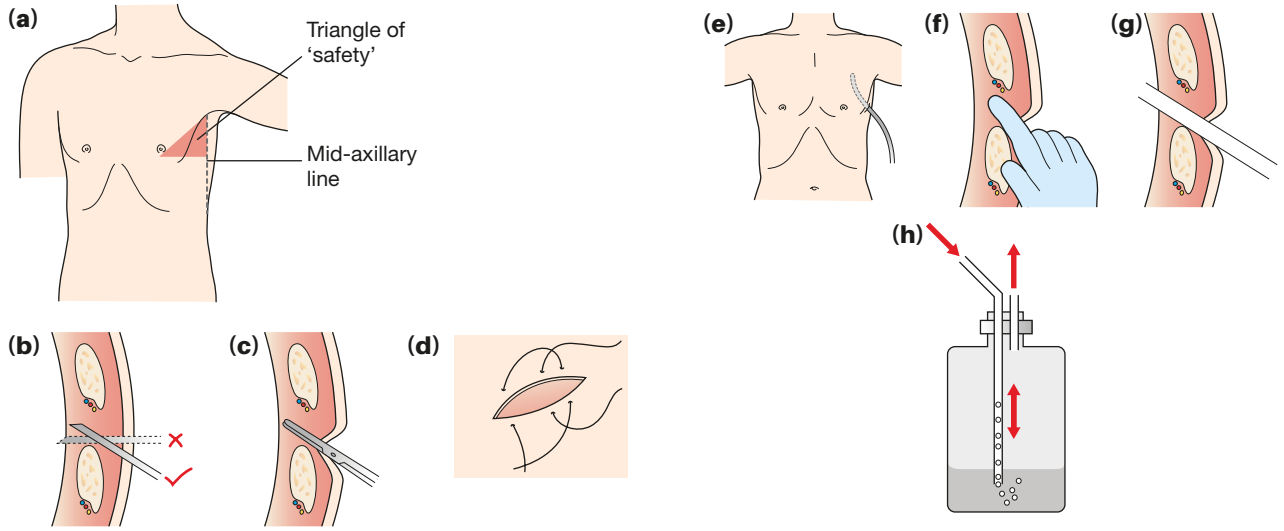

Figure 55.8 Insertion of chest drain: **(a)** triangle of safety; **(b)** penetration of the skin, muscle and pleura; **(c)** blunt dissection of the parietal pleura; **(d)** suture placement; **(e)** gauging the distance of insertion; **(f)** digital examination along the tract into the pleural space; **(g)** withdrawal of central trochar and positioning of drain; **(h)** underwater seal chest drain bottle.

Summary box 55.2

Suction on a pleural tube

- Be aware! Inserting the drain, and not the suction, is the life-saving manoeuvre
- If the lung is reluctant to expand, the suction deviates the mediastinum
- If the lung is fragile, it may worsen an air leak

Surgical management of pneumothorax

Pleurectomy and pleurodesis

Surgery for pneumothorax can be performed by video-assisted thoracoscopic surgery (VATS) or as an open procedure (thoracotomy). The object of the exercise is threefold:

- to deal with any leaks from the lung;
- to search for and obliterate any blebs and bullae;
- to make the visceral pleura adherent to the parietal pleura so that any subsequent leaks are contained and the lung cannot completely collapse.

Pleural adhesion is achieved in one of three ways:

- **Pleurectomy**: systematically stripping the parietal pleura from the chest wall.
- **Pleural abrasion**: a scourer is used to scrape off the slick surface of the parietal pleura.
- **Chemical pleurodesis**: usually talc is used and is insufflated into the chest cavity.

Pleural effusion

Pleural effusion can be readily understood with reference to the physiological mechanisms governing the flux of pleural fluid given above. Pleural effusions are divided into exudates and transudates, depending on protein content (more (exudates) or less (transudates) than 30 g/L), and characterised further according to glucose content, pH and lactate dehydrogenase content. The following are the most common ways in which the pleural fluid balance is disturbed.

- **Elevated pulmonary capillary pressure**. If left atrial pressure rises, the pulmonary capillary pressure must rise with it, as a result of either impaired cardiac performance or an overloaded circulation.
- **Reduced intravascular oncotic pressure**. If the plasma proteins fall because of renal or hepatic disease or malnutrition, the absorption mechanism fails.
- **Accumulation of pleural protein** due to obstruction of the mediastinal lymphatics secondary to lymphoma or cancers that invade the lymphatic system.
- **Excessive permeability of the capillaries** to fluid and protein as in inflammatory diseases, particularly the collagen vascular diseases. Of particular importance to the surgeon is the effusion associated with pleural infection (empyema) and malignant effusions.

Malignant pleural effusion

Pleural effusion is a common complication of cancer. This may be due to:

- lung cancer;
- pleural involvement with primary or secondary malignancy;
- mediastinal lymphatic involvement.

LUNG CANCER

There may be direct involvement of the parietal and/or visceral pleura, collapse of the lung parenchyma and spread to the mediastinal lymphatics, or a combination of these, causing pleural fluid accumulation. It is usually regarded as a feature that puts lung cancer beyond surgical cure.

PLEURAL MALIGNANCY

The only primary malignancy of the pleura seen with any regularity is malignant mesothelioma. This is a consequence of asbestos exposure, with few exceptions. The peak of asbestos importation into the UK was from 1960 to 1975 and the incidence of mesothelioma is rising and was expected to peak in 2015. Mesothelioma commonly presents with breathlessness because of pleural effusions, pain and systemic features of malignancy. Diffuse seeding of the parietal and visceral pleura is a common pattern of dissemination of cancers, particularly adenocarcinoma of any origin.

MEDIASTINAL LYMPHATIC INVOLVEMENT

In many instances, particularly in breast cancer, there is no evident disease in the pleura. The disease is in the mediastinal lymphatics, which are obstructed, and this upsets the balance of physiological forces that control pleural fluid.

SURGERY FOR PATIENTS WITH MALIGNANT PLEURAL EFFUSION

The surgeon has two roles: to make the diagnosis and to achieve effective palliation by draining the fluid and pleurodesis.

DIAGNOSIS

Pleural biopsy can be obtained by a range of techniques, with VATS being the most common. An unequivocally positive biopsy is useful but a negative biopsy may be a sampling error.

Summary box 55.3

Biopsy of the pleura

- Cytological examination of the pleural fluid (low yield)
- Abrams' needle (low yield in malignancy)
- Computed tomography (CT)-guided needle biopsy of a suspicious area
- VATS biopsy
- Open surgical biopsy

Pleural infection and empyema

Empyema is the end stage of pleural infection from any cause. It most commonly results from infection of the underlying lung, involving pneumonia or a lung abscess, but can occur as a complication of any thoracic operation. It is seen if a traumatic haemothorax becomes infected or in the course of management of pneumothorax or pleural effusions. It may be associated with pus under the diaphragm (*Table 55.3*).The pathological diagnosis requires the presence of thick pus with a thick cortex of fibrin and coagulum over the lung.

When empyema presents *de novo* it usually follows pneumonia, and three phases are described:

1 In the exudative phase, there is protein-rich (>30 g/L) effusion. If this becomes infected with the organisms from the lung (typically *Streptococcus milleri* and *Haemophilus influenzae* in children), the scene is set for empyema. At this stage antibiotics may be all that is required. Aspiration or drainage to dryness in addition is preferred.
2 Over subsequent days, the fluid thickens to what is known as the fibrinopurulent phase. Drainage at this stage is prudent as antibiotics on their own are unlikely to be curative.
3 The organising phase causes the lung to be trapped by a thick peel or 'cortex' for which surgical management may be required.

TABLE 55.3 Conditions that predispose to empyema formation.

Pulmonary infection	Unresolved pneumonia Bronchiectasis Tuberculosis Fungal infections Lung abscess
Aspiration of pleural effusion	Any aetiology
Trauma	Penetrating injury Surgery Oesophageal perforation
Extrapulmonary sources	Subphrenic abscess
Bone infections	Osteomyelitis of ribs or vertebrae

Surgical management of pleural effusions and infections

Thoracoscopy or video-assisted thoracoscopic surgery (VATS)

The direct-vision thoracoscope has been used for many years, but its use was limited mainly to performing biopsies. The instrument had a limited view and was uncomfortable to use for any length of time. All this has changed since the advent of video-assisted thoracoscopy (**Figure 55.9**); the surgeon's hands are freed because the camera is attached to the thoracoscope, which can be operated by an assistant with the image displayed on a screen. The surgeon is able to manipulate instruments with both hands to perform a variety of procedures. The number of ports required depends on the type and complexity of the surgery. The patient is usually positioned with the diseased side uppermost, having had a double lumen endotracheobronchial tube placed by the anaesthetist to allow for single-lung ventilation. The principal advantage is that a large incision is avoided, resulting in less postoperative pain and a more rapid recovery.

VATS drainage, pleural biopsy and talc pleurodesis

VATS drainage, pleural biopsy and talc pleurodesis is increasingly performed for the management of patients with an undiagnosed or malignant pleural effusion. It can be performed using a single port and allows direct visualisation of the pleural cavity for complete drainage, multiple pleural biopsies and excellent talc insufflation to achieve pleurodesis.

Leon David Abrams, 1923–2012, cardiothoracic surgeon, the United Birmingham Hospitals, Birmingham, UK.

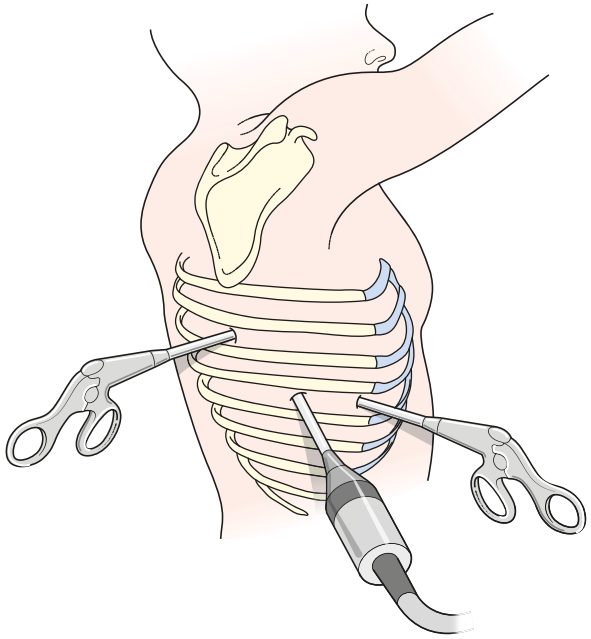

Figure 55.9 Video-assisted thoracoscopic surgery (VATS) utilises modern thoracoscopic instruments and digital technology and avoids large incisions.

VATS debridement of empyema

Pleural infection, particularly early in its evolution, requires drainage, but once the fluid component becomes fibrinopurulent and loculated it requires surgical debridement, which can often be achieved through a VATS approach. The lung is isolated through the use of a double lumen tube, the patient is positioned disease side up, and the pleural cavity is entered. The fluid and debris are vigorously debrided, freeing the lung and allowing for re-expansion. At the end of the case, carefully positioned chest drains are placed to allow for dependent drainage. The drain(s) must exit the skin anterior to the mid-axillary line otherwise the patient will have to lie on the drain(s), causing pain and possibly obstructing the tube. The drain should lie obliquely in its course through the skin and chest wall and into the pleura, or it will kink.

Following the procedure, the patient requires good analgesic control, typically using patient-controlled analgesia (PCA), and physiotherapy to help fully re-expand the lung prior to final removal of chest drains.

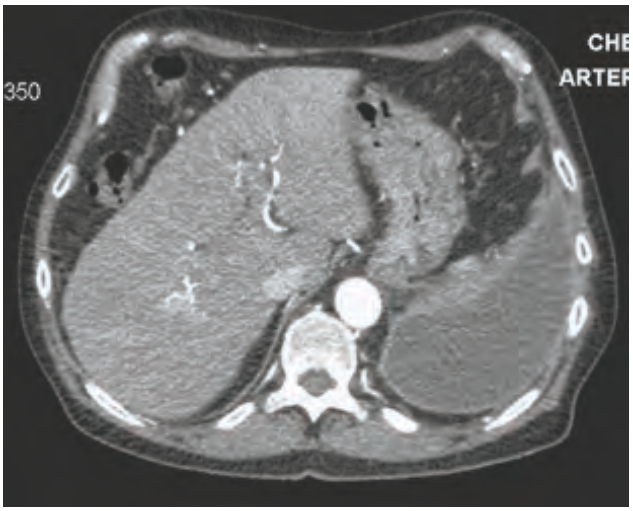

Figure 55.10 Chest computed tomography scan showing an empyema with a grossly thickened pleura.

Decortication

If the lung fails to re-expand after drainage of the empyema, the more radical operation of decortication may be required (**Figure 55.10**). The fibrous cortex or peel from the entrapped underlying lung is removed so that the lung can expand to obliterate the pleural space. This is usually performed through a posterolateral thoracotomy, though in selected cases it can be performed as a VATS procedure. It requires careful dissection to remove the parietal and visceral cortex, taking care not to damage the visceral pleura, so allowing the lung to re-expand fully.

DISORDERS OF THE AIRWAY

Haemoptysis

Diseases causing repeated haemoptysis include carcinoma, bronchiectasis, carcinoid tumours and some infections. Severe mitral stenosis is now a rare cause. Patients with repeated haemoptysis should be investigated, at the very least by chest radiography and bronchoscopy. Haemoptysis following trauma may be from a lung contusion or injury to a major airway. Treatment depends on the underlying cause.

Common associated chest symptoms include cough with or without sputum, pain, breathlessness, hoarseness and more general symptoms of systemic upset, including fatigue and loss of weight. Occasionally, chest disease may cause palpitation due to atrial fibrillation. Any of these symptoms in association with haemoptysis requires urgent investigation.

Investigation

BRONCHOSCOPY (*TABLE 55.4*)

Flexible bronchoscopy may be performed with the patient awake and the oropharynx anaesthetised with topical lignocaine (**Figure 55.11**). The bronchoscope is passed into the nose or mouth and through the vocal folds under direct vision. As the scope is flexible, its tip can be directed into the segmental bronchi with ease. Tissue and sputum samples may be obtained for diagnostic purposes. There is a greater range of movement with this instrument, but the biopsies are relatively small and suction limited.

TABLE 55.4 Uses of bronchoscopy.

Diagnostic	Confirmation of disease: carcinoma of the bronchus; inflammatory or infective processes
Investigative	Tissue biopsy
Preoperative assessment	Before lung resection Before oesophageal resection Persistent haemoptysis
Therapeutic	Removal of secretions Removal of foreign bodies Stent placement, endobronchial resection, etc.

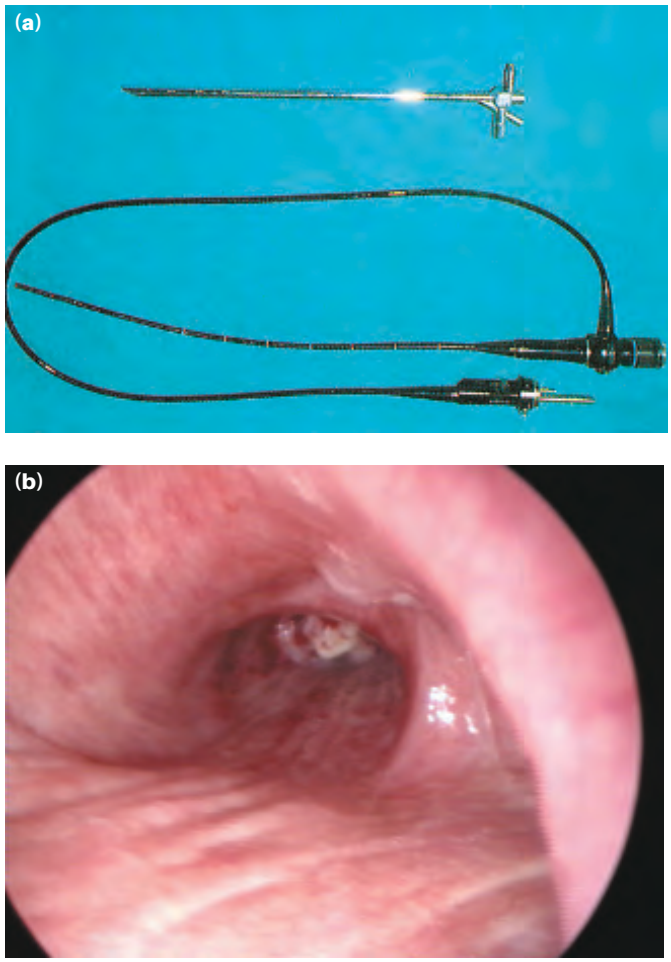

Figure 55.11 **(a)** Rigid and flexible bronchoscopes. **(b)** View past the carina into the left main bronchus with a tumour seen in the bronchial lumen.

Rigid bronchoscopy requires general anaesthesia in most instances. It is ideal for therapeutic manoeuvres, such as removal of foreign bodies, aspiration of blood and thick secretions, and intraluminal surgery (laser resection or stent placement). The surgeon and the anaesthetist share control of the airway. Continuous ECG and pulse oximetry monitoring are now essential. The technique involves the operator standing behind the patient and lifting the maxilla by the upper teeth, using the middle finger and forefinger of the left hand. The bronchoscope rests on the left thumb as it is introduced over the tongue in the midline. Care must be taken not to trap the lips or tongue between the teeth and the bronchoscope, and the fulcrum should be the left thumb and not the teeth. The bronchoscope is passed under direct vision into the oropharynx, behind the epiglottis, until the vocal folds are seen. Turning the instrument through 90° will help to negotiate the vocal folds; only then should the neck be extended.

The tracheal rings and the carina should be easily seen. Advancing the bronchoscope into the right or left main bronchus reveals the orifices of the more peripheral bronchi. Operability of an endobronchial tumour may be assessed in terms of its location (e.g. the proximity of a lesion to the carina). Complications are rare but include bleeding, pneumothorax, laryngospasm and arrhythmia.

Rigid bronchoscopy can be combined with endobronchial interventions to tackle airway tumours; these techniques include use of laser or cryotherapy, with heat or cold respectively, to excise potentially obstructing endobronchial tumours and improve airway patency and breathing.

Other techniques of biopsy of intrathoracic lesions are often necessary to confirm diagnosis, stage disease and plan treatment. The options range from percutaneous needle biopsy under radiological control, to endobronchial ultrasound and open-lung biopsy. However, high-quality, contrast-enhanced, multislice helical CT scanning has reduced the requirement for invasive assessment.

Summary box 55.4

Biopsy hazards

- Bleeding disorders
- Systemic anticoagulation
- Pulmonary hypertension

Airway obstruction

Tracheal obstruction may present acutely as a life-threatening emergency or insidiously with little in the way of symptoms until critical narrowing and stridor occur. The more common causes of airway narrowing are outlined in *Table 55.5*.

Treatment depends on the underlying cause. Tracheostomy may be required to overcome the obstruction, but there are few indications to do this as an emergency. Tracheal replacement with artificial substitutes has so far been unsuccessful, but resection of up to 6 cm of trachea is now possible. Sleeve resections of the major bronchi are also possible.

Inhaled foreign bodies

This is a fairly common occurrence in small children and is often marked by a choking incident that then apparently passes. Surprisingly large objects can be inhaled and become lodged in the wider-calibre and more vertically placed right main bronchus. There are three possible presentations:

- asymptomatic;
- wheezing (from airway narrowing) with a persistent cough and signs of obstructive emphysema;
- pyrexia with a productive cough from pulmonary suppuration.

TABLE 55.5 Causes of airway narrowing.

Intraluminal	Inhaled foreign body Neoplasm
Intramural	Congenital stenosis Fibrous stricture (post-intubation or tuberculosis)
Extramural	Neoplasm (thyroid cancer, secondary deposits) Aortic arch aneurysm

A chest radiograph is vital; even if the object is not radiopaque there may be other changes. An experienced anaesthetist is required. Endoscopic removal may be very difficult if there is a severe inflammatory reaction to the foreign body.

NEOPLASMS OF THE LUNG

Primary lung cancer

Lung cancer is one of the most common cancers throughout the world. In the UK, there are approximately 40 000 new cases a year. From the time of diagnosis, 80% of patients are dead within 1 year and only 5% survive 5 years, making lung cancer the most common cause of cancer death.

Surgical resection has a limited role in curative treatment because at the time of presentation many cancers are locally advanced or widely disseminated and are beyond surgical cure. The proportion of lung cancers in which resection is attempted varies but in most resource-rich countries approximately 20–30% of cases are potentially surgically resectable. The thoracic surgeon working in a cancer team has a role in diagnosis, staging and palliation, in addition to resection in appropriate cases. The disease is so common that surgeons of all disciplines will encounter cases of lung cancer presenting with various manifestations.

Cigarette smoking is undoubtedly the major risk factor for developing bronchial carcinoma and accounts for 85–95% of all cases. To a lesser extent, atmospheric pollution and certain occupations (mining of radioactive ore and chromium) contribute. The risk is related to the lifetime burden of cigarette smoking, which is commonly quoted as 'pack-years' (a 'pack' being 20 cigarettes): the number of packs smoked per day multiplied by the number of years of exposure. In the UK, the mortality rate from lung cancer for individuals smoking more than 40 cigarettes per day is over 210 deaths per 100 000 population per year. This compares with a mortality rate of less than 4 deaths per 100 000 population per year in non-smokers.

Pathological types

For practical purposes, lung cancers are divided into small cell lung cancer and non-small cell lung cancer (NSCLC), which are seen in a ratio of about 1:4.

- The pattern of disease, the prognosis and the results of treatment for small cell (also known as oat cell) carcinoma differ from all other types sufficiently for these to be managed differently from the outset on the basis of the histological classification.
- Subdivisions of NSCLC according to histological characteristics are much less important, but pathological staging is critical to treatment and outcome.

Histological classification of lung cancer

Small cell lung cancers were known as oat cell cancers because of the packed nature of small dense cells. They are a type of neuroendocrine tumour (NET) and represent about 20% of all lung cancers. They tend to metastasise early to lymph nodes and by blood-borne spread. The median survival is measured in months. The tumours are very responsive to chemotherapy such that median survival may be doubled (although it is still short) but they are rarely, if ever, cured. Surgery is rarely offered unless in very limited stage disease.

Adenocarcinoma is now the most common of the NSCLC types, having overtaken squamous cancer. The increasing incidence is partly due to an increasing incidence in women and may be the result, in part, of a move towards lower-tar cigarettes that are inhaled more deeply to get the same effect.

Squamous carcinoma typically appears as a cavitating tumour.

Large cell undifferentiated is a discrete histological type of NSCLC and is included within NETs.

Bronchioalveolar carcinoma (BAC), also known as **adenocarcinoma-*in-situ***, has a distinct pattern of growth following the pre-existing pulmonary architecture and is thus much less dense; it appears as a patchy diffuse shadow ('ground glass') on radiographs rather than a solid mass and has a histological appearance to match. Recently, the pathological nomenclature for BAC, a subtype of adenocarcinoma, has changed and they are now known as 'lepidic' neoplastic lesions, which have further been classified into precursor lesions, minimal invasive lepidic adenocarcinomas and frankly malignant lepidic adenocarcinomas. After resection, the cancer can appear in another lobe or on the other side, and these are often regarded as multifocal primary tumours rather than metastatic disease. Further resection may be appropriate depending on patient fitness and extent of disease.

Neuroendocrine tumours of the lung are a group of lung cancers that incude small cell cancer and large cell undifferentiated lung cancer, but also include other less aggressive tumour types including typical carcinoid and atypical carcinoid tumours. These occur in the major (central) bronchi and 20% are found peripherally. They are characteristically slow growing and highly vascular. Most behave in a benign way; however, approximately 15% metastasise. The patient often presents with a history of recurrent pneumonia or haemoptysis, but carcinoid syndrome is rare unless there are extensive pulmonary or hepatic metastases. Surgical excision is preferred because the prognosis following complete resection is excellent (>90% 10-year survival). Segmental or wedge resection may be sufficient for a small peripheral tumour, while lobectomy or pneumonectomy may be necessary for central tumours. Where possible, a lung-sparing bronchoplastic or sleeve resection should be considered. This allows resection of proximal endobronchial lesions in an effort to preserve more distal, uninvolved lung parenchyma.

Accurate diagnosis and staging of the tumour are vital if surgery is to be considered.

Clinical features

Clinical features of lung carcinoma depend on:

- the site of the lesion;
- the invasion of neighbouring structures;
- the extent of metastases.

Common symptoms include a persistent cough, weight loss, dyspnoea and non-specific chest pain.

- Haemoptysis occurs in fewer than 50% of patients presenting for the first time.
- Cough, or a changed cough, is a common presentation but non-specific in this population.
- Severe localised pain suggests chest wall invasion with the infiltration of an intercostal nerve. Invasion of the apical area may involve the brachial plexus, leading to Pancoast's syndrome.
- Dyspnoea may come from loss of functioning lung tissue, lymphatic invasion or the development of a large pleural effusion.
- Pleural fluid is an ominous feature and the presence of blood in a pleural effusion suggests that the pleura has been directly invaded.
- Clubbing **(Figure 55.12)** and hypertrophic pulmonary osteoarthropathy accompany some lung cancers and may resolve with excision of the primary lesion.
- Invasion of the mediastinum may result in hoarseness (because of recurrent laryngeal nerve involvement), dysphagia (because of the involvement of, or extrinsic pressure on, the oesophagus) and superior vena caval obstruction.
- Small cell carcinoma is associated with the development of myopathies including the Eaton–Lambert syndrome, which is similar to myasthenia gravis.

Summary box 55.5

Symptoms of lung cancer

- Haemoptysis: <50% of patients
- Cough, new or changed pattern
- Pain
- Dyspnoea
- Clubbing
- Hoarseness
- Myopathies

Treatment of lung cancer

Careful investigation is required to determine which tumours are operable and will benefit from a major thoracic resection. The internationally agreed tumour–node–metastasis (TNM) staging system gives prognostic information on the natural history of the disease. Tumours graded up to T3, N1, M0 can be encompassed within an anatomical surgical resection and have a much improved prognosis when treated surgically so the tumour must be staged accurately before resection *(Table 55.6)*. A number of non-tumour related factors, including the general fitness of the patient and the results of lung function tests, help to determine the appropriate treatment. In patients with incurable disease, treatment is palliative to maximise quality of life.

Figure 55.12 Example of finger clubbing in a patient with bronchogenic carcinoma.

Survival

Carcinoma of the bronchus generally has a low survival rate after diagnosis *(Table 55.7)*. Important factors in determining prognosis are the histological type of the tumour, the spread (stage) and the general condition of the patient. Early detection and surgical resection offer the best hope for cure.

Diagnosis and staging

Increasing emphasis in recent years has been the early detection of lung cancer, with guidance on symptoms and signs of potential lung cancer that require urgent chest x-ray and referral to a lung cancer team *(Table 55.8)*.

Non-invasive investigations

CHEST RADIOGRAPHY

A chest radiograph will detect most lung cancers but some, particularly early curable tumours, are hidden by other structures. Secondary effects such as pleural effusion, distal collapse and raised hemidiaphragm may be evident **(Figure 55.13)**.

COMPUTED TOMOGRAPHY

Computed tomography (CT) is the first investigation in suspected lung cancer. The surgeon needs to know whether the primary is resectable (T stage) and which, if any, lymph nodes are involved (N stage). Lymph nodes more than 2 cm in diameter are likely to be involved in the disease (70%) **(Figure 55.14)** and those less than 10 mm in the shorter axis are unlikely to be involved. If the presence of cancer in the nodes is critical to management, further evidence from positron emission tomography with radiolabelled fluorodeoxyglucose (FDG-PET) or biopsy (see below) is essential. Remote metastases to the liver, adrenal glands or elsewhere may be detected.

POSITRON EMISSION TOMOGRAPHY

The patient is given radiolabelled FDG, which is taken up by all metabolising cells but more avidly by cancer cells.

Henry Khunrath Pancoast, 1875–1939, Professor of Radiology, The University of Pennsylvania, Philadelphia, PA, USA, described this condition in 1932.
Lee M. Eaton, 1905–1958, neurologist who was a professor at The Mayo Clinic, Rochester, MN, USA.
Edward H. Lambert, b.1915, Professor of Physiology, The University of Minnesota, MN, USA. Eaton and Lambert described this condition in a joint paper in 1956.

TABLE 55.6 The international tumour–node–metastasis (TNM) staging system.

T: Primary tumour	
Tx	Primary tumour cannot be assessed or tumour proven by presence of malignant cells in sputum or bronchial washings but not visualised by imaging or bronchoscopy
T0	No evidence of primary tumour
Tis	Carcinoma *in situ*
T1	Tumour ≤3 cm in greatest dimension surrounded by lung or visceral pleura without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e. not in the main bronchus)[a]
T1a(mi)	Minimally invasive adenocarcinoma[b]
T1a	Tumour 1 cm in greatest dimension[a]
T1b	Tumour >1 cm but ≤2 cm in greatest dimension[a]
T1c	Tumour >2 cm but ≤3 cm in greatest dimension[a]
T2	Tumour >3 cm but ≤5 cm or tumour with any of the following features:[c] – involves main bronchus regardless of distance from the carina but without involvement of the carina – invades visceral pleura – associated with atelectasis or obstructive pneumonitis that extends to the hilar region, involving part or all of the lung
T2a	Tumour >3 cm but ≤4 cm in greatest dimension
T2b	Tumour >4 cm but ≤5 cm in greatest dimension
T3	Tumour >5 cm but ≤7 cm in greatest dimension or associated with separate tumour nodule(s) in the same lobe as the primary tumour or directly invades any of the following structures: chest wall (including the parietal pleura and superior sulcus tumours), phrenic nerve, parietal pericardium
T4	Tumour >7 cm in greatest dimension or associated with separate tumour nodule(s) in a different ipsilateral lobe than that of the primary tumour or invades any of the following structures: diaphragm, mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, oesophagus, vertebral body, and carina
N: Regional lymph nodes involvement	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
M: Distant metastasis	
M0	No distant metastasis
M1	Distant metastasis present
M1a	Separate tumour nodule(s) in a contralateral lobe; tumour with pleural or pericardial nodule(s) or malignant pleural or pericardial effusion[d]
M1b	Single extrathoracic metastasise
M1c	Multiple extrathoracic metastases in one or more organs

[a]The uncommon superficial spreading tumour of any size with its invasive component limited to the bronchial wall, which may proximal to the main bronchus, is also classified as T1a.
[b]Solitary adenocarcinoma, ≤3 cm with a predominately lepidic pattern and ≤5 mm invasion in any one focus.
[c]T2 tumours with these features are classified as T2a is ≤4 cm in greatest dimension or if size cannot be determined, and T2b if >4 cm but ≤5 cm in greatest dimension.
[d]Most pleural (pericardial) effusions with lung cancer are due to tumour. In a few patients, however, multiple microscopic examinations of pleural (pericardial) fluid are negative for tumour and the fluid is non-bloody and not an exudate. When these elements and clinical judgement dictate that the effusion is not related to the tumour, the effusion should be excluded as a staging descriptor.
[e]This includes involvement of a single distant (non-regional) lymph node.

The FDG enters the Kreb's cycle but cannot complete it and accumulates in proportion to the glucose avidity of the cells. High accumulation is associated with lung cancers and secondaries. Infection or other inflammation, and lymphadenopathy secondary to it, are also FDG avid (**Figure 55.15**).

SPUTUM CYTOLOGY

Sputum cytology may reveal malignant cells but the false-negative rate is high.

Invasive investigations

Once lung cancer is suspected, diagnosis and further staging are sought. The choice of investigation depends on the

Sir Hans Adolf Krebs, 1900–1981, Professor of Biochemistry, The University of Oxford, Oxford, UK.

TABLE 55.7 Survival table following operation for carcinoma of the bronchus.

	(%)
Five-year survival according to presurgical staging	
Stage I	56–67
Stage II	39–55
Stage IIIa	23
Stage IIIb	<10
Five-year survival according to cell type	
Squamous cell carcinoma	35–50
Adenocarcinoma	25–45
Adenosquamous carcinoma	20–35
Undifferentiated carcinoma	15–25
Small cell carcinoma	0–5

position of the primary tumour in the lung (peripheral or central) and the clinical stage of the cancer (presence of enlarged lymph nodes or metastasis).

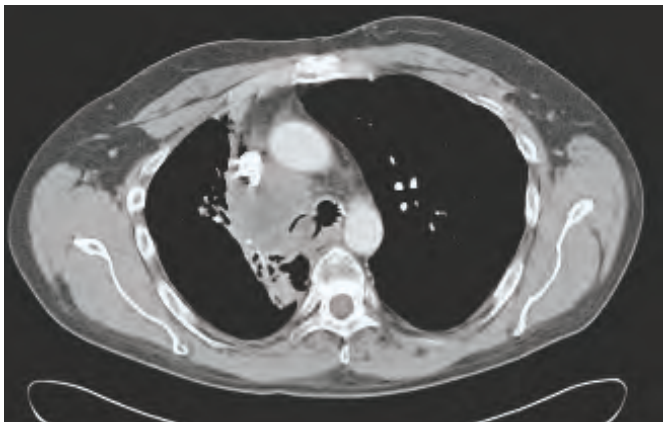

Figure 55.14 Paratracheal lymphadenopathy shown on a computed tomography scan.

BRONCHOSCOPY

Flexible bronchoscopy is usually performed under sedation, particularly in patients with more centrally placed lung cancers. It allows assessment of the segmental airway, cytological testing through brushing and washing of the concerned segmental bronchi and transbronchial needle aspiration (TBNA).

ENDOBRONCHIAL ULTRASOUND (EBUS)

EBUS allows bronchoscopic assessment of suspicious mediastinal lymph nodes with an ultrasound probe incorporated into the tip of the bronchoscope to aid TBNA (**Figure 55.16**). Endoscopic ultrasound (EUS) is a similar technique that, by passing the probe down the oesophagus, allows fine needle aspiration (FNA) of less approachable mediastinal lymph nodes.

COMPUTED TOMOGRAPHY-GUIDED BIOPSY

Percutaneous CT-guided FNA may give a good yield of cells for cytological examination. Alternatively, a core of tissue can be obtained for formal histology. These techniques are best for larger and more peripheral lesions. Pneumothorax is

TABLE 55.8 Recent National Institute for Health and Care Excellence (NICE) guidance on referral in patients with suspected lung cancer.

Symptoms and signs indicating urgent chest x-ray	Offer urgent chest x-ray to patients presenting with haemoptysis, or any of the following if unexplained or present for more than 3 weeks:	Cough Chest/shoulder pain Dyspnoea Finger clubbing Signs suggesting metastases (for example, in brain, bone, liver or skin) Weight loss Chest signs Hoarseness Cervical/supraclavicular lymphadenopathy
Symptoms and signs indicating urgent referral	Offer urgent referral to lung cancer MDT (usually the chest physician) while waiting for chest x-ray results if any of the following are present:	Persistent haemoptysis in a smoker or ex-smoker older than 40 years Signs of superior vena cava obstruction (swelling of the face and/or neck with fixed elevation of jugular venous pressure) Stridor
	Offer urgent referral to lung cancer MDT (usually the chest physician) if:	A chest x-ray or CT scan suggests lung cancer (including pleural effusion and slowly resolving consolidation) or Chest x-ray is normal, but there is a high suspicion of lung cancer

CT, computed tomography; MDT, multidisciplinary team.

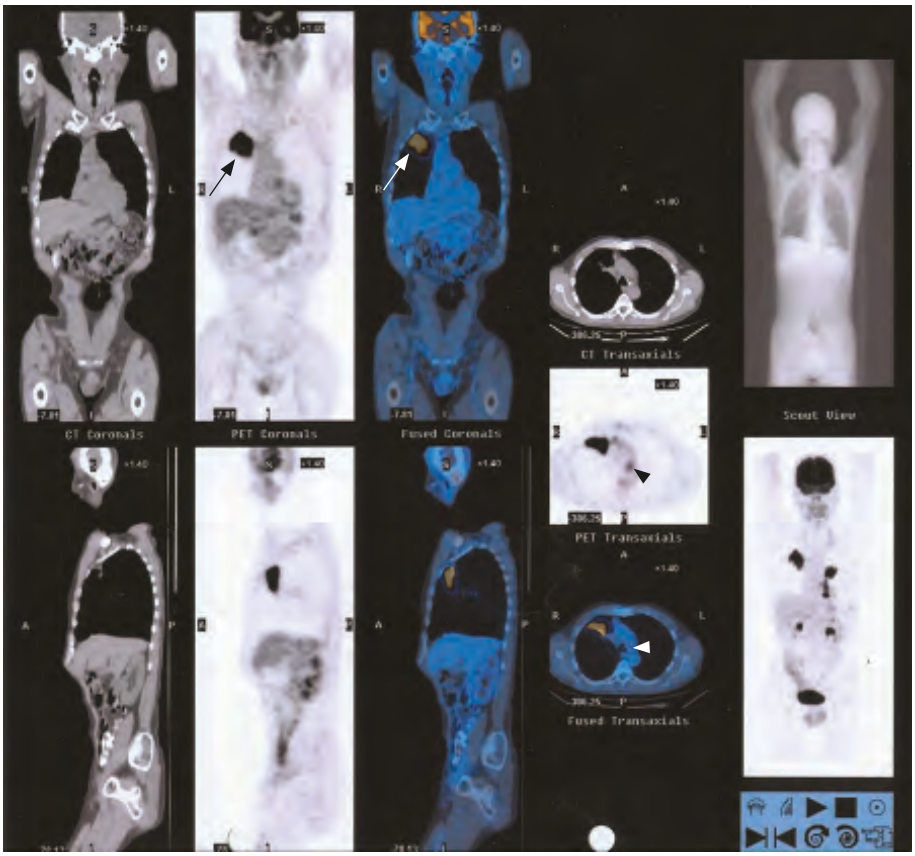

Figure 55.15 Multiple FDG-avid mediastinal lymph nodes (arrowheads) shown on a positron emission tomography/computed tomography scan (main tumour, arrows) (courtesy of Dr Sally Barrington).

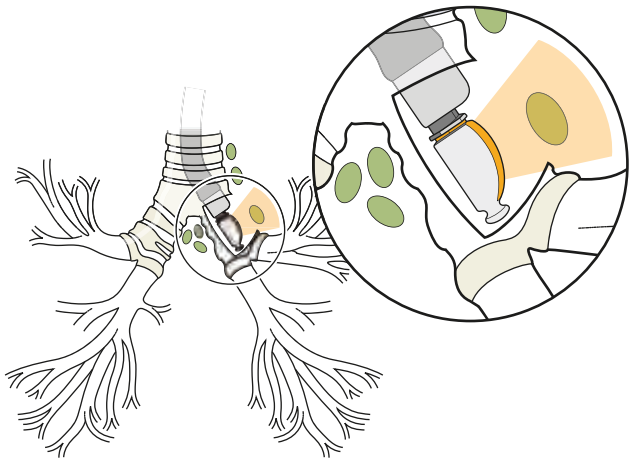

Figure 55.16 Endobronchial ultrasound (EBUS) allows accurate detection of enlarged mediastinal lymph nodes for diagnosis and staging of lung cancer.

common (30%) but rarely requires intercostal tube drainage. The contraindications include poor respiratory reserve, when even a small pneumothorax would be hazardous.

Surgical diagnosis and staging

Mediastinoscopy, mediastinotomy, VATS or thoracotomy lymph node/lung biopsy are aimed at establishing a tissue diagnosis and assessing the degree of spread (staging), which determines resectability. Histological proof of the status of mediastinal nodes may be important to avoid unnecessary thoracotomy for incurable cancers and, conversely, to avoid denying surgery to patients whose lymph nodes are enlarged but benign.

MEDIASTINOSCOPY

This procedure is performed under general anaesthesia with the patient supine and his or her neck extended (**Figure 55.17**). A transverse incision is made 2 cm above the sternal notch and deepened until the strap muscles are reached. These are retracted laterally and the thyroid isthmus is retracted superiorly to reveal the pretracheal fascia. Careful blunt dissection in this plane allows access to the paratracheal and subcarinal nodes. A mediastinoscope is introduced for direct visualisation and biopsy. Great caution should be used in the presence of superior vena caval obstruction. Complications include pneumothorax and haemorrhage.

MEDIASTINOTOMY

An incision is made through the second intercostal space to gain access to some of the mediastinal lymph nodes on the affected side. On the left, this includes lymph nodes in the para-aortic or subaortic fossa. Damage to the internal mammary artery and the phrenic nerve must be avoided. Mediastinal extension of tumour can also be assessed, for example left upper lobe tumours which invade the mediastinum around the aortic arch.

Figure 55.17 Mediastinoscopy. The mediastinoscope slides down immediately in front of the trachea, behind the aortic arch, and behind and between the great vessels of the head and neck.

These techniques may also be used in the diagnosis of other mediastinal conditions, including:

- lymphoma;
- anterior mediastinal tumours;
- thymoma;
- sarcoid, tuberculosis or any other cause of lymphadenopathy.

VATS MEDIASTINAL LYMPH NODE AND LUNG BIOPSY

For inaccessible mediastinal lymph nodes, or when diagnosis of the lung tumour has not been possible through radiological or bronchoscopic techniques, VATS performed through two or three ports allows diagnosis of the tumour, staging of the mediastinum and gives the opportunity to assess the likely operability of the lung cancer.

Surgical approach to lung cancer resection

Thoracotomy

Although the most frequent indication for thoracotomy is lung cancer, all surgeons dealing with trauma should be able to perform a thoracotomy if required. The standard route into the thoracic cavity is through a posterolateral thoracotomy. The incision is used for access to the:

- lung and major bronchi;
- pleura;
- thoracic aorta;
- oesophagus;
- posterior mediastinum.

A double-lumen endotracheal tube is used to allow ventilation of one lung while the other is collapsed, to facilitate surgery and to protect the non-operated lung and retain control of ventilation (**Figure 55.18**).

The patient is turned to the lateral position with the affected side up (**Figure 55.19**). The lower leg is flexed at the hip and the knee, with a pillow between the legs. Table supports are used to maintain the position and additional strapping is used at the hips for stability. The patient's hips are placed below the break point of the operating table to allow opening of the intercostal spaces as the table is angulated. The upper arm may be supported by a bracket in a position of 90° flexion. The lower arm is flexed and positioned near the head. It is important for both the surgeon and the anaesthetist to be completely satisfied with the position of the patient and the tube and lines at this stage.

- The incision passes 1–2 cm below the tip of the scapula, and extends posteriorly and superiorly between the medial border of the scapula and the spine.
- The incision is deepened through the subcutaneous tissues to the latissimus dorsi. This muscle is divided with coagulating diathermy, taking care over haemostasis.

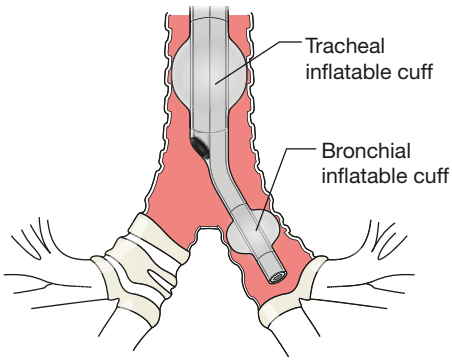

Figure 55.18 The double-lumen tube permits separate ventilation of the right and left lungs.

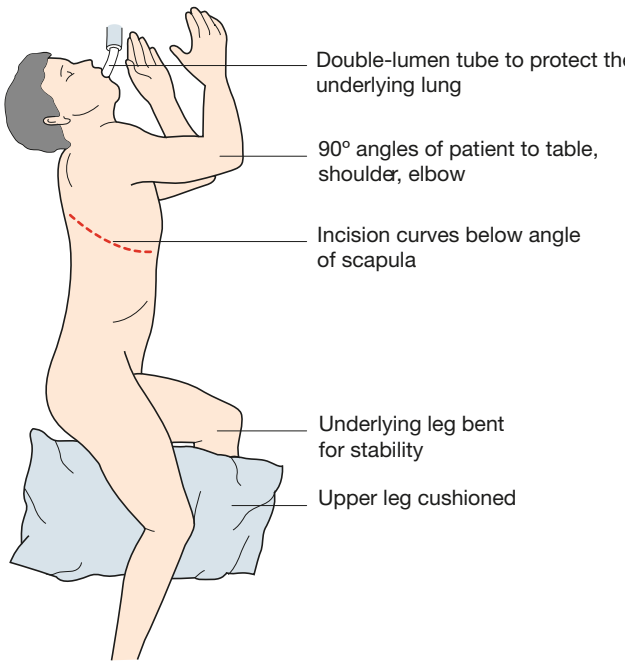

Figure 55.19 Correct positioning for thoracotomy.

- A plane of dissection is developed manually, deep to the scapula and serratus anterior. The ribs can be counted down from the highest palpable rib (which is usually the second) and the sixth rib periosteum is scored with the diathermy near its upper border. A periosteal elevator is used to lift the periosteum off the superior border of the rib or, alternatively, the intercostal muscle is cut with diathermy just above the rib (**Figure 55.20**).
- This reveals the pleura, which may be entered by blunt dissection. A rib spreader is inserted between the ribs and opened gently to prevent fracture.
- Exposure may be facilitated by dividing the rib at the costal angle or by dividing the costotransverse ligament. Resection of a rib is not usually required.
- The anaesthetist is now able to deflate the affected lung to allow a better view of the intrathoracic structures.

In an emergency thoracotomy for penetrating wounds of the heart, a more anterior approach is used and no specialised supporting equipment is required (**Figure 55.21**). The incision is taken down to the fourth or fifth rib with a scalpel, and the pleural cavity is opened using scissors. This gives rapid access to the left pleural cavity in cases of massive left hamothorax and the pericardium if cardiac tamponade is supected. A left anterior thoracotomy can be quickly converted to a clamshell or bilateral thoracotomy if necessay.

Following the operation, 24–28 Fr chest drain/s are placed, typically through the seventh or eighth intercostal space, anterior to the mid-axillary line, so that the patient does not lie on them. Even if the site to be drained is posterior, as in empyema, the drains are tunnelled to emerge more anteriorly for easier management. The thoracotomy is closed using paracostal sutures placed around the rib above and below to reapproximate the ribs or, alternatively, intercostal muscles are sutured to the intercostal muscle below the stripped rib with a continuous absorbable suture. The fascia and muscles

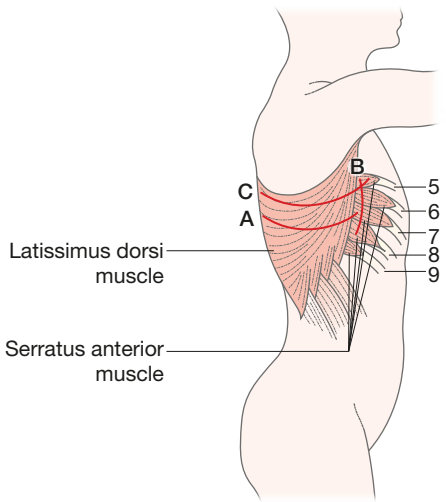

Figure 55.20 Incision and layers encountered during anterolateral thoracotomy. A, The latissimus dorsi is divided in line with the skin incision. B, If the serratus anterior is divided, it should be close to its attachment to ribs 6, 7 and 8. It can be left intact and mobilised along its inferior border. C, The intercostal muscles are stripped off the upper border of the rib.

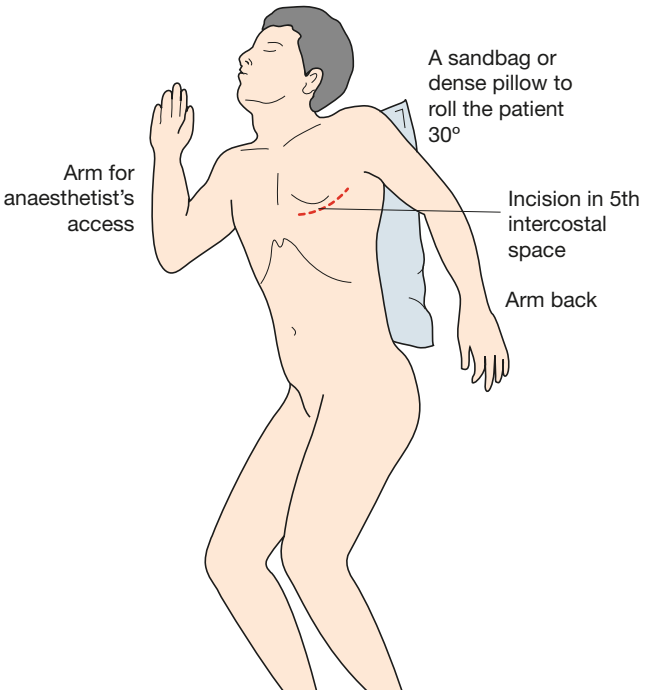

Figure 55.21 Emergency left anterior thoracotomy for access to the heart. This requires no special supports or devices.

are closed in layers using an absorbable suture. Skin closure is a matter of personal preference.

Analgesia is an important aspect of postoperative care, and the process may be started prior to thoracotomy with an epidural catheter placed by the anaesthetist, or intraoperatively by infiltrating the intercostal nerves in the region of the incision with a long-acting local anaesthetic via a surgically sited paraveretebral catheter. Various strategies have been developed to deliver analgesics postoperatively to facilitate a normal breathing pattern.

Video assisted thoracoscopic surgery (VATS)

Various approaches utilising thoracoscopic techniques can be used to gain access to the chest cavity and facilitate lung resection. A combination of a smaller thoracotomy incision and VATS has been described, but increasingly lung resections can be performed through one to three port incisons and the dissection of hilar structures completed entirely through VATS. The technique avoids rib-spreading and appears to reduce postoperative pain and length of stay, and aids a speedier recovery.

Surgical management of lung cancer

The principle of surgery is to remove all cancer (the primary and the regional lymph nodes) but to conserve as much lung as possible. The selection of patients in terms of the stage of the lung cancer and fitness to undergo such surgery is paramount. Surgery with curative intent is offered to patients with early stage lung cancer (T1–3, N0–1) (*Table 55.9*). Assesment of a patient's fitness to undergo lung cancer resection involves considering premorbid conditions, which can be aided using

TABLE 55.9 National Institute for Health and Care Excellence (NICE) recommendations for surgery for non-small cell lung cancer (NSCLC).

Surgery with curative intent for NSCLC
Offer patients with NSCLC who are fit for surgery, open or thoracoscopic lobectomy as the treatment of first choice. If complete resection is possible, consider segmentectomy or wedge resection for patients with smaller tumours (T1a–b, N0, M0) and borderline fitness
Offer more extensive surgery (bronchoangioplastic surgery, bilobectomy, pneumonectomy) only when needed to obtain clear margins
Perform hilar and mediastinal lymph node sampling or *en bloc* resection for all patients undergoing surgery with curative intent
For T3 NSCLC with chest wall involvement, aim for complete resection by extrapleural or *en bloc* chest wall resection

risk scores such as Thorascore, Cardiovascular function and Lung function (see BTS guidelines in Assessment of Fitness for major thoracic surgery, above, and NICE guidelines in *Table 55.10*). Lung function, in particular, will aid the surgeon in selecting the type of procedure offered and the likelihood of breathlessness or dyspnoea following lung resection.

Choice of lung resection

SEGMENTECTOMY AND WEDGE RESECTION

Segmentectomy and wedge resections are performed in patients with small tumours, and with borderline fitness, through thoracotomy or VATS. Each lobe of the lung has segments, which allows anatomical dissection and ligation of the segmental pulmonary artery, vein and bronchus (segmentectomy) (see **Figure 55.2**), or non-anatomical excision can be performed (wedge resection) combined with removal of regional lymph nodes.

LOBECTOMY

Lobectomy remains the treatment of choice for patients with early-stage lung cancer. The surgery can be performed via thoracotomy or VATS. Following dissection of the fissure and hilar structures, the branches of the pulmonary artery and veins to the lobe are isolated and ligated. The bronchus is usually stapled but can be sewn.

At completion of the operation, the remaining lung is reinflated. Some air leak is common and usually settles within a few days. One or two intercostal drains are inserted. The patient does not routinely need intensive care and postoperative ventilation is best avoided. The 30-day mortality rate is 2–3%, with morbidity such as chest infection or cardiac arrhythmia at around 10%. The average length of stay is around 5–7 days.

PNEUMONECTOMY

Pneumonectomy is removal of a whole lung and has a higher mortality rate (5–8%). The surgeon must be satisfied that the patient is fit to tolerate this procedure from the preoperative work-up. This procedure is reserved for either centrally placed tumours involving the main bronchus or those that straddle the fissure. At thoracotomy, inspection of the lung and direct palpation of the mass will determine resectability and lymph node spread. Fixation of the tumour to the aorta, heart or oesophagus implies irresectability. Involvement of the mediastinal lymph node chain is associated with a poor prognosis. With modern preoperative imaging, resection is abandoned in only about 3% of cases.

Pneumonectomy is anatomically more straightforward than lobectomy and involves dissecting and ligating the main

TABLE 55.10 National Institute for Health and Care Excellence (NICE) recommendations for assessing fitness for treatment with curative intent (including surgery).

Perioperative mortality	Consider global risk score, such as Thoracoscore	Ensure patient is aware of risk before consenting
Cardiovascular function	Assess risk factors and cardiac functional capacity	Avoid surgery within 30 days of MI
		Optimise primary cardiac treatment and begin secondary cardiac prophylaxis as soon as possible
		Offer surgery if two or fewer risk factors and good cardiac functional capacity
		Seek cardiology review if active cardiac condition, three or more risk factors or poor cardiac functional capacity
		Consider revascularisation before surgery in stable angina
		Continue anti-ischaemic treatment in perioperative period. Discuss perioperative platelet treatment if patient has a coronary stent
Lung function	Perform spirometry, measure T_LCO if disproportionate breathlessness or other lung pathology, perform segment count and assess exercise tolerance	Offer surgery if normal FEV_1 and good exercise tolerance or FEV_1 or T_LCO below 30% and patient accepts the risks of dyspnoea
	Consider shuttle walk testing (cut-off 400 m) and cardiopulmonary exercise testing (cut-off 15 mL/kg/minute) if moderate to high risk of postoperative dyspnoea	Offer radiotherapy with curative intent if lung function poor but patient is otherwise suitable for radiotherapy with curative intent and volume of irradiated lung is small

From NICE clinical guideline 21, available from: www.nice.org.uk/nicemedia/live/13465/54208/54208.pdf. FEV_1, forced expratory volume in 1 s; MI, myocardial infarction; T_LCO, transfer factor for carbon monoxide.

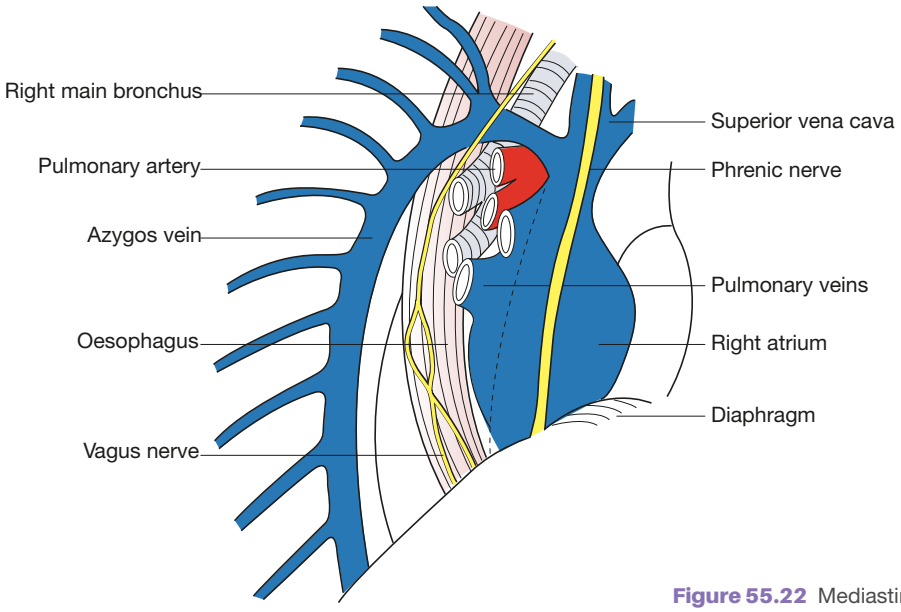

Figure 55.22 Mediastinal structures after removal of the right lung.

pulmonary artery, the superior and inferior pulmonary veins and the main bronchus, which is divided so that no blind stump remains (Figure 55.22). The technique of stump closure is important if a bronchopleural fistula is to be avoided. The tissues are carefully handled and the stump is usually stapled and sometimes covered using pleura, pericardium or a vascular pedicle such as an intercostal muscle. Drainage of the space is a matter of debate. Most use an underwater-seal drain and either leave it unclamped or unclamp it for 1 minute every hour until the drainage ceases; others prefer not to drain. The critical point is that no suction should be applied as there is now a sealed space with the mobile mediastinum on one side of it. The air in the pneumonectomy space is gradually absorbed and the fluid level within the space rises (Figure 55.23).

BRONCHOPLASTIC LUNG RESECTIONS

Increasingly, owing to the associated complications and higher mortality of a pneumonectomy, preservation of lung tissue is being considered, but without compromise of the surgical resection margins. Sleeve lung resections involve removing a central tumour that is invading a major bronchus, such as the left or right main bronchus, together with the lobe of the lung involved, with re-anastomosis of the cut major bonchus to the remaining lobar bronchus. This type of operation is particularly useful in dealing with tumours such as carcinoids that, despite low-grade malignant potential, are often found in a major bronchus.

