Remembering Richard S. Weiner, Ph.D.

While standing upon the shoulders of giants certainly helped many advances to occur, the genius of Richard S. Weiner, Ph.D. was more accurately due to the fact that he could see the finished puzzle within the constituent pieces. He could take pre-existing parts and ideas that others had ignored or overlooked, pull them together in slightly altered ways and create new results. He created harmony from the same puzzle pieces in which others only perceived chaos. He did more than talk about the developing field of pain management; he walked the walk and co-founded the American Academy of Pain Management with Kathryn A. Weiner, Ph.D. Together, the Weiners created a new organization that finally met the needs of its pain practitioner members through pain-related education, practitioner credentialing, pain program accreditation, outcome measurement, and many other offerings. Bringing together leaders in the field of pain management to create the American Academy of Pain Management's textbook, *Pain Management: A Practical Guide for Clinicians*, was one of his greatest accomplishments and was a continuing source of pride for Richard. Revising six editions became proof not only of his commitment to the advancement of the pain management profession, but also his stamina.

For Richard, editing a textbook was a challenging process that required more than a year of preparation. Richard weathered this process six times in 12 years to make certain that the American Academy of Pain Management's textbook was clinically useful, current, and the best source for multidisciplinary information about the assessment, evaluation, and treatment of pain. For Richard, this was his labor of love and he gave his very best to this process.

Many might say that authoring textbooks is just too much work. It is far more effort than most people would ever willingly take upon themselves. Richard never saw the textbook as too much work for himself. He looked forward to the revision process and the updating of the chapters with each new edition. He enthusiastically called authors, new and old alike, to talk with them about their submissions, suggested points to discuss, and then called others to tell them about what he had learned in the new chapters when he received them. No matter how many hours or how many authors were involved, he treated each of the authors with consideration, excitement, and respect. He asked more of the authors than some knew they had within themselves, but always knew what they could accomplish if properly motivated. Richard was the consummate manager, who not only managed ideas, but the people bringing the ideas to fruition.

Knowing that he was quite seriously ill in 2001, Richard began to consider future goals for the American Academy of Pain Management. He knew that in another couple of years the seventh edition of the textbook would need to be written to maintain the currency associated with the book. In his own amazing way, and in his attempt to find goodness and humor even in the worst of circumstances, he speculated that he wouldn't have to edit any more textbooks if he didn't respond to his anti-cancer therapies. He even tried to cheer up those who were so concerned about him by telling us that the chemotherapy was easier than editing the textbook. Before his death in May 2002, he helped identify a worthy successor as the next editor for the seventh edition of the textbook.

Practitioners fortunate enough to have personally known Richard continue to mourn his passing. His hundreds of personal friends and members of his immediate family remember all that he gave to our evolving profession. Always the gentleman in his dealings with others, he shall best be remembered as the man who gathered together the many disciplines that constitute the modern field of pain management to improve the treatment of pain for so many unfortunate sufferers he never met. He never wanted special recognition, but wanted the profession to mature and to see the "mainstreaming" of pain management services.

I miss Richard. Never a day goes by when I do not think about something he said to me, some lesson he taught me, or some opportunity he created for all of us who now follow in his footsteps. Few men pass through our lives and have as significant an impact as he did for me personally and for so many of my colleagues. While his life was far too short, his accomplishments more than filled his lifetime and left a permanent legacy for all of us. It is only fitting that this Sixth Edition be dedicated to the outstanding work of Dr. Richard S. Weiner.

Table of Contents

Dedication

Pain and suffering is an issue that has affected society throughout the ages. Its impact has led healthcare professionals throughout the world to aggressively explore methods to reduce and eliminate the pain that afflicts thousands annually. Numerous attempts have been made to discover effective methods to diagnose and treat the problem time and again, yet the condition continues to exist. Throughout our research and treatments we have learned more about this topic by integrating multiple disciplines and cultures into our quest for answers. By incorporating this broad base of knowledge and experience, we are led to believe that our continuous contribution to this effort gives each of us an opportunity to make a difference in the study of pain management.

This book is dedicated to those who can and do make a difference in the lives of others. Special recognition goes to Barbara E. Norwitz, Publisher, CRC Press, Tiffany Lane, Editorial Assistant, Barry E. Cole, M.D., M.P.A., Kathryn A. Weiner, Ph.D., and the Board, Staff, and Members of the American Academy of Pain Management.

Preface

Significant advances in our understanding of pain and suffering, clinical and laboratory reports, and concepts for multidisciplinary team interaction, combined with a renewed desire to understand the whole patient delivery system require updating and further documenting the new information provided in this 6th edition of *Pain Management: A Practical Guide for Clinicians* Interest in the field of pain management has grown dramatically since the 1970s. This has been attributable to the outstanding contribution of pioneers, who provided leadership in this field, such as Dr. John Bonica, Dr. Benjamin Crue, Mme. Abel Fessard, Dr. Burtram Wolf, Dr. John Leibskind, Drs. Richard and Kathryn Weiner, and so many others, leading to the current global, exponential, informational avalanche. To bring together this enormous amount of new and refined knowledge and data, the original two volumes have been reorganized and expanded several times.

So universal has this interest become, it can be likened to a pebble in the pond starting a propagation wave. Interest has grown exponentially; knowledge and wisdom constantly unfold. Quality pain management originally generated from a relatively small group of specialized experts forming a dynamic epicenter. These early leaders initiated a spread of integrated knowledge, team care, and multidisciplinary responses with many other health professionals, starting from basic neuroscience, which has blossomed to where we now encompass the special interest of many disciplines. Knowledge travels in many directions and today we have many primary care practices able to integrate tools and philosophies refined by pain management over the years. Many pain patients find care with a growing cadre of alternative and integrated disciplines. The primary care physician and clinician are often gate keepers because they are most frequently the first health professionals to see individuals with significant clinical problems and must decide to manage or seek referral from an appropriate specialist. Proper assessment and treatment planning are especially important for complex pain syndromes as they often are present with overlapping preexisting comorbidity. The needs of the patient must be best served when a “cure” is not possible. Chronicity complicates management for the health practitioner and patient. An integrated mind–body–spirit concept provides a fuller understanding for the complaint of pain. This holistic view in turn manifests complex interactive emotional and physical factors. Treatment programs must be individualized. Many pain syndromes are acute, chronic, and/or cancer related; one size does not fit all!

New chapters, advances in diagnosis employing new clinical testing methods, increase our scientific perspective and aid in our ability to evaluate the interpretation of many co-existing psychological, physical, functional, pathological, and structural impairments. When they indeed need to be separated or correlated for patient care within managed care agencies and medical–legal communities, we must remember that treatment decisions impact the whole fabric of a person’s life. An appreciation of a “systems” view facilitates change. Clinically applied, this knowledge and experience can better guide treatments that are more cost effective. The clinician must be able to differentiate physiological signs associated with range of motion, reflex, proprioception, and other responses. Activities of daily living, body habits and age-related changes must be evaluated in terms of related impairments and measured for quality of life. How do you evaluate preexisting and comorbid conditions that may overlap in personal injury cases and may be associated with situations where life style matters? How do we factor weight, diabetes, and postoperative failed back syndrome, superimposed on congenital spinal changes and reactive depression? Not a simple matter; only a careful, knowledgeable, and experienced assessment, supported by laboratory data, will be convincing to third party reimbursement programs, and credible for the medical–legal community. When are such tests really necessary? Are there alternatives?

A clinical practitioner can choose from more than 8000 laboratory tests. Which are reasonable and necessary to verify injury or disease? There is also the responsibility of the clinician to consider laboratory tests that may have false positive or false negative reports. Relevant, reflective, clinical correlation is required to develop a credible conclusion. Furthermore, the clinician must exercise judgment about when to order a special study. Corroborating or repeating serial tests, whose initial results are felt not to be consistent with clinical findings, may provide valuable information. In certain delivery systems, authorization for a service may be difficult to obtain. Often administrative or clinical denial sets the tone for clinical practice at the new millennium. Test selection is especially important in view of rapidly advancing technology. For example, how do you compare varying magnetic radiation imaging test results between 0.5, 1.0, and 1.5 tesla resolution. When do your order 3-D reconstruction or tomograms? When are vitamins, nutritional,

or other tests appropriate? It is exceedingly important to consider the fact that abnormal anatomic or structural tests can be misleading. There is no substitute for talking with the patient and often other persons for additional information. Frequently, patients who have injuries that remain unresolved come to involve a medical–legal setting. The inclusion of the judiciary provides an additional interactive issue based on an adversarial approach. The clinician may provide retrospective medical evaluations, declarations of permanent status, and need for future medical and vocational considerations, as well as describe how preexisting or comorbid factors influence rehabilitation. Regional pain syndrome (RPS) that causes functional impairments may be difficult to evaluate.

Reimbursement and cost shifting delays often impact care. Today, the astute clinician must understand his or her discipline to be able to work within a multidisciplinary team, document and justify opinions, and handle myriad tasks, that were far less demanding in years gone by. Authors will address these complex issues.

Today, there is an unprecedented need to justify treatment. There are barriers facing today's clinician, namely the highly interpretative rule and documentation to demonstrate necessity and reasonableness of care. Standards have frequently not been defined by statute. Experienced authors will address these issues. Moreover, third party payers are with greater frequency introducing a relatively new type of evolving medical management that could be called "contract medicine." Access to care is subject to wide interpretations. Disputes arise and this increases the frequency and involvement of the legal community with resultant adversity, which can be protracted and costly. State statutes or rules have long recognized that if there is a dispute, reimbursement may not be paid for extended periods of time, if at all. Practice management must be part of today's clinician's repertoire, as the dynamics of health policy and economics change. These issues will be reviewed in this new edition.

New and significant pharmacologic advances and treatment with respect to classes of drugs known as analgesics, anti-inflammatories, and receptor-specific forms of intervention are being discovered and re-emphasized. How do we keep up with this enormous growth in the ever expanding annual physician desk reference, compendiums across disciplines, integration of new approaches with traditional methods? New generations of drugs that affect the neuronal network; the ever expanding neural transmitters, presynaptic substance P, and others affecting specific and nonspecific receptors and effectors are updated in these chapters. New information will address complex class drug interactions. We do know that prescribed and frequently modified medication programs must be individualized and monitored. What are the advantages and risks of the Cox I and Cox II medications? New transcutaneous, oral, sublingual, and nasal aerosol delivery systems will be reviewed. Advances in both nonnarcotic and opioid therapy are discussed. How does the patient's compliance affect the treatment program if some classes of drugs are taken abusively or, conversely, below schedule? What role does psychoneuroimmunology play in etiology and intervention? How can new approaches help trigger informational transmitters that can influence peptides and emotional well-being? What is the role of over-the-counter (OTC) and herbal medications? What may be the effect on polypharmacy, herbaceuticals, and electrotherapy treatments? These questions will be discussed in expanded chapters. Caution must be exercised in prescribing new treatment and new regimes. Is there evidence from clinical trials? Do indications described have regulatory (FDA) approval? The practicing clinician is responsible for keeping current.

Advancements in our knowledge and understanding of rehabilitation have occurred in the field of muscular and skeletal disease, and new treatments are reported in this 6th edition. The authors address outcomes of treatment and evidence-based medicine, while retaining an understanding for evaluating meaningful individual responses. Outcome studies are tools that can be used to improve care, but they can be subject to manipulation for restricting access to certain treatment. Thus, it is particularly important to understand today's political environment and to analyze treatment and the opinions expressed by health professionals concerning policy matters for important decisions, in order to comment upon the milieu of practice. The important role of the health professional is to provide both relevant specialized information and to relate the impact of such information for each patient. Treatment and social decisions depend upon fair and comprehensive assessments. When should disability be reevaluated, especially if improvement occurs or if leisurely recreational personal activities are perceived not to cause significant functional impairment? How do you re-evaluate a progressive, worsening condition?

Long-term care has at times been called "palliative care." Where a management treatment program is available to stabilize or improve quality of life, treatment has been ruled reimbursable by some courts despite the fact that a cure is not possible. On the other hand, reimbursement for palliative care programs has also been denied by many third-party reimbursement programs. It should be noted that certain classes of diseases are resistant to complete cure, for example, arthritis, cardiovascular disease, certain metabolic diseases, and certain cancer syndromes, in spite of a multidisciplinary approach and may for some be at best only managed. Chronic complex regional pain syndromes associated with ongoing functional impairment such as failed back syndrome and reflex sympathetic dystrophy (RSD) or sympathetically maintained pain (SMP) also fall into this category. Intractable pain can be managed so that the patient can be brought to the highest level of personal activities of daily living and be potentially gainfully employed

through rehabilitation. Suffering from "psychological pain impairment," so well defined as "perceived nociception" by Dr. John Loeser, may be difficult to evaluate, but can often be ameliorated with an individualized, humanistic, behavioral treatment program. These issues and others will be reviewed. When are stress, anxiety, and depression (SAD) misinterpreted as malingering? An exceedingly important question. New therapies are available, based on sound psychological counseling and psychiatric experience. Home care counseling, peer counseling, and cost-effective packaged audio and visual programs are now available for selected patients. These subjects will be addressed by experienced authors.

New treatment programs combing electromodulation continue to be developed in a dynamic process as technology changes and evidence is monitored by our continuing use of outcome studies. Integrating new approaches, new routes of delivery, new roles for team members, and even new roles for the patient/client and his or her significant others is addressed in this new edition. These modalities can be adjunctive to other treatments or prescribed alone. There is preliminary evidence that a home care program can significantly reduce costs when supported with good patient education. Electrotherapy treatment modalities that combine both psychological stress, somatic pain management therapy and clarification to help patients search to rediscover meaning in life, are catapulting us to a new frontier in wellness and recovery.

Bioengineering principles that benefit and affect pathophysiogical processes, while not harming normal physiology, are the continuing quest for such modality treatment. The technology that results is controlled by regulators and agencies and may be mandated by statutory legislation. A relatively new field that I refer to as "energetics" is emerging in which psychoneuroimmunology is being studied for its ability to modulate response through noninvasive means of therapy.

New chapters which review molecular-specific neurophysiological–electrochemical events altered by receptor-specific inducement have been added to this compendium. Concurrently, one notices a move away from ablative surgery in the modulation of intractable, desultory pain syndromes.

Some of these chapters critically review newer methods of differentiating algorithmic pathways, clinically quantifying perceptual thresholds of alpha, beta, and C-fibers to wavelength-specific neural pathways of identified subsets of pain sensation. Treatments by electromodulation of spinal and cranial selective stimulation, present significant advances in pain management reported by specialists in neuromodulation of pain. New chapters in alternative medicine borrowed from European and Asian fields of healing have been added and updated. The role of spirituality is better understood in these therapies. Why do some tolerate pain better than others? These subjects will be addressed. Regulatory agencies separate experimental from investigative from approved categories of devices and further sub-classify them into three categories according to the Medical Device Act of 1976. Clinical pain associations network and have liaisons with these institutions. Clinicians are held responsible for using technology that is safe and approved for specific conditions. Scientific associations act as an important liaison between regulatory agencies. Associations help provide for testing of devices and develop guidelines and standards for protocols. The prescribing clinician, however, must be cautious and use only those devices approved for use with human subjects and understand the legal ramifications for using devices and substances for nonapproved indications. Care must be further exercised in not prescribing copied or "me, too" devices with exaggerated claims provided by the marketing department. The clinician must look for devices with established consensus by experienced investigative clinicians incorporating evidence from controlled trials and anecdotal case descriptions. This information will discussed in revised chapters.

The all important changes affecting pain management in regard to the medical–legal community are addressed in view of the changing dynamic role of the many important court discussions and new precedents. This area of inquiry assists medical, research, regulatory, legal, judicial, and legislative bodies by updating relevant new information for their respective responsibilities in decision making.

As we move forward into the 21st century with improved relations and technologies borrowed from many disciplines, we are closing the gaps in the lack of understanding conferred upon us by scientific ignorance. At the same time we are more cognizant of the need for understanding human relationships, habitats, and social policies.

History shows us that the schism of Descartes' mind–body dualism is being narrowed as we move from Aristotelian understanding of the natural order of things to Bacon's view of interrelated orders. However, we should recall an observation from Albert Einstein that "All important things cannot be measured and all things that can be measured are not necessarily important." Clinical judgment based on experience remains, therefore, paramount.

As we move into the 21st century, the emerging field of "energetics" will help modify genetics or acquired impaired neural networks that influence perceptual pain, will provide great optimism for improving the future of our ecosystem, and will improve our understanding of simple and complex syndromes. The 21st century will move us out of Descartes' "cave of ignorance" and beyond physical Newtonian concepts. We still do not understand how an anatomic neural network can also have consciousness, although general systems theory and complex theory aid our understanding. This will provide for treatments not yet imagined. The broad question whether pain perception is peripheral or centrally

mediated is still debated. Is it a combination of both? What are the roles of aging, culture, and genetic predisposition? Can we not do more to understand the yin–yang and context of the psychoneural biology of acute, chronic, cancer, and psychogenic pain syndromes, each with its different mechanisms? While learning to view individuals as part of a whole, we continue to learn pattern and structure, environment and heredity, and we improve the credibility of our knowledge. The 6th edition of *Pain Management* will provide the reader with an expanding horizon as we advance, to paraphrase Delaware's former governor, Russell Peterson, into a better world by applying integrated approaches to pain management as our contribution to a meaningful legacy. According to Hippocrates, "The future is bright but fraught with difficulty." Some day we may have a dolometer or pain meter. In conclusion, according to Helen Keller, "Alone we can do little, together we do a lot."

This text is dedicated to all those who participate in these initiatives.

Pierre L. LeRoy, M.D., F.A.C.S.

Editor's Note

PAIN MANAGEMENT: A NEW APPROACH TO PAIN AND SUFFERING

We have entered a new millennium and indications are that we shall continue the odyssey and quest for affordable, quality pain management. We are witness to new emerging historic events. In 2001, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) published new Pain Management Standards. Hospitals, skilled nursing facilities, and other similar programs in the United States desiring JCAHO accreditation must comply with the new Pain Management Standards. The University of Integrated Studies became the first American University to provide distance education and degree granting (M.A. and Ph.D.) in Pain Management, and today more clinicians practice multidisciplinary pain management than ever. As a result of these trends, many people in pain can find improved care and there is renewed hope for further reduction of pain and suffering.

HISTORICAL TREATMENT OF PAIN

Throughout the millennia, problems associated with pain and attempts to control pain have historically been one of the principal reasons why individuals have sought health care. Alleviating pain is not a recent concern. Relief of suffering has been the helping profession's primary objective throughout time. However, the way we view pain and the treatments available have been altered considerably.

Individuals in prescientific cultures felt less control over their environment than is common in contemporary society. Consequently, people sought explanations and meaning for their lives in mystical, supernatural, or God-like concepts. The common thread was a feeling of very limited control over events. Attribution theory has been offered by social psychologists to explain coping mechanisms by which people ascribe a cause to an unpleasant event in the hope of establishing a difference between themselves and the "inflicted one." Such a process could comfort one into a belief of invulnerability. Thus, early men and women attributed pain to evil, at times vengeful, spirits who invaded the body of an unworthy host. However, these spirits were amenable to negotiation. Culturally differentiated rituals were used to exorcize the pain. That ancient communities paid great attention to the treatment of pain is suggested by one of the earliest vocational specialties developed by humanity: the medicine man or witch doctor. Throughout recorded history, the healer or reliever of pain was given a special status in his or her community.

Ancient healers or shamans practiced a sacred art and were viewed as catalysts who could negotiate with an angry God or who could, by ritual, restore balance with nature. In this orientation, intervention was possible, but the final outcome was not within the control of mortals. The context of the illness and pain represented more of a wholeness than presently exists in disease of the body, disease of the mind, or disease of the spirit. An illness affected the total person, who consisted of an integration of these components.

Philosophically, this concept changed when Descartes conceptually separated the body from the soul and described pain as a signal of mechanical dysfunctioning. As a result, narrow specialties, often fragmented and with little common language, developed. Although such an epistemological approach has resulted in great scientific breakthroughs in many areas of acute health care, it has often created a barrier in our understanding of intractable pain.

THE PROFESSIONAL ENVIRONMENT OF PAIN MANAGEMENT

Great strides have been made in our ability to help individuals who suffer from pain. We have gone beyond the historical method of providing treatment in which a sole practitioner works with a chronic pain patient. Interdisciplinary and multidisciplinary pain clinic facilities have demonstrated a new service delivery approach to pain management. There has been a phenomenal growth in the number and variety of inpatient and outpatient clinics. Professionals from several disciplines who work together have reintroduced an awareness that pain patients experience physical, emotional, interpersonal, financial, and spiritual problems. This reintegrated blend of art and science within the team concept helps establish the pain practitioner as a renaissance healer.

In 1988, the American Academy of Pain Management (AAPM) was incorporated so that clinical pain practitioners from all disciplines could work together for the purpose of developing standards for practice and codes of ethical conduct, and for the purpose of establishing a credentialing process for clinical pain practitioners.

CONTINUING EDUCATION

Many current pain management professionals entered the field without the benefit of specific formal graduate training in pain management. Clinicians completed a terminal degree — be that medicine, mental health, pharmacy, or one of the other therapies — and began practice. In recent years, in the United States, a select few physicians, primarily anesthesiologists, could avail themselves of a Fellowship in Pain Management.

In 2000, the AAPM developed a graduate curriculum that combined useful and practical information with the distance learning education format. A graduate committee composed of multidisciplinary clinicians and academicians developed a graduate program in Pain Studies. Graduate degrees (M.A. and Ph.D.) became available. As with the new JCAHO Pain Management Standards, the University of Integrated Studies presents evidence that the field of pain management has crossed a watershed.

EMERGING DISCIPLINE

The 6th edition of *Pain Management: A Practical Guide for Clinicians* represents a continuing commitment by the AAPM in assisting pain practitioners to more fully understand the art and science of pain management. The authors whose work is presented in this text are among the leaders in pain management. They write with a vision based on experience. The collection of their wisdom, represented here, is relevant for pain management clinicians and professionals from all disciplines who wish a consultative state-of-the-art resource for their practice. *Pain Management: A Practical Guide for Clinicians* is intended to be an updatable resource. Additional chapters will be written, and as new insights are gleaned from the real world of pain management, revisions will allow expansion, both increasing the value of this project and creating a living resource that will not soon become outdated.

Each chapter has been written to allow the reader to independently read topics of interest and thus may be viewed as a self-contained study. The collection of chapters allows an authoritative self-study on many of the pressing issues faced by pain practitioners. The writing style of each author has been left intact, further highlighting the unique contribution of each chapter to the total project.

The chapters and information presented may not represent any consensus of beliefs. We do not presuppose that all readers will agree with the sentiments that they find here, and some clinicians may disagree with others; however, we hold that by presenting this information, including divergent ideas, we provide a forum for discourse. It remains the clinician's responsibility to assure that all treatment is consistent with community standards, is lawful, and is approved for the condition being treated.

Although we have come a long way in our understanding of the impact of pain and in our ability to help reduce the toll of pain on the lives of our patients/clients, we have not yet eliminated the scourge of pain. It is my hope that this 6th edition will help illuminate our present ability and encourage future analysis.

CONCLUSION

Pain is a great leveler. Those in pain and those who suffer recognize that pain perception changes according to intensity, frequency, and duration. The multidisciplinary model remains the best hope for reducing pain and suffering as we integrate information from many disciplines to understand the whole patient. As we look ahead, past and present traveling together, we can envision the spirit of integration leading the world to a better time. The AAPM salutes multidisciplinary pain management professionals as early representatives helping to improve scientific, social, and ethical change affecting health policy in pain management. To that spirit, it is my hope that this edition will help illuminate the road we all travel.

Section I

Pain in Perspective

1

Pain and Its Magnitude

Barry Fox, Ph.D.

Trying to estimate the size of the crowd at a large public gathering — such as a protest at the White House — can be difficult. People pour through the streets and parks; they do not stand still, they come and go. You cannot count the number of tickets sold or seats set out because there are neither tickets nor seats. The police give one estimate of the crowd size, the event's organizers another. Some people make "guesstimates" of crowd size by tallying up how many t-shirts or bags of popcorn were sold by vendors, or how much trash remains to be cleaned up.

Determining how many people suffer pain is also a difficult proposition. Lacking firm measuring sticks, health statisticians look to several indicators in order to develop reasonably accurate estimates of the numbers of people suffering from various types of chronic pain and the associated costs.

Unfortunately, even the "best" numbers from the most prestigious sources are only estimates. It is simply impossible to develop precise numbers, for many reasons. To begin with, we do not have a national health registration system, or a comprehensive national health database to track the numbers. Instead, the millions of people in this country are treated by a patchwork quilt of HMOs, private physicians, county hospitals, student health centers, etc., and we do not yet have a system to correlate the statistics from all these disparate entities. But even if we had a national system for tracking all complaints reported to physicians, we would not be able to account for those people who do not report their pain, preferring to ignore it, to self-treat, or to seek help from alternative health providers. To complicate matters more, there are differing ways of grouping types of pain. For example, some organizations have a very broad definition of arthritis, yielding a greater number of arthritis sufferers, while other groups use a narrower, more restrictive definition that produces a smaller tally. One estimate of the number of people suffering from chronic pain will include those with cancer pain, while another will not.

Despite the many difficulties, several organizations have developed estimates of the magnitude of the problem in this country. According to the American Pain Foundation (APF) (2000), "over 50 million Americans suffer from chronic pain …, " adding that another 25 million develop acute pain following surgery or injuries. The American Pain Society (APS) presents an expanded set of numbers, stating that while 50 million Americans suffer from chronic pain, an additional "25 million suffer with moderate-to-severe pain, and another 8 million suffer with cancer pain" (Pain Legislation, 2000). These figures, impressive as they are, may understate the problem. In the 1998 edition of this volume, Tollison noted that "some 75–80 million people in the United States are estimated to suffer chronic pain," adding that "this is generally considered a conservative estimate" (Tollison, 1998).

For seniors, pain can be a constant companion. The American Geriatrics Society estimates that "25% to 50% of older persons living in the community have pain problems," with 20% of older people taking pain medicines several times weekly (National Institutes of Health, 1998).

Let us set aside the abstract numbers for a moment to listen to some of the ways people describe their suffering: Aching, agonizing, beating, biting, burning, constant, cramping, crushing, cutting, darting, depressing, drilling, dull, excruciating, flickering, grinding, gripping, heavy, hot, intermittent, killing, light, mild, moderate, nagging, nauseating, numbing, piercing, pinching, pounding, pulsing, racking, radiating, ripping, sharp, shooting, sore,

0-8493-0926-3/02/$0.00+$1.50

splitting, squeezing, stabbing, stinging, tearing, throbbing, thumping, tight, and tingling.

With such an extensive pain vocabulary, it is clear that the problem is significant. No matter whether the total number of people suffering from chronic pain is as high as 80 million or as "low" as 50 million, it is clear that the magnitude of the problem is great and greatly troubling.

MILLIONS SUFFER FROM THE MAJOR "TYPES" OF PAIN

Chronic and intermittent pain comes in a variety of forms, most commonly joint pain, headaches, and back pain, and it may be triggered by a large number of diseases, conditions, and states, including arthritis, fibromyalgia, injuries, infection, cancer, trigemimal neuralgia, shingles, sickle cell disease, and angina. There is also the aching, burning pain of Central Pain Syndrome, which may develop after one has suffered a stroke or brain or spinal cord injury, developed multiple sclerosis, or had a limb amputated. Here are some estimates of the numbers of people suffering from some of the more common forms of pain:

- Arthritis — According to the National Institute of Arthritis and Musculoskeletal and Skin Diseases (1998), some 40 million Americans are afflicted by arthritis, "and many have chronic pain that limits daily activity." The total number of those suffering from arthritis is projected to reach 59 million by the year 2020. The Centers for Disease Control and Prevention (2001) give a slightly higher figure, stating "arthritis and related conditions have affected nearly 43 million Americans in 1998." The APF (2000) arrives at an even higher figure, estimating that "1 in 6 Americans suffers from arthritis." With a population of slightly over 284 million Americans as of May 2001 (U.S. Census Bureau, 2001), this means that some 47.3 million people have arthritis. Of them, 20.7 million suffer from osteoarthritis, the most common form of the disease, and 2.1 million have rheumatoid arthritis (National Institute of Arthritis, 1999).
- Headaches — According to the National Institute of Neurological Disorders and Stroke (NINDS, 2000b), "an estimated 45 million Americans experience chronic headaches. For at least half of these people, the problem is severe and sometimes disabling." The APF (2000) reports that more than 25 million Americans grapple with migraine headaches.
- Back pain — Over 25 million Americans aged 20 to 64 are hit with frequent back pain (APF, 2000). Over 5 million suffer from low back pain so severe as to be disabling (Collacott, et al., 2000; American College of Rheumatology).* The Occupational Safety and Health Administration (1993) quotes the Bureau of Labor Statistics to report that "more than one million workers suffer back injuries each year."
- Pelvic pain — One out of every six women suffers from chronic pelvic pain (Adamson, 1998).
- Cancer pain — In 1999, the American Cancer Society estimated that "approximately 8.2 million Americans alive today have a history of cancer", and expected another 1.2 million new cases to be diagnosed that year. The Society (1998) further reports that "one out of every three being treated for cancer has related" pain.
- Jaw pain — According to a report from The National Institute of Dental and Craniofacial Research, as many as 7.5 million Americans complain of pain in the face, or specifically in the jaw joint (Slavkin, 1996). The APF (2000) weighs in with a much higher number, stating that "20 million Americans experience jaw and lower facial pain (TMD/TMJ) each year."
- Fibromyalgia — Nearly 4 million Americans suffer from the pain of fibromyalgia (APF, 2000). Most of these are women.
- Reflex Sympathetic Dystrophy Syndrome — According to the Reflex Sympathetic Dystrophy Syndrome Association of American (2000), the severe burning pain and terrible sensitivity to touch seen with the regional pain syndrome afflict some 1.5 million people in this country. The Association describes the syndrome as being "pain-filled" and "under-treated".
- Whiplash — An editorial appearing in the New England Journal of Medicine notes that more than 1 million Americans suffer from a whiplash injury every year. Of those, 20 to 40% develop "symptoms that are sometimes debilitating and last for years (Carette, 1994)." The authors of an article in the Archives of Neurology offer a more conservative estimate of the lasting impact of whiplash, stating that "after 12 months, between 15% and 20% of patients remain symptomatic, and only about 5% are severely affected" (Bogduk & Teasell, 2000).
- On the job injuries — Reporting on work-related musculoskeletal disorders, the Occupational Safety & Health Administration ([OSHA], 1999) stated that "in 1996, more than 647,000 American workers experienced serious injuries due to overexertion or repetitive motion on the job."

* The American College of Rheumatology puts the number of Americans disabled at 5.4 million.

Just as we have difficulty determining the total number of people suffering from pain, we cannot pinpoint the precise number of people suffering from various "types" of pain (arthritis pain, back pain, headache pain, etc.). As you can see from the numbers above, sometimes reporting organizations are fairly close in their estimates, and other times they are far apart.

Even reasonably sound numbers put forth by advocacy organizations, such as the American Cancer Society or the Reflex Sympathetic Dystrophy Syndrome Association of American, may be attacked by those who argue that these organizations overstate the magnitude of the problem in order to draw more attention to the problem and/or to raise more money. In the same vein, critics can argue that government organizations such as the National Institute of Neurological Disorders and Stroke exaggerate the scope of a problem because it is the nature of government bureaucracies to view problems as being larger than they really are. Nevertheless, the problem is clearly dramatic, afflicting people from all walks of life.

THE DOLLAR COST OF PAIN

No one can put a price tag on a person's suffering, but we can make some estimates of the dollar cost of pain to the nation as a whole. As with the numbers of people in pain, the estimates vary.

- Total Costs— The APF (2000) reports that "pain costs an estimated $100 billion each year," and that over 50 million work days per year are lost to pain. The National Institute of Dental and Craniofacial Research weighs in with a lower figure, specifically for chronic pain, stating that "estimated annual costs — including direct medical expenses, lost income, lost productivity, compensation payments and legal fees — are close to $50 billion" (Slavkin, 1996).
- Arthritis — According to the Centers for Disease Control (2001), arthritis costs the nation "nearly $65 billion annually" and is the second leading cause of work disability. The Centers (1999) also report that "persons with arthritis and other rheumatic conditions accounted for 2.4% (approximately 744,000) of all hospital discharges and 2.4% (approximately 4 million) of days of care in 1997.
- Back pain— "Back pain is the leading cause of disability in Americans under 45 years old" (APF, 2000). Low back pain is responsible for more than 93 million lost workdays per year and "costs more than $5 billion in health care each year" (Slavkin, 1996). The American College of Rheumatology puts the costs of low back pain at $16 billion a year. In an article appearing in the Journal of the American Medical Association, Collacott, et al. (2000) state that "the direct cost of treating low back pain is estimated at $15 billion, with indirect costs as high as $100 billion annually." The Bureau of Labor Statistics reports that back injuries are involved in 25% of all claims for workers compensation, "costing industry billions of dollars" (OSHA, 1993).
- Headaches— Headaches send people to their doctors for 8 million visits each year, and migraine headaches force people to lose more than 157 million workdays annually (NINDS, 2000). Some $4 billion goes to pay for headache medications every year (Slavkin, 1996).
- Work-related musculoskeletal disorders— The repetitive motion injuries, back pain, and other musculoskeletal problems suffered on the job are estimated to cost us between $13 billion and $20 billion annually in the form of compensation claims and lost work days (Steering Committee, 1999).

THE PERSONAL COST OF PAIN

We are all familiar with the "watch out!" pain that warns us, for example, that we've rested a hand on a hot stove or pushed the sewing needle just a little too far through the material and into a finger. We welcome this pain, which spurs us into taking immediately protective action. We have also experienced the "next time you'll pay more attention" pain that reminds us, for instance, not to leave our fingers between a rapidly closing door and the door jamb. We do not like either of these types of pain, but we understand their meaning and applaud their purpose.

Chronic pain, however, seems to have neither meaning nor purpose. Sometimes the cause of chronic pain is clear: cancer of the pancreas, for example, which has spread to the back. But oftentimes doctors and patients are baffled because the original condition has healed and the pain should have vanished. And, quite often, no one can determine why the pain developed in the first place.

Ultimately, there is no meaning to chronic pain. It is not a "watch out!" warning or a "next time you'll pay more attention" reminder. It may be telling us that tissue is being damaged, but it keeps telling us, long after we have received the message. Sometimes there is no damage for the chronic pain to be speaking about.

Long-lasting and lacking meaning, chronic pain can bring on the "'terrible triad' of suffering, sleeplessness and sadness" (NINDS, 2000a). When the "terrible triad" sets in, victims find it hard, sometimes impossible, to work. Certain movements may be difficult, even basic ones such as getting up out of bed or reaching for a glass.

Sleep may be disturbed, leading to constant fatigue and weariness. Irritability and depression may soon follow. The appetite may suffer, or the person may turn to food in an attempt to assuage distress. Hit by a pain that seems to strike without rhyme or reason, unable to find relief, perhaps told that "it's all in your head," chronic pain patients may lose hope.

Arnold Fox, M.D. (personal communication, September 12, 2000), Past President of the American Academy of Pain Management, speaks of the "Eight Ds" of chronic pain, the eight "side effects" he has seen in chronic pain patients. They are

1. Depression — Patients wind up feeling that there is no point in trying to get on with their lives.
2. Distraction — Victims focus on their pain so much that they may have difficulty handling other aspects of their lives.
3. "Doctor Dancing" — Patients go from one doctor to the next in their desperate search for relief.
4. Disability — People in pain may be unable to work or take care of themselves because of their physical or emotional symptoms. Compounding the problems, their muscles may weaken because of disuse.
5. Disease — Pain depresses the immune system, rendering us less able to fight off other illnesses.
6–7. Drinking and Drugs — Sufferers may go to great lengths in their attempts to block chronic pain.
8. Death — In some cases, suicide may appear to be the only way to end the suffering.

The Eight Ds may appear singly or in combination. They may attack when pain is new or after it has "settled in." In any case, they are devastating.

PROFILE OF PEOPLE IN PAIN

Everyone responds to pain uniquely, but it is possible to sketch pictures of some "typical" pain patients by looking at the results of a survey of 805 adult pain patients whose pain had lasted at least six months and was rated at "5" or more on a scale of 1 to 10, and who were not suffering from pain due to cancer (APS, 2000).

Over 50% of pain patients have been in pain for 5 years or more. Some 40% feel their pain is out of control. Just about all of them have gone to doctors looking for relief. Almost half have switched physicians at least once, primarily because they still hurt, and also because they do not feel their doctors know enough about pain and do not give the problem as much attention as it deserves. More than 20% have changed doctors three or more times for these same reasons.

Moderate to severe chronic pain takes a big bite out of quality of life. Eighty-one percent report that their pain has interfered with their ability to exercise; 79% report that it interferes with their ability to get a good night's sleep; 67% say it interferes with leisure activities and 65% with household chores; 59% report that it hampers walking; 54% report pain-related problems with sexual activity; 49% find that it hampers their ability to concentrate; and 41% say it hinders their ability to do their jobs. Emotional difficulties are triggered by uncontrolled pain. Thirty-five percent report irritability; 27% listlessness; 25% depression; 18% feelings of uselessness; 11% feeling unable to cope.

Chronic pain patients tend to feel that narcotic medications do the best job of providing relief, rating them at 7.6 on a scale of 0 to 10 (10 being total relief). Prescription NSAIDs are rated at 6.2 on the same scale, and over-the-counter medicines at 5.2. (Among those in very severe pain, the narcotics, NSAID, and OTC ratings were 7.4, 5.3, and 4.4, respectively.)

Seventy percent of the people report taking their medicines as prescribed by their physicians, but 21% say they do not follow their doctors' orders. The reasons for this include wishing to take their medicine only when they need it and wanting to decide how much they will take.

SLEEP AND PAIN

Lack of restful sleep is a common complaint among chronic pain patients. By one estimate, pain costs one third of all American adults 20 hours of sleep per month (APF, 2000). A study conducted at the University of California, San Francisco, School of Medicine utilized 24 oncology outpatients to examine the relationship between pain, sleep, and fatigue (Lamberg, 1999b). The researchers found that it took the pain patients four times longer to fall asleep, on average, than it takes healthy people. The pain patients awakened frequently. And while healthy controls had a mean sleep efficiency (time sleep compared to time in bed) of 90%, the pained subjects had a mean sleep efficiency of only 71%. In another measure of the effects of long-lasting pain on sleep, 141 patients reporting to Emory University's pain clinic were questioned: 127 of them had suffered from problems with sleep (Lamberg, 1999b). A Gallup survey conducted for the National Sleep Foundation found that one-quarter of American adults had their sleep disrupted by pain 10 nights or more every month — and headaches and back pain were the culprits cited most often. Many were able to sleep only 5 hours per night, on average, when pain struck (Lamberg, 1999a).

Arthritis patients also report difficulty in sleeping. When researchers at Texas Woman's University in Denton surveyed 90 men and women with osteoarthritis or rheumatoid arthritis (Lamberg, 1999b), they found high

agreement with the statements, 'I often have trouble going to sleep' and 'Pain often awakens me.'

Sleep studies conducted in the laboratory confirm that pain patients have sleep difficulties. Donald Bilwise, Ph.D., head of Emory University's Sleep Disorders Center, reports that "pain patients have more light sleep and less deep slow-wave sleep … as well as more frequent brief arousals and more waking, or alpha brain activity in slow wave sleep than do healthy persons" (Lamberg, 1999a).

The disturbances in sleep patterns may be partially due to the pain itself, as well as accompanying anxiety and other emotional upset. Furthermore, many medicines used to treat pain can alter sleep patterns. For example, nonsteroidal anti-inflammatories can delay the onset of deep sleep, while steroids may decrease REM sleep (Lamberg, 1999a).

PAIN IS UNDERTREATED

Most authorities agree that a fair amount of pain is left undertreated. The National Institutes of Health report (1998) that up to "80% of nursing home residents may have substantial pain that is undertreated." The pain of cancer is "widely undertreated, even though it can be effectively controlled in up to 90 percent of all cancer patients," according to Philip Lee, M.D., Assistant Secretary for Health, Department of Health and Human Services, and Director of the Public Health Service (1994). Patients at the end of life are also at risk of suffering from inadequate pain management.

A 1999 survey released by the American Academy of Pain Medicine, the American Pain Society (APS) (1999), and Janssen Pharmaceutica found that "more than four out of every 10 people with moderate to severe chronic pain have yet to find adequate relief." Alarmingly, 56% of those with moderate to severe chronic pain have been hurting for over 5 years. Patients complain that their doctors are not able to relieve their pain, do not know enough about pain relief, and do not approach the problem aggressively or seriously enough.