Complications of lung resection

- **Bleeding**. Bleeding should be avoidable by the use of a careful surgical technique, but may be severe in the presence of dense adhesions.
- **Respiratory infection**. Many of these patients are ex-smokers and therefore basal collapse and hypoxaemia are common postoperatively.
- **Persistent air leak**. Chest drains are placed at the time of surgery to deal with the air leak. Rarely, the air leak persists and the remaining lung does not expand. Re-thoracotomy may then be necessary to seal the leak.
- **Bronchopleural fistula**. This is a serious complication. Following pneumonectomy the space left behind is initially filled with air. This is slowly reabsorbed and the space fills with tissue fluid. The fluid level rises until the air is finally reabsorbed. Dehiscence of the bronchial stump leads to the development of a bronchopleural fistula and the fluid in the space (which is almost inevitably infected) is expectorated in large quantities. This complication has a high morbidity and mortality rate. The patient is nursed sitting up and turned so that the affected space is dependent, to prevent infected fluid from entering the remaining lung while arrangements are made to site a pleural drain. This should be connected to an underwater seal but not suction. Bronchopleural fistulas are unlikely to resolve spontaneously and management is highly specialised.

POSTOPERATIVE CARE

Patients have limited respiratory reserve following lung resection, so infection and fluid overload are to be avoided. Once air leaks have settled, the drains are removed. Mobilisation, breathing exercises and regular physiotherapy are begun as soon as the patient's condition permits.

POSTOPERATIVE PAIN

It is important to deal with post-thoracotomy pain effectively so that a normal breathing pattern and gas exchange are achieved in the early postoperative period. Three strategies are routinely used in combination:

- patient-controlled analgesia (PCA) with intravenous boluses of opiates;
- paravertebral/extrapleural or epidural catheter-delivered local anaesthetic;
- background oral analgesia with paracetamol.

Long-term post-thoracotomy pain can be reduced by careful attention to detail during the operation. Sources of

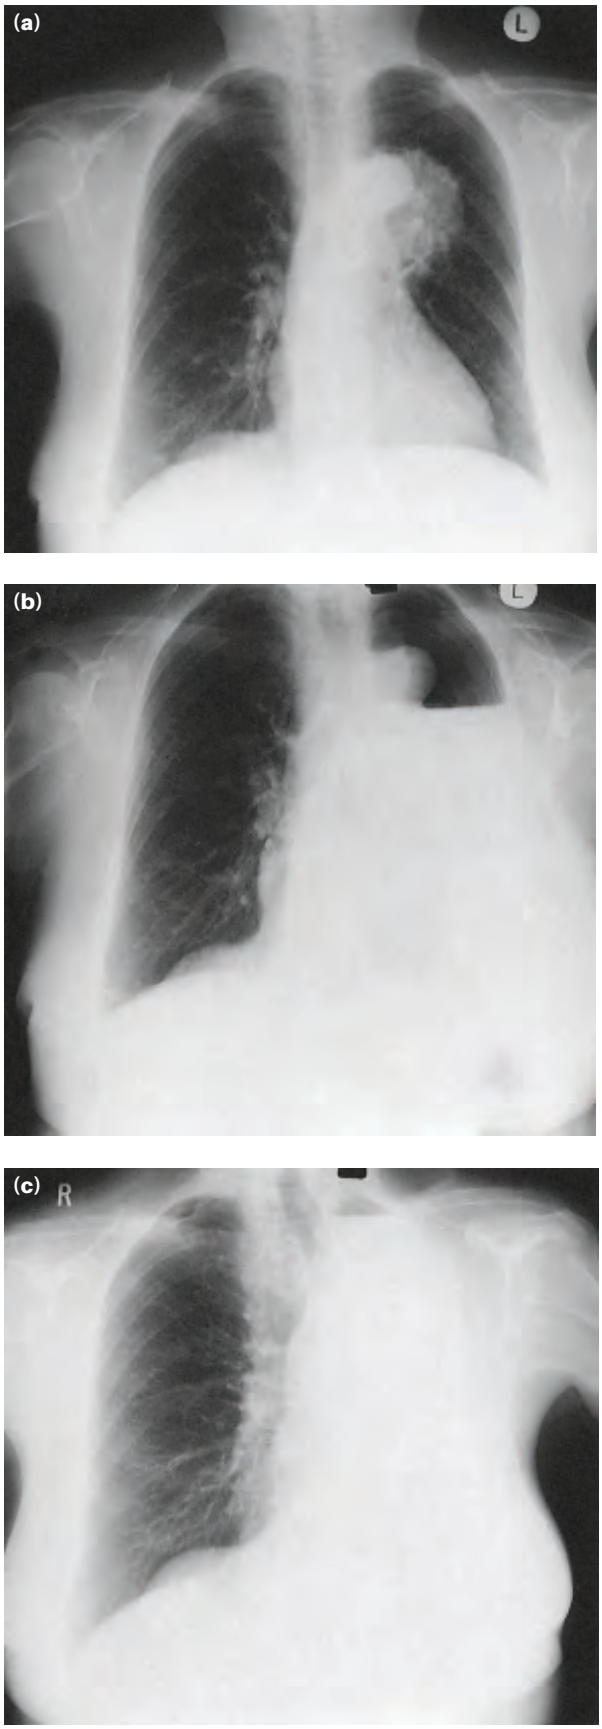

Figure 55.23 Chest radiographs **(a)** pre- and **(b)** post-pneumonectomy, with rising fluid level **(c)** in the left haemothorax.

avoidable chronic pain include rib fracture and the entrapment of intercostal nerves during wound closure.

LUNG METASTASES

For all malignancies, the lung is the most common site of metastases, that often develop through haemotogenous spread. The presence of metastases is regarded as a sign of advanced disease and few curative treatment options exist, however surgical resection of lung metastases may result in a significant survival advantage, particularly with metastases from solid tumours such as colorectal cancer. This has not yet been proven in the context of a randomised controlled trial. The selection criteria often used when considering lung metastasectomy include control of primary tumour; no evidence of metastases outside the lung; possibility of complete resection utilising lung sparing techniques; and acceptable operative risks with adequate pulmonary function.

Various approaches can be considered, though VATS is increasingly favoured over thoracotomy owing to reduced postoperative pain and length of stay, and therefore speedier recovery. The disadvantage of VATS is the inability to palpate and evaluate the lung in its entirety to locate other nodules deeper within the lung parenchyma, particularly those not identified on prior CT imaging. Median sternotomy can also be considered if there are bilateral lung metastases, located anteriorly or in the upper lobes, as this may be less painful than considering bilateral thoracotomies. The main principle when resecting lung metastases is to utilise lung-sparing techniques as much as possible, e.g. wedge resections rather than lobectomy, because it is likely that later reoperations to resect new metastases may be necessary.

Long-term outcome depends on the primary tumour type, with germ-cell tumours having the best outcome. Patients with epithelial tumours (carcinomas) generally have a 30–40% 5-year survival, as reported in several retrospective series.

BENIGN LUNG TUMOURS

Benign tumours of the lung are uncommon and account for fewer than 15% of solitary lesions seen on chest radiographs. A peripheral tumour usually causes no symptoms until it is large; a central tumour may present with haemoptysis and signs of bronchial obstruction while still small. A tumour is likely to be benign if it has not increased in size on chest radiographs for more than 2 years or it has some degree of calcification; however, a tissue diagnosis is usually pursued.

Most benign nodules are **granulomas** (tuberculosis or histoplasmosis). The most common benign tumour is a **hamartoma**, a developmental abnormality containing mesothelial and endothelial elements. Diagnosis (and definitive treatment) is achieved by excision of the lesion. Any of the mesodermal elements of the lung may form a mesodermal tumour (chondroma, lipoma, leiomyoma). Deposits of amyloid may have a similar radiographic appearance to a nodule (pseudotumour).

THE MEDIASTINUM

The mediastinum refers to the central area in the chest between the thoracic inlet and the diaphragm, between the right and left pleural surfaces, and which extends from the inner aspect of the sternum to the vertebral column. It contains the heart, great vessels, trachea and oesophagus, and is arbitrarily subdivided into compartments (superior, inferior, anterior, middle and posterior). Many of the regional lymph node chains draining the chest and its organs are also found in the mediastinum. Various surgical procedures to approach structures, and particularly lymph nodes, in the mediastinum are performed, usually as diagnostic procedures. The surgical approach when mediastinal tumours require resection depends on the antomical location of the tumour (**Figure 55.24**) and includes median sternotomy for anterior mediastinal pathology, thoracotomy or VATS for posterior mediastinal pathology and transcervical (neck incisions) for superior mediastinal pathology. The middle mediastinum can usually be approached through thoracotomy or VATS.

Primary tumours of the mediastinum

Thymoma, neurogenic tumours, germ cell tumours and lymphoma are the usual primary tumours of the mediastinum.

- **Thymoma**. This is the most common mediastinal tumour, accounting for 25% of the total, and is derived from the thymus gland (**Figure 55.25**). Thymomas vary in behaviour from benign to aggressively invasive, as reflected in the Masoaka classification system used to stage thymomas (*Table 55.11*). They are often related to mysthenia gravis (MG), a neuromusclar condition which can have a high associated incidence of thymomas, and interestingly may respond to excision of the thymus gland even when the gland has no associated thymoma present. The only reliable indicator of malignancy is capsular invasion. Diagnosis and treatment are best achieved by complete thymectomy, which is usually performed as a median sternotomy. However, if the thymoma is small or when the patient has MG and the thymus is being excised as a treatment, a transcervical approach with or without an additional VATS procedure can be performed.
- **Germ cell tumour**. The anterior mediastinum is the most common site of extragonadal germ cell tumours. They account for 13% of all mediastinal masses and cysts and contain elements from all three cell types (mesoderm, endoderm and ectoderm). They tend to present in young adults and 75% are benign and cystic, although they may cause compression of neighbouring structures; hence, dermoid cysts are best excised. Malignancy is suspected if elevated levels of serum alpha-fetoprotein, human chorionic gonadotrophin and carcinoembryonic antigen are detected. After initial treatment with chemotherapy, a patient with tumour marker normalisation and a persistent mass on CT may be considered for surgical resection. If tumour markers fail to normalise, further chemotherapy is usually offered.
- **Lymphoma**. Lymphoma is a common cause of a mediastinal mass lesion, particularly in the anterior mediastinum, and can lead to superior vena cava obstruction or other symptoms of local compression. The main treatment is

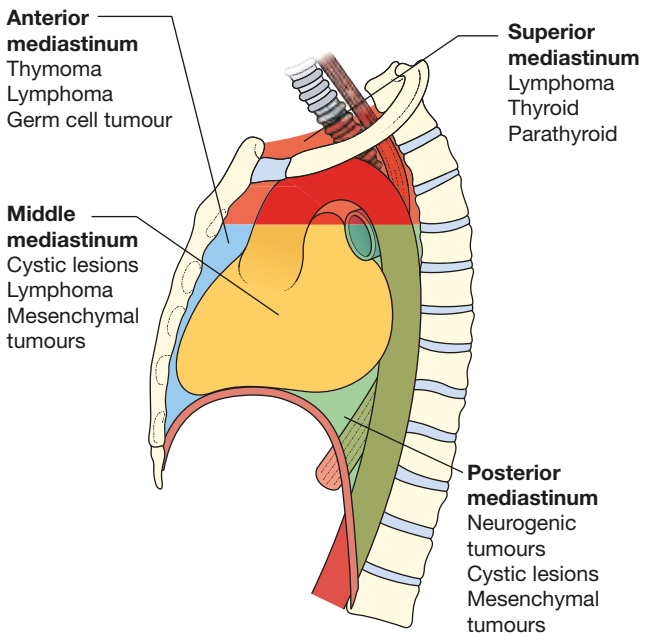

Figure 55.24 Mediastinal pathology. Subdivisions of the mediastinum with the most common mediastinal masses.

Figure 55.25 Computed tomography scan showing a thymoma presenting as a mediastinal mass.

TABLE 55.11 Masaoka thymoma staging system.

Stage	Description
I	Macroscopically completely encapsulated
	Microscopically no capsular invasion
II	Macroscopic invasion into surrounding fatty tissue or mediastinal pleura
	Microscopic invasion into the capsule
III	Macroscopic invasion into neighbouring organs (pericardium, great vessels, lungs)
IVA	Pleural or pericardial dissemination
IVB	Lymphogenous or haematogenous metastasis

After Masaoka A *et al., Cancer* 1981; **48**: 2485.

chemotherapy, and surgery is rarely required apart from obtaining tissue for diagnosis.

- **Mesenchymal tumours**. Lipomas are common in the anterior mediastinum. Other mesenchymal tumours are very rare.
- **Thyroid**. Ectopic thyroid (and parathyroid) tissue may be found in the anterior mediastinum but usually the mass is an extension of a thyroid lesion (retrosternal goitre). Excision of retrosternal thyroids may be required if there is local airway compression and stridor and can be performed via a transcervical incision, but occasionally median sternotomy may be required.
- **Neurogenic tumours**. These may derive from the sympathetic nervous system or the peripheral nerves and are more prevalent in the posterior mediastinum. They may be painful but are more often discovered accidentally on routine chest radiography and can be quite large (**Figure 55.26**). They include neuroblastoma in childhood, and Schwannomas and neurofibromas in adults, which are usually benign. Phaeochromocytoma arises from the sympathetic chain and produces the characteristic endocrine syndrome. Excision of neurogenic tumours is generally recommended, particularly if the patient is developing symptoms. This can be performed through a thoracotomy, though for smaller tumours a VATS approach can be used (**Figure 55.27**).
- **Enlarged mediastinal lymph nodes** are commonly involved by metastatic tumour, mimicking a primary mediastinal lesion. Symptoms are generally secondary to compression or invasion of a structure within the mediastinum. Surgery such as mediastinoscopy is reserved for diagnosis only.

Other conditions of the mediastinum

Many of the primary tumours such as neurogenic tumours and germ cell tumours can present as cysts or have a cystic quality. In addition, the mediastinum can contain other cysts, often with an embyrological aetiology. Thymic cysts, pericardial cysts, bronchogenic and foregut cysts can all present asymptomatically or with local compression (**Figure 55.28**). Surgical excision is recommended if diagnosis is unclear or the patient has symptoms.

Figure 55.28 Computed tomography scan of the chest showing a bronchogenic cyst splaying the carina.

MEDICAL CONDITIONS FOR WHICH SURGERY MAY BE REQUIRED

Bronchiectasis

Bronchiechtasis is chronic irreversible dilatation of the medium-sized bronchi, which may occur following a suppurative pneumonia or bronchial obstruction. It is the pathological end stage of a range of conditions. If generalised it is almost never considered for surgical resection. Cases caused by whooping cough and measles are decreasing in frequency in resource-rich countries.

Treatment

Removal of the bronchiectatic part of the lung for symptoms of bleeding, recurrent infection or copious symptoms can be very effective when the disease is localised.

Theodor Schwann, 1810–1882, Professor of Anatomy and Physiology successively at Louvain (1839–1848) and Liege, Belgium (1849–1888).

Lung abscess

The causes of lung abscess are shown in *Table 55.12*. The chest radiograph shows a cavity with a fluid level or in myecetoma a fungal ball. Most acute abscesses resolve with appropriate antibiotic therapy and postural drainage. Surgery is avoided. Small radiologically sited drains are used sometimes in the intensive care unit.

TABLE 55.12 Causes of lung abscess.

Specific pneumonia	Streptococcal Staphylococcal Pneumococcal *Klebsiella* spp. Anaerobic
Bronchial obstruction	Carcinoma Carcinoid Foreign body Postoperative atelectasis
Chronic respiratory sepsis	Sinusitis Tonsillitis Dental infection
Septicaemia	
Penetrating lung injury	

Tuberculosis

Surgery is rarely indicated for tuberculosis in resource-rich countries but, when it is, it must be combined with adequate antitubercular chemotherapy or the benefit of surgery will be lost.

Summary box 55.6

Tuberculosis: indications for surgery

- Suspicious lesion on chest radiograph in which neoplasia cannot be excluded
- Chronic tuberculous abscess, resistant to chemotherapy
- Aspergilloma within a tuberculous cavity
- Life-threatening haemoptysis

Diagnosis

Surgical procedures may be necessary to establish the diagnosis if suspected clinically but sputum or pus cultures are persistently negative.

Complications such as an aspergilloma in a chronic cavity causing life-threatening haemoptysis may require lobectomy.

Pulmonary sequestration

This describes a section of non-functional lung separated from the normal bronchial connection with other abnormalities of development, which often include a direct systemic arterial supply from the aorta. Venous return is to the pulmomary veins in the majority of cases. The segment becomes cystic and infected, resulting in the common appearance of a solid lung mass that may be homogeneous or heterogeneous, occasionally with cystic changes on CT scan. Interlobar sequestration occurs within the lung substance. It may present with recurrent chest infections and/or haemoptysis. Patients with extralobar sequestration are usually asymptomatic because air spaces are not present, and therefore it usually presents as an incidental finding.

Lung cysts

Developmental lung cysts have a tendency to become infected. Acquired lung cysts may contain air or fluid and may be single or multiple. Pulmonary hydatid disease is a cause in endemic areas. Air cysts (bullae) may be spontaneous but may be secondary to emphysematous degeneration (**Figure 55.29**).

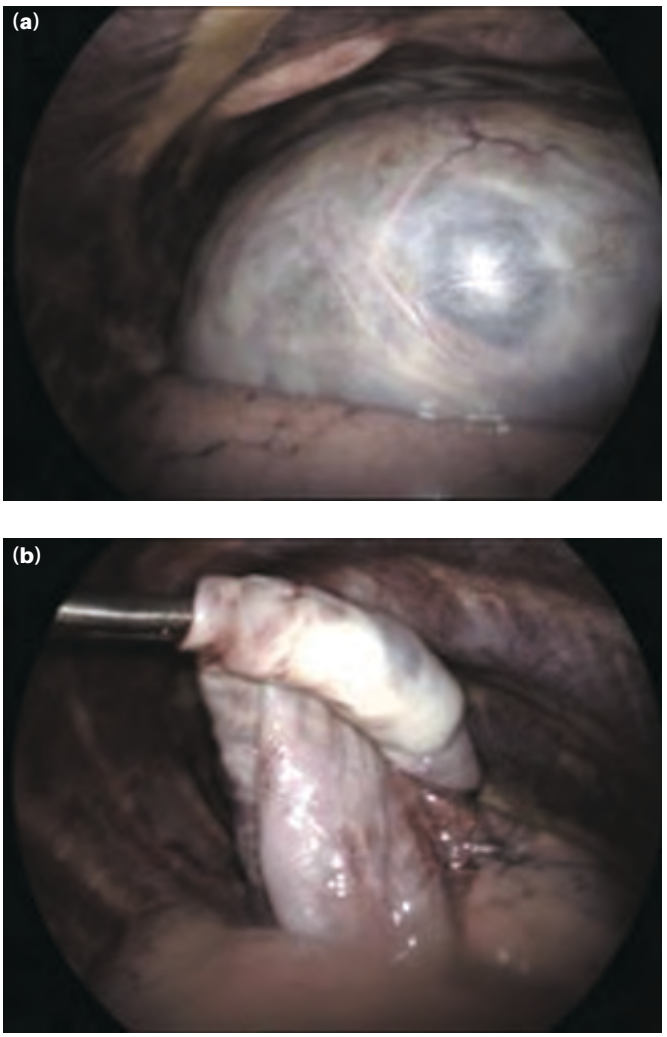

Figure 55.29 **(a)** A large solitary bulla seen on videothoracoscopy. **(b)** The bulla deflated and rolled in preparation for staple resection.

Theodor Albrecht Edwin Klebs, 1834–1913, Professor of Bacteriology successively at Prague, Czech Republic; Zurich, Switzerland; and The Rush Medical College, Chicago, IL, USA.

LUNG TRANSPLANTATION (SEE ALSO CHAPTER 82)

Lung transplantation is an established therapy for those with end-stage parenchymal or pulmonary vascular disease; it is limited by the number of donor lungs available.

CHEST TRAUMA

The approach to trauma must be methodical and exact, because the signs, particularly in the presence of other injury, may easily be missed. The general principles of resuscitation and ATLS (Advanced Trauma and Life Support) must be followed.

Thoracic trauma is responsible for over 70% of all deaths following road traffic accidents. Blunt trauma to the chest in isolation is fatal in 10% of cases, rising to 30% if other injuries are present. The indications for emergency room thoractomy in blunt chest trauma include massive haemothorax, suspected cardiac tamponade and witnessed cardiac arrest in the resuscitation area. Success rates are low. Penetrating thoracic wounds vary according to the prevalence of civil violence, with a mortality rate of 3% for simple stabbing to 15% for gunshot wounds. The indications for emergency room thoracotomy are similar to those for blunt chest trauma. The standard approach is a left anterior thoracotomy, unless the penetrating injury is in the right chest, however it may be necessary to extend the incision to bilateral thoracotomies or a clampshell incision.

Early deaths after thoracic trauma are caused by hypoxaemia, hypovolaemia and tamponade. The first steps in treating such patients should be to diagnose and treat these problems as early as possible because they may be readily corrected. Young patients have a large physiological reserve, and serious injury may be overlooked until this reserve is used up, by which time the situation is critical and may be irretrievable. The best approach is to remain highly suspicious if life-threatening conditions are to be anticipated and treated. Early consultation with a regional thoracic centre is advised in cases of doubt. In an emergency it is essential that experienced help is summoned.

Management of chest trauma is covered in detail in Chapter 27.

THE DIAPHRAGM

The diaphragm is the fibromuscular structure separating the thorax from the abdomen.

Disorders of the diaphragm

Disorders of the diaphragm can be broadly classified as disorders of innervation, leading to paralysis of the diaphragm, with elevation and reduction of thoracic volume leading to breathlessness, and disorders of anatomy, which are further categorised into congenital diaphragmatic hernias or acquired hernias, usually secondary to trauma. There are two well-recognised congenital sites where abdominal viscera can herniate into the chest (**Figures 55.30 and 55.31**).

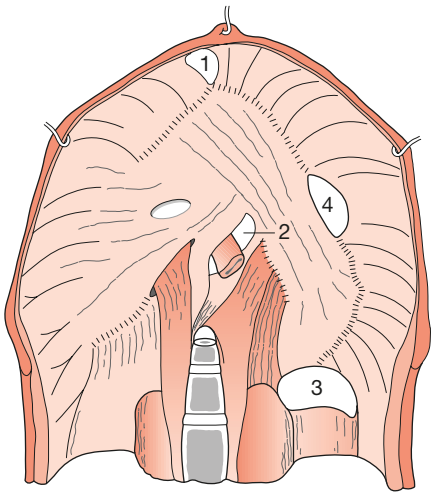

Figure 55.30 Diagram of sites of hernias. The usual sites of congenital diaphragmatic hernia: 1, foramen of Morgagni; 2, oesophageal hiatus; 3, foramen of Bochdalek (pleuroperitoneal hernia); 4, dome.

- **The foramen of Morgagni**: a hernia in the anterior part of the diaphragm with a defect between the sternal and costal attachments. The most commonly involved viscus is the transverse colon.
- **The foramen of Bochdalek**: through the dome of the diaphragm posteriorly.

Traumatic rupture of the diaphragm may occur with blunt trauma. Unless there is severe bleeding or strangulation of the viscera it is best managed after an interval. In a severely injured patient being ventilated it can wait until other injuries are dealt with and weaning from the ventilator is being considered.

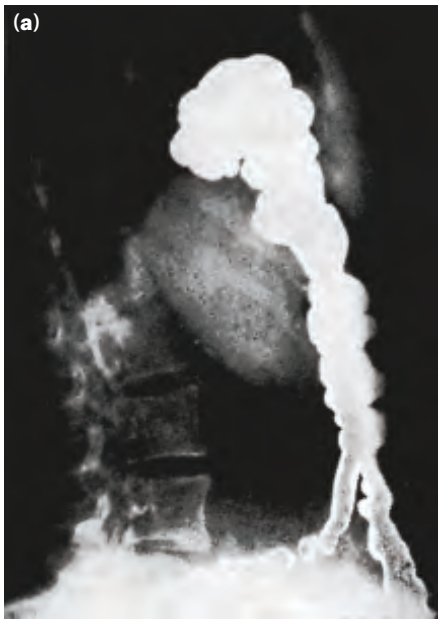
When the diaphragm is breached, as in anatomical disorders, repair with either primary closure or with a mesh is usually possible via a thoracotomy. Diaphragmatic paralysis, particularly idiopathic unilateral paralysis, can be treated by plication, returning the diaphragm to a lower position and improving thoracic volume.

DISORDERS OF THE CHEST WALL

Tumours of the chest wall

These can be tumours of any component of the chest wall, i.e. bone, cartilage and soft tissue. They are treated similarly to those that occur at other sites and require specialist surgical input only if major resection and chest wall reconstruction are contemplated.

Giovanni Battista Morgagni, 1682–1771, Professor of Anatomy, Padua, Italy for 59 years, regarded as 'the founder of Morbid Anatomy'.
Victor Alexander Bochdalek, 1801–1883, Professor of Anatomy, Prague, Czech Republic.



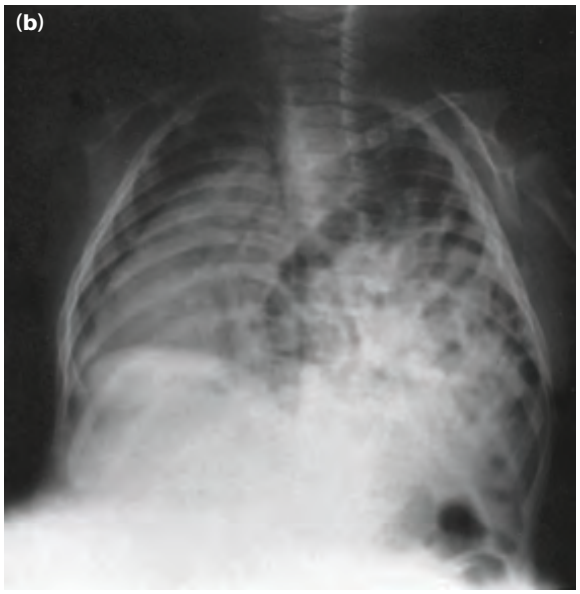


Figure 55.31 Chest x-ray of congenital diaphragmatic hernia. **(a)** Colon occupying a Morgagni hernia (courtesy of Dr Oliver Smith, Birmingham, UK). **(b)** Foramen of Bochdalek hernia on the left side in an infant. The left pleural cavity is occupied by intestine, the mediastinum is displaced to the right and the right lung is aerated very little.

Other diseases of the chest wall

Congenital abnormalities are often incidental findings on chest radiography (e.g. bifid rib), but there are some important exceptions.

Cervical rib and thoracic outlet syndrome

This rib is usually represented by a fibrous band originating from the seventh cervical vertebra and inserting onto the first thoracic rib. It may be asymptomatic, but because the subclavian artery and brachial plexus course over it a variety of symptoms may occur. The lower trunk of the plexus (mainly T1) is compressed, leading to wasting of the interossei and altered sensation in the T1 distribution. Compression of the subclavian artery may result in a poststenotic dilatation with thrombus and embolus formation. The diagnosis, assessment and surgery are fraught with uncertainties and are best left to those with a well-developed interest in this problem.

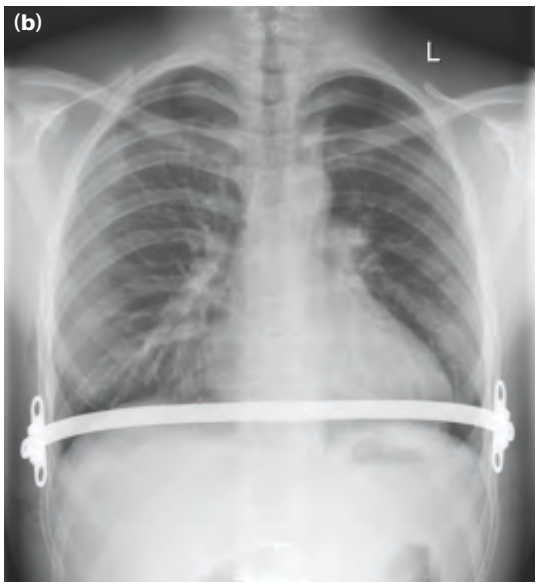

Figure 55.32 **(a)** Insertion of preformed bar placed thoracoscopically beneath the pectus excavatum. **(b)** Chest x-ray following insertion of a metal bar bracing the sternum forward (the Nuss procedure).

Pectus excavatum

The sternum is depressed, with a dish-shaped deformity of the anterior portions of the ribs on one or both sides. It is never a cause of respiratory problems. It can be repaired to improve its cosmetic appearance either as an open procedure (the Ravitch procedure) which involves resecting the affected costal cartilages and mobilising the sternum, or as a minimally invasive technique, the Nuss procedure. A metal bar is paced behind the sternum to hold this central panel in its new position and has to be removed after a period of time **(Figure 55.32)**.

Mark M Ravitch, 1910–1989, paediatric surgeon, University of Pittsburg, PA, USA.
Donald Nuss, contemporary, paediatric surgeon, Norfolk, VA, USA, described this technique in 1987.

Pectus carinatum (pigeon chest)

In this condition the sternum is elevated above the level of the ribs and treatment is offered for cosmetic reasons. The sternum is mobilised and allowed to fall back into place.

It often comes to light during the growth spurt at adolescence when, of course, the teenager is particularly sensitive about appearance. Most patients are asymptomatic and the only justification for treatment is on cosmetic grounds. Some surgeons make a very good case for this but the risk of morbidity and of a less than perfect result must be clearly spelt out to the patient and his/her parents. Surgery involves mobilising the sternum with the costal cartilages so that the sternum can be flattened to a more anatomical position. Surgery is best left until the late teens, when further growth of the chest wall is unlikely.

PART 10

Vascular

Chapter 56

Arterial disorders

Learning objectives

To understand:

- The nature and associated features of occlusive peripheral arterial disease
- The investigation and treatment options for occlusive peripheral arterial disease
- The principles of management of the severely ischaemic limb
- The nature and presentation of peripheral aneurysmal disease, particularly of the abdominal aorta
- The investigation and treatment options for peripheral aneurysmal disease
- The arteritides and vasospastic disorders

INTRODUCTION

Arterial disorders represent the most common cause of morbidity and death in Western societies. Much of this is due to the effects of atheroma on the arteries supplying the heart muscle (coronary thrombosis and myocardial infarction) and brain (stroke), although atheroma is also common at other sites. This chapter addresses diseases that are typically the province of the vascular surgeon, namely those affecting the peripheral arterial system: vascular disease that alters the normal structure and function of the aorta, its visceral branches and the arteries of the lower extremity.

ARTERIAL STENOSIS AND OCCLUSION

Cause and effect

Peripheral arterial stenosis or occlusion is predominantly caused by atherosclerosis and/or thromboembolic disease, but may also occur as a result of trauma, particularly in the younger adult. Stenosis or occlusion produces symptoms and signs that are related to the organ supplied by the artery: e.g. lower limb – claudication, rest pain and gangrene; brain – transient ischaemic attacks and stroke; myocardium – angina and myocardial infarction; kidney – hypertension and renal failure (Figure 56.1); intestine – abdominal pain and infarction. The severity of the symptoms is related to the size of the vessel occluded and whether the stenosis or occlusion occurs suddenly (acute) in a previously normal artery or gradually (chronic) with progressive narrowing of the artery over time. In chronic arterial narrowing, a collateral circulation may develop and provide an alternative route for blood flow that reduces symptoms until a critical stenosis or occlusion has developed (Figure 56.2).

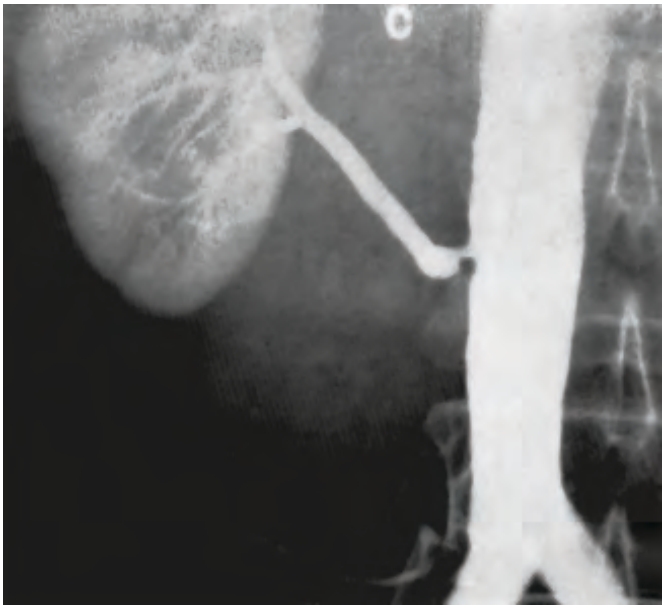

Figure 56.1 Renal artery stenosis. Angiogram by retrograde femoral catheterisation. Note the poststenotic dilatation.

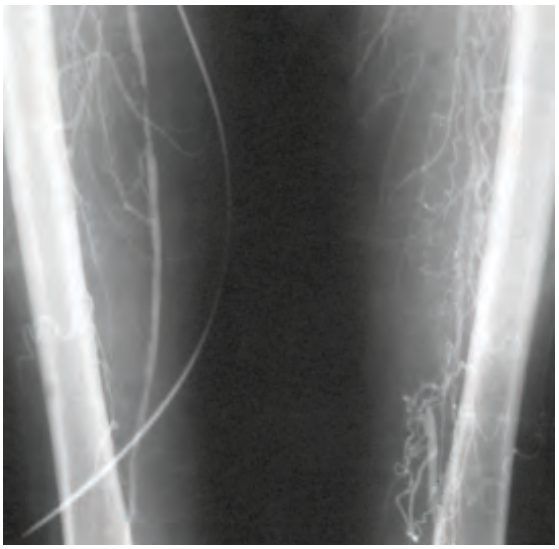

Figure 56.2 Right superficial femoral stenosis. Left superficial femoral occlusion with collateral vessels present, causing claudication.

Features of chronic arterial stenosis or occlusion in the leg

Intermittent claudication

Intermittent claudication occurs as a result of anaerobic muscle metabolism and is classically described as debilitating cramp-like pain felt in the muscles that is:

- reliably brought on by walking;
- not present on taking the first step (unlike osteoarthritis);
- reliably relieved by rest both in the standing and sitting positions; usually within 5 minutes (unlike nerve compression from a lumbar intervertebral disc prolapse or osteoarthritis of the spine or spinal stenosis, which are typically relieved only when resting in the sitting position for greater than 5 minutes).

The distance that a patient is able to walk without stopping varies (claudication distance) only slightly from day to day. It is decreased by increasing the work demands and hence oxygen requirements of the muscles affected, e.g. walking up hill, increasing the speed of walking and/or carrying heavy weights, and secondly by general health conditions that reduce the oxygen delivery capacity of the arterial system, e.g. anaemia or heart failure.

The muscle group affected by claudication is classically one anatomical level below the level of arterial disease and is usually felt in the calf because the superficial femoral artery is the most commonly affected artery (70% of cases). Aorto-iliac disease (30% of cases) may cause thigh or buttock claudication. Buttock claudication in association with sexual impotence resulting from arterial insufficiency is eponymously called Leriche's syndrome. It is very rare.

Rest pain

As disease progression occurs the claudication distance decreases and perfusion to the leg may be so severely compromised that anaerobic respiration occurs even at rest, typically affecting the foot and/or calf. The pain is exacerbated by lying down or elevation of the foot due to loss of the gravitational effects on perfusion pressure in the foot. The patient characteristically describes pain that is worse at night and may be lessened by hanging the foot out of bed or by sleeping in a chair (effects of gravity restored). Even the pressure of bedclothes on the foot may make the pain worse.

Ulceration and gangrene

Ulceration occurs with severe arterial insufficiency and may present as painful erosion between toes or as shallow, non-healing ulcers on the dorsum of the feet, on the shins and especially around the malleoli. The blackened mummified tissues of frank gangrene are unmistakable **(Figure 56.3)**, and superadded infection often makes the gangrene wet. Patients with rest pain and/or ulceration/gangrene – critical limb ischaemia – should be considered to have an imminently threatened leg and require urgent vascular assessment/intervention.

Colour, temperature, sensation and movement

Unlike an acutely ischaemic foot that is often cold, white, paralysed and insensate, a chronically ischaemic limb tends to equilibrate with the temperature of its surroundings and may feel quite warm under the bedclothes. Chronic ischaemia does not produce paralysis and sensation is usually intact. Patients with critical limb ischaemia who have been waiting for a consultation with their leg in dependence may have a red swollen foot that may be mistaken for cellulitis by the unwary clinician. However, elevation of the limb reveals the severity of the ischaemia, with venous guttering and foot pallor that changes to a red/purple colour when the limb is allowed to hang down again (dependent rubor or the sunset foot sign) **(Figure 56.4)**. The capillary refill time may be elicited by pressing the skin of the heel or toe causing blanching

Figure 56.3 Severe chronic ischaemia with dry gangrene.

Claudication from the Latin *claudicare* – to limp. The Roman emperor Claudius (10 BC to 54 AD) walked with a limp, which was possibly due to poliomyelitis.
Rene Leriche, 1879–1955, Professor of Surgery, Strasbourg, France, described this syndrome.

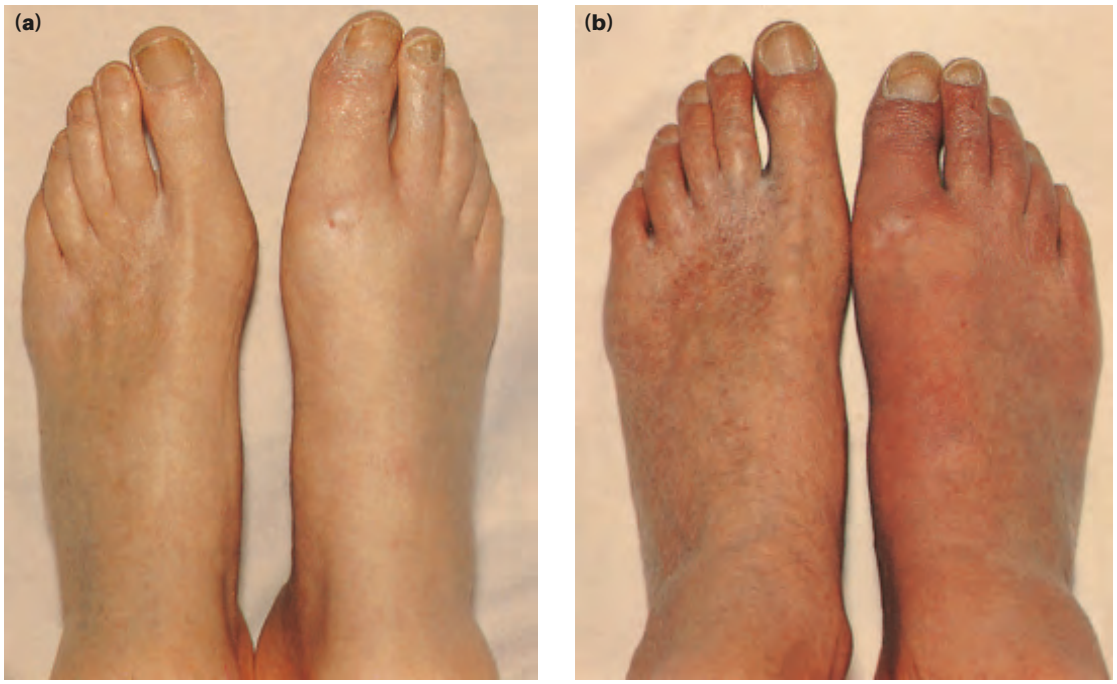

Figure 56.4 Colour changes with elevation **(a)** and dependency **(b)**.

(press for 5 seconds) and then releasing to allow colour to return; normally this takes 2–3 seconds but may be prolonged to 10 seconds in severe ischaemia.

Arterial pulses

It is standard practice to examine the femoral, popliteal, posterior tibial and dorsalis pedis arteries together with the abdomen for an aortic aneurysm or renal artery bruit, which may coexist with lower limb occlusive disease. Diminution of a femoral and/or popliteal pulse can often be appreciated by comparing it with its opposite number; however, pedal pulses are either clinically palpable or absent. Popliteal pulses are often difficult to feel; a popliteal artery aneurysm should be suspected if the popliteal pulse is prominent with concomitant loss of the natural concavity of the popliteal fossa. Pulsation distal to an arterial occlusion is usually absent although the presence of a highly developed collateral circulation may allow distal pulses to be palpable – this is most likely to occur with an iliac stenosis. In this case, exercise (walking until claudication develops) usually causes the pulse to disappear as vasodilation occurs below the obstruction, causing the pulse pressure to reduce. An arterial bruit, heard on auscultation over the pulse, indicates turbulent flow and suggests a stenosis. It is an unreliable clinical sign as tight stenoses often do not have bruits. A continuous 'machinery' murmur over an artery usually indicates an arteriovenous fistula.

Relationship of clinical findings to site of disease

In most cases the site of arterial obstruction can be determined from the symptoms and signs (*Table 56.1*). Severe ischaemia (rest pain, ulceration, gangrene) is usually caused by multilevel disease, e.g. iliac and femoropopliteal disease.

Summary box 56.1

Features of chronic lower limb arterial stenosis or occlusion

- Intermittent claudication
- Rest pain
- Dependent rubor or sunset foot
- Ulceration
- Gangrene
- Arterial pulsation diminished or absent
- Arterial bruit
- Slow capillary refilling

TABLE 56.1 Relationship of clinical findings to site of disease.

Aortoiliac obstruction	Claudication in buttocks, thighs and calves
	Femoral and distal pulses absent in both limbs
	Bruit over aortoiliac region
	Impotence (Leriche)
Iliac obstruction	Unilateral claudication in the thigh and calf and sometimes the buttock
	Bruit over the iliac region
	Unilateral absence of femoral and distal pulses
Femoropopliteal obstruction	Unilateral claudication in the calf
	Femoral pulse palpable with absent unilateral distal pulses
Distal obstruction	Femoral and popliteal pulses palpable
	Ankle pulses absent
	Claudication in calf and foot

Investigation of arterial occlusive disease

Most patients with symptoms of arterial disease do not need invasive treatment, such as angioplasty or surgical reconstruction, and the decision whether or not to intervene can often be made without recourse to special investigations. When further investigation is indicated, the purpose is to confirm the presence and severity of peripheral arterial disease, identify the anatomical location of disease and assess the suitability of the patient for intervention.

General investigation

Patients with arterial disease tend to be elderly and atherosclerosis is often a multisystem disease process; the presence of arterial disease in the leg is suggestive of disease in other arterial trees, including the coronary (50%) and cerebral (25–50%). Many patients have other age-related diseases, such as chronic obstructive pulmonary disease and malignancy, that may impact on both their symptoms and suitability for intervention. Blood tests to exclude anaemia, diabetes, renal disease and lipid abnormalities should include a full blood count, blood glucose, lipid profile and serum urea and electrolytes. High blood viscosity (polycythaemia and thrombocythaemia) may be caused by smoking but may also be associated with cancer; renal impairment (raised serum creatinine and low estimated glomerular filtration rate) may be caused by drugs and may be exacerbated by intravenous contrast agents used during angiography.

Electrocardiography (ECG) may show coronary ischaemia, left ventricular hypertrophy or a cardiac dysrhythmia although a normal ECG does not rule out these conditions. More information may be gained by an echocardiogram or exercise testing. Arterial blood gases and pulmonary function test may be appropriate in patients with severe lung disease.

Doppler ultrasound blood flow detection

A hand-held Doppler ultrasound probe is very useful in the assessment of occlusive arterial disease (**Figures 56.5 and 56.6**). A continuous-wave ultrasound signal is transmitted from the probe at an artery, and a receiver within the probe itself picks up the reflected beam. The change in frequency in the reflected beam compared with that of the transmitted beam is due to the Doppler shift, resulting from the reflection of the beam by moving blood cells. The frequency change may be converted into an audio signal that is typically pulsatile. Doppler ultrasound equipment can be used in conjunction with a sphygmomanometer to assess systolic pressure in small vessels. This is possible even when the arterial pulse cannot be palpated. Both the pressure and signal quality are important; a normal artery has a triphasic signal that can be detected by a trained observer. However, although the presence of a Doppler signal indicates moving blood, it does not necessarily indicate that the blood flow is sufficient to maintain limb viability and prevent limb loss.

Figure 56.5 Simple hand-held Doppler ultrasound probe.

Figure 56.6 Hand-held Doppler probe and sphygmomanometer used to determine systolic pressure in the dorsalis pedis artery, as part of assessing the ankle–brachial pressure index.

Quantitative assessment can be performed at the bedside by measuring the ankle–brachial pressure index (ABPI); the ratio of systolic pressure at the ankle to that in the ipsilateral arm. The highest pressure in the dorsalis pedis, posterior tibial or peroneal artery serves as the numerator, with the highest brachial systolic pressure being the denominator. The normal resting ABPI is 0.9–1.3; values below 0.9 indicate some degree of arterial obstruction (claudication), <0.5 suggests rest pain and <0.3 indicates imminent necrosis. However, the

Christian Johann Doppler, 1803–1856, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler Principle' in 1842.

values are merely a guide and normal values may be present with intermittent claudication. Retesting after exercise to the onset of pain can be useful; a drop in the resting ABPI of >20% after exercise is indicative of flow-limiting arterial disease. Artificially high ABPI readings (>1.3) can be caused by calcified, incompressible arteries that are often found in diabetic patients.

Duplex scanning

This major non-invasive technique uses B-mode ultrasound to provide an image of vessels (**Figures 56.7 and 56.8**). The image is created because of the varying ability of different tissues to reflect the ultrasound beam. A second ultrasound beam is then used to insonate the imaged vessel and the Doppler shift obtained is analysed by a computer. Most scanners now have colour coding, which allows detailed visualisation of blood flow, turbulence, etc. Different colours indicate changes in direction and velocity of flow, with areas of high flow usually indicating a stenosis. In experienced hands, duplex scanning is as accurate as angiography and has the advantages of cost-effectiveness and safety. However, the aortoiliac segment can be difficult to visualise particularly in obese patients. A computed tomography (CT) angiogram can provide better imaging of this segment in these cases (see below).

Figure 56.7 Colour duplex scanner.

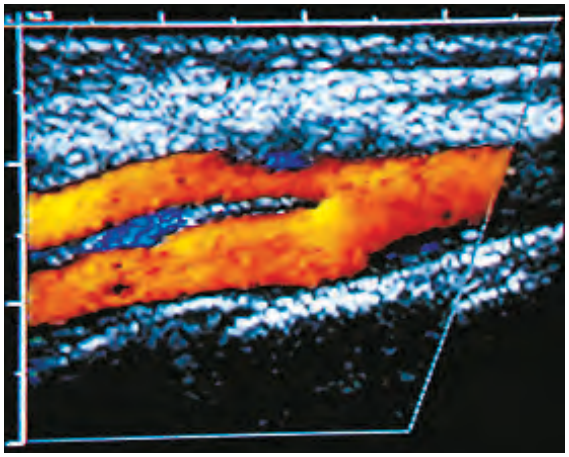

Figure 56.8 Colour duplex scan of carotid vessels in the neck showing stenosis at the common carotid bifurcation (courtesy of Dr Paul Allan, Royal Infirmary, Edinburgh, UK).

Digital subtraction percutaneous angiography

Digital subtraction percutaneous angiography (DSA) involves injection of a radio-opaque dye into the arterial tree by a percutaneous catheter method (Seldinger technique), usually involving the femoral artery (**Figures 56.9 and 56.10**). The images obtained are digitalised by computer and the extraneous background (bone, soft tissues, etc.) is removed to provide clearer images. The benefits of DSA are that it provides dynamic arterial flow information and can be combined with a definitive endovascular intervention when indicated. However, it is associated with potential complications including

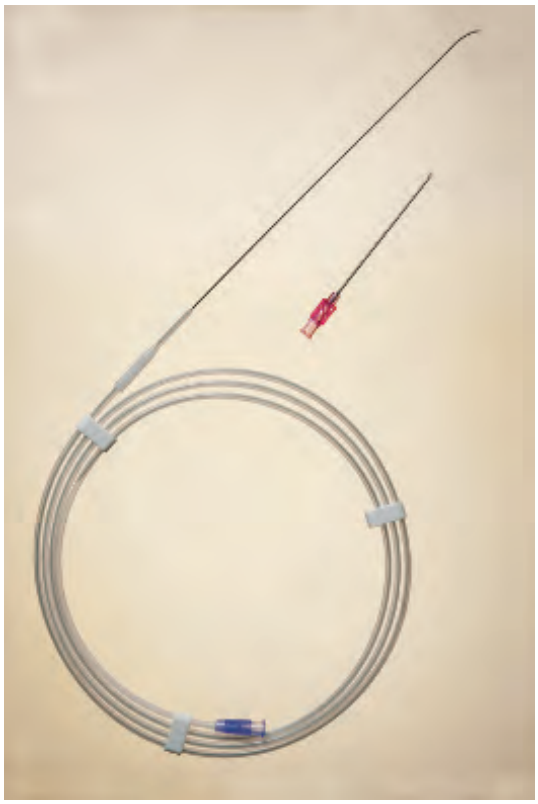

Figure 56.9 Seldinger needle and guidewire for introducing an arterial catheter.

Sven Ivar Seldinger, 1921–1998, radiologist, Karolinska Institute, Stockholm, Sweden, introduced percutaneous arterial catheterisation in 1956.

Figure 56.10 Arterial occlusion just above the knee causing claudication of the calf; good collateral circulation (a non-digital subtraction arteriogram by the Seldinger technique).

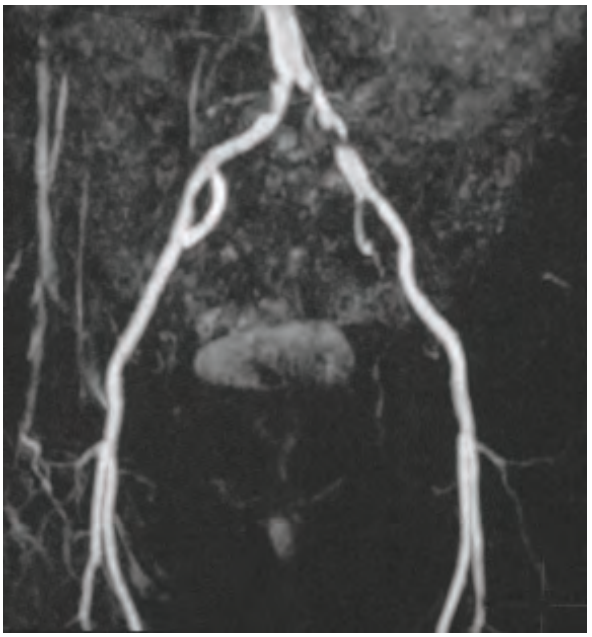

Figure 56.11 Magnetic resonance angiogram showing a tight stenosis at the midpoint of the left common iliac artery.

bleeding, haematoma, false aneurysm formation, thrombosis, arterial dissection, distal embolisation, renal dysfunction and allergic reaction, which may occur in up to 5% of procedures. Furthermore, it is relatively expensive compared to other investigation modalities and its usage should be limited to patients in whom a concomitant intervention is predicted.

CT angiography and magnetic resonance (MR) angiography **(Figure 56.11)** are newer techniques gaining in popularity, although the image quality is not as good as DSA. They can be useful where duplex scanning is not possible (intrathoracic arteries) or produces poor images (aortoiliac segment). MR has the added advantage of avoiding the need for ionising radiation, but may be contraindicated in patients suffering with claustrophobia or those with certain metallic implants, e.g. pacemakers.

Management of arterial stenosis or occlusion

General

Only one-quarter of patients presenting with intermittent claudication will experience symptomatic deterioration during their lifetime, but the overall risk of progression to critical leg ischaemia and amputation is small with <5% of patients requiring amputation over a 5-year period. Patients with an ABPI of <0.50 are twice as likely to deteriorate as patients with an ABPI of >0.50, and a deteriorating ABPI is predictive of future limb loss. For patients with rest pain or tissue necrosis, intervention is usually required to prevent major amputation.

Claudication is often a marker of silent coronary arterial disease, whose extent correlates with the ABPI; a 0.1 decrease in ABPI below 0.9 is associated with a 10% increase in the relative risk of a major cardiovascular event. Similarly, one-quarter of patients with claudication have significant atherosclerotic disease affecting their carotid and renal arterial systems. It is thus not surprising that the risk of suffering a major cardiovascular event per year in patients with claudication is >5%, and that 50% of claudicants will die within 10 years from myocardial infarction or stroke. The common modifiable risk factors for peripheral arterial disease mirror those for coronary artery disease: smoking, diabetes mellitus, hypertension and hyperlipidaemia. Therefore, the two main aims when treating claudication are prevention of major cardiovascular morbidity through risk factor modification and symptom relief/improvement.

Non-surgical management

For many patients with claudication a structured exercise programme – at least 2 hours of exercise per week for 3 months – in combination with smoking cessation will lead to sustained improvement in claudication distance and a reduction in cardiovascular risk. Diabetes mellitus increases the risk and severity of claudication proportional to the duration of affliction. Strict control in combination with weight loss in the obese patient is vital to reduce cardiovascular risk and prevent symptom deterioration.

DRUGS

Medication may be required for diseases associated with arterial disorders, such as hypertension and diabetes; some antihypertensives (particularly β-blockers) may exacerbate claudication. Raised blood lipids require active drug treatment, but even when the lipid profile is normal a statin (HMG-CoA reductase inhibitor) should be prescribed as they may stabilise atherosclerotic plaques and protect against cardiac death independently of baseline serum lipid levels. An antiplatelet agent is also necessary: recent National Institute for Health and Care Excellence (NICE) guidelines recommend 75 mg per day of clopidogrel, or 75 mg per day of aspirin as an alternative. Other agents, such as vasodilators, are unlikely to provide either significant or sustained benefit. Drugs are now available to help with smoking cessation.

TRANSLUMINAL ANGIOPLASTY AND STENTING

Arterial occlusive disease may be treated by inserting a balloon catheter into an artery and inflating it within a narrowed or blocked area **(Figures 56.12 and 56.13)**. This technique is suitable for patients with claudication, rest pain or tissue necrosis **(Figures 56.14 and 56.15)**. Following percutaneous femoral artery puncture under local anaesthetic, a guidewire is inserted and negotiated through the stenosis or occlusion under fluoroscopic control. A balloon catheter is then inserted over the guidewire and positioned within the lesion. The balloon is then inflated at high pressure for approximately 30 seconds and deflated. Satisfactory dilation of the lesion is confirmed by performing an angiogram. Percutaneous transluminal angioplasty (PTA) has proved very successful in dilating the iliac and femoropopliteal segments; the results below the knee are less successful. Long occlusions may be treated by the technique of subintimal angioplasty, where the guidewire crosses the lesion in the subintimal space (in the arterial wall) and a new lumen is created by inflation of the balloon. Complications occur in about 5% of cases and include failure, haematoma, bleeding, thrombosis and distal embolisation; these may impact on the surgeons' ability to perform a subsequent open surgical revascularisation procedure.

If the vessel fails to stay adequately dilated (often caused by elastic recoil of the artery), it may be possible to hold the lumen open using a metal stent **(Figures 56.16 and 56.17)**. This may be introduced on a balloon catheter and expanded by balloon inflation; or alternatively, a self-expanding stent may be used that is contained inside a plastic sheath and deployed by withdrawal of the sheath.

Figure 56.12 Balloon catheter for percutaneous transluminal angioplasty.

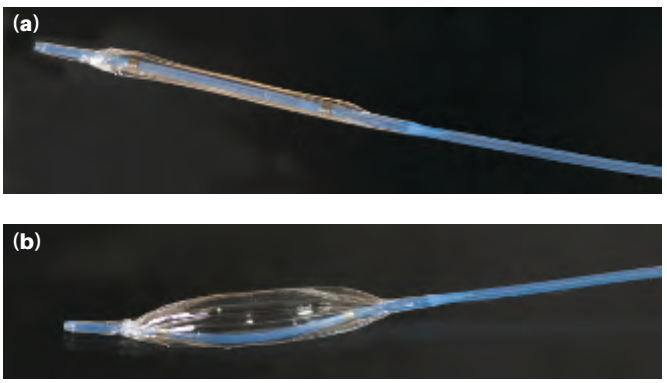

Figure 56.13 **(a)** Catheter balloon deflated; **(b)** balloon inflated.

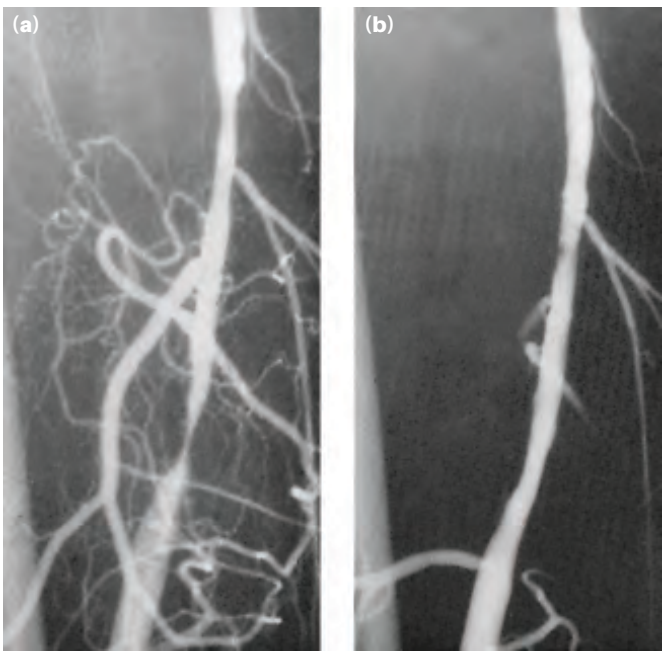

Figure 56.14 **(a, b)** Narrowed superficial femoral artery before and after transluminal angioplasty (courtesy of J McIvor, FRCR, London, UK). The advantage of this technique is that it can be carried out under local anaesthesia using the Seldinger technique of percutaneous arterial puncture, and is therefore especially useful in the treatment of patients who are medically unfit for major surgery.

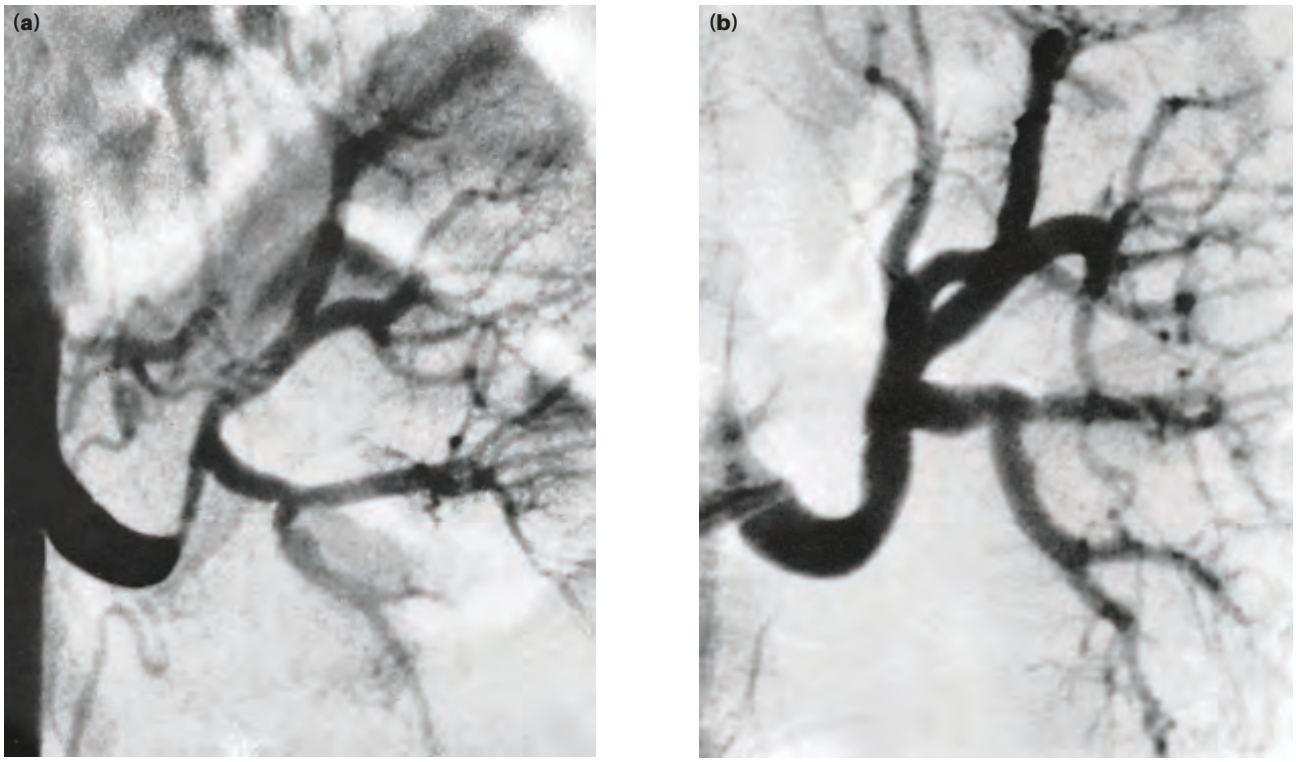

Figure 56.15 Before **(a)** and after **(b)** balloon dilatation of a severely stenosed left renal artery in a 20-year-old woman with uncontrollable hypertension. The blood pressure fell to normal after the procedure. The stenosis was probably due to fibromuscular hyperplasia, but no tissue was available for histological diagnosis.

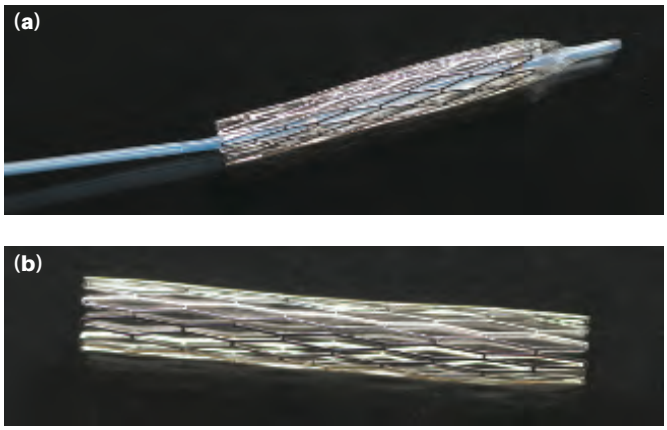

Figure 56.16 **(a)** Balloon catheter carrying stent; **(b)** expanded stent.

Operations for arterial stenosis or occlusion

Site of disease and type of operation

Surgical operations are usually reserved for patients with severe symptoms where angioplasty has failed or is not possible. Aortoiliac occlusion responds well to aortofemoral bypass **(Figure 56.18a)** using a Dacron graft **(Figure 56.19a)**; although the operation carries a perioperative mortality and systemic morbidity rates of about 5% and 15%, respectively. In unfit patients, an axillofemoral bypass is an alternative, although patency rates are less. If only one iliac system is occluded, an iliofemoral or femorofemoral crossover graft may be performed.

Superficial femoral artery disease can be treated by femoropopliteal bypass **(Figure 56.18b)**; long-term graft patency is determined by the quality of inflow and outflow, graft length (whether the distal anastomosis is above or below the knee) and the conduit used for the bypass. Autologous long saphenous vein (LSV) gives the best results and can be used reversed or *in situ* after valve disruption. If the LSV is not available from either leg, short saphenous or arm veins may be used. If no vein is available, a prosthetic polytetrafluoroethylene (PTFE) graft may be employed **(Figure 56.19b)** although patency rates are lower; many surgeons construct the lower anastomosis using a small collar of vein (Miller cuff) between the PTFE and the recipient artery, which may improve patency. Isolated common femoral artery or profunda disease can be treated with endarterectomy and patch (vein or prosthetic) or a short bypass in the groin.

Sometimes, in patients with critical leg ischaemia, the occlusion extends beyond the popliteal artery into the tibial vessels. Limb salvage can be attempted with a femorodistal bypass, with success even more dependent on the state of the run-off vessel and the quality of the vein conduit (minimum diameter 3 mm). The risk of early graft failure with limb loss is high and these long bypasses are only appropriate for limb salvage.

Justin H Miller, vascular surgeon, Royal Adelaide Hospital, Adelaide, SA, Australia.

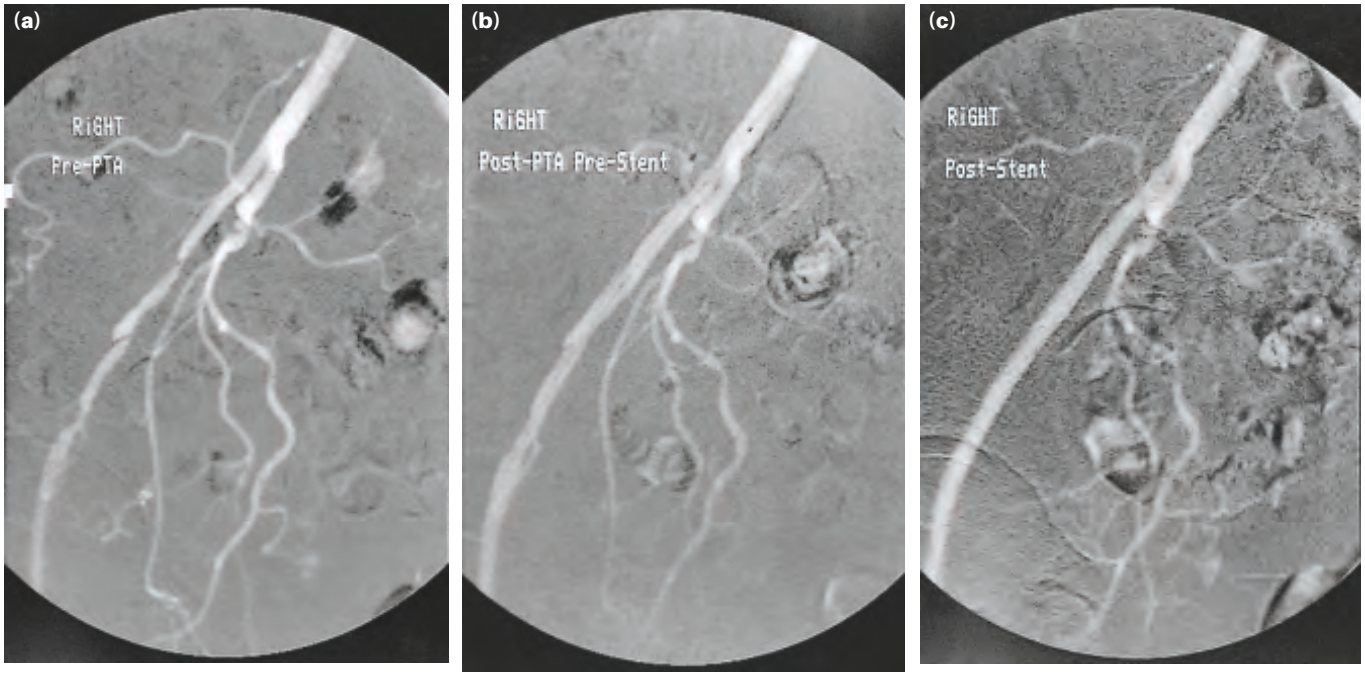

Figure 56.17 **(a)** External iliac artery stenosis before dilatation; **(b)** after dilatation by percutaneous transluminal angioplasty; and **(c)** dilated artery patency assured by stent (courtesy of Johnson and Johnson Interventional Systems, Bracknell, UK, and Dr W. Shaw, Ninewells Hospital, Dundee, UK).

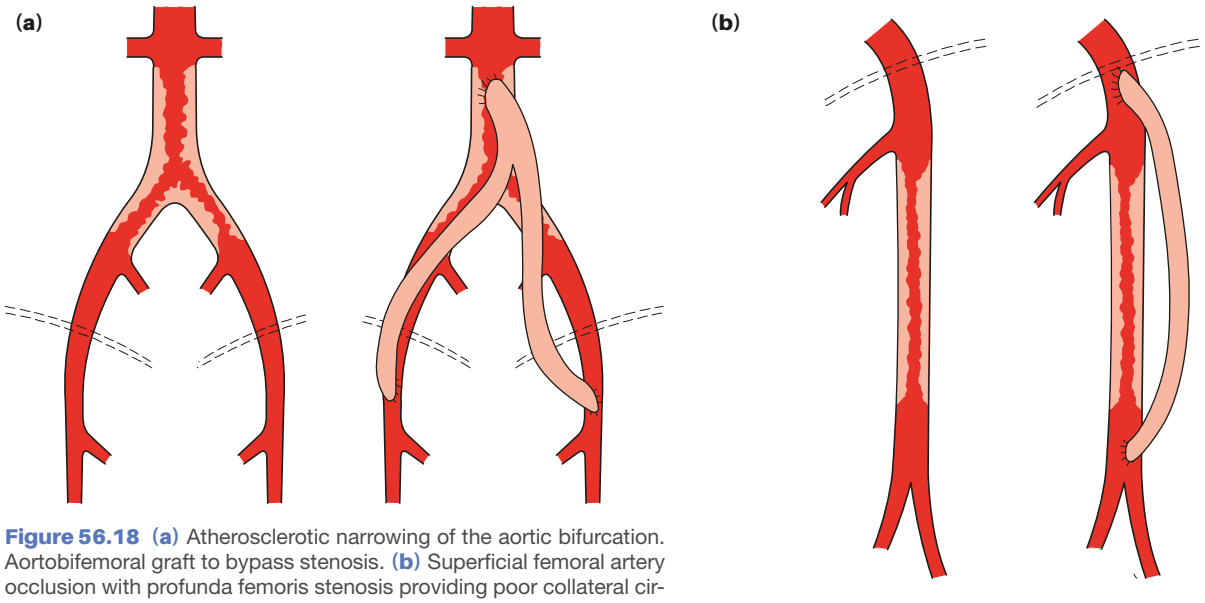

Figure 56.18 **(a)** Atherosclerotic narrowing of the aortic bifurcation. Aortobifemoral graft to bypass stenosis. **(b)** Superficial femoral artery occlusion with profunda femoris stenosis providing poor collateral circulation. Femoropopliteal graft used to bypass the occluded area into good 'run-off' below.

Technical details

For aortofemoral bypass, the aorta should be approached through a midline abdominal incision; a transverse abdominal incision divides the inferior epigastric vessels (important collateral vessel in patients with an occluded aorta) and should be avoided. The common femoral arteries and their branches are exposed through vertical groin incisions. The small bowel is retracted to the right and the posterior peritoneum opened. Retroperitoneal tunnels are made from the aorta to the groins. Heparin (5000 U) is given intravenously and the vessels clamped. A vertical incision is made in the anterior aspect of the aorta to which an obliquely cut, bifurcated Dacron® graft is sutured end-to-side with a non-absorbable suture (polypropylene). The graft limbs are then fed down to the groins where they are anastomosed end-to-side to the common femoral arteries or, if there is evidence of profunda stenosis, to an arteriotomy running from the common femoral vessel down into the profunda. The posterior

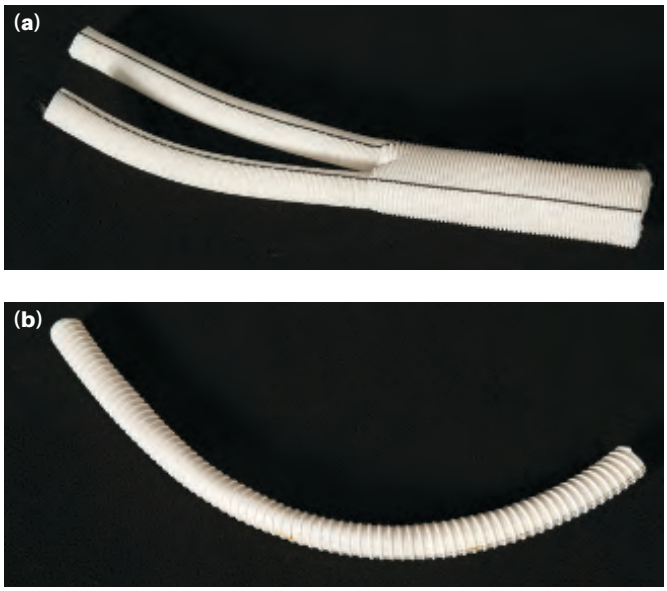

Figure 56.19 **(a)** Dacron® bifurcation graft; **(b)** polytetrafluoroethylene graft.

peritoneum is closed over the Dacron® to prevent adhesion of the graft to bowel, and the abdomen and groin wounds are closed.

For femoropopliteal bypass the popliteal artery above or below the knee is exposed through a medial incision. The common femoral artery is exposed at groin level. The LSV may be used in two different ways. First, it may be excised, its tributaries tied, and the vein used in a reversed fashion so the valves do not obstruct the flow of blood. Alternatively, it may be left in place (*in situ*) and the valves disrupted with a valvulotome. The graft is sutured to the femoral artery proximally and to the popliteal artery distally. Femorodistal bypass involves fashioning the distal anastomosis to a tibial vessel. If no suitable vein is available, prosthetic material (usually PTFE) may be used, with or without a small vein collar (Miller cuff) at its distal end **(Figures 56.20)**.

A femorofemoral crossover graft involves tunnelling a prosthetic graft subcutaneously above the pubis between the groins. An axillofemoral graft is tunnelled subcutaneously between the axillary artery proximally, to reach one or both femoral arteries; the patency rate of an axillobifemoral bypass is better than that of an axillo(uni)femoral bypass.

Results of operation

Long-term results of aortoiliac reconstructive surgery are good, usually marred only by progressive infrainguinal disease. Femoropopliteal surgery is less successful. Immediate postoperative success for vein bypass exceeds 90% but the 5-year patency is around 60%. PTFE bypass yields poorer results than vein bypass, with 5-year success rates of less than 50%. Although the results of femorodistal bypass are even less satisfactory, such surgery can ensure limb salvage in patients who are generally debilitated and whose expected lifespan is limited; long-term patency is less important.

Figure 56.20 **(a)** Completion angiogram of femoropopliteal bypass graft (with Miller cuff). **(b)** Completion angiogram of femorodistal bypass graft *in situ*.

Other sites of atheromatous occlusive disease

The principles of arterial surgery outlined above can be applied at other arterial sites. Carotid stenosis (at the carotid bifurcation in the neck) may cause transient ischaemic attacks (TIAs). These short-lived mini-strokes are often recurrent and cause unilateral motor or sensory loss in the arm, leg or face, transient blindness (amaurosis fugax) or speech impairment. They are caused by distal embolisation of platelet thrombi that form on the atheromatous plaque into the cerebral circulation. They are a warning of impending major stroke. Patients should be assessed with a duplex scan. If a tight stenosis (>70%) is detected, carotid endarterectomy should be offered **(Figure 56.21)**. Current guidelines for carotid endarterectomy are listed in *Summary box 56.2*. This involves clamping the vessels, an arteriotomy in the common carotid artery continued up into the internal carotid artery through the diseased segment, removal of the occlusive disease (endarterectomy) and closure of the arteriotomy, often with a patch. Many surgeons also use a temporary shunt to maintain cerebral blood flow while the carotid system is clamped.

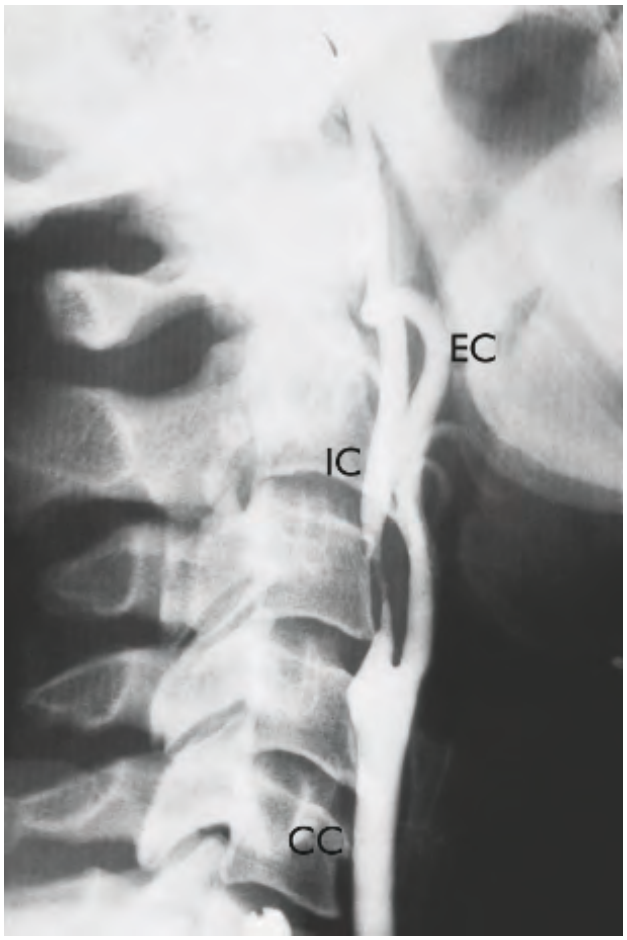

Figure 56.21 Carotid stenosis. A unilateral localised stenosis suitable for operation. CC, common carotid; EC, external carotid; IC, internal carotid.

Summary box 56.2

Indications for carotid endarterectomy in symptomatic patients

70% or greater carotid stenosis and:

- Ipsilateral amaurosis fugax or monocular blindness
- Contralateral facial paralysis or paraesthesia
- Arm/leg paralysis or paraesthesia
- Hemianopia
- Dysphasia (if dominant hemisphere)
- Sensory or visual inattention/neglect

Subclavian artery stenosis may cause claudication in the arm or digital ischaemia from distal embolisation. It may be treated by angioplasty or surgical bypass. Sometimes subclavian artery lesions are associated with neck pathology, such as a cervical rib, which should be removed during arterial repair (see Chapter 57, **Figure 57.37**). Subclavian steal syndrome may occur if the first part of the subclavian artery is occluded. Arm exercise causes syncope because of reversed flow in the vertebral artery leading to cerebral ischaemia. It can be treated by angioplasty or surgery and is rare.

Mesenteric artery occlusive disease may cause pain after eating (intestinal angina) and weight loss. In general, two of the three enteric vessels (coeliac axis, superior mesenteric artery, inferior mesenteric artery) must be occluded to produce symptoms and other intestinal disorders must be excluded before treatment with PTA, endarterectomy or bypass.

Renal artery stenosis may cause hypertension and eventual renal failure. Although it is possible to improve renal blood flow with PTA or surgery, the mainstay of treatment is the use of drugs to control hypertension, diabetes, etc.

GANGRENE

Gangrene refers to death of macroscopic portions of tissue, which turns black because of the breakdown of haemoglobin and the formation of iron sulphide. It usually affects the most distal part of a limb because of arterial obstruction (from thrombosis, embolus or arteritis). Dry gangrene occurs when the tissues are desiccated by gradual slowing of the bloodstream; it is typically the result of atheromatous occlusion of arteries. Wet gangrene occurs when superadded infection and putrefaction are present. Crepitus may be palpated as a result of infection by gas-forming organisms, commonly in diabetic foot problems, and should be considered a surgical emergency with urgent tissue debridement or amputation required.

Separation of gangrene

A zone of demarcation between the truly viable and the dead or dying tissue will eventually appear. Separation is achieved by the development of a layer of granulation tissue that forms between the dead and the living parts. In dry gangrene, if the blood supply of the proximal tissues is adequate, the final line of demarcation appears in a matter of days and separation occurs neatly and with the minimum of infection. If bone is involved, complete separation takes longer than when soft tissues alone are affected, and the stump tends to be conical as the bone has a better blood supply than its coverings. In moist gangrene, the infection and suppuration extend into the neighbouring living tissue, causing the final line of demarcation to be more proximal than in dry gangrene.

If the arterial supply to the proximal living tissue is poor, the line of final demarcation is very slow to form or does not develop at all. Unless the arterial supply can be improved, the gangrene will spread to adjacent tissues or will suddenly appear as 'skip' areas further up the limb. These skip lesions may occur on the other side of the foot, on the heel, on the dorsum of the foot or even in the calf. Infection may also cause gangrene to spread proximally into areas of extensive inflammation. To attempt local amputation in the presence of poor circulation will result in failure and gangrene will reappear in the wound or skin edges.

Treatment of gangrene

How much of a limb or digit can be salvaged depends on the blood supply proximal to the gangrene. Poor circulation can sometimes be improved by radiological or surgical intervention and this may allow a more conservative debridement or distal amputation. However, major limb amputation may be required in the presence of life-threatening sepsis, when the

blood supply cannot be improved or in patients whose limb is useless because of contractures, stroke, etc.

Specific varieties of gangrene

Diabetic gangrene

Diabetic gangrene is usually caused by a combination of three factors – ischaemia secondary to macrovascular disease and microvascular dysfunction, peripheral sensorimotor neuropathy (PSN), which leads to trophic skin changes, and immunosuppression caused by excess of sugar in the tissues, which predisposes to infection (Figure 56.22). Macrovascular disease is atherosclerotic and typically affects the crural vessels with relative sparing of the pedal vessels, whereas increased microcirculatory shunting causes microvascular dysfunction. The PSN is usually sensory in the early phase, classically in a stocking distribution and renders the patients at high risk of soft tissue injury and its subsequent neglect. The PSN may extend to the joints of the foot and ankle, resulting in loss of nociceptive and proprioceptive protective reflexes and a repeated cycle of joint injury and bony destruction. Motor involvement causes an imbalance between flexors and extensor muscle groups of the foot, promoting altered foot biomechanics and abnormal pressure loading and resulting in thick callosities developing on the sole of the foot.

Ischaemia and PSN act synergistically to increase the risk of diabetic foot ulceration and reduce its subsequent healing potential. Superadded infection due to poor wound care can spread rapidly and proximally in subfascial planes leading to fulminant foot sepsis, gangrene and death.

Treatment depends on the degree of arterial involvement, which should be investigated and treated rapidly with angioplasty or surgery. The gangrene is treated by drainage of pus, liberal debridement of dead tissue and antibiotics. Unfortunately, a number of patients present with life-threatening systemic upset and should undergo primary amputation.

Bedsores

A bedsore is gangrene caused by local pressure (Figure 56.23). Bedsores are predisposed to by five factors: pressure, injury, anaemia, malnutrition and moisture. They can appear and extend rapidly in immobile patients and in those with debilitating illness. Prophylactic measures must be taken, including the avoidance of pressure over bony prominences by the use of foam blocks or similar, regular turning and nursing on specially designed beds that reduce the pressure to the skin. A waterbed or a ripple bed is sometimes desirable. Skilled nursing and the use of appropriate dressings must prevent maceration of the skin by sweat, urine, faeces or pus.

A bedsore can be expected if erythema appears that does not change colour on pressure. Once pressure sores develop, they are difficult to heal. They should be kept clean and debrided if necessary. Advice from a plastic surgeon should be sought for major lesions; vacuum dressings and rotation flaps can be effective.

Figure 56.22 Diabetic gangrene.

Figure 56.23 Bedsores typically appear over areas exposed to pressure, such as the sacrum and (as in this case) the heel.

Frostbite

Frostbite is caused by exposure to cold. It is seen both in climbers at high altitudes and in the elderly or the vagrant during cold weather (Figure 56.24). Cold injury damages the wall of the blood vessel, which causes swelling, and leakage of fluid together with severe pain. When the pain disappears, a waxy appearance remains; blistering and then gangrene follow. Treatment is gradual rewarming, analgesics and delayed conservative amputation after demarcation of devitalised tissue.

ACUTE ARTERIAL OCCLUSION

Sudden occlusion of an artery is usually caused by an embolus. It may also happen when thrombosis occurs on an atherosclerotic plaque, although the outcome is usually less dramatic because collaterals are likely to have developed in chronic arterial stenosis.

Embolic occlusion

An embolus is an object that has become lodged in a vessel causing obstruction having been carried in the bloodstream from another site. It is often a thrombus that has become detached from the heart or a more proximal vessel. Sources include the left atrium in atrial fibrillation, a left ventricular mural thrombus following myocardial infarction, vegetations on heart valves in infective endocarditis, thrombi in aneurysms and on atherosclerotic plaques. Emboli may lodge in any organ and cause ischaemic symptoms.

Figure 56.24 **(a)** Frostbite of the foot. Note the clear demarcation. **(b)** Frostbite of the middle finger in the same patient. The index finger was lost 2 years before, also from frostbite.

- Arm and leg – pain, pallor, paralysis, pulselessness and paraesthesia (**Figure 56.25**). Acute arterial occlusion due to an embolus differs from occlusion due to thrombosis on pre-existing atheroma; in the latter case a collateral circulation has often built up over time (**Figures 56.26 and 56.27**). It is essential to differentiate between the two, as they require different management.
- Brain – the middle cerebral artery (or its branches) is most commonly affected, resulting in major or minor (TIA) stroke.
- Retina – amaurosis fugax is fleeting blindness caused by a minute thrombus emanating from an atheromatous plaque

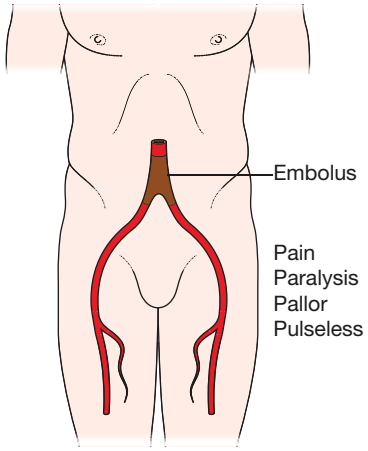

Figure 56.25 The symptoms and signs of embolism (four Ps). The fifth feature, anaesthesia, is often stated to be paraesthesia (the fifth P) but, in truth, complete loss of sensation in the toes and feet is characteristic.

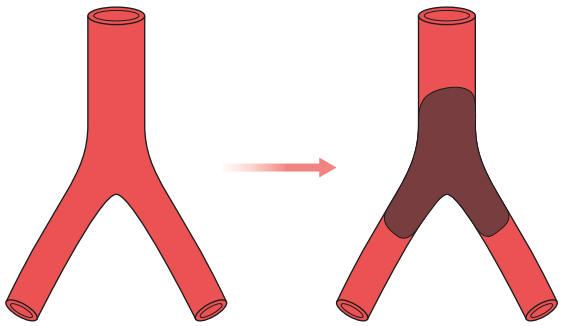

Figure 56.26 Aortic bifurcation embolus. Source of embolus is a recent myocardial infarct or atrial fibrillation. This causes severe, dramatic symptoms.

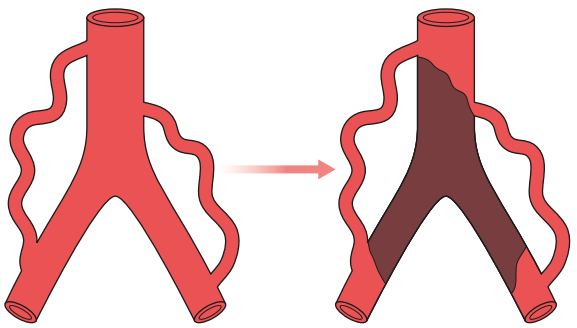

Figure 56.27 Aortic bifurcation thrombosis. No source of embolus but previous claudication worsens but there are no sudden features of distal ischaemia.

in the carotid artery passing into the central retinal artery. Lasting obstruction causes permanent blindness.
- Mesenteric vessels – possible gangrene and perforation of the corresponding loop of intestine.

Acute limb ischaemia

Clinical features

Embolic arterial occlusion is an emergency that requires immediate treatment. Ischaemia beyond 6 hours is usually irreversible and results in limb loss. The leg is often affected, with pain, pallor, paralysis, loss of pulsation and paraesthesia (or anaesthesia) (Figure 56.25). The limb is cold and the toes cannot be moved, which contrasts with venous occlusion when muscle function is not affected. The diagnosis can be made clinically in a patient who has no history of claudication and has a source of emboli, who suddenly develops severe pain or numbness of the limb, which becomes cold and mottled. Movement becomes progressively more difficult and sensation is lost. Pulses are absent distally but the femoral pulse may be palpable, even thrusting, as distal occlusion results in forceful expansion of the artery with each pressure wave despite the lack of flow. A similar picture will occur in the arm with a brachial embolus.

Treatment

Because of the ensuing stasis, a thrombus can extend distally and proximally to the embolus. The immediate administration of 5000 U of heparin intravenously can reduce this extension and maintain patency of the surrounding (particularly the distal) vessels until the embolus can be treated. The relief of pain is essential because it is severe and constant. Embolectomy and thrombolysis are the treatments available for patients with limb emboli.

Embolectomy

Local or general anaesthesia may be used. The artery (usually the femoral), bulging with clot, is exposed and held in silastic vessel loops. Through a transverse incision the clot begins to extrude and is removed, together with the embolus (Figure 56.28), with the help of a Fogarty balloon catheter. The catheter, with its balloon tip, is introduced both proximally and distally until it is deemed to have passed the limit of the clot. The balloon is inflated and the catheter withdrawn slowly, together with any obstructing material (Figure 56.29). The procedure is repeated until bleeding occurs. An angiogram may be performed in the operating theatre at the end of the procedure to ensure that flow to the distal leg has been restored. Postoperatively, heparin therapy is continued until long-term anticoagulation with warfarin is established to reduce the chance of further embolism.

Figure 56.28 Embolic material removed from the common femoral artery, along with a long distal extension thrombus.

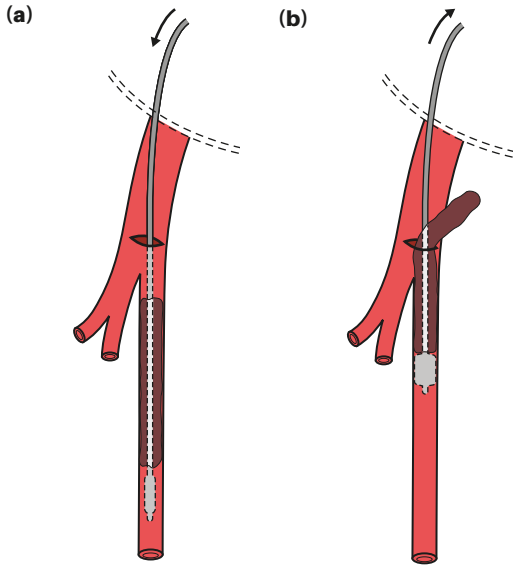

Figure 56.29 **(a)** A Fogarty catheter is inserted through an arteriotomy in the common femoral artery and fed distally down the superficial femoral artery and through the embolus. **(b)** The balloon is inflated and the catheter withdrawn, removing the embolus; the deep femoral and iliac arteries are similarly treated.

Thrombolysis

If ischaemia is not so severe that immediate operation is essential, it may be possible to treat either embolus or thrombosis by intra-arterial thrombolysis (Figure 56.30). At arteriography of the ischaemic limb (usually via the common femoral artery) a narrow catheter is passed into the occluded vessel and left embedded within the clot. Tissue plasminogen activator (tPA) is infused through the catheter and regular arteriograms are carried out to check on the extent of lysis, which, in successful cases, is achieved within 24 hours. The method should be abandoned if there is no progression of dissolution of clot with time. There are several contraindications to thrombolysis, the most important of which are recent stroke, bleeding diathesis and pregnancy; results in those over 80 years old are poor.

Compartment syndrome

In limbs that have been subject to sudden ischaemia followed by revascularisation, oedema is likely. Muscles swell within confined fascial compartments and this can itself be a cause of tissue ischaemia, with both local muscle necrosis and nerve damage due to pressure, and systemic effects such as renal failure secondary to the liberation of muscle breakdown products. Liberal concomitant usage of fasciotomy following revascularisation of a prolonged ischaemic limb is advisable.

Thomas J Fogarty, b.1932, surgeon, University of Oregon Medical School, Portland, Oregon, USA.

Figure 56.30 Angiogram of an occluded popliteal artery before thrombolysis **(a)**, during successful lysis **(b)** and after completion of lysis **(c)**.

The classical clinical picture is that of severe pain out of proportion with clinical findings that worsens with time, despite appropriate analgesia. The patient often complains of numbness/paraesthesia in the distribution of nerves running within the compartment (non-myelinated type C sensory fibres are most sensitive to hypoxia). Examination of the limb reveals a tense compartment with passive flexion and extension of muscles causing pain. The presence of palpable pulses **does not** rule out compartment syndrome.

The treatment is urgent compartment fasciotomy to release the compression. The usual site for fasciotomy is the calf (especially the anterior tibial compartment), but compartment syndrome may occasionally affect the thigh and the arm.

Acute mesenteric ischaemia

Acute mesenteric occlusion may be either thrombotic (following atheromatous narrowing) or embolic. Embolic occlusion results in sudden, severe abdominal pain, with bowel emptying (vomiting and diarrhoea) and a source of emboli present (usually cardiac). Unfortunately, the diagnosis is often only made at laparotomy with widespread infarction of the small and large bowel present; in this situation, it is often fatal. Occasionally, the degree of bowel infarction is more limited; resection of the dead bowel and embolectomy of the superior mesenteric artery or bypass surgery can reduce the otherwise high mortality rate in these patients. A 'second look' laparotomy 24 hours later to check the viability of the bowel may be indicated.

Other forms of embolism

Infective emboli of bacteria or an infected clot may cause mycotic aneurysms, septicaemia or infected infarcts. Parasitic emboli, caused by the ova of *Taenia echinococcus* and *Filaria sanguinis hominis*, may occur in some countries. Tumour cells (e.g. hypernephroma and cardiac myxoma) are rare causes of emboli. Fat embolism may follow major bony fractures. However, venous emboli to the lungs are more common.

Air embolism

Air may be accidentally injected into the venous circulation or sucked into an open vein during head and neck surgery or a cut throat. It may also occur following Fallopian tube insufflation or illegal abortion. If a large volume of air reaches the right side of the heart it may form an air lock within the pulmonary artery and cause acute right heart failure.

The treatment of air embolism is to put the patient in a head-down (Trendelenburg) position to encourage the air to enter the veins in the lower part of the body. The patient should also be placed on the left side to help the air to float to the ventricular apex, away from the ostium of the pulmonary artery. In extreme cases, air may be aspirated from the heart through a needle introduced below the left costal margin.

Therapeutic embolisation

This is used to arrest haemorrhage from the gastrointestinal, urinary **(Figure 56.31)**, gynaecological and respiratory tracts, to treat arteriovenous malformations by blocking their arterial supply and to control the growth of unresectable tumours. Arterial embolisation requires accurate selective catheterisation using the Seldinger technique. A variety of materials may be used, including gelfoam sponge, plastic microspheres, balloons, ethyl alcohol, quick-setting plastics and metal coils.

Friedrich Trendelenburg, 1844–1924, Professor of Surgery successively at Rostock, Bonn and Leipzig, Germany.

AMPUTATION

General

Amputation should be considered when part of a limb is dead, deadly or a dead loss. A limb is dead when arterial occlusive disease is severe enough to cause infarction of macroscopic portions of tissue, i.e. gangrene. The occlusion may be in major vessels (atherosclerotic or embolic occlusions) or in small peripheral vessels (diabetes, Buerger's disease, Raynaud's disease, inadvertent intra-arterial injection). If the obstruction cannot be reversed and the symptoms are severe, amputation is required.

A limb is deadly when the putrefaction and infection of moist gangrene spreads to surrounding viable tissues. Cellulitis and severe toxaemia are the result. Amputation is required as a life-saving operation. Antibiotic cover should be broad and massive. Other life-threatening situations for which amputation may be required include gas gangrene (as opposed to simple infection), neoplasm (such as osteogenic sarcoma) and arteriovenous fistula.

A limb may be deemed a dead loss in the following circumstances: first, when there is relentless severe rest pain without gangrene and reconstruction is not possible – amputation will improve quality of life; second, when a contracture or paralysis makes the limb impossible to use and renders it a hindrance; and third, when there is major unrecoverable traumatic damage.

Summary box 56.3

Indications for amputation

Dead limb

- Gangrene

Deadly limb

- Wet gangrene
- Spreading cellulitis
- Arteriovenous fistula
- Other (e.g. malignancy)

'Dead loss' limb

- Severe rest pain with unreconstructable critical leg ischaemia
- Paralysis
- Other (e.g. contracture, trauma)

Distal and transmetatarsal amputation

In patients with small-vessel disease, typically caused by diabetes mellitus, gangrene of the toes may occur with relatively good blood supply to the surrounding tissues. In such circumstances, local amputation of the digits can result in healing. However, if the metatarsophalangeal joint region is involved, a ray excision is required, taking part of the corresponding metatarsal bone and cutting tendons back. Most surgeons leave the wound open. Early mobility aids drainage provided that cellulitis is not present. For less extensive gangrene, if amputation is taken through a joint, healing is improved by removing the cartilage from the joint surface. A transmetatarsal amputation may be required when several toes are affected but the proximal circulation is adequate. The wound may be closed with a viable long plantar flap (**Figure 56.32**) or left open.

Major amputation

Choice of operation

The major choice is between an above- and below-knee operation. A below knee amputation preserves the knee joint and gives the best chance of walking again with a prosthesis. However, an above knee amputation is more likely to heal and may be appropriate if the patient has no prospect of walking again. If the femoral pulse is absent, the amputation should be above the knee. Unfortunately, the presence of a femoral pulse does not guarantee healing of a below-knee amputation, and sometimes a failed below-knee amputation may require revision to an above-knee procedure.

For above- or below-knee amputations with a good stump shape, it is possible to hold a prosthesis in place simply by suction, without any cumbersome and unsightly straps. The stump should be of sufficient length to give the required leverage, i.e. not less than 8 cm below the knee (preferably 10–12 cm) and not less than 20 cm above the knee.

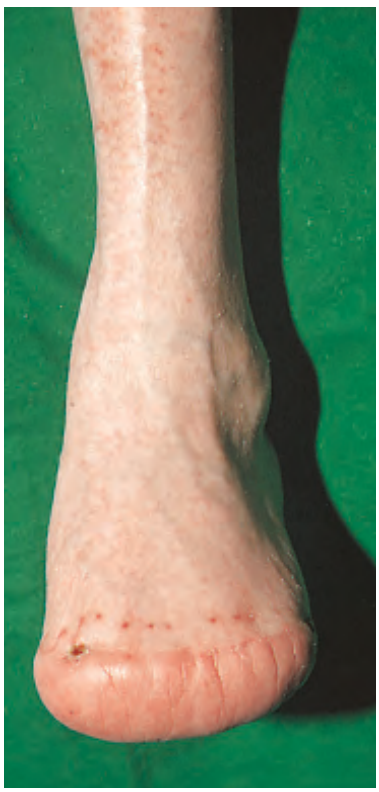

Figure 56.32 Transmetatarsal amputation for diabetic gangrene of the toes.

Leo Buerger, 1879–1943, Professor of Urologic Surgery, New York Polyclinic Medical School, New York, USA, described thromboangitis obliterans in 1908.
Maurice Raynaud, 1834–1881, physician, Hospital Lariboisière, Paris, France, described this condition in 1862.

Below-knee amputation

Two types of skin flap are commonly used: long posterior flap and skew flap (described by KP Robinson). For both methods, the total length of flap must be at least one and a half times the diameter of the leg at the point of bone section.

The long posterior flap technique is the older method and remains the more popular, probably because of its relative simplicity. The proposed incision should be marked carefully: the tibial tuberosity identified and a distance 10 cm measured distally and marked with a sterile marker pen; this is the anterior landmark. The circumference is measured at this landmark with a long suture tie and this length divided into two thirds. The suture is centred over the anterior landmark so that there is one-third either side. The suture ends should be pulled directly posterior; this represents the posterior limit of the transverse incision (**Figures 56.33a–c**). The transverse incision is then marked. From these posterior limits, the incision line is going to extend

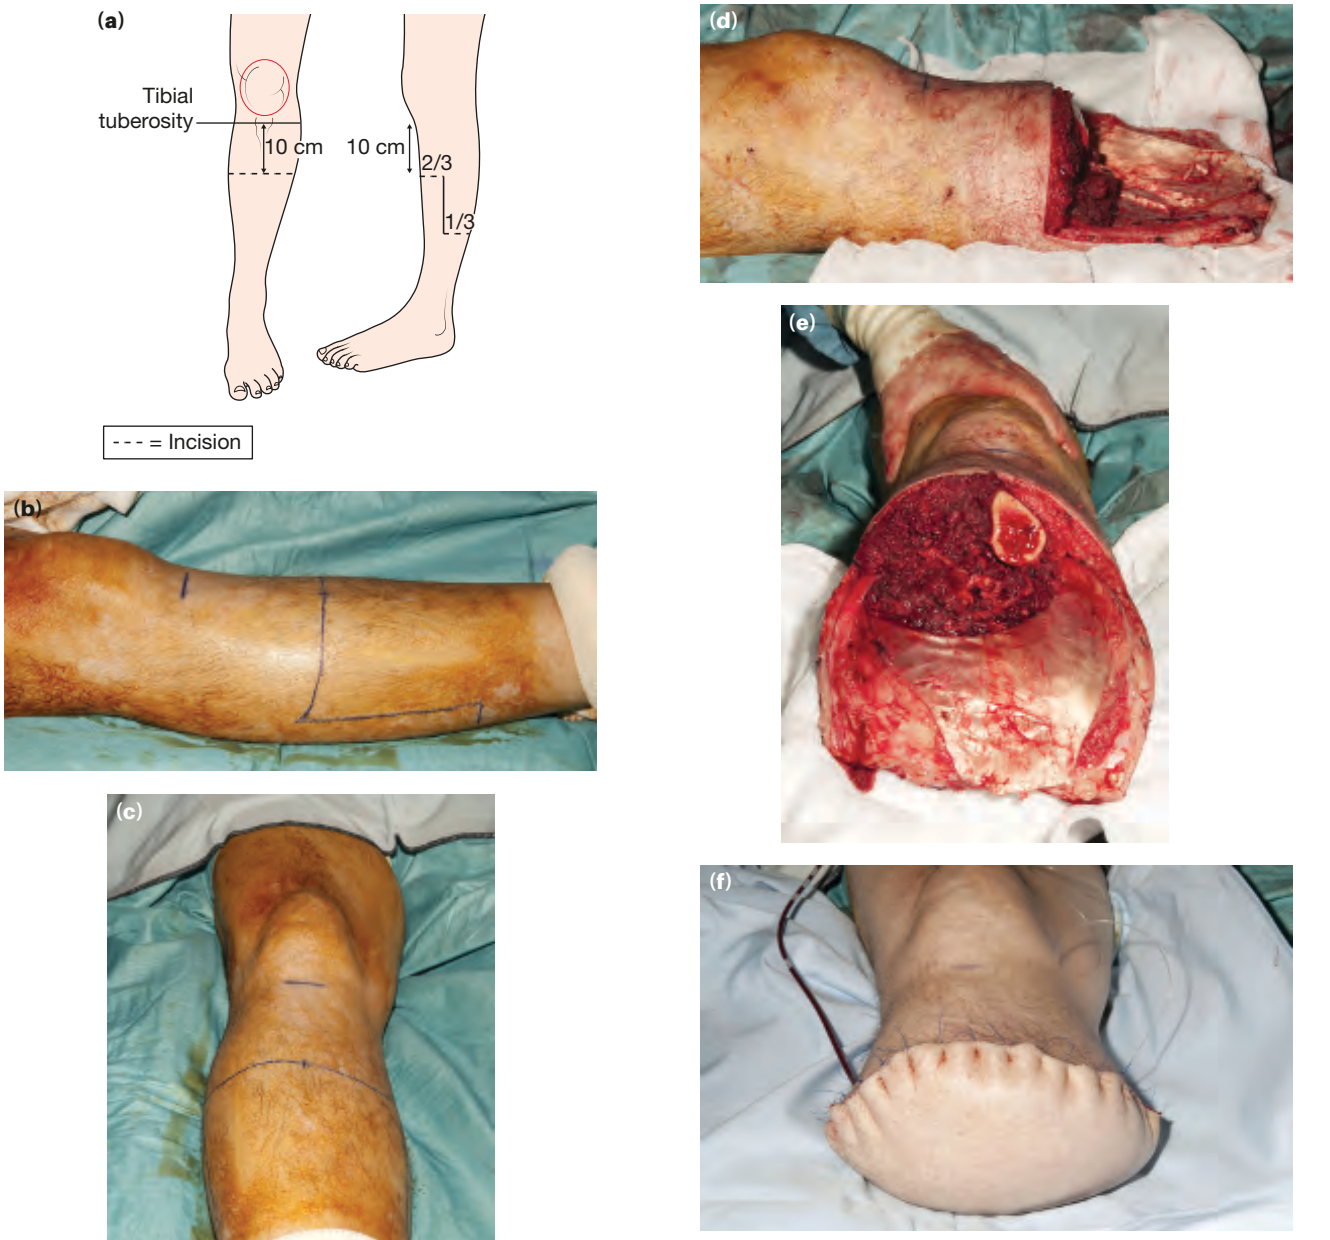

Figure 56.33 **(a)** Schematic representation of operative markings for a long posterior flap below-knee amputation. **(b)** Lateral view of operative markings. **(c)** Anterior view of operative markings. **(d)** Lateral view following removal of the leg. **(e)** Anterior view following removal of the leg. **(f)** Wound closure with suction drain and local anaesthetic infusion 'stump' catheter.

Kingsley Peter Robinson, formerly surgeon, the Westminster Hospital, London, UK.

longitudinally at least half the circumference of the leg at the level of the anterior landmark. The line of incision is now extended transversely around the back of the limb to join the distal extent of the longitudinal incisions. An incision is then made along the previously measured and marked lines through skin, subcutaneous fat and deep fascia. Anteriorly, the incision is deepened to bone and the lateral and posterior incisions are fashioned to leave the bulk of the gastrocnemius muscle attached to the flap, muscle and skin being transected together at the same level.

If bleeding is inadequate, the amputation is refashioned at a higher level. Blood vessels are identified and ligated. Nerves are not clamped but pulled down gently and sharply transected as high as possible. Vessels in nerves are ligated. The fibula is divided 2 cm proximal to the level of tibial division using bone cutters. The tibia is cleared and transected at the desired level, the anterior aspect of the bone being sawn obliquely before the cross-cut is made. This, with filing, gives a smooth anterior bevel, which prevents pressure necrosis of the flap. The long muscle/skin flap is tapered after removing the bulk of the soleus muscle (much of the gastrocnemius may be left unless it is very bulky) **(Figures 56.33d, e)**. The area is washed with saline to remove bone fragments and the muscle and fascia are sutured with an absorbable material to bring the flap over the bone ends. A suction drain is placed deep to the muscle and brought out through a stab incision in the skin; a local anaesthetic infusion 'stump' catheter can be inserted for perioperative pain relief. The skin flap should lie in place with all tension taken by the deep sutures **(Figure 56.3f)**. Interrupted skin sutures are inserted. Gauze, wool and crepe bandages are usually used for the stump dressing.

The skew flap amputation makes use of anatomical knowledge of the skin blood supply. Equally long fascial-cutaneous flaps are developed; they join anteriorly 2.5 cm from the tibial crest, overlying the anterior tibial compartment, and posteriorly at the exact opposite point on the circumference of the leg. After division of bone and muscle in a fashion similar to that described above, the gastrocnemius myoplastic flap is sutured over the cut bone end to the anterior tibial periosteum with absorbable sutures. Finally, drainage and skin sutures are inserted and the limb dressed as for the long posterior flap operation.

Above-knee amputation

The site is chosen as indicated above but may need to be higher if bleeding is poor on incision of the skin. Equal curved anterior and posterior skin flaps are made of sufficient total length. Skin, deep fascia and muscle are transected in the same line. Vessels are ligated. The sciatic nerve is pulled down and transected cleanly, as high as possible, and the accompanying artery ligated. Muscle and skin are retracted and the bone cleared and sawn at the point chosen. Haemostasis is achieved. The muscle ends are united over the bone by absorbable sutures incorporating the fascia. A suction drain deep to the muscle is brought out through the skin clear of the wound. The fascia and subcutaneous tissues are further brought together so that the skin can be apposed by interrupted sutures. Gauze, wool and crepe bandages form the stump dressing.

Through-knee amputation

More recently through-knee or knee disarticulation has regained popularity as an alternative to above-knee amputation if soft-tissue viability permits. This amputation preserves the full length of the femur and patella, providing a long mechanical lever that is controlled by stronger muscles as the line of muscle transection is distal and occurs through fascial tissue, as opposed to thick muscular bellies as is the case with an above-knee amputation. The bulbous nature of the amputation end, initially thought a hindrance for subsequent prosthetic fitting, is now seen as beneficial as it allows for a self-suspending prosthetic that is less likely to rotate compared to an above-knee amputation prosthetic. For the patient unlikely to mobilise with a prosthetic, e.g. elderly patients or patients with bilateral amputations, the increased length of the stump provides better counterweight to the torso, enabling better core stability.

The line of incision is marked preoperatively: equal anterior and posterior semicircular flaps are constructed, with the proximal extent of incision being the joint line laterally and medially, and the distal extent of the anterior flap being 3 cm below the tibial tuberosity and directly posterior to this level for the posterior flap. The anterior incision is carried down to the tibia and the patellar tendon insertion into the tibial tuberosity is identified and released. The patellar tendon is followed proximally to the patella, releasing it from surrounding fascial structures. The anterior knee capsule is entered and the lateral and medial capsule divided along with the collateral knee ligaments. The cruciate ligaments are released from their tibial insertions. The knee is flexed to 90° and the dense posterior capsule divided, paying attention to identify the popliteal artery and vein located immediately behind the capsule. The tibial and peroneal nerves are sharply divided. The medial head of the gastrocnemius muscle along with its vascular pedicle is transected 3 cm below the tibial plateau. The lateral head of the gastrocnemius muscle is divided at the level of the knee joint. The popliteal artery and vein are ligated distal to the medial head of gastrocnemius pedicle origin. The posterior flap incision is now carried through to join the anterior dissection and the limb is removed. The menisci do not need to be removed but can be trimmed to provide a smooth surface. With the hip flexed the patellar tendon is pulled down and sutured to the posterior cruciate ligament with polypropylene, restoring the normal position of the patellar tendon between the femoral condyles. The hamstring muscles are sutured to the posterior capsule. The residual head of gastrocnemius is retroflexed and sutured to the knee capsule, to provide a covering of the femur and reduce synovial fluid drainage. A suction drain is applied to the muscle bed and the skin flaps closed with skin clips or sutures

Postoperative care of an amputee

Opiate pain relief should be given regularly. Care of the good limb must not be forgotten, as a pressure ulcer on the remaining foot will delay mobilisation despite satisfactory healing of the stump. Exercise and mobilisation are of the greatest importance. After surgery, flexion deformity must be

prevented and exercises started to build up muscle power and coordination. Mobility is progressively increased with walking between bars and the use of an inflatable artificial limb, which allows weight-bearing to be started before a pylon or temporary artificial limb is ready (Figure 56.34). Early assessment of the home is part of the programme; it allows time for minor alterations, such as the addition of stair rails, movement of furniture to give support near doors and provision of clearance in confined passages.

Complications

Early complications include haemorrhage, which requires return to the operating room for haemostasis; haematoma, which requires evacuation; and infection, usually in association with a haematoma. Any abscess must be drained and appropriate antibiotics given. Gas gangrene can occur in a mid-thigh stump from faecal contamination. Wound dehiscence and gangrene of the flaps are caused by ischaemia; a higher amputation may be necessary. Amputees are at risk of deep vein thrombosis and pulmonary embolism in the early postoperative period and prophylaxis with subcutaneous heparin is essential.

Later complications include pain resulting from unresolved infection (sinus, osteitis, sequestrum), a bone spur, a scar adherent to bone and an amputation neuroma. Patients frequently remark that they can feel the amputated limb (phantom limb) and sometimes remark that it is painful (phantom pain). The surgeon's attitude should be one of firm reassurance that this sensation will almost certainly disappear with time; amitriptyline or gabapentin may help. Other late complications include ulceration of the stump because of pressure effects of the prosthesis or increased ischaemia.

Figure 56.34 Inflatable artificial limb.

ANEURYSM

General

Dilatations of localised segments of the arterial system are called aneurysms when there is a >50% increase in the diameter of the vessel; below 50% they are termed ectactic. They can either be true aneurysms, containing the three layers of the arterial wall (intima, media, adventitia) in the aneurysm sac, or false aneurysms, having a single layer of fibrous tissue as the wall of the sac, e.g. aneurysm following trauma. Aneurysms can also be grouped according to their shape (fusiform, saccular) or their aetiology (atheromatous, traumatic, mycotic, etc.). The term mycotic is a misnomer because, although it indicates infection as the cause of the aneurysm, it is due to bacteria, not fungi. Aneurysms may occur in the aorta, iliac, femoral, popliteal, subclavian, axillary, carotid, cerebral, mesenteric, splenic and renal arteries and their branches. The majority are true fusiform atherosclerotic aneurysms.

Summary box 56.4

Classification of aneurysms

Wall

- True (three layers: intima, media, adventitia)
- False (single layer of fibrous tissue)

Morphology

- Fusiform
- Saccular

Aetiology

- Atheromatous
- Mycotic (bacterial rather than fungal)
- Collagen disease
- Traumatic

Clinical features

The majority of arterial aneurysms are asymptomatic at the time of identification and are often identified during routine health checks or investigations for other pathologies. All aneurysms can cause symptoms, but aneurysms measuring twice the size of the corresponding normal vessel are at increased risk of complications. The symptoms relate to the vessel affected and the tissues it supplies and occur as a result of compression of surrounding structures, thrombosis, rupture or the release of emboli. Many aneurysms of clinical significance can be palpated and, typically, an expansile pulsation is felt. Transmitted pulsation through a mass lesion, cyst or abscess lying adjacent to a large artery may be mistaken for aneurysmal pulsation. Before incising a swelling believed to be an abscess, it is essential to make sure that it does not pulsate. Finally, a tortuous (and often ectatic) artery, usually the innominate or carotid, may seem like an aneurysm to the inexperienced clinician.

Abdominal aortic aneurysm

Abdominal aortic aneurysm (AAA) is by far the most common type of large vessel aneurysm and is found in 2% of the population at autopsy; 95% have associated atheromatous degeneration and 95% occur below the renal arteries. Most remain asymptomatic until rupture occurs; the risk of rupture increases with increasing size (diameter) of the aneurysm. Asymptomatic aneurysms are found incidentally on physical examination, radiography or ultrasound investigation. A national screening programme for AAA has recently started in England and offers an ultrasound scan to men in their 65th year. Symptomatic aneurysms may cause minor symptoms, such as back and abdominal discomfort, before sudden, severe back and/or abdominal pain develops from expansion and rupture. Rarely, symptoms may occur as a result of erosion or compression of surrounding structures, e.g. aortoenteric fistula, ureteric obstruction.

Asymptomatic abdominal aortic aneurysm

An asymptomatic abdominal aortic aneurysm **(Figure 56.35)** in an otherwise fit patient should be considered for repair if >55 mm in diameter (measured by ultrasonography). The annual incidence of rupture rises from 1% or less in aneurysms that are <55 mm in diameter to a significant level, perhaps as high as 25%, in those that are 70 mm in diameter. Assuming open elective surgery (transabdominal) carries a 5% mortality rate, the balance is in favour of elective operation once the maximum diameter is >55 mm, provided there is no major comorbidity. Regular ultrasonographic assessment is indicated for asymptomatic aneurysms <55 mm in diameter.