Part of the problem is that we have no objective means of quantifying pain. No one can tell how your pain hurts you, or to what degree. X-rays may reveal that a bone is broken, and the presence of inflammation indicates that the body is fighting disease. But only you know if, where, and how much you hurt. It would be nice if doctors could say, for example: "Twenty sensory neurons in the patient's right little finger are signaling 18 units apiece of pressure pain; 20 times 18 equals a pain rating of 360." Unfortunately, we cannot do that because we do not know exactly how many sensory neurons each patient has in his or her body, how much stimulus is required before the nerves will begin firing off pain messages, and how patients' emotions, psychological makeup, and past experiences affect the way their brains process pain messages.

The sensation of pain, for example, is determined to a surprising degree by a person's history of pain experience. A man who was terrified as a child after being attacked by a dog may find all dog bites extremely painful, no matter how objectively minor they may seem to a physician. Cultural attitudes or genetic makeup also may affect the way a person experiences pain. Several studies, for instance, have found that people of Nordic origin tend to be more stoic about expressing pain than are people of Jewish or Italian stock. Studies also point to differences in the way that northern and southern Italians view and respond to pain.

Soldiers fighting for a cause they hold dear are often able to shrug off pain that might force others who are less motivated to give in. But even soldiers fighting for the same cause may react differently to pain. After Allied troops stormed the Italian beach at Anzio in 1944, doctors noted that some soldiers with minor injuries reported severe pain, while others who were seriously injured registered few complaints. Likewise, athletes determined to win have shown a remarkable tolerance for bearing pain. A football player with a broken foot may run 90 yards for the touchdown without feeling any pain.

Factoring into the pain equation a person's attitudes toward pain, his fears, experiences, religious and cultural background, motivation, and other emotional and psychological factors is not yet possible. In the near future we will undoubtedly develop scanners that can count the number of sensory neurons in any part of the body, but we do not even know how to begin to measure the emotional and psychological influences on the brain's interpretation of pain. And, if we cannot agree on how acute pain should be measured, despite knowing exactly what causes the problem, how can we come to any consensus on measuring chronic pain that appears to have no objective cause, let alone set universal standards for treatment?

In the absence of objective means to measure pain, as well as generally accepted treatment guidelines, some doctors are worried that pain patients will become addicted should they be given "too much" of certain medications. Other physicians, along with some psychiatrists and psychologists, surmise that people whose pain will not respond to their ministrations are using the pain for "secondary gain," to gain sympathy or attention, for example. Or, they conclude, such people are not motivated to recover, are exaggerating their pain to get out of work or avoid responsibility, are addicted to pain-killing medications, or suffer from mental or emotional conditions.

Some patients undoubtedly invent or exaggerate pain symptoms for various reasons. But the overwhelming majority of pain patients suffer from real pain. And they want to be cured.

Historical Perspective of Pain Management

C. Norman Shealy, M.D., Ph.D., D.Sc. and Roger K. Cady, M.D.

Most people fear death less than they fear continuing pain. Indeed, many individuals who commit suicide during terminal or potentially fatal illnesses do so to avoid pain themselves and philosophically to spare their families psychological suffering. Bonica (1990, p. 2) has estimated that 15 to 20% of the population has acute pain and 25 to 30% has some form of chronic pain. The Nuprin Pain Report (1986) suggests that pain affects a huge majority of Americans each year. Obviously, any consideration of pain has to begin with an understanding that pain is a natural part of life and has been a major factor in human development throughout time. Prehistorical evidence through archeological findings suggests that the most primitive of populations suffered from diseases which would be expected to involve pain, and in the history of every civilization of the world, there are numerous references to the plague of pain. The concept of counter-stimulation through rubbing, massaging, or pressure on painful points or around painful areas probably has been used throughout history. Theory and management have indeed evolved together.

At least 4500 years ago, the Chinese already had a well-developed system of pain management–acupuncture. Competent pain medicine clinicians today recognize that acupuncture remains one of the most powerful treatments for both acute and chronic pain. Although we are not certain of the details involved, it is clear that the Chinese used herbs and, very early in their history, opioids or narcotics.

The Egyptians chronologically stand next in line in recorded history. The Egyptians appear to have believed that pain was inflicted by either a god or a disincarnate spirit, and, as in India, the Egyptians considered the head to be the center of sensation. The ancient Indians attached much more significance to the emotional roots of pain. Looking forward in history, the ancient Greeks introduced the concept that the brain is the organ in which sensation becomes conscious, although that concept, introduced by Alcmaeon, was vigorously fought by Aristotle, who considered the heart the center of sensation. Hippocrates, the "father of medicine," had a concept that was very similar to the Chinese theory of five elements, except that the Chinese included only four humors: blood, phlegm, yellow bile, and black bile. An excess or deficiency of one of the humors was supposed to lead to pain. Eventually, the reality of the brain as the seat of sensation was recognized, and it was the ancient Greeks who demonstrated that the brain and the peripheral nerves were intimately connected and that there were two types of nerves: those for muscle control and those for sensation. Ancient Rome added relatively little to the concept of pain, but Galen demonstrated the central and peripheral nervous system as well as cranial and spinal nerves and sympathetic trunks. Even so, Galen continued to follow Aristotle's concept of pain as "a passion of the soul."

The center of civilization moved to Arabia approximately 1000 years ago, where Avicenna described 15 different types of pain and treatment, including exercise, heat, massage, opium, and other natural herbal remedies. Paracelsus, who died only 450 years ago, advocated the use of opium and natural herbs, but added various electrical stimulation techniques, massage, and exercise.

Remarkably, even William Harvey, who described the circulation of the blood, considered the heart to be the site where pain was felt. Descartes, who is often attacked by holistic philosophers as the individual who tore the body and mind apart, nevertheless made great contributions to the concept of pain. Unfortunately, as was true of much

0-8493-0926-3/02/$0.00+$1.50

early philosophy, he was rather inaccurate. He considered that pain was a direct transfer through a tubular structure and that strong impulses were transferred directly from the periphery to the brain. He is credited with essentially creating the first "specialty" therapy for pain transmission.

Although opium and, undoubtedly, alcohol were used as analgesics from very early times, exorcism and various religious ceremonies were also an integral aspect of pain control in many cultures. Nevertheless, many early cultures used surgical trephination of the skull for headache, and acupuncture, moxibustion, massage, physical exercise, and diet have all been used for pain control in a variety of cultures. In ancient Egypt, Greece, and Rome, electric shock was used for the treatment of gout, headache, and neuralgia through the use of the electric fish.

The first major innovation in pain treatment in almost 2000 years occurred in the late 18th century when Joseph Priestley introduced nitrous oxide, and it was later found to be a significant analgesic. Throughout the 19th century, great progress was made in neurophysiology in general and pain physiology in particular. Johannes Muller introduced "The Doctrine of Specific Nerve Energies" in 1840.

Other important 19th century innovations were the isolation of morphine from crude opium; the discovery of codeine, aspirin, ether, and cocaine (especially as a local anesthetic); needles and syringes; hypnosis; the first neurological procedures for ablation of peripheral nerves or the spinal cord in the management of pain; electrotherapy, hydrotherapy, and diathermy; and the introduction of the X-ray, for both diagnostic and therapeutic purposes.

During the middle to latter portion of the 19th century, the specificity theory became the dominant concept of most scientists. Just as Galen, Avicenna, Descartes, and Muller had theorized, specificity seemed to consolidate the idea of specific pathways and specific receptors for pain. It is interesting that as early as 1858, Schiff had demonstrated analgesia by sectioning the anterior quadrants of the spinal cord of an animal, and it was over 50 years later that a clinician in Philadelphia introduced the concept of spinal cordotomy in the human being. von Frey (1894) discovered specific end organ receptors for pain and touch and expanded Muller's concept to include warmth and cold.

The origin of the pattern theory, another dominant pain theory, was introduced by Goldscheider (1894), who believed that certain patterns of nerve activation were produced by summation of sensory input from the skin in the dorsal horn. This theory was further formalized when Nafe (1934) introduced the concept that all sensation is the result of spatial and temporal patterns of nerve impulses rather than the result of specific receptors or pathways. Building upon this, Sinclair (1955) and Weddell (1955) emphasized that all free endings, except those innervating hair follicles, are similar and that it is only the pattern that is important in sensory discrimination. Unfortunately, both the specificity and the pattern theories were incomplete.

Hardy, Wolff, and Goodell (1952) objected to the pattern and specificity theories and insisted that there was a difference between reception of pain and reaction to pain. They, perhaps more than any others of their time, introduced the concept of major cognitive, psychological, and emotional factors as important in chronic pain management. There are numerous other minor theories related to pain, but the next major innovation and the one that sparked the most intense change in the management of pain in the past 5000 years was gate control.

Melzack and Wall (1965) introduced the theory that the information coming in over C-fibers was modulated through presynaptic inhibition from incoming beta fibers in the substantia gelatinosa. This "gating" mechanism depends upon the relative quantity of information coming in over the larger fibers versus the smaller fibers. Thus, there are two major ways in which pain "gets through" the gate: either through damage to the beta fibers, which allows spontaneous pain or sensory deprivation pain, or by activation of the C-fibers by excess stimulation through inflammation or pressure upon the C-fibers (Figure 2.1).

Later work by Shealy (1966) physiologically demonstrated that approximately 60% of C-fiber activity was crossed to the opposite side (Figure 2.1) of the spinal cord and distributed fairly diffusely in all parts of the spinal cord except the dorsal columns. That is, 60% of the total volume of central distribution of C-fiber activation goes contralaterally, not into the spinothalamic tracts but through the entire gray and white matter of the cord other than the dorsal columns, and 40% is similarly distributed ipsilaterally. Strong stimulation of beta fibers is capable of inhibiting at this initial gate the activity from the dorsal columns (Shealy & Tyner, 1966; Shealy & Taslitz, 1967).

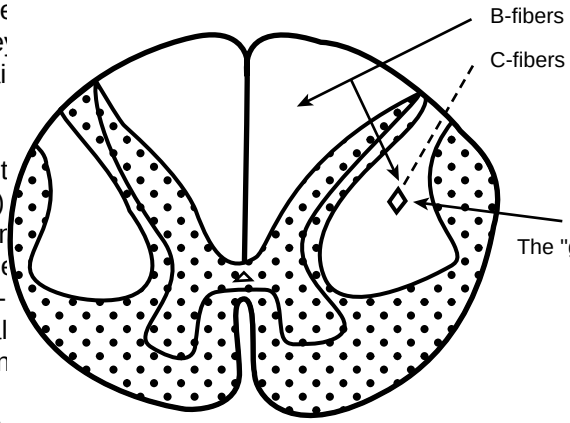

FIGURE 2.1 The dorsal columns are "pure" projections of beta fibers. The gate is closed by increased input of beta fibers and opened by excessive C-fiber activity.

It appears that the major contribution to the spinothalamic tracts is the input from the gamma-delta fibers, which primarily bring in acute or sharp brief pain as well as touch, vibratory sensation, etc. The dominant role of the dorsal columns seems to be similar to an FM radio station, modulating input from the other sensory fibers.

Shealy (Shealy, Resnick, & Tyner, 1966; Shealy & Taslitz, 1967), after discussing the gate control theory with Wall and Melzack, reasoned that stimulation of the dorsal columns would conceivably antidromically inhibit the gate, and he demonstrated this initially in animals and later in humans. Both Melzack and Wall, in their original theory, emphasized that there were descending controls of the gates coming from the cortex and other central brain locations, as well as the peripheral control through the beta fibers. Shealy, Mortimer, and Resnick (1967) had demonstrated adequate safety of long-term stimulation of the dorsal columns, in cats and monkeys, to insert the first dorsal column stimulator in a human suffering from terminal metastatic cancer.

In 1967, Shealy resurrected an old external electrical stimulator, the Electrea™, and began encouraging the engineers at Medtronic, Inc. to make a modern solid-state electrical stimulator. Shealy, working in collaboration with Long, and each working independently, prompted Norman Hagfers (who left Medtronic to form StimTec, Inc.) and Donald Maurer (at that time still with Medtronic) to produce the first two solid-state transcutaneous electrical nerve stimulators. Shealy had already demonstrated that the two most useful types of electric current for pain relief were the spike and the square wave. Various transcutaneous electrical nerve stimulation devices were introduced in the early 1970s, using both square waves and spikes, although most devices currently use some form of modified square wave. The largest known collection of material related to the use of electrical stimulation for various purposes is at the Bakken Library of Electricity and Light (5337 Zenith Avenue, South Minneapolis, MN 55416); Earl Bakken is one of the co-founders and is the chief executive of Medtronic, Inc.

In 1969, following Shealy's presentation of the results of his first eight cases of dorsal column stimulation, a national Dorsal Column Study Group was formed. Its purpose was to have a number of neurosurgeons do the procedure and monitor the results over a 5-year period. William H. Sweet, former Chairman of the Department of Neurosurgery at Massachusetts General Hospital, declined joining the Dorsal Column Study Group, and as a result, two companies began manufacturing dorsal column stimulators, Medtronic and Avery. During the next few years, the Dorsal Column Study Group inserted approximately 480 dorsal column stimulators. In the fall of 1972, Avery began advertising dorsal column stimulators as a therapeutic technique for use by all neurosurgeons, and Medtronic followed suit in the spring of 1973.

Unfortunately, in going from a research project to a clinical application, the design of the electrodes was changed from a solid platinum plate to a tinsel wire electrode. The solid platinum plate electrodes had proven remarkably sturdy and efficacious. Numerous problems developed with the tinsel wire electrodes, which seemed to polarize and develop increased impedance or break fairly easily. The thickness of the machine-made electrodes was also greater than that of the solid platinum plate, which led to increased technical difficulties. As a result, Shealy permanently stopped doing dorsal column stimulation in 1974 because he reasoned that the technology had not been adequately researched to make the procedure widely useful clinically. In his first paper on dorsal column stimulation, Shealy had emphasized the possibility of inserting dorsal column stimulators percutaneously, and it is worth noting that a variety of percutaneous dorsal column stimulators available today have less risk than the totally surgically implanted ones that require a laminectomy. Nevertheless, the long-term success rate is so poor that Shealy still considers dorsal column stimulation to be a technique that is rarely indicated and then only in extremely desperate situations.

The same year that Shealy presented his paper on the experimental results of dorsal column stimulation, Fordyce (1966) introduced the concept of behavioral modification or operant conditioning for management of pain.

In 1970, Shealy recognized that he was selecting only 6% of the patients sent to him for dorsal column stimulation and began investigating the possibility of alternative solutions to pain management in the vast majority of such patients. In 1971, he visited Fordyce's program. Fordyce had treated approximately 100 patients with his 2-month in-patient behavioral modification program, working with up to 25 patients at a time. In 1972, Shealy organized a national meeting on the management of pain, which some 400 individuals attended. As a result of that meeting, several physicians set up similar multidisciplinary comprehensive pain clinics, modeled after the Shealy system. Over the next few years, increasing numbers of physicians established various types of pain clinics.

In 1976, *Medical World News* presented a cover article entitled "Management of Pain, Medicine's New Growth Industry". The article suggested that there were approximately 50 pain clinics in the U.S., 20 of which *Medical World News* considered "holistic," with others based upon the Bonica model. After the cover article appeared, pain clinics indeed did become one of medicine's growth industries. By 1977, Bonica reported at the Walter Reed Pain Symposium that there were some 800 pain clinics in the U.S.

Shealy and Shealy's (1976) active behavioral modification program was transformed in 1974 to place greater emphasis on biofeedback, autogenic training, and

self-regulation techniques as a major modality for changing behavior. Although there have been some refinements in techniques and technology in the last two decades, there has been no further major innovation in the management of pain. Thus, as we move toward the next millennium, it is worth noting the quantum leaps in the management of pain made in the latter part of the 19th century through the introduction of transcutaneous and percutaneous electrical nerve stimulation, to some extent implanted electrical stimulators, and the use of biofeedback, autogenic training, and related techniques for behavioral modification.

The innovations in pain management sparked by the gate control theory have also led to a number of new organizations and pain-related publications. Perhaps one of the most interesting aspects of modern life is that at the end of the 20th century, the National Institutes of Health has recognized acupuncture as a useful modality in the management of pain!

Some major American-based organizations related to pain are:

- American Association for the Study of Headache
- International Association for Study of Pain
- American Pain Society (regional pain societies, e.g., Eastern, Midwestern)
- American Academy of Pain Medicine (originally American Academy of Algology)
- American Academy of Pain Management
- Some major publications related to pain are
  - Pain
  - Headache
  - Clinical Journal of Pain
  - Anesthesia & Analgesia — Current Research
  - Pain Practitioner
  - The American Journal of Pain Management

A summary of the history of development of pain treatment is provided in Table 2.1.

TABLE 2.1
The History of Pain Treatment

2600 + B.C.
Acupuncture
Massage
Exercise

ANNOTATED BIBLIOGRAPHY

Abbe, R. (1911). Resection of posterior roots of spinal nerves to relieve pain, pain reflex, athetosis, and spastic paralysis—Dana's operation. Medical Records (New York), 79, 377–381.

The first spinal rhizotomies were done by Abbe.

Anstie, F. E. (1873). Papers on electrotherapy. 1. On the relations of faradic electricity to pain. The Practitioner: A Journal, 2351–2360.

Francis E. Anstie published an article on the relations of faradic electricity to pain in London in 1873.

Behan, R. J. (1922). Pain: Its origin, conduction, perception, and diagnostic significance. New York: Appleton and Co.

This is a good early treatise.

Bonica, J. J. (1967). Management of intractable pain. In E. L. Way (Ed.), Concepts of pain (pp. 155–167). Philadelphia: Davis.

Bonica has emphasized the necessity for the use of a nerve block to determine if the surgical procedure would yield the desired results.

Bonica, J. J. (1976, January). Recent studies on the nature and management of acute pain. Hospital Practice, 6–7.

According to John Bonica, the use of narcotics as analgesics for nonsurgical pain and for surgical anesthesia goes "2,000, 3,000 or 4,000 years." Morphine was isolated 170 years ago.

Bonica, J. J. (1990). The management of pain (2nd ed., Vol. 1). Philadelphia: Lea & Febiger.

"There is only one pain that is easy to bear," said the French surgeon Rene Leriche, "and that is the pain of others."

Braunwald, E., Epstein, S. E., Glick, G., Wechsler, A. S., & Braunwald, W. S. (1967). Relief of angina pectoris by electrical stimulation of the carotid-sinus nerves. New England Journal of Medicine, 227, 1278–1283.

Perhaps the first use of implanted stimulators for relief of pain was that of carotid sinus nerve stimulation which relieved the pain of angina.

Brockbank, W. (1954). Ancient therapeutic arts. London: Heinemann.

The Ebers Papyrus, written about 1500 B.C., has one of the first written records of treatment for pain. For "suffering in the abdomen", they recommended an enema of oil and honey. It is interesting to note that at the Massachusetts General Hospital, when I was a resident, milk and molasses enemas were sometimes recommended.

Cupping seems to have been practiced in primitive cultures for thousands of years, and Hippocrates mentions it as being practiced in 400 B.C. The American Indians used a buffalo horn for cupping. Leeching is mentioned at least 200 years B.C. and was an important part of medical and lay healing technique for many centuries. In fact, it is still done in some Third World countries. Blistering also seems to have been used for many years, and written accounts of the use of blistering appear in the 2nd century.

Hippocrates is quoted as having said, "Those diseases which medicines do not cure, iron cures [meaning the knife]. Those which iron cannot cure, fire cures, and those which fire cannot cure to be reckoned wholly incurable."

Fordyce, W. E. (1976). Behavioral methods for chronic pain and illness. St. Louis: C.V. Mosby.

Fordyce created the concept of behavioral responses of operant conditioning as the major underlying causes for pain. The Fordyce concept is that pain is a learned or conditioned response to a given stimulus or "operant" condition. "Respondents can therefore be said to be controlled by antecedent stimuli. Operants, on the other hand, in contrast, are responsive to the influence of the consequences that systematically follow their occurrence. Operants can and do occur as a direct and automatic response to antecedent stimuli, as is true of respondents." In other words, punishment vs. reward benefits from particular behaviors determine whether or not they are learned and become part of the individual.

Fordyce, W. E. (1988, April). Pain and suffering: A reappraisal. American Psychologist, 276–283.

Fordyce emphasizes in particular the difference between pain and suffering.

Francois-Franck, C. A. (1899). Signification physiologique de la resection du sympathique dans la maladie de basedow, l'epilepsie, l'idiotie et le glaucome. Bulletin. Academie de Medecine (Paris), 46, 565–594.

Sympathectomy for relief of pain was introduced by Francois-Franck.

Garrison, F. H. (1929). History of medicine (4th ed.). Philadelphia: Saunders.

The pattern theory has been supported by Weddell and Sinclair. A neurologist, Spiller, noted a patient with a tuberculoma of the anterior lateral quadrant of the spinal cord who lacked pain sensation on the opposite side of the body. He encouraged Frazier, a neurosurgeon, to perform a cordotomy in 1899. It was Frazier who also began sectioning roots of the fifth nerve for trigeminal neuraligia in 1901.

Hammond, B. J. (1965). A history of electric therapy: Part one. World Medical Electronics, , 3–44,

In 1551, Jerome Cardan differentiated between the electricity of amber and the magnetism of lodestone and introduced the "fluid therapy of electricity," which is accepted as marking the transition from supernational to physical accounts of the phenomenon.

Horsley, V., Taylor, J., & Colman, W. S. (1891). Remarks on the various surgical procedures device and the relief or cure of trigeminal neuraltic ("tic douloureux"). British Medical Journal, 2, 1139–1143, 1891A; 2, 1191–1193, 1891B; 2, 1249–1252, 1891C.

Victory Horsley, the great British neurosurgeon, introduced the concept of gasserian neurectomy in 1891.

Jenkner, F. L., & Schuhfried, F. (1981). Transdermal and transcutaneous electric nerve stimulation for pain: The search for an optimal wave form. Applied Neurophysiology, 44(5–6), 330–337.

The question of the optimal waveform for electrical stimulation has never been adequately settled. Jenkner has emphasized what he considers to be an optimal waveform.

Kellaway, P. (1946). The part played by electric fish in the early history of bioelectricity and electrotherapy. Bulletin of Historic Medicine, 20, 112–137.

This is a marvelous article on the role of the electric fish and was the William Osler Medal Essay. The author comments that even in the early days in the U.S., electric fish were used and often kept in tanks on plantations to be used for pain control, and these were "much favored by the Indians and the Negros."

Letievant, J. J. E. (1873). Traite des sections nerveuses: Physiologie pathologique, indications, procedes operatoires. Paris: Balliere.

Apparently the first book on surgery pain was written by Letievant in 1873 and was primarily concerned with neurectomies for neuralgias of the face and extremities.

Lytle, L. D., Messing, R. B., Fisher, L., & Phebus, L. (1975). Effects of long-term corn consumption on brain serotonin and the response to electric shock. Science, 190, 692–694.

Hyperalgesia, which appears with tryptophan deficiency (serotonin deficiency), is well discussed in this article.

Mann, F. (1971). Acupuncture: The ancient Chinese art of healing. London: William Heinemann.

The oldest records of acupuncture date to bone etchings of 1600 B.C., and the first book on acupuncture was written about 200 B.C.

Medtronic Neuro Division. (1983). A newsletter published by Medtronic, Inc., Minneapolis, MN,

An extensive bibliography on transcutaneous electrical nerve stimulation was published by the Medtronic Neuro Division in March 1983.

Melzack, R., & Wall, P. D. (1965). Pain mechanisms: A new theory. Science, 150(3699), 971–979.

It was the advent of the gate control theory by Melzack and Wall which really revolutionized modern pain therapy. Their theory incorporates both physiological specialization as well as central summation and input control. Basically, they believe that at the level of the substantia gelatinosa in the spinal cord, input over the smallest fibers, C-fibers, is presymmetrically inhibited by information coming over the larger beta fibers. Beta fiber stimulation never creates a painful sensation, whereas unopposed C-fiber sensation is perceived as very agonizing pain.

Mitchell, S. W. (1872). Injuries of nerves and their consequences. Philadelphia: Lippincott.

"Perhaps few persons who are not physicians can realize the influence which long continued and unendurable pain may have upon both body and mind."

Mortimer, J. T. (1968). Pain suppression in man by dorsal column electroanalgesia. Unpublished Ph.D. dissertation. School of Engineering, Case Western University, Cleveland, OH.

The subject of pain has been likened by Mortimer to the fable of the blind men and an elephant. Each saw and interpreted the elephant only as that particular part of the elephant with which he had come in contact. Thus, pain has been viewed throughout much of history from a noncomprehensive point of view, each person and each discipline having a rather limited view of the whole.

Reynolds, D. V., & Sjoberg, A. E. (Eds.). (1971). Neuroelectric research: Electroneuroprosthesis, electroanesthesia and nonconvulsive electrotherapy. Springfield, IL: Charles C Thomas.

Kratzenstein, a German physicist, was probably the first modern scientist to report therapy with "electrification" in 1744. Interestingly, he reported that it increased his pulse and allowed a better quality of sleep. He used it to treat partial paralysis as well.

Of course, we all know the work of Benjamin Franklin, who was very cautious about interpretation. He stated, "I never saw any advantage from electricity in palsies that was permanent." In the late 1800s, there was a great deal of activity in electrotherapy. Rousell reported, "It is especially in the genital organs that electricity is truly marvelous. Impotence disappears, strength and desire of youth return, and the man, old before his time, whether by excesses or privations, with the aid of electrical fustigation, can become fifteen years younger." Machines as large as 8 feet in diameter were used to create an electrical static discharge. Out of this, of course, grew convulsive electroshock therapy. "Some treatments and instruments have been introduced as original as many as a dozen times since the early 1700's.

Schmidt, J. E. (1959). *Medical discoveries*. Springfield, IL: Charles C Thomas.

Surgeons gradually moved higher and higher in the nervous system, attempting to relieve pain with destructive procedures. Finally, in 1950 Mandel introduced the frontal lobotomy for the relief of intractable pain. It had been used, of course, over 10 years earlier for treatment of psychosis (p. 180).

Shealy, C. N., & Mauer, D. (1974). Transcutaneous nerve stimulation for control of pain: A preliminary technical note. *Surgical Neurology, 2*(1), 45–47.

These are the first two scientific articles on the use of what is known as TENS or transcutaneous electrical nerve stimulation.

Smith, R. H. (1963). *Electrical anesthesia*. Springfield, IL: Charles C Thomas.

"Safe anesthesia produced by application of electrical current has been a goal for over eighty years [in 1963]." Russian electrosleep therapy was described in 1914 by Robinovitch. "Anesthesia produced by the application of electrical current has been called electronarcosis." In 1902, Leduc published his early work with electronarcosis. He tried various frequencies of current, but mostly used 100 cycles per second of direct current square wave. Although he produced a rather cataplectic state in which patients were unable to move, they were still aware of pain. Glen Smith reported successful electronarcosis in dogs over 200 times, in rhesus monkeys 6 times, and in the chimpanzee once.

Solomon, R. A., Vierstein, M. C., & Long, D. M. (1980, February). Reduction of postoperative pain and narcotic use by transcutaneous electrical nerve stimulation. *Surgery*, 142–146.

This is another good article to quote.

Spiller, W. G., & Martin, E. (1912). Treatment of persistent pain of organic origin in the lower part of the body by division of the anterolateral column of the spinal cord. *Journal of the American Medical Association, 58*, 1489–1490.

According to Sweet and White (1955), in 1905 Spiller of Philadelphia discovered the problem with tuberculoma of pain, and Martin was the one to carry out the first successful cordotomy.

Tapio, D., & Hymes, A. C. (1987). *New frontiers in transcutaneous electrical stimulation*. Minnetonka, MN: LecTec Corporation.

Electric eels were known by ancient Egyptians and Hippocrates as potentially useful for producing an electrical shock to control pain, but it was apparently Scribonius Largus who first used the electric ray torpedic fish for treatment of both headache and gout and recorded it in 46 A.D. William Gilbert was reported to have been the first to classify and generalize the phenomenon of electricity (1544–1603). In 1756, Richard Lovett, "The Subtil Medium," proved dozens of cures for many diseases using electricity. John Wesley, founder of the Methodist church, was extremely enthusiastic about this treatment and also described many examples of diseases "cured" with electrotherapy, including sciatica, headache, gout, pleuritic pain, and angina pectoris. Between 1750 and 1780, 26 publications dealing with clinical electricity appeared. John Birch, an English surgeon, used electrical current to control pain in 1772. Beginning in the early 1900s, various electrical stimulators were sold to the public by door-to-door salesmen as well as in various catalogs. These instruments were very popular and came with all types of claims and cures, including curing cancer. The FDA banned the sale of such instruments in the early 1950s. In 1967, Shealy introduced the concept of dorsal column stimulation for control of pain, and that led to work with electromodulation.

Thorsteinsson, G., Stonnington, H. H., Stillwell, G. K., & Elveback, L. R. (1977). Transcutaneous electrical stimulation: A double-blind trial of its efficacy for pain. *Archives of Physical Medicine and Rehabilitation, 58*, 8–13.

A number of double-blind studies have emphasized that transcutaneous electrical nerve stimulation is not a placebo.

U.S. Department of Health, Education and Welfare. National Institutes of Health. *Pain*. (1968, September).

In 200 A.D., Galen advocated opium and mandragora as well as electrotherapy for control of pain. The first public demonstration of anesthesia on a patient was in 1846. The most important contribution to the management of pain was the development of the syringe and hypodermic needle (1845–1855). Cocaine was introduced into medical practice in 1884. Dr. William Halstead of Johns Hopkins discovered the principle of block anesthesia, which was the injection of cocaine into a nerve trunk. Spinal anesthesia was introduced in 1898. In 1967, the National Institutes of General Medicine Sciences offered the first center grant to the University of Pennsylvania and the second in 1968 to Harvard University to develop "anesthesia research and training centers where teams of scientists in many disciplines worked together in studying basic molecular research to anesthesia techniques in the operating room."

Implementing a Pain Management Program

Anne Marie Kelly, B.S.N., R.N.C.

> The purpose of human life is to serve, to show compassion, and to help others.
>
> Albert Schweitzer

INTRODUCTION

Relieving pain and suffering is at the heart of the healthcare profession. Despite attempts at treating pain over the decades, fear of unrelieved pain remains a major concern of patients in all healthcare settings. In 1992, the Agency for Healthcare Policy and Research (AHCPR) published guidelines on acute pain which state that the institutional responsibility for pain management begins with the affirmation that patients should have access to the best level of pain relief that may be provided safely. Regarding ethical responsibility, the guidelines stress that the ethical obligation to manage pain and relieve the patient's suffering is at the core of a healthcare professional's commitment (Acute Pain Management, 1992). Today, healthcare institutions are challenged with the responsibility and ethical obligation to develop the necessary means and resources to effectively treat pain in all patients. As the guidelines focus on improving the quality of pain relief, the need for programs that address this is becoming increasingly apparent. One of the best means to ensure optimum pain control is the availability of a pain management program that combines the expertise and commitment of a healthcare team whose members are dedicated to the prevention and treatment of pain. Formalized programs are necessary to bring pain control to its rightful place in the healthcare system. This chapter focuses on the key components and steps necessary for the successful implementation of an effective pain management program

TABLE 3.1
Key Components of a Successful Program

1. Institutional commitment
2. Interdisciplinary team
3. Education
4. Continuous quality improvement

IDENTIFY INSTITUTIONAL LEADERS

> Well begun is half done.
>
> Aristotle

The first step in identifying institutional leaders is the appointment of a task force to determine a plan of action. Seek out the "champions" in your institution who have a vested interest and knowledge in pain management. It is important to give those who feel a sense of commitment and ownership the opportunity to contribute to the development of the program. Peters (1987) suggests that those vested "look inward, work with colleagues and customers, work with everyone, to develop and instill a philosophy and vision that is enabling and empowering" (p. 482). Once the task force has been selected, conduct an institutional assessment to examine your organization's culture, strengths, and weaknesses related to current pain management practices. This group should address the following issues:

1. Is pain management an institutional priority?
2. Who has a knowledge base about pain management?
3. Do the policies and procedures ensure quality pain control?

0-8493-0926-3/02/$0.00+$1.50

4. Who is accountable for pain management?
5. How is quality measured?

Although pain is a common problem, it remains largely an invisible one. The task force can serve as a catalyst involved in promoting increased visibility of the problem of unrelieved pain. Its focus is to collect and provide necessary data to initiate efforts to address the existing problems. The results can provide strong evidence pointing to the need to standardize pain assessment policies, make changes in institutional procedures, and develop standards of acceptable practice. Making the problem of pain visible in your institution is the initial step in developing a formalized approach to pain management.

DEVELOP A MISSION STATEMENT FOR THE PROGRAM

It is imperative that the mission statement reflect the values and purpose of the organization related to pain management practices. By articulating its purpose and what it stands for, the institution directs the work of the staff. In describing the importance of a clearly articulated purpose, Ulschak (1988) states that, "until there is agreement about purpose, an institution has no direction, no tool to measure progress, no real reason to be motivated, and no clear focus for its energy." For institutional commitment to be achieved, it must start at the top. Administration must provide leadership that can result in institutional change, encourage employee commitment, and ensure improved standards of care. Leaders in the organization will need to help staff understand why change is necessary and how it relates to the mission. Staff members must clearly see that the institution's priority and goal is to promote high standards of safe, effective pain relief to all patients within its care. Institutional commitment and administrative support are the foundation on which to build a quality program and are absolutely essential to success.

DEFINE STANDARDS OF CARE

Defining standards is a key step in developing an effective program. Pain management is arguably one of the most complex topics in medicine today. From dealing with acute, chronic, and cancer pain, to providing palliative and compassionate end-of-life care, caregivers are faced with multiple issues that extend far beyond the question of what medication to administer. Written standards are necessary to define the expectations of the caregivers and show how the care delivery system is organized and managed. The mission of the institution sets the direction for all written standards. Standards make quality a day-to-day goal.

The Joint Commission on Accreditation of Healthcare Organizations (JCAHO, 1999) set new standards for the assessment and management of pain which healthcare institutions must be prepared to meet in 2001 (Dahl, 1999). These standards call upon hospitals, home care agencies, nursing homes, behavioral healthcare facilities, outpatient clinics, and healthcare plans to:

- Recognize the right of patients to receive appropriate assessment and management of pain.
- Assess the existence and, if so, the nature and intensity of pain in all patients.
- Record the results of the assessment in a way that facilitates regular reassessment and follow up.
- Determine and assure staff competency in pain assessment and management.
- Address pain assessment and management in the orientation of all new staff.
- Establish policies and procedures which support the appropriate prescription or ordering of effective pain medications.
- Ensure that pain does not interfere with participation in rehabilitation.
- Educate patients and their families about effective pain management.
- Collect data to monitor the appropriateness and effectiveness of pain management.
- Address patient needs for symptom management in the discharge planning process.

These standards serve as guidelines in developing policies and procedures for all healthcare facilities. Clearly defined standards will positively affect the quality of patient care. The JCAHO standards establish the foundation for a system-wide initiative in pain management.

DEVELOP AN INTERDISCIPLINARY APPROACH TO PAIN MANAGEMENT

Because pain is a multidimensional experience, it requires an interdisciplinary approach. Pain profoundly affects not only the physical, but the psychological, social, cultural, and spiritual dimensions of life (Ferrell, Dean, Grant, & Coluzzi, 1995; Saunders, 1984). Successful pain control requires attention to all aspects of care and suffering, and no amount of well-prescribed analgesia will relieve the pain unless the elements that are compounding the problem are addressed. Care provided by a team of specialized healthcare professionals is required to treat the diverse aspects of pain. For modern-day pain therapy to be effective, institutions need to direct their attention to the importance of interdisciplinary teams. An interdisciplinary team is a valuable resource that serves the organization in many ways:

- It serves the organization by assisting in the development of policies and procedures, offering consultation, and providing a forum for the resolution of difficult pain management issues.
- It serves the patients by attending to the multiple dimensions of optimum pain management and integrates all aspects of care.
- It serves the families by providing support and guidance as they confront the common challenges associated with caring for a loved one coping with pain.
- It serves the community by promoting educational programs for families and the general public that focus on pain assessment, pain treatments, drug addiction, and how to communicate with healthcare professionals about pain. A holistic approach is critical to breaking down the barriers to pain management and is successful because it allows physicians, nurses, and other clinicians to learn more about the "person" than just the disease (National Institutes, 1987).

A pain management team includes professionals from various disciplines who meet regularly to discuss and develop an individualized plan of care for each patient. A typical team may include one or more physicians, nurses, pharmacists, physical therapists, occupational therapists, pastoral care counselors, social workers, dieticians, and staff educators. Depending on the setting, you may want to include a certified nursing assistant, therapeutic activity therapist, and trained volunteer. A team can address the great need for accountability in pain management and prevent further fragmentation of care (see Table 3.2). This is the best approach for responding to pain and a critical component of an effective pain management program (Gordon, Dahl, & Stevenson, 1996, pp. 10–36).

TABLE 3.2
Role of Interdisciplinary Team

1. Identify patient, family, and staff needs in pain management
2. Assure pain relief goals are met
3. Collaborate with healthcare providers to facilitate optimum pain control
4. Promote practice changes through outcome quality improvement monitoring

DEFINE ACCOUNTABILITY

Each team member is accountable for carrying out a specific task and plays a key role in the management of pain. Team members:

- Assess the physical, psychosocial, spiritual, functional, emotional, and cultural needs of the patient.
- Use standard tools to assess the patient.
- Discuss summary of findings with attending physician and make appropriate recommendations.
- Review treatment plan and pain relief goal with the patient and family and encourage participation in decision making.
- Include both pharmacologic and non-pharmacologic therapies.
- Attend weekly, interdisciplinary team meetings to review plan of care and problem solve.
- Communicate plan of care to appropriate staff members.
- Assess for pain relief regularly throughout the course of treatment.
- Visit the patient at least once a week to assess progress.
- Educate patient and family about pain management.
- Measure outcomes to continually improve pain management practices.

Success of the team is measured by its ability to provide pain relief in a safe and effective manner to meet the needs and expectations of the patient and family. The following case example, in which the author was part of the interdisciplinary team, illustrates these points.

Case Example

Mr. F. was a 79-year-old man with terminal rectal cancer who resided in a long-term care facility. He was an alert, oriented, and religious man who understood his prognosis and elected to receive comfort measures only. His pain had been fairly well controlled and his medications had been titrated up to 400 mg of Oxycontin b.i.d., Actiq 400 mg q 3 h. p.r.n. for breakthrough pain, Celebrex 100 mg b.i.d., and Nortriptyline 25 mg @ h.s. Mr. F. was able to maintain his independence and did not exhibit any major side effects from the medications. During this time, he was also referred to the pain clinic for consultation regarding pain control measures. As the rectal tumor enlarged, his pain escalated and became more difficult to manage. He was once again seen by the anesthesiologist at the pain clinic who recommended the placement of a tunneled, epidural catheter for optimum pain control. Mr. F. consented to the procedure and his attending physician agreed this was the best course to follow. However, this created a challenge for the long-term care facility for the following reasons:

1. The facility had no written policies and procedures for epidural analgesia and the nurses felt ill-prepared having little or no knowledge in this area.

2. Mr. F. wanted to come back to the facility where he felt at "home" and wished to die in a loving environment with the staff he considered his "family."

3. The facility's mission statement clearly articulated that the institution's priority was the relief of pain.

Following a discussion with administration and the interdisciplinary team, all members agreed it was the institution's responsibility and ethical obligation to provide the necessary means and resources to care for Mr. F. during his final days. With administrative support, the members of the interdisciplinary team developed the necessary policies and procedures and provided education to the clinical staff in every aspect of care. With adequate education and support from the team, the nurses felt confident and prepared for Mr. F.'s return from the hospital. The nurses knew the moment they saw Mr. F. that they had made the right decision. Upon arrival, Mr. F. looking at the nurses with a big smile on his face stated, "It's a miracle. I have no pain." His pain was controlled with 1% Bupivicaine and Fentanyl 5 mcg/cc at 6 to 14cc/h and bolus doses of Fentanyl 5 cc q 10 min via a PCA pump. His pain ratings ranged from 0 to 2 and he remained comfortable until his death, four weeks later. Although saddened by his death, the staff tempered their grief knowing that they had made a difference in his life. Mr. F. died peacefully, with dignity, and in a loving environment surrounded by dedicated staff who understood that life is a gift to be cherished up until its final moments. His wishes had been fulfilled and the facility's goal had been met.