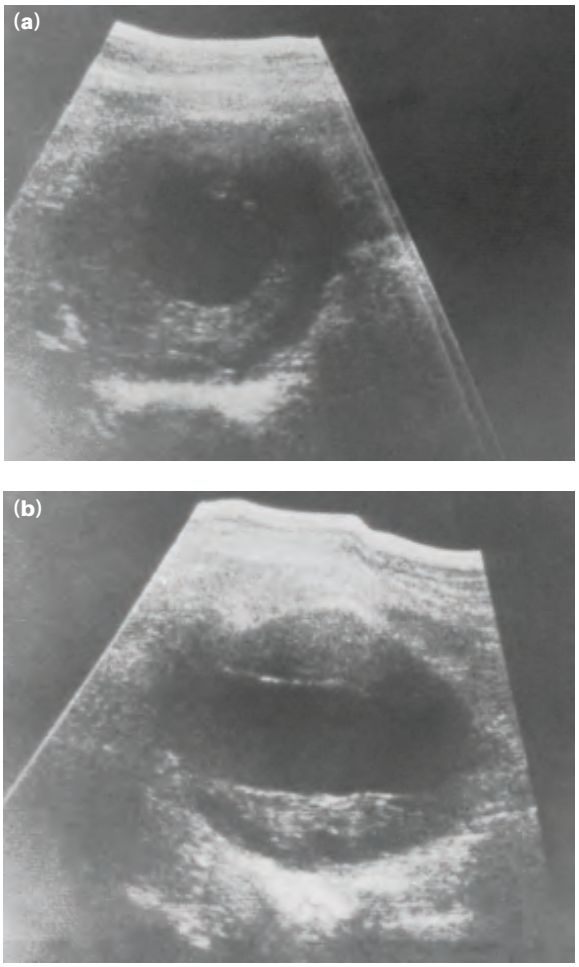

Figure 56.35 Ultrasonogram of an aortic aneurysm showing the large clot-filled sac with a small central lumen (transverse and longitudinal scans).

Investigations

Full blood count, electrolytes, liver function tests, coagulation tests and blood lipid estimation should be performed. Blood should be cross-matched a few days prior to surgery. Many patients now have an anaesthetic assessment and the need for cardiac and respiratory function tests are decided at this time. ECG and chest radiographs are essential; further assessment may include echocardiography or isotope ventriculography, cardiopulmonary exercise testing and spirometry.

The morphology of the aneurysm is best assessed by CT scan **(Figures 56.36 and 56.37)**. 75% of aneurysms are suitable for endovascular (minimally invasive) repair, usually via the femoral arteries in the groin. If lower limb pulses are absent, there may be associated arterial occlusive disease that should be assessed by duplex scanning initially. Further assessment with CT, MR or DSA may be required and angioplasty may be appropriate. The aneurysm is often filled with circumferential clot **(Figure 56.38a)** that produces a falsely narrowed appearance on DSA **(Figure 56.38b)**; this method should not therefore be used to assess aneurysm size.

Choice of operation – open or endovascular repair

Open aneurysm repair

Under general anaesthesia, with the patient lying supine, a full-length midline or supraumbilical transverse incision is

Figure 56.36 Computed tomogram of the abdomen showing an aortic aneurysm. Blood flowing through the thrombus-containing sac is enhanced with contrast agent and appears white.

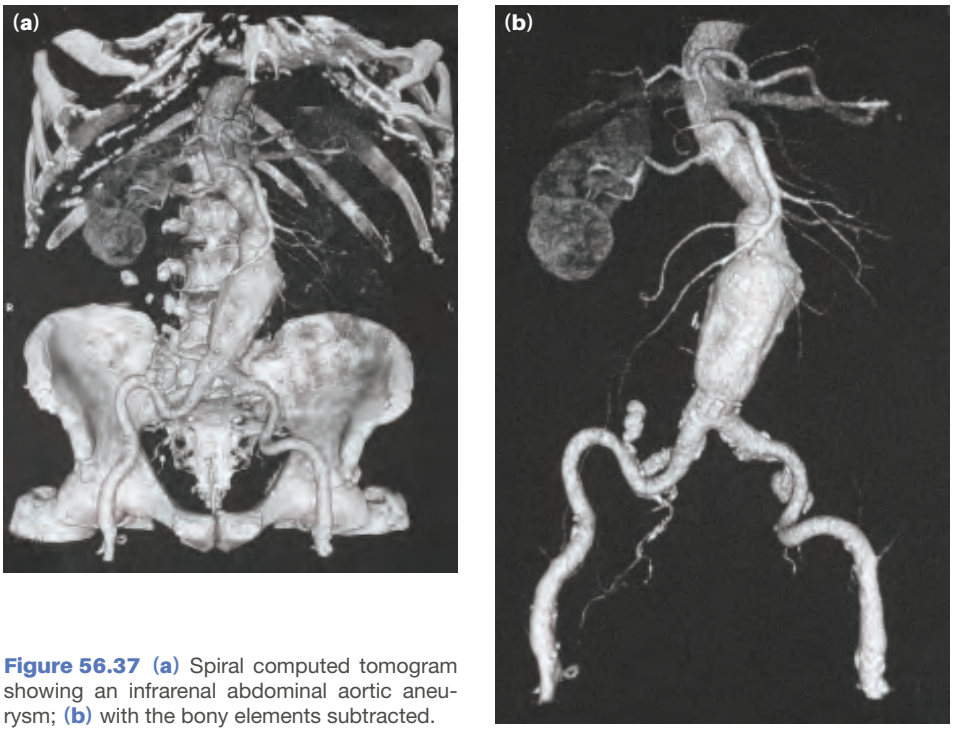

Figure 56.37 **(a)** Spiral computed tomogram showing an infrarenal abdominal aortic aneurysm; **(b)** with the bony elements subtracted.

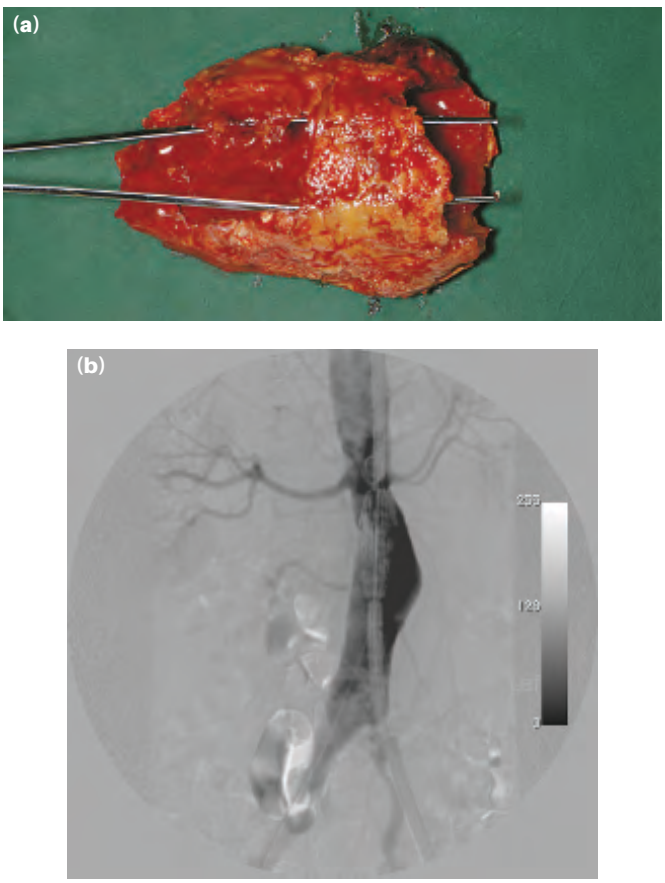

Figure 56.38 **(a)** Thrombus removed from an abdominal aortic aneurysm; this thrombus is the reason an angiogram may give a false impression of aneurysm diameter on digital subtraction angiography **(b)**.

made. The small bowel is lifted to the patient's right and the aorta identified. The posterior peritoneum overlying the aorta is opened and the upper limit of the aneurysm identified. The aorta immediately above the dilatation is exposed; this is generally just inferior to the left renal vein and renal arteries (**Figure 56.39**). The common iliac arteries are then exposed and clamps applied above and below the lesion. Many surgeons give systemic heparin before clamping. The aneurysm is opened longitudinally and back-bleeding from lumbar and mesenteric vessels controlled by sutures placed from within the sac. Upper and lower aortic necks are prepared to which an aortic prosthesis is then sutured end-to-end inside the sac with a monofilament non-absorbable suture (**Figure 56.40**). Clamps are released slowly to prevent sudden hypotension. If haemostasis is satisfactory at this point, the aneurysm sac is closed around the prosthesis to exclude both it and the suture lines from the bowel, to reduce the risk of adherence and potential fistula formation. The abdomen is then closed. Occasionally, when the iliac vessels are also involved with dilatation or severe atheroma, it is necessary to construct an aortobi-iliac or aortobifemoral bypass, rather than use a simple aortoaortic tube.

Endovascular aneurysm repair

Endovascular aneurysm repair (EVAR) is now established in clinical practice and has been shown to reduce mortality compared to open repair over the first 6 years. Currently, about 75% of infrarenal aneurysms are suitable for EVAR, depending on the morphology of the aneurysm assessed by CT scan. Common causes of unsuitability include a short, flared or angulated neck and difficult iliac artery access because of

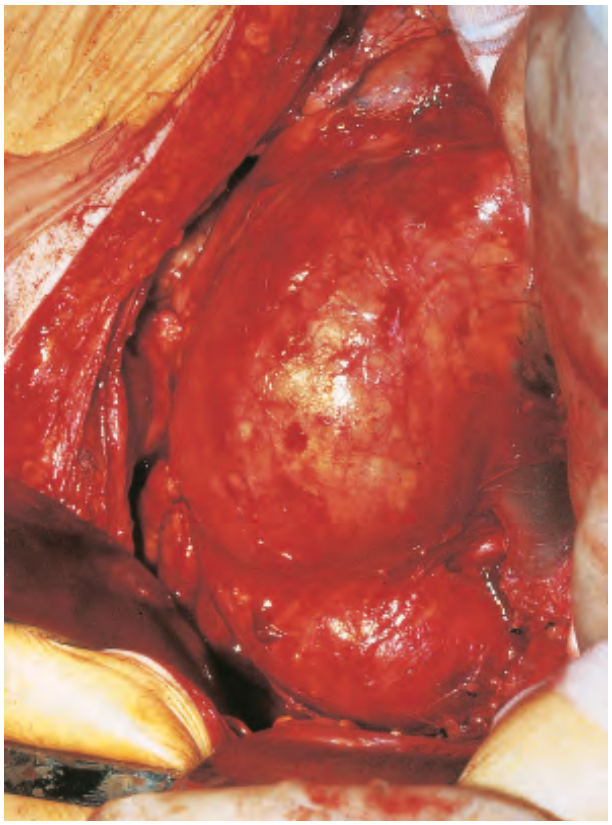

Figure 56.39 Operative appearance of a large, non-ruptured infrarenal abdominal aortic aneurysm.

narrowing or tortuosity. The usual technique is to expose both femoral arteries (under general or local anaesthetic), which allows access to the aorta. Then, under radiological control, guidewires and catheters are used to cross the aneurysm and an angiogram performed to mark the level of the renal arteries.

The endovascular prosthesis (often termed a 'stent graft') is usually made up of three separate parts – a main body **(Figure 56.41a)** and two limbs, which are enclosed in separate delivery catheters **(Figure 56.41b)**. Some types have only two pieces, a main body with ipsilateral limb attached and a separate contralateral limb. The prosthesis is made from Dacron® or PTFE, with integral metallic stents for support. The delivery catheter is inserted in the aneurysm sac and the stent-graft deployed by withdrawal of the delivery system. Most systems now have hooks or barbs to anchor the prosthesis in the aortic wall and some surgeons inflate a moulding balloon catheter in the stent-graft to ensure the hooks and barbs are engaged and a good seal is obtained **(Figure 56.42)**. Although the top edge of the fabric of the stent-graft has to be deployed below the renal arteries (infrarenal fixation), some systems have additional bare metal stents at the proximal end of the main body that lie across the renal arteries to give better support and fixation (suprarenal fixation). Blood flows between the metal struts of the stent into the renal arteries. Success is dependent on a good seal between the stent-graft and the proximal and distal 'landing zones' in the aorta and iliac arteries. Failure to achieve a good seal results in an endoleak, that means that the aneurysm is not excluded from the circulation and may still expand and rupture. Patients who undergo EVAR require

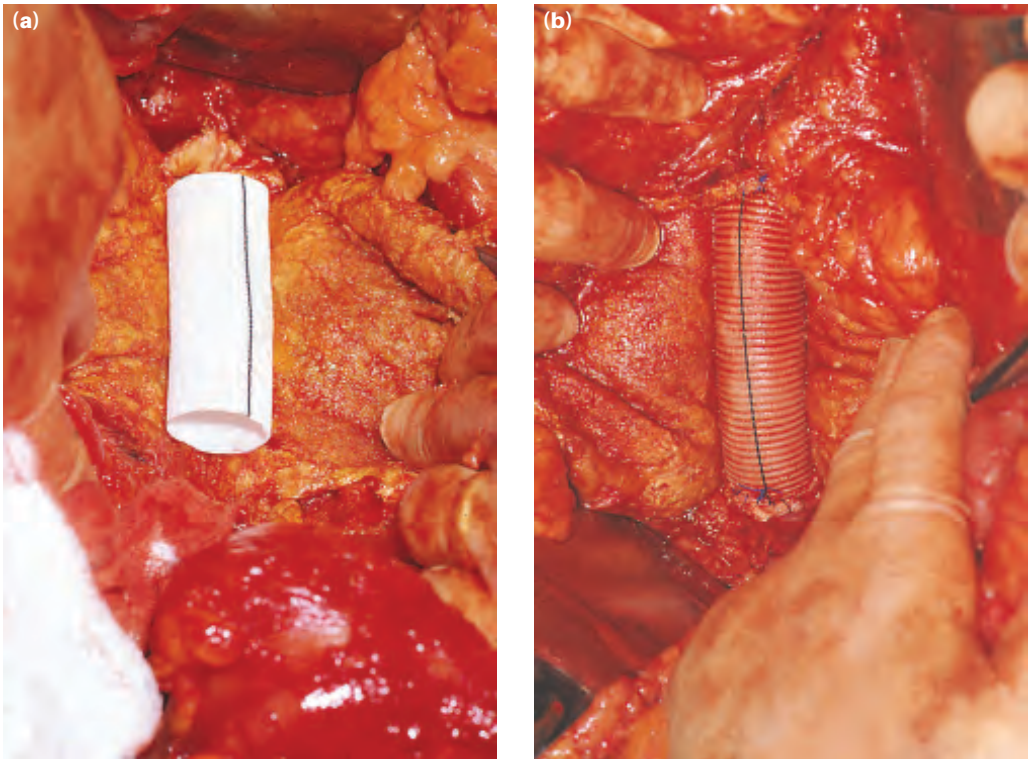

Figure 56.40 **(a)** Aneurysm sac opened. Note that the posterior wall of the aorta immediately above and below the sac is not divided. A Dacron tube graft is laid in place within the sac ready for suture. **(b)** Graft sutured in place and vascular clamps removed.

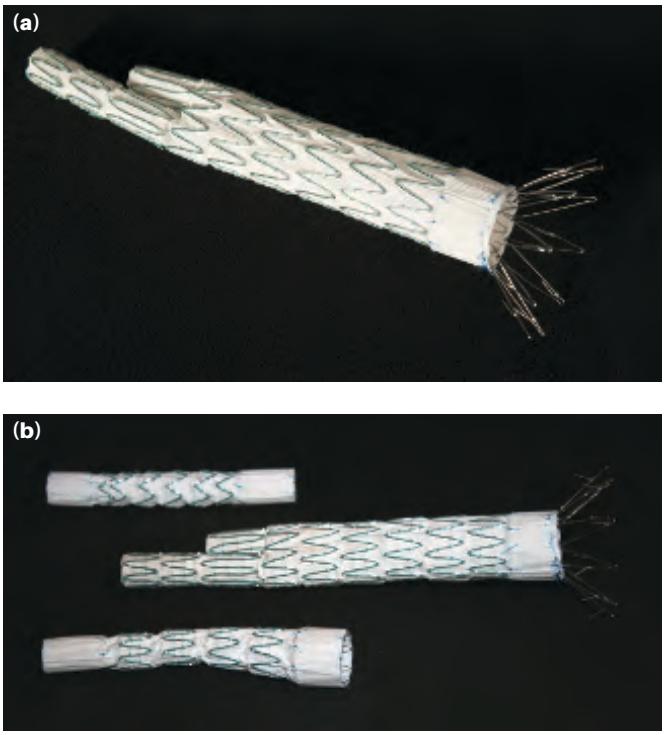

Figure 56.41 **(a)** Endovascular prosthesis main body, with separate limbs **(b)**.

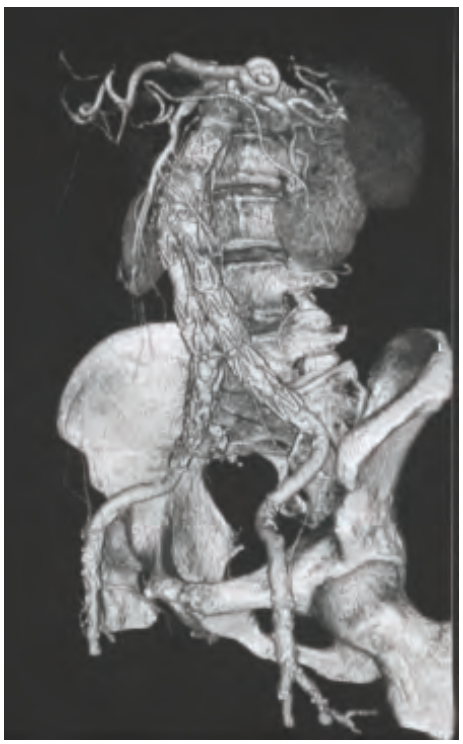

Figure 56.42 Spiral computed tomogram showing an endoluminal aortoiliac 'stent-graft'. The metallic stent structure is clearly observed.

life-long follow-up and surveillance with duplex or CT scans to detect endoleak, disconnection of the components and migration of the stent-graft, all of which predispose to late rupture (**Figure 56.43**).

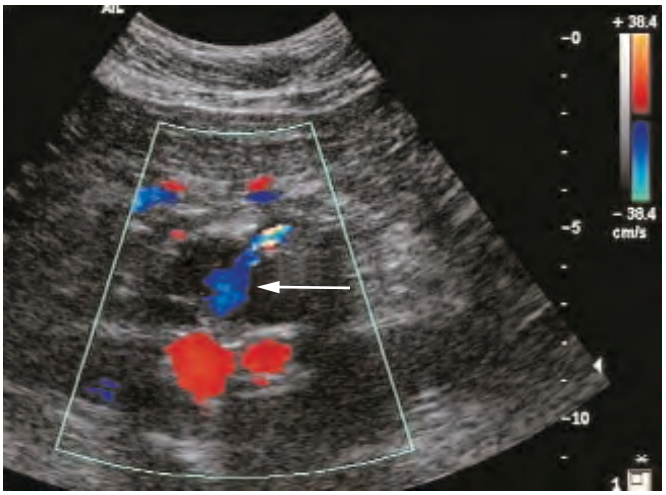

Figure 56.43 Duplex ultrasound scan post endovascular aneurysm repair (EVAR), showing the aortic sac in cross-section and two limbs of EVAR (red ovals). There is a type II endoleak from the inferior mesenteric artery, with blood flowing retrogradely into the aneurysm sac (arrow)

Ruptured abdominal aortic aneurysm

Abdominal aortic aneurysms can rupture anteriorly into the peritoneal cavity (20%) or posterolaterally into the retroperitoneal space (80%). Less than 50% of patients with rupture survive to reach hospital. Anterior rupture results in free bleeding into the peritoneal cavity; very few patients reach hospital alive. Posterior rupture, on the other hand, produces a retroperitoneal haematoma (**Figure 56.44**). Often a brief period ensues when a combination of moderate hypotension and the resistance of the retroperitoneal tissues arrests further haemorrhage and may allow transport to hospital. The patient may remain conscious but in severe pain. If no operation is performed, death is virtually inevitable. Operative mortality is around 50% and the overall combined mortality (community and hospital) is around 80–90%.

Ruptured abdominal aortic aneurysm is a surgical emergency; it should be suspected in a patient with the triad of severe abdominal and/or back pain, hypotension and a pulsatile abdominal mass. If there is doubt about the presence of an aneurysm an ultrasound scan may help, but this **cannot** diagnose rupture. CT scanning should be used to establish the diagnosis and to determine whether an endovascular repair is possible.

Good venous access is needed for infusion of saline or volume expanding fluids, but the systolic blood pressure should not be raised any more than is necessary to maintain consciousness and permit cardiac perfusion (<100 mmHg). Many surgeons now adopt a policy of permissive hypotension, where fluids are withheld if the patient is conscious (and cerebral perfusion is therefore adequate) in order to avoid provoking further uncontrolled haemorrhage. After CT scanning, the patient should be transferred immediately to an operating theatre, where a urinary catheter and arterial line are usually inserted. If the patient appears stable, surgery may be delayed

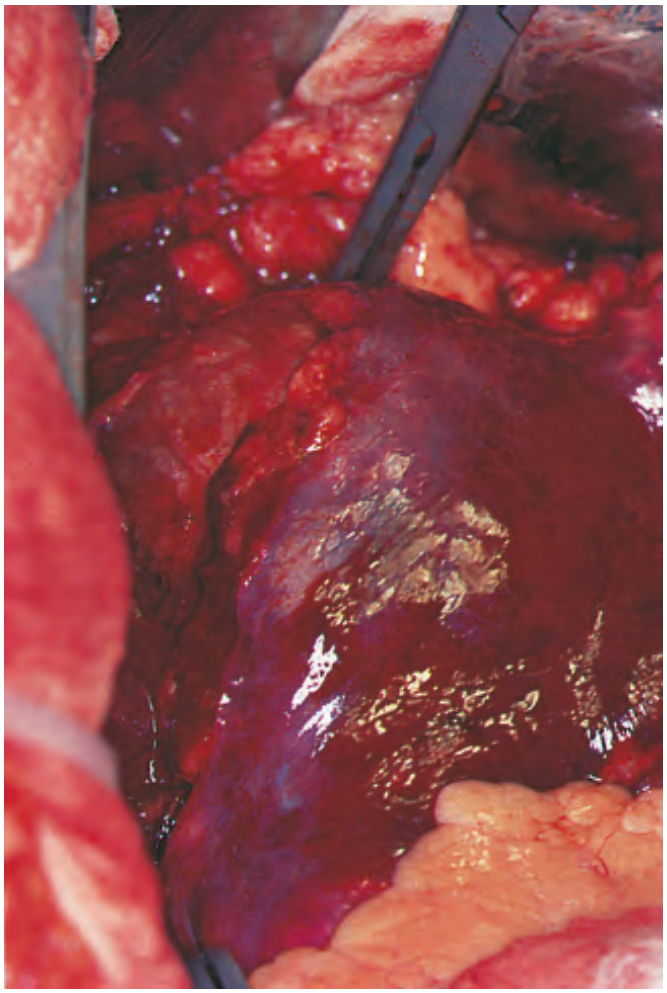

Figure 56.44 The retroperitoneal haematoma of a ruptured aortic aneurysm. The aortic pulsation is palpated through the haematoma at its upper limit and fingers are insinuated on each side of the aorta. With finger control, the upper clamp is positioned and closed on the aorta. The procedure is then as for a planned case. In this illustration, the clamp is at the proximal end of the aneurysm; the haematoma has spread from the left paracolic gutter to encircle the aneurysm and the aortic bifurcation.

until cross-matched blood is available but surgery should commence immediately if haemodynamic instability develops. The abdomen is usually prepared and draped with the patient awake. It is important to remember that the treatment of ruptured aneurysm is operation, not monitoring and resuscitation.

Summary box 56.5

Management of ruptured abdominal aortic aneurysm

- Early diagnosis (abdominal/back pain, pulsatile mass, shock)
- Immediate resuscitation (oxygen, intravenous replacement therapy, central line)
- Maintain systolic pressure, but not >100 mmHg, consider permissive hypotension
- Urinary catheter
- Cross-match 6 units of blood
- Rapid transfer to the operating room

Symptomatic abdominal aortic aneurysm

These patients most commonly present with abdominal and/or back pain but the aneurysm is not ruptured on CT scan. Pain may also occur in the thigh and groin because of nerve compression. Gastrointestinal, urinary and venous symptoms can also be caused by pressure from an abdominal aneurysm. About 3% of all aneurysms cause pain as a result of inflammation of the aneurysm itself (**Figure 56.45**). Finally, a few cause symptoms from distal embolisation of fragments of their intraluminal thrombus. An operation is usually indicated in patients who are otherwise reasonably fit. Pain may be a warning sign of stretching of the aneurysm sac and imminent rupture; surgery should be performed as soon as possible (usually on the next available operating list). The operative mortality of symptomatic aneurysms is usually higher than elective cases.

Postoperative complications

The most common complications after open repair are cardiac (ischaemia and infarction) and respiratory (atelectasis and lower lobe consolidation). A degree of colonic ischaemia

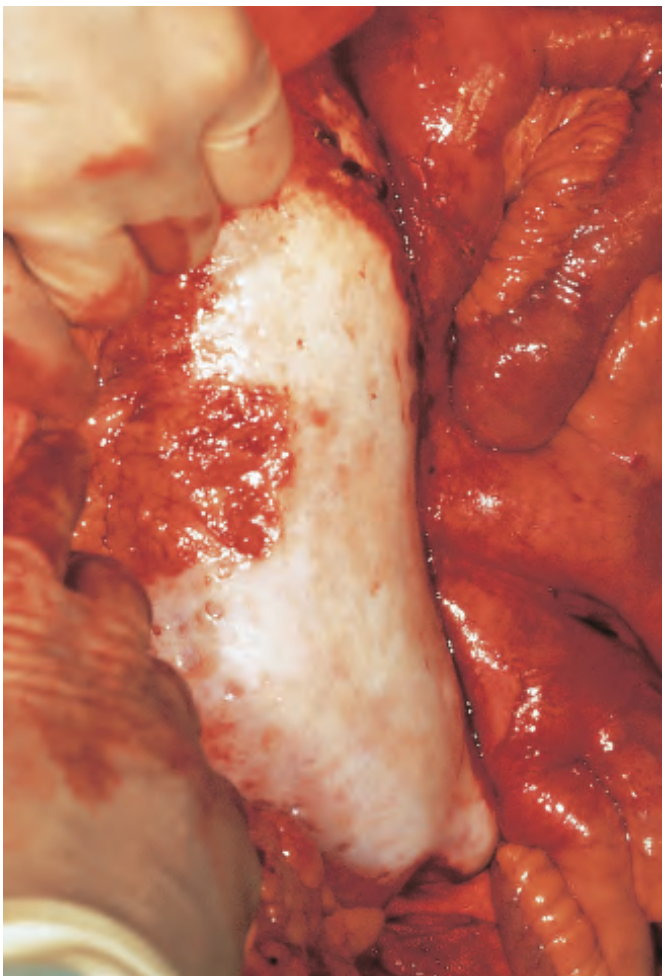

Figure 56.45 An inflammatory abdominal aortic aneurysm. Note the white 'icing' effect. Such lesions can be technically difficult to manage.

because of lack of a collateral blood supply occurs in about 10% of patients, but fortunately this usually resolves spontaneously. Renal failure is an uncommon event after elective procedures but may complicate procedures undertaken for rupture. Renal failure is more likely if there is preoperative renal impairment or considerable intraoperative blood loss. Neurological complications include sexual dysfunction and spinal cord ischaemia. An aortoduodenal fistula is an uncommon but treatable complication of abdominal aortic replacement surgery. It should be suspected whenever haematemesis or melaena occurs in the months or years after operation. Prosthetic graft infection is also uncommon; it may require explantation of the original graft and replacement with an autologous deep vein (superficial femoral vein) graft limb, or removal of the original graft with oversewing of the aortic stump and limb revascularisation by insertion of an axillobifemoral bypass. Both techniques are associated with significant risk of perioperative morbidity and mortality.

Cardiac, respiratory, renal and neurological complications are less common after endovascular repair. However, there are complications that are unique to EVAR such as endoleak, graft migration, metal strut fracture and graft limb occlusion. Life-long surveillance with duplex or CT (together with plain abdominal x-ray for strut fracture) is required to detect endoleak and migration. High-pressure endoleaks may require repeat ballooning or a proximal cuff or distal limb extension to reseal the endograft. Migration may also require extension of the graft. Overall, 10–20% of patients with EVAR will require secondary interventions to treat complications at some future date, although many of the interventions can be performed with a percutaneous approach via the femoral artery in the angiography suite.

Peripheral aneurysm

Popliteal aneurysm

Popliteal artery aneurysm accounts for 70% of all peripheral aneurysms classically diagnosed in males in their seventh decade of life; 50% are bilateral. Examination of the abdominal aorta is indicated if a popliteal aneurysm is found because one-third are accompanied by aortic dilatation.

Popliteal aneurysms present as a swelling behind the knee or with symptoms caused by complications, such as severe ischaemia following thrombosis or distal ischaemia as a result of emboli. The diagnosis is usually confirmed with duplex scanning but assessment of the distal vessels (with CT, MR or DSA) is important prior to repair if the foot pulses are diminished or absent. An asymptomatic aneurysm exceeding 20 mm in diameter should be considered for elective repair, to prevent future complications. Some surgeons would also offer elective repair for smaller diameters if the sac contains thrombus, because of a perceived increased risk of distal embolisation. All symptomatic popliteal aneurysms, including those in which single crural vessel embolisation has occurred, should be considered for repair.

Two techniques for surgical repair may be used: exclusion bypass and inlay repair. An exclusion bypass involves a medial approach to the above- and below-knee popliteal arteries, ligation of the aneurysm and restoration of flow to the foot with a bypass graft using saphenous vein. Many surgeons favour this approach because the anatomy is similar to that for a femoropopliteal bypass and therefore familiar. An inlay graft repair is performed through a posterior approach and has the benefits of allowing free ligation of feeding geniculate branches as well as aneurysmectomy in cases with neurovascular compression. However, the posterior approach limits exposure of the superficial femoral and crural arteries and should only be used when the popliteal aneurysm is confined to the popliteal fossa.

In the acute situation, the presentation is usually with a thrombosed aneurysm and an ischaemic foot; popliteal aneurysms very rarely rupture. Surgery is often unsuccessful because the distal vessels are thrombosed and difficult to clear. Attempts should be made with a Fogarty catheter and intra-arterial thrombolysis. The limb loss rate is high (50%).

Femoral aneurysm

True aneurysm of the femoral artery is uncommon. Complications occur in less than 3% so conservative treatment is generally indicated, but it is important to look for aneurysms elsewhere as over half are associated with abdominal or popliteal aneurysms. Large aneurysms should be repaired. False aneurysm of the femoral artery occurs in 2% of patients after arterial surgery at this site. Local repair may involve reanastomosis of the bypass in the groin under suitable antibiotic cover. However, if infection is the cause, the treatment may involve excision of the infected graft and insertion of a further bypass routed around the infected area. In the latter case, the failure rate is high, and limb loss may be unavoidable. For false aneurysms caused by femoral artery puncture measuring <3 cm, thrombin injection under ultrasound guidance may be successful and avoids surgery. False aneurysms measuring >3 cm are unlikely to be successfully treated by thrombin injection and require open surgical arterial repair with suturing of the puncture site.

Iliac aneurysm

This usually occurs in conjunction with aortic aneurysm and only rarely on its own. When occurring in isolation it is difficult to diagnose clinically, so about half present already ruptured. Open surgery usually involves an inlay graft but some iliac aneurysms may be suitable for EVAR.

Arteriovenous fistula

Communication between an artery and a vein (or veins) may be either a congenital malformation or the result of trauma. Arteriovenous fistulas for haemodialysis access are also created surgically. All arteriovenous communications have a structural and a physiological effect. The structural effect of arterial blood flow on the veins is characteristic; they become dilated, tortuous and thick walled (arterialised). The physiological effect, if the fistula is big enough, is an increase in cardiac output. In extreme circumstances this can cause left ventricular enlargement and even cardiac failure.

A pulsatile swelling may be present if the lesion is superficial. A thrill is detected on palpation and auscultation reveals

a buzzing continuous bruit ('machinery murmur'). Dilated veins may be seen, in which there is rapid blood flow. Pressure on the artery proximal to the fistula reduces the swelling and the thrill and bruit cease.

Duplex scan and/or angiography confirms the lesion, which is noteworthy for the speed with which venous filling occurs.

Management

Treatment is by embolisation. Excision surgery can be advocated only rarely, perhaps for severe deformity or recurrent haemorrhage; the assistance of a plastic surgeon is wise. It is important to realise that ligation of a 'feeding' artery on its own is of no lasting value and is actually detrimental as it may preclude treatment by embolisation.

ARTERITIS AND VASOSPASTIC CONDITIONS

Thromboangiitis obliterans (Buerger's disease)

This is characterised by occlusive disease of small- and medium-sized arteries (plantar, tibial, radial, etc.), thrombophlebitis of the superficial or deep veins and Raynaud's syndrome; it occurs in male smokers, usually under the age of 30 years. Often, only one or two of the three manifestations are present. Histologically, there are inflammatory changes in the walls of arteries and veins, leading to thrombosis. Treatment is total abstinence from smoking, which arrests, but does not reverse, the disease. Established arterial occlusions are treated as for atheromatous disease, but amputations may eventually be required.

Other forms of arteritis

Arteritis occurs in association with many connective tissue disorders, e.g. rheumatoid arthritis, systemic lupus erythematosus and polyarteritis nodosa. This is usually the province of the specialist physician, but the surgeon may be called on to carry out minor amputations. Sympathectomy has previously been used but is usually ineffective.

Temporal arteritis is a disease in which localised infiltration with inflammatory and giant cells leads to arterial occlusion, ischaemic headache and tender, palpable, pulseless (thrombosed) arteries in the scalp. Irreversible blindness occurs if the ophthalmic artery becomes occluded. The surgeon may be required to perform a temporal artery biopsy, but this should not delay immediate steroid therapy to arrest and reverse the process before the ophthalmic artery is involved. The length of the biopsy should be at least 2.5 cm.

Takayasu's disease is an arteritis that obstructs major arteries, particularly the large vessels coming off the aortic arch. It usually pursues a relentless course.

Cystic myxomatous degeneration

This is typified by an accumulation of clear jelly (like a synovial ganglion) in the outer layers of a main artery, especially the popliteal artery. The lesion may narrow the vessel, causing claudication. Duplex scan is the investigation of choice. Decompression, by removal of the myxomatous material, is often all that is required, but the 'ganglion' may recur, necessitating excision of part of the artery with interposition vein graft repair.

Raynaud's disease

This idiopathic condition usually occurs in young women and affects the hands more than the feet. There is abnormal sensitivity in the arteriolar response to cold. These vessels constrict and the digits (usually the fingers) turn white and become incapable of fine movements. The capillaries then dilate and fill with slowly flowing deoxygenated blood, resulting in the digits becoming swollen and dusky. As the attack passes off, the arterioles relax, oxygenated blood returns into the dilated capillaries and the digits become red. Thus, the condition is recognised by the characteristic sequence of blanching, dusky cyanosis and red engorgement, often accompanied by pain. Superficial necrosis is very uncommon. This condition must be distinguished from Raynaud's syndrome, which has similar features (see below). Treatment of Raynaud's disease consists of protection from cold and avoidance of pulp and nail bed infection. Calcium antagonists, such as nifedipine, may also have a role to play and electrically heated gloves can be useful in winter. Sympathectomy has been used in the past but it is either ineffective or its effects are short-lived.

Raynaud's syndrome

Although peripheral vasospasm may be noted in atherosclerosis, thoracic outlet syndrome, carpal tunnel syndrome, etc., the term Raynaud's syndrome is most often used for a peripheral arterial manifestation of a collagen disease, such as systemic lupus erythematosus or rheumatoid arthritis. The clinical features are as for Raynaud's disease but they may be much more aggressive. Raynaud's syndrome may also follow the use of vibrating tools. In this context, it is a recognised industrial disease and is known as 'vibration white finger'.

Treatment is directed primarily at the underlying condition, although the conservative measures outlined above are often helpful. The syndrome when secondary to collagen disease leads frequently to necrosis of digits and multiple amputations. Sympathectomy yields disappointing results and is not recommended. Nifedipine, steroids and vasospastic antagonists may all have a role in treatment. Patients with vibration white finger should avoid vibrating tools.

Acrocyanosis

Acrocyanosis may be confused with Raynaud's disease but it is painless and not episodic. It tends to affect young women

Mikito Takayasu, 1860–1938, Japanese ophthalmologist, described this disease in 1908.

and the mottled cyanosis of the fingers and/or toes may be accompanied by paraesthesia and chilblains.

Cervical sympathectomy

Open cervical sympathectomy was previously performed for vasospastic conditions affecting the hands and to treat palmar (sometimes axillary) hyperhidrosis. The operation is now obsolete, having been replaced by endoscopic transthoracic sympathectomy. Furthermore, it has been increasingly recognised that the vasospastic conditions do not respond to this form of treatment, rendering the endoscopic intervention a therapy that is suitable solely for hyperhidrosis.

Lumbar sympathectomy

Lumbar sympathectomy has been used to treat chronic lower limb ischaemia in the past. Lumbar sympathectomy by open operation has, however, been obsolete for several years and even chemical sympathectomy, its minimally invasive equivalent, can now be regarded as outdated. Chemical sympathectomy requires the injection of small quantities of a sclerosant into the lumbar sympathetic chain under radiographic control.

Chapter 57

Venous disorders

Learning objectives

To understand:

- Venous anatomy and the physiology of venous return
- The pathophysiology of venous hypertension
- The clinical significance and management of superficial venous reflux
- The management of venous ulceration
- Venous thromboembolism

INTRODUCTION

Up to 40% of the adult population in resource-rich countries have diseases of the veins of the leg. This extraordinary prevalence along with the associated impairment in health-related quality of life make it a very important area of surgical practice. Surgical intervention has been revolutionised by the development of endovenous techniques, and level 1 evidence has demonstrated that treatment can be associated with very high clinical- and cost-effectiveness. Despite the considerable importance placed on lower limb function during the management of orthopaedic and arterial diseases, venous diseases are often forgotten or dismissed as cosmetic practice. An understanding of the nature and management of venous disease is critical to address this imbalance and improve the quality of patients' lives.

THE ANATOMY OF THE VENOUS SYSTEM OF THE LOWER LIMB

The venous system of the lower limb can be divided anatomically into the **superficial venous system**, which is located within the superficial tissues and the **deep venous system**, beneath the deep fascia of the leg, accompanying the arterial tree. The superficial veins drain into the deep system, either at junctions or via fascial perforating veins, and the deep veins then return blood to the right atrium of the heart. Venous anatomy is characteristically variable. The terminology used below is consistent with international consensus.

The deep veins of the lower limb (**Figure 57.1a**) include three pairs of venae commitantes, which accompany the three crural arteries (anterior and posterior tibial and peroneal arteries). These six veins intercommunicate and come together in the popliteal fossa to form the popliteal vein, which also receives the soleal and gastrocnemius veins. The popliteal vein passes up through the adductor hiatus to enter the subsartorial canal as the femoral vein, which receives the deep (profunda) femoral vein (or veins) in the femoral triangle before passing behind the inguinal ligament to become the external iliac vein. The internal iliac vein combines with the external iliac vein in the pelvis to form the common iliac vein. The left common iliac vein passes behind the right common iliac artery to join the right common iliac vein on the right side of the abdominal aorta to form the inferior vena cava, which goes on to the right atrium.

Far more anatomical variations exist within the superficial veins of the lower limb, but there are almost always two trunks or axes, the great and small saphenous veins (**Figures 57.1b, c**). These lie superficial to the fascia lata (deep fascia) but deep to the saphenous fascia, in the saphenous 'envelope'.

As the sole of the foot is often placed under significant pressure, the majority of the venous drainage of the foot is into the dorsal venous arch, running in the subcutaneous tissues over the metatarsal heads. The medial end of this arch drains into the first axis: the great saphenous vein (GSV). This is the longest vein in the body and the most frequently affected by superficial incompetence. The GSV passes anterior to the medial malleolus and ascends the leg accompanied by the saphenous nerve in the superficial tissues medial to the tibia, looping posteriorly at the level of the medial condyle of the femur and continuing in the medial thigh. In the groin, it unites with tributaries corresponding to the arterial branches of the common femoral artery, before piercing the cribriform fascia covering the saphenous opening (approximately 2.5 cm below and lateral to the pubic tubercle, but often somewhat higher) and terminates by draining into the common femoral vein (CFV) at the saphenofemoral junction (SFJ). Throughout its course the GSV unites variably with other superficial tributaries. The anterior (accessory) saphenous vein (ASV) is one of the most common. This is often seen originating

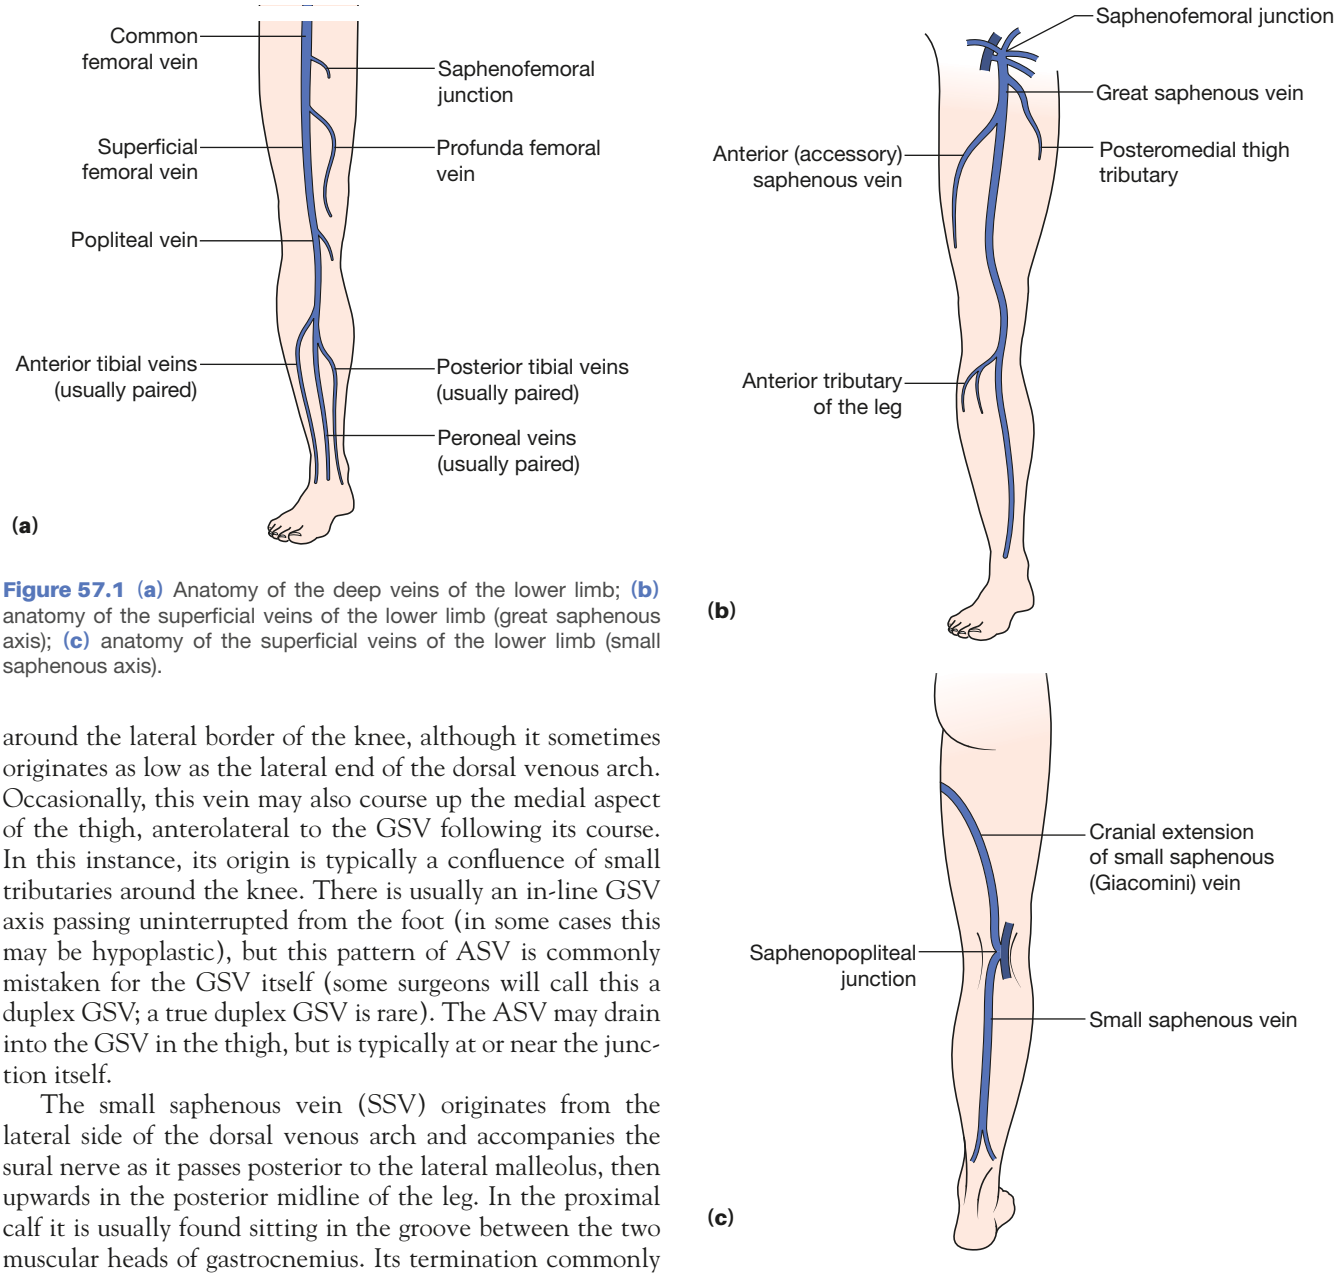

Figure 57.1 **(a)** Anatomy of the deep veins of the lower limb; **(b)** anatomy of the superficial veins of the lower limb (great saphenous axis); **(c)** anatomy of the superficial veins of the lower limb (small saphenous axis).

around the lateral border of the knee, although it sometimes originates as low as the lateral end of the dorsal venous arch. Occasionally, this vein may also course up the medial aspect of the thigh, anterolateral to the GSV following its course. In this instance, its origin is typically a confluence of small tributaries around the knee. There is usually an in-line GSV axis passing uninterrupted from the foot (in some cases this may be hypoplastic), but this pattern of ASV is commonly mistaken for the GSV itself (some surgeons will call this a duplex GSV; a true duplex GSV is rare). The ASV may drain into the GSV in the thigh, but is typically at or near the junction itself.

The small saphenous vein (SSV) originates from the lateral side of the dorsal venous arch and accompanies the sural nerve as it passes posterior to the lateral malleolus, then upwards in the posterior midline of the leg. In the proximal calf it is usually found sitting in the groove between the two muscular heads of gastrocnemius. Its termination commonly occurs by piercing the fascia of the popliteal fossa to drain into the popliteal vein at the saphenopopliteal junction (SPJ). However, this junction is highly variable and the vein may terminate as low as the mid-calf. The SSV may extend cranially beyond the SPJ, in which case it is known as either a cranial extension of the SSV, which terminates by piercing the fascia in the posterior thigh to drain into the deep system, or the Giacomini vein, which communicates with the GSV system occasionally joining the GSV at or about the SFJ. In some cases, the SSV does not terminate at or below the popliteal fossa at all, but continues on as described above.

In the calf and thigh there are a number of valved perforating (communicating) veins that join the superficial to the deep veins at inconstant sites and which allow blood to flow from the superficial to the deep venous system. The most important of these are the direct perforating veins of the medial and lateral calf and the communicating veins around the knee and in the mid-thigh.

VENOUS PATHOPHYSIOLOGY

The purpose of the venous system is primarily to return blood back to the heart so that it can be delivered into the pulmonary circulation. The venous system contains approximately 60% of the total blood volume, with an average pressure of around 5–10 mmHg. Mechanical factors, alongside the autonomic nervous and endocrine systems, control the rate

Carlo Giacomini, 1840–1898, anatomist, Turin, Italy, on his death left his skeleton to the Anatomical Museum in Turin.

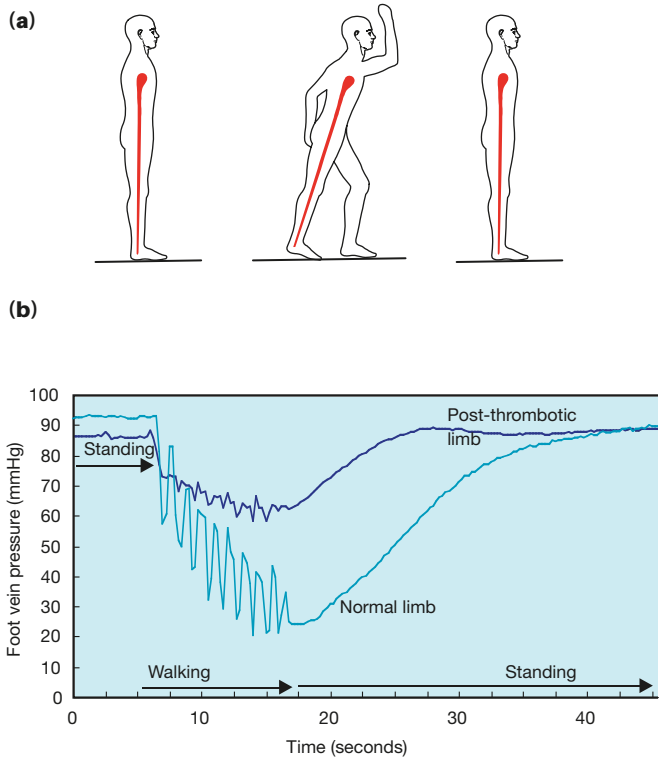

Figure 57.2 (a, b) Effect of exercise on the superficial venous pressure in health and disease.

at which blood is delivered to the right atrium. Through its effects upon myocardial contractility via the Starling mechanism, venous return is one of the factors responsible for determining cardiac output.

Blood enters the lower limb through the femoral arteries before passing through arterioles into the capillaries, which have a pressure of about 32 mmHg at their arterial ends. This pressure is reduced along the course of the capillaries and is approximately 12 mmHg at the venular end of the capillary. The pressure continues to fall in the main veins, and is as low as 5 mmHg at the upper end of the vena cava where it enters the right atrium.

The venous pressure in a foot vein on standing is equivalent to the height of a column of blood extending from the heart to the foot, e.g. approximately 100 mmHg (**Figure 57.2**). To enable blood to be returned against gravity in the standing position a pressure gradient must exist between the veins in the leg and the chest. This gradient is created in two ways. Firstly, the increase in thoracic volume during inspiration decreases intrathoracic pressure. Secondly, the pressure in the veins of the leg is increased by compression by the surrounding muscles (the 'calf muscle pump') and to a lesser extent the tone of the venous wall. The deep veins of the calf are capacious and are joined by blind-ending sacks called the soleal sinusoids, which force blood into the popliteal and crural veins during calf muscle pump contraction, e.g. walking. The foot pump also ejects blood from the plantar veins during walking. As the calf muscles contract, the veins are compressed and the valves only allow blood to pass in the direction of the heart. The pressure within the calf compartment rises to 200–300 mmHg during muscle contraction. Rapid blood flow in the deep veins at junctions and perforators draws blood from the superficial veins, driving this up the deep veins also. During muscle relaxation, the pressure falls and further blood from the superficial veins enters the deep vein. Each time this occurs the pressure falls in the superficial venous compartment until a threshold is reached, when the venous inflow keeps pace with ejection from the deep veins. This is normally around 30 mmHg, a fall of approximately two-thirds of the resting venous pressure. The net reduction in the pressure of the superficial system is dependent on the presence of a pressure gradient between the leg and the thorax and a patent and compliant venous system containing competent valves. An absence of one or more of these results in venous hypertension, which leads to further vein wall damage including loss of compliance, thickening, dilatation and valvular dysfunction. This venous damage goes on to reduce the function of the affected veins, worsening the venous hypertension in a vicious cycle. When exposed to high venous and capillary pressures chronically, the soft tissues of the leg will be damaged, causing a spectrum of damage that become irreversible. The causes of venous hypertension are listed in *Table 57.1*.

TABLE 57.1 Factors causing venous hypertension.

- Pressure gradient dysfunction:
  - Increased abdominal or thoracic pressure:
    - COPD
    - Pregnancy
    - Obesity
    - Large tumour
    - Constipation
  - Decreased calf muscle pump function:
    - Immobility
    - Ankle joint fusion
    - Paralysis
- Dysfunction of the venous system:
  - Venous structural deficit:
    - Valvular agenesis
    - Valvular incompetence
    - Venous dilatation
    - Venous tortuosity
    - Loss of vein wall compliance
    - Loss of venous tone
    - Arteriovenous fistula
  - Venous occlusion:
    - Agenesis
    - Thrombosis
    - Iatrogenic/trauma
  - Venous compression:
    - May–Thurner syndrome
    - Pelvic/abdominal tumour
    - Pelvic/abdominal radiotherapy

COPD, chronic obstructive pulmonary disease.

Ernest Henry Starling, 1866–1927, physiologist, University College, London, UK.
Rudolf Virchow, 1821–1902, pathologist Charite Hospital, Berlin, Germany, was the first to be credited with describing iliac vein compression. It was not until 1957 that May and Thurner (Innsbruck, Austria) clearly described compression of the left common iliac vein by the right common iliac artery.

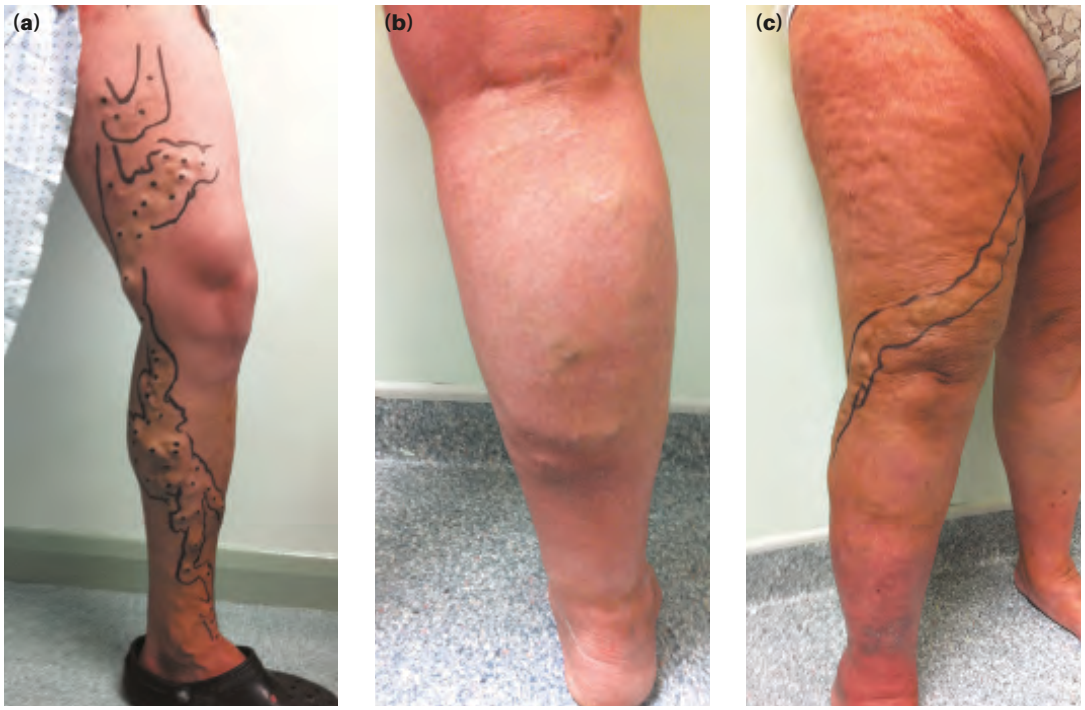

Figure 57.3 Varicose veins: **(a)** left leg varicose veins in the distribution of an incompetent great saphenous vein (marked for intervention); **(b)** right leg varicose veins in the distribution of the small saphenous system with a recent episode of phlebitis; **(c)** varicose veins in distribution of an isolated incompetent anterior accessory saphenous vein with associated gaiter area skin changes.

The majority of patients with venous disease have a problem primarily with the vein wall structure and in most this is confined to the superficial veins. Little is known about the mechanism of initiation of the changes in the vein wall. These changes are complex, but are typified by valvular failure allowing retrograde flow within the vein with gravity (venous incompetence). It is no longer thought that venous incompetence is caused by a primary mechanical valvular failure.

The vein wall changes include inflammatory cell infiltration and activation, dysfunctional smooth muscle cell proliferation, collagen deposition, decreased elastin content and increased matrix metalloproteinases. These effects typically lead to loss of compliance, dilatation, elongation (causing tortuosity) and secondary valvular dysfunction. This process can be initiated anywhere in the venous tree. Secondary varicose veins may develop in patients with post-thrombotic limbs and in patients with congenital abnormalities such as the Klippel–Trenaunay syndrome or multiple arteriovenous fistulae.

The extent and number of incompetent veins governs the extent of the venous hypertension and correlates to the severity of the soft tissue complications seen. Importantly however, neither the reflux burden nor the presence of skin changes, short of ulceration, correlate with the presence or degree of symptoms.

CLINICAL FEATURES OF VENOUS HYPERTENSION OF THE LEG

The following clinical features are commonly seen:

- Varicose vein: subcutaneous dilated vein 3 mm in diameter or larger. They are frequently elongated and tortuous, with intermittent 'blowouts', but are defined by the presence of reflux and may be straight and uniform tubes morphologically **(Figure 57.3)**.
- Telangiectasia (thread veins, spider veins, and hyphen webs): represent tiny intradermal venules less than 1 mm in diameter **(Figure 57.4)**.
- Reticular vein: small dilated 'bluish' subdermal vein 1–2.9 mm in diameter, usually tortuous, can be difficult to distinguish this from a normal subdermal vein in someone with white thin transparent skin.
- Saphena varix **(Figure 57.5)** is a (usually painless) groin swelling apparent on standing.
- Corona phlebectatica (malleolar flare): a fan-shaped pattern of telangiectasia on the ankle or foot. It is thought to be an early sign of advanced venous disease.
- Oedema: increased volume of fluid in the skin and soft tissues of the leg. Commonly starts distally and moves more proximally with increasing venous dysfunction. Classically this is 'pitting oedema', with firm digital pressure leaving an indentation in the soft tissues.

A gaiter is a leather or cloth covering for the lower leg and ankle. The name is derived from the French 'guetre' for the same piece of clothing.
Maurice Klippel, 1858–1942, neurologist, La Salpêtrière, Paris, France.
Paul Trenaunay, b.1875, French neurologist. Klippel and Trenaunay described this condition in a joint paper in 1900.

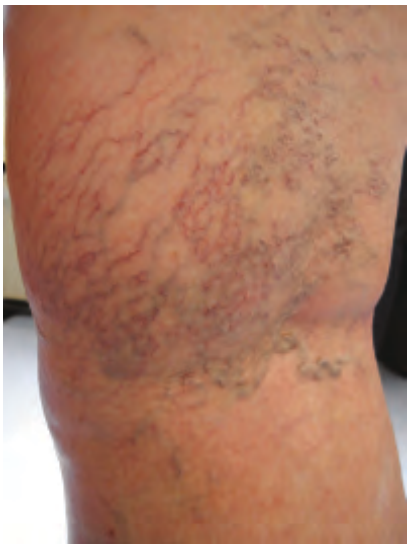

Figure 57.4 Telangiectasia and reticular veins.

Figure 57.5 A saphena varix.

- Eczema: an erythematous dermatitis, often appears minor, although it may be associated with significant itching and discomfort. In extreme cases it may progress to blistering and weeping **(Figures 57.6–57.8)**.
- Pigmentation (haemosiderosis): a brownish discolouration of the skin, usually permanent. It is usually seen around the ankle, but is also seen in proximity to varicose veins and incompetent perforators **(Figures 57.7 and 57.9)**
- Lipodermatosclerosis (LDS): chronic inflammation and fibrosis of the skin and subcutaneous tissues, resulting in a tight, contracted, 'woody' leg on examination. It occasionally results in significant contractures of the Achilles tendon. This is a sign of severe chronic venous disease **(Figures 57.6 and 57.9)**.
- Atrophie blanche: localised areas of atrophic, white skin, often surrounded by telangiectasia and pigmentation. Some authors distinguish this from the white scarring left by ulceration, others do not. Either way, this is a sign of severe chronic venous disease **(Figure 57.6)**.

Figure 57.6 Advanced skin changes – lipodermatosclerosis, eczema and atrophie blanche.

Figure 57.7 Pigmentation (haemosiderosis) and mild eczema.

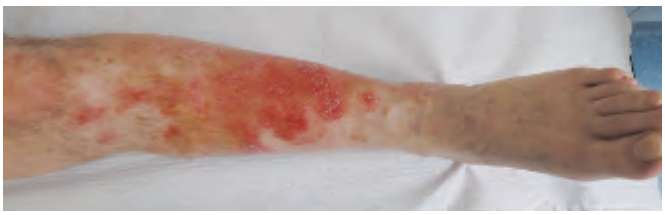

Figure 57.8 Severe eczema.

Figure 57.9 Haemosiderosis and mild lipodermatosclerosis of the calf skin.

- Venous ulcer: full-thickness skin loss, usually around the ankle, which fails to heal spontaneously and is propagated by continuing venous hypertension and the changes associated with chronic venous disease **(Figure 57.10)**.

Figure 57.10 Venous ulcer.

Classification system

The descriptive CEAP (Clinical-aEtiology-Anatomy-Pathophysiology) classification for chronic venous disorders is widely utilised.

For clinical classification:

- C0: no signs of venous disease;
- C1: telangectasia or reticular veins;
- C2: varicose veins;
- C3: oedema;
- C4a: pigmentation or eczema (some include malleolar flare in this category);
- C4b: lipodermatosclerosis or atrophie blanche;
- C5: healed venous ulcer;
- C6: active venous ulcer.

Each clinical class is further characterised depending upon whether the patient is symptomatic (S) or asymptomatic (A), e.g. $C2_S$.

For aetiological classification:

- Ec: congenital;
- Ep: primary;
- Es: secondary (post-thrombotic);
- En: no venous cause identified.

For anatomical classification:

- As: superficial veins;
- Ap: perforator veins;
- Ad: deep veins;
- An: no venous location identified.

For pathophysiological classification:

- Pr: reflux;
- Po: obstruction;
- Pr,o: reflux and obstruction;
- Pn: no venous pathophysiology identifiable.

VARICOSE VEINS

In clinical practice, patients are normally categorised as having 'varicose veins' or 'venous ulcers'. Cases of varicose veins may be uncomplicated or complicated. Complications include superficial thrombophlebitis, bleeding or any of the skin changes listed above. Uncomplicated varicose veins may be asymptomatic or symptomatic.

Epidemiology

The adult prevalence of visible varicose veins is between 30% and 50%. Factors affecting prevalence include:

- Gender: the vast majority of studies report a higher prevalence in women than men, though community prevalence may differ.
- Age: the prevalence of varicose veins increases with age. In the Edinburgh Vein study, the prevalence of trunk varicosities in the age groups 18–24 years, 25–34 years, 35–44 years, 45–57 years and 55–64 years was 11.5%, 14.6%, 28.8%, 41.9% and 55.7%, respectively.
- Ethnicity: does seem to influence the prevalence of varicose veins.
- Body mass and height: increasing body mass index and height may be associated with a higher prevalence of varicose veins.
- Pregnancy: increases the risk of varicose veins.
- Family history: evidence supports familial susceptibility to varicose veins.
- Occupation and lifestyle factors: there is inconclusive evidence regarding increased prevalence of varicose veins in smokers, patients who suffer constipation and occupations that involve prolonged standing.

Symptoms

Varicose veins frequently cause symptoms. Patients describe aching, heaviness, throbbing, burning or bursting over affected areas and sometimes the whole limb. Such symptoms typically increase throughout the day or with prolonged standing, and are relieved by elevation or compression hosiery. Itching is also commonly described, though is more frequent in the presence of complications as is swelling of the ankle. Venous symptoms in the absence of complications can be vague and it may be difficult to ascertain from history alone whether they are truly venous in origin and, therefore, whether treatment will help. A trial of compression hosiery can help as venous symptoms should show some beneficial improvement.

Symptoms can be very severe and interfere with a patient's daily activities such as work, recreation and caring for

children and adults. Such symptoms are independent of the degree of venous incompetence or the presence of complications, including skin changes short of ulceration. Studies have also shown that symptoms are associated with a significant deficit in health-related quality of life, and significant improvements are seen with treatment to remove or ablate the refluxing veins. The maximal benefit is seen in those with uncomplicated symptomatic varicose veins, as skin changes and a proportion of the associated morbidity are frequently irreversible.

Telangiectasia (not associated with malleolar flare) and reticular veins occur very commonly in the absence of significant reflux or obstruction and in the vast majority do not cause any physical symptoms, though cosmetic treatment is commonly sought.

Signs

The presence of tortuous dilated subcutaneous veins is usually clinically obvious. These are confined to the GSV and SSV systems in approximately 60% and 20% of cases, respectively. The distribution of varicosities may indicate which superficial axis is defective; medial thigh and calf varicosities suggest GSV incompetence **(Figure 57.3a)**, posterolateral calf varicosities are suggestive of SSV incompetence **(Figure 57.3b)**, whereas anterolateral thigh and calf varicosities may indicate isolated incompetence of the ASV **(Figure 57.3c)**. Any of the clinical features above may be present. Large dilated veins around the SFJ may present as a (usually painless) lump, emergent when standing and disappearing when recumbent. This is a saphena varix **(Figure 57.5)**. Gentle palpation over the varix during coughing may elicit a thrill, though it may be mistaken for a groin hernia.

Investigation

Tourniquet tests and the use of hand-held Doppler have now largely been abandoned. There is good evidence to support the policy of duplex ultrasound scanning for all patients with varicose veins prior to any intervention. The best clinical results come from clinicians who are personally very skilled in the use of duplex ultrasound and use it to design a bespoke treatment for each individual patient, based upon their unique anatomy.

A high-frequency linear array transducer of 7.5–13 MHz is appropriate for the majority of lower limbs in order to obtain good quality images. The B-mode settings (depth, focal zone, overall gain and dynamic gain) should be optimised to ensure the area of interest is in the centre and occupies the majority of the image, and that the lumen of the vein appears as a dark void in the subcutaneous and deep tissues. The pulsed wave spectral or colour Doppler settings should be optimised for the low-flow velocities encountered within veins. It is conventional to use blue to represent antegrade venous flow towards the heart and red for the reverse. Visible venous flow can be augmented by a calf squeeze.

The aim of the duplex scan in a patient with varicose veins is to establish:

- The presence of reflux in the deep and superficial venous system.
- The exact distribution and extent of reflux in the superficial venous system including affected junctions and perforators.
- The presence of obstruction in the deep venous system.
- The suitability of the incompetent superficial veins for the different treatments available (based upon diameter, extent, tortuosity, saphena varix).
- The presence of thrombus within the superficial veins.
- An indication of a pelvic source of reflux or obstruction.

In order to standardise measurements of venous diameter and reflux, it is recommended that examination of the superficial veins is performed with the patient standing. Superficial or crural vein reflux is defined as retrograde flow in the reverse direction to physiological flow lasting for 0.5 seconds or more. The proximal deep veins require a duration of 1 second or more to be classified as incompetent. Reflux may be elicited by release of a calf or foot squeeze for proximal or calf varicosities, respectively, manual compression over varicosity clusters, pneumatic calf cuff deflation, active foot dorsiflexion and relaxation or the Vasalva manoeuvre.

The patient should stand facing towards the examiner with the leg rotated outwards, heel on the ground and weight on the opposite limb **(Figure 57.11)**. The use of a platform,

Figure 57.11 Patient position for venous duplex examination of the great saphenous system.

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler Principle' in 1842.

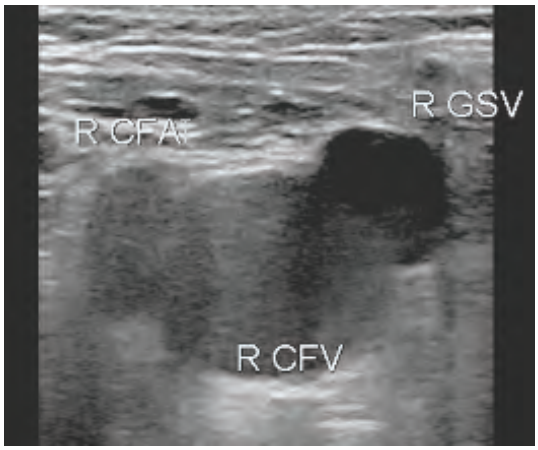

Figure 57.12 'Micky Mouse' transverse B-mode image of the right common femoral vein (CFV) and artery (CFA), great saphenous vein (GSV) and saphenofemoral junction.

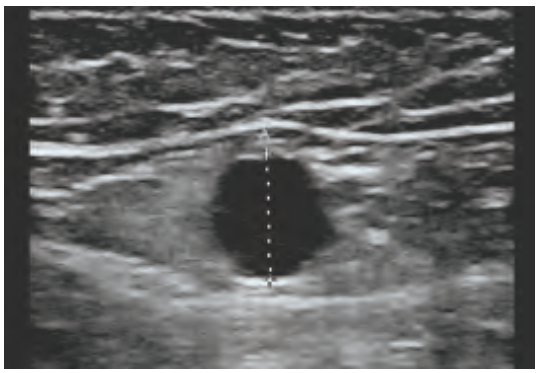

Figure 57.13 'Saphenous eye' transverse B-mode view of the great saphenous vein in fascial compartments of the thigh. The fascial line above the vein is the saphenous fascia. A true great or small saphenous vein will not cross this line, although the fascia may become discontinuous around the knee. The line deep to the vein is the fascia lata, with the muscle beneath.

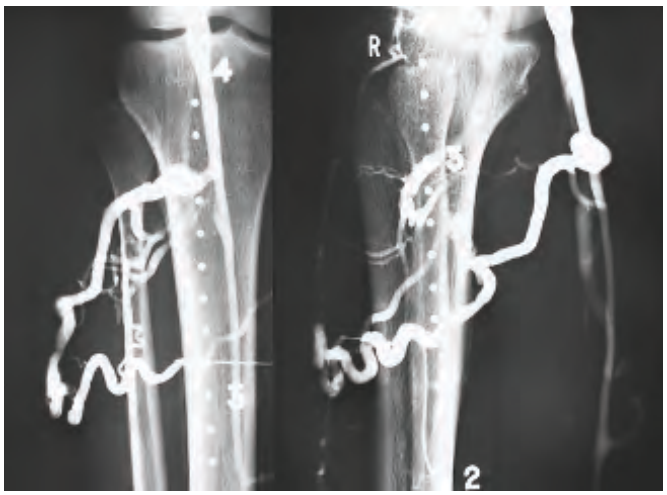

Figure 57.15 Varicogram

ideally with a handle or support bar for the patient and a stool that can drop to a low height, will improve the ergonomic comfort of both the sonographer and the patient. The scan should commence in the groin, using a transverse view to identify the GSV and CFV lying medial to the common femoral artery (the 'Micky Mouse' sign, **Figure 57.12**). SFJ competence is assessed in the transverse view and potential destinations for reflux, including the GSV, the ASV and other major thigh tributaries superficial to the saphenous fascia, are noted. Any indication of a pelvic source of reflux suggests the need for more proximal imaging. The full length of the GSV within its fascial compartment should be examined **(Figure 57.13)**, and its diameter measured if required. The groin is next examined for reflux or obstruction in the CFV, superficial femoral vein, and SFJ using spectral and/or colour Doppler **(Figure 57.14)**.

A loss of phasic flow with respiration in the CFV suggests upstream obstruction and the need for proximal imaging. The presence and competence of thigh and calf perforators should be noted and the crural veins examined for reflux or obstruction. For examination of the SSV and posterior thigh extension of the SSV (Giacomini vein), the patient is positioned facing away, knee slightly flexed, heel on the ground and the weight taken on the opposite leg. If the SPJ is incompetent, the level of the SPJ in relation to the knee crease and whether the SSV joins the popliteal vein posteriorly, medially or laterally is noted if open surgical ligation is to be entertained. In the transverse view, the SSV vein is followed distally, checking its competence and diameter in the proximal, mid and distal calf. Finally, the patency and competence of the popliteal vein is assessed.

Pelvic and iliac veins may be investigated using transabdominal or transvaginal duplex. Very occasionally investigations other than duplex are required, and these may be non-invasive, such as MR venography, or invasive such as contrast venography or intravenous ultrasound (IVUS). The use of varicography has become historical **(Figure 57.15)**.

Management

Many patients with asymptomatic varicose veins do not progress to develop complications, although a significant proportion do, and little is known about whether treating such patients prevents the development of future complications.

There is clear evidence, however, that those with symptoms and/or complications see a significant quality of life benefit from treatment to remove or ablate refluxing superficial veins.

When interventional treatment is planned there are considerable variations in practice and treatment strategies. A detailed description of the nuances, merits and criticisms of the various options is beyond the scope of this chapter; however, a description of the basic treatment modalities available is presented below. An experienced surgeon will have his/her own preferred methods, but will frequently employ several or all methods in chosen circumstances, not infrequently in the same patient.

Compression

Compression hosiery relies on graduated external pressure to improve deep venous return and reduce venous pressures. It may be knee length or thigh length; there is no evidence which length of stocking is more effective and hence below-knee stockings are usually prescribed as they are easier to don and have much better patient acceptance. Compression hosiery are classified according to the pressure they exert: the British classification class 1 stockings exert pressure of 14–17 mmHg, class 2 exert 18–24 mmHg and class 3 exert 25–35 mmHg.

Compression hosiery significantly improves varicose vein symptoms but is not popular with patients, with compliance rates and long-term tolerance being universally poor. There is no evidence to suggest that compression hosiery prevents the occurrence or progression of varicose veins. Furthermore, incorrect application of compression hosiery can have serious consequences (pressure necrosis, tourniquet effects); thus assessment, prescription and application of compression hosiery should be limited to those with the appropriate skills and training. There are level 1 trial data to demonstrate that interventional treatment offers superior improvements in quality of life and is cost-effective. Compression is therefore to be regarded as an adjunct to assessment or treatment, unless by patient choice.

Endothermal ablation

Endothermal ablation technologies replaced surgical ligation and stripping as the gold standard treatment once randomised trials demonstrated that they were marginally safer, have extremely high technical efficacy, offer superior quality of life post procedure (with a rapid recovery) and equivalent improvements in quality of life in the longer term. The techniques are cost effective as they can be performed as an outpatient under local anaesthetic. The basic concept is that a treatment device is inserted into the incompetent axial vein percutaneously. The vein is surrounded by tumescent local anaesthetic solution. This compresses the vein onto the treatment device, emptying it of blood. It also hydro-dissects tissues such as nerves away from the zone of injury. Finally, it acts as a heat sink, mopping up excess thermal energy to prevent remote damage. The treatment device then produces thermal energy that destroys the structure of the vein, resulting in permanent occlusion. Two broad technologies exist: laser and radiofrequency ablation.

LASER ABLATION

Endovenous laser ablation (EVLA) utilises a small flexible glass fibre that is inserted into the vein. Laser energy (typically at a wavelength of 1470 nm) is transmitted down the fibre and is absorbed at the point of treatment at the end of the fibre. Absorption of this radiation results in a vigorous production of thermal energy. The tip of the fibre may be bare, focusing the energy in a very small area; divergent forward firing, spreading the energy over a larger area; or divergent side or radial firing. It is postulated that the latter two designs allow a more even distribution of energy, reducing vein wall perforations that are thought to be associated with postprocedural pain and bruising. There is no clear evidence to support one design over another. This procedure is very good for treatment of any vein that will allow the passage of a guidewire. No technique has reported a higher technical efficacy rate.

The procedure begins with ultrasound-guided marking of the truncal vein to be treated and the site of proposed cannulation. The varicosities are also marked at this stage if concomitant treatment (phlebectomy or foam sclerotherapy) is to be undertaken. The patient is then positioned on the procedure couch in the reverse Trendelenberg position. For the GSV, the patient is supine with the hip of the leg to be treated externally rotated and slightly flexed. A pillow under the contralateral hip/lower back may improve patient comfort. For the SSV the patient is positioned in the prone position. The vein is then cannulated percutaneously under ultrasound guidance, at the lowest point of reflux. Some devices allow passage of the fibre directly through a short sheath, while others use a wire first, allowing passage of a catheter that then carries the laser fibre. The former is slightly faster with fewer steps, the latter allows greater success with more tortuous veins. Accurate positioning of the fibre tip with ultrasound is crucial **(Figure 57.16)**, but the exact location is controversial, with some surgeon positioning the tip several centimetres distal to the junction and others aiming for a flush occlusion. Proponents of the former cite that this strategy protects the deep vein from inadvertent damage and/or thrombosis. Proponents of the latter argue that neoreflux in junctional tributaries is a common pattern of recurrence

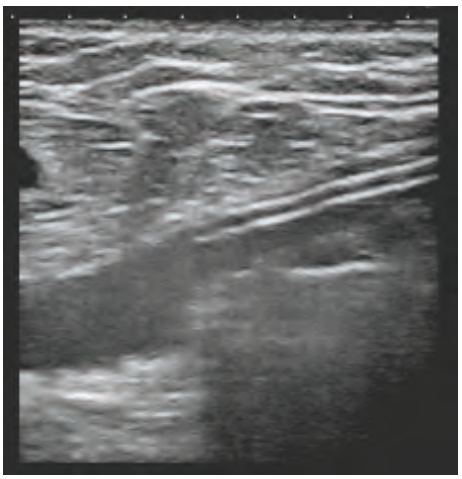

Figure 57.16 Endovenous laser ablation; B-mode image of catheter tip positioning at the saphenofemoral junction.

and that in expert hands the rate of deep vein injury is no different and the thrombosis rate may be lower (presumably as there is minimal patent stump in which to form thrombus). Following the administration of perivenous tumescent anaesthesia (Figure 57.17), the ablation can be performed. Practice varies as to the power of the laser and the withdrawal speed, but commonly an energy delivery of around 60 J/cm is used to achieve a durable closure. There is no clear evidence to guide the optimal power and pullback speed. Following treatment compression is applied, but there is no consensus over the method, degree or duration, and this is true of post-procedural compression with all techniques.

RADIOFREQUENCY ABLATION

Radiofrequency ablation (RFA) uses the same treatment principles, but an electromagnetic current is used to create the thermal energy. A range of different devices have been created but the most popular, which has the most supportive evidence, is the ClosureFast™ device (Medtronic) (Figure 57.18). This device has a wire coil on the end of a treatment catheter. The generator passes an electrical current through the coil until the surrounding temperature reaches 120°C. This is then maintained for a treatment cycle of 20 seconds. The coil is then withdrawn for a set length and another treatment cycle is commenced. Coils of 3 cm and 7 cm are produced, with the latter increasing the speed of treatment, while still being suitable for most anatomies.

There have been a range of studies comparing EVLA and RFA. The evidence is generally equivocal, with both treatments having relative advantages and disadvantages; choice often comes down to personal preference. Both are excellent treatment options and can be applied successfully to the majority of patients.

Advantages in favour of EVLA over RFA include:

- EVLA can ablate any vein that can take a guidewire successfully, with a very low rate of recanalisation. While the RFA catheter can be advanced over a 0.014 guidewire, in practice the relatively inflexible tip may not advance through very tortuous veins. Recanalisation rates may be higher for larger-diameter veins as the energy delivery and penetration are limited.
- A standard EVLA fibre may be used to treat perforators, whereas a specific additional device is required for RFA, increasing costs.

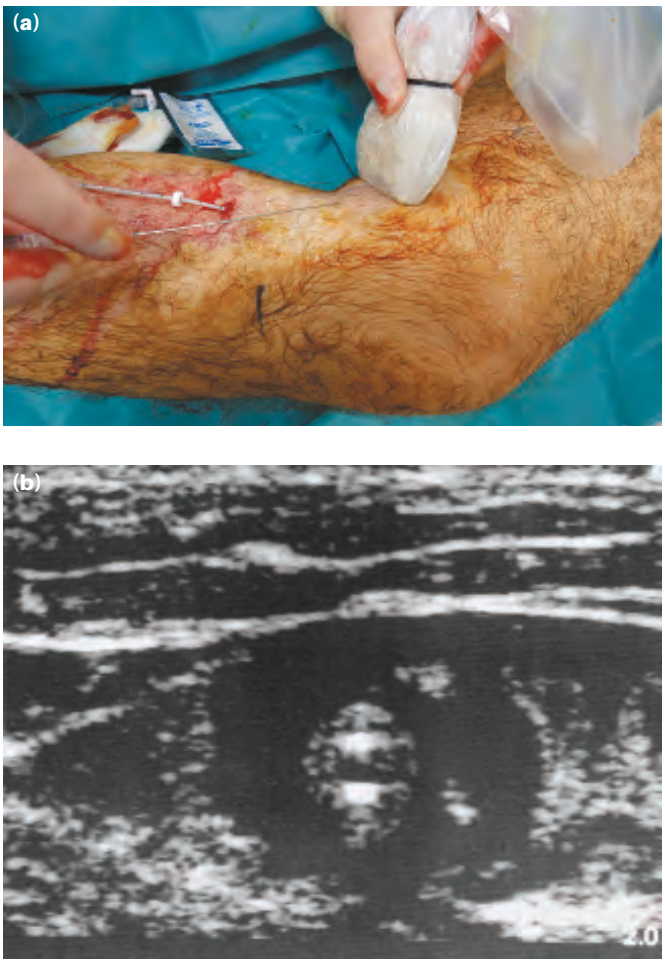

Figure 57.17 (a) Ultrasound-guided infiltration of perivenous tumescent anaesthetic via a long spinal needle. The anaesthetic solution is infiltrated using an electronic foot operated pump; **(b)** ultrasound image of perivenous 'halo' of anaesthetic solution around the vein and catheter in transverse section.

Figure 57.18 Radiofrequency ablation with ClosureFast™ introducing the treatment catheter through a sheath. The distal 7 cm of this device comprises a metal coil.

- Laser fibres are relatively inexpensive to produce, reducing the procedural costs.
- In a catheter-based system, the catheter can be used to deliver targeted foam sclerotherapy, for instance to areas of neovascularisation, prior to the actual laser fibre being inserted.

Advantages in favour of RFA over EVLA include:

- RFA has a standardised treatment protocol that is automated, minimising the uncertainty and learning curve for the ablation portion of the procedure and the possibility of a novice making a mistake with the energy delivery.
- RFA does not require a continuous pullback, again reducing the learning curve. This also frees the surgeon's focus allowing better communication with the patient and indeed, with care, concurrent treatment, e.g. infiltrating local anaesthetic into the tributaries and performing phlebectomy, reducing procedural times.
- RFA does not require laser safety precautions, reducing the administrative burden associated with setting up a service and location and allowing it to be performed in a wider range of settings with minimal adaptations.
- RFA may be associated with a marginal reduction in pain and bruising, athough this has not been shown to impact upon periprocedural quality of life or recovery.

As endothermal ablation treats only junctional and truncal incompetence, debate exists regarding the management of varicosities. These can be managed concomitantly or sequentially by either phlebectomy or sclerotherapy. Concomitant phlebectomy **(Figure 57.19)** results in a more rapid improvement in disease-specific quality of life, and allows the vast majority of patients to complete treatment in a single visit.

Non-endothermal, non-tumescent ablation

Endothermal ablation was a large step forwards in the management of superficial incompetence; however, all techniques require the injection of tumescent local anaesthetic solution and this can be uncomfortable for the patient. Other techniques that avoid injection are being developed.

ULTRASOUND-GUIDED FOAM SCLEROTHERAPY

Sclerotherapy is the original non-endothermal, non-tumescent technique and has been performed for over 100 years. It involves the injection of a sclerosing agent directly into the superficial veins. The most commonly used is sodium tetradecyl sulphate. The direct contact with detergent causes cellular death and initiates an inflammatory response, aiming to result in thrombosis, fibrosis and obliteration (sclerosis). Blood deactivates the action of the sclerosing agent and the doses administered need to be limited to avoid adverse effects, causing a trade-off between poor efficacy and safety. This led to the development of ultrasound-guided foam sclerotherapy (UGFS). The use of foam increases the effective volume of the agent, maximising endothelial contact and displacing any blood that deactivates it.

The procedure commences with the patient standing, and the sites of venous cannulation are selected and marked using ultrasound. With the patient supine, the major venous trunks and superficial varicosities to be treated are then all cannulated using ultrasound guidance prior to any injection **(Figure 57.20)**. Once all injection sites are cannulated the foam can be prepared. The most widely used method is that of Tessari, which utilises two syringes connected using a three-way tap. A 1:3 or 1:4 ratio mixture of sclerosant and air is drawn into one syringe, and is then oscillated vigorously between the two syringes about 10 or 20 times **(Figure 57.21)**. The foam produced in this way is stable for about 2 minutes so it should be injected as soon as it has been made. The leg is then elevated to empty the veins of blood, and injection of foam commences first with superficial varicosities and ends with injection of the GSV or SSV. Only 1 or 2 mL of foam should be injected at a time and the distribution of the foam should be monitored and massaged with the ultrasound probe. When the foam is visualised at the site of junctional incompetence no further foam should be injected. The maximum volume of foam that should be injected at a single session should not exceed 10–12 mL as the incidence of complications is directly related to the volume of foam injected. Compression is then

Figure 57.19 Phlebectomy performed under tumescent anaesthesia following endothermal ablation.

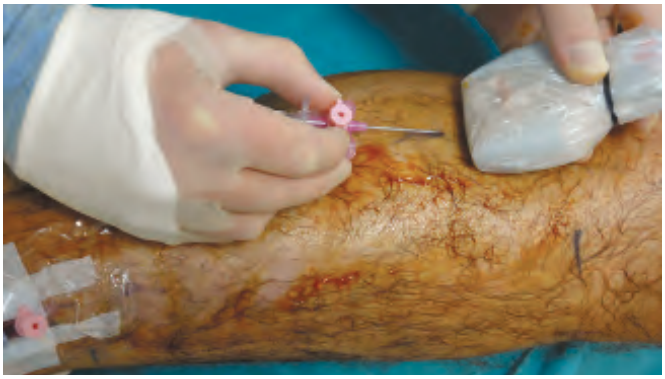

Figure 57.20 Foam sclerotherapy; cannulation of veins during ultrasound-guided foam sclerotherapy.

Lorenzo Tessari, b.1949, physician Trieste, Italy.

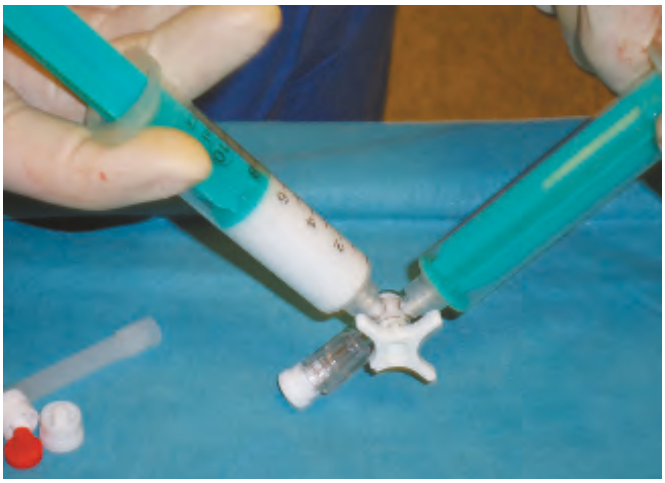

Figure 57.21 Foam sclerotherapy; Tessari method of foam sclerosant preparation.

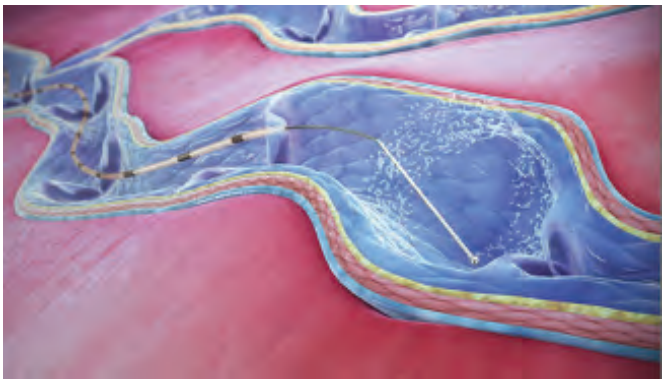

Figure 57.22 Mechanochemical ablation device (reproduced with permission of Vascular Insights).

Figure 57.23 Endovenous glue device (reproduced with permission of Medtronic Inc.).

applied as following endothermal ablation. While it is postulated that compression may have a larger effect upon efficacy for this treatment, practice is not informed by evidence and a wide variation exists.

Outside of a small number of centres, the efficacy of UGFS is significantly worse than for endothermal ablation, leading to high reintervention rates, and the rates of complications such as phlebitis and pigmentation can be high. UGFS does however carry some significant advantages:

- It avoids tumescent anaesthetic and is therefore a less painful procedure (although postoperative pain is probably similar).
- No axial or tributary veins are too tortuous.
- It also allows the treatment of calf veins with overlying skin damage or ulceration without the need to pierce through damaged skin.
- Consumable treatment costs are very low.

These factors mean that many surgeons using endothermal techniques also use foam sclerotherapy as an adjunct in specific circumstances.

CATHETER-DIRECTED SCLEROTHERAPY AND MECHANICOCHEMICAL ABLATION

The efficacy of sclerotherapy relies on endothelial contact with fresh, undiluted sclerosant. Some have therefore experimented with catheter-delivered sclerotherapy rather than trying to milk the sclerosant down the vein lumen. There is no good evidence to date that this increases efficacy and the technique is not in widespread use.

A related technology that has shown more promise is mechanicochemical ablation (**Figure 57.22**). This involves a treatment device that deploys an angled wire from the end. This attaches to a motorised handle. The catheter is placed within the vein lumen as for endothermal ablation. The trigger on the handle is depressed, spinning the wire around and liquid sclerosant is infiltrated via the catheter simultaneously during catheter withdrawal. It is thought that the spinning wire causes physical damage to the endothelium and allows a deeper penetration of the sclerosant into the vein wall. The technique is possible in most cases without tumescent anaesthesia, although a small number of patients find the procedure uncomfortable and the device can 'snag' on the vein, tearing it or rarely stripping it altogether. Early studies suggest similar early efficacy rates as for endothermal ablation, which is encouraging. The axial ablation is usually less painful than endothermal ablation, but this advantage is lost when it is combined with phlebectomy of the tributaries; therefore, it is uncertain whether it can replace endothermal ablation, unless axial ablation is to be performed in isolation. Treating longer veins can also be challenging due to limitations in catheter length and the safe dose of sclerosant. It is a good choice for a patient with needle phobia, who is happy to forgo treatment of varicose tributaries.

ENDOVENOUS GLUE

The final non-tumescent technique is the endoluminal application of cyanoacrylate adhesive (**Figure 57.23**). Again, this involves a treatment catheter placed within the vein lumen. A handle is used to infiltrate the adhesive in 0.1 mL applications via the catheter. The vein is then compressed, sealing the lumen closed. Early efficacy results are similarly promising and patients experience minimal intraprocedural pain. Long-term results and, similar to mechanicochemical ablation, the optimal management of tributaries are unknown. The consumable costs are currently the highest for any venous ablative technique.

Open surgery

The principles of traditional ligation and stripping are to fully dissect the point of junctional incompetence and to remove the refluxing axial vein and dilated tributaries. The operation is usually performed under general anaesthesia but loco-regional anaesthesia is used by some and the infiltration of tumescent local anaesthesia around the axial vein prior to stripping may have some advantages, but is not widely used.

The role of open surgery as a primary treatment of a refluxing superficial axis has been considerably reduced with development of the minimally invasive techniques described above, the long-term results of which are at least comparable with open surgery, but with significantly less morbidity and faster recovery. Experienced endovenous surgeons do still use open surgery in some circumstances and a venous surgeon needs to be trained and experienced in this area.

Surgical adjuncts including phlebectomy and, occasionally, perforator ligation are much more commonly used, and the former has been shown to have a significant impact upon outcome.

SAPHENOFEMORAL LIGATION AND GREAT SAPHENOUS STRIPPING

An oblique groin incision is made at the level of, and lateral to, the pubic tubercle, ideally above the groin crease. The GSV is identified and dissected to the SFJ, which should be clearly established before the vein is divided to avoid disastrous inadvertent transection of the superficial femoral vein. The anatomy is often variable but six GSV tributaries may be encountered close to the SFJ:

- Laterally:
  - superficial inferior epigastric vein;
  - superficial circumflex iliac vein;
- Medially:
  - superficial external pudendal vein;
  - deep external pudendal vein;
- Distally:
  - anterior accessory saphenous vein;
  - posteriomedial thigh vein.

Classically, these are ligated distal to their divisions. A flush SFJ ligation is then performed and the GSV retrogradely stripped to around the knee (**Figure 57.24**). Phlebectomy is performed as discussed above.

Closure of the cribriform fascia, with sutures or synthetic patches over the ligated SFJ, does not reduce groin recurrence. Stripping to the lowest point of reflux may improve results, but at a cost of increased saphenous nerve complications and is not widely performed. More recently, some surgeons argue that surgical trauma and subsequent inflammation in the groin is associated with neovascularisation, which in turn may lead to recurrence. Furthermore, others hypothesise that it is the loss of the normal groin tributaries that may be responsible for driving the process of neovascularisation. These concepts have led some to believe that ligation of the refluxing vein should be distal to the tributaries and that the junction itself should be left untouched. There is no clear clinical evidence to support these hypotheses.

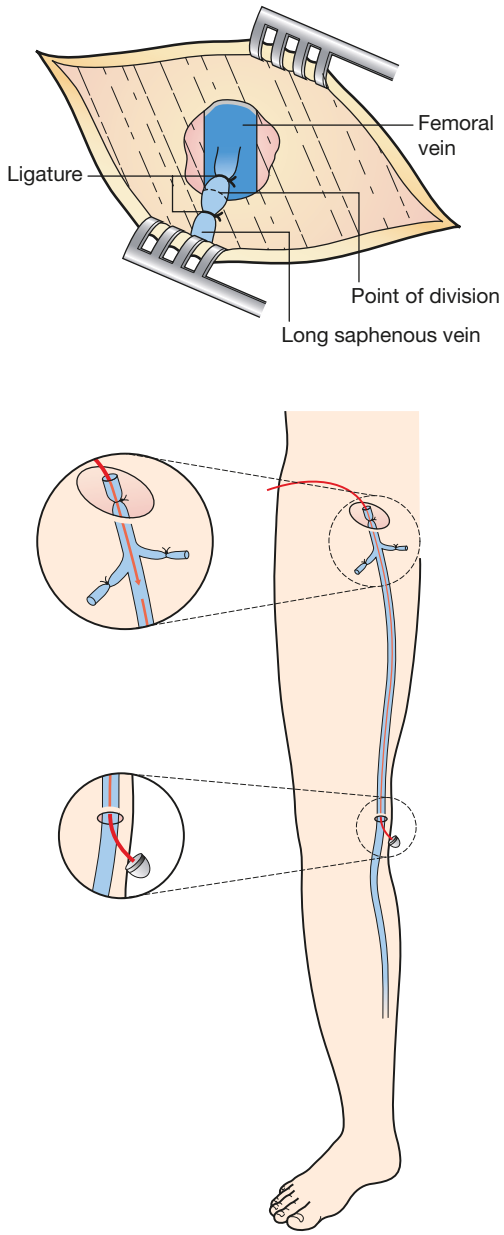

Figure 57.24 Saphenofemoral junction ligation and great saphenous vein stripping.

SAPHENOPOPLITEAL JUNCTION LIGATION AND SMALL SAPHENOUS STRIPPING

Preoperative duplex to mark the position of the SPJ is highly recommended (**Figure 57.25**). The patient is positioned in the prone position, a transverse incision is made over the premarked SPJ, the fascia is divided and the SSV is exposed. The SPJ can then be formally dissected with a flush ligation or the SSV can be gently retracted and ligated as proximally as possible. No good evidence exists to favour one technique over the other; proponents of the flush ligation would argue that it avoids leaving a stump of SSV, a common source of recurrence, while proponents of the simple SSV ligation technique argue it reduces the incidence of the most common serious complications, nerve injury and popliteal vein injury.

Figure 57.25 Preoperative marking of the saphenopopliteal junction and small saphenous vein mapped using duplex scanning.

The SSV can then either be stripped or the proximal section of the vein can be resected. Those who strip argue it reduces the incidence of recurrence, while opponents feel it increases the incidence of sural nerve injury. There are no randomised trials comparing these techniques. Once again, phlebectomy is then performed.

Adjunctive surgical techniques

PHLEBECTOMY

This may be performed following treatment of junctional incompetence and axial vein reflux, or as sole treatment under local anaesthetic in patients with isolated tributary incompetence, or possibly in very early axial reflux, which reverts to normal upon occlusion of the refluxing tributary on duplex ultrasound. Phlebectomy is usually performed through small stab incisions using small mosquito forceps and/or phlebectomy hooks that have been demonstrated to be superior in terms of bruising, pain and generic quality of life than transilluminated-powered phlebectomy (see **Figure 57.19**).

PERFORATOR LIGATION

The majority of studies assessing the role of perforator ligation have been in patients with venous ulcers, analysing the effects on ulcer healing, and even in this situation randomised data are lacking. The role of perforator ligation in patients with uncomplicated varicose veins is even less clear. In uncomplicated varicose veins, perforators may be ligated through a small, duplex-guided incision, while in patients with skin changes, subfascial endoscopic perforator ligation may be preferred, although the benefits are unproven. Perforators can also be ablated with endovenous techniques.

Complications of standard varicose vein surgery

Complications (minor and major) are reported in up to 20% of patients who undergo traditional varicose vein surgery. Wound infections, the most common complication, are reduced by prophylactic antibiotics. Nerve injury is the most common serious complication. The incidence of saphenous nerve neuralgia is up to 7% following GSV stripping to the knee (the incidence is higher with stripping to the ankle). The incidence of sural nerve neuropraxia and common peroneal nerve injury may be as high as 20% and 4%, respectively, following SSV surgery. The incidence of venous thromboembolic complications is approximately 0.5% following varicose vein surgery; however, patient risk factors must be individually assessed and appropriate prophylaxis administered according to guidelines.

Recurrent varicose veins

Approximately 10–20% of patients who present to hospital with varicose veins have had previous intervention. Prospective data on long-term results following intervention for recurrent varicose veins are sparse and the criteria for defining recurrence are variable.

Significant clinical recurrence 5–10 years following varicose vein surgery occurs in 10–35% of patients, but minor/duplex-detected recurrence is much more common, being in the order of 70%. Causes of recurrence include: neovascularisation, reflux in residual axial vein, inadequate initial surgery and new junctional reflux. Neovascularisation is the development of new veins within postsurgical tissue. These veins lack valves and over time can span the tissue between a ligated junction and nearby tributary veins. If significant in size and/or number, these may contribute to recurrent venous hypertension.

Recurrence is more common following SSV versus GSV surgery, and in patients with high body mass index, while stripping of the incompetent axial vein reduces recurrence rates. Limited data suggest recurrence rates following endovenous thermal ablation may be lower than following surgery. Recurrent varicose veins often have an atypical distribution and duplex assessment is mandatory (**Figures 57.26 and 57.27**). Open surgery for recurrent varicose veins is associated with a high (40%) complication rate, the most common being lymph leak and wound infection, thus endovenous interventions would seem to offer an attractive alternative, where feasible.

VENOUS LEG ULCER

Venous disease is responsible for around 85% of all chronic lower limb ulcers in resource-rich countries. Community-based prevalence is 0.1–0.3% in adults (2–4% in the elderly). Venous leg ulcer has a disproportionate cost to society, with profound impairment in health-related quality of life for

Summary box 57.1

Varicose veins

- Are one of the most common conditions causing a physical impairment in quality of life
- Interventional treatment improves quality of life and is highly cost-effective
- Anatomical and physiological assessment using duplex ultrasound is invaluable in the diagnosis and planning of treatment
- Ultrasound-guided endovenous ablation has revolutionised treatment, minimising procedural morbidity while being highly effective

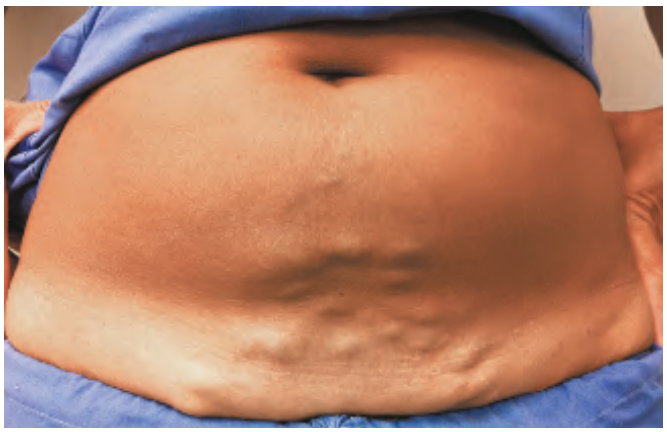

Figure 57.26 Recurrent anterior abdominal wall varicose veins following saphenofemoral junction ligation complicated by iliac deep vein thrombosis.

both patients and their carers; the dressings alone account for 1–3% of western healthcare expenditure. Furthermore, 15–30% of patients with 'venous' leg ulcers have concomitant arterial occlusive disease. This is termed a 'mixed' ulcer. There are many other causes of leg ulcers and these must be excluded in any patient presenting with ulceration. Causes of leg ulceration include:

- venous disease: superficial incompetence, deep incompetence or obstruction;
- arterial ischaemic ulcers;
- vasculitic ulcers;
- traumatic ulcers;
- neuropathic ulcers;
- neoplastic ulcers;
- infections, especially in resource-poor countries.

Pathophysiology of ulceration

The exact pathophysiology of ulcer development has not been established. Originally, it was thought that static blood within the superficial veins led to hypoxia, which caused tissue death (stasis ulcers). This was not confirmed by investigation of venous oxygen saturation, which was found to be higher in ulcerated limbs. This led to the concept of arteriovenous fistulae, which were thought to develop in response to the high

Figure 57.27 Recurrent varicose veins secondary to an incompetent thigh perforator.

venous pressure; however, this could not be confirmed. High venous pressure was found to be associated with a pericapillary infiltrate. This includes fibrin and other proteins, which are known to lead to fibrosis. It was hypothesised that these 'cuffs' could act as an impediment to diffusion of oxygen and nutrients.

Leukocytes were found to decrease in the venous effluent coming out of dependent limbs. This decrease in leukocyte passage was shown to increase if short-term venous hypertension was induced by application of a tourniquet. This led to the concept of white cell 'trapping', which, however, has not been confirmed by further investigation. Polymorphonuclear leukocytes were not found within the tissues, but increased numbers of mast cells, monocytes and lymphocytes have been found in periulcer tissues.

Reactive oxygen species are increased in the ulcer environment and these may generate free radicals, leading to tissue damage. Proteolytic enzymes are also increased in ulcers and the fibroblasts in the ulcer surrounds are also abnormal, being in a 'senescent' state. Growth factors may be inhibited, leading to poor repair, and their absence may also lead to ulceration. It is proving difficult to show whether any of these factors is the cause of or the result of an ulcer.

At present, ambulatory venous hypertension is the only accepted underlying cause of venous ulceration. This also explains why venous ulcers are never seen in the upper limb. It is important to try to define the exact mechanism of ulcer development. Venous hypertension may be the result of primary valve incompetence of the saphenous veins, incompetence of the perforating veins or incompetence or obstruction of the deep veins.

Clinical features

The ulcer must be carefully examined. A venous ulcer usually has a gently sloping edge and the floor contains granulation tissue covered by a variable amount of slough and exudate. Any significant elevation of the ulcer edge should indicate the need for a biopsy to exclude a carcinoma (usually a squamous cell).

The venous ulcer of the leg characteristically develops in the skin of the gaiter region, the area between the muscles of the calf and the ankle. This is the region where many of the Cockett perforators join the posterior tibial vein to the surface vein, known as the posterior arch vein. The majority of ulcers develop on the medial side of the calf, but ulcers associated with SSV incompetence may develop on the lateral side of the leg. Ulcers can develop on any part of the calf skin in patients with post-thrombotic syndrome (PTS); however, venous ulcers rarely extend on to the foot or into the upper calf and, if there is ulceration at these sites, other diagnoses should be seriously considered. Ulcers often develop in response to minor trauma; many patients notice some itching, perhaps associated with mast cell degranulation, before the ulcers develop. Almost all venous ulcers have surrounding haemosiderosis (seen as pigmentation) and the more chronic ulcers develop lipodermatosclerosis with associated fibrosis of the subcutaneous tissue (see **Figure 57.10**). This is manifest as thickening, pigmentation, inflammation and induration of the calf skin. The pigmentation comes from haemosiderin and melanin and the haemosiderin itself may be an important factor in ulcer development.

A full examination of the front and back of the limbs with the patient standing should be carried out to assess the presence of varicosities and truncal incompetence of the saphenous systems (note that venous ulcers are not always accompanied by varicose veins). All patients should have their pulses palpated and, if there is any doubt, their arterial Doppler pressures should be measured. Sensation and proprioception should be assessed to exclude neuropathy, especially in diabetic patients. A careful examination of the hand and other joints may confirm the presence of rheumatoid arthritis or osteoarthritis.

Investigation

Most vascular surgeons will carry out a duplex scan when the patient with an ulcer is first seen to assess the status of the deep and superficial veins. The presence of reflux in these veins does not confirm a venous ulcer, but supports the diagnosis in the absence of another cause and helps direct treatment.

All patients presenting for the first time with a new leg ulcer should have a full blood count, blood glucose, erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) and sickle cell test if they have an appropriate racial background. Anaemia can both cause ulcers (e.g. sickle cell disease and pernicious anaemia) and be a result of ulceration (e.g. iron deficiency anaemia and the anaemia of chronic disease). Polycythaemia is a rare cause of ulceration. An antibody screen should be obtained if the ulcer appears 'atypical' or there is any suggestion of joint disease (e.g. rheumatoid arthritis). All patients presenting with a new ulcer should have their Doppler pressures measured, unless the foot pulses are easily palpable and have been confirmed as such by a vascular specialist.

Venous ulcers are characteristically difficult to heal; however, persistence may indicate that there is another or coexisting cause (e.g. malignancy, rheumatoid arthritis or arterial ischaemia). Biopsies are indicated if malignancy is suspected and it is important to remember that a Marjolin's type of ulcer (a squamous cell or basal cell carcinoma) can develop in a chronic long-standing venous ulcer **(Figure 57.28)**.

Management

Compression

The very best results are seen in specialist multidisciplinary ulcer services. The cause of a venous leg ulcer is venous hypertension and the key-stone of management is to decrease this hypertension. The primary way of doing this is with the use of compression. Most patients are suitable for the classic 'four-layer bandaging system' (4LB):

- Orthopaedic wool: distributes the pressure and reduces undue pressure on sensitive areas susceptible to pressure damage. Also helps to absorb excess exudate that escapes the primary dressing.
- Cotton crepe: smooths the wool and holds it in place.

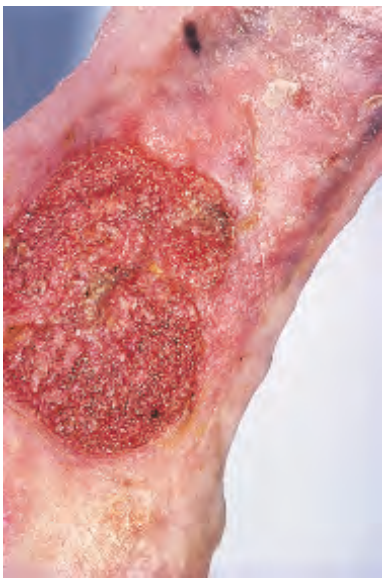

Figure 57.28 A Marjolin's ulcer (a squamous cell cancer arising in a chronic venous ulcer).

Frank Bernard Cockett, 1916–2014, surgeon, St. Thomas's Hospital, London, UK.
Jean-Nicholas Marjolin, 1780–1850, surgeon, Paris, France, described the development of malignant ulcers in scars in 1828.

- Elastic bandage: first compressive layer, contributes about one-third of the interface pressure.
- Cohesive bandage: second compressive layer, increases stiffness and adds approximately two-thirds of the interface pressure

The ideal interface pressure in pure venous ulceration is 35–40 mmHg. Skilled application of these dressings is essential for both safety and efficacy, and the best results come from specialist nursing teams either based in secondary care or in the community. Newer compression systems are being created with the aim of reducing the learning curve and variability in application, and some are designed to be applied by patients themselves. There remains little evidence that these are set to replace 4LB for the time being. The interval between bandage applications is based upon the amount of exudate and the speed of healing and best judged by an experienced nurse.

Compression in mixed ulcers is controversial, but emerging evidence suggests that it is both safe and effective when performed and monitored appropriately. With an ankle brachial pressure index (ABPI) of 0.5–0.8 modified compression with an interface pressure of 30 mmHg is safe and effective and pressures of up to 40 mmHg have been described in studies using inelastic bandages without ill effect. Contrary to conventional thinking, studies have shown an increase in perfusion in patients treated in this way, presumably by a reduction in capillary back pressure. Patients do see respectable healing rates in this group, but they remain lower than in those patients with an ABPI >0.8. It is not clear whether revascularisation followed by full compression yields better results, but this is common practice. Patients with an ABPI <0.5 or an ankle pressure <60 mmHg must undergo revascularisation prior to any compression treatment.

Superficial venous ablation or surgery

The next method of reducing venous hypertension is to treat superficial reflux. There has been only one trial of adequate power and design to answer the question of whether the abolition of superficial reflux improves ulcer healing rates. This trial has completed recruitment, but follow-up is ongoing and practice continues to vary.

Other treatments

The only drug that shows promise to date is pentoxifylline, which increases microvascular perfusion by decreasing plasma cellular viscosity and cytokine inhibition, although its exact mechanism of action is not fully understood.

A number of biological dressings have been developed, including fetal keratinocytes and collagen meshes, which have been shown to improve healing; however, they are not cost-effective for the majority of ulcers. Pinch grafts and ulcer excision with mesh grafting have been shown to provide good early healing with moderate long-term results (50% healed at 5 years).

Antibiotics do not speed ulcer healing in the absence of cellulitis and all other specific ulcer-healing drugs are of dubious validity. A large range of topical therapies and primary dressings have similarly failed to have an impact.

Prevention of recurrence

Once an ulcer has healed the patient must be re-evaluated in an attempt to prevent recurrence. If not already performed, there is level 1 evidence that patients should undergo treatment for their superficial venous incompetence, unless they have deep venous occlusion. Class II below-knee graduated compression stockings should be prescribed for all patients with residual reflux or deep venous occlusion, or those with recurrent ulceration despite not being in this group. These should be worn for life.

Prognosis

Nearly all venous ulcers can be healed but, even in those who have successful ablation or wear their stockings religiously, there is a 20–30% incidence of reulceration by 5 years. The greatest risk of reulceration is in the post-thrombotic leg.

Summary box 57.2

Venous leg ulcer

- Is associated with a profound impairment in quality of life
- Ulcers are not infrequently difficult to heal and prone to recurrence
- The treatment of these chronic wounds is associated with high costs to healthcare systems and patients
- The mainstay of treatment is the reduction in venous hypertension, with compression and increasingly superficial venous ablation

PELVIC CONGESTION SYNDROME

Pelvic congestion syndrome (PCS) is among the differential diagnoses to be considered in female patients presenting with chronic pelvic pain and may be significantly under-diagnosed. PCS sufferers are typically premenopausal, multiparous women aged 20–45 years, who present with severe dull aching pelvic pain thought to be the direct result of ovarian and pelvic varicosities. The pain is usually non-cyclical, and may be precipitated by prolonged standing. Other symptoms include dysmenorrhoea, menorrhagia, rectal discomfort or urinary frequency. Signs may include tenderness over the uterus/ovaries, vulval varicosities and haemorrhoids. There may be vulval and atypically distributed thigh varicosities. The road to a diagnosis of PCS is often a long and laborious one, usually only made following extensive investigations to exclude other more common causes of pelvic pain. Abdominal, pelvic and transvaginal duplex examination allows dynamic visualisation of pelvic blood flow and should be the initial investigation of choice, as these are rapid, readily accessible outpatient procedures that are also valuable in excluding other pathologies. Alternatives include magnetic resonance (MR) venography and diagnostic venography.

Medical treatments for PCS include psychotherapy, progestins, danazol, gonadotrophin receptor agonists (GnRH)

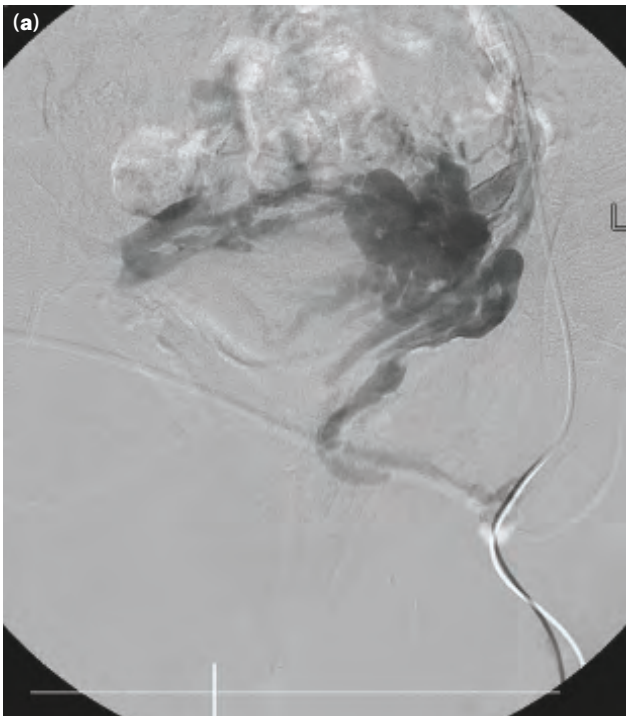

Figure 57.29 (a, b) Left ovarian vein incompetence supplying pelvic and pudendal varicosities: **(a)** diagnostic venogram; **(b)** therapeutic embolisation.

with hormone replacement therapy, and non-steroidal anti-inflammatory drugs. Historical open surgical procedures (extraperitoneal resection of ovarian veins) have now largely been superseded by percutaneous pelvic vein embolisation (**Figure 57.29**), reducing peri- and postprocedural morbidity while maintaining high success rates.