During those four weeks, the interdisciplinary team invested all its skill and effort into relieving his pain and suffering. The physician monitored his condition and ordered medications for pain control; the pharmacist made certain the medications were prepared and delivered in a timely manner; the nurses assessed him regularly for pain relief and potential side effects; the nursing assistants provided physical care with a compassionate touch; the physical and occupational therapists evaluated his ability to maintain optimum independence for as long as possible and made recommendations for his comfort; the social worker listened to his expressions of fear and other emotions and offered support; the pastoral care counselor addressed his spiritual needs by praying with him daily and being present; the dietician monitored his nutritional needs and paid special attention to his food preferences and his ability to swallow; the recreational therapist provided him with musical tapes he enjoyed and taught him relaxation techniques and guided imagery to distract him from any pain; the staff educator provided ongoing education and assessed the competency of the staff; the hospice nurse offered respite care and support to the patient, family, and staff. The interdisciplinary team, composed of dedicated professionals, was a vital force in diminishing his physical, psychosocial, and spiritual pain. When team members listen and acknowledge all aspects of pain, the patient experiences a feeling of worth, dignity, peace, and wholeness.

Although this was one of the most challenging cases for the long-term care facility, it was also the most gratifying. Everyone understood firsthand the meaning of institutional commitment and saw how a concerned and knowledgeable team is vital to successful pain management.

DEVELOP AN EDUCATION PLAN

> There is no knowledge that is not power.
>
> Ralph Waldo Emerson

Traditionally, medical and nursing schools have devoted very little, if any, time to the subject of pain management. Healthcare providers cannot be expected to practice what they do not know. Inadequacies in the education of health professionals has contributed to fears and misconceptions regarding the use of pain medications, addiction, and consequently inadequate pain management (Liebeskind & Melzack, 1998).

Education is the key step to improving pain management practices that result in institutional changes. Identifying the learning needs of your staff is vital to your educational efforts. This can be accomplished in a variety of ways:

- Administer a pretest to assess the knowledge level of your staff and to determine who has a knowledge base about pain management.
- Involve the interdisciplinary team members in conducting a survey in each of their practice areas to assess the learning needs of each discipline.
- Use the baseline data collected in your institutional assessment about current pain management practices. This is essential to planning education for the improvement of staff performance.
- Establish focus groups of about 6 to 10 people from different disciplines and ask their opinions about learning needs. Including "grass roots" input is useful for correcting inadequacies that exist.

Once you have identified the learning needs of the staff, it is important to outline an education plan including

curriculum content, staff time, and programming costs. For developing a comprehensive pain management program, consider including these core content areas:

- Physiology of pain
- Pain assessment
- Types of pain
- Assessment tools and pain rating scales
- Analgesics: non-opioids, opioids, adjuvant medications
- Symptom management
- Psychosocial, spiritual, and cultural issues
- Pain management in the elderly
- Barriers to effective pain management
- Ethical issues in pain management
- Non-pharmacologic interventions

PLAN EDUCATION STRATEGIES THAT INVOLVE ALL CAREGIVERS

> Organizations learn only through individuals who learn.
>
> Peter Senge

There are a variety of formal and informal teaching strategies that can be used to enhance the learner's understanding of pain management. Healthcare educators and providers need to employ creative ways of providing education to staff, patients, families, and the community that are timely, cost-effective, and informative. Each teaching strategy is advantageous for certain outcomes and has considerations that influence its choice. Some examples of informal teaching strategies include:

Pain Management Education Week — Designate a week in your facility that is set aside just for pain management education. This time is a great opportunity to teach everyone that pain management is an institutional priority. Invite each interdisciplinary team member to set up an exhibit displaying learning materials and equipment that can help participants to understand their role in relieving pain. Team members can be available at alternating times for demonstration, skill practice, and answering questions. Communicate this event to everyone through fliers and newspaper articles. This is an excellent way for disseminating information to staff, patients, families, other healthcare providers, and the public. It stimulates interest in a dynamic way and facilitates education about the different pain control measures used in the facility. This strategy serves as a great marketing tool by conveying a strong message about the organization's commitment to quality pain management practices.

Pain Management Poster Presentations — This is a unique and enjoyable way to involve all departments and demonstrate that pain management requires an interdisciplinary approach. Encourage creativity by inviting employees from all departments to design a poster of their choice related to pain management. Employees can work individually or as a group, and are given a deadline to complete the project. Display the posters throughout the facility. This provides valuable information to insiders and outsiders. Select different categories and ask some of your volunteers or family members to choose the winning posters. Offer prizes that can be donated by your consultants and vendors. Invite the winners to give poster presentations and offer participants continuing education credits. Ask your public relations department to take pictures of the activities and send an article to the local newspapers. This teaching method generates enthusiasm, teamwork, and publicity and clearly articulates to everyone that successful pain management is the result of interdisciplinary involvement.

Portable Educational Cart — A mobile cart displaying fact sheets and equipment is another useful way to educate staff. Keep carts in an area for a specified amount of time allowing staff members to use them when time permits. Quizzes or self-learning packets on the content can be given by the staff educator if validation is required. This is an easy way to impart information that does not require an explanation or discussion. Depending on where the cart is located, it is also a good format for providing physicians, patients, and families with updated information about pain management. This activity clearly identifies that learning about pain control is everyone's responsibility.

Pain Management Bulletin Board — Employ the use of an education bulletin board strategically placed in the facility where it is visible to everyone. The board can be used to post brochures about upcoming workshops, seminars, and programs on pain management. The facility's education calendar can be posted, indicating the times and dates of all pain management inservices. Include a spot on the bulletin board to place self-learning packets, updated articles and handouts, information on new policies and procedures, and fliers on special events related to

pain management activities. This is a unique way to demonstrate to your customers" that pain management education is considered important in the facility.

These strategies facilitate education that is system-wide and promote public awareness about the institution's efforts to provide optimum pain management. They speak loudly about the value of education to those who enter your doors.

Formal methods of education can include lectures, case studies, videotapes, audiotapes, teleconferences, CD-ROMs, grand rounds, skills labs, closed circuit TV, panel discussions, seminars, and workshops. To keep educational costs at a minimum, ask members of your medical, nursing, and other professional staff who are knowledgeable about pain management to provide inservices to the staff. Videotaping the inservices is a cost-effective means of providing education to staff members who are unable to attend the presentations. Education of all healthcare providers involved in the care of the patient is crucial if you are to have an effective pain management program. Institutions need to promote education to students involved in clinical care and continuing education for practicing professionals to keep up with changing trends and maintain their skills and competency. Knowledge about pain management empowers physicians, nurses, and other clinicians to assume the most basic mission of their practice— the relief of pain and suffering.

TABLE 3.3
Why Teamwork in Quality Improvement?

1. Instills ownership of the process
2. Involves the people who know best
3. Creates respect, cooperation, and openness
4. Breaks down barriers between departments
5. Spreads quality
6. "None of us is as smart as all of us"
   More ideas
   Better ideas

TABLE 3.4
JCAHO Ten-Step Quality Monitoring Process

1. Assign responsibility
2. Delineate scope of service
3. Identify important aspects of service
4. Identify indicators related to the important aspects of service
5. Establish thresholds for evaluation
6. Collect and organize data
7. Evaluate service when indicated by the threshold
8. Take action when opportunities for improvement or problems are identified
9. Assess the effectiveness of actions
10. Communicate relevant information to the organization-wide program for continuous quality improvement

From Joint Commission on Accreditation of Healthcare Organizations, 1991. An Introduction to Joint Commission Nursing Care Standards, Oakbrook Terrace, IL: JCAHO. With permission.

DEVELOP A QUALITY IMPROVEMENT MONITORING PROCESS

JCAHO (1994) defines quality of care as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge." Continuous quality improvement is the key component that will help to demonstrate the pain program's benefit to the institution's mission. CQI is a process that ensures optimum pain control by building excellence into every aspect of care and creating an environment that encourages all disciplines to contribute to its success (see Table 3.3). Monitoring pain management outcomes is an ongoing responsibility shared by members of the interdisciplinary team. Every organization must choose which processes and outcomes are important to monitor based on its mission and the scope of care and services provided. JCAHO (1991) has designed a 10-step quality monitoring and evaluation process for healthcare agencies (see Table 3.4). In that 10-step process, the first five steps establish the mechanism to be used for monitoring and evaluation, the sixth and seventh steps encompass collection and evaluation of relevant data, and the last three steps reflect attempts to improve the provision of services rendered.

Performance monitoring and improvement are data driven. Institutions need to develop a formal plan for evaluating the quality of pain management and collect data about the needs, expectations, and satisfaction of individuals served. There are a number of ways to obtain input from these groups, including:

- Periodic satisfaction surveys of patients and families including questions about pain intensity, pain relief goals, and staff responsiveness.
- Chart audits to assess documentation of pain assessments, patient response to treatment, and teaching outcomes.
- Chart audits to monitor analgesic drug use and treatment side effects.
- Focus groups to elicit feedback regarding pain management practices.
- Regularly scheduled meetings with family members.

The detail and frequency of data collection is determined as appropriate for monitoring ongoing performance

by the organization. Whenever possible, data collection should be incorporated into day-to-day activities. High quality pain management is not a static destination to be reached, but a dynamic entity toward which we must continually strive. We must act on the basic belief…the patient is the reason we exist.

CONCLUSION

> The reward of a thing well done is to have done it.
>
> Ralph Waldo Emerson

As we look to the future, we must use our time, skills, and energy to make a defining difference in pain management. It is time for pain management programs to be incorporated into all parts of the health- care delivery system, and for physicians, nurses, and other healthcare providers to make pain control part of their routine practice. As professionals involved in a healing ministry, we must proactively promote optimum pain management by interdisciplinary teams that can enhance the quality of life and diminish pain and suffering in patients and families. As patient advocates, we must implement quality programs that increase our capabilities to serve, show compassion, and help others.

The Classification of Pain

Ole Thienhaus, M.D., M.B.A., F.A.P.A. and B. Eliot Cole, M.D., M.P.A., F.A.P.A.

INTRODUCTION

The International Association for the Study of Pain (IASP) defined pain as "an unpleasant sensory and emotional experience associated with actual and potential tissue damage, or described in terms of such damage or both" (IASP, 1986). The definition emphasized the subjective and psychological nature of pain, and appropriately avoided making the authenticity of pain contingent on an externally verifiable stimulus. Pain was understood to motivate those afflicted to seek relief from it.

Price (1999) proposed an updated definition that described pain as a somatic perception containing a bodily sensation with qualities like those reported during tissue-damaging stimulation, an experienced threat associated with this sensation, and a feeling of unpleasantness or other negative emotion based on this experienced threat. By modifying the definition, there was no requirement to objectively demonstrate actual or potential tissue damage, nor was there a requirement that an association be made between sensation and tissue damage. This revised pain definition was very helpful because making a linkage between sensation and tissue damage was frequently impossible to demonstrate.

In setting the stage for the 2001 implementation of pain-related standards of care, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) also linked pain to both physical and emotional responses (JCAHO, 2000). As justification for these pain-related accreditation standards, the JCAHO linked unrelieved pain to negative physiological and psychological effects, and generalized these adverse trends from the traditional acutely hospitalized patient to the majority of patients in most healthcare settings (hospitals, long-term care, surgical centers, mental health facilities, home health services, and health system networks).

Why do we bother to classify pain? Classifying pain is necessary for research and clinical purposes. Relating a clinical database to a categorical reference system facilitates the tasks of clinical assessment, treatment planning, and formulation of an accurate prognosis. Conventionally, pain is classified according to location, underlying cause, frequency, intensity, and duration. The clinical data, thus categorized, serve as an input variable for determining the correct diagnosis and developing the optimal treatment plan. Investigators in the field of pain management work to expand the classification of pain, and to specifically tailor treatment options for each diagnostic possibility. Clinicians and researchers must attempt to know the cause of each pain problem to understand how it is to be treated. Classification improves the flow of communication between patient and clinician, ensuring that the clinician obtains a complete picture of the complaint and makes it possible for both patient and provider to speak the same language when they try to define the nature of the problem, response to treatment, and the development of secondary problems such as side effects of treatment or newly developing symptoms.

There continues to be a need for the expanded classification of pain as long as patients suffer from pains that we do not understand and that are inadequately treated. According to Wall (1989), pain classified by our ignorance about underlying mechanisms and therapy falls into three groups: (1) pains where the cause is apparent but the treatment is inadequate (deep tissue disorders, peripheral nerve disorders, root and cord disorders); (2) pains where the cause is not known but the treatment is adequate (trigeminal neuralgia, tension headaches); and (3) pains

0-8493-0926-3/02/$0.00+$1.50

where the cause is not known and the treatment is inadequate (back pain, idiopathic pelvic and abdominal pain, migraine headache).

The classification of pain is a source of confusion for many clinicians, and as a result of this confusion pain practitioners now commonly use a number of different classification systems. Clear distinctions between pain classification systems are not always possible, but the more simplistic the classification of pain, the more omissions and overlaps occur (Pasero, Paice & McCaffery, 1999). Pain is classified according to the time course, the involved anatomy, the intensity, the type of patient, and the circumstances of the pathology. To be a successful pain practitioner one must be able to work with pain classifications encompassing all of these areas, and be capable of switching from one model to another. While the distinctions between one system and another may seem arbitrary, without some framework to categorize pain complaints, the unsophisticated clinician easily becomes lost in the pain behavior of the patient and the demand for quick solutions. Treatment options are linked to the type of pain involved, and accurate pain classification is essential for successful pain management. The pain conditions that the clinician cannot recognize and accurately diagnose cannot be satisfactorily treated.

At a more practical and human level, patients want to know if their pain will ever completely go away. Patients are frightened that their pain is attributable to unrecognized pathology and so search for the ultimate cure. Going from practitioner to practitioner serves to worsen their confusion, and patients hope that someone will be able to illuminate their difficulties. By being able to classify the pain into a recognizable and explainable syndrome, the pain practitioner, unlike the other clinicians, is able to offer some hope. Although treatment often does not yield a completely pain-free state for these patients, understanding the basis for their pain and knowing that awful diseases do not exist often provides significant relief from their suffering.

Case Example

Ms. W. was a 45-year-old woman who had seen a number of practitioners during the previous three years since her car accident. Physical therapy, massage therapy, acupuncture, and psychotherapy in isolation after thorough evaluation by neurologists, neurosurgeons, and orthopedic surgeons failed to produce lasting comfort. When she was referred to the pain clinic she was tense, angry, and argumentative. She was informed that she would never be completely pain free as a result of her well-established myofascial pain, but could eventually resume her life if she entered a pain management program. She was surprised to learn that her pain condition had a name, was recognized by the physician as a non-cancer pain process, and could respond to interdisciplinary treatment. Previous clinicians had recommended that she learn to live with the pain, but did not tell her how to do this. Although no specific treatment occurred during the evaluation in a conventional sense, she was relaxed and more comfortable when she left the office.

It is not always certain that pain can be conveniently classified into some system. Some patients will present with more than one pain problem over time, and can have the pains classified simultaneously into different categories. The chronic pain patient may experience acute painful episodes unrelated to the original pain condition, the chronic non-cancer pain patient may develop cancer-related pain after years of marginal pain management, and the acute pain patient may experience a number of different aches and pains from the original pathophysiologic process, or as a consequence of the therapies to correct it.

CLASSIFICATION BY LOCATION

Pain may be classified by body location. Two overlapping schema relate the pain to the specific anatomy and/or body system thought to be involved. The anatomical classification addresses sites of pain as viewed from a regional perspective. Typical examples include lower back pain, headache, and pelvic pain. The body system pain classification focuses on classical body systems such as musculoskeletal, neurological, and vascular. Both systems of classification address only a single dimension, where or why does the patient hurt, and may ultimately fail to adequately define the underlying neurophysiology of the pain problem (Turk & Okifuji, 2001).

CLASSIFICATION BY TIME COURSE

The duration of the pain process, the temporal perspective, is the most obvious distinction that is made when classifying most pain complaints. This temporal distinction is an important consideration for understanding the neurophysiology of pain (Crue, 1983). Acute pain is limited to pain of less than 30 days, while chronic pain persists for more than six months. Subacute pain describes the interval from the end of the first month to the beginning of the seventh month for continued pain. Recurrent acute pain defines a pain pattern that persists over an extended period of time, but recurs as isolated pain episodes. Chronic pain is further divided by the underlying etiology, into non-cancer (often called "benign" pain) and cancer (often called "malignant" pain) related (Crue, 1983; Foley, 1985; Portenoy, 1988).

The primary distinction between acute and chronic pain regardless of the etiology is crucial. Acute pain is useful and serves a protective purpose. It warns of danger, limits utilization of injured or diseased body parts, and signals the departure of pathology when the limiting condition resolves. Without acute pain it is doubtful that most

of us would be able to survive at all (Cousins, 1989). We would literally suffer needless burns, cuts, and other injuries. Not being able to experience pain is literally incompatible with life. Chronic pain has little protective significance, persists despite normalization after injury or disease, and ultimately interferes with productive activity. Patients with chronic pain live their lives as if they are having full-time nightmares, where pain relief is constantly sought yet rarely obtained without professional help, and the pain controls their activities of daily living. Chronic non-cancer pain occurs with or without adequate patient coping. The patients who cope with the chronic pain manage to live productive lives, while the patients who are not able to cope with their pain are disabled by chronic suffering (Crue, 1983).

Acute Pain

Acute pain is almost always self-limited. When the condition that produces the pain resolves, or when the nociceptive input is blocked by a local anesthetic or altered by the use of peripheral or central analgesic medications, the pain leaves. The skin heals, the fractures mend, the inflammation subsides, and the nociceptive input stops, so the pain intensity fades away and disappears (Crue, 1983). The use of comfort measures such as applications of heat or cold, splinting, casting, or brief, time-limited analgesic medication all help to relieve this discomfort. Sentiments of concern and expected recovery from friends and family help to aid in the relief of pain for the acute pain sufferer.

> Case Example
> Mr. B. was a 22-year-old downhill skier who sustained a shoulder dislocation in a fall. His shoulder was relocated in the field and he was placed in a shoulder immobilizer for one week. He was assured that his injury was not significant by his physician and would not interfere with his participation in an important race later in the season. After limited physical therapy to restore his range of motion and strength, he was able to resume competitive racing with no detectable difficulties.

The pain after surgery, postoperative pain, is a specific type of acute pain. No matter how successful or how deftly conducted, operations produce tissue trauma and cause the release of potent mediators of inflammation and pain. Pain is often poorly managed because patients receive significantly less opioid analgesics than are ordered, the nursing staff are overly concerned about opioid addiction, analgesics are irration-ally selected, and many physicians have inadequate knowledge of the pharmacology of analgesics (Waldman, 1990). Although postoperative pain is experienced by millions of patients throughout the world, it is rarely recognized as producing harmful physiological or psychological effects (Cousins, 1989). The axiom, "No one ever died from pain, they just wish they could," is clearly incorrect with the modern recognition that unrelieved pain increases cardiac work, increases metabolic rate, interferes with blood clotting, leads to water retention, lowers oxygen levels, impairs wound healing, alters immune function, interferes with sleep, and creates negative emotions (Akca, et al., 1999; Dinarello, 1984; Egdahl, 1959; Kehlet, 1982; Kehlet, Brandt, & Rem, 1980; Liebeskind, 1991; Melzack, 1990). Unrelieved pain may delay the return of normal gastric and bowel function in the postoperative patient (Wattwil, 1989). Recognition of the widespread inadequacy of pain management prompted the U.S. Department of Health and Human Services to publish the Acute Pain Management Clinical Practice Guidelines as the first set of federal practice recommendations (AHCPR, 1992).

Chronic Pain

Chronic pain confuses most sufferers because it dominates, depresses, and debilitates. If chronic pain is treated by using acute pain models only, it may become more intense and the patients may experience increased disability and suffering. Instead of comfort measures alone, chronic pain is managed by the use of rehabilitative techniques when it is primarily of a non-cancer origin, or by aggressive and supportive techniques when it is primarily due to cancer.

"Tincture of time", coupled with injury- or illness-specific therapy, may be appropriate for many acute pain conditions because most painful conditions are time limited. Acute pain is reasonably managed and usually resolves with the efforts of a single practitioner; however, chronic pain frequently requires the coordinated efforts of a broadly based treatment team bringing a number of physical, psychological, and spiritual strategies together. Chronic pain patients demand more effort and resources than a single, well-meaning practitioner can usually provide. In isolation, the solo practitioner is generally unable to address the variety of complex physical, psychosocial, and spiritual problems that chronic pain causes, and so resorts to symptom management usually by overusing a single therapeutic approach.

> Case Example
> Ms. D. was a 28-year-old woman referred for the management of chronic, mechanical low back pain secondary to an industrial lifting injury. Her referring neurosurgeon, who had been treating her unsuccessfully for three years, became motivated to refer her to a pain management program when his partners began to complain about her drug seeking behavior whenever they were on call for him. A full review of her medical record revealed that she had received 3900 oxycodone and acetaminophen tablets in the six months prior to referral. At the time of referral she was taking 12 to 15 of the oxycodone and acetaminophen combination tablets,

60 milligrams of diazepam, and an uncertain number of butalbital, aspirin, and caffeine-containing tablets every day to obtain marginal pain relief. She was admitted to an outpatient chronic pain management program, and over six weeks was successfully detoxified from all of her medications, while simultaneously learning many new strategies to help her deal with her chronic pain. She eventually returned to the work force in a less physically demanding position after completing the chronic pain management program.

A specialized taxonomy was introduced to facilitate the classification of chronic pain syndromes. This taxonomy turned out to be of particular utility in the area of pain research (IASP, 1986). The multiaxial approach taken in this system was hoped to be of practical use for clinicians. Using multiaxial categorization by topography, organ system, and underlying pathophysiology helped to relate the presenting complaint to the domains of traditional medical practice, and served to facilitate consultative communication with patients' primary physicians. Descriptive axes such as axis III (pattern of occurrence) and axis IV (intensity) recognized the patient's experiential and subjective inputs. These latter two dimensions were subdivided into 10 detailed gradations by severity, reflected in numerical codes. In clinical investigations (see below), this permitted the application of parametric statistical analysis to database collections.

While acute pain usually only briefly disables patients during their initial recovery time, chronic pain often prevents patients from ever returning to any meaningful and gainful employment. Some chronic pain patients are not able to return to their former, high-paying work due to pain-related limitations, and others are unable to return to work due to the unwillingness of their employers to make reasonable accommodations because they fear losing profits (Chapman & Brena, 1989). These chronic pain patients are caught in the ridiculous position of having to maintain their disability, rather than risk returning to an entry-level position with inadequate financial compensation for their needs. Legal entanglements further cloud chronic non-cancer pain problems and contribute to the inability to resolve the suffering. The desire for the best legal settlement, often the only reward for pain problems, often prevents chronic pain patients from making full recoveries.

It is sadly said that pain problems are chronic in nature when the referral letter from one practitioner to another begins with an apology for making the referral! Chronic pain patients are so often viewed as angry, hostile, depressed, and manipulative, that they evoke feelings of anxiety, resentment, and desperation in their treating clinicians. Pain patients requesting that the results of their initial evaluations must be sent to their attorneys should alert pain practitioners to potential involvement in impending litigation. As some lawyers actually send patients for pain management assessments to strengthen their positions for claims of pain and suffering after accidents or injuries, it is necessary to understand whose interests are being served by the evaluations. Patients and lawyers stand to gain more financially from any legal action if patients do not recover from their injuries and illnesses (Chapman & Brena, 1989).

Subacute Pain and Recurrent Acute Pain

Subacute pain is possibly the last opportunity for a full restoration and a pain-free existence, much as acute pain must be recognized before the pain becomes chronic. Subacute pain is quite similar to acute pain in its etiological and nociceptive mechanisms (Crue, 1983). Unfortunately, once the pain has been established for more than six months, the likelihood of complete pain relief is small. The first 100 days of pain appear to respond fully to therapy and return the patients to near normality. Beyond the first 100 days, most patients still may recover the majority of lost function, but do not feel fully restored or comfortable. By the time pain becomes subacute, the rehabilitative approach used for chronic pain is usually more appropriate than further acute pain management strategies.

Recurrent acute pain is the acute flare-up of peripheral tissue pathology due to an underlying chronic pathological entity and occurs with headaches, gastrointestinal motility disorders, degenerative disk and joint disease, collagen vascular disease, sickle cell disease, and similar functional processes (Crue, 1983). Unlike chronic or subacute pain, recurrent acute pain implies discrete acute episodes, which return over time. The dividing line between recurrent acute and subacute pain is often a judgment decision by the pain practitioner. Daily pain for several weeks is subacute pain, but several limited pain episodes over many months or years is typical of recurrent acute pain. The importance of recognizing recurrent acute pain is to apply a more comprehensive management approach of patient education, contingency planning, and family involvement than a single pain episode would ordinarily require.

CLASSIFICATION BY UNDERLYING PATHOLOGY

Regardless of time course of the pain, its intensity, frequency, and location, every attempt must be made to arrive at an etiologic formulation. Ideally, treating the underlying cause will bring about the definitive cure of the pain syndrome. At a minimum, etiologic clarification will tell the clinician whether causative or symptomatic treatment is possible or, commonly, whether a combination of both is necessary. Within the classificatory axis of causative factors, the differentiation between cancer pain and pain due to non-cancer causes assumes particular pertinence whenever the evaluator is confronted with pain of more than 6-months duration (chronic pain, see above).

Non-Cancer

Chronic non-cancer pain, the grist for most pain clinics, involves a number of different pathophysiologic problems that render the sufferer unable to enjoy life, but do not threaten to end life. This type of pain is often described in relationship to an anatomical site and engenders considerable anxiety. Myofascial pain, pain arising from muscle and connective tissue, accounts for a considerable amount of chronic non-cancer pain, and requires specific active therapy (stretching, trigger-point injections) and corrective actions for pain relief (Simons, Travell, & Simons, 1999; Travell & Simons, 1983).

Cancer

Chronic cancer pain is generally managed for the patient, while non-cancer pain is better managed by the patient through education, empowerment, and rehabilitation. Cancer-related pain management, like acute pain management, focuses on the comfort of the patient and involves a strategy of palliation. Palliative care involves the liberal use of medication, often opioid analgesics, with maximum comfort through symptom relief, but with toxicity from therapy kept acceptable relative to the distress produced by the symptoms being addressed.

Cancer pain is divided by the presumed pathophysiology into somatic, visceral, and deafferentation (also called neuropathic). This classification system focuses on the site of nociception (potential tissue damaging situations), being peripheral for somatic pain, intra-abdominal for visceral pain, and involving injury to afferent neural pathways for deafferentation. The pain that results from somatic processes is well localized, constant, aching, or gnawing in character. The visceral pain is poorly localized by comparison, but is constant and aching in character. It is referred to cutaneous sites. Deafferentation (neuropathic) pain is characterized by tingling, sharp paroxysmal sensations or burning dysesthesia, and is traditionally managed with adjuvant medications including antidepressants and anticonvulsants, not opioid analgesics as are visceral and somatic pains (Foley, 1985).

Bruera, Walker, and Lawlor (1999) challenged the traditional view of neuropathic pain management when they reported that more than two thirds of patients with neuropathic cancer pain achieved good analgesia with opioids alone in a prospective open study. Because the effectiveness of adjuvant medications rarely exceeded 30%, Bruera, Walker, and Lawlor recommended that opioids remain the first line of treatment for neuropathic pain patients, with adjuvants added when patients reach opioid dose-limiting toxicity.

Temporally, chronic cancer pain may worsen over time, due to the disease progression and from the various interventions (chemotherapy, radiotherapy, and surgery) used to treat the disease. The need for increasing doses of opioid analgesics is more often related to these situations, not to the rapid development of tolerance or medication abuse, as many practitioners mistakenly believe. Chronic non-cancer pain may also worsen over time, resulting in significant behavioral changes (pain behavior) and excessive use of analgesic medication.

It was recommended by Foley (1979, 1985) to classify cancer patients with pain into five groups: (1) patients with acute cancer-related pain, (2) patients with chronic cancer-related pain due to either progression or therapy, (3) patients with preexisting chronic non-cancer pain and cancer-related pain, (4) patients with a chemical dependency history and cancer-related pain, and (5) actively dying patients who must be provided comfort measures (Portenoy, 1988). This system of classifying pain according to the type of patient allowed for a rich psychosocial approach and prospective planning for the comprehensive needs of the patient, rather than too narrowly focusing on a single dimension of the pain. It also explained some of the unusual situations that developed while treating cancer pain patients, such as the following.

Case Example

Mr. P. was a 50-year-old gentleman with invasive head and neck squamous cell cancer. He had previously declined surgery but had had radiation therapy 1 year before entering the hospice program with an ulcerated, foul-smelling neck mass. His pain was initially managed by his referring physician with acetaminophen and codeine elixir, 600 mg/60 mg every 4 h, and oral lidocaine 2% viscous solution every four 4 h as needed. While not appreciated at first, it became readily obvious that he had a long-standing alcohol abuse disorder. He regularly supplemented his gastric tube feedings with liberal quantities of vodka, beer, and coffee liquor. He alleged that he only used small amounts of these beverages to cleanse the feeding tube, but was found to be intoxicated on many occasions. When his pain became more difficult to control with codeine, after 3 months of hospice involvement, he was given morphine concentrate (20 mg/ml) via the gastric tube. He quickly began to abuse the morphine, and occasionally took as much as 100 to 200 mg at a time, when only 20 to 30 mg had been prescribed. He ultimately stopped abusing the alcoholic beverages, but enjoyed the large doses of morphine at night when he wanted to sleep.

Few cancer pain patients exist in isolation, and most of these patients are cared for to some degree by concerned family members and friends. The support of the primary caregiver, with an emphasis on anticipatory bereavement, is an important element of hospice management. During the impending death of the cancer patient, the family members frequently become uncertain about their ability to provide continued care. To be able to keep the dying patient comfortable, unpleasant symptoms (nausea, vomiting,

seizures, terminal restlessness) are aggressively controlled, and the caregiver is routinely provided support and respite breaks (Cole & Douglass, 1990).

CLASSIFICATION BY PAIN INTENSITY

Non-cancer-related pain is often rated along a continuum from mild to moderate to severe, but the words incapacitating, overwhelming and soul stealing become necessary qualifiers for cancer pain. The intensity of the pain is perhaps the least desirable system for classifying pain as intensity varies for most pain patients over time and is uniquely subjective. One pain patient might describe the pain experience due to some pathological condition as a 10, while another with the same pathology might feel that the intensity of pain is only a 5 (using a 0 to 10 scale where 0 signifies no pain at all and 10 represents the worse pain one could ever imagine). This has been noted under experimental conditions when identically calibrated pain stimuli, such as small electrical impulses, are administered to subjects and they rate them at widely divergent intensity levels. No clear correlation with any particular descriptor variables of the subjects could be established. Furthermore, factors lowering the cancer patient's pain threshold (the point at which a given stimulus provokes the report of pain) involve discomfort, insomnia, fatigue, anxiety, fear, anger, and depression; while restful sleep, relaxation, sympathy and understanding, elevation of mood, and diversion from the pain serve to raise the pain threshold (Twycross, 1980).

Rather than focus on a specific amount of pain, it is more useful to look at the disruption that pain causes for patients. Pain interfering with appetite, pleasurable activities, or sleep is more distressing than pain otherwise leaving an intact life, regardless of the reported intensity. Over time, most patients adapt to the pain and demonstrate either very little or markedly exaggerated pain behavior. Some patients may suffer with modest levels of pain, while others are able to function despite high levels. Suffering, an emotional response to the pain experience, is not necessarily linked to only the intensity of the pain as much as it is to the co-existence of anxiety, depression, and the failure to integrate the pain into the overall life experience. Suffering becomes an important issue when pain patients have concerns about the purpose, value, or meaning of their lives and an inability to foresee a future with function.

There is no way to know how much another person is in pain, and it is best to assume that the pain exists whenever a patient says it does and is whatever the patient says it is (McCaffery, 1999). Pain behavior is influenced and shaped by the environment, so the emphasis on function over intensity is critical for the rehabilitative approach to control chronic non-cancer pain. Family members and significant others, by altering their response to the pain behavior, are potentially involved with helping the patient to manage the chronic pain.

MENTAL HEALTH ISSUES IN PAIN CLASSIFICATION

Co-existing psychiatric disorders are not rare when pain is severe (Guggenheim, 2000). Mental health consultants are frequently asked to evaluate patients for suspected "psychogenic pain." This type of pain is included in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, where it is classified as a Pain Disorder (Table 4.1). Pain disorder is characterized by pain in one or more anatomical sites that is the predominant focus of the patient's clinical presentation and is of sufficient severity to warrant clinical attention; the pain causes clinically significant distress or impairment in social, occupational, or other important areas of functioning; psychological factors are judged to have an important role in the onset, severity, exacerbation, or maintenance of the pain; the symptom or deficit is not intentionally produced or feigned; and the pain is not better accounted for by a mood, anxiety, or psychotic disorder and does not meet criteria for dyspareunia (American Psychiatric Association, 1994). This condition further requires coding for the subtypes of pain disorder associated with psychological factors (acute or chronic), pain disorder associated with both psychological factors and a general medical condition (acute or chronic), and pain disorder associated with a general medical condition (acute or chronic).

There is little doubt that a relationship between pain and other mental disorders exists, but the exact nature of the relationship is less than clear (King, 1999). It must be emphasized that all pain is real to the patient, and little is to be accomplished by challenging the validity of the pain. Because pain is experienced in the mind and requires the interpretation of bodily sensations, there is a psychological overlay with most pain problems. It is artificial and absurd to try to partition pain into real or psychological types, especially when the distinction is too often based upon the treating practitioner's lack of ability to identify objective pathology. To fully understand the relationship between nociception and the psychological effects of acute and chronic pain, the practitioner must recognize emotional distress rather than purely nociception as a cause of pain, and understand that psychological mechanisms do intensify pain perception (Abram, 1985). An emotional reaction to pain does not mean that pain is caused only by an emotional problem (McCaffery & Pasero, 1999).

Psychosomatic pain is unfortunately synonymous with imagined pain, yet this pain may be as severe and distressing as somatogenic pain (Abram, 1985). While the threshold, the point where pain is first noted, is fairly

TABLE 4.1
Pain Disorder Diagnostic Features

A. Pain in one or more anatomical sites is the predominant focus of the clinical presentation and is of sufficient severity to warrant clinical attention.
B. The pain causes significant distress or impairment in social, occupational, or other important areas of functioning.
C. Psychological factors are judged to play a significant role in the onset, severity, exacerbation, or maintenance of the pain.
D. The pain is not intentionally produced or feigned as in Factitious Disorder or Malingering.
E. Pain Disorder is not diagnosed if the pain is better accounted for by a Mood, Anxiety, or Psychotic Disorder, or if the pain presentation meets criteria for Dyspareunia.

Pain Disorder is coded according to the subtype that best characterizes the factors involved in the etiology and maintenance of the pain:

307.80 Pain Disorder Associated with Psychological Factors: This subtype is used when psychological factors are judged to have the major role in the onset, severity, exacerbation, or maintenance of the pain. In this subtype, general medical conditions play either no role or a minimal role in the onset or maintenance of the pain. This subtype is not diagnosed if criteria for Somatization Disorder are also met.

Acute: This specifier is used if the duration of the pain is less than 6 months.

Chronic: This specifier is used if the duration of the pain is 6 months or longer.

307.89 Pain Disorder Associated with Both Psychological Factors and a General Medical Condition: This subtype is used when both psychological factors and a general medical condition are judged to have important roles in the onset, severity, exacerbation, or maintenance of the pain. The anatomical site of the pain or associated general medical condition is also coded.

Acute: This specifier is used if the duration of the pain is less than 6 months.

Chronic: This specifier is used if the duration of the pain is 6 months or longer.

293.83 Pain Disorder Associated with a General Medical Condition: (Note: This subtype of Pain Disorder is not considered a mental disorder. It is included to facilitate differential diagnosis.) The pain results from a general medical condition, and psychological factors are judged to play either no role or a minimal role in the onset or maintenance of the pain. The ICD-9-CM code for this subtype is selected based on the location of the pain or the associated general medical condition if this has been established or on the anatomical location of the pain if the underlying general medical condition is not yet clearly established—for example, low back (724.2), sciatic (724.3), pelvic (625.9), headache (784.0), facial (784.0), chest (786.50), joint (719.4), bone (733.90), abdominal (789.0), breast (611.71), renal (788.0), ear (388.70), eye (379.91), throat (784.1), tooth (525.9), and urinary (788.0).

From the American Psychiatric Association (1994). Diagnostic and Statistical Manual of Mental Disorders (4th ed.). Washington, D.C. American Psychiatric Press. With permission.

constant from person to person, the tolerance, what pain a person will endure, is highly variable (Bowsher, 1983). Factors such as depression, anxiety, and motivation significantly influence the tolerance for pain and may determine the amount of suffering and pain behavior generated. Secondary gain, the practical advantage resulting from the symptom of pain, is not the same as malingering or factitious disorder and does not signify that pain is purely psychological in origin (Dunajcik, 1999).

The use of placebo medication or therapy to determine the reality of pain is highly deplorable and potentially very costly (Frank-Stromborg & Christiansen, 2000). Because the ability to respond positively to a placebo has to do with the belief system of the patient, nothing about the reality of the pain will be learned from the use of sham therapies. The only accurate conclusion about a person who responds positively to a placebo is that he wants pain relief and that he trusts someone or something to help him (Edmondson, 2000). Curiously, we give placebos to patients who are the least likely to respond to them, the patients we do not like, and those who do not believe in our efforts. Rarely do we use placebos with the cooperative patients who could respond to them.

RESEARCH CLASSIFICATION

A complex pain classification system has been published by the International Association for the Study of Pain (1986), and provides the clinician with descriptive lists about pain syndromes (Table 4.2). This taxonomy defines pain syndromes, allows improved communication between clinicians and researchers, and leads to improved treatment options that are specific for each syndrome. A five axes coding scheme signifies the region of the pain (Axis I), organ system (Axis II), temporal characteristics and pattern of occurrence (Axis III), patients' statement of intensity and duration since onset of pain (Axis IV), and the presumed etiology (Axis V). Using the IASP classification of chronic pain the practitioner is able to obtain definition, site, main features, associated symptoms, laboratory findings, usual course, complications, social and physical disabilities, pathology, summary of essential features and diagnostic criteria, and differential diagnosis for most pain problems. Specific definitions with notes on usage are included, providing consistency in describing pains itself.

The IASP pain classification system is not yet proven to be reliable and valid, and has not been widely accepted since development in the 1980s. Further research is still needed to determine the psychometric properties and to facilitate modifications to the system (Turk & Okifuji, 2001). Presently, few clinicians or payment sources in the U.S. use the IASP classification system. It is the most thorough and best effort at codification available at this time. The IASP classification system allows pain syndrome diagnoses to be made with inclusion, not exclusion criteria. Pain syndromes

TABLE 4.2
International Association for the Study of Pain Coding for Chronic Pain

Axis I: Regions	
Head, face, and mouth	000
Cervical region	100
Upper shoulder and upper limbs	200
Thoracic region	300
Abdominal region	400
Lower back, lumbar spine, sacrum, and coccyx	500
Lower limbs	600
Pelvic region	700
Anal, perineal, and genital region	800
More than three major sites	900
Axis II: Systems	
Nervous system (central, peripheral, and autonomic) and special senses; physical disturbance or dysfunction	00
Nervous system (psychological and social)	10
Respiratory and cardiovascular systems	20
Musculoskeletal system and connective tissue	30
Cutaneous and subcutaneous and associated glands	40
Gastrointestinal system	50
Genitourinary system	60
Other organs or viscera	70
More than one system	80
Unknown	90
Axis III: Temporal characteristics of pain: pattern of occurrence	
Not recorded, not applicable, or not known	0
Single episode, limited duration	1
Continuous or nearly continuous, nonfluctuating	2
Continuous or nearly continuous, fluctuating	3
Recurring irregularly	4
Recurring regularly	5
Paroxysmal	6
Sustained with superimposed paroxysms	7
Other combinations	8
None of the above	9
Axis IV: Patient's statement of intensity: time since onset of pain	
Not recorded, not applicable, or not known	0.0
Mild, 1 month or less	0.1
Mild, 1–6 months	0.2
Mild, more than 6 months	0.3
Medium, 1 month or less	0.4
Medium, 1–6 months	0.5
Medium, more than 6 months	0.6
Severe, 1 month or less	0.7
Severe, 1–6 months	0.8
Severe, more than 6 months	0.9
Axis V: Etiology	
Genetic or congenital disorders	0.00
Trauma, operation, burns	0.01
Infective, parasitic	0.02
Inflammatory (no known infective agent), immune reaction	0.03
Neoplasm	0.04

Degenerative, mechanical	0.06
Dysfunctional (including psychophysiologic)	0.07
Unknown or other	0.08
Psychological origin	0.09

Examples:

Metastatic cancer (0.04) pain involving skull, shoulder, sacrum, hip, femur (900) and surrounding "soft tissue" (30); continuous in nature with fluctuations related to movement and position (3); severe intensity, more than six months in duration (0.9) is coded as 933.94.

Lower back pain (500) due to myofascial dysfunction (30); continuous and nonfluctuating (2); mild intensity for more than 6 months (0.3); exacerbated by obesity ((0.05) is coded as 532.35.