VENOUS THROMBOEMBOLISM

Venous thromboembolism (VTE) is an important condition within surgery, and autopsy studies suggest that it is the most common direct cause of death in surgical patients. Venous thrombosis is the formation of a semisolid coagulum within the venous system and may occur in the superficial system (usually described as superficial thrombophlebitis) or the deep system (deep venous thrombosis, DVT). Venous thrombosis of the deep veins of the leg may be complicated by the immediate risk of pulmonary embolus and sudden death. Subsequently, patients are at risk of developing PTS (**Figure 57.30**) and venous ulceration. While DVT may occur in the upper limb, it is the leg that gives rise to the vast majority of the morbidity and subsequent complications of this condition.

Aetiology

The three factors described by Virchow over a century ago are still relevant in the development of venous thrombosis. These are:

- contact of blood with an abnormal surface (e.g. endothelial damage);
- abnormal flow (e.g. stasis);
- abnormal blood (e.g. thrombophilia).

There are many predisposing causes for VTE. These are listed in *Table 57.2*. The most important factor is a hospital admission for treatment of a medical or surgical condition. Injury, especially fractures of the lower limb and pelvis, pregnancy and the oral contraceptive pill are other well-recognised predisposing factors. Endothelial damage is now known to be critically important. The interaction of the endothelium with inflammatory cells, or previous deep vein damage, renders the endothelial surface hypercoagulable and less fibrinolytic.
Stasis is a predisposing factor seen in many of the conditions described in *Table 57.2*, especially in the postoperative period, in patients with heart failure and in those with arterial ischaemia.

Behçet's disease
Homocystinaemia

TABLE 57.3 Abnormalities of thrombosis and fibrinolysis (thrombophilia) that lead to an increased risk of venous thrombosis.
Congenital
Deficiency of antithrombin III, protein C or protein S
Antiphospholipid antibody or lupus anticoagulant
Factor V Leiden gene defect or activated protein C resistance
Dysfibrinogenaemias
Acquired
Antiphospholipid antibody or lupus anticoagulant

A number of conditions are associated with increased coagulability of the blood (thrombophilia) (*Table 57.3*). Deficiencies of antithrombin, activated protein C and protein S have all been shown to predispose to venous thrombosis in young patients. Activated protein C deficiency is associated with inheritance of the factor V Leiden gene and may account for the higher incidence of venous thrombosis in Caucasian populations (being present in 6–7%). It results in a small increase in the risk of VTE, although it may act in concert with some of the other predisposing factors. A thrombophilia should be excluded in any patient presenting with an episode of VTE who gives a family history of VTE or in whom there is no other predisposing factor.

Although the development of DVT is probably multifactorial, immobility (and hence stasis) remains one of the most important factors. DVT is recognised as a complication of long-haul flights and other forms of travel.

Pathology

The thrombus commences as a platelet aggregate. Subsequently, fibrin and red cells form a mesh until the lumen of the vein wall occludes. The coralline thrombus then progresses as a propagated loose red fibrin clot containing many red cells (**Figure 57.31**). This is likely to extend up to the next large venous branch and it is possible for the clot to break off and embolise to the lung as a pulmonary embolus. In this situation the embolus arising from the lower leg veins becomes detached, passes through the large veins of the limb and vena cava, through the right heart and lodges in the pulmonary arteries. This may totally occlude perfusion to all or part of one or both lungs. This results in a clinical spectrum from tachycardia and pain, through respiratory failure (despite adequate ventilation) to cardiovascular collapse and death. Moderate-sized emboli can cause pyramidal-shaped infarcts on imaging.

Diagnosis

The most common presentation of a DVT is pain and swelling, especially in the calf, usually in one leg; however, bilateral DVTs are common, occurring in up to 30%. When the

Figure 57.31 An organised thrombus.

Hulusi Behçet, 1889–1948, Turkish dermatologist described a disease of inflamed blood vessels in 1937.

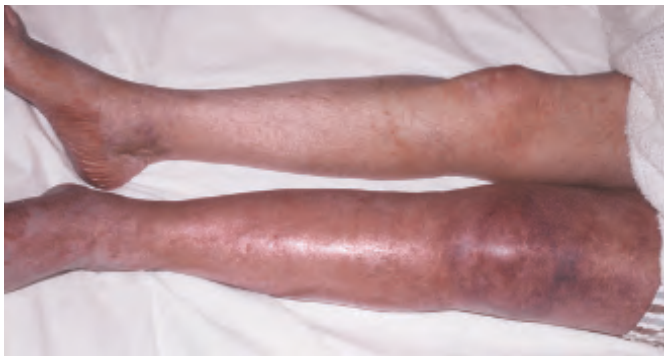

Figure 57.32 Phlegmasia cerulea dolens.

Figure 57.33 A foot with venous gangrene. The gangrene is symmetrical involving all of the toes. There is no clear-cut edge and there is marked oedema of the foot.

swelling is bilateral, DVT must be differentiated from other causes of systemic oedema, such as hypoproteinaemia, renal failure and heart failure. Some patients have no symptoms of thrombosis and may first present with signs of a pulmonary embolus, e.g. pleuritic chest pain, haemoptysis and shortness of breath. Patients may also develop shortness of breath from chronic pulmonary hypertension. Sometimes the leg appears cellulitic and very occasionally it may be white or cyanosed: phlegmasia alba dolens and phlegmasia cerulea dolens (**Figure 57.32**). This indicates venous pressures that are so high that they are impeding tissue perfusion. Patients who present with venous gangrene (**Figure 57.33**) often have an underlying neoplasm.

Clinical examination for DVT is unreliable. Physical signs may also be absent. Mild pitting oedema of the ankle, dilated surface veins, a stiff calf and tenderness over the course of the deep veins should be sought. Leg pain occurs in about 50% of patients with DVT but is nonspecific. Homans' sign – resistance (not pain) of the calf muscles to forcible dorsiflexion – is not specific and should not be elicited. Tenderness occurs in 75% of patients but is also found in 50% of patients without objectively confirmed DVT. The pain and tenderness associated with DVT does not usually correlate with the size, location or extent of the thrombus. Clinical signs and symptoms of pulmonary embolus occur in about 10% of patients with confirmed DVT.

A low-grade pyrexia may be present, especially in a patient who is having repeated pulmonary embolus. Patients may have signs of cyanosis, dyspnoea, raised neck veins, a fixed split second heart sound and a pleural rub if they have pulmonary emboli causing right heart strain, although these signs may be subtle or absent.

Investigation

The diagnosis of DVT and pulmonary embolus should be established by special investigations as the symptoms and signs are non-specific and may be absent. In addition, treatment with anticoagulation is not without risk and the diagnosis must be made with reasonable certainty.

Many centres direct investigation based upon the modified Wells score (*Table 57.4*), with further imaging dictated by these results. These scores can be unreliable though, especially in hospital inpatients, and should only be considered a guide.

Venous duplex ultrasound is commonly performed to look for evidence of thrombosis throughout the deep or superficial venous system. Ideally, this should be performed by an experienced vascular sonographer, but the volume of cases is such that compression ultrasound is frequently being performed by non-specialists. Compression ultrasound involves applying pressure with the ultrasound probe over the common femoral and popliteal veins. Under normal circumstances these veins

TABLE 57.4 Modified Wells criteria for predicting deep vein thrombosis (DVT).

Variable	Score
Lower limb trauma or surgery or immobilisation in a plaster cast	1
Bedridden for >3 days or surgery in last 4 weeks	1
Tenderness along the line of femoral or popliteal veins	1

Philip Wells, contemporary, physician, University of Ottawa, Canada.

will compress tightly shut. In the presence of DVT they will not fully compress. It is rapid to both learn and perform, but not ideal and most importantly misses calf vein thrombosis. Calf vein thromboses may propagate to form a more extensive thrombus, which may in turn embolise. The optimal management of calf vein thrombosis when detected is not clear, and some units use surveillance, with others anticoagulating such patients upon detection.

Ascending venography, which shows a thrombus as a filling defect, is now rarely required unless thrombolysis is being considered **(Figure 57.34)**. MR venography may also be used. Pulmonary embolus is diagnosed definitively by computed tomography (CT) pulmonary angiogram, which will demonstrate the presence of filling defects in the pulmonary arteries **(Figure 57.35)**. Pulmonary angiography is rarely required unless thrombolysis is being considered.

The differential diagnosis of a DVT includes a ruptured Baker's cyst, a calf muscle haematoma, a ruptured plantaris muscle, a thrombosed popliteal aneurysm and arterial ischaemia. Duplex scanning will detect many of these conditions but often patients present with non-specific pain in the calf that resolves with no firm diagnosis being made. The differential diagnosis of a pulmonary embolism includes myocardial infarction, pleurisy, pneumonia and aortic dissection.

Prophylaxis

Prophylactic methods can be divided into mechanical and pharmacological. A variety of mechanical methods have been tried, but only the use of graduated elastic compression stockings and external pneumatic compression have been shown to be worthwhile by reducing the incidence of thrombosis. Newer devices, such as electronic nerve stimulators, lack evidence of efficacy to date. Compression-based prophylactic measures should be avoided in patients with peripheral vascular disease.

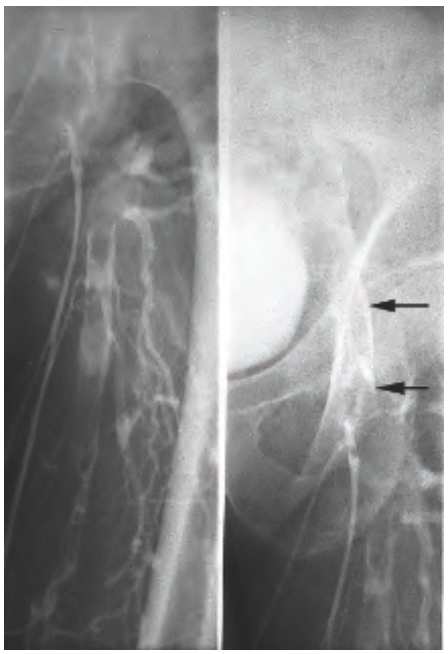

Figure 57.34 An ascending venogram of a deep vein thrombosis seen as filling defects (arrows) with contrast passing around the thrombus.

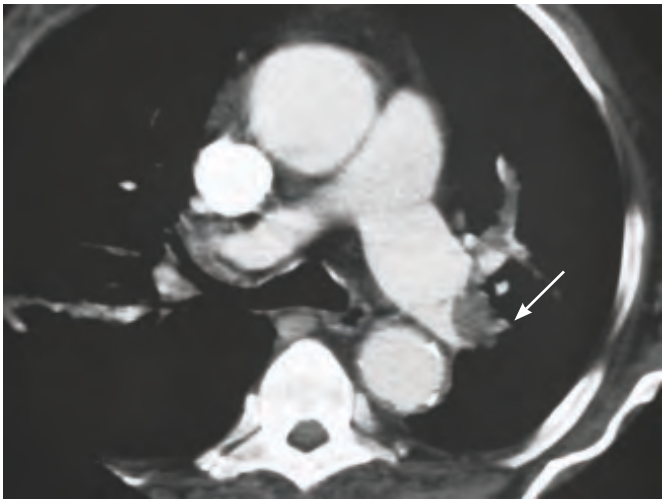

Figure 57.35 A computed tomography pulmonary angiogram showing pulmonary emboli as filling defects (arrow) in the pulmonary artery.

Pharmacological methods are more effective than mechanical methods at risk reduction, although they carry an increased risk of bleeding. In the past, low-dose unfractionated heparin was used both intravenously and subcutaneously. In the absence of renal impairment, most centres currently use low molecular weight heparin (LMWH) given subcutaneously. This is given once daily, does not require monitoring and has a lower risk of bleeding complications.

Patients who are being admitted for surgery may be graded as low, moderate or high risk for PE and VTE (*Tables 57.5* and *57.6*). Patients in the medium- or high-risk groups should be considered for pharmacological prophylaxis with an anticoagulant medication. A combination of mechanical and pharmacological treatment with heparin can be used in patients considered at high risk.

TABLE 57.5 Modified Wells criteria for predicting pulmonary embolism (PE).

Variable	Score
Clinical signs and symptoms of deep vein thrombosis (DVT) (minimum of leg swelling and pain on palpation of deep veins)	3
Alternative diagnosis less likely than PE	3
Heart rate >100 bpm	1.5
Immobilisation >3 days or surgery within past 4 weeks	1.5
Previous DVT or PE	1.5
Haemoptysis	1
Malignancy (treatment or palliation within past 6 months)	1

A score of <4 means PE is unlikely (12.4%), >4 is suggestive of PE (37.1%).

LOW
Minor surgery <30 minutes; any age; no risk factors
Major surgery >30 minutes; age <40; no other risk factors
Minor trauma or medical illness
MODERATE
Major surgery; age 40+ or other risk factors
Major medical illness: heart/lung disease, cancer, inflammatory bowel disease
Major trauma/burns
Minor surgery, trauma, medical illness in patient with previous DVT, PE or thrombophilia
HIGH
Major orthopaedic surgery or fracture of pelvis, hip, lower limb
Major abdominal/pelvic surgery for cancer
Major surgery, trauma, medical illness in patient with DVT, PE or thrombophilia
Lower limb paralysis (e.g. stroke, paraplegia)
Major lower limb amputation

DVT, deep vein thrombosis; PE, pulmonary embolus.

Treatment

Deep vein thrombosis

The management of DVT has in the past been focused upon reducing the risk of pulmonary embolus. Patients who are confirmed to have a DVT on duplex imaging should be rapidly anticoagulated with a 'treatment dose' of subcutaneous LMWH. Patients with significant renal impairment should be commenced on intravenous unfractionated heparin. Patients who have a sensitivity towards heparinoids, such as those with heparin-induced thrombocytopenia, should commence on another anticoagulant, such as fondaparinux (an indirect factor Xa inhibitor) or bivalirudin (a direct thrombin inhibitor). This will achieve rapid anticoagulation and reduce the risk of embolisation. Typically, patients will then commence on warfarin for at least 3 months (or longer depending upon the persistence of risk factors or in recurrent cases). Patients who cannot be safely anticoagulated (usually due to bleeding risks) should be considered for a temporary inferior vena cava filter, until either they are safe to be anticoagulated or the risk of embolisation has subsided and the filter may be retrieved. Patients with active cancer typically remain on a LMWH. There is a range of newer or 'novel' anticoagulants (NOACs). These oral agents either directly inhibit factor Xa (rivaroxaban and apixaban) or thrombin (dabigatran). Work is ongoing to explore their place within patient management.

Alongside the risk of pulmonary embolus is the risk to the patient's leg. Two-thirds of patients will have developed a PTS within 5 years of their DVT. A PTS limb may present with any of the symptoms, signs and complications of venous hypertension discussed earlier, but are typically towards the most severe end of the spectrum and patients face a considerable deficit in their quality of life. A small number of centres are performing procedures aiming to treat this and these include venous recanalisation and stenting and sometimes venous bypass procedures. These procedures can be very challenging and although good results are possible, many patients are condemned to lifelong compression with unaddressed symptoms and complications. As the treatment of PTS is so challenging, attention is being turned towards prevention with the use of thrombolysis, endovenous thrombectomy and stenting.

During thrombolysis, an agent such as tissue plasminogen activator is administered directly into the thrombus, either via the popliteal vein or by direct puncture in the groin. New devices are being marketed that physically disrupt the thrombus at the same time as local lysis is carried out. Some thrombi can be compressed by stent grafting, allowing the venous lumen to be opened, especially in the iliac region. A meta-analysis of randomised trials has shown that these treatments result in a significant reduction in PTS at 5 years (from 67% to 39%) but at a cost of an increased risk of significant bleeding complications (from 4% to 10%). Patient selection is important. Despite such promising data, access to these treatments remains limited.

Pulmonary embolus

Most pulmonary emboli can be treated by anticoagulation and observation, but severe right heart strain and shortness of breath indicates the need for thrombolysis or radiologically guided catheter embolectomy.

Superficial thrombophlebitis

This is a superficial venous thrombosis. An abnormal endothelium is a much more common precipitating factor than in most DVTs. Common causes include external trauma (especially to varicose veins), venepunctures and infusions of hyperosmolar solutions and drugs. The presence of an intravenous cannula for longer than 24–48 hours often leads to local thrombosis. Some systemic diseases such as thromboangiitis obliterans (Buerger's disease) and malignancy, especially of the pancreas, can lead to a flitting thrombophlebitis (thrombophlebitis migrans), affecting different veins at different times. Finally, coagulation disorders such as polycythaemia, thrombocytosis and sickle cell disease are often associated, as is a concomitant DVT.

The surface vein feels solid and is tender on palpation. The overlying skin may be attached to the vein and in the early stages may be erythematous before gradually turning brown. A linear segment of vein of variable length can be easily palpated once the inflammation has died down.

A full blood count, coagulation screen and duplex scan of the deep veins should usually be obtained. Any suggestion of an associated malignancy should be investigated using

Leo Buerger, 1879–1943, Professor of Urologic Surgery, The New York Polyclinic Medical School, New York, NY, USA, described thromboangiitis obliterans in 1908.

appropriate endoscopy and imaging studies, such as an abdominal CT scan.

Most patients are treated with non-steroidal anti-inflammatory drugs and topical heparinoid preparations and the condition resolves spontaneously. Rarely, infected thrombi require incision or excision. Ligation to prevent propagation into the deep veins is almost never required, although some advocate saphenofemoral ligation when the thrombus is seen on ultrasound to be at the SFJ. Associated DVT or thrombophilia is treated by anticoagulation.

Summary box 57.3

Venous thromboembolism

- May be unprovoked, in which case an association with an inherited 'thrombophilia' should be considered
- Is much more commonly seen as a complication of illness or surgery
- Is associated with both quality of life impairment and a risk of mortality
- All healthcare professionals should actively assess the risk and consider preventative measures where this risk is increased
- Management should involve measures to reduce the risk of extension and/or embolisation, typically with systemic anticoagulation
- Consideration should be given to local thrombolysis to reduce the risk of postphlebitis limb

CONGENITAL VENOUS ANOMALIES

There are four main types of anomaly:

- aplasia;
- hypoplasia;
- duplication;
- persistence of vestigial vessels.

Aplasia is most commonly seen in the inferior vena cava and has a similar presentation to the post-thrombotic limb. Membranous occlusion of the left common iliac vein (May–Thurner syndrome) often develops where the vein passes behind the right common iliac artery (iliac vein compression syndrome). This leads to an iliac vein thrombosis, which most commonly affects the left common and external iliac veins. Membranes may also narrow the hepatic veins, which can become totally occluded, leading to a Budd–Chiari syndrome.

Hypoplasia results in a narrow vein, which frequently offers little significant venous function and amounts to a functional venous occlusion, being circumvented by enlarged collateral venous tributaries. Duplications are quite common, with double vena cava, femoral and renal veins; they often present as an incidental finding.

Figure 57.36 Two patients with Klippel–Trenaunay syndrome. **(a)** This patient has a longer leg and a capillary naevus; **(b)** this patient has a large lateral anomalous axial vein.

Klippel–Trenaunay syndrome

This is a combined anomaly of a cutaneous naevus, persistent vestigial veins with varicose veins and soft tissue and bone hypertrophy. The condition is a mesodermal abnormality that is not familial **(Figure 57.36)**.

Segments of the deep veins are hypoplastic or aplastic and there may be an associated obstruction of the lymphatics. The condition must be distinguished from the Parkes-Weber syndrome, in which there are multiple arteriovenous fistulae causing venous hypertension, ulceration and high-output cardiac failure.

Virtually all patients with Klippel–Trenaunay syndrome should be treated conservatively with compression hosiery; however, some will benefit from laser ablation of the naevus, stapling of the bones to avoid leg length discrepancy and occasional removal of large superficial varicose veins, provided the deep veins are patent. LMWH should be given to all patients having surgery as this syndrome is associated with an increased risk of VTE.

VENOUS ENTRAPMENT SYNDROMES

The axillary vein and the popliteal vein are the two veins that are most commonly compressed. The former is compressed at the thoracic outlet between the first rib and the clavicle, where it usually presents as an axillary vein thrombosis (see below) **(Figure 57.37a)**. The latter is compressed by

George Budd, 1808–1882, Professor of Medicine, King's College Hospital, London, UK, described this syndrome in 1845.
Hans Chiari, 1851–1916, Professor of Pathological Anatomy, Strasbourg, Germany (Strasbourg was returned to France after the end of World War I, in 1918), gave his account of this condition in 1898.
Frederick Parkes-Weber, 1863–1962, physician, The German Hospital, Dalston, London, UK.

an abnormal insertion of the gastrocnemius muscles. Entrapment may cause discomfort and swelling of the limb during exercise before thrombosis develops. Treatment is by surgical decompression, excising the first rib or dividing the abnormal musculature of the gastrocnemius insertion.

AXILLARY VEIN THROMBOSIS

Thrombosis of the axillary vein (Paget–Schrötter disease) may occur following excessive exercise in a patient with an anatomically abnormal thoracic outlet, but is also associated with excessive muscle bulk as found in weight lifters. The vein may be compressed by a cervical rib if this is present (Figure 57.37b). The arm is swollen and painful and, at an early stage, the thrombus can be disrupted by thrombolysis delivered through one of the arm veins. The vein must then be imaged to see if there is any compression on elevation of the arm. If this is confirmed, thoracic outlet decompression can be carried out by resecting the cervical rib or first rib.

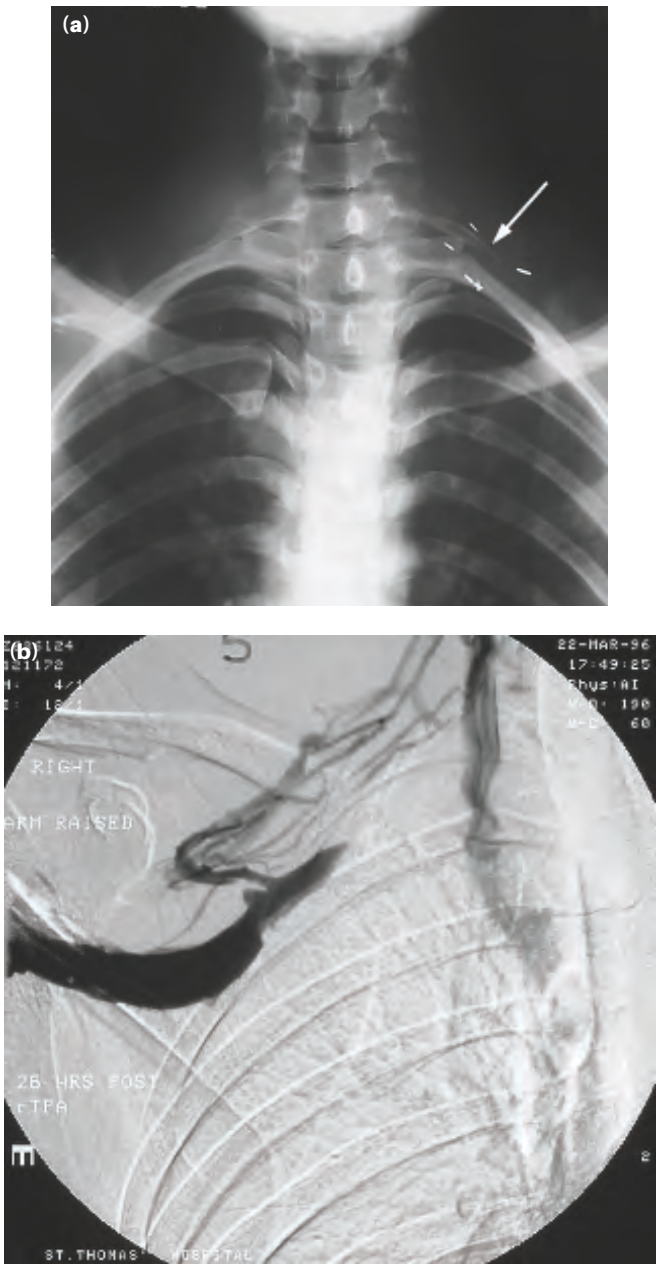

Figure 57.37 Thoracic outlet syndrome: **(a)** cervical ribs on plain x-ray; **(b)** elevation of the arm causing occlusion of the axillary vein with collaterals. The patient has had previous surgery to decompress the left side.

VENOUS INJURY

Blunt or penetrating trauma almost always damages some small- and medium-sized veins, which can be safely ignored or ligated without causing any problems. Larger axial venous channels have in the past been ligated when injured, but it is now recognised that these axial veins should be repaired whenever possible to reduce subsequent morbidity (pain and swelling in the tissues being drained) and limb loss when associated with a concomitant arterial injury. Many venous injuries remain undiagnosed at the time of injury (e.g. crural vein damage associated with a fractured tibia) and only present many years later when post-thrombotic changes become apparent. Venous injuries occur from both civilian and military trauma but the incidence of venous military injuries has been particularly well documented. In total, 40–50% of arterial injuries have concomitant venous injuries, especially in the popliteal fossa.

The mechanism may be laceration, contusion or avulsion (Figure 57.38). Iatrogenic injuries result from damage at the time of surgery and from punctures caused by catheter insertion. Thrombosis, haemorrhage and embolisation are all common complications and arteriovenous fistulae may develop when there is a local concomitant arterial injury.

Associated injuries to soft tissue, arteries and bones often overshadow the venous injury. Massive haemorrhage from the pelvic bones or the inferior vena cava can rapidly lead to hypovolaemic shock and death if left untreated. Haematomas are common and engorgement, cyanosis and swelling are also indicative of a major venous injury.

Management

As with all traumatic injuries, the management priorities are the assessment and management of issues affecting the airway, then breathing and then circulation. Venous injuries have the potential to threaten life through massive bleeding and patients require vascular access, circulatory support and blood products. Trauma patients with life-threatening haemorrhage are at risk of hypothermia, acidosis, functional and consumptive coagulopathy and paradoxical thrombosis, and these issues need to be prevented where possible and managed when present (see Chapter 2).

Venous pressures are low and so where there is access to the site of injury, pressure will control bleeding and in most cases offer definitive management. Intervention is required

Sir James Paget, 1814–1899, English surgeon and pathologist, best known for his description of Paget's disease of the bone.
Leopold von Schrötter, 1837–1908, Austrian physician and laryngologist, Chair of Laryngology, University of Vienna, Austria.

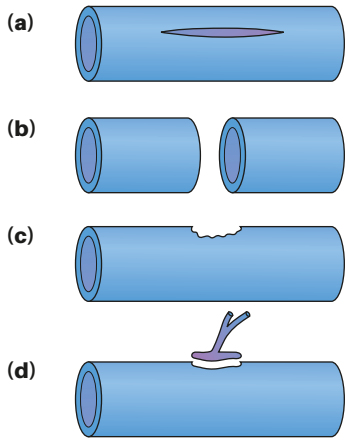

Figure 57.38 Types of venous damage: **(a)** incision; **(b)** transection; **(c)** irregular laceration; **(d)** avulsion of a tributary.

where pressure cannot be applied, or where the loss of venous function itself threatens life or limb. Intervention can include reduction and stabilisation of a fracture (e.g. pelvis), endovenous embolisation or stent grafting.

A small proportion of venous injuries will require formal exploration and ligation or repair. Different types of repair are shown in **Figure 57.39**; the type of repair carried out depends on the extent of the venous injury, including how much venous wall has been lost or damaged. Lateral sutures and vein patches are ideal methods of repair and end-to-end anastomosis is satisfactory, provided that it is not carried out under tension. A jump graft may be required.

Vein replacement should be by autogenous tissue whenever possible, using vein harvested from another site, e.g. the internal jugular vein or the GSV from an undamaged limb. Artificial grafts, such as PTFE grafts, are at risk of infection and have given poor results in recent conflicts. The use of anticoagulants and an arteriovenous fistula to reduce the risk of thrombosis in the vein graft are controversial and depend on the associated injuries that are present. In contaminated wounds, tetanus toxoid and antibiotics should be given. A fasciotomy should always be considered if there is a concomitant arterial and venous injury.

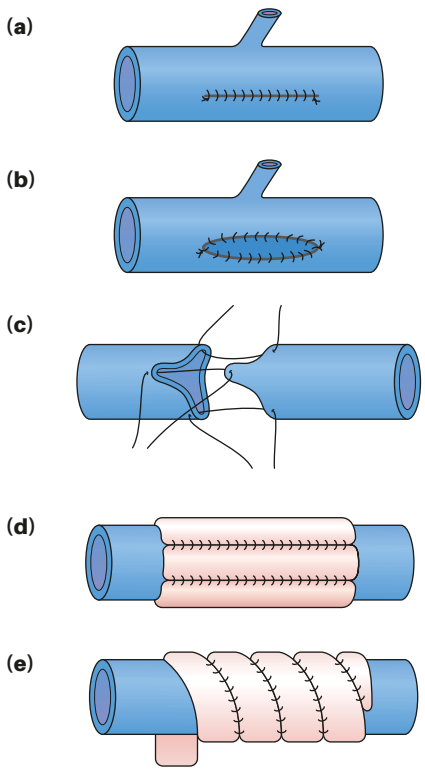

Figure 57.39 Types of venous repair: **(a)** lateral suture (risk of stenosis); **(b)** patch graft; **(c)** Carrel triangulation technique of venous anastomosis; **(d)** panel graft; **(e)** spiral graft.

Prognosis

It is now recognised that repair of a major vein can be carried out with a 70–80% success rate, reducing the morbidity of a combined arterial and venous injury considerably (especially limb loss). Complex repairs should not, however, be carried out if a patient's life is at risk, when ligation may have to suffice in the short term.

VENOUS TUMOURS

Venous malformation cavernous angioma/haemangioma

These malformations are common, representing one end of a spectrum of arteriovenous malformations. They often affect the skin but also extending into the deep tissues, including bones and joints. They usually present with variable swelling and dilated veins beneath the skin. Occasionally, there is no visible mass and the complaint is one of pain. Haemorrhage and thrombophlebitis may exacerbate the pain. A soft compressible mass, which is venous in colour especially if it is under the skin, is usually present **(Figure 57.40a)**. A dark blue tinge is often apparent, even if the malformation is deeply situated. Nodules within the mass usually represent previous episodes of thrombosis. The size and extent of the haemangioma are best visualised by nuclear MR with a short tau inversion recovery (STIR) sequence **(Figure 57.40b)** or CT scanning with contrast enhancement. Venography rarely shows an abnormality, but direct puncture with contrast injection shows the connections of the malformation.

Treatment is a highly specialised area. Treatment options nowadays rarely initially involve surgical excision as once this is done future embolisation and sclerotherapy are very difficult. No treatment is entirely curative because it is difficult to remove all of the angiomatous tissue or sclerose the angioma completely. Sclerosis can be dangerous when the veins connect to the deep system, particularly near the central nervous system.

Alexis Carrel, 1873–1944, a French surgeon who emigrated to work at the University of Chicago, IL, USA. He was awarded the Nobel Prize in Physiology or Medicine in 1912 for pioneering vascular suturing techniques.

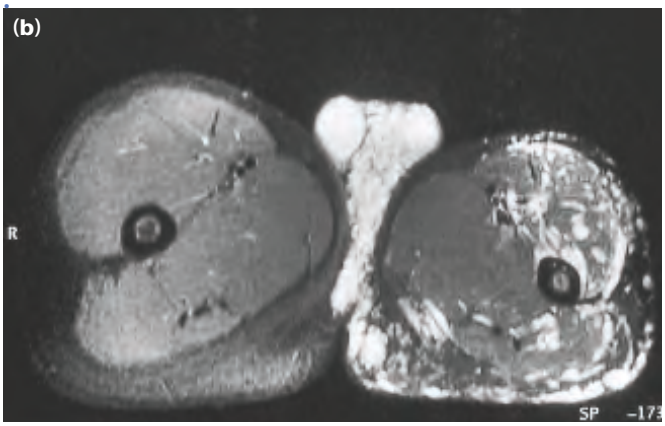

Figure 57.40 **(a)** Venous angioma of the leg; **(b)** magnetic resonance imaging showing extensive angioma (white) throughout the superficial tissues, anterior and posterior compartments of the left leg.

Leiomyoma and leiomyosarcoma of the vein wall

These are extremely rare tumours that are usually slow growing. They present with pain and a mass with signs of venous obstruction, e.g. oedema and distended veins. Duplex scanning, CT **(Figure 57.41)** and MR imaging show a filling defect within the vein wall. Treatment is by resection with replacement by autogenous vein taken from another site. Rarely, a PTFE graft is required. When the tumour affects the vena cava it must be resected and replaced with a prosthetic graft.

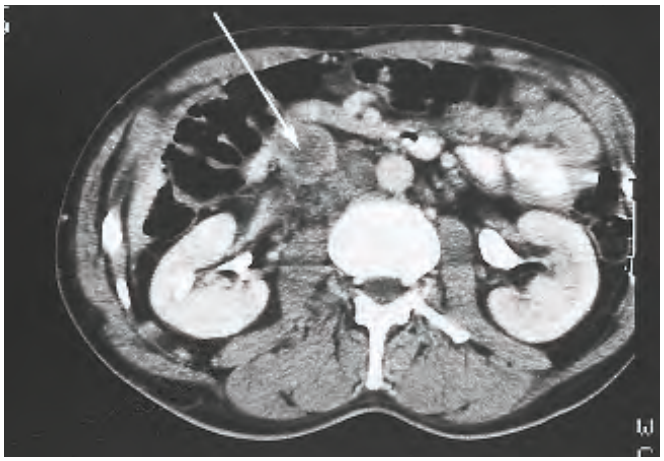

Figure 57.41 Inferior vena cava containing a filling defect from a leiomyosarcoma (arrow).

Cystic degeneration

As in the peripheral arterial system, cystic degeneration of the vein wall is an uncommon cause of venous occlusion. It may be detected by ultrasound. The cyst may be deroofed or the venous segment excised.

Chapter 58

Lymphatic disorders

Learning objectives

To understand:

- The main functions of the lymphatic system
- The development of the lymphatic system
- The various causes of limb swelling
- The aetiology, clinical features, investigations and treatment of lymphoedema

INTRODUCTION

The lymphatic system was first described by Erasistratus in Alexandria more than 2000 years ago. William Hunter, in the late eighteenth century, was the first to describe the function of the lymphatic system. Starling's pioneering work on the hydrostatic and haemodynamic forces controlling the movement of fluid across the capillary provided further insights into the function of the lymphatics. However, there is much about the lymphatic system that is not understood and debate continues over the precise aetiology of the most common abnormality of the system, namely lymphoedema.

ANATOMY AND PHYSIOLOGY OF THE LYMPHATIC SYSTEM

Functions

The principal function of the lymphatics is the return of protein-rich fluid to the circulation through the lymphaticovenous junctions in the jugular area. Thus, water, electrolytes, low molecular weight moieties (polypeptides, cytokines, growth factors) and macromolecules (fibrinogen, albumin, globulins, coagulation and fibrinolytic factors) from the interstitial fluid (ISF) return to the circulation via the lymphatics. Intestinal lymph (chyle) transports cholesterol, long-chain fatty acids, triglycerides and the fat-soluble vitamins (A, D, E and K) directly to the circulation, bypassing the liver. Lymphocytes and other immune cells also circulate within the lymphatic system.

Development and macroanatomy

In the human embryo lymph sacs develop at 6–7 weeks' gestation as four cystic spaces, one on either side of the neck and one in each groin. These cisterns enlarge and develop communications that permit lymph from the lower limbs and abdomen to drain via the cisterna chyli into the thoracic duct, which in turn drains into the left internal jugular vein at its confluence with the left subclavian vein. Lymph from the head and right arm drains via a separate lymphatic trunk, the right lymphatic duct, into the right internal jugular vein. Lymphatics accompany veins everywhere except in the cortical bony skeleton and central nervous system, although the brain and retina possess cerebrospinal fluid and aqueous humour, respectively.

The lymphatic system comprises lymphatic channels, lymphoid organs (lymph nodes, spleen, Peyer's patches, thymus, tonsils) and circulating elements (lymphocytes and other mononuclear immune cells). Lymphatic endothelial cells are derived from embryonic veins in the jugular and perimesonephric areas from where they migrate to form the primary lymph sacs and plexus. Both transcription (e.g. Prox1) and growth (e.g. vascular endothelial growth factor-C (VEGF-C)) factors are essential for these developmental events.

Microanatomy and physiology

Lymphatic capillaries

Lymphatics originate within the ISF space from specialised endothelialised capillaries (initial lymphatics) or non-endothelialised channels such as the spaces of Disse in the

Erasistratus of Chios, c.300–250BC, of the Medical School at Alexandria in Egypt is regarded by many as the first physiologist.
William Hunter, 1718–1783, anatomist and obstetrician who became the first Professor of Anatomy at the Royal Academy of Arts, London, UK. He was the elder brother of John Hunter, the anatomist and surgeon.
Ernest Henry Starling, 1866–1927, Professor of Physiology, University College, London, UK.
Josef Disse, 1852–1912, a German anatomist.

liver. Initial lymphatics are unlike arteriovenous capillaries in that:

- they are blind-ended;
- they are much larger (50 µm);
- they allow the entry of molecules of up to 1000 kDa in size because the basement membrane is fenestrated, tenuous or even absent and the endothelium itself possesses intra- and intercellular pores;
- they are anchored to interstitial matrix by filaments. In the resting state, initial lymphatics are collapsed. When ISF volume and pressure increases, initial lymphatics and their pores are held open by these filaments to facilitate increased drainage.

Terminal lymphatics

Initial lymphatics drain into terminal (collecting) lymphatics that possess bicuspid valves and endothelial cells rich in the contractile protein actin. Larger collecting lymphatics are surrounded by smooth muscle. Valves partition the lymphatics into segments (lymphangions) that contract sequentially to propel lymph into the lymph trunks.

Lymph trunks

Terminal lymphatics lead to lymph trunks, which have a structure similar to that of veins, namely a single layer of endothelial cells, lying on a basement membrane overlying a media comprising smooth muscle cells that are innervated with sympathetic, parasympathetic and sensory nerve endings. About 10% of lymph arising from a limb is transported in deep lymphatic trunks that accompany the main neurovascular bundles. The majority, however, is conducted against venous flow from deep to superficial in epifascial lymph trunks. Superficial trunks form lymph bundles of various sizes, which are located within strips of adipose tissue, and tend to follow the course of the major superficial veins.

Starling's forces

The distribution of fluid and protein between the vascular system and ISF depends on the balance of hydrostatic and oncotic pressures between the two compartments (Starling's forces), together with the relative impermeability of the blood capillary membrane to molecules over 70 kDa. In health, there is net capillary filtration, which is removed by the lymphatic system.

Transport of particles

Particles enter the initial lymphatics through interendothelial openings and vesicular transport through intraendothelial pores. Large particles are actively phagocytosed by macrophages and transported through the lymphatic system intracellularly.

Mechanisms of lymph transport

Resting ISF pressure is negative (-2 to -6 mmH_2O), whereas lymphatic pressures are positive, indicating that lymph flows against a small pressure gradient. It is believed that prograde lymphatic flow depends upon three mechanisms:

1 transient increases in interstitial pressure secondary to muscular contraction and external compression;
2 the sequential contraction and relaxation of lymphangions;
3 the prevention of reflux because of valves.

Lymphangions are believed to respond to increased lymph flow in much the same way as the heart responds to increased venous return, in that they increase their contractility and stroke volume. Contractility is also enhanced by noradrenaline, serotonin, certain prostaglandins and thromboxanes, and endothelin-1. Pressures of up to 30–50 mmHg have been recorded in normal lymph trunks and up to 200 mmHg in severe lymphoedema. Lymphatics may also modulate their own contractility through the production of nitric oxide and other local mediators. Transport in the thoracic and right lymph ducts also depends upon intrathoracic (respiration) and central venous (cardiac cycle) pressures. Therefore, cardiorespiratory disease may have an adverse effect on lymphatic function.

In summary, in the healthy limb, lymph flow is largely due to intrinsic lymphatic contractility, although this is augmented by exercise, limb movement and external compression. However, in lymphoedema, when the lymphatics are constantly distended with lymph, these external forces assume a much more important functional role.

ACUTE INFLAMMATION OF THE LYMPHATICS

Acute lymphangitis is an infection, often caused by *Streptococcus pyogenes* or *Staphylococcus aureus*, which spreads to the draining lymphatics and lymph nodes (lymphadenitis) where an abscess may form. Eventually this may progress to bacteraemia or septicaemia. The normal signs of infection (rubor, calor, dolor) are present and a red streak is seen in the skin along the line of the inflamed lymphatic (**Figure 58.1**). The part should be rested to reduce lymphatic drainage and elevated to reduce swelling, and the patient should be treated with intravenous antibiotics based upon actual or suspected sensitivities. Failure to improve within 48 hours suggests

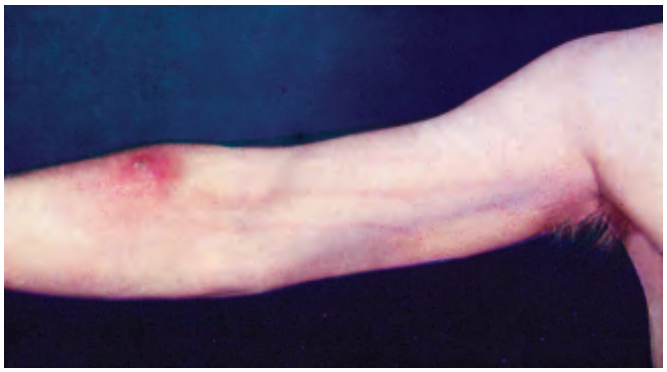

Figure 58.1 Acute lymphangitis of the arm. Erythematous streaks extend from the site of primary infection on the volar aspect of the forearm to epicondylar nodes at the elbow, and from there to enlarged and tender axillary lymph nodes.

inappropriate antibiotic therapy, the presence of undrained pus or the presence of an underlying systemic disorder (malignancy, immunodeficiency). The lymphatic damage caused by acute lymphangitis may lead to recurrent attacks of infection and lymphoedema; patients with lymphoedema are prone to so-called acute inflammatory episodes (see below).

LYMPHOEDEMA

Definition

Lymphoedema may be defined as abnormal limb swelling caused by the accumulation of increased amounts of high protein ISF secondary to defective lymphatic drainage in the presence of (near) normal net capillary filtration.

The scope of the clinical problem

At birth, 1 in 6000 people will develop lymphoedema with an overall prevalence of 0.13–2%. The condition is not only associated with significant physical symptoms and complications but is also a frequent cause of emotional and psychological distress, which can lead to difficulties with relationships, education and work.

Summary box 58.1

Symptoms frequently experienced by patients with lymphoedema

- Swelling, clothing or jewellery becoming tighter
- Constant dull ache, even severe pain
- Burning and bursting sensations
- General tiredness and debility
- Sensitivity to heat
- 'Pins and needles'
- Cramp
- Skin problems, including flakiness, weeping, excoriation and breakdown
- Immobility, leading to obesity and muscle wasting
- Backache and joint problems
- Athlete's foot
- Acute infective episodes

Despite this significant impact on quality of life, many sufferers choose not to seek medical advice because of embarrassment and a belief that nothing can be done. Patients who do come forward for help, especially those with non-cancer-related lymphoedema, often find they have limited access to appropriate expertise and treatment. Lymphoedema is often misdiagnosed and mistreated by doctors, who frequently have a poor understanding of the importance of the condition, believing it to be primarily a cosmetic problem in the early stages. However, making an early diagnosis is important because relatively simple measures can be highly effective at this stage and can prevent the development of disabling late disease, which is often very difficult to treat. It is also an opportunity for patients to make contact with patient support groups.

Summary box 58.2

What every patient with lymphoedema should receive

- An explanation of why the limb is swollen and the underlying cause
- Guidance on skin hygiene and care and the avoidance of acute infective episodes
- Antifungal prophylactic therapy to prevent athlete's foot
- Rapid access to antibiotic therapy if necessary, hospital admission for acute infective episodes
- Appropriate instructions regarding exercise therapy
- Manual lymphatic drainage (MLD)
- Multilayer lymphoedema bandaging (MLLB)
- Compression garments and, if appropriate, specialised footwear
- Advice on diet
- Access to support services and networks

The severity of unilateral limb lymphoedema can be classified as:

- mild: <20% excess limb volume;
- moderate: 20–40% excess limb volume;
- severe: >40% excess limb volume.

Pathophysiology

The ISF compartment (10–12 litres in a 70-kg man) constitutes 50% of the wet weight of the skin and subcutaneous tissues and, in order for oedema to be clinically detectable, its volume has to double. About 8 litres (protein concentration approximately 20–30 g/L, similar to ISF) of lymph is produced each day and travels in afferent lymphatics to lymph nodes. There, the volume is halved and the protein concentration doubled, resulting in 4 litres of lymph re-entering the venous circulation each day via efferent lymphatics. In one sense, all oedema is lymphoedema in that it results from an inability of the lymphatic system to clear the ISF compartment. However, in most types of oedema this is because the capillary filtration rate is pathologically high and overwhelms a normal lymphatic system, resulting in the accumulation of low-protein oedema fluid. In contrast, in true lymphoedema, when the primary problem is in the lymphatics, capillary filtration is normal and the oedema fluid is relatively high in protein. Of course, in a significant number of patients with oedema there is both abnormal capillary filtration and abnormal lymphatic drainage, as in chronic venous insufficiency (CVI) for example.

Lymphoedema results from lymphatic aplasia, hypoplasia, dysmotility (reduced contractility with or without valvular insufficiency), obliteration by inflammatory, infective or neoplastic processes, or surgical extirpation. Whatever the primary abnormality, the resultant physical and/or functional obstruction leads to lymphatic hypertension and distension, with further secondary impairment of contractility and valvular competence. Lymphostasis and lymphotension lead to the accumulation in the ISF of fluid, proteins, growth factors and other active peptide moieties, glycosaminoglycans and particulate matter, including bacteria. As a consequence, there is increased

collagen production by fibroblasts, an accumulation of inflammatory cells (predominantly macrophages and lymphocytes) and activation of keratinocytes. The end result is protein-rich oedema fluid, increased deposition of ground substance, subdermal fibrosis and dermal thickening and proliferation. Lymphoedema, unlike all other types of oedema, is confined to the epifascial space. Although muscle compartments may be hypertrophied because of the increased work involved in limb movement, they are characteristically free of oedema.

Classification

Two main types of lymphoedema are recognised:

1 **Primary lymphoedema**, in which the cause is unknown (or at least uncertain and unproven); it is thought to be caused by 'congenital lymphatic dysplasia'.
2 **Secondary or acquired lymphoedema**, in which there is a clear underlying cause.

Primary lymphoedema is usually further subdivided on the basis of the presence of family history, age of onset and lymphangiographic findings (*Tables 58.1* and *58.2*).

TABLE 58.1 Aetiological classification of lymphoedema.

Primary lymphoedema	Congenital (onset <2 years old): sporadic; familial (Nonne–Milroy's disease)
	Praecox (onset 2–35 years old): sporadic; familial (Letessier–Meige's disease)
	Tarda (onset after 35 years old)
Secondary lymphoedema	Parasitic infection (filariasis)
	Fungal infection (tinea pedis)
	Exposure to foreign body material (silica particles)
	Primary lymphatic malignancy
	Metastatic spread to lymph nodes
	Radiotherapy to lymph nodes
	Surgical excision of lymph nodes
	Trauma (particularly degloving injuries)
	Superficial thrombophlebitis
	Deep venous thrombosis

TABLE 58.2 Clinical classification of lymphoedema.

Grade (Brunner)	Clinical features
Subclinical (latent)	There is excess interstitial fluid and histological abnormalities in lymphatics and lymph nodes, but no clinically apparent lymphoedema
I	Oedema pits on pressure and swelling largely or completely disappears on elevation and bed rest
II	Oedema does not pit and does not significantly reduce upon elevation, positive Stemmer's sign
III	Oedema is associated with irreversible skin changes, i.e. fibrosis, papillae

Risk factors for lymphoedema

Although the true risk factor profile for lymphoedema is not currently known, a number of factors are thought to predispose an individual to its development and predict progression, severity and outcome of the condition (*Table 58.3*).

Symptoms and signs

In most cases, the diagnosis of primary or secondary lymphoedema can be made and the condition can be differentiated from other causes of a swollen limb on the basis of history and examination without recourse to complex investigation (*Table 58.4*). Unlike other types of oedema, lymphoedema characteristically involves the foot (**Figure 58.2**). The contour of the ankle is lost through infilling of the submalleolar depressions, a 'buffalo hump' forms on the dorsum of the foot, the toes appear 'square' because of confinement of footwear and the skin on the dorsum of the toes cannot be pinched because of subcutaneous fibrosis (Stemmer's sign). Lymphoedema usually spreads proximally to knee level and less commonly affects the whole leg (**Figure 58.3**). In the early stages,

Figure 58.2 The foot of a patient with typical lymphoedema.

Robert Stemmer, 1925–2000, phlebologist, Strasbourg, France.

TABLE 58.3 Risk factors for lymphoedema.

Upper limb/trunk lymphoedema	Lower limb lymphoedema
Surgery with axillary lymph node dissection, particularly if extensive breast or lymph node surgery	Surgery with inguinal lymph node dissection
Scar formation, fibrosis and radiodermatitis from postoperative axillary radiotherapy	Postoperative pelvic radiotherapy
Radiotherapy to the breast or to the axillary, internal mammary or subclavicular lymph nodes	Recurrent soft tissue infection at the same site
Drain/wound complications or infection	Obesity
Cording (axillary web syndrome)	Varicose vein stripping and vein harvesting
Seroma formation	Genetic predisposition/family history of chronic oedema
Advanced cancer	Advanced cancer
Obesity	Intrapelvic or intra-abdominal tumours that involve or directly compress lymphatic vessels
Congenital predisposition	Orthopaedic surgery
Trauma in an 'at-risk' arm (venepuncture, blood pressure measurement, injection)	Poor nutritional status
Chronic skin disorders and inflammation	Thrombophlebitis and chronic venous insufficiency, particularly post-thrombotic syndrome
Hypertension	Any unresolved asymmetrical oedema
Taxane chemotherapy	Chronic skin disorders and inflammation
Insertion of pacemaker	Concurrent illnesses such as phlebitis, hyperthyroidism, kidney or cardiac disease
Arteriovenous shunt for dialysis	Immobilisation and prolonged limb dependency
Air travel	Air travel
Living in or visiting an area for endemic lymphatic filariasis	Living in or visiting an area for endemic lymphatic filariasis

lymphoedema will 'pit' and the patient will report that the swelling is down in the morning. This represents a reversible component to the swelling, which can be controlled. Failure to do so allows fibrosis, dermal thickening and hyperkeratosis to occur. In general, primary lymphoedema progresses more slowly than secondary lymphoedema. Chronic eczema, fungal infection of the skin (dermatophytosis) and nails (onychomycosis), fissuring, verrucae and papillae (warts) are frequently seen in advanced disease. Ulceration is unusual, except in the presence of chronic venous insufficiency.

Lymphangiomas are dilated dermal lymphatics that 'blister' onto the skin surface. The fluid is usually clear but may be blood-stained. In the long term, lymphangiomas thrombose and fibrose, forming hard nodules that may raise concerns about malignancy. If lymphangiomas are <5 cm across, they are termed lymphangioma circumscriptum, and if they are more widespread, they are termed lymphangioma diffusum. If they form a reticulate pattern of ridges then it has been termed lymphoedema *ab igne*. Lymphangiomas frequently weep (lymphorrhoea, chylorrhoea), causing skin maceration, and they act as a portal for infection. Protein-losing diarrhoea, chylous ascites, chylothorax, chyluria and discharge from lymphangiomas suggest lymphangectasia (megalymphatics) and chylous reflux.

Ulceration, non-healing bruises and raised purple-red nodules should lead to suspicion of malignancy. Lymphangiosarcoma was originally described in postmastectomy oedema (Stewart–Treves' syndrome) and affects around 0.5% of patients at a mean onset of 10 years. However, lymphangiosarcoma can develop in any long-standing lymphoedema, but usually takes longer to manifest (20 years). It presents as single or multiple bluish/red skin and subcutaneous nodules that spread to form satellite lesions, which may then become confluent. The

Summary box 58.3

Malignancies associated with lymphoedema

- Lymphangiosarcoma (Stewart–Treves' syndrome)
- Kaposi's sarcoma (human immunodeficiency virus)
- Squamous cell carcinoma
- Liposarcoma
- Malignant melanoma
- Malignant fibrous histiocytoma
- Basal cell carcinoma
- Lymphoma

Ab igne is Latin for 'from fire'.
Fred Waldorf Stewart, 1894–1991, Chairman of Pathology, Memorial Sloan-Kettering Hospital, New York, NY, USA. An annual award was instituted in his name by the Department of Pathology called the Fred Waldorf Stewart Award.
Norman Treves, 1894–1964, American surgeon. He had a special interest in male breast cancer.
Stewart and Treves reported this condition in a joint paper in 1948.

TABLE 58.4 Differential diagnosis of the swollen limb.

Non-vascular or lymphatic	General disease states	Cardiac failure from any cause
		Liver failure
		Hypoproteinaemia due to nephrotic syndrome, malabsorption, protein-losing enteropathy
		Hypothyroidism (myxoedema)
		Allergic disorders, including angioedema and idiopathic cyclic oedema
		Prolonged immobility and lower limb dependency
	Local disease processes	Ruptured Baker's cyst
		Myositis ossificans
		Bony or soft-tissue tumours
		Arthritis
		Haemarthrosis
		Calf muscle haematoma
		Achilles tendon rupture
	Retroperitoneal fibrosis	May lead to arterial, venous and lymphatic abnormalities
	Gigantism	Rare
		All tissues are uniformly enlarged
	Drugs	Corticosteroids, oestrogens, progestagens
		Monoamine oxidase inhibitors, phenylbutazone, methyldopa, hydralazine, nifedipine
	Trauma	Painful swelling due to reflex sympathetic dystrophy
	Obesity	Lipodystrophy
		Lipoidosis
Venous	Deep venous thrombosis	There may be an obvious predisposing factor, such as recent surgery
		The classical signs of pain and redness may be absent
	Post-thrombotic syndrome	Swelling, usually of the whole leg, due to iliofemoral venous obstruction
		Venous skin changes, secondary varicose veins on the leg and collateral veins on the lower abdominal wall
		Venous claudication may be present
	Varicose veins	Simple primary varicose veins are rarely the cause of significant leg swelling
	Klippel–Trenaunay's syndrome and other malformations	Rare
		Present at birth or develops in early childhood
		Comprises an abnormal lateral venous complex, capillary naevus, bony abnormalities, hypo(a)plasia of deep veins and limb lengthening
		Lymphatic abnormalities often coexist
	External venous compression	Pelvic or abdominal tumour including the gravid uterus
		Retroperitoneal fibrosis
	Ischaemia–reperfusion	Following lower limb revascularisation for chronic and particularly chronic ischaemia
Arterial	Arteriovenous malformation	May be associated with local or generalised swelling
	Aneurysm	Popliteal
		Femoral
		False aneurysm following (iatrogenic) trauma

diagnosis is usually made late and confirmed by skin biopsy. Amputation offers the best chance of survival but, even then, most patients live for less than 3 years. It has been suggested that lymphoedema leads to an impairment of immune surveillance and so predisposes to other malignancies, although the causal association is not as definite as it is for lymphangiosarcoma.

William Morrant Baker, 1839–1896, surgeon, St Bartholomew's Hospital, London, UK, described these cysts in 1877.
Maurice Klippel and Paul Trenaunay, two French physicians, described this syndrome in 1900.

Figure 58.3 The lower leg of a patient with typical lymphoedema.

PRIMARY LYMPHOEDEMA

Aetiology

It has been proposed that all cases of primary lymphoedema are due to an inherited abnormality of the lymphatic system, sometimes termed 'congenital lymphatic dysplasia'. However, it is possible that many sporadic cases of primary lymphoedema occur in the presence of a (near-)normal lymphatic system and are actually examples of secondary lymphoedema for which the triggering events have gone unrecognised. These might include seemingly trivial (but repeated) bacterial and/or fungal infections, insect bites, barefoot walking (silica), deep venous thrombosis (DVT) or episodes of superficial thrombophlebitis. In animal models, simple excision of lymph nodes and/or trunks leads to acute lymphoedema, which resolves within a few weeks, presumably because of the development of collaterals. The human condition can only be mimicked by inducing extensive lymphatic obliteration and fibrosis. Even then, there may be considerable delay between the injury and the onset of oedema. Primary lymphoedema is much more common in the legs than the arms. This may be because of gravity and a bipedal posture, the fact that the lymphatic system of the leg is less well developed, or the increased susceptibility of the leg to trauma and/or infection. Furthermore, loss of the venoarteriolar reflex (VAR), which protects lower limb capillaries from excessive hydrostatic forces in the erect posture, with age and disease (CVI, diabetes), may be important.

Classification

Primary lymphoedema is usually classified on the basis of apparent genetic susceptibility, age of onset or lymphangiographic findings. None of these is ideal and the various classification systems in existence can appear confusing and conflicting, as various terms and eponyms are used loosely and interchangeably. This has hampered research and efforts to gain a better understanding of underlying mechanisms, the effectiveness of therapy and prognosis.

Genetic susceptibility

Primary lymphoedema can be familial or sporadic. In familial cases the genetic mutations can be inherited in an autosomal dominant, recessive or x-linked pattern. In the last few years the application of Next Generation Sequencing, which allows identification of genetic mutations, even in sporadic cases and smaller families, has increased our understanding of the genetic basis of lymphoedema.