Abdominal pain (400) due to pancreatitis (50); recurring irregularly (4); severe intensity for less than 1 week per episode (0.7) associated with alcohol use (0.05) is coded as 454.75.

Note: This system establishes a five-digit code for each chronic pain diagnosis. (From International Association for the Study of Pain (1986), Classification of chronic pain: Descriptions of chronic pain syndromes and definitions of pain terms. *Pain*, 3(Suppl.), S1–S225. With permission.)

are diagnosed by what they are, not what they are not. Patients want to know what they have, not be told to live with what their clinicians cannot diagnose.

CONCLUSION

A perceptual phenomenon, like pain, is not accessible to objective validation. The subjective experience of pain is universal and one of the most common reasons that patients seek a clinician's help. An extensive armamentarium of medical, surgical, psychological, social, and rehabilitative interventions is available to address pain. In order to intervene effectively, however, the clinician must have a conceptual frame of reference. A biopsychosocial model recognizing the biological/physiological, psychological/behavioral, and environmental influences is likely the best conceptualization and the only one able to explain all patients and their pain (Robinson & Riley, 1999).

The widespread use of the Internet and the demand by healthcare payers to provide meaningful outcome data has made pain classification more than just an academic exercise. Pain practitioners from different disciplines and specialties must be able to effectively communicate with one another. Well-defined pain classification systems are necessary and must become part of the clinical record (Derasari, 2000).

Pain means suffering. It has plagued humanity as long as humans have existed. To attempt to remedy the suffer-

ing and relieve the pain, accurate assessment and diagnosis must occur. Although many pain syndromes still do not have specific therapies, by classifying pain into certain categories it is now possible to design treatment approaches to benefit most of our patients and, over time, hopefully, we will help the others.

Starting a Pain Clinic

Clayton A. Varga, M.D.

DEVELOPMENT CHECKLIST

1. Ask: Am I sure I want to do this?
2. Identify a leader: Am I qualified?
3. Select the clinic structure.
4. Assess the need.
5. Develop the business plan.
6. Research financial options.
7. Select the participating professionals.
8. Hire support and administrative personnel.
9. Develop the marketing plan.
10. Select the site.
11. Determine equipment needs.
12. Plan billing and collections procedures.
13. Developing a capitated contract.

ARE YOU SURE YOU WANT TO DO THIS?

The formation of any business requires a great deal of forethought and an investment of time, energy, and money to be successful. Starting a pain clinic is no exception. Individuals who wish to engage in the business of pain should ask themselves the following questions: Am I completely committed to the success of the business? Am I willing to be the effective leader of the business? If not, do I have someone to fulfill this function? Do I recognize that the financial aspects of the clinic require as much attention and expertise as the practice aspects? If the answer to any of these questions is no, then all further efforts will most likely be wasted.

IDENTIFY A LEADER

Ask yourself: Am I qualified by education and temperament to start and run a pain clinic? Do I possess the specialized clinical background necessary to develop and implement the needed structure for evaluation and treatment of patients in a multidisciplinary setting? Am I able to participate in the development of contracts and marketing plans and oversee administrative decisions? If you are unable to fulfill these requirements, then it is necessary to secure the participation of one or more individuals who can before proceeding to the next step.

SELECTION OF CLINIC STRUCTURE

Having made the decision to move forward, the desired clinic structure must be selected. Practice types and accompanying brief descriptions are as follows:

1. Single modality: A single practitioner (e.g., neurologist, acupuncturist, chiropractor) seeing and treating patients without regular input from other practitioners.
2. Multimodality: Practitioners of different specialties, treating patients in a similar location without regular, structured discussion of the patients by all practitioners.
3. Multidisciplinary: Practitioners of multiple different specialties, including a minimum of one representative from each of the following fields: physician, physical therapy, and psychology. Often present are occupational therapy,

0-8493-0926-3/02/$0.00+$1.50

acupuncture, nursing, and chiropractic. The members of the clinic have made a commitment to attend regular patient conferences and to provide integrated care of the patient.

The applicability of each item discussed in this chapter will largely depend on the clinic model developed. The less complex the model, the less important certain aspects of the development process become. However, even the simplest single-modality model would benefit from following most of the steps in the development checklist.

The more complex the structure, and the greater the number of participants, the more time, energy, and money will be required to take the business from concept to a fully operational entity. The remainder of this chapter is directed toward a multidisciplinary pain clinic that has a full-time medical director and provides, as a minimum, physical therapy and psychology services and may well offer nursing, occupational therapy, and acupuncture services.

ASSESSMENT OF NEED

Once a preferred structure for the clinic has been selected, then an assessment of need must take place. The purpose of the assessment of need is to determine the demand for the product. It determines if the clinic, in the geographic area to be served, can reasonably expect to draw enough patients to pay all debt and still produce a profit. The assessment should take into account the following:

1. What is the size of the population served (i.e., what is the catchment area)?
2. What is the willingness of physicians within the catchment area to refer patients for the services you are providing?
3. Who is the competition? Are similar facilities already present?
4. What percentage of the population is served by HMOs, PPOs, or IPAs? What will be your ability to gain access to those patients?
5. Can you develop a relationship with an existing healthcare provider who will guarantee patient referrals prior to beginning operations?

The first step is to define your likely catchment area. This represents the geographic boundaries from which you can reasonably expect to draw patients.

In an urban or suburban environment, this usually represents a distance of 15 to at most 30 miles from the business. Obviously, there will be regional variation in the size of the catchment area, depending on the proximity of the clinic to major transportation arteries and traffic patterns and perceived excellence of the clinic. Once defined, the population within the catchment area should be estimated. While no hard and fast rules exist, if the catchment area has a population of less than 100,000, its ability to support a true multidisciplinary clinic or center is questionable.

Competing service providers need to be evaluated. If one or several high-quality providers already exist in the proposed catchment area and if they have excess capacity, then concrete reasons for believing that you can capture a large enough portion of the market share to survive must be identified before business start-up. In such a situation, contracts with a PPO or IPA to be the sole provider for pain management services and verbal assurances of appropriate patient referrals from independent physicians should be obtained prior to entering the marketplace.

Talk to local HMO, PPO, and IPA administrators. Assess your ability to draw patients from these ranks. Meet with attorneys, case workers, and insurance carriers who are involved locally in the workers' compensation system and assess how many referrals are likely from these sources.

Having done the above, estimate the total number of monthly referrals you expect from all sources. If enough patients are forthcoming to support the business, then development of a detailed business plan becomes the next step. If patient referrals appear to be insufficient, then it is wise to explore other sources of patient referral before proceeding. If, after further exploration, more patients are not forthcoming, it is probably best to rethink your proposed catchment area, moving to one with a more favorable referral pattern.

THE BUSINESS PLAN

If, based on the assessment of need, it is likely that the business will be profitable in the selected catchment area, then a detailed business plan is developed. The purpose of the plan is to secure on paper a description of the components of the operation and a schedule of their implementation. This should occur prior to spending the first dollar on the program.

The business plan has two major components. The first is a narrative which contains a brief description of the business, in which the purpose and structure of the business are outlined. Included is a description of the personnel involved, the function each fulfills, an outline of the marketing plan, and a general description of the facility requirements. The narrative section should briefly address each of the following components:

1. The purpose of the business
2. The market niche served by the business
3. The personnel involved and the function of each
4. Facility requirements
5. Outline of the marketing plan
6. Plan for dissolution of the business

The second portion of the business plan is done as a spreadsheet. It can be prepared by hand using a large ledger sheet or more easily by using one of a number of commercially available electronic spreadsheets (e.g., Lotus 1-2-3).

A sample business plan for a hospital-based multidisciplinary clinic that provides primarily outpatient services is shown in Table 5.1. The business plan estimates fixed and variable costs, revenues, and the amount of start-up capital needed to begin the business and keep it running until the revenue stream produces a profit. Total cost is simply the summation of the individual cost estimates. The sample spreadsheet in Table 5.1 lists most of the individual cost estimates that are required for a multidisciplinary clinic. Each expenditure is estimated on a month-by-month basis for at least one year and entered into the spreadsheet. This produces a time estimate of how long it will take to generate a profit and estimates the revenue position of the business at any point along the time line.

The cost estimate should be as detailed as possible. It is possible to accurately predict almost all of the costs, especially fixed costs, when doing the business plan. This is in contrast to revenue estimation, which will be, at best, a rough guess. Nailing down the cost projections as accurately as possible will, in turn, allow for the greatest possible accuracy in predicting the net revenue estimate.

It is best to shift as much of the cost as possible from fixed to variable. This minimizes expenses when revenue is low. Several examples of doing this are hiring personnel on part-time or flexible-time schedules, increasing hours as patient load increases, and having billing and collection done by an outside service, with cost based on a percentage of collections.

Obtaining the revenue estimate requires developing an approximate charge per patient. If the clinic is based on one or several structured programs, in which each patient participates in a relatively uniform program for a predetermined length of time, then average charges are easy to estimate. If the clinic structure is such that revenue generation is spread over a wide range of activities, then generating an average charge per patient is more difficult. In this situation, it is necessary to develop multiple average patient charges and estimate what portion of the total predicted patient flow falls into each group.

Subtracting total cost from total revenue yields the predicted financial position of the business at any point along the time line. It is wise to do estimates using best guess, worst case, and best case revenue projection scenarios. If you are prepared to survive the worst case scenario, then the business should succeed.

FINANCING

The business plan will project the necessary capital required for business formation and development. The most common cause of a new business failure is undercapitalization. It is important to generate at least as much capital as is required based on the business plan. It is also wise to have a credit line available for emergencies. Once capitalization requirements have been determined, options for obtaining the capital must be explored. Numerous financing possibilities exist. Those most commonly employed are as follows:

1. Joint venture: This almost always consists of a limited partnership. The limited partnership consists of both limited and general partners. The general partners oversee the business formation and development and have a greater degree of legal responsibility should the enterprise fail. Limited partners invest money into the partnership but are passive in the business formation and development. Their losses are limited to their investments.

   An example of a joint venture is as follows: The director of the proposed facility develops a detailed business plan. A lawyer is hired to prepare a joint venture agreement, wherein the director is the general partner and the individuals supplying the money are limited partners. The director oversees the development and daily running of the business, for which he or she receives a portion of the profits generated by the business. The director may also receive monies generated via professional activities carried out at the business. The remaining profits are disbursed to the limited partners.
2. Borrowing of money by one or several individuals from conventional lending sources (i.e., a practice loan).
3. Utilization of personal capital to begin the business.

SELECTION OF PARTICIPATING PROFESSIONALS

The type of clinic or operating structure chosen will determine the professional components of the clinic. The quality of the professional personnel will be one of, if not the most important determinants of success. Careful thought must be given to this topic. Not only must the professionals be well trained in their own disciplines, but they must understand the fundamental difference between practicing in a unidimensional office vs. a multidisciplinary setting. They must be willing to make what are often perceived as personal sacrifices to make the system work and to regularly attend patient conference meetings and provide input in those meetings in a useful fashion. They must understand the need to promote the clinic as an entity, as

[a] Employee benefits calculated at 28% (e.g., medical/dental/workers' compensation insurance/FICA/FWH labor costs will vary, depending upon urban location).
[b] Medical director and psychologists can be paid on a 1099 basis, assuming IRS criteria are met.
[c] Physical therapists' employee benefits 25%.
[d] This individual could function in a marketing capacity in addition to nursing/social work duties.
[e] Federal taxes in first year will be based on the NOI plus capitalized investment not written off in first year.
[f] Capital expenses and office rent could be what joint venture partners might provide for an equity interest in the clinic business. Note that both capital investment and business start-up are paid back in the first year of operation.
[g] Net operating income in the first year is a function of how quickly the marketing strategy/plan can tap into the client referral sources such HMOs, IPAs, personal injury attorneys, and workers' compensation case workers/attorneys.

well as themselves as individuals, and be willing to defer at times to other members of the team in the treatment of any particular patient. Many physicians and other professionals are not suited by character to function easily in such an environment and, despite any academic or other professional qualifications, are best excluded from the multidisciplinary setting. When selecting clinical members for the team, consideration of board certification in pain management should not be overlooked.

SUPPORT PERSONNEL

Personnel to perform all of the non-patient care activities are obviously necessary for the business to function. These areas include billing and collections, reception, ordering of supplies, scheduling, transcription, and paying bills, to name a few. These individuals should already have been taken into consideration as part of the business plan. All of these people need not be hired at the beginning of the business. It is preferable to keep start-up fixed costs as lean as possible. Even a multidisciplinary center can easily start with a single support person if time-consuming tasks, such as billing and transcription, are subcontracted to outside firms. This plan has the advantage of changing a fixed cost to a variable cost, which will be much cheaper when patient volume is low. As patient volume rises, these functions can easily be transferred in-house at such time as it becomes financially advantageous to do so.

If one individual is initially hired, then this person should be told that he or she is expected to be a jack-of-all-trades. This individual should also be someone who can become the office manager as other employees are put in place. The author believes that it is cheaper to hire one well-paid, highly motivated employee than two poorly paid, poorly motivated employees. As the business matures, additional employees can be added as need dictates.

SITE SELECTION

Having decided upon both the general geographic location and the specific structure of the clinic, it is possible to begin specific site selection. If a joint venture with a hospital has been undertaken, then the hospital may have unused space which can serve as the clinic site. This has several advantages. It serves to bind the interests of the hospital and the clinic. It provides the clinic with some instant name recognition, if the hospital name is incorporated into the clinic name, and it may help speed referrals to the clinic from members of the hospital medical staff. It also allows easy proximity between inpatient and outpatient care, if both are provided. The hospital may allow the space to be used in exchange for equity in the business, thus limiting operational costs.

If an off-hospital site is selected, then several factors need to be taken into consideration: proximity to other doctors' offices, ease of access to the likely patient base, cost per square foot, the ability of the site to be tailored to your needs, and the ability to expand into adjacent space in the future without having to relocate.

How much and what type of space will be needed will be determined by the clinic structure. Office rental cost represents one of the largest fixed expenses. The clinic structure should be well planned to maximally utilize each square foot of space. Initially, some, if not all, of the professional participants will have other practice locations. It is less expensive to time-share offices between practitioners, and it is unusual for all individuals to be seeing patients at the same time.

EQUIPMENT

Equipment used in a multidisciplinary pain clinic will depend on the clinic structure. If the clinic site is within a hospital, often all of the diagnostic, occupational, and physical therapy, and procedural (nerve block, laboratory testing, radiologic, and operating) equipment and facilities are already available. Supplying a site with the ability to see patients for medical and psychological evaluation, basic physical therapy treatment, minor office procedures (such as certain types of nerve blocks), relaxation training, biofeedback, and group as well as individual psychotherapy will require an expenditure of $50,000 to $75,000. This includes the purchase of furniture, exam and treatment tables, office and medical supplies, biofeedback equipment, fax, typewriter, photocopy equipment, and a phone system. This may or may not include computer equipment for word processing or billing. (As this is expensive, it is another reason to subcontract these services, at least during the first several years of the business.)

MARKETING

It is important to have an overall marketing plan that extends for a period of several years. This should take into consideration how much money is to be allocated to marketing efforts and what types of advertising and other promotional projects will be undertaken. It is not possible to be all things to all people. The marketing plan needs to reflect the market niche and present a consistent message.

Marketing medical services is a complicated and sometimes delicate job. Ethical standards regarding medical marketing vary regionally, and knowledge of local standards is crucial prior to beginning the marketing program. Being the first to employ a specific type of advertising in an area (e.g., radio commercials) can have a negative impact with referring physicians. However, certain techniques (discussed below) can be used in any environment.

Announcements and brochures should be sent to referring physicians, workers' compensation caseworkers, and attorneys. These should be mailed shortly after opening

the practice. The announcement should be mailed first with the brochure to follow one to two months later. This reinforces your message and is more effective than sending both at the same time.

Taking the time to personally contact and talk to local physicians, workers' compensation caseworkers, and lawyers is important in building referral patterns. PPOs, IPAs, and HMOs control a majority of the patient population in many areas. The clinic director must take the time to educate and negotiate with these groups to secure appropriate patient referral.

Lectures and community forums are useful tools for educating referring physicians as well as potential patients not only about the problem of pain, but about your business as well. Professionally prepared stationary, the development of a logo, and production of a newsletter are all effective means of advertising. The clinic's listing in the local phone directory should be easily visible. Radio, television, and print media all offer opportunities for exposure. These represent expensive and potentially sensitive areas of advertising for which local ethos should be considered and professional marketing help engaged.

A presence on the Internet by individual healthcare providers is becoming progressively more common and in the near future will become ubiquitous. A basic Web site can be developed and hosted by a good commercial Web development company relatively inexpensively. This provides an excellent avenue for continuous marketing exposure and a way for patients, providers, and third party referral sources to access information about your program at their convenience. A basic site would include information about yourself and any other service providers in your practice; your location including directions, office hours, and phone numbers; and a description of the services provided. More detailed sites can also include information about specific procedures performed by you or your colleagues including photographs or even short video segments, hot links to other complementary Web sites, and informational databases. Your Web address should be included on your business cards and all other promotional materials and activities. The author recommends dealing with an experienced Web development and hosting service. Consider starting with a basic Web page that allows for some scalability. This way you can add features or increase the complexity of the site without loosing your investment in the initial development.

Advertising and promotion make physicians and patients aware of the services the clinic provides. They do not replace the need to provide concerned, compassionate, and effective care. If the office is disorganized, the receptionist curt, or physicians and therapists chronically late, no amount of advertising can overcome the bad will spread by irate patients and referring physicians.

BILLING AND COLLECTIONS

Even the best conceived and instituted treatment program will not succeed if efficient billing/collections operations are not instituted from day one. Billing and collections can be done internally or subcontracted. This decision should be made while formulating the business plan. The billing system should be in place before the first patient is seen.

A number of local and nationwide medical billing services are available and usually charge between 6 and 10% of collections. Interview several and consider not only the cost, but also the comprehensiveness of the service rendered. Look for a company that has some expertise in billing for a similar entity or is willing to invest the start-up time to learn the peculiarities of the field. Billing externally can significantly reduce capital investment at the time of business start-up and help to reduce fixed costs at a time when cash flow will be slow.

If billing is done internally, the appropriate software, hardware, and support forms to carry out the task must be purchased. It is important to hire someone with previous billing experience to make the system work. There are numerous companies that sell medical billing systems, with a large range of capabilities. Billing, collection, scheduling, accounting, and payroll functions are all available. Software and hardware can be purchased separately or as a complete system. Prices range from $1,000 to $50,000 or more, depending on the system.

DEVELOPING A CAPITATED CONTRACT

Payment for pain management services is transitioning from a fee-for-service model to a capitated model. The extent to which this has already occurred varies dramatically from region to region. In some large metropolitan areas, the market share of managed care exceeds 80%. In other areas, total managed care penetration for 1995 was as low as 7%. Managed care will most likely continue to expand and become de facto market-driven national healthcare reform over the next 5 years, irrespective of any other national or regional political agenda. In this climate, it will be essential for the successful provider of pain management to understand the differences between fee-for-service and capitated reimbursement models and to be able to negotiate a good capitated contract.

In a capitated contract, the clinic receives a payment each month based on the number of members covered by the contract and the rate per member (the per member per month, or PMPM, rate). If the contract covers 50,000 members at a rate of $0.20 PMPM, then the payment would be $10,000 a month. This is independent of the actual number of patient visits, supplies used, or resources consumed in a particular month. If the cost of service delivery for the month was $5,000, then a $5,000 profit

would be realized. Obviously, if the cost to deliver care under the contract was in excess of $10,000 for the month, then a loss would be incurred.

In order to be able to develop a price structure that makes sense, the following information should be obtained and analyzed:

1. The utilization rate for the CPT codes covered under the contract for the most recent 12-month period for the population in question.
2. Your actual reimbursement for each CPT code by insurance type. The most important, of course, is the reimbursement from the entity with which you are negotiating, if you have previous claims experience with that entity.
3. Knowledge of the range of cap rates for similar contracts in your immediate or similar geographic areas.

The above information will allow you to develop a PMPM rate that will maintain profitability. You should develop a PMPM rate based on your own analysis of prior utilization. Then check this against other contracts as a safety check. Obviously, rates can vary extensively depending on which CPT codes are covered by the contract.

It is important to build the following safeguards into the contract:

1. Input into if not direct control over utilization. If you accept the risk of fixed payments, then you must be able to control utilization to help mitigate that risk.
2. Renegotiation of the contract if actual utilization significantly exceeds projected utilization.

It is important to have in place a system to monitor utilization prior to beginning the contract. Utilization information, along with expense information, will be needed to determine the profitability of the contract. It is important to monitor this closely and move to renegotiate unprofitable contracts quickly.

Multidisciplinary Pain Clinics

C. Norman Shealy, M.D., Ph.D., D.Sc. and Roger K. Cady, M.D.

INTRODUCTION

The management of chronic pain began to evolve from the witch doctor approach (exorcism, drugs, and ablative surgery) to the modern concept as the result of three innovations:

1. Dr. John Bonica's concept of a multidisciplinary, interdisciplinary team approach to pain management
2. The Wall-Melzack theory for gate control of pain
3. Fordyce's behavioral modification or operant conditioning concept

Bonica's concept of a multidisciplinary, interdisciplinary clinic began following World War II and evolved over a period of 10 years or so. As late as 1960, the clinic that he founded at the University of Washington was the major such clinic in the United States, but a few other university centers were beginning to follow his model. This model is called the nerve block drug-cut psychiatry clinic because it was originally run entirely by anesthesiologists and led to an unfortunate sequence of events. Even though a group of up to 15 to 20 different health specialists were represented in the weekly reviews of patients, the initial major approach was to look at the patient as having a reasonable physical cause of pain and as a potential anatomical specimen where one could do a peripheral or differential spinal nerve block, relieve the pain, or send the patient to the neurosurgeon for ablation of the appropriate pain pathway.

The failure of destructive neurosurgery is what led to the development of transcutaneous and dorsal column stimulation, because the only types of pain that respond to ablation successfully in the long run are cancer pain, trigeminal neuralgia, and facet joint pain. In virtually all other situations, long-term success from neurosurgical destructive procedures is roughly less than 10%. Thus, patients tend to have nerve blocks and destructive procedures, sometimes have a second set of nerve blocks and destructive procedures, try on a wide variety of drugs, and at that point are told that "it's all in their heads" and sent to see a psychiatrist.

Until at least the mid-1970s, many physicians tended to believe that if patients did not respond to surgical ablative surgery and hard drugs, then they must be "crazy" or seriously psychologically disturbed. On more than one occasion Shealy was told by a psychiatrist, "When you have taken care of the physical component of the pain, send the patient to me and I will take care of the psychological part." But Shealy never saw a patient with chronic pain helped by a psychiatrist. The major approach of psychiatrists has been to make patients feel either guilty, for being an imposition on their families or society, or angry at someone. This approach simply does not work.

On the other hand, the basic concept of a true multidisciplinary, interdisciplinary team is currently the most valid one. The model that Shealy evolved is very different from that at the University of Washington, where the primary approach has also evolved from just nerve blocks and cutting to what he would call a somewhat more comprehensive approach. At the present time in Seattle, patients have pain education, physical therapy, occupational therapy, vocational counseling, individual psychotherapy, and a modicum of relaxation therapy. The University of Washington program considers itself likely to be successful when the patient is suffering from physician-prescribed inappropriate medications, physical deactiva-

0-8493-0926-3/02/$0.00+$1.50

tion, depression, superstitious behaviors and when the patient has beliefs about the body and reasonable outcome goals. The educational program at the clinic has gradually taken on many of Fordyce's concepts, as described later.

Although Bonica is responsible for the concept of a major pain clinic, Wall and Melzack's gate control theory sparked more innovation in the management of pain than any other concept in history. As a direct result of Wall and Melzack's theory, Shealy was prompted to develop dorsal column stimulation and transcutaneous electrical nerve stimulation, which by 1971 led him to start the first holistic comprehensive multimodal, multidisciplinary pain management clinic. The details of the gate control theory were covered in Chapter 2.

Fordyce's concept of pain as an operant or conditioned response also has been critically important in the development of today's pain clinics. Fordyce (1976) emphasized that the "reinforcing consequences" provided by family, friends, and acquaintances when an individual suffers from pain often reinforce pain behavior. Individuals who have been deprived of social recognition and nurturing at a subconscious level often find the tremendous attention that they receive when they suffer from chronic illness provides them a long-neglected nurturing-type environment. This reinforcement pattern must be brought to the patient's attention and often more forcefully to the attention of the spouse or other family members if the chronic cycle of an invalid pain status is to be broken.

In 1965, having been sent a copy of the gate control theory of pain prior to its publication, Shealy visited Pat Wall and then theorized that the most effective way to influence the gate was to stimulate the dorsal column of the spinal cord, because at that anatomical level the beta fibers are separated from the C-fibers, the only place in the body where that is a significant anatomical fact. This led Shealy to the development of both dorsal column stimulation (the first patient being implanted in 1967) and the concept that transcutaneous electrical nerve stimulation would be more effective in a wider variety of people than would the implanted device.

Because of the tremendous number of patients sent to Shealy for dorsal column stimulation who were not candidates for the procedure due to psychological (operant or behavioral) aspects of their illness, in 1971 Shealy opened the first nonuniversity pain clinic and the first pain clinic to offer a truly holistic approach to the concept of pain. From the beginning, the policy was that any safe modality would be included, but all the social, environmental, physical, emotional, chemical, and spiritual stresses in an individual's life would also be examined. The treatment program evolved from an inpatient treatment program to an outpatient model.

Starting in 1971, Shealy's program, with an inpatient active behavioral modification program rather than a passive behavioral modification program, lasted an average of 32 days of inpatient management, with 25 patients in a special unit where the nurses were trained to ignore pain behavior or pain complaints. The patients were advised in advance that this would be the approach. An extremely active day was planned, beginning at 7:00 A.M. following breakfast in an ambulatory dining area. During the day, patients were scheduled from morning until at least 7:00 P.M. and often until 9:00 P.M. They were assigned to walk the hall, given a number of laps which increased each day; ride a stationary bicycle for an increasing number of minutes; and do various other physical exercise activities. Five days a week they went to a swimming pool where they had 1 hour of water calisthenics. Five days a week they went to occupational therapy for 1 hour. Each patient had vigorous slapping massage of the area of pain for at least 5 min four times a day, followed by at least a 5-min rubdown of the area of pain. Patients had generalized mechanical vibratory massage for 15 minutes four times day, were in a whirlpool twice a day, and had a hands-on total body massage every other day.

Transcutaneous electrical nerve stimulation and acupuncture were intimate parts of pain management in this clinic from the beginning. For the first year, "group therapy" was handled by a psychiatrist. At the end of that time, having attended one of the group therapy sessions, Shealy believed group therapy had negative reinforcing qualities and it was discontinued. Instead, he introduced autogenic training for 30 min twice a day and began to introduce temperature, EEG, and electromyelogram (EMG) feedback.

By the end of the first year, Shealy had treated over 400 patients, of whom approximately 6% had had dorsal column stimulators inserted and 1% had had peripheral nerve implanted stimulators.

At the end of 32 days (the average hospital stay), 75% of the patients were off drugs, were markedly improved in their pain complaints and behaviors, and had a significant increase in physical activity. Over the next year and a half, reliance upon stress reduction and cognitive educational aspects increased, and during this time Shealy developed the concept of Biogenics®. The Biogenics retraining component of Shealy's pain management program (Shealy, 1978) became so prominent that the inpatient program was closed in 1974, and Shealy began to run an outpatient-only pain management program. Today, most clinicians consider it inappropriate to hospitalize chronic pain patients for anything other than drug withdrawal or severe psychiatric problems.

PAIN MANAGEMENT FOR THE 1990s

The single most important factor in managing chronic pain is evaluation of the patient. This must include the following:

Aspirin, Tylenol, etc.	up to 10 per day	10
	up to 20 per day	25
Valium, Ativan, diazepams	up to 20 mg per day	25
	up to 40 mg per day	50
	over 40 mg per day	75
Librium	up to 20 mg per day	25
	up to 40 mg per day	50
	over 40 mg per day	75
Phenothiazines, Serax, Thorazine, etc.	up to 20 mg per day	25
	up to 40 mg per day	50
	over 40 mg per day	75
Tricyclic antidepressants:	up to 4 per day	25
Elavil (10 mg), Vivactil (5 mg),	4–8 per day	30
Tofranil (10 mg), Aventyl	8–12 per day	40
	over 12 per day	50
Monoamine oxidizers	up to 4 per day	60
(antidepressants): Nardil, etc.	4–8 per day	75
Mild to moderate addicting, codeine (30–60 mg), Percodan, Talwin tablets, Darvon, Darvocet, Stadol, Nubain, barbiturates (30–60 mg)	over 8 per day	90
Demerol, injectable Talwin,	up to 4 doses per day	75
morphine, Dilaudid	up to 8 doses per day	90
	over 8 doses per day	100
Sleeping medicines	up to 1 per day	25
	2 per day	50

FIGURE 6.1 Drug usage.

1. A comprehensive history of the patient's pain problem, including:
   - Onset
   - Predisposing factor
   - Drug history (see Figure 6.1)
   - Surgical history
   - Family history
   - Social interactions
   - Symptom index
   - Pain profile (see Figure 6.2)
   - Total life stress (see Figure 6.3)
2. A review of all diagnostic tests
3. A comprehensive physical and neuromuscular examination, including particular attention to the sacrum, posture, and spinal mechanics
4. Special tests that might be needed, including:
   - Myelogram
   - CAT scan
   - MRI
   - EMG and sensory nerve conduction studies
   - Neuropsychological tests
   - Psychological tests, including:
     - California Personality Inventory (CPI)
     - Minnesota Multiphasic Personality Inventory (MMPI)
     - Myer-Briggs Type Indicator (MBTI)
   - Evaluation by a physical therapist
   - Evaluation by a psychologist
5. The minimum team needed for comprehensive pain management includes:
   - Physician (M.D. or D.O.)
   - R.N.
   - Psychologist, psychotherapist, or someone with a Master's degree in social work
   - Physical therapist

On the columns below, grade yourself (circle your choice):																					
Pain intensity (severity)	0	5	10	15	20	25	30	35	40	45	50	55	60	65	70	75	80	85	90	95	100

Name: Date:

Read your stress points on the lines in the right-hand margin and indicate subtotals in the boxes at the end of each section. Then add your subtotals to determine your total score.

A.	Dietary stress		
	Average daily sugar consumption		
	Sugar added to food or drink	1 point per 5 teaspoons	_____
	Sweet roll, piece of pie/cake, brownie, other dessert	1 point each	_____
	Coke®, or can of pop; candy bar	2 points each	_____
	Banana split, commercial milkshake, sundae, etc.	5 points each	_____
	White flour (white bread, spaghetti, etc.)	5 points	_____
	Average daily salt consumption		
	Little or no "added" salt	0 points	_____
	Few salty foods (pretzels, potato chips, etc.)	0 points	_____
	Moderate "added" salt and/or salty foods at least once per day	3 points	_____
	Heavy salt user regularly (use of "table salt" and/or salty foods at least twice per day)	10 points	_____
	Average daily caffeine consumption		
	Coffee	1/2 point each cup	_____
	Tea	1/2 point each cup	_____
	Cola drink or Mountain Dew®	1 point each cup	_____
	2 Anacin® or APC tabs	1/2 point per dose	_____
	Caffeine benzoate tablets (NoDoz®, Vivarin®, etc.)	2 points each	_____
	Average weekly eating out		
	2–4 times per week	3 points	_____
	5–10 times per week	6 points	_____
	More than 10 times per week	10 points	_____
		DIETARY SUBTOTAL	[ ] A
B.	Environmental Stress		
	Drinking water		
	Chlorinated only	1 point	_____
	Chlorinated and fluoridated	2 points	_____
	Soil and air pollution		
	Live within 10 miles of city of 500,000 or more	10 points	_____
	Live within 10 miles of city of 250,000 or more	5 points	_____
	Live within 10 miles of city of 50,000 or more	2 points	_____
	Live in the country but use pesticides, herbicides, and/or chemical fertilizer	10 points	_____
	Soil and air pollution		
	Exposed to cigarette smoke of someone else more than 1 hour per day	5 points	_____
		ENVIRONMENTAL SUBTOTAL	[ ] B
C.	Chemical stress		
	Drugs (any amount of usage)		
	Antidepressants	1 point	_____
	Tranquilizers	3 points	_____
	Sleeping pills	3 points	_____
	Narcotics	5 points	_____
	Other pain relievers	3 points	_____
	Nicotine		
	3–10 cigarettes per day	5 points	_____
	11–20 cigarettes per day	15 points	_____
	21–30 cigarettes per day	20 points	_____
	31–40 cigarettes per day	35 points	_____
	Over 40 cigarettes per day	40 points	_____
	Cigar(s) per day	1 point each	_____
	Pipeful(s) of tobacco per day	1 point each	_____
	Chewing tobacco "chews" per day	1 point each	_____

FIGURE 6.3 Personal stress assessment: total life stress test.

Average daily alcohol consumption		
1 oz. whiskey, gin, vodka, etc.	2 points each	_____
8 oz. beer	2 points each	_____
4–6-oz. glass of wine	2 points each	_____
	CHEMICAL SUBTOTAL [ ]	C

D. Physical stress

Weight		
Underweight more than 10 lbs.	5 points	_____
10–15 lbs. overweight	5 points	_____
16–25 lbs. overweight	10 points	_____
26–40 lbs. overweight	25 points	_____
More than 40 lbs. overweight	40 points	_____
Activity		
Adequate exercise,* 3 days or more per week	0 points	_____
Some physical exercise, 1 or 2 days per week	15 points	_____
No regular exercise	40 points	_____
Work stress		
Sit most of the day	3 points	_____
Industrial/factory worker	3 points	_____
Overnight travel more than once a week	5 points	_____
Work more than 50 hours per week	2 points per hour over 50	_____
Work varying shifts	10 points	_____
Work night shift	5 points	_____
	PHYSICAL SUBTOTAL [ ]	D

* Adequate means doubling heartbeat and/or sweating minimum of 30 minutes per time.

E. Holmes-Rahe Social Readjustment Rating*

(Circle the mean values that correspond with life events listed below which you have experienced during the past 12 months.)

Death of spouse	100	Change in responsibilities at work	29
Divorce	73	Son or daughter leaving home	29
Marital separation	65	Trouble with in-laws	29
Jail term	63	Outstanding personal achievement	28
Death of close family member	63	Spouse begin or stop work	26
Personal injury or illness	53	Begin or end school	25
Marriage	50	Change in living conditions	24
Fired at work	47	Revision of personal habits	23
Marital reconciliation	45	Trouble with boss	20
Retirement	45	Change in work hours or conditions	20
Change in health of family member	44	Change in residence	20
Pregnancy	40	Change in schools	19
Sexual difficulties	39	Change in recreation	19
Gain of new family member	39	Change in church activities	18
Business readjustment	39	Change in social activities	17
Change in financial state	38	Mortgage or loan less than $20,000	16
Death of close friend	37	Change in sleeping habits	15
Change to different line of work	36	Change in eating habits	15
Change in number of arguments with spouse	35	Vacation, especially if away from home	13
Mortgage over $20,000	31	Christmas or other major holiday stress	12
Foreclosure of mortgage or loan	30	Minor violations of the law	11

(Add the mean values to get the Homes-Rahe total. Then refer to the conversion table to determine your number of points.)__ _____

F. Emotional stress

Sleep		
Less than 7 hours per night	3 points	_____
Usually 7 or 8 hours per night	0 points	_____
More than 8 hours per night	2 points	_____

FIGURE 6.3 (CONTINUED) Personal stress assessment: total life stress test.

Relaxation		
Relax only during sleep	10 points	_____
Relax or meditate at least 20 minutes per day	0 points	_____
Frustration at work		
Enjoy work	0 points	_____
Mildly frustrated by job	1 point	_____
Moderately frustrated by job	3 points	_____
Very frustrated by job	5 points	_____
Marital status		
Married, happily	0 points	_____
Married, moderately unhappy	2 points	_____
Married, very unhappy	5 points	_____
Unmarried man over 30	5 points	_____
Unmarried woman over 30	2 points	_____
Usual mood		
Happy, well adjusted	0 points	_____
Moderately angry, depressed, or frustrated	10 points	_____
Very angry, depressed, or frustrated	20 points	_____
Any other major stress not mentioned above you judge intensity (specify):	(10–40 points)	_____

EMOTIONAL SUBTOTAL [ ] F

Add A _____ + B _____ + C _____

FIGURE 6.3 (CONTINUED) Personal stress assessment: total life stress test.

6. Once it is ascertained that the patient does not have a problem which needs primary surgery or medical drug management, the following modes of therapy need to be considered:
   - Educational approaches — Of critical importance to the patient are the following:
     - Understanding the anatomy and physiology of pain and appropriateness of surgical vs. drug therapy
     - Thorough understanding of stress:
       - Physical
       - Chemical
       - Emotional
       - Spiritual
     - An understanding of the concept of retraining the nervous system (Biogenics)
     - Understanding the dynamics of interpersonal relationships
   - Physical approaches
     - Acupuncture
     - Nerve blocks of:
       - Muscle trigger points
       - Facet joints
       - Sacroiliac joints
       - Caudals (rarely)
       - Intercostal blocks (rarely)
     - Miscellaneous:
       - Occipital
       - Supraorbital
       - Infraorbital
       - Mental nerves
     - Transcutaneous electrical nerve stimulation
     - Use of different types of devices:
       - Cranial electrical stimulation
       - Percutaneous electrical nerve stimulation (medium and intense)
     - Soft tissue mobilization:
       - Myofascial massage
       - Strain/counterstrain
       - Manipulative techniques
       - Vibratory massage
       - Mechanical massage
       - Heat
       - Ice
     - Exercise
       - Limbering
       - Aerobic
       - Muscle strengthening
       - Work hardening
   - Pharmacological approaches
   - Nutritional approaches
     - Special attention to vitamin C, vitamin B6, and magnesium (all deficient in a majority of patients)
   - Chemical approaches — Possible therapeutic implications include:
     - Dilantin
     - Elavil or other antidepressant drugs
     - Mexitil (especially for sensory deprivation pain)
   - Psychological and spiritual approaches
     - Pragmatic
     - Practical
     - Spiritually oriented

BIOGENICS

The backbone of Shealy's self-regulation training program is Biogenics. Biogenics incorporates the work of a number of individuals, including Dr. Elmer Green, Roberto Assagioli, Edmond Jacobson, Emil Coue, Carl Jung, and, of course, J.H. Schultz. Essentially, many of these individuals have touched on aspects that interrelate to one another. As Shealy began synthesizing the techniques of self-regulation, the following steps were most emphasized:

- Positive attitude
- A belief in self ("I can do it") — Biofeedback proves this
- Relaxation
- Conscious control of sensation (Balancing Body Feelings) — Individuals are taught the following balancing body feelings techniques:
  - Talking to the body
  - Feeling the localizing pulsation of heartbeat
  - Imaging
  - Loving the body
  - Tensing and relaxing
  - Breathing through the body
  - Collecting and releasing
  - Circulating the electrical energy
  - Expanding the electromagnetic energy field
  - Mental induction of anesthesia
  - Balancing emotions
  - Recognizing that all distress is the result of fear of loss of:
    - Life
    - Health
    - Money
    - Love
    - Moral values
  - Logically and internally recognizing that the only solutions are:
    - Assertion to correct the problem
    - Divorcing an unacceptable problem with joy
    - Accepting and forgiving (going for sainthood)

  - Programming goals (organ-specific phrases)
- Spiritual attunement

Because some 90% of individuals state that they believe in life after death, God, and living the Golden Rule, this universal belief is incorporated into teaching. Individuals are exposed to philosophical concepts to develop the transcendent will or the will of the soul, starting with the concept that all individuals have basic needs and desires in addition to those necessary for survival. The major part of cognitive understanding relates to accepting that pain, most psychologically aggravated, is the result of unfulfilled desires or failure to accept things as they are. Ultimately, individuals must learn that there are a limited number of situations that can be totally changed and that one should put effort into those that can be changed and learn total emotional–psychological detachment from those aspects of life which cannot be changed; in other words, to be at peace with the unchangeable aspects of life. At the same time, they are taught to control pain through the Biogenics techniques of Balancing Body Feelings.

Obviously, there are many models of pain clinics. Some current clinics specialize only in doing nerve blocks, especially caudal nerve blocks, whereas others primarily emphasize transcutaneous electrical nerve stimulation, and still others emphasize more physical therapy approaches. All of these techniques are valuable in managing chronic pain. The indications for specific physical approaches such as acupuncture and nerve blocks are beyond the province of this chapter. References to some of the technology can be found at the end of this chapter.

COST EFFECTIVENESS OF COMPREHENSIVE PAIN TREATMENT

No discussion of pain clinics would be adequate without attention to the catchphrase of today—cost effectiveness. Shealy's study in 1984 is one of the few that have been published.

At the Shealy Institute, over 7000 patients have been evaluated and/or treated intensely in a 13-day comprehensive program. At the present time, only 10 to 15% of patients evaluated enter the intense program. Most of the others are satisfactorily managed with one or two modalities of treatment with occasional follow-up visits. Of those who enter intense therapy, 60% have had unsuccessful back surgery, 10% have back pain without prior surgery, 10% have headaches, and the remainder have a wide variety of posttraumatic, postsurgical metabolic or degenerative pain syndromes. Sixty percent are women, and 40% are men. They range in age from 8 to 90 years, with most patients between 35 and 67 years old. Approximately 20% have had workers' compensation injuries.

Patients have been incapacitated for 1 to 7 years plus. Medical expenses have ranged from $10,000 to $450,000, with average medical expenses of over $10,000.

RESULTS FOLLOWING COMPREHENSIVE TREATMENT

In any given year, 5 to 7% of patients who enter the program fail to complete it. About 1% are sent home because of open resistance to therapy. The others who drop out do so because they "don't believe in it." Almost all of these dropouts are male smokers and are either workers' compensation or Medicaid patients.

Of the 94% who complete the program, follow-up data at 6 months and 2 to 3 years from 800 patients (600 followed up at 2 + years and 200 followed up at 6 months) consistently reveal that:

- 35% return to work.
- 90% are off all drugs except aspirin or acetaminophen.
- 70% are improved 50 to 100% (at 6 months 72% are greatly improved, and over the next 2 years this decreases to 70%).
- 30% who do not improve greatly almost invariably did not practice the techniques taught.
- 5% had a facet rhizotomy.
- 25% have continued use of transcutaneous electrical nerve stimulation for at least 6 months.
- Pain intensity is reduced an average of 70%.
- Percent of time pain is present is reduced an average of 65%.
- Mood is improved in 90% of patients.
- A majority have significant stress illness, such as hypertension, diabetes, peptic ulcer, etc.
- Less than 5% have additional surgical procedures after treatment.
- Drug expenses after therapy are reduced 85%.
- Hospitalization after therapy is reduced 90%.
- Total medical expenses are reduced after therapy 80 to 85%.
- Cost of the treatment ranges from $3,500 to $6,000 and is rarely more, depending upon need for hospitalization, drug withdrawal, etc.

In 1972, Fordyce reported that his average patient had prior expenses of $50,000. At the time, his program cost $5,000. Most pain clinics today charge from $5,000 to $35,000. Fordyce estimated that society would break even if only 10% of his patients returned to work. If one takes into account the income produced by those who return to work, even less than a 10% return-to-work success rate would produce a break even for society.

Presently, with prior medical expenses often exceeding $60,000 on average and an average cost of less than

$5,000 for the comprehensive treatment program, society breaks even if only 8% return to work. Because 35% of Shealy's patients return to work, the cost effectiveness is at least 3.4 to 1. Because total medical expenses are reduced by well over 75%, the cost of the comprehensive rehabilitation program is recouped in less than 6 months. In medical costs alone, in just a 2-year period, the cost effectiveness is 4 to 1. That is, within 2 years, society saves four times as much money as the cost of the treatment program. When the added benefit of 35% return to work is considered, the cost effectiveness is even greater than 4 to 1.

The data reported here apply only to treatment at the Shealy Institute for Comprehensive Health Care and cannot be extrapolated to other pain treatment programs or modalities (Shealy, 1976).

The advent of DRGs in 1982 began a process that is increasingly cumbersome and detrimental in all aspects of patient care. In no area has this had a greater impact than in pain management. Although the HMO, PPO, Managed Care system has continued to cover major interventional approaches such as epidurals reasonably well, almost all other aspects of pain management have been severely curtailed. In our opinion, the least effective treatment for all forms of chronic pain is epidural anesthetics. Biofeedback, transcutaneous electrical nerve stimulation, neuromuscular re-education techniques, and acupuncture, which are the hallmarks for successful pain management, are extremely poorly covered in the current situation. Thus, multidisciplinary pain clinics continue to suffer from the lack of coverage by third-party payers. Interestingly, at the Shealy Institute patients have been willing to pay out of pocket to obtain the comprehensive care that is often not covered by medical insurance.

CERTIFICATION OF PAIN CLINICS

In 1983, CARF (Commission for Accreditation of Rehabilitation of Facilities) instituted a program of accreditation for both outpatient and inpatient pain clinics. The number of pain clinics in this country is very difficult to ascertain. Fortunately, in 1996 the American Academy of Pain Management instituted its review process for certification of pain clinics and at that time certified 70 active pain clinics. These included outpatient facilities, inpatient facilities, and outpatient/inpatient facilities.

Columbia Medical Plan Pain Management Group Manual

Clark Brill, M.D., Juliet Scotti Post, D.C., Thomas Ferguson, Ph.D., Harry Shabsin, Ph.D., Jane Tenberg, M.A., Kathleen Wooding, M.A., Marilyn Lauffer, M.S., R.N., Robin Thomas, M.S., R.N., R.D., and Mary Ann Buchmeier, M.S., R.D.

INTRODUCTION

All pain practitioners come to realize soon in their careers that chronic pain is a volatile mix of pathological stimuli combined with host factors of pain perception and behavioral reaction to the stimuli.

This paradigm forces us to take a more holistic approach to treatment in addressing both the organic stimulus and these host factors when necessary. Obviously, each case lies somewhere along a spectrum where some patients have a more definable pathology and fewer confounding host factors, in which case our efforts are aimed at removing the stimulus via a procedural approach. Others have either less obvious pathology or a condition that simply has no effective treatment coupled with psychological characteristics of hyperawareness or magnified response. In these patients the resources are better spent working on perception/reaction behaviors vs. pursuing multiple futile procedures.

This sounds good on paper but we all know how difficult it can be to treat these "host factors." We are also painfully aware that insurance companies seem to be willing to pay for procedural care more quickly than psychological techniques targeting these host factors.

Nonetheless, research tells us addressing these characteristics such as locus of control, depression, and coping styles is fruitful, as if our own anecdotal testimonials were not sufficient. How then do we address these host factors?

First, an analogy to other chronic diseases must be drawn. A diabetic has an incurable condition but diabetic patients can minimize the effects of the disease by making the right choices — eating properly, foot care, etc. Conversely, they can jeopardize their health and increase chances for diabetic complications by making poor choices.

Similarly, those with chronic pain can make choices to magnify their painful experience or mitigate it. To use a phrase from a family practitioner friend of mine: The pain is there — misery and suffering are optional. This then is the mission of treating host factors — we must act as guides to help each patient live a good life despite experiencing chronic pain as opposed to living in misery with it.

A group setting is ideal for teaching these skills because it is very cost effective to bring a group of people together at one site to present this material vs. repeating oneself in an office setting ad nauseum. There is also the "group dynamic" effect where patients previously feeling isolated and hopeless are working together in a positive environment and can feed off each other's strengths.

What follows is a detailed outline of one such successful group — The Columbia Medical Plan group seminar for chronic pain patients — for those interested in starting a group of their own. This was an 8-week outpatient group experience that was intensely studied for outcomes; these were presented to the American Academy of Pain Management (AAPM) at the 1994 annual conference. Patients completing the group decreased doctor visits for pain complaints by 50%.

0-8493-0926-3/02/$0.00+$1.50

The basic philosophy of the group was a simple motto — "no brain, no pain". That is, the state of mind one brings to the pain experience affects the pain itself as well as its impact on one's life.

Each group meeting consisted of a presentation and discussion of areas where patients were encouraged to make good life choices such as exercise, eating habits, and thinking patterns. These were areas they still had control over as opposed to focusing on pain levels that they may have had little control over.

Of course, the patients had to begin with a belief in this brain–pain model and this foundation was established at the initial meeting by a physician presentation on rudimentary anatomy and physiology of pain mechanisms in the human body, including Gate theory, antipain pathways, serotonin, and other neuromodulation structures.

The outline for the Columbia Medical Plan Group treatment for chronic pain follows.

PURPOSE OF MANUAL

This manual is designed to assist healthcare providers in running groups for chronic pain patients. The outlines of material to be presented are general. Providers are encouraged to add their own individual creativity and to adapt the manual to their own particular needs.

OVERALL PAIN CLINIC PROGRAM

A pain management group is an effective and cost-effective modality, and an important part of an overall pain treatment program that may include pharmaceutical management, physical therapy, injection therapy, exercise, biofeedback, and psychotherapy. An ongoing support group for chronic pain patients helps them maintain the benefits gained from the pain management group.

PAIN MANAGEMENT GROUP

I. Objectives of Pain Management Group
   A. Educating patients in causes and treatment of pain
   B. Helping patients develop cognitive and behavioral skills for pain management
   C. Creating a support group for pain patients and those involved with them to manage pain behavior
II. Structure of group sessions
   A. A closed 8-week group for 12 to 15 patients
   B. Group that runs for 1 h, once a week
   C. Group that is staffed by
      1. A psychotherapist who is present every week
      2. A physiatrist
      3. An exercise therapist
      4. A nutritionist
   D. Each week, the session involves
      1. Presentation on pain management
      2. Discussion time
      3. A relaxation exercise
III. Participants
   A. Most pain patients in pain clinic recommended for the Pain Management Group
   B. Preferable that clients complete biofeedback before entering group
   C. Patients who cannot interact well in a group setting and those who have a high rate of cancellation not recommended for the group
IV. Outline of the Pain Management Group
   A. Weekly presentations made on some aspect of pain management by a member of the treatment team covering:
      1. Anatomy and physiology of pain — physiatrist
      2. Exercise and pain management — exercise therapist
      3. Treatment of pain — physiatrist
      4. Imagery techniques in pain management — exercise therapist
      5. Cognitive treatment of pain — psychologist
      6. Behavioral treatment of pain — psychologist
      7. Nutrition and pain management — nutritionist
   B. Presentations followed by group discussion
   C. Relaxation training included in each session
   D. Homework reviewed weekly
      1. A pain management chart filled out weekly
      2. Exercise and relaxation practice charted weekly
      3. Thoughts and emotions in response to pain examined
   E. Patients referred to Chronic Pain Support Group after completing Pain Management Group

THE PROGRAM

Week One

Summary

I. Welcome and introductions
II. Presentation by physiatrist
   A. Anatomy and physiology of pain
   B. Discussion of presentation
III. Homework — weekly pain management chart
   A. Explaining chart
   B. Emphasizing daily relaxation

IV. Relaxation— progressive
V. Closing

Week One

I. Welcome and introductions
  A. Group leader introducing self and welcoming group
  B. Other professionals introducing themselves
  C. Group members introducing themselves
  D. Guidelines for group
    1. Attendance
    2. Fees
    3. Outline of program
    4. Announcement of Chronic Pain Support Group (biweekly)
II. Presentation by physiatrist on anatomy and physiology of pain
  A. Definition — "Pain is a stimulus that is perceived as uncomfortable"
    1. Stimulus
      a. Torn tissue
      b. Loud noise
      c. Discomforting sight
      d. Stressful situation
    2. Perceptions
      a. Perception depends on mind set
      b. Distraction decreases perception
      c. Focusing on perception makes it stronger
    3. Being uncomfortable
      a. Not able to measure discomfort or suffering
      b. Relativity — difference among people's sensitivities and tolerances
      c. Existence of cultural differences
      d. Dependence on past history of experiences
  B. Pain pathways
    1. Stimulus site
      a. Nerve endings firing even after stimulus removed
      b. Chemicals released that enhance strength of stimulus
      c. Additive effects of stimuli
    2. Spinal cord
      a. Nerves entering at "gate" that can be open or closed
      b. Competing stimuli at this level
      c. Example of gate: rubbing skin when bump leg
    3. Brain
      a. No pain until conscious appreciation
      b. No brain — no pain!
      c. Making a conscious decision "this is uncomfortable"
      d. Degree of discomfort depending on mind set — stress, depression
      e. If no other stimuli present, pain getting in — night pain
  C. Antipain pathways
    1. Descending pathways
      a. Nerves coming down from brain to close gates
      b. Nerves coming down from brain to release endorphins
    2. Endorphin system
      a. Body's natural pain-fighting system
      b. Responsible for placebo response
      c. Can be elevated by many means
        i. Drugs
        ii. Relaxation
        iii. Exercise
      d. Causes natural "high"
  D. Summary— pain not "all in your head" or "all in your body"
  E. Discussion of presentation
III. Homework
  A. Introducing weekly pain management chart — see Appendix 7.1
  B. Any questions/discussions arising from review of chart
IV. Relaxation
  A. Progressive relaxation — see Appendix 7.2
  B. Sharing relaxation experience
  C. Stressing importance of daily relaxation
V. Closing
  A. Thanking presenter
  B. Checking that everyone will attend next week
  C. Positive comments about today's group

Week Two

Summary

I. Welcome and check-in
II. Presentation by exercise therapist
  A. Role of exercise in pain management — part I
  B. Discussion of presentation
III. Homework
  A. Recording exercise and relaxation on chart
  B. Discussing pain management section of chart
IV. Relaxation— flowing light
V. Closing

Week Two

I. Welcome and check-in
   A. Group leader and staff members reintroducing themselves
   B. Patients giving brief comments on how the week has been — especially new and good examples
   C. Group leader checking who has done relaxation and exercise
   D. Giving out Exercise Handout* I
II. Presentation by exercise therapist on role of exercise in pain management — part I
   A. Attitudes toward exercise
      1. Eliciting words from the group members that describe what comes to their minds when they think of "exercise" (writing these words on blank flip chart — both positive and negative — and discuss)
      2. Emphasizing importance of developing "positive" attitudes toward exercise
      3. "No pain, no gain"
         a. Philosophy obsolete
         b. New focus: "Train, don't strain"
   B. Benefits of exercise
      1. Physical
         a. Increases stamina, strength, flexibility, coordination
         b. Improves cardiovascular efficiency
         c. Affects medical problems
            i. Hypertension
            ii. High cholesterol levels
            iii. Diabetes
         d. Increases lung capacity
         e. Burns calories — weight control
         f. Increases pain tolerance
         g. Is associated with longevity
      2. Psychological
         a. Improves self-image/self-esteem
         b. Helps alleviate depression
         c. Enhances ability to handle stress
         d. Fosters sense of "being in control"
   C. Disadvantages of exercise
      1. Overexercise possibly causing injuries
      2. May increase pain short term
      3. Takes time
   D. Proper way to exercise — choose proper sport for your body
      1. Type
         a. Aerobic vs. anaerobic
         b. Using large muscle groups
         c. Low impact
         d. Examples
            i. Biking
            ii. Walking
            iii. Swimming
            iv. Aerobic dance
      2. Frequency
         a. 3 to 5 days per week
      3. Duration
         a. Ideal 15 to 60 min
         b. Minimum: 15 to 20 min, plus warm-up and cool-down
      4. Intensity— based on target heart rate
         a. Review of heart rate chart
         b. Level of perceived exertion
         c. Medication possibly affecting heart rate
      5. Measuring heart rate
         a. Where?
            i. Neck
            ii. Wrist
         b. How?
            i. Counting for 1 min or 15 s four times
         c. When?
            i. At rest
            ii. During exercise
            iii. After exercise
      6. Importance of practice
         a. Walking program with warm-up and cool-down
   E. Exercise precautions—be careful if the following occur:
      1. Dizziness
      2. Light headedness
      3. Chest pain or pressure
      4. Excessive fatigue
      5. Excessive shortness of breath
   F. Exercise clothing
      1. Hot weather
         a. Loose, light layered
         b. Avoiding heavy sweaters, plastic or rubberized clothing
      2. Cold weather
         a. Layered, porous clothing
         b. Avoiding overdressing
         c. Covering head, ankles, and hands
   G. Exercise shoes
      1. Choosing correct shoes for your sport
      2. Awareness of stability, cushioning
      3. Wearing absorbent socks
      4. Preventing blisters
   H. Strategies to get going
      1. Making walking a pleasure
         a. Scenery
         b. Cassettes, radio

* Handouts are not provided as part of this manual. It is suggested that program leaders provide material for the specific needs of their groups from materials collected and available to them.

c. Pleasant company
2. Linking walking with a pleasurable activity as a "reward"
3. "Foot out the door" approach

I. Discussion of presentation

III. Homework
A. Commenting on weekly pain management charts by patients
B. Stressing importance of relation — checking who did it
C. Collecting charts and giving out new ones
D. Giving out "Tapes and Books for Health Management" — see Appendix 7.3

IV. Relaxation
A. Flowing light relaxation — see Appendix 7.4
B. Sharing relaxation experience
C. Asking how relaxation was helpful to patients this week

V. Closing
A. Thanking presenter
B. Checking next week's attendance
C. Positive comments about today's group

Week Three

Summary

I. Welcome and check-in
II. Presentation by physiatrist
A. Treatment of chronic pain
B. Discussion of presentation
III. Homework — reviewing exercise and relaxation
A. Reviewing weekly pain management charts
IV. Relaxation — breathing and beach imagery
V. Closing

Week Three

I. Welcome and check-in
A. Welcoming everyone back
1. Positive comments on attendance
2. Positive comments on adherence
B. Checking on who has done exercise, relaxation charts
C. Brief review of week
1. Positive orientation encouraged
D. Announcing Chronic Pain Support Group again

II. Presentation by physiatrist on treatment of pain
A. Must fight pain at all levels — cannot separate body/brain
B. Pharmaceutical management
1. Decreasing narcotics — interfering with natural pain-fighting systems
2. Serotonin possibly useful — pumps up body's pain-killing system
3. Other useful medications
a. Anti-inflammatories
b. Antihistamines
c. Antivascular
d. Antianxiety
e. Antidepressants
C. Physical management
1. Exercise
a. Increases endorphins
b. Increases pain threshold
c. Helps mood
d. Reconditions body
2. Activity gates
a. Heat
b. Cold
c. Nerve stimulation
d. Acupuncture
3. Inactivity increasing pain by decreasing competitive stimuli
D. Psychological management
1. Decreasing perception using power of the mind
a. Biofeedback
b. Relaxation
c. Hypnosis
d. Imagery
2. Addressing other cortical issues that increase pain
a. Depression
b. Anxiety
c. Stress
3. Support systems
a. Family
b. Pain support groups
c. Outside activities
E. Role of pain
1. At first, pain may be useful — acute for protection
a. Causes withdrawal, e.g., broken limb — not using it
2. Later, pain can be a useless habitual signal
3. Pain can even cause benefits at times
a. Financial
b. Attention
4. Internal vs. external focus of control
a. Making changes – flexibility
b. Avoiding joylessness
5. Victor vs. victim
6. Process takes courage
F. Discussion of presentation

III. Homework
A. Commenting on how patients did on charts

B. Collecting old charts and giving out new ones
IV. Relaxation
A. Breathing induction and beach imagery
B. Sharing relaxation experience
C. Exploring images that help patients reduce pain
V. Closing
A. Thanking presenters
B. Checking next week's attendance
C. Reminding patients about charts

Week Four

Summary

I. Welcome and announcements
II. Homework — daily pain management charts
III. Relaxation — self-guided — classical music
IV. Presentation by nutritionist
A. Nutrition and pain management
B. Discussion of presentation
V. Closing

Week Four

I. Welcome and announcements
A. Checking on week
B. Checking on relaxation practice and exercise
II. Homework
A. Introducing new daily management charts
1. To be done for 2 weeks — see Appendix 7.4
B. Collecting old charts and giving out new
C. Reinforcing adherence to charts, exercise, relaxation
III. Relaxation
A. Relaxation induction using breathing
B. Self-guided imagery using classical music
C. Bringing patients back to group and discussing experiences
IV. Presentation by nutritionist on nutrition and pain management
A. Short-term/long-term effects of diet on well-being
1. Short-term effects less obvious — therefore often neglected
a. Affecting energy level for work, play
b. Needed for steady supply of fuel — sugar for effective pain management
c. Constant supply of blood sugar necessary for optimal functioning of brain, muscles, and organs
d. Avoiding destabilizers in sugar supply (e.g., caffeine, alcohol)
e. Considering nutrients that fight pain and depression — amino acids and B vitamins
2. Long-term effects are preventative maintenance for the body
a. Proper diet can help ward off
i. Osteoporosis
ii. Heart disease
iii. Certain cancer types
iv. Diabetes
v. Gallbladder disease, etc.
b. Need to avoid or deal with obesity to lessen certain muscle, bone, or joint pain
B. Dietary Guidelines for Americans*
C. NRC's dietary recommendations
1. Eating five or more half-cup servings of vegetables and fruits every day
2. Moderating protein intake — Recommended Daily Allowances (RDA) to twice RDA
3. Maintaining adequate RDA calcium intake
4. Avoiding use of dietary supplements in excess of RDA
5. Maintaining optimal intake of fluoride
D. Relating guidelines to balanced diet (food groups)
E. Examining own diet (class exercise)
1. Writing 24-hour dietary recall
2. Comparing to dietary guidelines and food groups
3. Determining strong and weak points of diet and prioritize any desirable changes
4. Working on making dietary changes
F. Diet and drug interactions
1. Obtain a list of medications used by class participants prior to this presentation
2. Adverse side effects with nutritional implications
a. Drugs that may cause these side effects
b. Dietary suggestions to alleviate or prevent side effects
G. Arthritis (if time and relevant to class participants)
1. No nutritional cures, though many myths abound
a. No proof that selenium, turnips, fish oils, or vitamins help
b. Possible that saturated fats, dairy products, chocolate, tomatoes, and citrus fruits may aggravate rheumatoid arthritic symptoms in some people

* Giving out nutritional handouts.

2. Achieving healthy body weight
   a. Being overweight — stress aggravating to arthritic joints
   b. Following diet low in fat, sugar, and salt and high in complex carbohydrates
   c. Increasing physical activity to burn more calories
   d. Rheumatoid arthritis — food consumption— underweight
   e. Increasing calories to offset being underweight
   f. Adjusting meal planning and food preparations to offset stiffness, pain, and fatigue
3. Reasons to eat well
   a. Boosts energy
   b. Makes you feel healthier
   c. Reduces flare-ups
   d. Helps you cope better with arthritis

H. Vitamin and other supplements
1. Reasons for taking supplements
   a. Meeting unusually high demand for nutrients
      i. Pregnancy
   b. Poor nutritional status
      i. Iron deficiency
      ii. Anemia
   c. Diet that does not meet body nutrient needs
2. RDA vs. megadoses
   a. RDA encompassing nutrient needs of general population
   b. Megadoses usually of no benefit and often harmful to health
   c. Vitamin C only proven effective in reducing cold symptoms, yet chronic megadoses possibly cause diarrhea and kidney stones
   d. Megadoses of fat-soluble vitamins and iron are toxic
   e. Other examples
   f. Obtaining nutrients through foods safe and natural
3. Health claims on nutritional supplements
   a. How to determine legitimacy
   b. Always checking with physician before taking megadoses
   c. Asking pharmacist about potential dangers

I. Migraine headaches
1. Well-balanced diet and evenly spaced meals
2. Relatively safe foods
3. Foods to avoid list
   a. Not applicable to everyone, therefore test own reactions
   b. Most common offenders
   c. Reading food labels
4. Dietary suggestions to alleviate anorexia and nausea

J. Discussion of presentation

V. Closing
A. Thanking presenter
B. Emphasizing to patients importance of looking at their thinking patterns this week

Week Five

Summary

I. Welcome and announcements
II. Presentation by behavioral psychologist
A. Cognitive treatment of pain
B. Discussion of presentation
III. Discussing thought substitution chart
IV. Relaxation— progressive/imagery
V. Homework— daily pain management chart
VI. Closing

Week Five

I. Welcome and announcements
A. Welcoming groups and positive comments regarding progress of group
B. Checking on who has done exercise, relaxation, charts
C. Brief check-in by patients
D. Announcing Chronic Pain Support Group

II. Presentation by behavioral psychologist on cognitive treatment of chronic pain
A. Henry Beecher — soldier vs. civilian story — see Appendix 7.6
1. Meaning of story
2. Groups reaction

B. Pain vs. bodily sensation
1. How we label something that will affect our experience of it
   a. Snake story — see Appendix 7.7
   b. Childbirth— the stronger the contractions, the closer the birth
   c. Difference in labeling pain as a “sensation” instead of “suffering”
2. Control of sensory input
   a. Focusing on pain that may increase tension and therefore intensify pain
   b. Distractions such as entertainment, relaxation, and meditation decrease tension and pain

c. Some examples of controlling sensory input through altered states are dental hypnosis and fire walking

C. Meaning of patient symptoms
1. Attributing meaning to our symptoms whether we are aware of it or not
a. e.g., religious meaning "offer it up" — story of Job
b. Personal identity — pain and illness possibly beginning to define who the person is
c. Symptoms that determine the roles we play in relationships such as
i. Victim
ii. Martyr
iii. Hero
d. Spinal cord experience — paraplegics choose opposite responses story — see Appendix 7.8

D. Developing internal locus of control
1. Internal vs. external locus of control
a. Patients with internal locus of control
b. Relaxation and meditation ways to help develop internal locus of control
2. Man's search for meaning story — see Appendix 7.9

E. Discussion of presentation

III. Discussing thought substitution chart
A. Reviewing thought substitution chart — see Appendix 7.10
B. Having one patient describe event
C. Having other patients complete columns on chart
D. Repeating exercise for second event
E. Discussing how patients are working on their thinking/feeling patterns

IV. Relaxation
A. Progressive relaxation — Appendix 7.2
B. Imagery of place in nature

V. Homework
A. Asking patients to discuss thought substitution chart with their families
B. Collecting daily pain management charts and giving out new ones

VI. Closing
A. Reminding patients that family members are invited next week
B. Thanking presenter

Week Six

Summary

I. Welcome and introductions
II. Presentation by behavioral psychologist
A. Family interactions and pain management
B. Becoming an exceptional patient
C. Discussion of presentation
III. Small group discussion
IV. Homework — patient management chart
A. Discussing thought substitution chart with family
V. Closing

Week Six

I. Welcome and introductions
A. Welcoming and explaining why families were invited
B. Having patients introduce family members and tell why they are important
C. Any additional comments from family members
D. Checking on who did relaxation and exercise

II. Presentation by behaviorist on family interactions in management of chronic pain
A. Stranger, supportive spouse, unsupportive spouse story — see Appendix 7.11
1. Meaning of story
2. How others can affect pain perception
3. How others are affected by pain
4. Group's reaction to story

B. What others can do to help pain patients
1. Not overreacting (not just doing something; sitting there)
a. Letting patient care for self
b. Not discussing/asking about symptoms
c. Treating person in a normal fashion
2. Attention for nonpain behavior
a. Inappropriate attention only reminding person of symptoms
b. Persons in pain needing to be left alone, not attended
i. Go to their rooms
ii. Praise for nonpain behavior
3. Acute vs. chronic pain
4. Other means of expressing love and concern besides attending to pain

C. Conclusion— persons with chronic pain helped best by
1. Increasing self-reliance
2. Increasing levels of activity
3. Treated as well, instead of ill

D. Becoming an exceptional patient — Bernie Siegel, M.D.
1. Defining the exceptional patient
a. 15 to 20% of patients are
i. Difficult
ii. Uncooperative

iii. Assertive
iv. Demanding
v. Optimistic
vi. Rule breakers

b. Exceptional patients are the ones most likely to get well
c. Exceptional patients are willing to accept all the risks and challenges of life

2. Taking responsibility for your own health
a. Refusing to be a victim
b. Recognizing that happiness is an "inside job"
c. Asking to be educated by your doctor and becoming your own doctor
d. Refusal to hope is nothing more than a decision to die: "In the face of uncertainty, there is nothing wrong with hope" — Bernie Siegel
e. Becoming a survivor! Ignoring the statistics
f. We missed that one story — see Appendix 7.12

3. Letting go of fear
a. Exceptional patients knowing that health depends on inner peace and letting go of fear
b. Finding ways to make peace with yourself
c. Finding ways to make peace with others
d. Taking good care of yourself through relaxation (having fun), exercise, and good food

4. Helping yourself decrease or eliminate symptoms
a. Decreasing need to attend to symptoms
b. Understanding possible payoff of symptoms, e.g., avoidance of something
c. Developing positive attribution style — I am hopeful
d. Learning distraction techniques
e. Reevaluating what you can learn from your symptoms
i. Appreciating good health
ii. Having empathy with people
f. Recognizing situations that are related to the onset of symptoms
g. Avoiding onset situations such as
i. Stress
ii. Specific physical activities
iii. Anticipatory anxiety
iv. Overreacting
v. Repeated discussion of symptoms with others

5. At peace with life and death
a. Getting well not the only goal
b. Importance of learning to live without fear and to be at peace with life and death

6. How to become an exceptional patient
a. Assertiveness
b. Having information/knowledge
c. Having hope
d. Taking good care of yourself
e. Letting go of fear
f. Finding inner peace

7. Discussion of presentation

III. Small group discussion
A. Inviting group to divide up into small groups of two or three patients
B. Discussing what response from family members really helps client and what they learned from thought substitution chart
C. If appropriate, therapist intervening to confront patterns that maintain pain behavior/thinking

IV. Homework
A. Collecting daily pain management charts and giving out new weekly charts
B. Giving out another copy of thought substitution chart to work on with family member

V. Closure
A. Thanking family members for coming
B. Asking if they would like to come again in week 8
C. Thanking presenter

Week Seven

Summary

I. Welcome and announcements
II. Discussing what patients want to do in last session
III. Relaxation — healing visualization for pain management
IV. Presentation by exercise therapist
A. Exercise and pain management — part II
B. Discussion of presentation
V. Homework— weekly pain management chart
VI. Closing

Week Seven

I. Welcome and announcements
A. Discussing reactions to family coming to group

B. Reviewing charts, relaxation, exercise practice
II. Discussing what patients want to do in last session — possible options:
A. Discussing their ideas
B. Sharing and feedback
1. Patients sharing what they have learned in the group and what changes still have to be made in their lives
2. Family members sharing what changes they have seen in patient while they have been in treatment
3. Group members giving each other feedback on changes they have seen in each other and offering any suggestions for the future
C. Small group discussion
1. Patients divide into small groups based on common symptoms for discussion
a. Headaches
b. Back pain
c. Fibromyalgia, etc.
III. Healing visualization
A. Explaination of designing your own imagery — healing visualization –see Appendix 7.13
B. Patients filling out imagery sheets
C. Guiding patients through imagery
D. Patients sharing imagery in pairs
E. Discussing imagery with group
IV. Presentation by exercise therapist on role of exercise in chronic pain management — part II
A. Review
1. Targeting heart rates — discussing any problems patients may have
2. Exercise records — checking everyone is exercising regularly
B. Three parts of exercise
1. Endurance
a. Heart— increased size, decreased rate
b. Arteries— dilated
c. Muscles— increased oxygen absorption
d. Lungs— increased capacity
2. Flexibility
a. Increasing agility and mobility
b. Decreasing chances of injury
c. Improving posture
d. Relieving tension and stiffness
3. Strength
a. Cannot grow new muscles — must tone what we have
b. Muscle cells take less space than fat cells
c. Muscles burn more calories
d. Muscles contour the body
e. Firm muscles reinforce joints, reducing sprains and strains
f. Using dumbbells, circuit weights
C. Home exercise equipment
1. Exercise bikes
a. Not weather dependent
b. Transferring skills outside
c. Addition of fans, book stands, digital readouts
2. Rowing machines
a. Use of upper and lower body
b. May not be good for back problems
3. Cross-country skiing equipment
a. Uses upper and lower body
b. Can be expensive
4. Treadmills
D. Health clubs
1. Aspects to consider in a health club
a. Equipment
b. Costs— especially extras
c. Location— close by?
d. Hours— work for you?
e. Membership contracts
E. Handouts— Exercise Handout II
1. Reviewing exercise comparison
2. Reviewing cost/benefit ratios
F. Conclusion: "Adding years to your life and adding life to your years through exercise"
G. Discussion of presentation
V. Homework
A. Give out weekly pain management charts
B. Reinforce ongoing exercise and relaxation programs as lifestyle changes
VI. Closing
A. Thanking presenter
B. Reminding patients to bring family member/friend next time, but if you can't, to come anyway
C. Inviting group members to bring snacks for final session

Week Eight

Summary

I. Welcome and announcements
II. Group discussion
III. Ongoing group treatment
IV. Closing
V. Evaluation of program
VI. Refreshments

Week Eight

I. Welcoming and announcements
   A. Welcome patients and families
      1. Positive comments on progress of the group
   B. Patients reintroducing family members/ friends
II. Group discussion
   A. Discuss whatever patients may have requested during last session
   B. Alternatives
      1. Patients share what they have changed in their lives as a result of being in the group
      2. Family members share positive changes they have seen
      3. Patients give each other feedback on growth they have seen in each other over the weeks
   C. Small group discussions, divided by symptoms
      1. Headaches
      2. Back pain
      3. Fibromyalgia, etc.
III. Ongoing group treatment
   A. Introducing therapist from Chronic Pain Support Group
   B. Patients committing to ongoing treatment in group
IV. Closing
V. Pain group evaluations — see Appendix 7.14
VI. Refreshments

Handouts

Exercise Handout I

1. Reasons to exercise
2. Heart rate chart
3. Sample walking program
4. Information on exercise shoes
5. General stretching exercises
6. Comparisons of different forms of exercise
7. Log of exercise practice
8. Cost/benefit ratios of different forms of exercise

Exercise Handout II

1. Guidelines for working out
2. Lower-body warm-up exercises
3. Middle-body warm-up exercises
4. Upper-body warm-up exercises

Nutritional Handout

1. Nutritional guidelines
2. Foods that may increase pain — headaches
3. Nutrients that fight pain — amino acids
4. Dietary supplements/vitamins in a healthy diet
5. Caffeine content of beverages
6. Drug-nutrient information sheet

Appendices

WEEK ONE

Appendix 7.1 Weekly Pain Management Chart

Name:					Date:		
Week number:							
Day (Example)	**Monday**	**Tuesday**	**Wednesday**	**Thursday**	**Friday**	**Saturday**	**Sunday**
Daily relaxation: 30 min Practice: Legs Time: Heavy Experience: Relieved Headache							
Exercise time: 40 min Type: Walking Self-talk re: Pain: This pain is terrible. When will it end? Daily medications: Aspirin							

Appendix 7.2 Progressive Relaxation

A. Using relaxation music, asking group to tense and release their muscles in the following sequence:
   1. Clenching hands and relaxing
   2. Bending hands back at wrist and relaxing
   3. Tensing biceps and relaxing
   4. Tensing forehead (raise brows) and relaxing
   5. Tensing face (squinting) and relaxing
   6. Tensing mouth and jaw and relaxing
   7. Tensing neck and upper shoulders (neck and chest) and relaxing
   8. Tensing shoulders, back, and chest (taking a large breath and pull shoulders back) and relaxing
   9. Tensing stomach and relaxing
   10. Tensing thighs (raising legs up slightly) and relaxing
   11. Tensing calves (heels off floor) and relaxing
   12. Tensing feet (curl up toes) and relaxing

B. Asking patients to bring themselves back by being aware of the room around them and of other group members

C. Asking patients to open their eyes as you count from one through five

D. Asking group members to share their relaxation experience and whether anyone had any difficulties

E. Encouraging daily relaxation practice at home

WEEK TWO

Appendix 7.3 Tapes and Books for Health Management

Tapes

Letting Go of Stress — Emmett Miller
Images for Optimal Health — Emmett Miller
Change the Channel on Pain — Emmett Miller
Headache Relief — Emmett Miller
Healing Journey — Emmett Miller
Positive Imagery for People with Cancer — Emmett Miller
All available from: Source, P.O. Box W, Stanford, CA 94309, (415) 328–7171 or (800) 52-TAPES
Seasons for Healing — Stress and Pain Management — Jule Scotti Post (Vol. 1 — Winter-Spring; Vol. II — Summer–Fall)
Available from: Healing Imagery, 4520 Kingscup Court, Ellicott City, MD 21042
Health Journeys — Belleruth Naparstek

Cancer Chemotherapy Depression
Grief General wellness

Available from: Image Paths, Inc., P.O. Box 5714, Cleveland, OH 44101
Cancer — Discovering Your Healing Power — Louis Hay
Available from: Hay House, Inc., Santa Monica, CA, (213) 394–7445
Rapid Pain Control — Carol Erickson and Thomas Condon
Self-Hypnosis for Reducing Your Stress — Carol Erickson
Available from: Changeworks, P.O. Box 4000-D, Berkeley, CA 94706

Relaxation Music

Zen Waterfall — Eliotoshu and Paul L. Warner, Global Pacific Distributions
Caverna Magica — Andreas Vollenweider, CBS Records
White Winds — Andreas Vollenweider, CBS Records
The Sky of the Mind — Andreas Vollenweider, CBS Records
Comfort Zone — Steve Halpern, Halpern Sounds
Spectrum Suite — Steve Halpern, Halpern Sounds
Winter Solstice — David Lanz and Michael Jones, Narada Productions
Pianoscapes — Michael Jones
Petals — Marcus Allen et al., Dreamwater Music
Harp and Soul — Georgia Kelly, Heru Records
Path of Joy — Daniel Kobialka, Li-Sem Enterprises
Silk Road — Kitaro, Sound Design
Silver Road — Kitaro, Sound Design
Silver Cloud — Kitaro, Sound Design
Toward the West — Kitaro, Sound Design
Silver Wings — Mike Rowland, Music Design, Inc.
Fairy Ring — Mike Rowland, Music Design, Inc.
Lovely Day — William Aura, Higher Octave

Music

Miracles — Rob Whitesides-Woo, Search for Serenity
Mountain Light — Rob Whitesides-Woo, Search for Serenity
Classical Music for Relaxation
Classic Fantasy — Anugama, Higher Octave Music
Relax with the Classics, Vol. I–IV — Lind Institute
Great Lakes Suite — Dan Gibson
The Classics — Dan Gibson

Appendix 7.4 Flowering Light Relaxation — with Relaxation Music

A. Breathing induction — give patients the following instructions
   1. Begin by taking a few deep breaths
   2. Let go of any tension throughout your body as you breathe
   3. Notice that as you become more relaxed, your breathing becomes softer and gentler
   4. Be aware of the rising and falling of your chest while breathing in and out

B. Flowing light imagery
   1. Continue with the following instructions:
      a. In your mind's eye, picture a small ball of radiant light resting gently on top of your head; either see the light or have a sense of it being present
      b. Imagine that light is now flowing down over your head around the back of your head and around your face
      c. Let any tension in the muscles in your head and face dissolve in that flowing light; let those muscles become deeply relaxed
   2. Continue relaxation instructions, asking patients to picture a warm light flowing around the following areas:
      a. Back and front of neck
      b. Shoulders and back
      c. Arms and hands
      d. Chest and stomach
      e. Thighs and calves
      f. Feet and toes
   3. After mentioning each area, ask patients to let any tension in the muscles in that area dissolve in that warm flowing light, and let those muscles become deeply relaxed
   4. When patients have relaxed all parts of their bodies, ask them to see that warm light flowing all around them and to feel themselves floating in that light

C. Coming back
   1. Ask patients to begin bringing themselves back by having an awareness of their bodies sitting in chairs with their feet on the floor
   2. Suggest patients be aware of the sounds around them in the room and how they are currently feeling
   3. Ask patients to open their eyes as you count back from five to one

D. Sharing
   1. Ask patients to share what this relaxation was like for them
   2. Call on individuals who haven't shared much with group

WEEK FOUR

Appendix 7.5 Daily Pain Management Chart

Name:				
Week Number:				
Time of Symptoms	Activity	Consequences of Choices Made (Including Meds, Relaxation, etc.)	Comments	Exerciese
Daily				Daily
Change in Intensity	When Pain Level Changed	Medication	Relaxation	
Example 8:15 a.m.	Headache	Getting ready to go to work	I stayed at home	Took Demerol (amount)
I can't stand this pain.	Walking	Asprin	1/2 hour	

WEEK FIVE

Appendix 7.6 Henry Beecher — Soldier vs. Civilian Story — Can How We Think Affect How We Feel?

Some years ago, Henry Beecher, a physician interested in the amount of pain experienced. Dr. Beecher hypothesized human pain mechanism, designed a study to investigate that the amount of pain a person felt was directly related the amount of tissue damage sustained in an injury and to the extent of an injury or the amount of damage to bone,

muscle, or other tissue. To prove this theory, he studied soldiers wounded in battle. Dr. Beecher was able to ascertain the amount of injury by examining the medical records of soldiers wounded in battle. He then compared this information with the amount of morphine, a narcotic analgesic, each of the soldiers took to control pain. As he had expected, the greater the amount of bodily injury, the greater the amount of morphine used by the wounded soldiers to obtain relief from pain. From these studies, Dr. Beecher concluded that pain was solely the result of injury to tissue and did not have a higher cognitive component related to thinking or to emotional reactions to an injury.