So far, mutations in more than 20 genes have been linked to the development of primary lymphoedema. In individuals with familial mutations the penetrance of lymphoedema can often be incomplete leading to a large variability in clinical presentation. Involvement of other systems (cardiovascular, respiratory, nervous, digestive) is common and can indicate a specific mutation. Presence of isolated lower limb lymphoedema at birth, classically described as Milroy's disease, suggests mutation in FMS-like tyrosine kinase 4 (FLT4)/vascular endothelial growth factor receptor-3 (VEGFR-3) or VEGF-C. In these patients, reduced initial uptake and presence of tortuous lymphatic tracts with evidence of rerouting in lymphangiography suggests mutation in the VEGF-C gene. The unique signs and lymphangiographic features of some of the genes currently known to cause primary lymphoedema are summarised in *Table 58.5*. Lymphoedema can also be present as a minor sign in some well-recognised syndromes. Primary lymphoedema is present in less than 10% of cases of tuberous sclerosis (TSC1 and 2 gene mutations). Lymphoedema has been reported in patients with Noonan syndrome in the presence of PTPN11, SOS1 or KRAS mutations, and in patients with Turner syndrome (monosomy X) and capillary malformation-arteriovenous malformation syndrome (RAS p21 protein activator 1 (RASA1) mutation).

William Forsyth Milroy, 1855–1942, Professor of Clinical Medicine, Columbia University, New York, NY, USA, described the condition in 1892.
Jacqueline Noonan, b.1928, paediatric cardiologist, University of Kentucky, USA.
Henry Hubert Turner, 1892–1970, Professor of Medicine, The University of Oklahoma, OK, USA.

TABLE 58.5 Genes associated with primary lymphoedema.

Affected gene	Unique clinical sign(s)	Lymphoscintigraphy findings
FMS- like tyrosine kinase 4 (FLT4)	Isolated lower limb oedema present at birth (Nonne–Milroy disease)	Failure of initial lymphatic absorption (functional aplasia)
Vascular endothelial growth factor C (VEGF-C)	Milroy-like disease	Reduced initial uptake with tortuous lymphatic tracts and evidence of rerouting
Forkhead box C2 (FOXC2)	Distichiasis, cleft lip and/or palate	Hyperplastic lymphatic vessels with reflux of lymph
Gap junction protein gamma-2 (GJC2)	Lymphoedema on all four extremities (Meige syndrome)	Significant reduction in initial uptake, normal lymphatic tracts
Gap junction protein alpha – 1 (GJA1)	Oculodentodigital dysplasia	Significant reduction in initial uptake, normal lymphatic tracts
Kinesin family member 11 (KIF11)	Microcephaly, chorioretinopathy, lymphoedema and intellectual disability (MCLMR syndrome)	Failure of initial lymphatic absorption (functional aplasia)
Collagen and calcium-binding EGF domain-containing protein 1 (CCBE1)	Microcephaly, unusual face and lymphoedema affecting all four limbs (Hennekam syndrome)	Abnormal lymph drainage in all four limbs and the thoracic duct
Homolog of drosophila FAT tumor suppressor 4 (FAT4)	Microcephaly, unusual face and lymphoedema affecting all four limbs (Hennekam syndrome)	Abnormal lymph drainage in all four limbs and the thoracic duct
Gata-binding protein 2 (GATA2)	Myelodysplasia (Emberger syndrome) Warts, recurrent viral and/or bacterial infections Predisposition to several cancers	Hypoplasia of the lymphatics
Inhibitor of kappa light polypeptide gene enhancer in B-cells, kinase gamma (IKBKG)	Ectodermal dysplasia, anhidrotic, osteopetrosis and immunodeficiency (OLEDAID syndrome)	
Protein-tyrosine phosphatase non- receptor-type 14 (PTPN14)	Choanal atresia	
SRY-Box 18 (SOX18)	Hypotrichosis, lymphoedema, telangiectasia and renal defects (HLTR syndrome)	
Hepatocyte growth factor (HGF)	Lymphangectasia	
Integrin subunit alpha 9 (ITGA9)	Fetal chylothorax	

Most of the proteins encoded by these genes belong to the VEGF-C-VEGFR-3 ligand–receptor signalling complex and RAS/MAPK axis. The VEGF-C–VEGFR-3 signalling pathway is a major regulator of lymphangiogenesis. Downstream, transcription factors such as FOXC2 and ITGA9 play a major role in the development of valves in the lymphatic vessels. Mutations in the FLT4 gene that encodes VEGFR-3 protein were the first to be discovered and affect the tyrosine-kinase domain of the receptor, causing congenital primary lymphoedema. Mutations in the genes encoding the RAS/MAPK pathway cause several rare genetic conditions often called RASopathies. All RASopathies have some common clinical features such as distinct facial features and cardiac abnormalities. In addition to lymphoedema, these patients can also present with chylothorax and chylous ascites.

Age of onset

Lymphoedema congenita (onset at or within 2 years of birth) is more common in males and is more likely to be bilateral and involve the whole leg. Lymphoedema praecox (onset from 2 to 35 years) is three times more common in females, has a peak incidence shortly after menarche, is three times more likely to be unilateral than bilateral and usually only extends to the knee. Lymphoedema tarda develops, by definition, after the age of 35 years and is often associated with obesity, with lymph nodes being replaced with fibrofatty tissue. The cause is unknown. Lymphoedema developing for the first time after 50 years should prompt a thorough search for underlying (pelvic, genitalia) malignancy. It is worth noting that, in such patients, lymphoedema often commences proximally in the thigh rather than distally **(Figure 58.4)**.

Max Nonne, 1861–1959, a neurologist of Hamburg, Germany, described this disease in 1891.
Raoul Hennekam, contemporary, geneticist, Amsterdam Medical Centre, the Nederlands.
Jean-Marie Emberger, contemporary, haematologist, Montpellier, France.
Henri Meige,1866-1940, physician, La Salpêtrière, Paris, France, gave his description of the disease in 1899.

Figure 58.4 This patient, in her sixth decade, presented with rapid onset of lymphoedema of the right leg. On further investigation she was found to have locally advanced bladder carcinoma. Note that unlike most cases of lymphoedema, the swelling is greater proximally than distally.

Lymphangiographic classification

Browse has classified primary lymphoedema on the basis of lymphangiographic findings (*Table 58.6* and **Figures 58.5 and 58.6**). These findings may be related to the clinical presentations described above. Some patients with lymphatic hyperplasia possess megalymphatics in which lymph or chyle refluxes freely under the effects of gravity against the physiological direction of flow. The megalymphatics usually end in thin-walled vesicles on the skin, serous surfaces (chylous ascites, chylothorax), intestine (protein-losing enteropathy), kidney or bladder (chyluria) (**Figure 58.7**).

SECONDARY LYMPHOEDEMA

This is the most common form of lymphoedema. There are several well-recognised causes including infection, inflammation, neoplasia and trauma (*Table 58.7*).

Figure 58.5 This patient presented with congenital lymphoedema of the right leg. The lymphangiogram shows lymphatic hypoplasia.

Filariasis

This is the most common cause of lymphoedema worldwide, affecting up to 100 million individuals. It is particularly prevalent in Africa, India and South America where 5–10% of the population may be affected. The viviparous nematode *Wuchereria bancrofti*, whose only host is man, is responsible for 90% of cases and is spread by the mosquito. The disease is associated with poor sanitation. The parasite enters lymphatics from the

TABLE 58.6 Lymphangiographic classification of primary lymphoedema.

	Congenital hyperplasia (10%)	Distal obliteration (80%)	Proximal obliteration (10%)
Age of onset	Congenital	Puberty (praecox)	Any age
Sex distribution	Male > female	Female > male	Male = female
Extent	Whole leg	Ankle, calf	Whole leg, thigh only
Laterality	Unilateral = bilateral	Often bilateral	Usually unilateral
Family history	Often positive	Often positive	No
Progression	Progressive	Slow	Rapid
Response to compression therapy	Variable	Good	Poor
Comments	Lymphatics are increased in number; although functionally defective, there is usually an increased number of lymph nodes. May have chylous ascites, chylothorax and protein-losing enteropathy	Absent or reduced distal superficial lymphatics. Also termed aplasia or hypoplasia	There is obstruction at the level of the aortoiliac or inguinal nodes. If associated with distal dilatation, the patient may benefit from lymphatic bypass operation. Other patients have distal obliteration as well

Sir Norman Leslie Browse, b.1931, formerly Professor of Surgery, the United Medical and Dental Schools of Guy's and St Thomas's Hospitals, London, UK; former President of the Royal College of Surgeons of England.

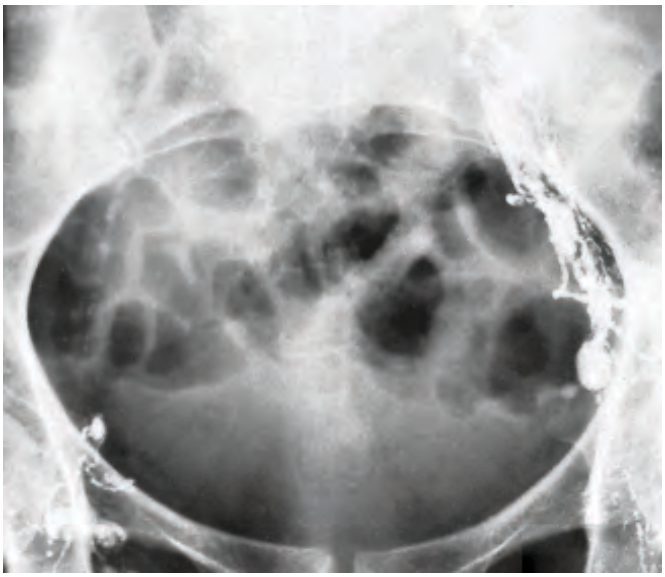

Figure 58.6 This patient presented with lymphoedema of the right leg. A bipedal lymphangiogram demonstrated normal lymphatics in the right leg up to the inguinal nodes, but no progression of contrast above the inguinal ligament – a case of proximal obstruction.

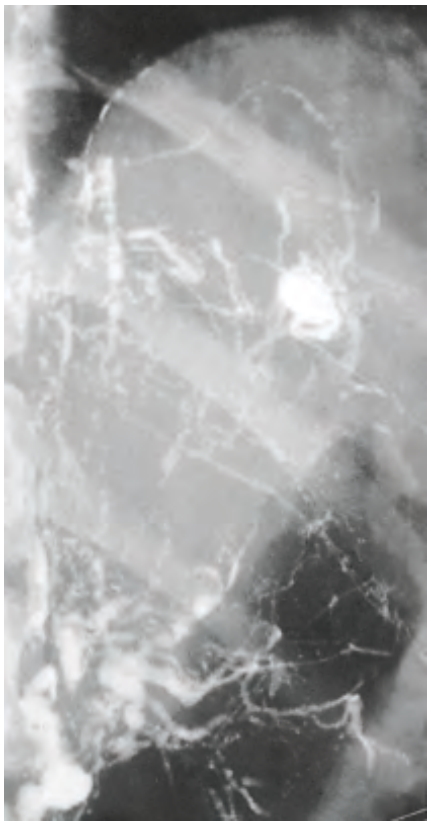

Figure 58.7 Lymphangiogram demonstrating reflux from dilated para-aortic vessels into the left kidney in a patient with filariasis who presented with chyluria.

blood and lodges in lymph nodes, where it causes fibrosis and obstruction, due partly to direct physical damage and partly to the immune response of the host. Proximal lymphatics become grossly dilated with adult parasites. The degree of

TABLE 58.7 Classification of causes of secondary lymphoedema.

Classification	Example(s)
Trauma and tissue damage	Lymph node excision
	Radiotherapy
	Burns
	Variscose vein surgery/harvesting
	Large/circumferential wounds
	Scarring
Malignant disease	Lymph node metastases
	Infiltrative carcinoma
	Lymphoma
	Pressure from large tumours
Venous disease	Chronic venous insufficiency
	Venous ulceration
	Post-thrombotic syndrome
	Intravenous drug use
Infection	Cellulitis/erysipelas
	Lymphadenitis
	Tuberculosis
	Filariasis
Inflammation	Rheumatoid arthritis
	Dermatitis
	Psoriasis
	Sarcoidosis
	Dermatosis with epidermal involvement
Endocrine disease	Pretibial myxoedema
Immobility and dependency	Dependency oedema
	Paralysis
Factitious	Self-harm

Summary box 58.4

Features of filariasis

Acute

- Fever
- Headache
- Malaise
- Inguinal and axillary lymphadenitis
- Lymphangitis
- Cellulitis, abscess formation and ulceration
- Funiculo epididymo-orchitis

Chronic

- Lymphoedema of legs (arm, breast)
- Hydrocoele
- Abdominal lymphatic varices
  - Chyluria
  - Lymphuria

oedema is often massive, in which case it is termed elephantiasis (**Figure 58.8**). Immature parasites (microfilariae) enter the blood at night and can be identified on a blood smear, in a centrifuged specimen of urine or in lymph itself. A complement fixation test is also available and is positive in present or past infection. Eosinophilia is usually present.

Diethylcarbamazine destroys the parasites but does not reverse the lymphatic changes, although there may be some regression over time. Once the infection has been cleared, treatment is as for primary lymphoedema. Public health measures to reduce mosquito breeding, protective clothing and mosquito netting may be usefully employed to combat the condition.

Figure 58.8 Elephantiasis due to filariasis.

Endemic elephantiasis (podoconiosis)

This is common in the tropics and affects more than 500 000 people in Africa. The barefoot cultivation of soil composed of alkaline volcanic rocks leads to destruction of the peripheral lymphatics by particles of silica, which can be seen in macrophages in draining lymph nodes. Plantar oedema develops in childhood and rapidly spreads proximally. The condition is prevented and its progression is slowed by the wearing of shoes.

Bacterial infection

Lymphangitis and lymphadenitis can cause lymphatic destruction that predisposes to lymphoedema complicated by further acute inflammatory episodes. Interestingly, in such patients, lymphangiography has revealed abnormalities in the contralateral, unaffected limb, suggesting an underlying, possibly inherited, susceptibility. Lymphatic and lymph node destruction by tuberculosis is also a well-recognised cause of lymphoedema, especially in resource-poor countries.

Malignancy and its treatment

Treatment (surgery, radiotherapy) for breast carcinoma is the most common cause of lymphoedema in resource-rich countries, but is decreasing in incidence as surgery becomes more conservative (see Chapter 53). Lymphoma may present with lymphoedema, as may malignancy of the pelvic organs and external genitalia. Kaposi's sarcoma, developing in the course of human immunodeficiency virus (HIV)-related illness, may cause lymphatic obstruction and is a growing cause of lymphoedema in certain parts of the world.

Trauma

It is not unusual for patients to develop chronic localised or generalised swelling following trauma. The aetiology is often multifactorial and includes disuse, venous thrombosis and lymphatic injury or destruction. Degloving injuries and burns are particularly likely to disrupt dermal lymphatics. Tenosynovitis can also be associated with localised subcutaneous lymphoedema, which can be a cause of troublesome persistent swelling following ankle and wrist 'sprains' and repetitive strain injury.

Lymphoedema and chronic venous insufficiency

It is important to appreciate the relationship between lymphoedema and CVI as both conditions are relatively common and so often coexist in the same patient, and it can be difficult to unravel which components of the patient's symptom complex are caused by each. There is no doubt that superficial venous thrombophlebitis (SVT) and DVT can both lead to lymphatic destruction and secondary lymphoedema, especially if recurrent. Lymphoedema is an important contributor to the swelling of the post-thrombotic syndrome. It has also been suggested that lymphoedema can predispose to DVT, and possible SVT, through immobility and acute inflammatory episodes. Certainly, tests of venous function (duplex ultrasonography, plethysmography) are frequently abnormal in patients with lymphoedema.

It is not uncommon to see patients (usually women) with lymphoedema in whom a duplex ultrasound scan has revealed superficial reflux (such reflux is present subclinically in up to one-third of the adult population). Although isolated, superficial venous reflux rarely, if ever, leads to limb swelling; such patients are frequently misdiagnosed as having venous disease

Moritz Kaposi, 1837–1902, Hungarian dermatologist, described multiple pigmented skin sarcoma in 1872.

rather than lymphoedema, and are subjected mistakenly to varicose vein surgery. Not only will such surgery invariably fail to relieve the swelling, it will usually make it worse as saphenofemoral and saphenopopliteal ligation, together with saphenous stripping, will compromise still further drainage through the subcutaneous lymph bundles (which follow the major superficial veins) and draining inguinal and popliteal lymph nodes.

Miscellaneous conditions

Rheumatoid and psoriatic arthritis (chronic inflammation and lymph node fibrosis), contact dermatitis, snake and insect bites and retroperitoneal fibrosis are all rare but well-documented causes of lymphoedema. Pretibial myxoedema is due to the obliteration of initial lymphatics by mucin.

Conditions mimicking lymphoedema

Factitious lymphoedema

This is caused by application of a tourniquet (a 'rut' and sharp cut-off is seen on examination) or 'hysterical' disuse in patients with psychological and psychiatric problems.

Immobility

Generalised or localised immobility of any cause leads to chronic limb swelling that can be misdiagnosed as lymphoedema; for example, the elderly person who spends all day (and sometimes all night) sitting in a chair (armchair legs), the hemiplegic stroke patient and the young patient with multiple sclerosis.

Lipoedema

This presents almost exclusively in women and comprises bilateral, usually symmetrical, enlargement of the legs and, sometimes, the lower half of the body because of the abnormal deposition of fat. It may or may not be associated with generalised obesity. There are a number of features that help to differentiate the condition from lymphoedema but, of course, lipoedema may coexist with other causes of limb swelling. It has been proposed that lipoedema results from, or at least is associated with, fatty obliteration of lymphatics and lymph nodes.

Summary box 58.5

Features of lipoedema that help differentiate it from lymphoedema

- Occurs almost exclusively in women
- Onset nearly always coincides with puberty
- Nearly always bilateral and symmetrical
- Involvement of trunk
- The feet are not involved, leading to an inverse shouldering effect at the malleoli
- No pitting
- No response to elevation or compression
- No skin changes of lymphoedema (negative Stemmer's sign)
- MRI shows subcutaneous fat but no fluid accumulation

INVESTIGATION OF LYMPHOEDEMA

Are investigations necessary?

It is usually possible to diagnose and manage lymphoedema purely on the basis of history and examination, especially when the swelling is mild and there are no apparent complicating features. In patients with severe, atypical and multifactorial swelling, investigations may help confirm the diagnosis, inform management and provide prognostic information.

'Routine' tests

These include a full blood count, urea and electrolytes, creatinine, liver function tests, thyroid function tests, plasma total protein and albumin, fasting glucose, C-reactive protein, urine dipstick including observation for chyluria, blood smear for microfilariae, chest radiograph and ultrasound.

Lymphangiography and isotope lymphoscintigraphy

Direct lymphangiography remains the 'gold standard' for showing structural abnormalities of larger lymphatics and nodes (**Figure 58.9**). However, it can be technically difficult, it is unpleasant for the patient, it may cause further lymphatic injury and, largely, it has become obsolete as a routine method of investigation.

Isotope lymphoscintigraphy has largely replaced lymphangiography as the primary diagnostic technique in cases of clinical uncertainty. Radioactive technetium-labelled protein or colloid particles are injected into an interdigital web space and specifically taken up by lymphatics, and serial radiographs are taken with a gamma camera. The technique provides a qualitative measure of lymphatic function rather than quantitative function or anatomical detail. Quantitative lymphoscintigraphy is performed using a dynamic (exercise) component in addition to the static test and provides information on lymphatic transport.

Computed tomography

A single, axial computed tomography (CT) slice through the mid-calf has been proposed as a useful diagnostic test for lymphoedema (coarse, non-enhancing, reticular 'honeycomb' pattern in an enlarged subcutaneous compartment), venous oedema (increased volume of the muscular compartment) and lipoedema (increased subcutaneous fat). CT can also be used to exclude pelvic or abdominal mass lesions. It can also be used to monitor response to treatment through serial measurements of cross-sectional area and tissue density.

Magnetic resonance imaging

Non-contrast magnetic resonance imaging (MRI) is also useful in identifying the classical circumferential reticular pattern (honeycomb) within the epifascial compartment.

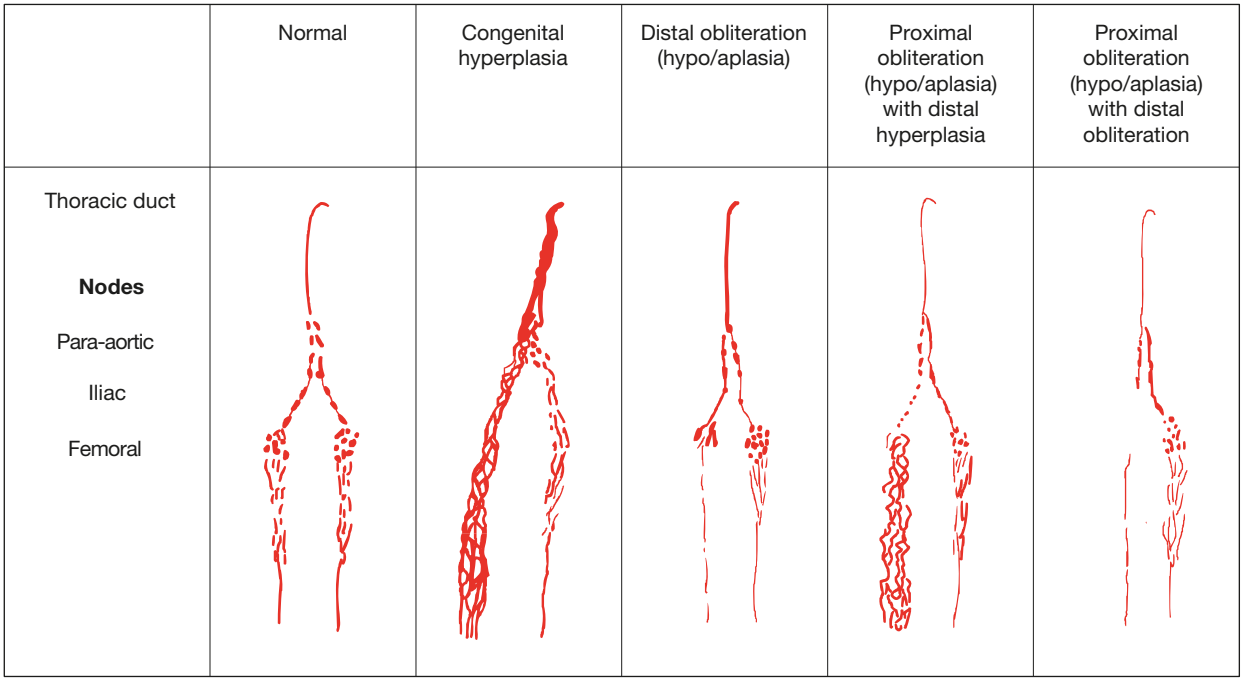

Figure 58.9 Lymphangiographic patterns of primary lymphoedema.

Involvement of the subfascial compartment is more suggestive of venous disease. In lipoedema, there is fat deposition in the subcutaneous tissues without the typical reticular pattern and lymphatic congestion. Using the principles of spin labelling MRI, the lymphatic flow velocities can be assessed and monitored. MRI lymphography, using gadopentetate dimeglumine contrast, correlates substantially with lymphoscintigraphy and provides detailed anatomical and functional status of lymphatic vessels and lymph nodes.

Ultrasound

Ultrasound can provide useful information about venous function including DVT and venous abnormalities.

Lympho-fluoroscopies

More recently, fluorescent molecules, such as indocyanine green (ICG), are being used to image the superficial lymphatic system. When excited using appropriate light energy, these molecules emit photons with a different wavelength that can be detected using dedicated near-infrared imaging devices, providing excellent anatomic and functional details of the lymphatic system. This imaging is increasingly being used to study the lymphatic system and the effects of some therapies.

Pathological examination

In cases in which malignancy is suspected, samples of lymph nodes may be obtained by fine-needle aspiration, needle core biopsy or surgical excision. Skin biopsy will confirm the diagnosis of lymphangiosarcoma.

Limb volume measurement

While not helpful in the diagnosis of lymphoedema, limb volume measurement is a useful tool to determine severity of lymphoedema, guide management and assess response to treatment. Limb volume is typically measured at diagnosis, following intensive treatment and at follow-up. In unilateral limb swelling the affected side can be compared to the contralateral unaffected limb. In bilateral swelling the volume of both limbs is tracked with time.

Measurements are recorded in millilitres or expressed as a percentage of the normal limb. Water plethysmography (water displacement) is the 'gold standard' method, but is limited by practicalities of measurement and hygiene issues. Other options include circumferential limb measurements and perometry (infrared light beams measure the outline of the limb to calculate volume).

MANAGEMENT OF LYMPHOEDEMA

Overview

The evaluation of the lymphoedema patient needs to be 'holistic' and their care delivered by a multiprofessional team comprising physical therapists, nurses, orthotists, physicians (dermatologists, oncologists, palliative care specialists), surgeons and social service professionals. Although surgery itself has a very small role, surgeons (especially those with breast and vascular interests) are frequently asked to oversee the management of these patients. Early diagnosis and institution of management are essential because at that stage relatively simple measures can be highly effective and will prevent

the development of disabling late-stage disease, which is extremely difficult to treat. There is often a latent period of several years between the precipitating event and the onset of lymphoedema. The identification, education and treatment of such 'at-risk' patients can slow down, even prevent, the onset of disease. In patients with established lymphoedema, the three goals of treatment are to relieve pain, reduce swelling and prevent the development of complications.

Summary box 58.6

Initial evaluation of the patient with lymphoedema

- History (age of onset, location, progression, exacerbating and relieving features)
- Past medical history including cancer history
- Family history
- Obesity (diet, height and weight, body mass index)
- Complications (venous, arterial, skin, joint, neurological, malignant)
- Assessment of physical, emotional and psychosocial symptoms
- Social circumstances (mobility, housing, education, work)
- Special needs (footwear, clothing, compression garments, pneumatic devices, mobility aids)
- Previous and current treatment
- Pain control
- Compliance with therapy and ability to self-care

Relief of pain

On initial presentation, 50% of patients with lymphoedema complain of significant pain. The pain is usually multifactorial and its severity and underlying cause(s) will vary depending on the aetiology of the lymphoedema. For example, following treatment for breast cancer, pain may arise from the swelling itself (radiation and surgery induced); nerve (brachial plexus and intercostobrachial nerve), bone (secondary deposits, radiation necrosis) and joint (arthritis, bursitis, capsulitis) disease; and recurrent disease. Treatment involves the considered use of non-opioid and opioid analgesics, corticosteroids, tricyclic antidepressants, muscle relaxants, antiepileptics, nerve blocks, physiotherapy and adjuvant anticancer therapies (chemo-, radio- and hormonal therapy), as well as measures to reduce swelling, if possible. In patients with non-cancer-related lymphoedema, the best way to reduce pain is to control swelling and prevent the development of complications. Whatever the cause, pain is a somatopsychic experience that is affected by mood and morale. These issues are important in patients with both cancer-related lymphoedema, who are concerned about recurrent disease and non-cancer-related disease, who often have poor self-esteem and problems with body image and perception.

Control of swelling

Physical therapy for lymphoedema, comprising bed rest, elevation, bandaging, compression garments, massage and exercises, was first described at the end of the nineteenth century, and through the twentieth century various eponymous schools developed. Although there is little doubt that physical therapy can be highly effective in reducing swelling, its general acceptance and practice has been hampered by a lack of proper research and confusing terminology. The current preferred term is decongestive lymphoedema therapy (DLT), which comprises two phases. The first is a short intensive period of therapist-led care and the second is a maintenance phase in which the patient uses a self-care regime with occasional professional intervention. The intensive phase comprises skin care, manual lymphatic drainage (MLD) and multilayer lymphoedema bandaging (MLLB), and exercises. The length of intensive treatment will depend upon the disease severity, the degree of patient compliance and the willingness and ability of the patient to take more responsibility for the maintenance phase. However, weeks rather than months should be the goal.

Skin care

The patient must be carefully educated in the principles and practice of skin care. The patient should inspect the affected skin daily, with special attention paid to skinfolds, where maceration may occur. The limb should be washed daily; the use of bath oil, e.g. Balneum, is recommended as a moisturiser and the limb must be carefully dried afterwards. A hair drier on low heat is more effective and hygienic, and less traumatic, than a towel. If the skin is in good condition daily application of a bland emollient, e.g. aqueous cream, is recommended to keep the skin hydrated. If the skin is dry and flaky then a bland ointment, e.g. 50:50 white soft paraffin/liquid paraffin (WSP/LP), should be used twice daily and, if there is marked hyperkeratosis, a keratolytic agent, such as 5% salicylic acid, should be added. Many commercially available soaps, creams and lotions contain sensitisers, e.g. lanolin in E45 cream, and are best avoided as patients with lymphoedema are highly susceptible to contact dermatitis (eczema). Apart from causing intense discomfort, eczema acts as an entry point for infection. Management comprises avoidance of the allergen (patch testing may be required) and topical corticosteroids. Fungal infections are common, difficult to eradicate and predispose to acute inflammatory episodes. Chronic application of antifungal creams leads to maceration and it is better to use powders in shoes and socks. Ointment containing 3% benzoic acid helps prevent athlete's foot and can be used safely over long periods. Painting at-risk areas with an antiseptic agent such as eosin may be helpful. Lymphorrhoea is uncommon but extremely troublesome. Management comprises emollients, elevation, compression and sometimes cautery under anaesthetic.

Apart from lymphangiosarcoma, acute inflammatory episodes are probably the most serious complications of lymphoedema and frequently lead to emergency hospital admission. About 25% of primary and 5% of secondary lymphoedema patients are affected. Acute inflammatory episodes start rapidly, often without warning or a precipitating event, with tingling, pain and redness of the limb. Patients feel 'viral'

Summary box 58.7

Skin care

- Protect hands when washing up or gardening; wear a thimble when sewing
- Never walk barefoot and wear protective footwear outside
- Use an electric razor to depilate
- Never let the skin become macerated
- Treat cuts and grazes promptly (wash, dry, apply antiseptic and a plaster)
- Use insect repellent sprays and treat bites promptly with antiseptics and antihistamines
- Seek medical attention as soon as the limb becomes hot, painful or more swollen
- Do not allow blood to be taken from, or injections to be given into, an affected arm (and avoid blood pressure measurement)
- Protect the affected skin from sun (shade, high-factor sun block)
- Consider taking antibiotics if going on holiday

and severe attacks can lead to the rapid onset of fever, rigors, headache, vomiting and delirium. Patients who have suffered previous attacks can usually predict the onset and many learn to carry antibiotics with them and self-medicate at the first hint of trouble.This may stave off a full-blown attack and prevent the further lymphatic injury that each acute inflammatory episode causes. It is rarely possible to isolate a responsible bacterium, but the majority are presumed to be caused by group A β-haemolytic streptococci and/or staphylococci. The diagnosis is usually obvious but dermatitis, thrombophlebitis and DVT are in the differential diagnosis. Oral amoxycillin is the treatment of choice with erythromycin or clarithromycin in those with penicillin allergy. Flucloxacillin should be added for those with evidence of *S. aureus* infection (folliculitis, crusted dermatitis). Oral clindamycin is a second-line agent for those with failure to respond to initial therapy. Hospital admission is required for patients with: signs of septicaemia; continuing or deteriorating systemic signs after 48 hours of antibiotic treament; unresolving or deteriorating local signs despite trials of first- and second-line antibiotics. Intravenous amoxycillin or benzyl penicillin with clindamycin in penicillin-allergic patients or as second-line therapy is most commonly recommended. Bed rest will reduce lymphatic drainage and the spread of infection, elevation will reduce the oedema and heparin prophylaxis will reduce the risk of DVT.

Analgesia is often required but non-steroidal anti-inflammatory drugs (NSAIDs) should be avoided as they have been associated with increased complications, including necrotising fasciitis. Any lymphatic massage should be ceased in the presence of active infection. Amoxycillin can be taken by patients who self-medicate. The use of long-term prophylactic antibiotics is not evidence based, but penicillin V 500 mg daily is probably reasonable in patients who suffer two or more attacks per year. However, the benefits of scrupulous compliance with physical therapy and skin care cannot be underestimated.

Manual lymphatic drainage

Several different techniques of MLD have been described and the details are beyond the scope of this chapter. However, they all aim to evacuate fluid and protein from the interstitial space and stimulate lymphangion contraction, with decongestion of impaired lymphatic pathways and development of collateral routes. The therapist should perform MLD daily; they should also train the patient (and/or carer) to perform a simpler, modified form of massage termed simple lymphatic drainage (SLD). In the intensive phase, SLD supplements MLD and, once the maintenance phase is entered, SLD will carry on as daily massage.

Multilayer lymphoedema bandaging and compression garments

Elastic bandages provide compression, produce a sustained high resting pressure and 'follow in' as limb swelling reduces. However, the sub-bandage pressure does not alter greatly in response to changes in limb circumference consequent upon muscular activity and posture. By contrast, short-stretch bandages exert support through the production of a semi-rigid casing where the resting pressure is low, but changes quite markedly in response to movement and posture. This pressure variation produces a massaging effect within the limb and stimulates lymph flow. Whether the aim is to provide support or compression, the pressure exerted must be graduated (100% ankle/foot, 70% knee, 50% mid-thigh, 40% groin).

Non-invasive assessment of the ankle–brachial pressure index (ABPI) using a hand-held Doppler ultrasound device is usually necessary prior to commencing any form of compression therapy, as it is rarely possible to feel pulses in the lymphoedematous limb. Standard MLLB and compression is used in patients with ABPI ≥0.8 and modified techniques with lower pressures in those with moderate arterial disease (ABPI 0.5–0.8). MLLB is contraindicated in severe arterial insufficiency (ABPI <0.5), uncontrolled heart failure and severe peripheral neuropathy.

It is generally believed that non-elastic MLLB is preferable (and arguably safer) in patients with severe swelling during the intensive phase of DLT, whereas compression (hosiery, sleeves) is preferable in milder cases and during the maintenance phase. MLLB is highly skilled and to be effective and safe it needs to be applied by a specially trained therapist. It is also extremely labour intensive, needing to be changed daily.

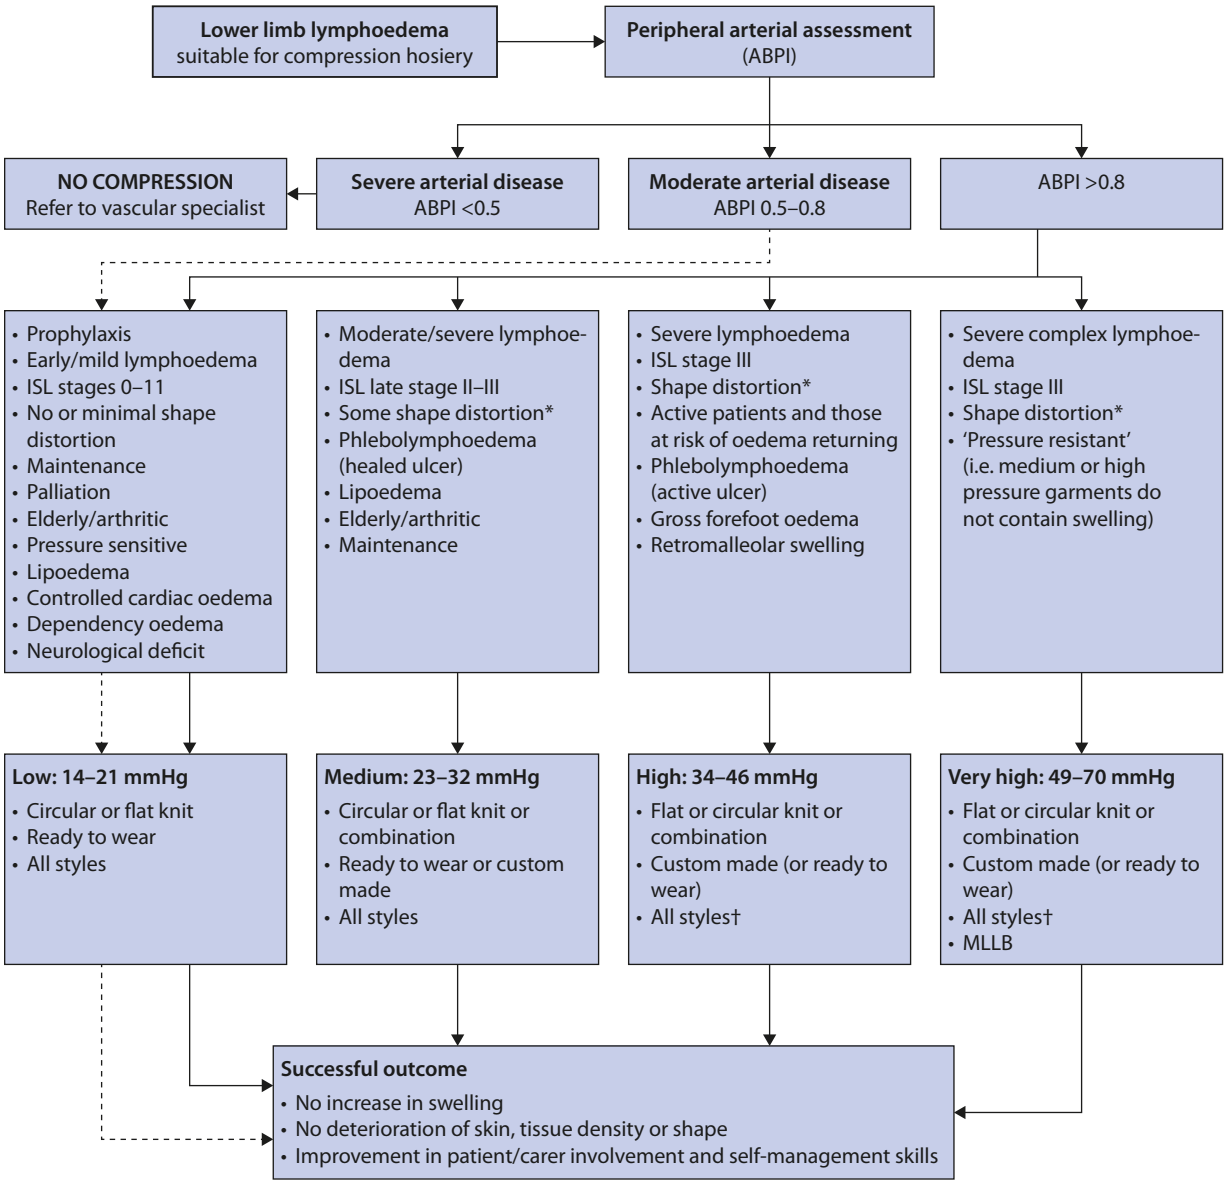
Summary box 58.8

Effects of multilayer lymphoedema bandaging

- Reduces oedema
- Restores shape to the affected area
- Reduces skin changes (hyperkeratosis, papillomatosis)
- Eliminates lymphorrhoea
- Supports inelastic skin
- Softens subcutaneous tissues

Compression garments form the mainstay of management in most clinics. The control of lymphoedema requires higher pressures (30–40 mmHg arm, 40–60 mmHg leg) than are typically used to treat CVI. These may be reduced to 15–25 mmHg in those with moderate arterial insufficiency (**Figure 58.10**). Confusingly, the British (classes I: 14–17 mmHg; II: 18–24 mmHg; III: 25–35 mmHg) and international (USA) (classes I: 20–30 mmHg; II: 30–40 mmHg; III: 40–50 mmHg; IV: 50–60 mmHg) standards are different. The patient should put the stocking on first thing in the morning before rising. It can be difficult to persuade patients to comply. Putting lymphoedema- grade stockings on and off is difficult and many patients find them intolerably uncomfortable, especially in warm climates. Furthermore, although intellectually they understand the benefits, emotionally they may find wearing them presents a greater body image problem than the swelling itself.

Enthusiasm for pneumatic compression devices has waxed and waned. Unless the device being used allows the sequential inflation of multiple chambers up to >50 mmHg, it will probably be ineffective for lymphoedema. The benefits to the patient are maximised and complications are minimised if these devices are used under the direction of a physical therapist as part of an overall package of care.



*For patients with shape distortion, flat knit hosiery is often preferable.

Exercise

Lymph formation is directly proportional to arterial inflow and 40% of lymph is formed within skeletal muscle. Vigorous exercise, especially if it is anaerobic and isometric, will tend to exacerbate lymphoedema and patients should be advised to avoid prolonged static activities, for example carrying heavy shopping bags or prolonged standing. In contrast, slow, rhythmic isotonic movements (e.g. swimming) and massage will increase venous and lymphatic return through the production of movement between skin and underlying tissues (essential to the filling of initial lymphatics) and augmentation of the muscle pumps. Exercise also helps to maintain joint mobility. Patients who are unable to move their limbs benefit from passive exercises. When at rest, the lymphoedematous limb should be positioned with the foot/hand above the level of the heart. A pillow under the mattress or blocks under the bottom of the bed will encourage the swelling to go down overnight.

Drugs

There are considerable, and scientifically inexplicable, differences in the use of specific drugs for venous disease and lymphoedema between different countries. The benzpyrones are a group of several thousand naturally occurring substances, of which the flavonoids have received the most attention. Enthusiasts will argue that a number of clinical trials have shown benefit from these compounds, which are purported to reduce capillary permeability, improve microcirculatory perfusion, stimulate interstitial macrophage proteolysis, reduce erythrocyte and platelet aggregation, scavenge free radicals and exert an anti-inflammatory effect. Detractors will argue that the trials are small and poorly controlled with short follow-up and 'soft' end points, and that any benefits observed can be explained by a placebo effect. In the UK, oxerutins (Paroven®) are the only such drugs licensed for venous disease and none has a license for lymphoedema. Diuretics are of no value in pure lymphoedema. Their chronic use is associated with side effects, including electrolyte disturbance, and should be avoided.

With increasing understanding of lymphangiogenesis pathways there is hope that specific pharmacological targets or gene therapy may become available in the future, but this remains in the very early stages at present.

Surgery

Only a small minority of patients with lymphoedema benefit from surgery. Operations fall into three categories: bypass procedures, liposuction and reduction procedures.

Bypass procedures

The rare patient with proximal ilioinguinal lymphatic obstruction and normal distal lymphatic channels might benefit, at least in theory, from lymphatic bypass. A number of methods have been described, including the omental pedicle, the skin bridge (Gillies), anastomosing lymph nodes to veins (Neilubowicz) and the ileal mucosal patch (Kinmonth). More recently, direct lymphaticovenular anastomosis (LVA) has been carried out on vessels of 0.3–0.8 mm diameter using super-microsurgical techniques. The procedures are technically demanding and not without morbidity. They are more often attempted in the upper limb following lymph node resection or radiotherapy for breast cancer. The outcomes are best in patients with earlier stages of lymphoedema, for whom the majority can be controlled with best medical therapy alone. In those with later stage disease who have failed conservative management, the outcomes of LVA have generally been disappointing.

Liposuction

Liposuction has been used in the treament of chronic lymphoedema. It is usually reserved for patients who have progressed to non-pitting oedema. Case series reported thus far have shown promising results with more than 100% reduction in limb oedema volume, which can be maintained by ongoing use of compression hosiery for at least 1 year. While liposuction appears to be safe, results of long-term efficacy and effects on the incidence of future lymphoedema complications (e.g. infection) are awaited.

Limb reduction procedures

These are indicated when a limb is so swollen that it interferes with mobility and livelihood. These operations are not 'cosmetic' in the sense that they do not create a normally-shaped leg and are usually associated with significant scarring. Four operations have been described.

SISTRUNK

A wedge of skin and subcutaneous tissue is excised and the wound closed primarily. This is most commonly carried out to reduce the girth of the thigh.

HOMANS

First, skin flaps are elevated, and then subcutaneous tissue is excised from beneath the flaps, which are then trimmed to size to accommodate the reduced girth of the limb and closed primarily. This is the most satisfactory operation for the calf **(Figure 58.11)**. The main complication is skin flap necrosis. There must be at least 6 months between operations on the medial and lateral sides of the limb and the flaps must not pass the midline. This procedure has also been used on the

Sir Harold Delf Gillies, 1882–1960, plastic surgeon, St Bartholomew's Hospital, London, UK. Born in New Zealand, he is widely considered the 'father of Plastic Surgery', Gillies started his craft to better the lives of the victims of the First World War. Later he became a pioneer in 'gender reassignment (sex-change) surgery'. He was joined in private practice by his cousin, the other world famous plastic surgeon, Sir Archibald McIndoe. He excelled in most sports – cricket, rowing, golf, and was an accomplished painter.

Jan Nielubowicz, 1915–2000, surgeon, Warsaw, Poland.

John Bernard Kinmonth, 1916–1982, surgeon, St Thomas's Hospital, London, UK.

Walter Ellis Sistrunk, 1880–1933, Professor of Clinical Surgery, Baylor University College of Medicine, Dallas, TX, USA.

John Homans, 1877–1957, Professor of Clinical Surgery, Harvard University Medical School, Boston, MA, USA.

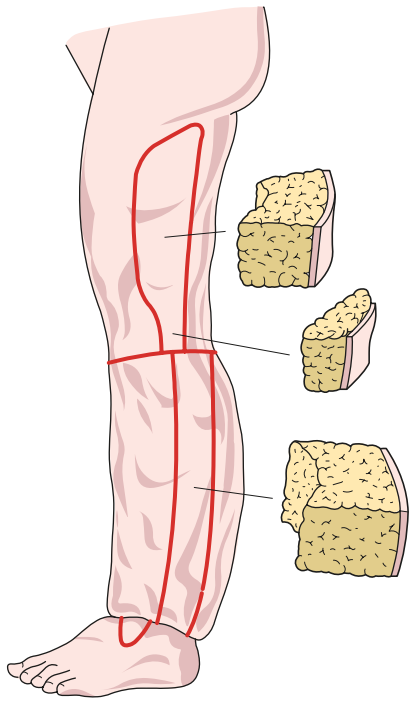

Figure 58.11 Homans' procedure involves raising skin flaps to allow the excision of a wedge of skin and a larger volume of subcutaneous tissue down to the deep fascia. Surgery to the medial and lateral aspects of the leg must be separated by at least 6 months to avoid skin flap necrosis.

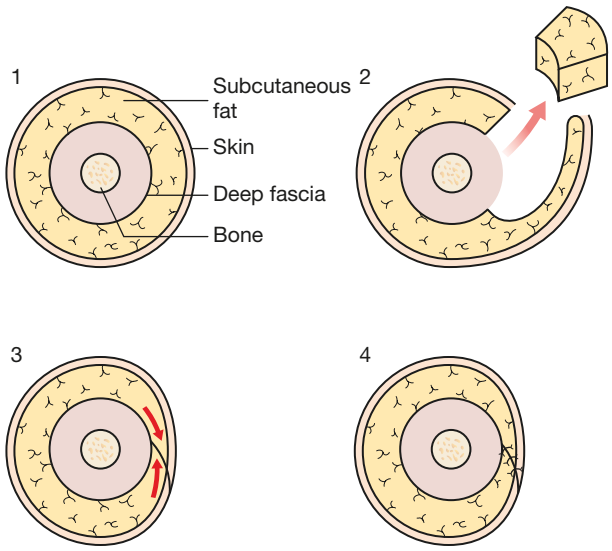

Figure 58.12 A cross-sectional representation of Thompson's reduction operation; red arrows illustrate the buried dermal flap sutured to deep fascia.

upper limb, but is contraindicated in the presence of venous obstruction or active malignancy.

THOMPSON

This is a modification of the Homans' procedure aimed to create new lymphatic connections between the superficial and deep systems. One skin flap is denuded (shaved of epidermis), sutured to the deep fascia and buried beneath the second skin flap (the so-called 'buried dermal flap') (Figure 58.12). This procedure has become less popular as pilonidal sinus formation is common. The cosmetic result is no better than that obtained with the Homans' procedure and there is no evidence that the buried flap establishes any new lymphatic connections.

CHARLES

This operation was initially designed for filariasis and involved excision of all of the skin and subcutaneous tissues down to the deep fascia, with coverage using split-skin grafts (Figure 58.13). This leaves a very unsatisfactory cosmetic result and graft failure is not uncommon. However, it does enable the surgeon to reduce greatly the girth of a massively swollen limb.

Summary box 58.9

Surgical options for lymphoedema

- Bypass procedures
  - Lymphatic bypass, e.g. omental pedicle, the skin bridge (Gillies) and the ilieal mucosal patch (Kinmonth)
  - Lymphaticovenular anastomosis (LVA)
  - Lymph nodes to vein anastomosis (Kinmonth)
- Liposuction
- Limb reduction procedures
  - Sistrunk
  - Homans
  - Thompson
  - Charles

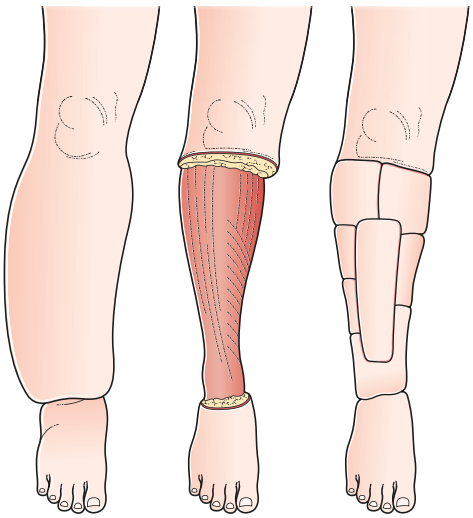

Figure 58.13 The Charles procedure involves circumferential excision of lymphoedematous tissue down to, and including, the deep fascia followed by split-skin grafting. This procedure gives a very poor cosmetic result but does allow the surgeon to remove very large amounts of tissue and is particularly useful in patients with severe skin changes.

Frederick Thompson, 1910–1975, plastic surgeon, The Middlesex Hospital, London, UK.
Major-General Sir Richard Havelock Charles, 1887–1934, surgeon in The Indian Medical Service.

Chylous ascites and chylothorax

These are associated with megalymphatics. The diagnosis may be obvious if accompanied by lymphoedema and lymphangioma. However, some patients develop chylous ascites and/or chylothorax in isolation, in which case the diagnosis can be confirmed by aspiration and the identification of chylomicrons in the aspirate. Cytology for malignant cells should also be carried out. A CT scan may show enlarged lymph nodes and CT with guided biopsy, laparoscopy or even laparotomy and biopsy may be necessary to exclude lymphoma or other malignancy. Lymphangiography may indicate the site of a lymphatic fistula that can be surgically ligated. Even if no localised lesion is identified, it may be possible to control leakage at laparotomy or even remove a segment of affected bowel. If the problem is too diffuse to be corrected surgically, a peritoneal venous shunt may be inserted, although occlusion and infection are important complications. Medical treatment comprising the avoidance of fat in the diet and the prescription of medium-chain triglycerides (which are absorbed directly into the blood rather than via the lymphatics) may reduce swelling. Chylothorax is best treated by pleurodesis, but this may lead to death from lymph-logged lungs as the excess lymph has nowhere to drain.

Chyluria

Filariasis is the most common cause, with chyluria occurring in 1–2% of cases 10–20 years after initial infestation. It usually presents as painless passage of milky white urine, particularly after a fatty meal. The chyle may clot, leading to renal colic, and hypoproteinaemia may result. Chyluria may also be caused by ascariasis, malaria, tumour and tuberculosis. Intravenous urography and/or lymphangiography will often demonstrate the lymphourinary fistula. Treatment includes a low-fat and high-protein diet, increased oral fluids to prevent clot colic, and laparotomy and ligation of the dilated lymphatics. Attempts have also been made to sclerose the lymphatics either directly or via instrumentation of the bladder, ureter and renal pelvis.

Lymphocoele

Lymphocoele is a localised collection of lymph without a distinct epithelial lining. It results from leakage of lymph into the soft tissues or body cavity secondary to surgical disruption of lymphatic vessels. They were first described as a postoperative complication after groin lymph node dissection for gynaecological tumours. Other causes include radical prostatectomy, vascular reconstructive procedures, renal transplant and body contouring surgery after massive weight loss. Clinically, lymphocoele presents as a non-tender, non-pulsatile mobile lump and can be differentiated from a seroma or a localised postoperative oedema by the presence of lymph-rich fluid. Depending upon the site and size they can deform the adjacent soft tissue structures or cause pressure symptoms. Complications include infection, chronic drainage (lymph fistula) and prolonged morbidity. In the early stages, repeated needle aspiration and compression can be attempted. However, lymphocoeles are generally refractory to these simple measures and may require insertion of drainage catheters, packing and compression or surgical excision. For a successful surgical result, combining preoperative lymphoscintigraphy with on-table isosulfan blue dye injection technique enhances the chance of accurately identifying the feeding lymphatic channels and ligation. After resecting a large lymphocoele the residual dead space may need muscle flap transposition to reduce recurrence. Other emerging concepts include performing prophylactic muscle flaps in high-risk groups and negative pressure wound therapy.

PART 11

Abdominal

Chapter 59

History and examination of the abdomen

Learning objectives

To understand:

- The pathway for clinical diagnosis of a patient presenting with an abdominal complaint
- The importance of recognising the organ or system responsible for the clinical features
- The pathophysiological basis of common abdominal symptoms and signs

To identify:

- Leading questions based on the organ or system affected and reach the most likely differential diagnosis
- The relevant physical signs and come to an appropriate clinical diagnosis

INTRODUCTION

Abdominal symptoms are a frequent cause for surgical consultation. The underlying cause may be acute, presenting with the euphemistically termed 'acute abdomen', subacute, indicating an evolving disorder, or long-standing, suggesting a functional or degenerative condition. Occasionally symptoms are due to disorders outside the abdomen, in which case the term 'referred' is used, for example epigastric pain experienced as a result of a myocardial infarction.

At first presentation, a detailed clinical history and careful clinical examination are essential to establish a differential diagnosis which, in turn, leads to appropriate triage into urgent and non-urgent investigation and subsequent treatment.

GATHERING INFORMATION

The experienced clinician will recognise the acuity and severity of the patient's condition even before a history has been taken. Initial observation provides clues to the direction that the history should take: general appearance, gait, position in bed, facial expression and tone of speech all provide useful hints. In an acute presentation, it is important to realise that the patient will feel anxious and vulnerable and may well be in severe pain; therefore, the clinician should introduce him-/herself, try to comfort the patient and gain his or her confidence. This is particularly important in a busy emergency department where the patient is only one among many.

Obtaining a history

The patient's history is obtained during the initial part of the consultation. It is crucial that the patient be allowed to explain the presenting complaint without interruption, after which carefully directed questions are used to further refine the history; this will then guide subsequent clinical examination and investigation.

Presenting complaint

To establish the presenting complaint one should start with an open question inviting the patient to explain the reason for seeking medical advice. In the acute situation, pain is the most common presenting feature. The classic features of site, nature, onset, duration, radiation, and aggravating or relieving features of the pain should be established. In a non-acute presentation anorexia, weight loss, jaundice, altered bowel habit, blood loss and fatigue are all features that should be enquired about.

Once the patient has finished explaining the problem, direct questions should be used to support or exclude possible diagnoses. It should be possible to identify a likely organ or system responsible for the patient's symptoms and come to a differential diagnosis.

Past history

The past history is important because it may have a bearing on the diagnosis and management. A history of previous similar episodes or past abdominal surgery often guides the diagnosis, for example adhesive small bowel obstruction in a patient with a history of laparotomy or recurrent left iliac fossa pain in a patient with a past history of diverticulitis. Some symptoms and signs may be due to cardiac, respiratory, haematological or musculoskeletal conditions, for example abdominal pain in sickle cell crisis.

Drug history and allergies

Some drugs will have an effect on the symptoms and signs or may have to be discontinued before surgery. For example, a patient with bleeding who is taking a β-blocking drug will not have tachycardia proportionate to the blood loss, a patient taking long-term corticosteroids will need intravenous steroid supplementation to prevent an adrenal crisis in the perioperative period and a patient taking anticoagulant drugs may require reversal of the effects before surgical intervention.

Social history

The use of alcohol and illicit drugs, smoking and occupation is important. Family background will inform potential difficulties with later discharge planning.

Family history

It is important to establish a family history of similar or related conditions, particularly cancer, inflammatory bowel disease, endocrine disease (e.g. hyperparathyroidism causing hypercalcaemia or renal calculi) and genetic disorders, including adverse reactions to anaesthetics or medications.

Review of the systems

A system review should highlight any comorbid disease, such as cardiac, vascular, respiratory or endocrine problems.

Summary box 59.1

Principles of history taking

- Identify the reason for consultation – the presenting complaint
- Determine the onset, duration and evolution of the symptoms
- Deduce the most likely organ or system affected
- Refine the history with relevant direct questions
- Establish relevant past, social, family, drug and allergy history
- Complete with a thorough review of other systems
- Devise a list of differential diagnoses

CLINICAL PRESENTATION OF ABDOMINAL PROBLEMS

Pain, weight loss, anorexia or vomiting, jaundice, alteration of bowel habit, and blood loss or anaemia are the common clinical presentations of abdominal pathology. It is important to be vigilant about insidious presentations of malignancies. Classic examples are right colon cancer presenting with symptoms of anaemia, metastatic liver cancer with weight loss, gastric cancer with loss of appetite, ovarian cancer with abdominal distension, and malignant obstruction of the extrahepatic biliary tree presenting with jaundice.

Summary box 59.2

Sources of abdominal symptoms

- Abdominal pain, weight loss, anorexia or vomiting, jaundice, alteration of bowel habit, and blood loss or anaemia are the common clinical presentations of abdominal pathology
- Occult malignancies may have atypical presentation

Abdominal pain

Pain is the most common of all abdominal symptoms and may be due to inflammatory, infective, obstructive, neoplastic or ischaemic pathology. Sometimes no organic cause can be found, a situation often labelled 'functional abdominal pain' for want of a better term. Improved understanding of pain pathways and the relationship with the gastrointestinal microbiome is likely to provide a more precise diagnosis, particularly in common 'functional' disorders such as non-ulcer dyspepsia and irritable bowel syndrome (IBS).