To apply these findings to civilians, Dr. Beecher did additional research with patients who were not soldiers and who received injuries from various accidents such as falls or automobile collisions. To help make his point, Dr. Beecher even matched up the wound between soldiers and the civilians. As before, he found that the greater the injury to the civilians, the more morphine they took to control pain. However, there was one difference between the soldiers and the civilians that Dr. Beecher had trouble accounting for. For the same amount of tissue damage, civilians took almost three times as much morphine as did the soldiers to control pain. It began to appear that something else besides tissue damage was influencing the amount of pain patients were experiencing.

After further investigation, Dr. Beecher concluded that a person's reaction to injuries could affect the amount of pain experienced. When he asked the soldiers what their injuries meant to them, they told him they were primarily relieved that their wounds had not resulted in death and that they felt confident about recovering and returning home. In other words, they reacted in a positive fashion to their injuries. Civilians, on the other hand, saw their injuries from a much more negative perspective, describing their injuries and accidents as awful events resulting in their lives being disrupted. For the most part, soldiers understated their pain and felt it was minor and it was tolerable. Civilians, however, tended to describe their pain as more intense and unbearable. Since these studies, many other reports have also described how emotional or cognitive reactions to injury can affect perceptions of pain.

Based on the research of Henry Beecher and others, the response to the question, "Can how we think affect how we feel?" appears to be yes. For those of you experiencing chronic pain, this implies that by learning to react differently to your pain symptoms or by adopting different coping strategies, you can affect the amount of pain you experience. In other words, if you are willing to think more positively about your life and your symptoms, you can learn to do something to help yourself feel better.

Appendix 7.7 Snake Story — Thinking Precedes Feeling

One of the contributing authors to this manual, Dr. Thomas Ferguson, described an experience he had in the following way:

> I attended graduate school at Arizona State University, and since this university is in the desert, there was an example given by one of my major professors of how thinking precedes feeling. This was a novel thought to me at that time, and I was skeptical until he gave an example that convinced me of the accuracy of this hypothesis.

The professor stated that if you went to a friend's house or apartment to water his plants while he was away on vacation and, as you opened the door, you saw what looked like a snake, you would have a thought! He said if you believed that it was a real snake, then this thought would translate into a physiological response and then an emotion. The adrenaline would start pumping. You would then be in a "fight or flight" mode, and you would either attack the snake to kill it, if you perceived it as dangerous, or you would flee, if you were fearful. However, if you knew this friend had a great sense of humor and loved to play practical jokes, you might look at the snake a little more closely to make a determination whether it was real or not. If you decided it was not real, then you would react with calm or laughter, rather than with the adrenaline-engendered "fight or flight" syndrome.

Therefore, if you examine your emotions, you will see that how you perceive a situation makes a difference in how you respond emotionally.

Appendix 7.8 Paraplegics Choose Opposite Responses

In 1967, a patient at Stanford Hospital was there to have back surgery. He was struck by how differently two other patients in the ward responded to their physical conditions. Both patients had similar spinal cord injuries, leaving them paraplegic.

One patient really enjoyed listening to music, especially Aaron Copeland's "Appalachian Spring." He was very upbeat and entertaining. The other patient was constantly miserable and complaining. He was obviously bitter and angry.

It was amazing to see that two people in such difficult circumstances could respond in such opposite ways. Both were paraplegic, but while one suffered constantly, the other was determined to live life as fully as he could.

We also have a choice about how we respond to our pain — to suffer constantly or make the most of the life we have.

Appendix 7.9 Man's Search for Meaning

The concept of internal vs. external locus of control is best examined by a reading of *Man's Search for Meaning* by Victor Frankl, M.D. Dr. Frankl was a Jewish psychiatrist living in Germany during the Nazi regime. At some point, he was arrested and taken to a concentration camp. During the first few nights in the concentration camp, a number of prisoners would hang themselves from the rafters out of despair. Dr. Frankl wrote that he also considered suicide as he examined his losses. The Nazis had taken his home, his profession, and his money. They had killed his family. They had even taken his bodily hair. He felt that they had complete control over him, with the exception of one aspect of his life that they could not control how he decided to respond to this abomination. He decided that he would tell the world what happened and that he would write a book about his experiences. His heroic struggle to survive for 5 years in Nazi concentration camps is an inspirational one to read. It underlines the importance of recognizing that no one can control how you respond to your external world, no matter how traumatic that may be.

Appendix 7.10 Thought Substitution Chart

Give at least five examples of your own automatic negative thoughts in response to pain and stress, and the feelings and consequences that follow them. Think about what positive thoughts you could substitute for your automatic thoughts, and what new feelings and consequences these would bring you. See the following example.

Event	Automatic Thoughts	Feeling/Consequences Responses	Substitute Thoughts Responses	New Feeling	Consequences
e.g., Pain begins.	This is going to be terrible. I can't bear it.	I feel angry, scared, anxious. I hate the pain. The pain increases. I take my pain killer.	I become more tense.	It is time to relax through the pain. I can deal with it.	I feel calm. I am used to it. I become relaxed focused. The pain is bearable. I avoid taking pain medication.

WEEK SIX

Appendix 7.11 Supportive Spouse Story — A Sight for Sore Eyes

We have all heard the phrase "a sight for sore eyes," but what about a sight for sore backs, or heads, or arms, or stomachs, or any other part of the body? Is it possible that just the sight of another person can make us feel better or worse? The answer appears to be yes. We have all at one time or another thought about others as being a "pain in the neck." However, for most of us, this is just a way to indicate that we are experiencing stress related to another person. We usually do not mean we actually have the physical sensation of pain in our necks. However, a group of researchers reported in the journal *Pain* that just the sight of another person might actually increase or decrease the experience of painful sensations. In this study, patients in the hospital for chronic pain were observed for signs of painful discomfort under three conditions: in the presence of a supportive spouse, in the presence of a nonsupportive spouse, and in the presence of a neutral observer.

The results from this study showed that patients with chronic pain appeared to be in more pain in the presence of a supportive spouse compared with a neutral person, but seemed to experience less pain when in the company of a nonsupportive spouse compared with a neutral observer. These results may seem surprising. However, although sympathy may be appropriate for short or acute periods of pain, the researchers concluded that for patients with chronic pain, a person providing sympathy over a prolonged period of time may begin to be viewed as rewarding. Because rewards tend to increase the behavior that obtained them, the sight of a rewarding person can increase pain if that pain was the reason for obtaining the reward of sympathy in the past. The opposite also appears to be true. If a person ignores a family member's pain, that person's pain tends to decrease because there are no positive benefits for having it. If this seems far-fetched, think of the example of working for a salary. If you were paid $50,000 or $100,000 a year for going to work, the chances are good that you would continue to go to work the next day. On the other hand, if you were paid only $5,000 a year, you might soon start missing days or leave your job altogether because your salary (reward) for working was not worth the effort.

These examples illustrate how powerful the effect of rewards (or lack of rewards) can be on our behavior. Although many times we are aware of how rewards affect our behavior, we do not necessarily have to be aware of this reward–behavior relationship to be affected by it. This

seems to be the case for patients with chronic pain. Even though we may not be aware of it, the way family members and friends interact with an individual with chronic pain can affect how that person feels.

Appendix 7.12 We Missed That One!

Contributing author Dr. Ferguson described another extraordinary experience in the following words:

> Dr. Bernie Siegel's quote, "In the face of uncertainty, there is nothing wrong with hope," was demonstrated to me in a courageous fashion by a 19-year-old patient that I treated during an internship at the University of Minnesota Hospital. He had been in a motorcycle accident and as a result was paraplegic. After surgery, he was sent to the rehabilitation medicine unit where I was serving as a psych intern. During our staff conferences on this patient, it was my assignment to convince him that he would never walk again, as he was in denial about the severity of his condition. He was insisting that he would overcome it. I spent the next three months working with him and after a relatively brief period of time gave up trying to convince him that he wasn't going to walk again. Instead, I supported his efforts to work hard in rehabilitation. I'll never forget the moment when he started to recover some movement in his lower extremities. By the time I finished my internship, he was walking with the aid of crutches. When I questioned the physiatrist about what had happened with the diagnosis, he shrugged his shoulders and said, "We missed that one". It taught me an important lesson: to never give up in the face of what appears to be a hopeless condition.

WEEK SEVEN

Appendix 7.13 Healing Visualization: Pain Management

Name:_____ Date: _____
History No: _____

1. Begining relaxation by breathing deeply
2. Imagining a warm light flowing all through your body, relaxing every muscle
3. Picturing your pain symbolically
4. Picturing the healing process symbolically
5. Seeing the healing process winning over the pain
6. Seeing your own body feeling good and relaxed and comfortable
7. Seeing yourself doing something you love to do
8. Having awareness of your body, and the room around you; when ready, opening your eyes

---

WEEK EIGHT

Appendix 7.14 Pain Group Evaluation

I. Please rate the following presentations in terms of their effectiveness for your pain management:

	Very helpful	Somewhat helpful	Not helpful
Causes and treatment of chronic pain			
Exercise and pain management			
Changing your thinking/working with family members			
Nutrition and pain management			
Relaxation and imagery			

II. Please use the following rating scale to answer the following questions:

1. Very much 2. Some 3. Not at all

1. How relevant were the presentations to the type of pain you experience?
2. Did you learn new information from the presentations?
3. Did the presentations change the way you think and/or feel about pain?
4. Did you feel able to speak freely in the group?
5. Overall, how much did the group experience help you?

III. Please rate the following aspects concerning pain and its effect on your life since taking this course.

Improved greatly	Somewhat improved	Not improved

1. Actual pain level experienced
2. Feelings of control over your pain
3. Feeling depressed or moody because of pain
4. Feeling good about yourself because of new skills or attitudes

IV. Please answer in your own words:
1. What did you like most about the group?
2. What would you like to see changed about the group?
3. What other comments do you have about the group?
4. Will you attend the bimonthly follow-up group?

Section III

Treatment of Commonly Occurring Pain Syndromes

8

Clinical Diagnosis of Heel Pain

Paula Lizak Gilchrist, L.P.T., D.P.M.

Heel pain (calcaneal pain) is one of the most common foot problems presenting to the clinical practitioner. In 1999, over 2 million doctor visits were involved with the treatment of heel pain. Age is not a discriminating factor. Heel pain can occur with any age group, but is most commonly found from the age of 8 to 80 years of age. Heel pain is noted in women, men, and children. It is responsible for loss of work days, loss of school days, and loss of income.

Disability from heel pain can be short term and mild to long term and fully debilitating. Problems with the heel can be associated with activity change, increase in weight, and change in shoe gear. Foot type (pronated or supinated foot) as well as atrophy of fat pads in the heel can contribute to heel pain.

In 1999 alone, a MedLine Search showed 11,849 "hits" with questions on heel pain. These questions ranged from the definition of heel pain, to causes, to treatments, to support groups.

Care for heel pain can range from the most conservative to the most radical. A myriad of treatment exists. Treatment such as rest, ice, compression, elevation, medication (oral anti-inflammatories, oral steroids, vitamin therapy), steroid injections, orthotics, physical therapy modalities, exercise for strength and flexibility, massage therapy, acupuncture, acupressure, splinting, strapping, and casts are a few of the conservative care measures. Steroid creams and anti-inflammatory creams have also been used.

Radical care, generally reserved for the most resistant cases, does include surgical measures. Plantar fasciotomy, plantar fasciectomy, exostectomy, bursectomy, calcaneal osteotomy, neurolysis and lysis of adhesions, and tendon lengthening are all within the surgical realm of possibility.

Practitioners from many arenas of traditional medicine and complementary care medicine treat heel pain. We all have our niche. Medical physicians tend to give medication for pain and inflammation. Podiatrists offer use of medication, orthotics for foot balancing, strapping, splinting, casting injections, and surgery. Osteopaths offer medication and bony adjustment (such as for a short leg). Chiropractors offer spinal alignment. Acupuncturists and acupressurists offer pain blocking care. Therapists, physical, massage, and others, offer deep tissue relief, myofascial care, scar reduction and body awareness. All have the same goal: reduction of pain, reduction of inflammation, and increase in function. There is no simple single line of treatment and no single rate of cure for those patients with heel pain.

Infectious processes as well as systemic diseases can cause heel pain. Diseases such as gout, rheumatoid arthritis, psoriatic arthritis, Reiter's syndrome, and ankylosing spondylitis can cause heel pain. However, for purposes of this discussion, the following pathologies are discussed:

1. Plantar fasciitis
2. Heel spur syndrome
3. Haglund deformity
4. Retrocalcaneal exostosis/Achilles tendon calcification
5. Achilles tendonitis
6. Tarsal tunnel syndrome
7. Flexor hallucis longus tendonitis

For an anatomical review of the foot, the reader is advised to consult a standard anatomy text for illustrations of the foot.

0-8493-0926-3/02/$0.00+$1.50

There are 26 bones in the human foot. This amount to one fourth of the bones found in the entire human body. The foot itself is divided into three bony sections.

1. Rearfoot: consisting of talus and calcaneus
2. Midfoot: consisting of navicular, cuboid, and cuneiform bones 1, 2, 3
3. Forefoot: consisting of metatarsals 1, 2, 3, 4, 5
   Five proximal phalanges
   Four middle phalanges
   Five distal phalanges

Note that the hallux (great toe) has only a proximal and a distal phalanx.

In terms of foot musculature, there are four distinct layers of plantar muscles. The layers ranging from superficial (plantar) to deep (dorsal) are

First layer: abductor digiti quinti, flexor digitorum brevis, abductor hallucis
Second layer: tendon of flexor hallucis longus, tendon flexor digitorum longus, four lumbricales, and quadratus plantae
Third layer: adductor hallucis, flexor hallucis brevis, flexor digiti minimi brevis
Fourth layer: three plantar and four dorsal interossei

Note that the tendon of the peroneus longus and tendon of the posterior tibialis muscles in the posterior half of the foot are close to this layer.

The plantar fascia, often discussed as an inflamed area in heel pain, consists of three separate compartments.

Medial fascia: encompasses abductor hallucis muscle
Central fascia: encompasses flexor digitorum brevis
Lateral fascia: encompasses abductor digiti minimi

The tarsal tunnel, located on the medial side of the ankle, is often implicated in impingement syndromes that can cause heel pain. The tarsal tunnel has four distinct canals that have the laciniate ligament (flexor retinaculum) as the roof and 2 septa that form the borders of the canals.

Canal 1: contains tibialis posterior muscle (primary function is to assist in plantar flexion and inversion of the foot)
Canal 2: contains flexor digitorum longus (assists in bending of the toes)
Canal 3: contains posterior tibial nerve (L4, L5, S1, S2, S3 nerve root) posterior tibial artery and vein
Canal 4: contains flexor hallucis longus muscle (responsible for great toe flexion and assists in push-off phase of gait; also assists in deceleration of forward motion of the tibia)

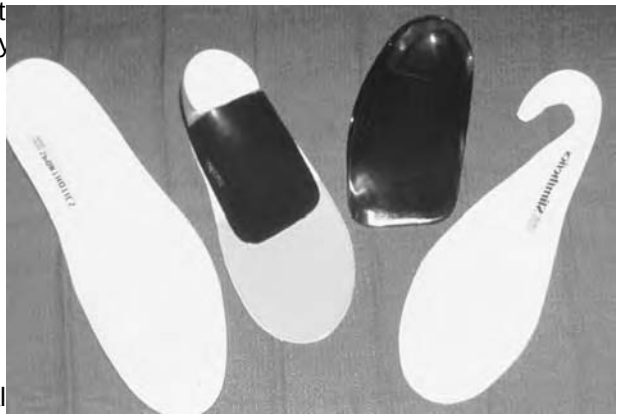

FIGURE 8.1 Different types of orthotics.

These four canal areas are prevented from bowstringing during standing and walking by the laciniate ligament (flexor retinaculum). The medial calcaneal nerve, a branch from the posterior tibial nerve, is noted to pierce through the laciniate ligament and give sensory innervation to the medial side of the heel.

PLANTAR FASCIITIS

Plantar fasciitis may perhaps be the most common heel problem presenting to the clinician. It is often associated with repetitive stress injuries and is not usually the result of direct trauma. It is a soft tissue problem that can be present for years (to some degree) before the patient seeks any type of treatment. Heel spurs can be present on radiograph without symptoms of plantar fasciitis.

Poststatic dyskinesia is often noted. Pain occurs with great intensity when the patient arises from a resting posture or from sleep. Pain is noted to diminish with activity; however, as the course of the day progresses, pain can be seen to increase. The greatest pain is noted after rest.

Inflammation can be detected at any area of the plantar fascial areas, but it is most commonly noted at the medial calcaneal tubercle attachments of the fascia onto the heel. This bony prominence serves as the point of origin of the anatomic central band of the plantar fascia, and the abductor hallucis, flexor digitorum brevis, and abductor digiti minimi muscles. Pain is generally elicited with deep palpation directly in front of the medial tubercle. Pain is also greatest at the push-off phase of gait when the already inflamed fascia is stressed and stretched as the forefoot begins to accept more body weight.

It is important to remember that the plantar fascia assists in maintaining the arch height of the foot; it connects the heel to the forefoot. With pathology present, the medial longitudinal arch of the foot can flatten. Passive toe extension with the ankle in full dorsiflexion and the knee in extension can elicit pain at the heel.

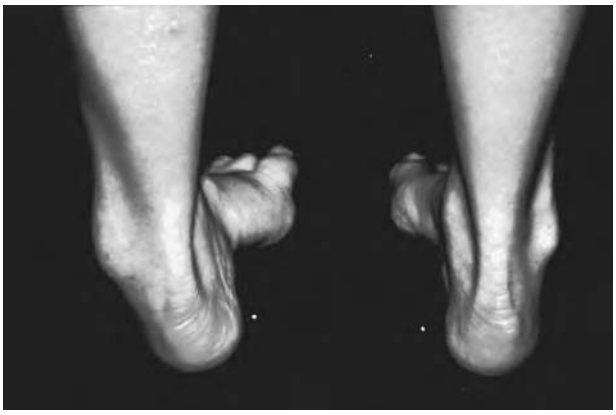

FIGURE 8.2 Cavus foot (high arch).

FIGURE 8.3 Pronated foot (low arch).

Pain from plantar fasciitis can be noted to increase when there is a decrease in the flexibility of the gastro-soleus (triceps surae) complex at the calf area. The triceps surae sends a slip of attachment to the plantar fascia. However, remember that when the plantar fascia is stretched, inversion of the heel occurs to a slight degree. Peroneal musculature (evertors) can be involved. Evaluation cannot always be contained to the heel itself. Musculature attachments to the heel and around the heel must be assessed.

One method to assess for calf tightness is to apply a heel lift that does not compress to less than 1/2 to 1 in. If the plantar heel pain eases, then calf tightness must be addressed in the process of eliminating heel pain. If calf tightness is noted, it is best to stretch the Achilles tendon bilaterally. The stretch should be done with the subtalar joint of the foot in neutral position. This helps maximize the stretch of the Achilles tendon. All stretches should be done as static holds, no bouncing. If heel lifts are needed, then the lifts should be worn in both shoes to reduce the risk of back pain until the flexibility of the gastro-soleus complex is restored.

Comment: When bouncing instead of static stretches is done during exercise, shortening rather than lengthening of the muscle is apt to occur. This shortening may cause a secondary Achilles tendonitis.

Plantar fasciitis can occur in either a supinated (cavus, high-arch type of foot) or in a pronated (low-arch) type of foot. In pronation, the talus plantarflexes and adducts while the calcaneus everts. A cavus-type of foot is noted to be inherently more rigid. This foot type may require extra cushioning for relief of heel pain. A planus-type of foot is generally quite flexible. Patients with this foot type may only require a heel lift for care. Note that a hint for balance is to assess the foot with the subtalar joint in neutral position and the midtarsal joint maximally pronated. Either foot type can respond nicely with the use of a mechanically balanced custom-made orthotic to control subtalar joint motion.

In the early stages of treatment, a foot strapping to lock the first ray and transfer pressure away from the fascia and onto the tendons and toes may help relieve pain. It is not uncommon to find scar tissue formation on the medial side of the heel due to repetitive stress in an unbalanced foot. Lateral shift of the infracalcaneal fat pad and atrophy of the infracalcaneal fat pad can occur. A heel cup may eliminate lateral shift and a heel lift may assist in cushioning the foot. Scar tissue may be eradicated with deep soft tissue massage and fascial release therapy.

HEEL SPUR SYNDROME

Infracalcaneal pain (heel spur syndrome) can occur if plantar fasciitis progresses and microtears of the proximal fascia occur at the calcaneal attachments. Low-grade periostitis occurs along with thickening in the area of trauma. Edema and fibroblastic inflammatory cell infiltration can also occur. Periosteal calcification occurs near fascial and tendonous attachments. The infracalcaneal heel spur forms in this manner. A "traction" type of spur from excessive pulling of the tissue is noted.

Lateral, oblique, and calcaneal axial X-rays of the foot are helpful to assess heel pain. However, for infracalcaneal

FIGURE 8.4 Infracalcaneal heel spur.

spurs, the lateral X-ray view often yields the most information as to the type and extent of spurring. Direct bony alignment of the foot can also be a contributing factor to heel spur formation.

Pain presentation is very similar to that of plantar fasciitis. Etiology can be overuse, excess weight in a pronated or supinated foot type. Conservative treatment is the same as in plantar fasciitis. The physical therapy modalities of iontophoresis and phonophoresis and electrical stimulation may be of great help to reduce inflammation.

Note that not all infracalcaneal spurs are symptomatic. Occasionally if the foot is well compensated, an infracalcaneal spur can be an incidental finding on X-ray examination.

Special attention to the thickness of the infracalcaneal fat pad is needed to assist in pain relief. Soft shoes with a long medial counter for cushioning and shock absorption may be helpful. Medial longitudinal arch support may also assist in easing inflammation.

HAGLUND DEFORMITY

Synonyms for Haglund deformity include pump bump (from female high heel shoes) and retrocalcaneal bursitis. This bony problem is often confused with Achilles tendonitis or bursitis.

This condition can occur in patients with a prominent posterosuperior aspect of the calcaneus who wear tight, rigid counter shoes. It refers to the part of the shoe that "cups the heel" and gives the heel stability in the shoes. The lateral X-ray view of the foot helps to assess this problem. In this entity, the counter of the shoe rubs the heel and causes pain and further enlargement of the posterosuperior aspect of the calcaneus. Clinically, the examiner should view the posterior aspect of the heels with the patient standing. The bulge is quite evident and is seen lateral to the Achilles tendon.

FIGURE 8.5 Haglund deformity. Note enlargement of the posterosuperior area of the calcaneus.

Pain symptoms are generally reported as dull aching at the posterior aspect of the heel, lateral to the attachment of the tendon Achilles. The pain is greatest when the foot is dorsiflexed. A possible etiology for this pain is the pinching of the retrocalcaneal bursal sac between the Achilles tendon and the heel. An adventitious (not an anatomically correct) bursal sac can form at the superficial surface of the Achilles tendon, which can further enhance pain.

Conservative treatment for this problem includes rest, soft heel lifts, and nonsteroidal anti-inflammatory medication or drug, NSAID, occasional removal of the posterior aspect of the heel counter, or open back shoes. Heel lifts of 1/2 to 3/8 in. are used to raise the point of heel irritation just superior to the counter of the shoes. Ice massage may also help. If conservative care fails, then removal of the inflamed bursal sac and partial calcaneal exostectomy or calcaneal osteotomy may be required.

Some clinicians may advocate steroid injection into the bursal sac only; however, this must be done with great caution and skill. If steroid is inadvertently placed into the Achilles tendon, spontaneous rupture of the tendon can occur.

RETROCALCANEAL EXOSTOSIS/ACHILLES TENDON CALCIFICATION

In this malady, heel spur or calcification is noted at the insertion of the Achilles tendon onto the posterior aspect of the heel or within the tendon itself. This problem can be isolated or can be found in combination with retrocalcaneal bursitis of Achilles tendonitis. The Achilles tendon itself can become thick and wide; lateral radiographs reveal calcification in the Achilles tendon.

Pain symptoms include dull aching, especially near the insertion of the Achilles tendon onto the heel. Pain

FIGURE 8.6 Retrocalcaneal and infracalcaneal spur.

FIGURE 8.6A Note calcification in the Achilles tendon.

FIGURE 8.7 Achilles tendonitis.

frequently occurs in the patient who is involved in athletics or dancing activities due to the active or passive range of motion of the ankle as well as with direct palpation of the area. Slightly less dorsiflexion of the involved ankle can be noted due to bony block and crepitation of the tendon. Crepitation can occur due to chronic inflammation and fibrous deposition throughout the tendon.

Conservative care consists of rest and modality care with great emphasis placed on stretches of the triceps surae. Ice can also decrease edema and decrease post-static dyskinesia. Surgical exostectomy can require splitting of the Achilles tendon or detaching the Achilles tendon from the heel to gain exposure of the retrocalcaneal spur. The muscle does tend to lose strength with this type of radical approach.

ACHILLES TENDONITIS

Tendon disabilities can be caused by irritation around a tendon sheath (paratenosynovitis), pathology of the sheath itself (tenosynovitis), lesions between the sheath and the tendon (such as lipoma), and lesions within the tendon itself (tenosynovitis). Peritendonitis is a term used to describe inflammation of a tendon with or without a sheath. The Achilles tendon is the largest and strongest tendon in the body.

Tendonitis is an inflammation of the tendon itself generally caused from repetitive stress experienced by athletes, dancers, and jumpers. Tendonitis crepitans can be noted due to chronic inflammation of the area.

Tendons, in general, receive blood supply from four areas: muscles, bone, paratenon, and mesotenon. The Achilles tendon has little supply from bone or muscle; much of its blood supply comes from the paratenon.

Achilles tendonitis is generally noted to be posterior on the heel with great tenderness noted approximately 3 cm proximal to the insertion of the Achilles tendon onto the heel. Pain is noted with dorsiflexion of the ankle due to tension on the heel cord itself. Tenderness can be associated with swelling, redness, and thickening of the tendon itself. In dancers, pain can be noted during landing just after a jump because the triceps surae is a decelerator of foot motion.

Treatment consists of longer warm-ups, use of heel lifts and flexibility training, cross-fiber massage, modalities, and nonsteroidal anti-inflammatories. Stretching is the key and can be done in several positions.

TARSAL TUNNEL SYNDROME

The tarsal tunnel is located on the medial side of the ankle. The roof of the tunnel is made up of the laciniate ligament. There are four distinct canals in the tarsal tunnel, which are formed by two individual septa. The contents of the canal are

FIGURE 8.8 Radiograph of planus foot type. Note sagging of midfoot.

Canal 1: posterior tibial muscle
Canal 2: flexor digitorum longus muscle
Canal 3: posterior tibial nerve (L4 L5 S1 S2 S3) artery and vein
Canal 4: flexor hallucis longus muscle

Tarsal tunnel syndrome is generally the compression or entrapment of the posterior tibial nerve as it courses under the laciniate ligament. The posterior tibial nerve divides into the medial and lateral plantar nerves and is responsible for great areas of sensory innervation in the foot. As a result, patients may not be able to pinpoint the source of pain, but may only describe general areas of pain located at the inferior region of the medial malleolus.

Pain with this syndrome is generally of gradual onset and is described as aching, burning, and unremitting. The triad of pain, paresthesia, and numbness are not uncommon with nerve injury. Pain is noted with weight bearing and with nonweight bearing. Pain can begin in the posterior aspect of the heel and can continue forward to just below the medial malleolus and into the toes themselves. A positive Tinel (pain radiation to toes) or Vallieux sign (pain radiation to calf) can be noted with percussion and compression of the posterior tibial nerve as it courses around the medial malleolus. An electromyogram may help to clinch the diagnosis.

Causes for tarsal tunnel syndrome include pronated (flat foot) that is decompensated, hypertrophy of the abductor hallucis longus muscle (causing nerve pressure), cysts of the nerve itself, or a poorly applied cast that incorporates the foot.

Differential diagnoses are many, including plantar fasciitis, medial calcaneal neuroma, digital plantar nerve entrapment, vascular disease, and lumbosacral radiculopathy.

FIGURE 8.9 Low-arch foot prior to orthotic care.

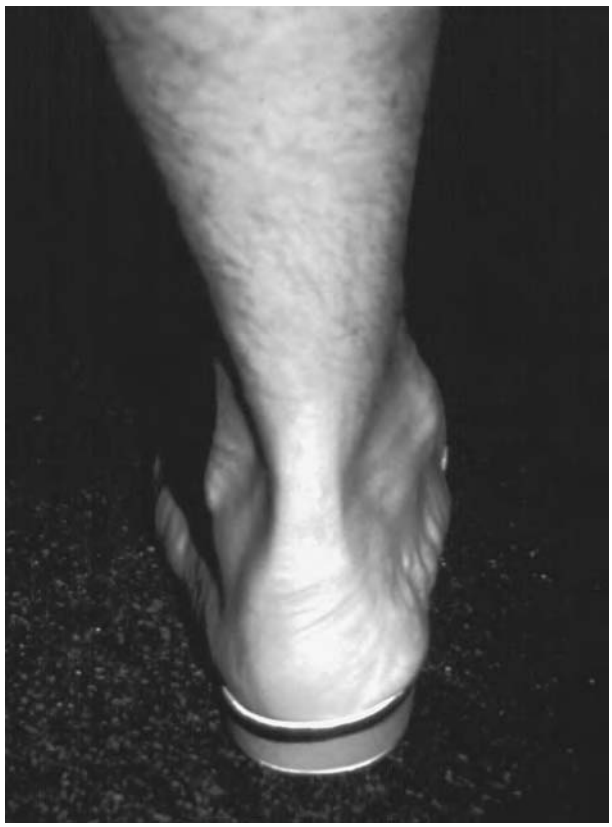

FIGURE 8.9A Low-arch foot with orthotic care. Note straighter position of Achilles tendon.

Conservative care of this lesion can include a medial longitudinal arch support, strapping, and control of the subtalar joint with a custom-made control orthotic. The goal is to control pronation. Medication and steroid injection can help in some cases when pathology is diagnosed early.

FLEXOR HALLUCIS LONGUS TENDONITIS

The flexor hallucis longus muscle assists in plantar flexion of the great toe. During the push-off phase of gait, the muscle locks the proximal phalanx of the great toe and assists in ease of weight distribution. This muscle helps decelerate the forward motion of the tibia onto a fixed foot. When tendonitis occurs here, it is generally the result of a mechanical disturbance. Overuse, other than direct trauma, is a common etiology. The patient complains of discomfort in the sole of the foot.

Tendon pain is not generally noted with passive stretch or dorsiflexion of the great toe. Pain is noted with local pressure at the point of pathology. On examination the flexor hallucis longus tendon stands out when the toe is passively dorsiflexed. Pain can occur the length of the tendon, but is more commonly noted at the proximal portion of the tendon. Tenderness is detected more superficial and distal to the area where heel spur tenderness is expected. The medial calcaneal tubercle is generally not tender.

Treatment for this lesion consists of soft sole shoes, modalities, and massage. A transverse archband may also help. Tendon injection with steroid medication is questionable and may cause tendon rupture.

It is hopeful that with therapeutic discussion of the prior pathologies, the practitioner may gain additional information for use in treatment of patients, or clients, with clinical heel pain.

Cervicogenic Processes: The Results of Injury

Alfred V. Anderson, M.D., D.C.

Injuries to the cervical spine present unique problems for the health care practitioner. This fragile stem between the body and the head is extremely vulnerable. As a result of injury, the spine develops processes to accommodate the mechanical and physiological changes that inherently take place due to such injury.

This chapter is based on the author/practitioner's experience over 30 years, applying a multidisciplinary approach to chronic, intractable pain. One of the first components was an exercise regimen.

Pain is currently defined as an unpleasant sensory/emotional experience related to tissue damage or described by the patient in such terms. Chronic noncancer pain (CNCP) is generally defined as pain lasting at least 6 months, more time than expected for tissue-to-tissue healing or the resolution of the underlying disease process. It may be due to a condition where there is ongoing nociception. Chronic noncancer pain is different than acute pain in both its presentation and pathophysiology.

Progress in basic science research is gradually discovering the biochemical and structural mechanism of peripheral and central sensitization that maintains chronic pain. Over the past several decades, the author has utilized this schematic of pain. Pain becomes the center of the patient's life producing inactivity, fatigue, anger, depression, and frustration (Figure 9.1). However, the most important aspect of this patient's life is function. Function is regained with the use of appropriate modalities, exercise, and, if necessary, medication to help the patient deal with the pain associated with increased activity.

There is a wide range of pain sensitivity, even with the same "objective" findings. Variations may be dependent on several factors including the patient's early experiences with pain. Even genetics may play a role in pain perception.

CERVICAL SYNDROMES

There are numerous cervical syndromes varying from developmental and congenital disorders to degenerative processes. Also included are conditions such as strain, sprains, subluxation, and chronic conditions such as fibromylagia.

CERVICAL ACCELERATION/DECELERATION: AN EXAMPLE

Cervical acceleration/deceleration (CAD) is an ideal condition to illustrate cervicogenic processes, because this type of injury and its sequelae involve almost all of the syndromes of the cervical spine.

The CAD pain patient is sometimes misled by myths that cause as much damage to the psyche as the physical injury. Myth: "The injury is simple strain and sprain, it will heal in 6 to 12 weeks." Fact: The sudden acceleration/deceleration injuries are six to ten times more likely to develop spondylosis or degenerative changes within the joints and disks leading to prolonged recovery time (Norris and Watts, 1983).

Myth: "Permanent injuries from sudden acceleration deceleration trauma are very rare." Fact: Approximately 40% have some persistent recurring pain; approximately 20% have pain that alters the quality of life (Taylor and Finch, 1993).

Myth: "The client had preexisting spinal degeneration; the pain is due to this rather than the accident." Fact: It is the experience of the author that patients can have degenerative changes occurring down through their life without any symptoms whatsoever. However, when subjected to trauma such as a sudden accelera-

0-8493-0926-3/02/$0.00+$1.50

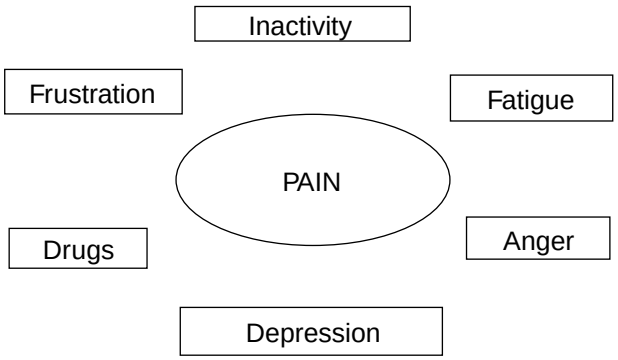

FIGURE 9.1 The results of pain.

tion/deceleration injury, these patients are predisposed to chronic pain.

ANATOMIC INJURIES

Anatomic injuries are addressed according to the intensity of the associated pain. Facet joints are now considered primary pain generators; they are subject to degeneration as well as capsular injury. The facets may undergo hypertrophy. They develop loss of articular cartilage, sclerosis, irregularity, and osteophytes; and these alterations take place over a number of years following trauma.

Symptoms

The facet joints are supplied with proprioceptive fibers; when these are traumatized, they tend to deliver signals to the brain that can confuse the brain's perception of visual and vestibular input. This condition is referred to as cervicogenic vertigo and is related to symptoms of unsteadiness that patients may describe as "standing in a rocky boat". Fractures of the facets can also lead to substantial changes in the mechanical function of the joint.

Case of facet injury —A 32-year-old male, wearing a seat belt, was hit from the left at approximately 30 mi/h by a car running a stoplight. He suffered immediate pain in the cervical spine with painful range of motion. He was taken to an emergency room on a backboard; evaluations were done, including X-ray studies in which a fracture was suspected. Approximately 2 weeks later, a magnetic resonance imaging (MRI) scan was done, which did reveal a facet fracture. The patient was immobilized with a Philadelphia collar for approximately 6 weeks. A good union was obtained. However, the pain persisted in the cervical spine with radiating pain into the base of the skull as well as localized pain at the lower part of the neck. A facet nerve injection was done that substantially reduced the symptoms. As a result of this procedure, the patient elected to have a radiofrequency rhizotomy performed. This substantially reduced the pain complex. He was followed for 6 months with good results.

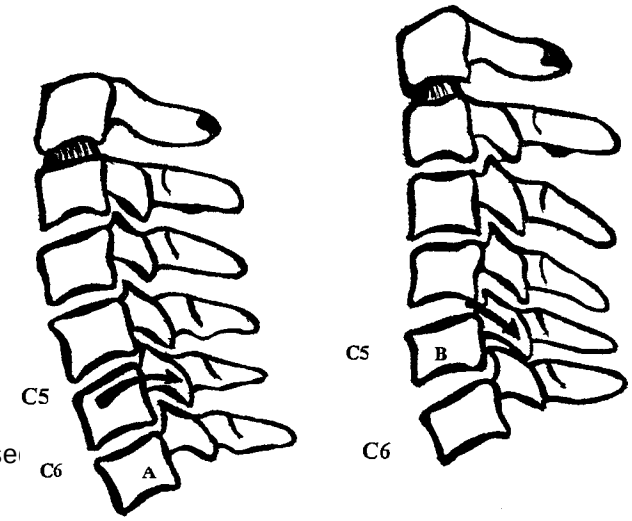

FIGURE 9.2 A, normal axis of movements of C5 on C6; B, change of axis and sudden acceleration/deceleration (SAD).

When the cervical spine incurs acceleration/deceleration injury, there is a substantial alteration of the mechanics of the spine. Studies by Ono, Daneoka, Wittek, and Kajzer (1997) and Croft (2000) have shown that there is an instantaneous change in the axis of extension of C5 on C6. The pivot point of extension normally is in the upper vertebral body of C6 (Figure 9.2). During a sudden acceleration/deceleration injury, the pivot point moves up to the lower portion of the vertebral body of C5, causing a crushing type of impact to occur with the facets of C5 onto the superior articulating surface of C6. This research shows that in a low impact accident of 6 mi/h, the spine obtains an "S" configuration with hyperflexion of the upper cervical spine and hyperextension of the lower cervical spine, particularly C5. The studies done by Ono and associates show that in low impact accidents the neck rarely exceeds the normal limits of range of motion; however, the substantial change in the force factors applied to the facets results in significant injury.

Bogduk and Marsland (1988) have estimated that about 60% of acceleration/deceleration injuries have their origins in the facet joints. Autopsies of persons subjected to acceleration/deceleration trauma who subsequently died of unrelated causes showed that significant trauma had occurred around the facet joints, which may not have been detectable by MRI scans. New diagnostic and treatment procedures such as facet nerve injections and radiofrequency rhizotomies have been shown to be effective in reducing the pain complex originating from facet joint injuries. Unfortunately, the hypertrophy occurring after trauma to the facet joints also adds to the possibility of stenosis in which the intervertebral foramina become narrowed, compressing the nerve root.

In chronic cases where bleeding or trauma occurs around the nerve root, fibrosis can develop following this hemorrhage, producing adhesions between the nerve and the spinal ligaments. MRI scans can detect this as perineuronal fibrosis (Seletz, 1958).

Invertebral Disk

Just opposite the nerve root is the intervertebral disk. In a sudden acceleration/deceleration injury the intervertebral disk at C5 to C6 is subjected to a significant shear force, causing disruption and tearing of the annular fibers. These fibers support one vertebra to the next and also retain the normal configuration of the nucleus pulposus.

There are, however, many cases in which the findings of the examination do not specifically correlate with the MRI studies. Schellhas, Smith, Gundry, and Pollei (1996) published a study relative to prospective correlation of MRI and discography in asymptomatic subjects as well as pain sufferers. Their conclusion showed that significant cervical disk annular tears often escape MRI detection and that MRI cannot reliably identify the sources of cervical discogenic pain. Clinical indications for cervical discography includes cases of chronic neck pain, head pain, or radicular pain. Discography should also be considered where normal, equivocal, or contradictory lateralizing pain complaints exist.

Freeman (1997) showed that damage to intervertebral disk results in infiltration of pain fibers into the inner third of the anulus fibrosus and into the nucleus pulposus. These findings tend to further validate the disk as a pain generator in chronic spine pain.

Although Freeman's (1997) studies were done primarily on low back pain patients, it certainly would seem feasible that this information could be extrapolated to the cervical spine as well. His findings of isolated nerve fibers that express substance P (an excitatory amino acid) deep within deceased intervertebral disks and their association with pain suggests that nerve growth into the intervertebral disk may play a role in the pathogenesis of low back pain.

Ligaments

Ligamentous injury is another result of sudden acceleration/deceleration. In a 15-mi/h collision, the head would accelerate with a force of 10 g (Macnab, 1964).

A 24-year-old female was seatbelted when hit from behind at approximately 15 mi/h. She was looking up and to the right. Following the accident she had severe neck pain with headaches. She was taken to the emergency room; X-rays were taken and she was released. Two weeks later an examination showed a normal neurological function with the exception of dizziness on range of motion testing. She had substantial loss of flexion with point tenderness at T1 through T3. A MRI scan of the cervical spine showed interspinous tearing at C7 to T1 and T1 to T2. A later study of the 24-year-old female showed a herniated disk at the C5 to C6 and C6 to C7 level.

When disk injury occurs in the upper three to four segments of the spine, it is not unusual for headaches to arise from these areas. However, many patients who have had successful disk surgery at the C4-5 and C5-6 levels report significant relief from cervicogenic headaches.

Headaches are common to persons suffering from sudden acceleration/deceleration injuries. The headaches can result from injury to the facet structures as well as the other pain generators of the cervical spine disks. Some authorities have suggested that muscle-contracture headache diagnoses be replaced with cervicogenic headache diagnoses in the posttrauma victims. A cervicogenic headache diagnosis seems feasible considering the pain associations relating to facets and disks. Persons with prior headaches are going to be predisposed to exacerbated pain following a sudden acceleration/deceleration injury.

Muscles

Various muscles have been implicated in headaches. Hack, Koritzer, Robinson, Hallgren, and Greenman (1995) described the rectus capitis posterior minor muscle, in which there is a connective bridge between this muscle and the dorsal spinal dura at the atlano-occipital junction. This was observed in every muscle specimen examined. Other muscles involved in cervicogenic headaches include all the suboccipital muscles as well as the upper trapezius and levator scapulae. After significant trauma, trigger points found in these muscle structures typically refer pain to the head. Patients respond well to trigger point injections, massage therapy, and stretching exercises. Acupuncture, manipulation, and other modalities have also been useful in controlling the pain of cervicogenic headaches.

A common sequel to the process of tissue repair is the development of inflammation of the muscle and fascia, commonly referred to as myofaciitis. Characteristic of myofaciitis is the presence of small sensitive nodes (trigger points), which are in the fascial sheath. Trigger points are painful hypersensitive areas within the muscle or its associative supportive tissue (fascia). Normal muscles do not contain trigger points, they do not have taut bands of muscle fibers, they are not tender to firm palpation, they do not exhibit local twitch responses, and they do not refer pain in response to applied pressure (Travell and Simons, 1992).

If the head and neck were subjected to impacts exceeding 10 to 15 mi/h, it would seem logical that muscle and ligaments would be injured, thereby generating the conditions described by Travell and Simons (1992). She describes the fibrous bands, containing trigger points,

which again are considered pain generators. Pain management specialists have treated these conditions for years with good results.

Spinal Cord

Other research currently underway shows that physiological changes within the spinal cord, particularly the dorsal horn of the spine are associated with pain. Excitatory amino acids such as substance P, glutamate, gamma aminobutyric acid (GABA), N-methyl-D-asparte (NMDA), and other factors that sensitize the dorsal horn, are implicated in pain. Much of current research emphasizes medication that modifies the activities of these substances. An ongoing study at the University of Minnesota has demonstrated that labeled substance P normally affects the tip of the dorsal horn. However, in the study of rats subjected to lengthy periods of pain, substance P was found to migrate deeper into the dorsal horn. At the time of this publication, it is postulated that if this phenomenon continues over a period of time that a permanent alteration in the physiology of the dorsal horn may occur. Many more studies are being done concerning the hypersensitivity of the dorsal horn.

FACTORS INFLUENCING PROGNOSIS OF INJURIES

Factors influencing the prognosis of an individual include symptoms that have lasted over 6 months. As pointed out by Loeser (2000), chronic pain is different from acute pain in that measures that provide only transient pain relief do not lead to resolution of the underlying pathological process. Loeser goes on to point out that injuries to the nervous system, either because of direct trauma or because of alterations related to massive input, may lead to chronic pain. Noxious stimuli can lead to changes within the peripheral and central nervous system that alter the spinal cord, particularly the dorsal horn.

If disk injury, nerve trauma, or specific joint injury are involved, the chances of total resolution of the pain complex are significantly reduced. In this respect, older individuals, who have progressive degeneration, typically have a more difficult time in recovery due to changes within the structure of the spine, which predisposes them to additional injury when they are subjected to further trauma (Ameis, 1986).

Some elements of the trauma incident contribute to the type and severity of injury. If an individual is in a small car, hit by a large car, the impact and the forces involved probably cause more damage to the individuals occupying the smaller car.

Other risk factors involved that increase a person's chances of substantial damage would include having the head turned to one side or the chin elevated slightly such as an individual looking in the rearview mirror at the time of impact (Havsy, 1994).

How a person sits in the car is also a decisive factor in the amount of damage resulting from a collision. If a person slouches with the head tilted somewhat forward, increasing the distance between the head and the headrest, a greater stress on the cervical vertebral would occur with a rear-end collision.

Shoulder harnesses, although proven to be life-saving devices, have contributed to increased numbers of neck injuries. The shoulder belt holds the torso in place, allowing the head and neck to move forward in a much smaller arc than is allowed without the shoulder belt. A shorter radius and the chin colliding with the chest produce more damage to the structures of the neck and temporomandibular joint.

TREATMENTS

Treatments for the various conditions that are described earlier were derived from the basic premise of exercise. Exercise, however, is sometimes intolerable to patients with moderate to severe pain. Therefore, the judicious use of adjunctive medication is recommended to help the patient through the initial phases of an exercise program. Medication gives the patient confidence to proceed with exercise as well as control of the increased pain brought on by stressing the various anatomic structures.

Biofeedback

Biofeedback has been helpful in controlling stress factors involved with pain. This technique also offers the patient a method of relaxing neck muscles when they are tending toward stages of spasm. Biofeedback is especially useful in the treatment of headaches resulting from the sequelae of cervical spine injuries. Patients learn to focus on the suboccipital muscles, the muscles of the temporomandibular joints, and as has been recently discovered, the rectus capitis posterior minor muscles.

Chiropractic Manipulation

Chiropractic manipulation has long been effective in treating neck injuries. Manipulation of traumatized joint structures increases range of motion for damaged facet structures. Kirkaldy-Willis, et al. (1985) studied the phenomenon of manipulation and found that therapeutic effects of manipulation involved breaking interarticular adhesions, freeing the fixated joint, and stretching the supporting muscles. It is his opinion that manipulation also tends to widen and improve the opening of the foramina, thereby reducing irritation to a potentially entrapped nerve. He is also of the opinion that stimulating the joint mechanoreceptors relieves pain. The stimulation of joint mechanoreceptors tends to

override the pain impulses at the dorsal horn. For example, if one hits a thumb with a hammer, the first impulse is to shake the hand and fingers. It is postulated that this tends to stimulate the joint mechanoreceptors, thereby overriding the pain impulses at the dorsal horn. This is, of course, also the concept in mobilizing the joints with exercise. Vernon, et al. (1986) also postulated that there is an increase in endorphins released after spinal manipulation.

Trigger Point Injections

Trigger point injections as advocated by Travell, have been used for years by this author; the techniques and results are well documented in other chapters of this text.

Others

Currently, other treatments, modalities, and systems that are implemented, include facet nerve injections, facet nerve rhizotomies, occipital nerve rhizotomies, and intradiscal electrothermy (IDET). Many of these treatments are reviewed in other chapters.

Future pain management will probably include new medications affecting the physiology of dorsal horn, medications such as COX 2 inhibitors to assist in reducing inflammatory processes, and other pharmaceuticals to modify the transmission of pain. The use of light and sound brain entrainment formerly known as evoked potentials may also prove helpful.

The author advocates the use of any treatment helpful in the care of an individual patient. After 30 years of practice it has become obvious that treatment plans must be individualized. Treatment must be geared toward increased function as well as decreased pain. When utilizing medication, the World Health Organization (WHO) criteria are appropriate and should be followed as closely as possible. This protocol starts the patients on adjunctive medication that might include antidepressants, anti-inflammatories, as well as dietary modifications and vitamin therapy. Cessation of tobacco use should be encouraged.

The next step is the prescribing of a narcotic, as well as exercise instruction to enhance overall function of the patient. The practitioner should not be fearful of including the more potent narcotics when necessary. Responses vary from patient to patient and each patient may respond differently to variations in dosages and/or types of drugs. Although one patient may respond very well to one type of narcotic, another patient may not. There is no formulary or predictive element involved in the selection of a specific narcotic for a particular patient. Judicious use of narcotics should be maintained; but the practitioner must keep in mind the variations in tolerance from one patient to the next. When chronic opioid analgesic therapy (COAT) is employed, both the patient and the doctor must sign an informed consent narcotic agreement. Examples of these narcotic agreements are available in other chapters of this text.

Prior to starting advanced medication, priorities must be placed on increasing the patient's overall capacity for exercise, emphasizing increased function as the primary goal. Medication cannot be justified on a long-term basis if the patient is not showing some indication of increasing function. In severe cases, this may only mean regaining and maintaining the ability to perform the activities of daily living or sustaining the will to live it.

Many authors have defined pain down through the years. It is this author's opinion that Dr. Janet Travell defines pain in the most accurate terms. "Pain is what the patient says it is."

Thyroid and Parathyroid Diseases and Pain

Stuart A. Dorow, M.D., D.C., Ph.D. and Gretajo Northrop, M.D., Ph.D.

INTRODUCTION

In the current medical arena, pain is often the most important indicator of the nature and seat of disease. It frequently signals an interruption of the harmony of the bodily organs; and many physicians insist most strenuously that the distinctive characteristics of the various kinds of pain be described as accurately as possible by the patient. Pain presenting as a throbbing sensation synchronous with the heart's action is called pulsating pain. Pain described as a feeling of tightness is referred to as tensive and when combined with heat, it is called burning. On the other hand, nervous pain may be recognized by its disposition to follow a certain course, without being rigidly limited to one particular part; by its subjection to perfect intermissions; and by the suddenness with which it comes and goes. Spasmodic pain is mitigated by pressure, by frictions, and by applications of heat; it presents suddenly with greater or lesser severity, terminating abruptly. Pain that is deemed inflammatory is constant, is attended by heat and quickened pulse, is increased by movement of the affected part, by touch, or pressure, and is usually relieved by rest. Frequently, pain occurs not in the diseased part but in a distant one and this manifestation is well known as referred pain. This is all very tidy and lends itself well by extrapolation to the Fox equation, which holds that "Germ X = disease X, germ Y = disease Y" (Fox & Fox, 1992). However, as that educator and countless others have discovered, this model fails in regard to that all-too-frequently illusive pain. A pain that defies labeling by any of the preceding definitions is, in every way, equally as debilitating. Is it merely psycogenic or some supratentorial phenomenon? Thus, some rethinking of the concepts involving pain may be required, particularly the pain resulting from thyroid and parathyroid diseases.

THYROID AND PARATHYROIDS IN HEALTH

The thyroid located just below the larynx is composed of left and right lateral lobes that lie on either side of the trachea. Both lobes are connected in the midline by a mass of tissue known as an isthmus and the entire structure is in front of the trachea just inferior to cricoid cartilage. When present, there is an additional projection, which extends cephalad from its attachment at the isthmus and is known as the pyramidal lobe. This endocrine gland weighs approximately 25 g and is profused by approximately 80 to 120 ml of blood per minute. The thyroid gland has a unique configuration histologically. It is composed of spherical sacks known as thyroid follicles with the walls of each sack consisting of cells that project into the lumen of the follicle and another layer of cells that does not. Cells in contact with the lumen area are called follicular cells whereas those not in contact are called C cells or parafollicular cells. When actively secreting hormones, the cells take on a columnar appearance and when not in an active state, they appear cuboidal in shape.

Follicular cells synthesize and liberate the substance known as thyroxine, or T4, by a process known as iodination, and the coupling of two tyrosine molecules while attached to a complex protein called thyroglobulin. T4 signifies that thyroxine contains four atoms of iodine. Triiodothyronine, or T3, is synthesized as well in the colloid and contains three iodine atoms. Collectively, these two hormones comprise the thyroid hormones. Thyroxine is present in greater quantity, whereas T3 is several times more potent and is formed in peripheral tissues such as the liver and kidneys as well as in most other cells by the deiodination of T4. Reverse T3 is biologically inactive and

0-8493-0926-3/02/$0.00+$1.50

is the metabolized form of T4. It is, however, the active form of T3 that binds to receptor sites and thus triggers end-organ effects. Functionally, both T3 and T4 are similar because they regulate metabolism, growth, and development, as well as the activity of the nervous system. Parafollicular C cells are not without their own manufacturing plant where they synthesize and secrete calcitonin, a compound that serves to lower the blood levels of calcium by its action on bones to increase absorption.

Clearly, thyroid cells can be seen to have three actions: the collection and transport of iodine, the synthesis of thyroglobulin for its secretion into the colloid, and the removal of the thyroid hormones from thyroglobulin for secretion into circulation (Ganong, 1989).

The parathyroid glands, four in number, are embedded in the four poles of the thyroid gland. There are two superior and two inferior glands located on the thyroid gland. These measure about the size of the tip of a small child's little finger. From the perspective of histology, two types of cells are represented, and are epithelial in nature. The chief cells, or principal cells, synthesize parathyroid hormone (PTH) and are the most numerous. PTH is released in response to a fall in extracellular ionized calcium. PTH is carried by the blood to the kidney where it causes calcium reabsorption and conversion of 25-hydroxy-vitamin D_3 to 1,25-dihydroxy vitamin D_3. This metabolite increases intestinal absorption of calcium and with PTH causes bone reabsorption of calcium. These are only a few of the actions of PTH. At different concentrations of PTH, action on target tissues may differ. Low levels of PTH result in skeletal anabolic action, whereas high levels of PTH may result in bone lysis. The remaining cells are called oxyphils and are believed to manufacture a reserve supply of PTH.

HORMONAL REGULATION

The thyroid and parathyroid glands never sleep because their role in active metabolism prohibits it. Thyroid hormones are essential for the normal maturation and metabolism of all bodily tissues. The effects of thyroid hormones on metabolism are, needless to say, diverse. Thyroid hormonal effects can be seen in their calorigenic action where T3 and T4 increase the oxygen consumption of almost all metabolically active tissues with the exception of the adult brain, testis, uterus, lymph nodes, spleen, and anterior pituitary. Nervous system effects can be seen centrally as well as in the peripheral nervous system. The effects on skeletal muscle become apparent in the patient with hyperthyroidism (thyrotoxic myopathy). Most of these patients demonstrate marked muscle weakness. Beta-adrenergic receptors on the heart are increased in number and affinity due to thyroid hormones. The increase in the number of receptors and their effect on the heart resembles the action of beta-adrenergic stimulation.

It is a well-known fact that thyroid hormones increase the rate of absorption of carbohydrate from the gastrointestinal tract, albeit most likely independently of any calorigenic action. In hyperthyroid patients, the blood glucose level can be seen to rapidly rise after a carbohydrate meal, often exceeding the renal threshold and subsequently fall just as rapidly. A topic that takes a prominent place in conversations today is cholesterol levels. The thyroid hormones are not without their effect on cholesterol levels because they have been shown to lower circulating cholesterol. The level of plasma cholesterol decreases prior to the metabolic rate rising and this action indicates that it may be independent of stimulation of oxygen consumption as well. Normal growth, development, and skeletal maturation are, in large measure, dependent on the thyroid hormones. Nowhere is this more evident than in a child who is hypothyroid and in whom bone growth is retarded and epiphyseal closure is delayed. The list of effects of the thyroid hormones on bodily tissues appears to be endless and those discussed here represent only a few of them.

The regulation of secretion of thyroid hormones can be seen in the hypothalamic–pituitary–thyroid axis where the tripeptide thyroid-releasing hormone (TRH) is secreted by the hypothalamus and triggers synthesis of a glycoprotein hormone, thyroid-stimulating hormone (TSH), from the anterior pituitary. TSH secretion sets in motion the synthesis of thyroid hormones T3 and T4. In turn, TSH production is regulated by feedback from circulating, unbound thyroid hormones (free T3 and T4). In the investigation of patients with thyroid disease, an understanding of these basics is essential for accurate interpretation of test results.

THYROID AND PARATHYROIDS IN DISEASE

Hyperthyroidism and hypothyroidism are fairly well-known disease entities, with the former being exposure of the tissues to exorbitant amounts of thyroid hormones, and the latter a paucity of those hormones. In the purest sense, for one to be hyperthyroid, there must be an overactivity of the thyroid gland itself, but thyrotoxicosis can manifest itself with ingestion of excess T4. In some cases, overstimulation of the thyroid by pituitary TSH can occur, although this is considered rare. Many factors enter into the differential diagnosis of hyperthyroidism, including overingestion of T4 as previously mentioned. Drugs frequently can be ingested and classified as goitrogens (goiter-producing agents), such as the antithyroid agents propylthiouracil (PTU), carbimazole, and methimazol (Adler, et al., 1988). Amiodarone drops have been shown to precipitate hyperthyroidism (Gaw, et al., 1995, p. 84). In addition, p-aminosalicylic acid (PAS), sulfonamides, amphenone, phenylbutazone, iodides, lithium carbonate,

and cobalt have been indicated in diffuse goiter formation (Murphy, 1988, p. 107). An often-overlooked common source of iodine ingestion, which may be seasonal, but nevertheless can be taken in excess is expectorants (Hopate, et al., 1996, p. 542). Among the more innocuous appearing agents in goiter formation are soy milk/flour, turnips, cabbage, brussels sprouts, and rutabagas, to mention a few. Causative agents identified here should not, by any means, be construed as all-inclusive. Multinodular goiters can be of the nodular hyperplastic type or adenomas, which are multiple. Benign adenomas, colloid nodules, thyroglossal duct cyst, granulomatous disease, lobulations of the thyroid, and hematomas comprise a miscellaneous group of solitary nodules. Malignancies such as lymphoma, anaplastic carcinoma, follicular carcinoma, medullary carcinoma (or a combination of follicular/papillary, papillary carcinoma, and metastatic disease) may also fall under the solitary classification (Burrow, 1987, p. 474).

According to Ingbar and Braverman (1986, p. 809), thyrotoxicosis or hyperthyroidism may manifest with either elevated or normal blood levels of T3 or T4. Euthyroid Graves'disease is diagnosed when blood levels of T4 and T3 are normal yet the patient has the thickened extraocular muscles associated with Graves'disease. Graves'disease is an autoimmune disease in which antibodies stimulate thyroid release from the gland. In addition, human chorionic gonadotropin (HCG) secreting tumors such as choriocarcinoma, hydatidiform moles, and testicular embryonal cell carcinomas can stimulate the thyroid gland abnormally. In cases of thyrotoxicosis without hyperthyroidism, as evidenced by a suppressed TSH in the TRH test, extrathyroidal sources of hormone such as iatrogenic or factitious ingestion may be suspect. Jod–Basedow disease is an iodine-induced source of thyrotoxicosis demonstrating reduced radioactive iodine uptake (RAIU).

Thyroiditis is considered a group of inflammatory thyroid disorders that may present as thyrotoxicosis without hyperthyroidism. This group is composed of subacute thyroiditis in either its "silent" (nonpainful) form, known as subacute lymphocytic thyroiditis, or its alternative "painful" form, known as giant cell thyroiditis (collectively referred to as simply subacute thyroiditis). However, the granulomatous form appears to be the most common cause of thyroid gland pain. Postpartum thyroiditis may evolve as hyper-, hypo-, or euthyroidism. Present thoughts are that pregnancy decreases immunologic responses whereas during the postpartum there is a "rebound effect" usually resulting in hyperthyroidism. Granulomatous thyroiditis has been known to follow upper respiratory infections of adenovirus, Epstein-Barr virus, echovirus, mumps virus, and coxsackie virus (Farwell & Brauerman, 1996). According to Bonica (1990, pp. 864–865), symptoms usually follow those of a respiratory infection as stated and include pronounced malaise and asthenia, as well as symptoms referable to stretching of the thyroid capsule, principally pain over the thyroid or pain referred to the lower jaw, ear, or occiput. Local or referred pain can predominate. Less commonly, the onset is acute, with severe pain over the thyroid accompanied by fever and occasionally by symptoms of thyrotoxicosis. Cardinal physical findings include exquisite tenderness and pain on palpation of the nodular thyroid.

Other types of thyroiditis include chronic lymphocytic thyroiditis (typically referred to as Hashimoto's thyroiditis). This disease has also been referred to as struma lymphomatosa and was first described by the Japanese surgeon H. Hashimoto who wrote his M.D. thesis on struma lymphomatosa (Firkin & Whitworth, 1990, p. 444). In the United States, it is the most common cause of goiter production, as well as the most common inflammatory thyroid gland condition (Hay, 1985; Hamburger, 1986). Dayan and Daniels (1996) indicate that lymphoma of the thyroid can be a complication of this disease but fortunately does not occur with great frequency. Several Type III autoimmune hypersensitivity reactions such as Sjogren's syndrome, rheumatoid arthritis, and systemic lupus erythematosus (SLE) have been associated with chronic lymphocytic thyroiditis. Diabetes mellitus and pernicious anemia have also been associated with chronic lymphocytic thyroiditis (Dayan & Daniels, 1996).

Acute supportive thyroiditis is an inflammatory condition resulting from invasion of the thyroid gland by Staphylococcus aureus or other Gram-positive organisms. It is reported that *S. aureus* is the most common invader (Dayan & Daniels, 1996). Patients may present with neck pain and/or tenderness, which appears localized to the thyroid gland. Pain associated with supportive thyroiditis does not appear in the posterior cervical region, assisting in differentiating it from that of musculoskeletal pain. The gland may also manifest rubor and calor, and cause dysphagia, which can be seen in association with pharyngitis and not surprisingly, tachycardia (Levine, 1983). Fortunately, the disease process is usually self-limiting and can be treated conservatively with microbial-sensitive antibiotics, corticosteroids, aspirin, localized heat, and restricted activity. Should an abscess develop, incision and drainage are indicated; if resolution is not obtained, surgical drainage may become a necessity.

Riedel's thyroiditis/struma (invasive fibrous thyroiditis) has the distinction of being the least common of the group of inflammatory thyroid diseases. It is a chronic thyroiditis of unknown etiology marked by localized areas of stony hard fibromas (Firkin & Whitworth, 1990). Riedel's thyroiditis is characterized by intense fibrosis of the thyroid gland and of the surrounding structures that lead to induration of the tissues of the neck, associated with some pain in the region of the neck. The condition can also be associated with mediastinal and

retroperitoneal fibrosis. It is unfortunate that this slowly enlarging, or in some cases suddenly expanding, hard mass in the anterior neck is often mistaken for thyroid cancer. Hypothyroidism occurs when the insidious fibrous infiltration finally invades the entire thyroid gland (Ferri, 1998, pp. 352–353). Multifocal fibrosclerosis can be expected, as well as involvement of various sites distant to the neck. The location of the involved structures determines the manifest symptoms, which can include dysphagia, stridor, and dyspnea (Malotte, et al., 1991). This disease is frequently self-limited but on occasion, may require surgical resection (Levine, 1983; Malotte, et al., 1991). Uncommonly, the diseases classified as thyrotoxicosis may be caused by pituitary adenomas, struma ovarii, metastatic thyroid cancer, embryonal carcinoma of the testes, chorio-carcinoma, hyperemesis gravidarum, and isolated pituitary resistance to thyroid hormone (Ferri, 1994, p. 47).

TABLE 10.1
Signs and Symptoms of Hyperthyroidism

Sign	Symptom
Restlessness	Increased bowel elimination/frequency
Nervousness	Weight loss despite increased appetite
Overactivity	Onycholysis separation at distal tuft
Tremor	Menstrual dysfunction, oligo/amenorrhea
Heat intolerance	Diffuse goiter with/without detectable bruit
Sweating	Velvet skin with moist warm hands
Hyperreflexia	Pulse pressure increases
Insomnia	Increased lacrimation
Exophthalmos	Pretibial myxedema[a]
Tachycardia	Panic attacks
Lid lag	Fixed gaze stare
Photophobia	Emotional lability
Diplopia	Atrial fibrillation
Systolic flow murmur	Blurring of vision

[a] Restricted to Graves disease.

GRAVES' DISEASE (TOXIC DIFFUSE GOITER)

Thyrotoxicosis is one of the most common endocrine disorders. Its incidence is highest in women 20 to 40 years of age. Thyrotoxicosis, when associated with ocular signs (ophthalmopathy) and related disturbances as well as a diffuse goiter, is given the name of Graves disease and is the most common cause of hyperthyroidism (Graber, et al., 1994, p. 214). In European and Latin American countries, this disease may be referred to as Basedow disease and is reported as such in their literature. This disease is interesting and often a clinical puzzle because instead of a diffuse goiter being present, a nodular toxic goiter (Hashitoxicosis) may demonstrate all the metabolic features of thyrotoxicosis and may occasionally be present without any visible or palpable enlargement of the thyroid gland. Hyperthyroidism is a condition caused by the oversecretion of hormones by the thyroid gland that ultimately influences the metabolism of cells throughout the body. Graves' disease is an autoimmune disease associated with a TSH-like immunoglobulin that binds to the TSH receptor sites of the thyroid gland, and in so doing stimulates the thyroid gland to increase production and release of thyroid hormone. The signs and symptoms of hyperthyroidism apply and are listed in Table 10.1.

Two signs that appear to be restricted to thyroid disease are pretibial nonpitting edema (infiltrative dermophathy) of myxedema and exophthalmos (proptosis). In a small number of patients with Graves disease (less than 5%), pretibial myxedema presents as a violaceous, nonpitting thickening of the skin in the pretibial region, ankles, and/or feet and is the result of mucopolysaccharide infiltration of the dermal tissue (DeBello, 1992, p. 219). Exophthalmos is considered diagnostic of Graves' disease when present; however, it may not be present at all or may be very minor in its presentation, and it may present at virtually any stage of the disease process. The protrusion of the globe from its orbital rim is believed to be the result of mucopolysaccharide deposition and fat accumulation behind the globe accompanied by edema of the extraocular muscles. Of interest is the fact that the cause of Graves disease has not been elucidated. Familial predisposition to the disease has led researchers to strongly suspect genetic etiology. The classic manifestations of the disease such as goiter, ophthalmopathy, and dermopathy may well be based on thyrotoxicosis and are often present independent of each other, possibly exhibiting cyclic periods of exacerbation and remission throughout the course of the disease. The manifestations with which the patient presents, increased serum T3 and/or T4, and suppression of TSH levels found by radioimmunoassay, can confirm the increased activity of the thyroid gland. Elevated levels of antithyroid immunoglobulins evidenced on blood tests may lend credence to a diagnosis of Graves disease. Graves disease and its prognosis vary on a case-by-case basis. Should symptom remission and eradication of disease-associated immunoglobulins result from appropriate treatment, recovery remains while immunoglobulins are reduced. With a resurgence of thyroid-stimulating immunoglobulins (TSI), the patient again becomes hyperthyroid. A potentially fatal Graves' disease complication known as "thyroid storm", presents as a severe episode of thyrotoxicosis with rapid onset of delirium, tachycardia, sweating, fever, pulmonary edema, and congestive heart failure requiring immediate emergency medical intervention (Bulens, 1981, pp. 668–670).

HYPOTHYROIDISM (CRETINISM)

Hypothyroidism refers to a condition in which a paucity of thyroid hormones is manufactured in, or secreted by, the thyroid gland. In adults, severe thyroid deficiency is referred to as myxedema. In utero and in the newborn, undiagnosed and untreated hypothyroidism leads to cretinism (Fisher, 1981). Cretinism can usually be diagnosed clinically without difficulty, but at times it must be distinguished from mongolism and other genetic disturbances. Immunochemisty is important in making the diagnosis. Fortunately, cretinism is appearing with less frequency today than in the past, in part, due to more aggressive detection efforts (Fisher, 1987). Congenital hypothyroidism in the neonate is usually detected early by statewide screening programs. Since their inception in the 1970s, the incidence and complications of untreated cases of primary congenital hypothyroidism have dramatically decreased. In light of the severity of long-term effects of hypothyroidism on brain tissue maturation (mental retardation), the mandated newborn TSH, free T3, T4 testing has brought some welcome relief.

Congenital hypothyroidism results from glandular absence (athyreosis), ectopic thyroid, lingual thyroid gland, or dyshormonogenesis (Burg, 1990, pp. 134–135). Most often, infants with congenital hypothyroidism appear normal at birth but can appear placid and frequently require arousal to feed. Typically, the infant presents 6 to 12 weeks after birth with a common finding of prolonged jaundice and prolonged indirect hyperbilirubinemia. The cry of the infant sounds harsh or hoarse and the infant may also be constipated. Additionally, macroglossia similar to that seen in Down's syndrome may be apparent along with an umbilical hernia, muscle hypotonia, and bradycardia. Infants with hypothyroidism may have a history of full-term or even post-term birth.

A second category of acquired hypothyroidism may appear and in this category, an autoimmune phenomenon with lymphocytic infiltration of the thyroid gland is most common. Hypothyroidism is often insidious in onset. Complaints of a neck mass or dysphagia along with weight gain, dry skin, constipation, and intolerance to cold may be reported by a parent. A goiter is characteristic of the acquired form of hypothyroidism and is usually small and firm, having a "bosselated" texture typical of that seen with thyroiditis (Mahoney, 1987). If the disease appears during the growing years, there may be obvious failure on the part of the child to grow normally with delayed puberty manifested as well. Of interest is the often-reported observation of excellent school performance owing to the relative indistractibility of the child with hypothyroidism. Accurate diagnosis of hypothyroidism in children frequently requires the physician to painstakingly collect and synthesize a host of vague complaints on history as well as sort out nonspecific physical exam findings coupled with misinterpreted and often misleading laboratory findings. In all cases of suspected hypothyroidism in children, therapy is essential to preserve mental function in the neonate and to preserve normal growth patterns in the child. Anhalt, et al. (1956, p. 153) warn, "Despite the fact that screening for congenital hypothyroidism is now almost universal in the United States, there are certain methodologic flaws with the testing; thus, when encountering a child with suspicious signs and/or symptoms, the physician must always keep this diagnosis in mind."

HYPOTHYROIDISM (MYXEDEMA)

The thyroid gland is a uniquely regulated metabolic powerhouse and maintains its uniqueness among other glands of the body in that it can synthesize and store immense quantities of hormones and then slowly and deliberately release these hormones in response to bodily demands (Tilkian, 1993). The causes of hypothyroidism in the adult can be of primary, secondary, or tertiary origin. Primary hypothyroidism refers to thyroid hormone deficiency as a result of thyroid gland disease or dysfunction and constitutes greater than 90% of the cases of hypothyroidism. Among the etiologies comprising the primary category is Hashimoto's thyroiditis (chronic lymphocytic thyroiditis). According to Nagataki (1993, pp. 539–545), Hashimoto's thyroiditis may well be the most common producer of hypothyroidism in America with some 5% of euthyroid, Hashimoto thyroiditis-afflicted persons advancing to the hypothyroid state with each passing year. Idiopathic myxedema, which may be a nongoiterous form of Hashimoto's thyroiditis, is also included in the primary category. The category is further expanded by the inclusion of those persons who have been treated for hyperthyroidism with iodine 131 therapy or have had subtotal thyroidectomy or radiation therapy of the neck for malignant disease. Subacute thyroiditis and iodine deficiency or excess along with drugs such as lithium, p-aminosalicylic acid (PAS), sulfonamides, phenylbutazone, amiodarone, and thiourea or prolonged treatment with iodides add to the list. Congenital cases constituting approximately 1:4000 live births are also included. Secondary causes result from TSH deficiency in the pituitary gland and can be due to any pituitary dysfunction such as postpartum necrosis, neoplasm, and TSH deficiency secondary to infiltrative disease. Hypothalamic disease due to neoplasms, granulomas, or irradiation contributes to the tertiary category of hypothyroidism and results in a deficiency of TRH from the hypothalamus. As expected, the prevalence (number of cases of a disorder that exist) varies with location and by study. Graber, et al. (1994) indicate that hypothyroidism is present in 1 to 6% of the population. Signs and symptoms related to hypothyroidism are listed in Table 10.2.

TABLE 10.2
Signs and Symptoms of Hypothyroidism

Sign	Symptom
Fatigue	Muscle weakness
Lethargy	Weight gain
Constipation	Slowed speech & deepened voice
Arthralgias	Vocal hoarseness
Bradycardia	Reduced memory
Retarded cerebration	Loss of memory
Paresthesias	Intolerance to cold
Blunted effect	Cerebellar ataxia
Muscular stiffness	Carpal tunnel syndrom
Pericardial effusion	Distant heart sounds
Hearing impairment	DTR delayed relaxation
Dry, cool, doughy skin	Slow moving lips
Brittle, coarse hair & loss	Thickened tongue
Vitiligo	Nonpitting edema eyelids and hands
Ascites	Loss of temporal one third of eyebrows

HYPOTHYROIDISM (MYXEDEMA COMA)

Myxedema crisis or coma fortunately is rare, developing in only 1% of hypothyroid patients, but nevertheless it is a life-threatening complication of hypothyroidism (Myers, 1991). Bodily stresses such as cold, trauma, surgery, infection, and medications including iodides, narcotics, and sedatives have been identified as precipitating factors. Hypothyroid decompensation in the form of severe respiratory failure (CO_2 narcosis), hypothermia, or sluggish cerebral perfusion all contribute to the development of coma. The diagnosis is based upon the clinical presentation and therapy must be instituted before the clinical suspicions are substantiated by laboratory tests, because delay may lead to a fatal outcome in this medical emergency (Cecil, 1993). Clinical awareness of the wide spectrum of presentation and a high index of suspicion of hypothyroidism will generally serve to identify most cases. However, a number of clinical conditions such as nephritic syndrome and cirrhosis including an associated reduction in serum TBG (thyroid binding globulin) and consequent low serum total T4 values can mimic hypothyroidism.

Patients with hypothyroidism may live for years but with some dysfunction of many organs are less able to tolerate the stress of additional illness, i.e, infection, surgery, seizures, congestive failure, stroke, drug toxicity, or exposure to extremes in heat or cold. T4 replacement is indicated. Expert modern medical management is essential. The mortality rate is still 50% and survival depends on early recognition and treatment of the hypothyroidism and any other factors contributing to the extremely serious medical condition including an altered level of consciousness. With prolonged, severe myxedema, overt psychosis may develop. Attempted suicide has also been reported with some patients never regaining sanity; “myxedema madness” has been applied to these conditions (Christy, 1975). With substitution therapy, the psychosis usually clears but on occasion, patients may develop overt psychosis with the advent of the therapy regimen.

HYPERPARATHYROIDISM, PRIMARY, SECONDARY, TERTIARY

Primary hyperparathyroidism refers to the condition in which the parathyroid glands liberate an excess of PTH (parathyroid hormone). The excess may result from one or more of the glands in spite of the fact that plasma ionizeded calcium is elevated. The normal adaptive response for the release of PTH involves parathyroid hyperplasia in reaction to lowered serum calcium levels. When prolonged for extended periods, these glands can and will hypertrophy, becoming a cause for secondary hyperparathyroidism. The majority of patients suffering with hyperparathyroidism appear to be women. The condition appears to be much less common in children. In primary hyperparathyroidism the pathogenesis appears to be unrestrained liberation of PTH but the etiology is unknown. In about 80% of patients a solitary benign parathyroid adenoma is responsible. A low percentage of hyperparathyroidism cases are due to parathyroid cancer. The small size of the gland can create a dilemma for the surgeon. Fortunately, the hormone secreted by this gland (parathyroid hormone) can be stained in paraffin sections and be used for the identification of normal parathyroid tissue or that ravaged by an invading carcinoma, particularly when the carcinoma occurs as a metastasis. This procedure takes about 30 minutes (Sherrod, 1986). An equally small percentage of hyperpathyroidism appears to be familial, with a portion of this category being associated with the syndromes of multiple endocrine neoplasia (MEN I, MEN IIa, IIb). The condition becomes suspect when routine blood chemistry reveals high calcium levels (total serum calcium > 10.5 mg/100 ml). Other conditions included in the differential may be hypercalcemia due primarily to increased bone resorption as a consequence of prolonged immobilization, hyperthyroidism, or malignancy involving bone such as metastic carcinoma to bone, leukemia, lymphoma, or multiple myeloma. Addison’s disease, sarcoidosis, hypervitaminosa A or D can result in hypercalcemia. Renal calcium reabsorption increases secondary to thiazide diuretic use. Addison disease or familial hypocalciuric hypercalcemia can also raise serum calcium levels as can ectopic hyperparathyroidism. Bronchogenic carcinoma has been known to cause hypercalcemia by enhanced absorption of calcium from the GI tract, kidney reabsorption, and resorption of calcium from

bone. The ingestion of large quantities of calcium carbonate and milk (milk-alkali syndrome) also elevate serum calcium levels. The signs and symptoms of hypercalcemia are listed in Table 10.3. Symptoms are usually due to bone pain/fracture, renal stones, nonspecific abdominal pain, constipation, duodenal ulcer, pancreatitis, or depression. Ask a medical student for the symptoms of hyperparathyroidism associated with hypercalcemia and after a short moment, his or her head will begin to nod and sway rhythmically as they mentally recite the poetic mnemonic "Bones stones, abdominal groans and psychic moans." Unfortunately, no rhythmic mnemonc exists for the additional presentations of joint stiffness, gait disturbances, hypertension, myopathy, dehydration, confusion, thirst, nocturia, and anorexia due to increased calcium levels. Approximately 25% of patients with hyperparathyroidism have prominent psychitric symptoms that may resemble mania, schizophrenia, or acute confusional states while an additional 50% may display symptoms suggesting depression (Cogan, 1987).

In hypercalcemic cases ectopic hyperparathyroidism as well as malignancy of lung, kidney, or pancreas may well come to mind. Granulomatous conditions, for example, sarcodiosis, tubercolisis, and others that may convert 25-$(OH)_2D_3$ to 1,25-$(OH)_2D_3$ in an unregulated fashion may lead to increased calcium adsorption from the gut as well as increased bone resorption. Routine radiographic findings may reveal osteoporosis wtih vertebral compression fractures on even more telltale subperiosteal resorption of the phlanges. Cyst-like lesions may be found in any part of the skeleton, even the skull (osteitis fibrosa cystica ostodystrophy).

These bone cysts are frequently seen and are accompanied by pain, especially when there is involvement of surrounding periosteum. Calcification of soft tissue such as lungs, tendon attachments, pancreas, or kidneys reveal stones may serve as a clue to the hyperparathyroid condition. When there is hypocalcemia, the parathyroid glands sense the calcium reduction and begin the process of hyperplasia and initiate the secretion of PTH in an adaptive effort to restore the body's mineral balance. If or when the patient suffers from renal failure, malabsorption syndrome, vitamin D deficiency, or renal tubular defects which lead to excess loss of calcium, hypocalcemia ensues and secondary hyperparathyroidism prevails. Drugs such as phenobarbital and phenytoin actively interfere wtih metabolism of vitamin D and in so doing diminish the ability of the gastrointestinal tract to absorb calcium. Renal tubular acidosis also contributes to calcium loss.

For osteomalacia in adults and rickets in children to occur defective mineralization of bone must precede it. Multiple types of osteomalacia exist depending upon the pathophysiology of the disease or malfunctioning diseased organ. Chronic renal failure results in phosphate retention with a reciprocal decrease in calcium leading to secondary hyperparathyroidism. Because of the effects of markedly elevated PTH levels upon metabolism, osteosclerosis, osteoporosis, and von Recklinghausen's disease of bone" (osteitis fibrosa cystica) may manifest as renal osteodystrophy (Price, 1986). Another form of oseodystrophy may develop because of the severity of the renal disease. The kidneys may no longer be capable of completing the conversion of 25-$(OH)D_3$ into the active form 1,25-dihydroxycholecalciferol (1,25-$(OH)_2D_3$ vitamin D) resulting in the most common bone disorder, osteomalacia (adult rickets). The disease can be identified radiologically by translucent bands (Loesser lines) that are pseudofractures involving part of the cortex perpendicular to the periostal margin of the bone. These lesion (infarctions) in the bone represent infarctions in the bone caused by compressive stresses that produce small cracks in the cortex

TABLE 10.3
Signs and Symptoms of Hypercalcemia (Hyperparathyroidism)

Neuromuscular	Gastrointestinal	Kidney
Myopathy	Vomiting	Renal stones
Hypotonia	Constipation	**Skin**
Muscular weakness	Ileus	Pruritus
CNS	**Pancreatitis**	**Cardiovascular**
Emotional labiality	Nausea	Hypertension
Mental confusion	Anorexia	QT interval shortened
Lethargy		Bradycardia
Stupor		Digitalis toxicity, increased potential
Coma		
Delirium		
Headache		

Azotemia (caused by effects of calcium precipitation in the renal parenchyma)
Polyuria (ADH prohibited by calcium from binding to receptor sites in the distal convoluted tubule)

and are pathognomonic of osteomalacia (Albright, 1946). Pseudofractures are frequently bilateral and symmetrical and are commonly seen in the axillary border of the scapula, the ribs, pubic and ischial rami, medial aspect of the neck of the femur, iliac bones, radii, and ulna (Aronoff, 1985). They were first described by Milkman (1930, 1934) and later became known as "Milkman's syndrome". For many years, it has been known that vitamin D (as above) is necessary for proper assimilation of calcium through the gastrointestinal tract (Hannon, 1934). Previously there was a siege of childhood rickets due to decreased vitamin D in the diet or from lack of exposure to ultraviolet rays. This siege was eventually eradicated with the fortification of many foods and food additives with vitamin D. Cases of vitamin D-resistant or persitent rickets, an X-linked autosomal dominant disease, have also occurred (Nora, 1994). Most cases of vitamin-D resistant or persistent rickets (rachitis tarda) probably represent osteomalacia caused by renal tubular insufficency (Fanconi syndrome), a primary defect in renal tubular phosphate resorption. With the decreased active form of vitamin D, absorption of calcium from the gut is grossly impaired. Osteomalacia is seen in nearly 60% of all pateints with chronic renal failure. Defective dimineralization of the bone occurs when there is a low serum calcium level and ineffective vitamin D leading to the replacement of normal bone with osteoid tissue. Bone with wide osteoid seams is structurally inferior to normal bone and easily deforms under stress and is prone to fractures.