It is essential to establish the site, nature and radiation of the pain, the rapidity of onset, and associated or relieving features. Thus biliary colic will classically result in colicky pain in the right upper quadrant of the abdomen which radiates to the angle of the scapula and is associated with food intake (which results in cholecystokinin release and gallbladder contraction). Acute pancreatitis often has an abrupt onset of severe epigastric pain radiating to the back, which may be similar to pain emanating from peptic ulcer perforation or a leaking aortic aneurysm. Intestinal colic is most frequently associated with periumbilical pain and abdominal distension: the more distal in the intestine the pathology, the greater the degree of distension. Vomiting is an early feature of proximal small bowel obstruction, whereas absolute constipation is an early feature of colonic obstruction. Renal or ureteric colic is intense, located in the flanks and radiating towards the lower midline. It is usually associated with either macroscopic or microscopic haematuria.

With regard to altered bowel habit, the onset, nature, duration, type of alteration (constipation or diarrhoea) and its relationship to abdominal pain will help to differentiate organic pathology causing obstruction or inflammation (colon cancer or inflammatory bowel disease [IBD]) from functional conditions such as IBS. When patients complain of diarrhoea, they may imply different meanings – some use the term for loose stools, others may mean frequent but normal stools. A long-standing increase in frequency of stools, with left-sided abdominal pain before defecation, that eases after defecation, is suggestive of IBS. However, if such symptoms are of recent onset or are associated with blood or mucus in the stools, colonic carcinoma or IBD is more likely. A history of progressive change in bowel habit with an acute presentation with abdominal pain, distension and absolute constipation suggests acute-on-chronic intestinal obstruction, often from a stenotic left colon cancer. Marked distension with tenderness over the caecal area suggests a closed-loop obstruction with impending caecal rupture.

Summary box 59.3

Classic presentations of abdominal pathology

- Obstructive and inflammatory pathology must be excluded in patients with abdominal pain and altered bowel habit
- Closed-loop obstruction with tenderness in the right iliac fossa is indicative of imminent caecal rupture
- Caecal cancer classically presents with anaemia
- Patients who have had previous abdominal surgery may have adhesions
- Check carefully for small incarcerated hernias, particularly femoral, in obese patients

PATHOPHYSIOLOGICAL BASIS OF COMMON ABDOMINAL SYMPTOMS AND SIGNS

The abdominal wall and parietal peritoneum are innervated by the somatic nervous system, whereas the abdominal organs and visceral peritoneum are innervated by the autonomic nervous system. Therefore pain may change in its character and distribution as the underlying pathology evolves. Visceral pain from the foregut is generally felt in the epigastrium, in the periumbilical area from the mid-gut and in the suprapubic area from the hind-gut.

The skin and the muscles of the abdominal wall are supplied by the lateral and anterior cutaneous branches of the lower six intercostal nerves, the iliohypogastric and ilioinguinal nerves (**Figure 59.1**). The dermatome levels of the xiphoid process, umbilicus and pubis are T7, T10 and T12, respectively. The parietal peritoneum is supplied segmentally by the same nerves that innervate the overlying muscles. The central part of the diaphragmatic peritoneum is supplied by the phrenic nerve (C4); therefore, pain arising in this region is referred to the tip of the shoulder as it has the same segmental supply. The peripheral rim of the diaphragmatic peritoneum is supplied by the intercostal nerves. The obturator nerve is the principal nerve supply of the pelvic parietal peritoneum.

Pain from the viscera is principally due to ischaemia, muscle spasm or stretching of the visceral peritoneum. Unlike somatic pain, autonomic pain is deep and poorly localised. This pain is transmitted via sympathetic fibres and so is referred to the appropriate somatic distribution of that nerve root from T1 to L2. However, when an inflamed organ touches the parietal peritoneum, the pain becomes sharp and localises to the appropriate segmental dermatome of the abdominal wall. Pain arising from the parietal peritoneum may radiate to the back or the front along the appropriate dermatome. This referral pattern is classically seen in acute cholecystitis when an inflamed gall bladder touches the parietal peritoneum. Pain then radiates round to the back along the involved dermatome. The overlying muscle and skin are supplied by the same nerve root, so, when the patient takes a deep breath, the tenderness in the right subcostal region is markedly increased, causing the patient to stop breathing; this is Murphy's sign. In children with abdominal pain, who hold their right hip in a flexed position to obtain relief from the pain, one should suspect retrocaecal appendicitis causing irritation of the psoas muscle.

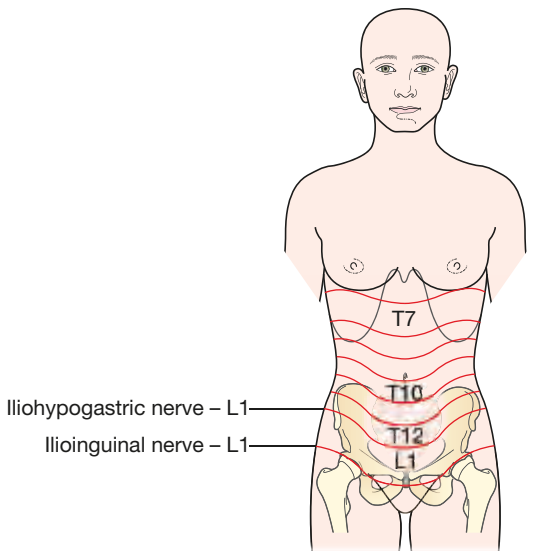

Figure 59.1 Distribution of the anterior abdominal wall dermatome and nerves.

Summary box 59.4

Nerves responsible for abdominal pain

- Abdominal wall and parietal peritoneum are supplied by the somatic nerves
- Abdominal organs and the visceral peritoneum are supplied by the autonomic nervous system
- Skin, muscles and parietal peritoneum are supplied by the iliohypogastric and ilioinguinal nerves and the lower six intercostal nerves
- Afferent pain fibres from the abdominal organs and visceral peritoneum travel with sympathetic nerves

Summary box 59.5

Specific characteristics of abdominal pain

- Visceral pain arises from ischaemia, muscle spasm or stretching of the visceral peritoneum
- Autonomic pain, deep and poorly localised, is referred to the equivalent somatic distribution of that nerve root from T1 to L2
- When an inflamed organ touches the parietal peritoneum, pain is then localised to the segmental dermatome of the abdominal wall
- The pain in the parietal peritoneum may radiate to back or front along the dermatome

Obstruction

Central colicky abdominal pain is a classic presentation of small bowel obstruction. The central distribution is because of the segmental nerve supply of the mid-gut. When the peristaltic waves hit an obstruction, the contractions increase to overcome the resistance, producing the colic. The pain reaches a crescendo and then disappears in minutes when the peristaltic wave passes. This is different from that of biliary

John Apley, 1909–1980, consultant paediatrician, Bristol, UK. The further away the chronic abdominal pain in a child is from the umbilicus, the more likely an organic cause.

John Benjamin Murphy, 1857–1916, Professor of Surgery, Northwestern University, Chicago, IL, USA, described his sign in 1903. He was the son of Irish immigrants fleeing the potato famine in Ireland, and was known as the 'Stormy Petrel' of American surgery, demonstrating the benefit of appendicectomy over conservative treatment among many things.

colic. When the gall bladder contracts against a stone, pain is relatively insidious in onset and reaches its peak in about half an hour and then eases off. A basal pain persists between the bouts of colic.

Summary box 59.6

Colicky abdominal pain

- Pain of 'small bowel colic' comes in waves and disappears completely in minutes when the peristaltic wave ceases
- Pain of biliary colic is insidious in onset, reaches the peak in half an hour or so and does not ease off completely between spasms
- Pain of ureteric colic is intense lasting one to two minutes of the ureter

Rupture and perforation of organs

The urinary bladder, gall bladder and gastrointestinal tract are hollow organs containing fluid. The gastrointestinal system also contains faeces, air and a high concentration of organisms. Trauma, ischaemia or tissue ulceration may cause perforation, with resulting leak of luminal contents, and peritonitis, with resulting severe abdominal pain. This may be localised to the area immediately adjacent to the perforation (for example, in a localised perforation of an appendix) or more generalised. The initial site of onset of the pain may give a clue as to the organ involved and so help with the differential diagnosis. For example, the diagnosis of a perforated peptic ulcer is supported by a past history of ulcer-type pain followed by sudden onset of upper abdominal pain.

The abdomen is divided into nine areas for ease of description (**Figure 59.2**). These regions are demarcated by the midclavicular lines in the vertical axis and by the transpyloric and transtubercular lines in the horizontal axis. **Figure 59.2** also indicates some of the common organs and pathological processes that commonly cause pain experienced in these regions.

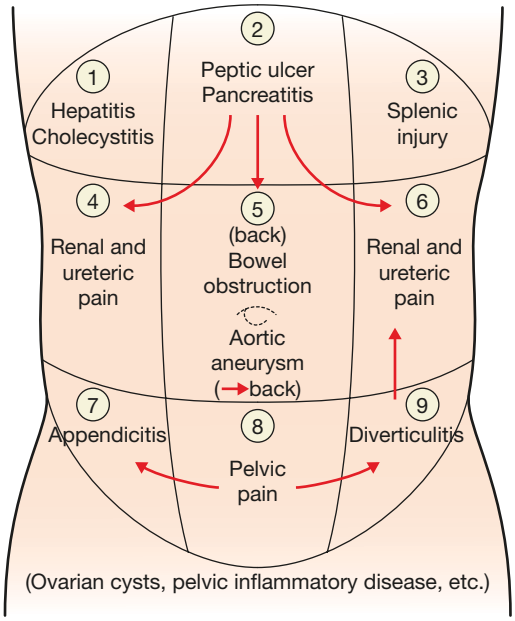

Figure 59.2 Nine sites of abdominal pain: 1, right subcostal; 2, epigastrium; 3, left subcostal; 4, right flank; 5, periumbilical; 6, left flank; 7, right iliac fossa; 8, suprapubic/hypogastrium; 9, left iliac fossa. (From Bailey and Love, 25th edn., courtesy of Mr Simon Paterson-Brown, Consultant Surgeon, Royal Infirmary of Edinburgh.)

EXAMINATION OF THE ABDOMEN

Abdominal examination must be preceded by a detailed general examination of the patient as a whole. Physical examination should be systematic using the following sequence: inspection, palpation, percussion and auscultation.

General examination

When examining the abdomen it is essential to obtain the patient's prior consent and to ensure the presence of a chaperone if appropriate. The examination should be performed in a comfortable environment that ensures privacy. The patient must be lying flat but without causing distress (this may require provision of a pillow) and the abdomen should be adequately exposed.

The examination should be performed sequentially, beginning with general inspection looking for evidence of weight loss, dehydration, anaemia, jaundice or abnormal pigmentation. Examination of the hands may provide evidence of anaemia or chronic liver disease whereas examination of the head and neck may identify features indicative of liver disease or lymph adenopathy (particularly left supraclavicular) suggestive of intra-abdominal malignancy. The patient's vital signs (heart rate, blood pressure, respiratory rate and body temperature) should always be noted. It is wise in the elective setting also to record the patient's weight at this point.

Inspection

Scars, abdominal distension, visible peristalsis or abdominal masses, dilated veins, pulsation or abdominal wall swelling suggestive of hernia should all be carefully sought. In an abdominal emergency look for Grey Turner's sign – skin discoloration of the flanks due to retroperitoneal haemorrhage in severe acute pancreatitis and leaking abdominal aortic aneurysm. Cullen's sign – discoloration around the umbilicus – may

Vermiculation: meaning wave-like contraction similar to a worm, particularly as referring to peristalsis of the ureter (from the Latin *vermiculus* – little worm).
George Grey Turner, 1877–1951, Professor of Surgery, the University of Durham (1927–1934) and at the Royal Postgraduate Medical School, Hammersmith Hospital, London, UK (1935–1946). He had the surgical club, Grey Turner Surgical Club, named after him. It is said that he dressed shabbily so that when his friends met him they used to ask him to 'mend the clock'. He had a habit of keeping his cup of tea warm by covering it with his bowler hat!
Thomas Stephen Cullen, 1868–1953, Professor of Gynecology, the Johns Hopkins University, Baltimore, MD, USA, described the sign in ruptured ectopic pregnancy in 1916.

Figure 59.3 Cullen's and Grey Turner's sign of skin discoloration of flanks and around the umbilicus (courtesy of Mr Pradip Datta, Honorary Consultant Surgeon, Wick, Scotland).

indicate severe acute pancreatitis, ruptured ectopic pregnancy or trauma to the liver. In these situations, blood tracks to the umbilicus along the ligamentum teres (**Figure 59.3**).

In a patient with acute abdominal pain, it is important to observe if the abdominal wall moves with respiration. A thin patient with diffuse peritonitis may be unable to lie flat and the abdominal wall will have a 'scaphoid' appearance due to protective contraction of the rectus abdominis muscles. It is often appropriate to ask the patient to cough gently – this will evoke sudden discomfort in the area of underlying peritoneal irritation (equivalent to eliciting rebound tenderness, but not as distressing for the patient). A cough will also help to identify an abdominal wall hernia, if present. Visible abdominal masses, mobility on respiration and peristalsis are all best observed if the clinician kneels by the patient's bed so that the observer's eye is at the level of the patient's anterior abdominal wall. The same position is useful during palpation for abdominal masses (**Figure 59.4**).

Figure 59.4 Eye at the level of patient's abdominal wall.

Palpation

Palpation should be performed in a systematic manner checking all nine regions of the abdomen (see **Figure 59.2**). Palpation should start in the region furthest away from the site of pain and the patient instructed to let the examiner know if tenderness is elicited. The examination should be gentle and the hands warm. The patient's facial expression will immediately reveal discomfort. Superficial palpation is followed by deep palpation if tenderness will allow. Finally, palpation during respiration is performed to identify the lower margins of the liver and spleen as they move with respiration.

Signs of parietal peritoneal irritation (tenderness, guarding, rebound tenderness, rigidity)

In the presence of abdominal pain, the degree of abdominal wall rigidity and involuntary guarding should be assessed. Guarding represents contraction of the abdominal wall muscles over the area of pain. This might occur 'voluntarily' when the patient wishes to avoid the pain from examination, or 'involuntarily' when the muscles go into spasm as the inflamed viscus touches the parietal peritoneum. This produces a reflex spasm of the overlying abdominal wall muscles. The presence of rebound tenderness indicates underlying peritoneal inflammation and is examined best using gentle percussion, although pain on coughing is also found when there is rebound tenderness. When the underlying peritoneal inflammation becomes generalised, the abdomen is 'board-like rigid' to palpation, and selective tenderness can no longer be elicited. This sign represents widespread involuntary guarding.

Abdominal masses

A mass arising from the anterior abdominal wall will usually be mobile when the patient is relaxed. On contracting the abdominal wall muscles (ask the patient to lift his or her legs with the knees extended, or perform Valsalva's manoeuvre for laterally placed swellings), lumps superficial to the abdominal wall muscles will become more obvious, and those attached to the deep fascia will become less mobile. Those arising within the muscle layer will become fixed and remain unchanged in size. Lumps arising deep to the abdominal wall (i.e. within the peritoneal cavity or behind the peritoneum) will become impalpable or less prominent on tensing the anterior abdominal wall muscles.

An intraperitoneal mass in contact with the diaphragm will move on respiration whereas retroperitoneal masses are usually fixed and do not move with respiration; an enlarged kidney is 'ballotable' and bimanually palpable. Normal aortic pulsations can be both seen and felt in a thin abdomen, but expansile pulsation is characteristic of an abdominal aortic aneurysm. This should be differentiated from transmitted pulsation of a mass sitting on the aorta (e.g. pseudocyst of the pancreas). When 'palpating during inspiration', the examining hand is placed distal to the normal site of the organ, and is held there until the edge of the organ descends

Antonio Maria Valsalva, 1666–1723, Professor of Anatomy in Bologna, of whom Morgagni wrote 'there is nobody of those times who goes ahead of him, very few who are his equals'.

and touches the examiner's fingers. Liver, spleen, gall bladder and kidneys are best palpated during inspiration. An abdominal mass in a female, the lower limit of which cannot be distinguished, is likely to arise from the pelvis. If the mass can be moved in a transverse direction, it is likely to be a uterine or ovarian mass.

Spleen

In a healthy patient the spleen is not normally palpable. An enlarged spleen descends downwards, forwards and medially. Palpation for an enlarged spleen is best performed in a supine patient. The examining hand should start in the right lower abdomen, with the tips of the fingers pointing upwards and pressed inwards. The patient is then asked to take a deep breath, and if the spleen is enlarged the lower edge with the characteristic notch will touch the fingers. If it is not palpable, then the hand is gradually moved upwards in the direction of the position of the edge of the normal-sized spleen with each breath. If the spleen is still not palpable, the patient is moved to the right lateral position and the examination repeated.

Liver

In a supine patient, the hand is placed in line with the potential enlarged liver edge lateral to the rectus muscle. The patient is then asked to take a deep breath. If the liver is enlarged sufficiently below the costal margin, then surface irregularities can also be felt.

Percussion

Percussion helps to distinguish distension due to bowel gas from solid masses and free fluid in the abdomen. Percussion is most sensitive when the examiner moves from resonant parts of the abdomen to dull areas. In patients with free fluid in the peritoneal cavity, percussion from the centre to the periphery reveals dullness of flanks. Shifting dullness is elicited if the patient is re-examined lying on his or her side. The margin of dullness is then found to shift when the patient has moved.

Percussion is a very sensitive and refined method of testing for rebound tenderness. If the patient winces with pain on abdominal percussion it denotes underlying peritonitis.

Auscultation

High-pitched bowel sounds are heard during early stages of mechanical intestinal obstruction. Aortic and iliac bruits are heard when blood flows through a stenosis. A succussion splash is a sound like 'shaking a half-filled bottle with water' and is found most often in patients with gastric stasis due to gastric outlet obstruction. In generalised peritonitis, bowel sounds will not be heard or be very few and far between.

Inspection of hernia sites, examination of genitalia, inspection of anal region and digital rectal examination

Abdominal examination is not complete until all external hernia sites and the anal area have been carefully inspected, the genitalia examined and a digital rectal examination performed. A vaginal examination may also be needed in females. The thoracic and lumbar spine and renal angles should also be examined.

VALUE OF OBSERVATION AND REVIEW

In the case of acute abdominal pain, there will be a subset of patients in whom, after full clinical assessment, the surgeon remains uncertain about the need for an urgent operation. This is probably the most difficult group to deal with compared with those in whom an urgent operation is either clearly required, or clearly not required, and undoubtedly the one in which the majority of errors occur. Further urgent investigations are obviously important in this group and these are discussed in some detail elsewhere in this book. However, while these are taking place, regular review of the patient is essential. This period of observation has now become an integral part of the early management of patients with acute abdominal pain.

Chapter 60

Abdominal wall, hernia and umbilicus

Learning objectives

To know and understand:

- Basic anatomy of the abdominal wall and its weaknesses
- Causes of abdominal hernia
- Types of hernia and classifications
- Clinical history and examination findings in hernia
- Complications of abdominal hernia
- Non-surgical and surgical management of hernia – including mesh
- Complications of hernia surgery
- Other abdominal wall conditions

THE ABDOMINAL WALL

Basic anatomy and function related to pathology

The abdominal wall is a complex structure composed primarily of muscle, bone and fascia. Its major function is to protect the enclosed organs of the gastrointestinal and urogenital tracts but a secondary role is mobility, being able to flex, extend, rotate and vary its capacity. Flexibility requires elasticity and stretch, which compromise abdominal wall strength.

The roof of the abdomen is formed by the diaphragm separating the thoracic cavity above, with negative pressure, from the abdomen below, with positive pressure. Weakness of the diaphragm can lead to much of the bowel being drawn into the chest down this pressure gradient. The bony pelvis forms the floor of the cavity but a muscular central portion, the perineum, may also weaken and allow rectum, bladder and gynaecological organs to bulge downwards, a condition called prolapse.

The overall design of the abdominal muscles is best seen on a transverse computed tomography (CT) scan through the mid-abdomen. Posteriorly the muscles are strong, further supported by the vertebral column, ribs and pelvis. Two regions called the posterior triangles represent areas of weakness which can lead to rare lumbar hernias. Laterally there are three thin muscle layers the fibres of which criss-cross for strength and flexibility. Surgeons can make use of these layers, by making releasing incisions, separating the layers and then sliding one layer over another to increase girth and allow closure of defects in the centre of the abdomen, e.g. the 'Ramirez slide' used in large incisional hernia repair (Figure 60.1).

Anteriorly the two powerful rectus abdominis muscles extend vertically from ribs to pelvis. Herniation through these strong muscles does not occur naturally but their central join, the linea alba, is an area of weakness resulting in epigastric and paraumbilical herniation. Divarification of the recti is the condition where the linea alba stretches laterally as the two rectus muscles separate. It occurs in the upper abdomen in middle-aged, overweight men (Figure 60.2) but also as a result of birth trauma in women when it occurs below the umbilicus.

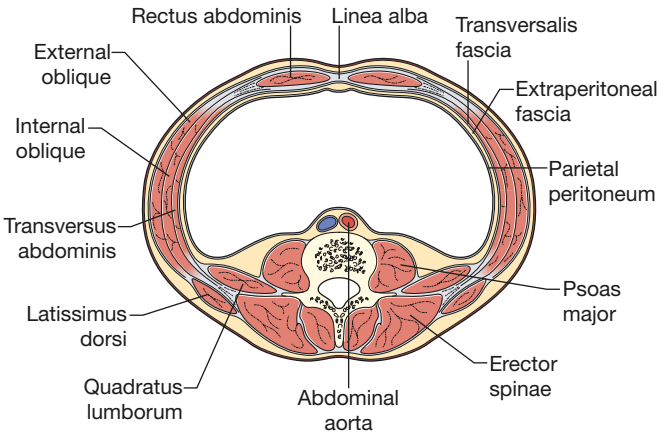

Figure 60.1 A cross-section of the midabdomen showing the muscular layout.

Abdominal pressure

The positive pressure within the abdomen is used by a surgeon when drains are placed to allow blood, pus, bile, bowel content and urine to flow outwards down the pressure gradient. However, this constant pressure from within can also lead to the condition of abdominal hernia where tissue, meant to be within the abdominal cavity, is forced outwards through defects in the muscular wall.

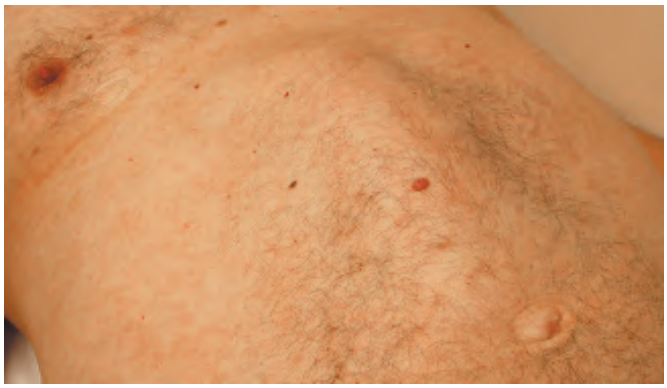

Figure 60.2 Divarification.

ABDOMINAL HERNIA

A hernia is the bulging of part of the contents of the abdominal cavity through a weakness in the abdominal wall.

Anatomical causes of abdominal wall herniation

Despite the complex design of the abdominal wall, the only natural weaknesses caused by inadequate muscular strength are the lumbar triangles and the posterior wall of the inguinal canal (**Figure 60.3**).

Many structures pass into and out of the abdominal cavity creating weakness which can lead to hernia formation. The most common example is the inguinal canal in males, along which the testis descends from abdomen to scrotum at the time of birth. The testicular artery, veins and vas pass though this canal (the round ligament in females). The resultant weakness leads to an indirect or lateral-type inguinal hernia. In adult surgery, 80% of all hernia repairs are for inguinal hernia. The evolutionary advantage of testicular descent must outweigh the disadvantage of a high risk of herniation. Other examples are: oesophagus → hiatus hernia, femoral vessels → femoral hernia, obturator nerve → obturator hernia, sciatic nerve → sciatic hernia.

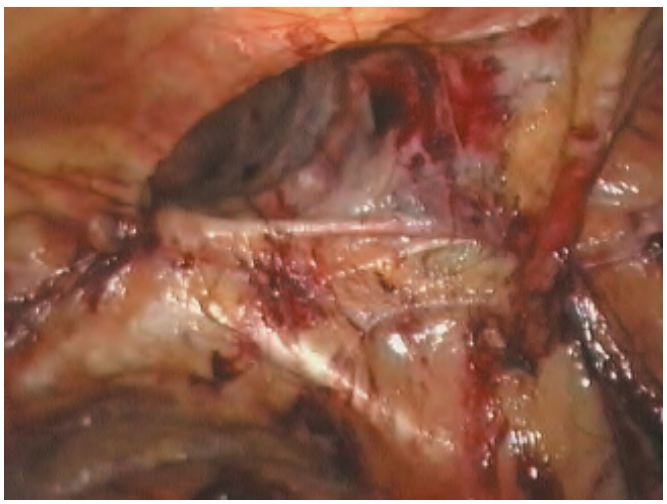

Figure 60.3 Posterior wall defect.

An inguinal hernia (indirect) also occurs through the developmental failure of the processus vaginalis to close. As the testis descends, it pulls a tube of peritoneum along with it. This tube should naturally fibrose and become obliterated but often it fails to fibrose and allows a hernia to form. Recent studies have shown that calcitonin gene-related peptide and hepatocyte growth factor influence the closure of the processus, raising the possibility of a hormonal cause of hernia development.

Failure of normal development may lead to weakness of the abdominal wall. Examples are diaphragmatic, umbilical and epigastric hernias. Muscles which should unite during development fail to form strong unions with hernia development at birth or in later life.

Herniation at the umbilicus has both components, i.e. weakness due to structures passing through the abdominal wall in fetal life and developmental failure of closure.

The risk of inguinal hernia is related to the anatomical shape of the pelvis and is higher in patients having a wider and shorter pelvis.

Weakness of abdominal muscles may be the result of sharp trauma. Most commonly, this results from abdominal surgery but also occurs after stabbing. A surgical scar, even with perfect wound healing, has only 70% of the initial muscle strength. This loss of strength can result in herniation in at least 10% of surgical incisions. Smaller laparoscopic port-site incisions have a hernia rate of 1%. Increasing use of this surgical approach should lead to a fall in the incidence of incisional hernia.

Muscle damage by blunt trauma or tearing of the abdominal muscles requires exceptional force and is rare.

The sudden presence of a mass in the rectus muscle may be a rectus sheath haematoma, occasionally due to trauma but nowadays more often due to excessive anticoagulation therapy.

Primary muscle pathology and neurological conditions can lead to muscle weakness and occasionally present to the surgeon as a 'hernia'.

Summary box 60.1

Causes of hernia

- Basic design weakness
- Weakness due to structures entering and leaving the abdomen
- Developmental failures
- Genetic weakness of collagen
- Sharp and blunt trauma
- Weakness due to ageing and pregnancy
- Primary neurological and muscle diseases
- ? Excessive intra-abdominal pressure

Pathophysiology of hernia formation

A normal abdominal wall has sufficient strength to resist high abdominal pressure and prevent herniation of content. Herniation has been attributed to high pressures from

constipation, prostatic symptoms, excessive coughing in respiratory disease and obesity. However, it has been shown that hernia is no more common in Olympic weight lifters than the general population, suggesting that high pressure is not a major factor in causing a hernia. Many patients will first notice a hernia after excessive straining.

There is good evidence that hernia is a 'collagen disease' and due to an inherited imbalance in the types of collagen. This is supported by histological evidence and relationships between hernia and other diseases related to collagen, such as aortic aneurysm.

Hernia development is more common in pregnancy due to hormonally induced laxity of pelvic ligaments. It is also more common in elderly people due to degenerative weakness of muscles and fibrous tissue. A recent Swedish report has shown that inguinal hernia is less common in obese patients, with hernia risk being negatively related to body mass index (BMI), contrary to widespread belief. Hernia is more common in smokers.

Common principles in abdominal hernia

An abdominal wall hernia has two essential components, a defect in the wall and content, i.e. tissue that has been forced outwards through the defect. The weakness may be entirely in muscle, such as an incisional hernia. It may also be in fascia, similar to an epigastric hernia through the linea alba. It may have a bony component, such as a femoral hernia. The weakness in the wall is usually the narrowest part of the hernia which expands into the subcutaneous fat outside the muscle. The defect varies in size and may be very small or indeed very large. The nature of the defect is important to understanding the risk of hernia complications. A small defect with rigid walls traps the content and prevents it from freely moving in and out of the defect, increasing the risk of complications.

The content of the hernia may be tissue from the extraperitoneal space alone, such as fat within an epigastric hernia or urinary bladder in a direct inguinal hernia. However, if such a hernia enlarges then peritoneum may also be pulled into the hernia secondarily along with intraperitoneal structures such as bowel or omentum; a good example is a 'sliding type' of inguinal hernia.

More commonly, when peritoneum is lying immediately deep to the abdominal wall weakness, pressure forces the peritoneum through the defect and into the subcutaneous tissues. This 'sac' of peritoneum allows bowel and omentum to pass through the defect. In most cases, the intraperitoneal organs can move freely in and out of the hernia, a 'reducible' hernia, but if adhesions form or the defect is small, bowel can become trapped and unable to return to the main peritoneal cavity, an 'irreducible' hernia, with high risk of further complications. The narrowest part of the sac, at the abdominal wall defect, is called the 'neck of the sac'.

When tissue is trapped inside a hernia it is in a confined space. The narrow neck acts as a constriction ring impeding venous return and increasing pressure within the hernia. Resulting tension leads to pain and tenderness. If the hernia contains bowel then it may become 'obstructed', partially or totally. If the pressure rises sufficiently, arterial blood is not able to enter the hernia and the contents become ischaemic and may infarct. The hernia is then said to have 'strangulated'. The wall of the bowel perforates, releasing infected, toxic bowel content into the tissues and ultimately back into the peritoneal cavity. The risk of strangulation is highest in hernias that have a small neck of rigid tissue, leading first to irreducibility and on to strangulation. The term 'incarcerated' is not clearly defined and used to imply a hernia that is irreducible and developing towards strangulation.

Summary box 60.2

Types of hernia by complexity

- Occult – not detectable clinically; may cause severe pain
- Reducible – a swelling that appears and disappears
- Irreducible – a swelling that cannot be replaced in the abdomen, high risk of complications
- Strangulated – painful swelling with vascular compromise, requires urgent surgery
- Infarcted – when contents of the hernia have become gangrenous, high mortality

In a special circumstance (Richter's hernia) only part of the bowel wall enters the hernia. It may be small and difficult or even impossible to detect clinically. Bowel obstruction may not be present but the bowel wall may still become necrotic and perforate with life-threatening consequences. Femoral hernia may present in this way often with diagnostic delay and high risk to the patient (**Figure 60.4**).

An interstitial hernia occurs when the hernia extends between the layers of muscle and not directly through them. This is typical of a spigelian hernia (see below under **Spigelian hernia**).

An internal hernia is a term used when adhesions form within the peritoneal cavity. leading to abnormal pockets into which bowel can enter and become trapped. As there is no defect within the abdominal wall, the term 'hernia' is confusing.

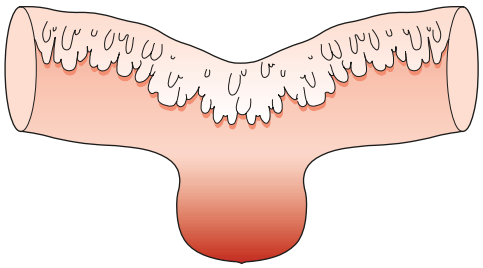

Figure 60.4 Diagrammatic representation of gangrenous Richter's hernia from a case of strangulated femoral hernia.

August Gottlieb Richter, 1742–1812, lecturer in Surgery, Göttingen, Germany described this form of hernia in 1777.

Clinical history and diagnosis in hernia cases

Patients are usually aware of a lump on the abdominal wall under the skin. Self-diagnosis is common. The hernia is usually painless but patients may complain of an aching or heavy feeling. Sharp, intermittent pains suggest pinching of tissue. Severe pain should alert the surgeon to a high risk of strangulation. One should determine whether the hernia reduces spontaneously or needs to be helped. The patient should be asked about symptoms that might suggest bowel obstruction.

It is important to know if this is a primary hernia or whether it is a recurrence after previous surgery. Recurrent hernia is more difficult to treat and may require a different surgical approach.

General questions about the cardiac and respiratory systems are necessary to assess a patient's anaesthetic risk.

In a man with a groin hernia, history of prostatic symptoms indicates a high risk of postoperative urinary retention.

Intake of anticoagulants such as warfarin is important because this impacts on future surgery. Many hernia operations can be performed as a day case or single overnight stay, so that suitability for such treatment needs to be assessed, including home support, distance from the hospital, mobility levels, etc.

Examination for hernia

The patient should be examined lying down initially and then standing as this will usually increase hernia size. In some cases no hernia will be apparent with the patient lying. The patient is asked to cough, when an occult hernia may appear. Divarification is best seen by asking a supine patient to simply lift his head off the pillow.

The overlying skin is usually of normal colour. If bruising is present this may suggest venous engorgement of the content. If there is overlying cellulitis then hernia content is strangulating and the case should be treated as an emergency.

In most cases a cough impulse is felt. Gentle pressure is applied to the lump and the patient is asked to cough. If an impulse is felt this is due to increased abdominal pressure being transmitted into the hernia. In cases where the neck is tight and the hernia irreducible there may be no cough impulse. This can lead to failure of diagnosis and is typical of femoral hernia where lack of an impulse leads the clinician to misdiagnose a lymph node. Cough impulse can also occur in a saphena varix (see Chapter 57), which may be referred to a surgeon as a suspected inguinal hernia. It is not unusual for a patient to describe an intermittent swelling but the surgeon finds nothing on examination. This is due to muscle tightening in an anxious patient.

If, on lying, the hernia does not reduce spontaneously, the surgeon asks the patient to attempt reduction because he may be well practised in this task although the surgeon might cause unnecessary discomfort. If neither the patient nor the surgeon can reduce the hernia then treatment is more urgent. An irreducible hernia may influence the decision between open and laparoscopic surgery. With the hernia reduced, the surgeon assesses the size, rigidity and number of defects. Multiple defects may be present in incisional hernia.

Summary box 60.3

Checks

- Reducibility
- Cough impulse
- Tenderness
- Overlying skin colour changes
- Multiple defects/contralateral side
- Signs of previous repair
- Scrotal content for groin hernia
- Associated pathology

Summary box 60.4

Examination

- A swelling with a cough impulse is not necessarily a hernia
- A swelling with no cough impulse may still be a hernia

Investigations for hernia

For most hernias, no specific investigation is required, the diagnosis being made on clinical examination. However, the patient may have symptoms suggesting a hernia, but no hernia is found, or have a swelling suggestive of hernia but with clinical uncertainty. It is important to be certain that any symptoms described are due to a hernia and not to coexisting pathology. There may also be a requirement for more detailed information than can be found by examination alone. A plain radiograph of the abdomen is of little value (**Figure 60.5**) although a hiatus hernia and diaphragmatic hernia may be seen on a chest radiograph. An ultrasound scan may be helpful in cases of irreducible hernia, where the differential diagnosis includes a mass or fluid collection, or when the nature of the hernia content is in doubt. Ultrasonography is very useful in the early postoperative period when a haematoma or seroma may develop, and be difficult to distinguish from

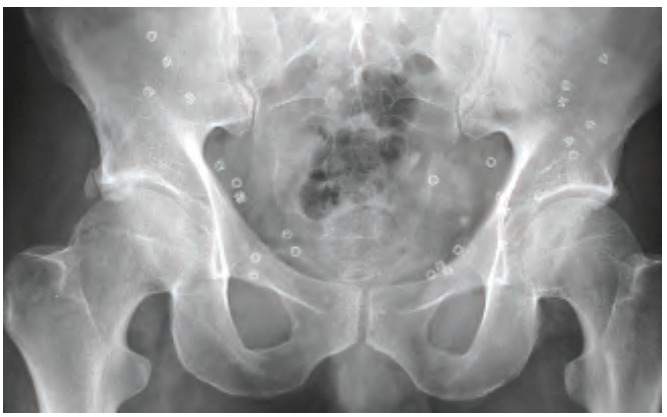

Figure 60.5 A radiograph showing spiral tacks causing chronic pain after transabdominal preperitoneal repair.

an early recurrence. Ultrasonography is non-invasive and low cost but operator dependent.

Computed tomography is helpful in complex incisional hernia, determining the number and size of muscle defects, identifying the content, giving some indication of presence of adhesions and excluding other intra-abdominal pathology such as ascites, occult malignancy and portal hypertension.

Contrast barium radiology is occasionally useful in the absence of CT. Contrast may also be injected directly into the peritoneum, a herniagram, to identify an occult sac, especially in occult inguinal hernia. Magnetic resonance imaging (MRI) can help in the diagnosis of sportsman's groin where pain is the presenting feature and the surgeon needs to distinguish an occult hernia from an orthopaedic injury.

Laparoscopy itself may be used. In incisional hernia, initial laparoscopy may determine that a laparoscopic approach is feasible or not depending on the extent of adhesions. In inguinal hernia repair by the transabdominal route, initial laparoscopy can determine the presence of an occult contralateral hernia which has been described in up to 20% of patients.

Summary box 60.5

Investigations

- Plain radiograph – of little value
- Ultrasound scan – low cost, operator dependent
- CT scan – incisional hernia
- MRI – good in sportsman's groin with pain
- Contrast radiology – especially for inguinal hernia
- Laparoscopy – useful to identify occult inguinal hernia

Management principles

An abdominal wall hernia does not necessarily require repair. A patient may request surgery for relief of symptoms of discomfort, for cosmesis or to establish the diagnosis when in doubt. The surgeon should recommend repair when complications are likely, the most worrying being strangulation with bowel obstruction and bowel infarction. All cases of femoral hernia, with high risk of strangulation, should be repaired surgically. Any case of irreducible hernia, especially where there is pain and tenderness, should be offered repair unless coexisting medical factors place the patient at very high risk from surgery or anaesthesia. Increasing difficulty in reduction and increasing size are indications for surgery. Surgery should be offered to younger adult patients as symptoms and complications are likely over time.

Summary box 60.6

Management

- Not all hernias require surgical repair
- Small hernias can be more dangerous than large
- Pain, tenderness and skin colour changes imply high risk of strangulation
- Femoral hernia should always be repaired

In reality, most patients with a hernia should be offered repair. In elderly people, if the hernia is asymptomatic, small in size, can be reduced easily and is not causing anxiety, then observation alone should be sufficient. This policy, called 'watchful waiting', has been studied in asymptomatic inguinal hernia. One study reported such a policy to be safe but a second study was abandoned when a small number of patients developed strangulation. A truss can be used to control a hernia but few surgeons would recommend this approach. Small paraumbilical hernias are often seen. They cause few symptoms and usually contain fat or omentum with a very low risk of complications.

Large incisional hernias, particularly recurrent, present a major problem. Surgical repair is a complex procedure with significant risk of complications and later recurrence. When the neck is wide, the risk of strangulation is low. In obese and elderly patients, these risks may outweigh the benefits of surgery and it is common for surgeons to adopt a conservative approach.

Any patient who presents with acute pain in a hernia, particularly if it is irreducible, should be offered surgery. Often, in a patient with an irreducible hernia, after admission to hospital and adequate analgesia, the hernia will reduce due to muscle relaxation. The likelihood of similar episodes is very high and surgery should be recommended at this admission or soon after.

Surgical approaches to hernia

All surgical repairs follow the same basic principles:

1. reduction of the hernia content into the abdominal cavity with removal of any non-viable tissue and bowel repair if necessary;
2. excision and closure of a peritoneal sac if present or replacing it deep to the muscles;
3. reapproximation of the walls of the neck of the hernia if possible;
4. permanent reinforcement of the abdominal wall defect with sutures or mesh.

Reduction of hernia content is essential for a successful repair. It is rare for a surgeon to fail to reduce the hernia but extensive dissection can lead to bowel injury, sometimes requiring bowel resection with subsequent risks of infection and bowel anastomotic complications.

Excision and closure of the peritoneal sac are ideal but not essential. During laparoscopic repair of incisional hernia, surgeons will often leave the sac *in situ* after reducing the hernia contents, and simply fix a mesh over the neck to prevent recurrence. There is risk of fluid formation within the sac (seroma). This is a common complication in all forms of hernia repair. In lateral (indirect) inguinal hernia, most surgeons excise the peritoneal sac but some leading experts recommend that it be dissected from surrounding tissue and simply pushed back through the deep inguinal ring. In laparoscopic repair of inguinal hernias, surgeons simply pull the sac back into the abdominal cavity from within and do not excise it.

Closure of the abdominal wall defect is ideal but may not be possible when the defect is large or tissues are rigid. Plastic surgical techniques have been developed to 'borrow' tissue from elsewhere in order to cover large muscle defects, but usually at the cost of leaving a weak area elsewhere. Over the past 20–30 years, surgeons have realised that simple closure of a hernia defect by sutures alone leads to a high recurrence rate.

Additional reinforcement of the defect with a non-absorbable mesh is now widely practised in most hernia repairs and evidence has shown that recurrence rates have improved but recurrence still remains a problem. There is some evidence that mesh repair delays but does not prevent recurrence. With improved surgical techniques and new meshes it is hoped that recurrence after surgery will fall further. Mesh repair has become so important in hernia surgery that some understanding of mesh technology is essential for the modern surgeon.

Mesh in hernia repair

The term 'mesh' refers to prosthetic material, either a net or a flat sheet, which is used to strengthen a hernia repair. Mesh can be used:

- to bridge a defect: the mesh is simply fixed over the defect as a tension-free patch;
- to plug a defect: a plug of mesh is pushed into the defect;
- to augment a repair: the defect is closed with sutures and the mesh added for reinforcement.

A well-placed mesh should have good overlap around all margins of the defect, at least 2 cm but up to 5 cm if possible. Suturing a mesh edge to edge into the defect (inlay), with no overlap, is not recommended. Mesh plug repairs have gained some popularity in small defects especially where overlap is hard to achieve. Plug operations are fast but plugs can form a dense 'meshoma' of plug and collagen. Other complications include migration, erosion into adjacent organs, fistula formation and chronic pain.

Mesh types

The wide array of meshes available can be classified as follows.

GROSS STRUCTURE

Net meshes are woven or knitted. Flat sheets are not porous but can be perforated with multiple holes. Net meshes allow fibrous tissue in growth between the strands and becoming adherent and integrated into host tissues within a few months. Initial fixation of the mesh is by glue, sutures or staples which may be absorbable. In laparoscopic inguinal hernia, no fixation is required at all as friction is sufficient to hold the mesh. 'Sheet' meshes do not allow host tissue in growth but become encapsulated by fibrous tissue. They always require strong, non-absorbable fixation to prevent mesh migration.

SYNTHETIC MESH

Most meshes used today are synthetic polymers of polypropylene, polyester or polytetrafluoroethylene (PTFE) (**Figure 60.6**). They are non-absorbable and provoke little tissue reaction. Polypropylene makes a strong monofilament mesh.

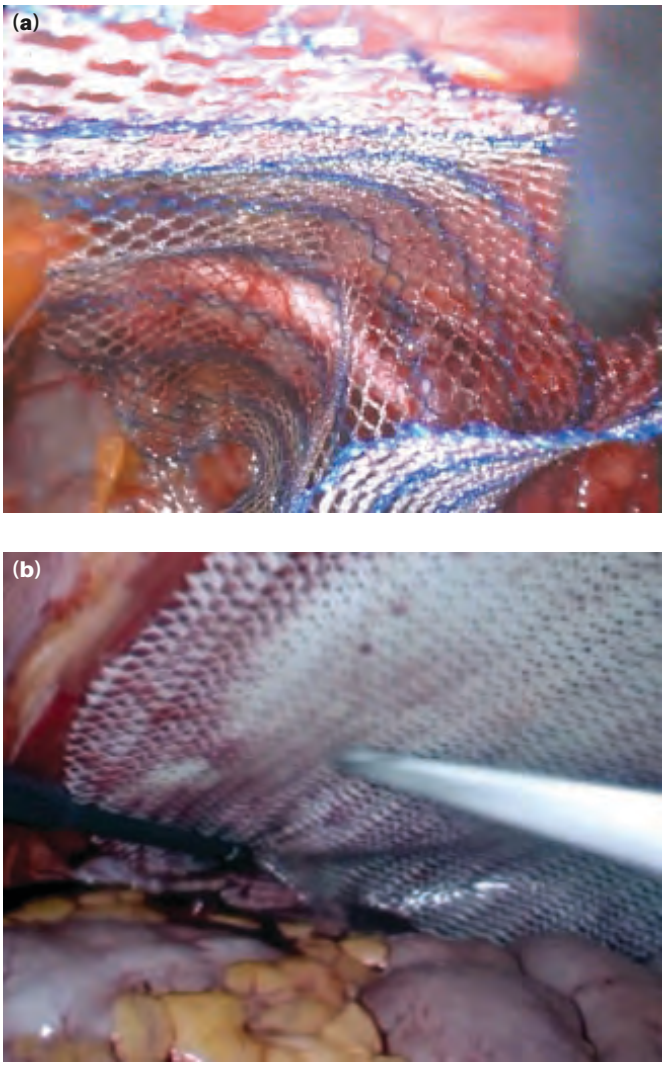

Figure 60.6 (a) Polypropylene mesh in totally extraperitoneal inguinal hernia repair and **(b)** polyester mesh in a paraumbilical hernia repair.

It does not have any antibacterial properties but its hydrophobic nature and monofilament microstructure impede bacterial in-growth. Polyester is a braided filament mesh. This structure may allow infection to take hold, aided by its hydrophilic property. However, this property also allows rapid vascular and cellular infiltration within the fibrils, aiding host immune responses to infection and providing a stronger host–tissue interface. PTFE meshes are flat sheets and as a result do not allow any tissue in-growth. They are used as a non-adhesive barrier between tissue layers.

WEIGHT AND POROSITY

Synthetic meshes are very strong and early meshes were much stronger than a human abdominal wall, so they are considered as 'over-engineered'. All meshes provoke a fibrous reaction. More dense or heavyweight meshes provoke a greater reaction, leading to collagen contraction and stiffening. The term 'mesh shrinkage' is often used to describe a progressive decrease in size of a mesh over time. It is due to natural contraction of fibrous tissue embedded in the mesh, reducing the

area of mesh itself. This can lead to tissue tension and pain, a common complication of mesh repair. It can also lead to hernia recurrence if the mesh no longer covers the defect. Meshes can shrink by up to 50% and, in occasional cases, even more. Meshes with thinner strands and larger spaces between them, 'lightweight, large-pore meshes', are preferred because they have better tissue integration, less shrinkage, more flexibility and improved comfort.

The terms 'light', 'medium' and 'heavy' are not precisely defined but meshes <40 g/m^2 are generally referred to as light and meshes >80 g/m^2 as heavy.

BIOLOGICAL MESH

There are 'biological meshes' that are sheets of sterilised, decellularised, non-immunogenic connective tissue. They derive from human or animal dermis, bovine pericardium or porcine intestinal submucosa. They provide a 'scaffold' to encourage neovascular in-growth and new collagen deposition. Host enzymes eventually break down the biological implant, which is replaced and remodelled with 'normal' host fibrous tissue. The rates of enzymatic degradation and collagen deposition vary between products and also depend on the local environment of the mesh. In the presence of infection, some biological meshes rapidly break down and weaken before remodelling can occur. Others remain strong, their labyrinthine microstructure allowing vascular in-growth to aid infection resistance. The choice of biological mesh depends on the clinical situation for which it is to be used. They are expensive.

ABSORBABLE MESHES

There are also synthetic absorbable meshes, such as those made from polyglycolic acid fibre. They are used in temporary abdominal wall closure and to buttress sutured repairs. They have no current role in hernia repair because they absorb and induce minimal collagen deposition.

TISSUE-SEPARATING MESHES

Most meshes induce fibrosis and, if placed within the peritoneal cavity, promote unwanted adhesions. New meshes have been designed for intraperitoneal use. Most of these have very different surfaces, one being sticky and one slippery. Good adherence and host–tissue in-growth is required on the parietal (muscle) side of the mesh, but the opposite (bowel) side needs to prevent adhesions to bowel. Usually one side of the mesh is coated by material that prevents adhesions (**Figure 60.7**), such as polycellulose, collagen, PTFE. A recent mesh made entirely of a sheet of condensed PTFE with multiple perforations can be used intraperitoneally because the peritoneum will grow in through its perforations whereas bowel will not adhere to its inside.

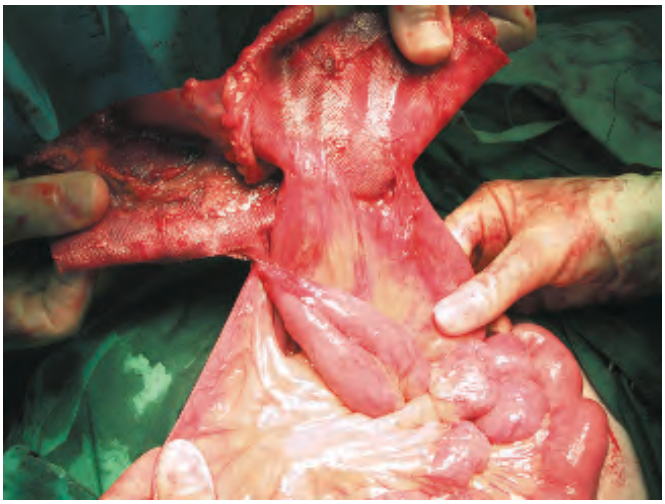

Figure 60.7 Adhesions to mesh.

Summary box 60.7

Mesh characteristics

- Woven, knitted or sheet
- Synthetic or biological – mainly synthetic
- Light, medium or heavyweight – lightweight becoming more popular
- Large pore, small pore – large pore causes less fibrosis and pain
- Intraperitoneal use or not – non-adhesive mesh on one side
- Non-absorbable or absorbable – mainly non-absorbable

Positioning the mesh

The strength of a mesh repair depends on host–tissue in-growth. Meshes should be placed on a firm, well-vascularised tissue bed with generous overlap of the defect. The mesh can be placed:

- just outside the muscle in the subcutaneous space (onlay);
- within the defect (inlay) – only applies to mesh plugs in small defects;
- between fascial layers in the abdominal wall (intraparietal or sublay);
- immediately extraperitoneally, against muscle or fascia (also sublay);
- intraperitoneally.

At open surgery all of these planes are used but laparoscopic surgeons currently use only intraperitoneal or extraperitoneal planes (**Figure 60.8**).

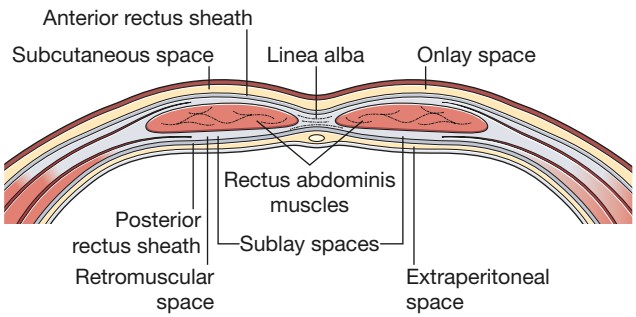

Figure 60.8 Diagrammatic representation of the various layers into which meshes are placed in ventral hernia repair.

Limitations to the use of mesh

The presence of infection limits the use of mesh, particularly heavyweight types. If a mesh becomes infected then it often needs to be removed. Some infected meshes can be salvaged using a combination of debridement of non-incorporated mesh, appropriate antibiotics and modern vacuum-assisted dressings.

Meshes are expensive, especially those for intraperitoneal use, but prices are falling and there are reports of low-cost solutions such as mosquito netting!

SPECIFIC HERNIA TYPES

Hernia sites are shown in **Figure 60.9**.

Inguinal hernia

The inguinal hernia, often referred to as a 'rupture' by patients, is the most common hernia in men and women but much more common in men. There are two basic types that are fundamentally different in anatomy, causation and complications. However, they are anatomically very close to each other, surgical repair techniques are very similar and ultimate reinforcement of the weakened anatomy is identical, so they are often referred to together as inguinal hernia.

Summary box 60.8

Inguinal hernia

- Types – lateral (oblique, indirect); medial (direct), sliding
- Origin – congenital or acquired
- Anatomy – inguinal canal
- Classification – latest European Hernia Society
- Diagnosis – usually clinical but radiological in special circumstances
- Surgery – open and laparoscopic

The congenital inguinal hernia is known as indirect, oblique or lateral whereas the acquired hernia is called direct or medial. There is a third 'sliding' hernia that is acquired but is lateral in position (see below).

Basic anatomy of the inguinal canal

As the testis descends from the abdominal cavity to the scrotum in males it firsts passes through a defect called the deep inguinal ring in the transversalis fascia, just deep to the abdominal muscles. This ring lies midway between the anterior superior iliac spine and the pubic tubercle, approximately 2–3 cm above the femoral artery pulse in the groin. The inferior epigastric vessels lie just medial to the deep inguinal ring, passing from the iliac vessels to rectus abdominis. Muscle fibres of the innermost two layers of the lateral abdominal wall, the transversus muscle and the internal oblique muscle, arch over the deep inguinal ring from lateral to medial before descending to become attached to the pubic tubercle. These two muscles fuse and become tendinous, hence this arch is referred to as the conjoint tendon. Below this arch there is no muscle but only transversalis fascia and external oblique aponeurosis, resulting in weakness (**Figure 60.10**).

The testis proceeds medially and downwards along the inguinal canal. Anterior to the canal is the aponeurosis of the external oblique muscle, the fibres of which run downwards and medially. The testis finally emerges through a V-shaped defect in the aponeurosis, the superficial inguinal ring, and descends into the scrotum. The inguinal canal is roofed by the conjoint tendon, its posterior wall is transversalis fascia, an anterior wall is the external oblique aponeurosis and a floor, which is also the external oblique, that rolls inwards at its lower margin and thickens to become the inguinal (Poupart's) ligament. The inguinal canal in males contains the testicular artery, veins, lymphatics and the vas deferens. In females, the round ligament descends through the canal to end in the vulva. Three important nerves, the ilioinguinal, the iliohypogastric and the genital branch of the genitofemoral nerve, also pass through the canal.

As the testis descends, a tube of peritoneum is pulled with the testis and wraps around it ultimately to form the tunica vaginalis. This peritoneal tube should obliterate, possibly under hormonal control, but it commonly fails to fuse either in part or totally. As a result, bowel within the peritoneal cavity is able to pass inside the tube down towards the scrotum. Inguinal hernia in neonates and young children is always of this congenital type. However, in other patients, the muscles around the deep inguinal ring can prevent a

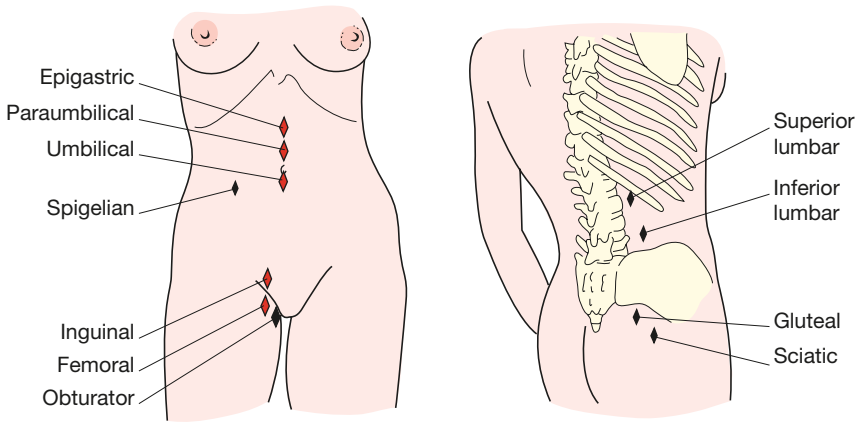

Figure 60.9 Diagram to show the sites of abdominal wall hernias, common in red and rare in black. Incisional and parastomal hernias can be found at various sites.

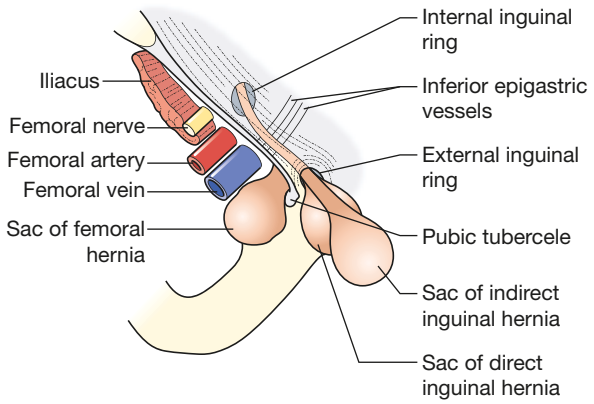

Figure 60.10 The close relationships of direct inguinal, indirect inguinal and femoral hernias.

hernia from developing until later in life, when, under the constant positive abdominal pressure, the deep inguinal ring and muscles are stretched and a hernia becomes apparent. As the hernia increases in size, the contents are directed down into the scrotum. These hernias can become massive and may be referred to as a scrotal hernia (Figure 60.11).

An indirect hernia is lateral because its origin is lateral to the inferior epigastric vessels. It is also oblique as the hernia passes obliquely from lateral to medial through the abdominal muscle layers.