Osteodystrophy may be detected using plain film radiographs that show bone with decreased density, most commonly in the fingers, skull, spine, and ribs. Osteitis fibrosa cystica occurs in more than 30% of patients with hyperparathyroidism and is characterized by osteolytic resorption of bone and its replacement by fibrous tissue. The lesions of demineralization may appear to be localized and cystic, hence its name, osteitis fibroa cystica. Radiographically, the lesions may show a generalized decrease in bone density. Classically, the lesion associated with this disease is the subperiosteal resorption of bone at the phalanges with or without scattered areas of demineralization in the skull that resemble a moth-eaten appearance. Osteosclerosis is the least common bone disorder and on radiographs demonstrates a characteristic "Rugger jersy spine" appearance which gives vertebrae alternating dark and light bands respresenting bone density variations. These lesions may appear solo or in any combination with other radiographic signs.

HYPOPARATHYROIDISM

Hypoparathyroidism is defined as a decrease in the production of parathormone or parathyroid hormone by the parathyroid glands. As a consequence, concentrations of circulating calcium are reduced and hypocalcemia ensues with all its ramifications. This condition is relatively rare and most commonly occurs following inadvertent removal of all four parathyroid glands during thyroid cancer surgery. Fortunately, congenital, genetic, idiopathic, and autoimmune causes are extremely rare but do exist (Damjanov, 1996, p. 423). Irradiation to the neck rarely may result in hypoparathyroidism, as can massive radioactive iodine administration for cancer of the thyroid gland. Candidiasis endocrinopathy syndrome is an inherited disease of functionally defective T cells. It is characterized by susceptibility to candidal infection with a strong predilection for parathyroid and adrenal glands. Autoimmune destruction of these glands may be due to an autoimmune disorder called multiple endrocrine deficiency, autoimmune candidiasis (MEDAC) syndrome (Camargo, 1987, p. 708). Glandular destruction regardless of the cause results in hypoparathyroidism and/or Addison's disease (Rubin & Farber, 1995, p. 84).

A severe form of deficient T-cell immunity is DiGeorge syndrome. This syndrome is caused by defective embryological development of the third and fourth pharyngeal pouches that become the thymus and parathyroid glands. In the absence of a thymus, T-cell maturation is interrupted at the pre-T-cell stage, and in the absence of parathyroid glands, hypoparathyroidism is inevitable (Sadler, 1990, p. 310). In the alcoholic patient, hypomagnesemia is a common concern; and when not replaced, it can lead to hypoparathyroidism and ultimately hypocalcemia by either impairing the secretion of PTH or interfering with end-organ responsiveness to the hormone. With an insidious onset of hypocalcemia, signs and symptoms may be negligible or absent altogether. Patients can be asymptomatic and have total serum calcium as low as 5 to 6 mg/100ml. The signs and symptoms of hypoparathyroidism are those of hypocalcemia (Dambro & Griffith, 1997) and are listed in Table 10.4.

When there is significant hypocalcemia, tetany may well be most striking in clinical presentations. Facial spasms can be so debilitating that the patient is unable to speak. Spasms affecting the hands and feet are frequently seen. When spasms become of such a magnitude that prevents the patient from talking, the clinician as well as family members must be diligent in looking for signs of laryngeal spasm requiring breathing assistance should respiration become significantly compromised. Trousseau's sign (carpal spasm in the hand) can be demonstrated by producing ischemia with a blood pressure cuff placed on the arm and inflated above the systolic blood pressure and held for 3 min. The hand will draw toward the ear and the fingers flex. The resultant carpal spasm is seen in the hand. Chvostek's sign is a facial twitch that may be induced by gently tapping the skin of the face over the area of the facial nerve slightly in front of the tragus of the ear. Numbness or tingling sensations of the face, hands, lips,

TABLE 10.4
Signs and Symptoms of Hypocalcemia (Hypoparathyroidism)

Diarrhea	Neuromuscular irritability	Fatigue
Weakness	Abdominal cramping	Alkalosis
Weight loss, dry skin	Bone pain	Tetany
Paresthesias	Carpal pedal spasm	Myalgia
Headache	Depression	Dementia
Seizures	Chvostek's sign	Trousseau's sign

and tongue are common findings in hypocalcemia, as are dryness of the skin, coarse dry hair with some hair loss, and fingernails with ridges that run longitudinally to the nail. Should extrapyramidal signs that resemble parkinsonism be exhibited, calcification of the basal ganglia may be the culprit and the plain skull film showing basal ganglia calcification can be confirmatory. Psychic disturbances (see Table 10.4) can be seen when hypocalcemia becomes chronic and the patients may exhibit signs of increased intracranial pressure with resultant papilledema. Hypotension, malabsorption syndrome, cataracts, and prolongation of the Q wave to T wave (QT) interval are all consequences of hypocalcemia. In cases of acidosis, circulating calcium is liberated from albumin and ionized calcium levels rise sharply. Conversely, alkalosis causes ionized calcium to bind to albumin binding sites that would be otherwise occupied by hydrogen ions; therefore the manifestations of hypocalcemia become exaggerated in either respiratory alkalosis or metabolic alkalosis.

An interesting biochemical phenomenon occurs in the normocalcemic patient whereby hyperventilation can blow off CO_2, creating a respiratory alkalosis; this, in turn, reduces the amount of circulating ionized calcium, and results in low calcium tetany if prolonged. An excellent study was conducted that reviewed the metabolic and respiratory changes in 21 patients who had suffered heat stroke reported that the predominant change was that of metabolic acidosis secondary to an increased lactate content, and/or a respiratory alkalosis. The study further reported that many of the patients also had hypo-calcemia. The researchers postulated that the lactic acidosis was most likely due to increased metabolic requirements resulting from hyperthermia compounded by hypotension and hypoxemia and an impairment in liver function that decreased the capacity to dispose of the lactate once it formed. They reported that the cause of the hypocalcemia was unclear (Appenzeller, 1986, p. 70). The authors of this chapter suggest that the reason for hypocalcemia in these and heat stroke patients is hypoxemia and hyperthermia shifting the oxygen disassociation curve to the right, which resulted in additional oxygen given off to the tissues as well as increased respiratory effort to meet the loss from blood to the tissues. In addition, increased lactic acid itself increases the respiratory effort. Thus, hypoxemia and hyperthermia plus respiratory alkalosis that lead to increased binding of ionized calcium to albumin lower the blood calcium in these patients. If tenany develops due to low calcium, additional lactate accumulates. Impairment in liver function makes lactate metabolism more difficult so a continuous cycle is established.

According to Herman and Sullivan (1959), biopsies taken from the livers of gold miners after suffering heat stroke revealed histological evidence of liver damage in the form of centrolobular necrosis and extensive cholestasis. It has been stated that the signs and symptoms of hypoparathyroidism are those of hypocalcemia. In light of the previous discussion and with continued research, heat stroke might in future literature be a viable candidate for addition to the list of etiologies in hypocalcemia.

Pseudohypoparathyroidism is an autosomal recessive disorder in which PTH target cells fail to respond to appropriate hormonal stimulation. Characteristically, the patient may be obese with short stature and round face, may be mentally retarded, and may demonstrate shortened metacarpals and metatarsals on radiographic examination (Ferri, 1998, p. 364). Resistance to multiple hormones in addition to PTH may also occur in patients with Albright's hereditary osteodystrophy. This is reported as pseudohypoparathyroidism Type I (Hope, et al., 1996, p. 542).

SUMMARY

In this chapter an attempt was made to discuss the major features of the thyroid and parathyroid glands, in health and disease and their relationship to pain. The authors now have a greater appreciation of, and renewed empathy for, the individual who sets out to go fishing with a large bucketfilled with water and a cooler full of ice to safely store the catch of the day, only to look into the bucket and cooler at the end of the expedition and find a lot of water and a lot of ice. However, if you ask the fisherman how the day went, the reply might be something like, "I did not catch much, but I had a wonderful time and I learned a lot about fishing." The authors of this chapter would like to echo the sentiment by saying we did not catch much, but we had a wonderful time and we learned a lot about thyroid and parathyroid glands during this fishing expedition. Other than the specific relationships mentioned about these glands and pain, there is paucity in the vast area of literature concerning this relationship. Quite possibly (and more likely, probably) other researchers have embarked on this same fishing expedition and in utter exasperation simply poured out the water and the ice at the end of the day and put away the boat only to fish in more fertile waters on the next expedition. A wealth of knowledge that far exceeds the scope and intentions of

this chapter is available on the endocrine scene concerning the thyroid and parathyroid glands; therefore, it is left for some future expedition. Our commitment was to seek out research that addresses a relationship between these two glands and pain and to report them. To this degree our expedition was a success.

Furthermore, when one reads in every book dealing with pain that it is a subjective finding encompassing a lifetime of emotions and feelings, there is small wonder why so little is written pertaining to the subject. We conclude that there may be much more to the subject of thyroid and parathyroid diseases and pain, but the difficulty may not be so much the manifestation of the pain but instead the verbal expression of it. Additionally, the pain associated with diseases of the thyroid and parathyroid glands may, in actuality, not be attributable to direct pain. Instead, pain associated with these glands may be due to the diverse effects on the body, and its cells and systems. Duress of disease influences one's ability not only to deal with the pain but also to express it.

Posttraumatic Headache: Pathophysiology, Diagnosis, and Treatment

Gary W. Jay, M.D., F.A.A.P.M., D.A.A.P.M.

INTRODUCTION

Posttraumatic headache (PTHA), as the name indicates, is a general, descriptive term for headache that occurs posttrauma. The types of trauma do not necessarily need to include an actual blow to the head, or even loss of consciousness. The majority of patients who experience PTHA do not have an associated minor traumatic brain injury (MTBI); however, PTHA is one of the most common sequelae of MTBI, but not moderate or severe traumatic brain injury.

Some have argued that PTHA is no different than nontraumatic headache in etiology or treatment. In many cases this may be true, although the assessment and diagnosis can be complex. Still, some researchers and clinicians are adamant about their feelings: PTHA is a sham; PTHA almost always has its etiology in the neck; the pathophysiology of PTHA is very different from other, primary forms of headache; and so on. This author believes that there is a spectrum of primary headache disorders, with PTHA a form of a primary headache disorder with possibly enhanced pathophysiological difficulties. Ockham's razor may be useful, but the clinical reality appears to necessitate a greater breadth of knowledge by the clinician.

On the other hand, there are pitfalls in the current classification systems, which seem to ensure difficulties in diagnosis, and not just nosologically. The ICD-10 classification system is based on criteria that primarily are concerned with the temporal relationship as well as pathogenicity between the relationship of PTHA to trauma, and ignore the clinical features of the PTHA (World Health Organization, 1997). This criterion states that the headache onset must occur within 2 weeks of the traumatic event or the patient's return to consciousness. However, posttraumatic cluster headache, for example, typically does not fit this time course. Furthermore, their criteria for acute or chronic PTHA require one of the following: loss of consciousness, a period of antrograde amnesia of at least 10 min, or abnormal neurological examination/neurodiagnostic testing. The ICD-10 criteria find that acute PTHA resolves in 8 weeks, whereas chronic PTHA lasts longer than 8 weeks. This is in counterdistinction to the IHS criteria (Headache Classification Committee [HCC], 1988).

These criteria are contrary to the most commonly accepted criteria, those of the brain injury special interest group of the American Congress of Rehabilitation Medicine (Kay & Harrington, 1993), which states that MTBI is a "traumatically induced physiological disruption of brain function" associated with at least one of the following: any period of loss of consciousness; any memory loss for events just before or after the accident; any alteration in mental state at the time of the accident, such as feeling dazed, disoriented, or confused; and focal neurological deficits that may or may not be transient. Most importantly, there is no necessity of direct head trauma to meet the diagnosis.

Another nosological problem is the synonymous use of various terminology: concussion, MTBI, postconcussion syndrome/disorder, and posttrauma syndrome. For a number of specific reasons, this author believes the postconcussion syndrome, which affects multiple organ

0-8493-0926-3/02/$0.00+$1.50

systems, should be differentiated from MTBI (Jay, 2000). Patients with PTHA do not, by definition and clinical analysis, have to have an MTBI.

Very briefly, the basic elements found in an MTBI may include axonal shearing; marked increases in the excitotoxic neurotransmitters including acetylcholine and glutamate; a lack of the cohesiveness of the blood–brain barrier, which become "porous" for 8 to 24 h or more; and possible changes in the hemodynamics of the brain. (Please see textbook for details [Jay, 2000].) The most important aspect to keep in mind is that the "type" of PTHA must be accurately diagnosed so that appropriate treatment can be prescribed.

Typically, PTHA is noted after acceleration/deceleration injuries (whiplash) in up to 90% of patients who experience MTBI (Keidel & Diener, 1997). These headaches can be determined to be posttraumatic tension-type, migraine, cluster, or possibly cervicogenic headache. PTHAs may be secondary to work-related injuries, slip and fall injuries, and violent altercations, aside from motor vehicle injuries. These headaches are frequently part of the postconcussive syndrome, which refers to a large number of signs and symptoms that may follow a blow to the head or an acceleration/deceleration injury, which may or may not induce an MTBI.

Acute posttraumatic tension type of headache, the most frequently diagnosed PTHA, (defined as 15 headache days or less a month) may last up to 3 to 6 months, after that it becomes, nosologically, chronic. The IHS has determined that 15 headache days or more a month defines chronic headache (HCC). General pain management principles place pain as chronic after 3 to 6 months, after physiological healing has occurred. Up to 80% of PTHA patients have their pain remit within 6 months, leaving an estimated 20% of patients with chronic PTHA, which may last years in many cases.

A simple concussion may also be associated with PTHA, as well as, in the extremes, vegetative and even psychotic difficulties (Kojadinovic, Momcilovic, Popovic, et al., 1998; Muller, 1974). PTHA may also be associated with dizziness, irritability, and decreased concentration, even without the additional finding of an MTBI. (Again, for the differentiation between the postconcussive syndrome and MTBI, please see the MTBI chapter in this textbook.)

The chronic PTHA patient frequently engenders significant difficulties for the typical general practitioner, as well as the neurological specialist. This may be especially true if there is evidence of de novo migraine or cluster headache.

Medico-legally, PTHA is a common problem, because the patient does not "look" ill and may have few if any abnormalities on examination. In depositions, or in court, a physician is frequently asked to explain why such a significant problem was found after a relatively minor "rear-end" automobile accident or slip and fall. Why, it is asked, do professional football players, for instance, not have a high incidence of PTHA and/or MTBI. The answer is simple and is based on two circumstances: physical conditioning and the fact that when they play, these people are always very prepared and always anticipate the possibility of physical contact or trauma. This differentiates them from the vast majority of people who are not even close to being in optimal physical condition, who are injured unexpectedly, before they are even aware of the impending trauma and are therefore unable to physically prepare themselves for a trauma, for example, by bracing themselves against the headrest before their car is struck from behind.

A great deal of research has shown that when the head is free instead of confined, it is more susceptible to the effects of an acceleration/deceleration injury. Six decades ago, it was shown in cats that less force was required to produce concussion when the head was free to move, as compared with when it was fixed or confined in place (Denny-Brown & Russell, 1941). The concept of whiplash, essentially a legal term, medically known as acceleration/deceleration, is very important because it involves a multitude of medical aspects. When an acceleration/deceleration injury occurs (most frequently from a rear-end automobile accident), the physical or gravitational forces of a massive object such as a car striking another automobile are passed onto the most fragile and unmovable object not firmly secured in the automobile that was struck: the passenger. Even when the passenger is wearing a seat belt, the head — the ball at the end of a tether (the neck) — is first thrown forward, and then backward, when the tether can reach no farther and snaps back. If the head is turned at the moment of impact, the rotational forces are also very important, particularly when an MTBI is found.

Posttraumatic headache encompasses a number of different diagnostic entities. Specific diagnosis is needed for appropriate treatment. These diagnoses include

- Posttraumatic tension-type headache
- Posttraumatic migraine headache
- Posttraumatic cluster headache
- Cervicogenic headache
- Temporomandibular joint (TMJ)-related headache
- Neuropathic pain syndromes

POSTTRAUMATIC TENSION-TYPE HEADACHE

PTTHA (with or without secondary analgesic rebound headache) is probably the most common primary headache disorder found after trauma. Diagnostically, and clinically,

this entity appears to be similar to acute and chronic tension-type headache without a traumatic etiology.

The diagnostic criteria of tension-type headache according to the IHS (HCC, 1998), states that episodic tension-type headache is a recurrent headache occurring on fewer than 15 days a month, lasting from 30 min to 7 days. The pain characteristics include two of four of the following: pain that has a pressing/tightening (nonpulsating) quality; pain that is mild to moderate in intensity and may inhibit, but not prohibit activities; pain that is always bilateral; and pain that is not aggravated by walking stairs or doing other routine physical activity. These criteria also state that both the following are true: no nausea or vomiting, but anorexia may occur, and photophobia and phonophobia are absent, or one but not the other is present. All other organic diagnoses must be ruled out first, as well as other primary headache diagnoses, including migraine and cluster headache.

In PTTHA, like non-posttraumatic tension-type headache, the pain is typically described as aching or pressure-like. The pain has also been described as feeling like a tight band, or a vice around the head. The pain is typically bilateral, although it may be unilateral. It may include various areas, some or all the occipito-nuchal, bifrontal, bitemporal, and suboccipital regions at the vertex (crown) of the head, as well as extend into the neck and shoulders.

The pain intensity may wax and wane depending on a number of factors including movement, activity level, stress, and others. Even in PTTHA, emotional/psychological aspects may increase pain. There is a female preponderance.

Unlike migraine headache patients, PTTHA patients may carry on with their activities. Most take some form of analgesic, frequently on a daily basis. Without question, PTTHA patients may also have migraine, posttraumatic or otherwise.

The chronic PTTHA patient has headache 15 or more days a month. This is also a diagnostic exercise, because most frequently, nosologically, PTTHA may be one of several headache diagnoses. All these are part of a chronic daily headache differential, which would include analgesic rebound headache, at a minimum.

PTTHA patients frequently have a headache daily or every other day. The headache is typically there when they awaken, and remains until they go to sleep. The intensity of the pain varies, decreasing for several hours after analgesics are taken. The majority of PTTHA patients, if seen early on, have associated pericranial muscle spasm and pain, whereas others do not, yet still complain of pain.

Patients with PTTHA also endure elements of depression and anxiety. There is a "chicken and egg" aspect to this, in terms of which problem comes first. In many cases, central neurochemical changes begin concurrent to the injury and manifest as both pain and affective disturbances (see later).

Nosologically, PTHA is incident to trauma. Some of the problems in making this diagnosis: the patient may not experience direct trauma to the head, but have an acceleration/deceleration injury (whiplash); there may not be significant physical findings on examination (conversely, there may be physical findings that are missed unless a good musculoskeletal examination is done); secondary to the lack of profound physical findings, the patient may be labeled with a psychogenic diagnosis, or worse, with the term malingering.

When one understands the pathophysiology of the problem, specifically PTTHA, it should be understood that the history and physical examination must be done quite specifically, not "one size fits all diagnoses." Knowing what questions to ask and what, on occasion, can be fairly subtle physical findings to look for on examination is obviously important.

PATHOPHYSIOLOGY OF POSTTRAUMATIC TENSION TYPE OF HEADACHE

The typical PTTHA begins postacceleration/deceleration injury, which most frequently occurs during a motor vehicle accident. A slip and fall accident as well as a sports-related injury or more obviously, a postviolent altercation can be the initiating event.

As described previously, the head and the neck, likened to a ball on a chain, is flung forward and backward from acceleration/deceleration forces, frequently without direct trauma to the head, or following direct trauma to the head. However it occurs, the physical forces involved cause the cervical and shoulder musculature, at a minimum, to be suddenly stretched and sustain both microtears and strain/trauma as well as endure a reflex muscle contraction after the sudden stretching. All this being said, it is obviously important to understand the myofascial pain syndrome (MPS).

Pathological changes in the musculoskeletal system may initiate, modulate, or perpetuate PTTHA. Episodic and chronic PTTHA are, at least at first, secondary to a muscle-induced pain syndrome that is typically associated with the previously mentioned MPS.

The central nervous system (CNS) controls muscle tone via systems that influence the gamma efferent neurons in the anterior horn cells of the spinal cord, which act on the alpha motor neurons supplying muscle spindles. The Renshaw cells, apparently via the inhibitory neurotransmitter gamma aminobutyric acid (GABA) influence this synaptic system. There is also supraspinal control from cortical, subcortical, and limbic afferent and efferent systems. Physiological and emotional inputs interact in the maintenance of tone. Adverse influences from both localized or regional

myofascial nociception, with or without limbic (affective) stimulation, may produce significant muscle spasm; if prolonged, this spasm becomes tonic with the additional aspects of increased anxiety or a maintained muscle contraction–pain cycle (Diamond & Dalessio, 1980; Speed, 1983). This helps to differentiate acute vs. chronic PTTHA, to a degree.

Tonic or continued posttraumatic muscle contraction may induce hypoxia via compression of small blood vessels. Ischemia, the accumulation of pain-producing metabolites (bradykinin, lactic acid, serotonin, prostoglandins, etc.) may increase and potentiate muscle pain and reactive spasm. These nociception-enhancing or algetic chemicals may stimulate central mechanisms that, through continued stimulation, may induce continued reactive muscle spasm/contraction and maintenance of the myogenic nociceptive cycle (Dorpat & Holmes, 1955; Hong, Kniffki, & Schmidt, 1978; Perl, Markle, & Katz, 1934).

As discussed later, the myofascial aspects of tension-type headache are clinically identical to those of PTTHA; the significant difference in diagnoses is the etiology, posttraumatic or otherwise.

The MPS was, for a long while, ignored in the pathophysiology of headache of any type. Some researchers found a causal relationship between muscle spasm and headache (Martin & Mathews, 1978; Rodbard, 1970; Sakuta, 1990) whereas others have felt that muscle spasm associated with headache is an epiphenomenon, not the etiology of headache (Haynes, Cuevas, & Gannon, 1982; Philips, 1978; Philips & Hunter, 1982; Riley, 1983; Robinson, 1980; Simons, Day, Goodell, & Wolff, 1943), but a reflexive response. Other authors have indicated that muscle activity/spasm or increased tone may be more pronounced in migraine than in tension-type headaches (Bakal & Kaganov, 1977; Cohen, 1978).

Unfortunately, this research, which was obtained via electromyographic (EMG) studies, appears to be problematic, because the various authors evaluated different groups of muscles in different types of patients, many of whom had poorly defined diagnoses (Anderson & Franks, 1981; Bakal & Kaganov, 1977; Martin & Matthews, 1978; Pozniak-Patewicz, 1976). Other authors defined chronic tension-type headache (CTTHA) as an entity with or without associated pericranial muscle disorder. The concept of muscle fatigue was not taken into consideration; metabolically spent muscles that may become relatively flaccid, lose aspects of increased tonus or spasm.

Also of interest is the fact that the vast majority of research deals with tension-type headache, not PTTHA, in spite of identical physical/clinical findings as well as historical findings, all are essentially the same, except for the presence of initiating trauma.

One study found a positive correlation between pericranial muscle tenderness and headache intensity, with the former felt to be a source of nociception (Langemark & Olesen, 1987). Another study (Langmark, Jensen, Jensen, & Olesen, 1989) found that pressure pain thresholds in patients with CTTHA were highly dependent on myofascial factors. This study indicated that the generally lower pain thresholds in the chronic tension-type headache patients suggested a dysmodulation of central nociception. A lower pain threshold in chronic tension-type headache patients, when compared with normal volunteers, was also noted (Borgeat, Hade, Elie, & Larouche, 1984).

Scalp muscle tenderness and sensitivity to pain in both migraine and tension-type headache patients was measured in another study, and the author indicated that the pathophysiology of tension-type headache may involve a diffuse disruption of central pain-modulating mechanism (Drummond, 1987). Lower pain thresholds were also found in patients diagnosed with MPSs, including lower back pain (Yang, Richlin, Brand, Wagner, & Clark, 1985; Malow, Grimm, & Olsen, 1980). It should be noted that the diagnoses in the majority of research papers include tension-type headache (TTHA), but whether they were associated with trauma is not indicated.

Both PTTHA and TTHA patients frequently have a stereotypic posture, with their shoulders raised and their heads flexed forward. This tightly held posture, or muscular splinting, is effective in preventing unconscious head movement that may induce pain. The continued splinting, by maintaining tonic muscle contraction, also works to increase myogenic nociception and perpetuate this cycle.

The pericranial muscles are innervated by sensory fibers in nerves from the second or third cervical roots and in the trigeminal nerve (Langemark & Jensen, 1988). The functions of these muscles contribute to the maintenance of posture and the stabilization of the head, as well as withdrawal and protection of the head. These factors contribute to the myofascial aspects of both TTHA and PTTHA.

Muscle fatigue occurs, both metabolic and neurochemical in nature, and typically follows prolonged or tonic muscle spasm. It may be secondary to "sympatheticopenia" or the depletion of epinephrine and norepinephrine (NEP), the peripheral sympathetic transmitters (Cailliet, 1993). The muscle spindle is directly affected by the sympathetic nervous system via these neurotransmitters, particularly NEP. Prolonged and sustained peripheral sympathetic activity may lead to depletion of NEP at the synaptic receptors. Continued afferent sympathetic input from myogenic nociception, at least in part from buildup though ischemia of nociceptive metabolites, may result in sympatheticopenia (Cailliet, 1993; Jay, 1996). There are also significant sympathetic aspects of myofascial pain, which are not dealt with in this chapter (Jay, 1995).

Tenderness of the cervical, thoracic, and lumbar paravertebral muscles is also positively correlated with pericranial muscle tenderness (Langemark, Olesen,

Poulsen, & Bech, 1988). It has also been noted that th contraction of shoulder and cervical muscles as well a emotional arousal contribute to TTHA (Murphy & Lehrer, 1990). These issues also are significant factors in PTTHA

Three mechanisms of muscle pain are thought to b relevant to acute, but more often CTTHA, which has the same physiological stigmata of PTTHA, in that myogenic nociception may be induced by (1) low-grade inflammation associated with the release of algetic, or pain-inducing substances, instead of signs of acute inflammation; (2 short- or long-lasting relative ischemia; and (3) tearing of ligaments and tendons secondary to abnormal sustaine muscle tension (Langemark & Jensen, 1988). These fac tors do not take into consideration the possibly more sig nificant initial trauma from acceleration/deceleration injuries, slip and fall accidents, and other reasons for direc or indirect head trauma that induces muscle trauma, pri marily or secondarily.

MYOFASCIAL PAIN SYNDROME

Travell and Rinzler identified the contribution of musculoskeletal factors in the etiology of acute and CTTHA (Travell & Rinzler, 1952). They demonstrated that there are consistent patterns of referred pain from trigger points within specific muscle and defined perpetuating factors that convert acute myofascial pain into a chronic pain syndrome (Travell & Simons, 1983).

The MPS is a localized or regional pain problem associated with small zones of hypersensitivity within skeletal muscle called trigger points. With palpation of these points, pain is referred to adjacent or even distant sites. Trigger points in the head, neck, and upper back may elicit headache, as well as tinnitus, vertigo, and lacrimation, all features noted in patients with PTTHA as well as CTTHA (Jay, 1995). (Figures 11.1 to 11.8).

Trigger points may be active, with consistently reproducible pain on palpation, or latent, with no clinically associated complaints of pain but with associated muscle dysfunction. Trigger points may shift between active and latent states. Clinically, continuous myogenic nociception from active trigger points appears to be a prime instigator of the central neurochemical nociceptive dysmodulation found in patients with chronic tension-type headache as well as PTTHA.

Increased stiffness, weakness, and fatigue as well as a decreased range of motion are typically found in muscles in which trigger points are identified. These muscles may be shortened, with increased pain perceived on stretching. Patients may protect these muscles by adapting poor posture with sustained contraction, as noted previously (Fricton, 1990; Langemark & Jensen, 1988). The resulting muscular restrictions may perpetuate existing trigger points and aid in the development of others.

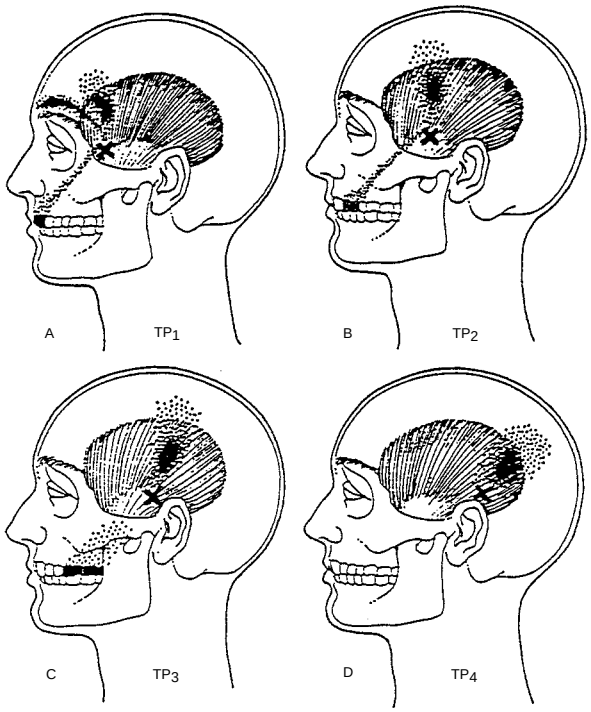

FIGURE 11.1 Referred pain patterns from trigger points (X) in the left temporalis muscle. Dark areas show essential zones; spillover zones are stippled. (A) Anterior spokes" of pain arising form the anterior fibers— trigger point 1 region. (B) and (C) Middle spokes— trigger point 2 and 3 regions. (D) Posterior supra-auricular spoke —trigger point 4 region. (From Jay, G.W., in Treating the Headache Patient, Cady, R.K. and Fox, A.W. (Eds.) Marcel Dekker, New York, 1995, pp. 213-233. With permission.)

Other authors (Fricton, Kroening, Haley, & Siegart, 1985) found that a large percentage of patients suffering from an MPS of the head and neck were found to have significant postural problems, with forward head tilt and rounded shoulders, as well as poor standing and sitting posture, all findings frequently seen in both CTTHA patients as well as those with PTTHA.

An MPS of the head and neck, via myofascial trigger point referred pain, may mimic other conditions, including migraine headache, TMJ dysfunction, sinusitis, and cervical neuralgias, as well as various otological problems including tinnitus, ear pain, and dizziness (Fricton, 1990).

The onset of an acute, single muscle MPS may be associated with trauma, such as an acceleration/deceleration injury, a slip and fall, or even a direct blow. It may also come on insidiously, for example, in patients who work multiple hours at a typewriter or at the computer. The MPS may show a spontaneous regression to a latent status, with continued muscular dysfunction, but with significant diminution of the initial pain complaints. In other patients, the MPS may "metastasize" and involve associated musculature, becoming regional, or even involving multiple muscular regions.

OTHER CLINICAL ASPECTS

After the onset of chronic posttraumatic tension type of headache (CPTTHA), emotional/psychological factors including stress, anxiety, and depression may become important in the maintenance or perpetuation of the

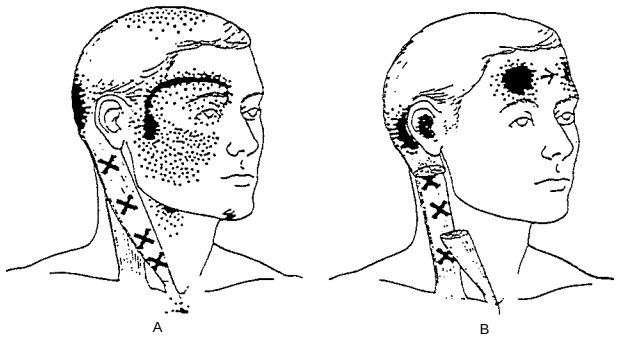

FIGURE 11.4 Referred pain patterns with location of corresponding trigger points (×) in the right sternocleidomastoid muscle. Dark areas show essential zones; spillover zones are stippled. (A) The sternal (superficial) division. (B) The clavicular (deep) dividion. (From Jay, G.W., in Treating the Headache Patient, Cady, R.K. and Fox, A.W. (Eds.) Marcel Dekker, New York, 1995, pp. 211–233. With permission.)

headache. This is frequently seen in the patients with the postconcussive syndrome. Patients with MTBI have other significant emotional stigmata that contribute to this headache diathesis.

A major difficulty in the literature is the fact that determinations of depression, anxiety, and other affective components to the PTTHA are found to occur in patients with CPTTHA. Without premorbid psychological analyses, it is very difficult to state with any certainty whether these patients were depressed or anxious prior to the onset of their headache problems. It is therefore possible that the neurochemical changes associated with CPTTHA, such as probable central serotonergic dysfunction, initiate depression as a response to these pain-induced neurochemical changes (see later).

Some authors have noted that the "conversion V" found in the hypochondriasis, depression, and hysteria scales of the Minnesota Multiphasic Personality Inventory (MMPI) is a marker for CTTHA as well as PTTHA, however, similar responses are found in chronic nonheadache pain patients (Jay, Grove, & Grove, 1987; Kudrow, 1986; Martin & Rome, 1967).

ASSOCIATED SLEEP DISORDERS

There appears to be an important relationship between sleep, headache, and muscle pain syndromes. Central biogenic amines, particularly serotonin and norepinephrine, are important to sleep physiology as well as to the central pain-modulating systems. Both human and animal research indicates that central serotonin metabolism plays a role in pain modulation, affective states, and regulation of nonrapid eye movement REM sleep (Goldenberg, 1990). A high incidence of sleep difficulties has been found in CTTHA (Matthew, Glaze, & Frost, 1958). Different

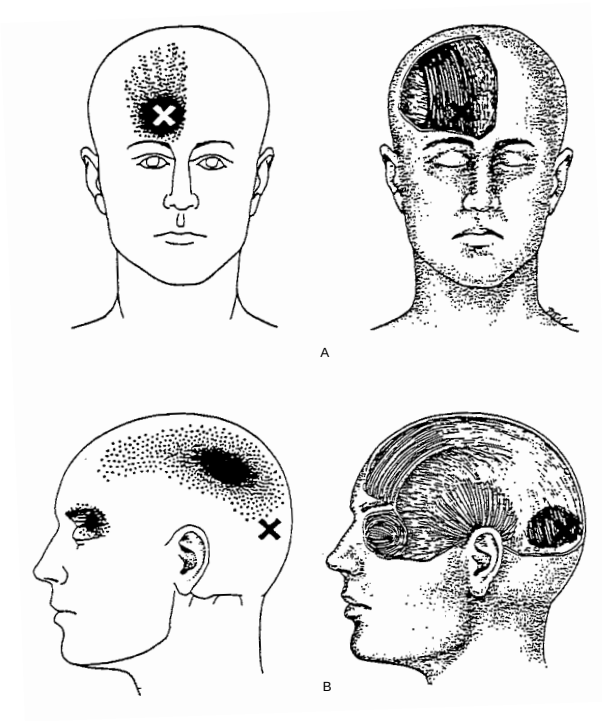

FIGURE 11.6 Pain patterns (shaded areas) referred from trigger points (×) in the occipitofrontalis muscle, commonly associated with unilateral, supraorbital, or ocular headache. 9a) right frontalis belly. (B) Left occipitalis belly. (From Jay, G.W., Treating the Headache Patient, Cady, R.K. and Fox, A.W. (Eds.) Marcel Dekker, New York, 1995, pp. 211–233. With permission.)

sleep disorders appear to be associated with different headache entities. CTTHA and CPTTHA appear to be similar if not identical. Migraine has been found to occur in association with REM sleep, and to have an association with excessive stages 3 and 4 and REM sleep (Shahota & Dexter, 1990). Chronic TTHA has been found to be associated with frequent awakenings and decreased slow wave sleep, as well as an alpha-wave intrusion into stage 4 sleep (Drake, Pakalnis, Andrews, & Bogner, 1990).

Moldofsky et al. (1975) noted a disturbance in stage 4 sleep to be the first laboratory-based abnormality found in fibromyalgia. They induced a similar alpha-non-REM pattern of alpha-wave intrusion in delta (stage 4) sleep in normal subjects by stage 4 sleep deprivation. These subjects developed musculoskeletal pain and affective changes comparable with those seen in fibromyalgia patients. Small doses of serotonergic tricyclic antidepressant medications, which reduced the alpha intrusions into stage 4 sleep, were utilized to ameliorate the symptoms.

Alpha-wave intrusions into deep sleep have also been found in patients with other chronic pain syndromes, including rheumatoid arthritis (Goldenberg, 1989). The alpha-non-REM disturbance has also been seen in asymptomatic people as well as in those who experience severe emotional stress, such as combat veterans (Goldenberg, 1990). In the latter group, the veterans with this sleep disorder also complained of chronic headaches, diffuse pain, and emotional distress.

Sleep disturbance is also associated with increased pain severity. As noted earlier, chronic headache patients seem to have a higher incidence of sleep abnormalities than do normal, pain-free subjects. Etiologic aspects of chronic headache may be linked to sleep abnormalities as an initiating event or as the result of the underlying pathologically dysmodulated neurochemical factors inducing a sleep disorder.

OTHER POSSIBLE ASSOCIATED FACTORS

There are several possible mechanical etiologies of chronic PTTHA. First is cervical spondylosis, which is defined as a degenerative disease affecting intervertebral disks and apophyseal joints of the cervical spine. Although several authors indicate a possible correlation between cervical spondylosis and TTHA and PTTHA (Diamond

& Dalessio, 1980; Simons, Day, Goodell, & Wolff, 1943; Speed, 1983), others conclude the contrary (Iansek, Heywood, Karnaghan, & Nalla, 1987), suggesting that the basis of existing headache is secondary to muscle contraction and/or central neurochemical dysmodulation. Cervicogenic headache, which is discussed in detail later, is a second suggestive diagnosis.

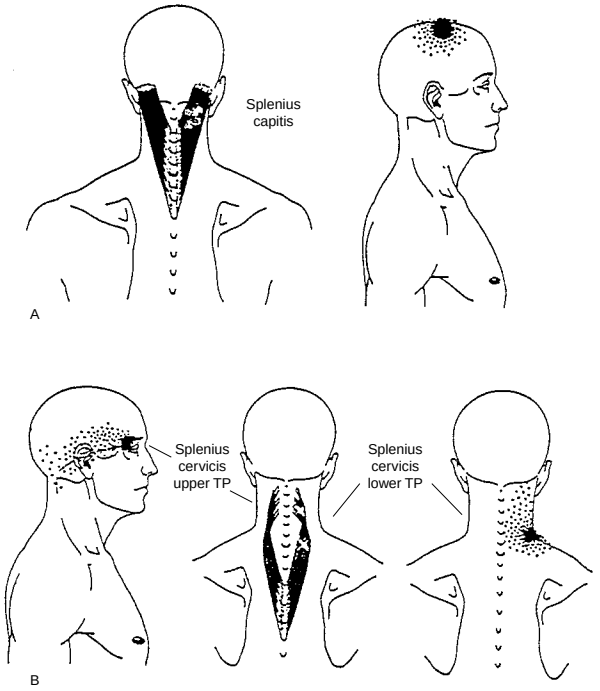

FIGURE 11.7 Trigger points (x) and referred pain patterns (shaded areas) for the right splenius capitis and splenius cervicis muscles. (A) the splenius capitis trigger point, which overlies the occipital traiangle. (B) (Left) The upper splenius cervicis trigger point (TP) refers pain to the orbit. The dashed arrow represents the pain shooting from the inside of the head to the back of the eye. (Right) Another site of pain referral. (From Jay, G.W., in Treating the Headache Patient, Cady, R.K. and Fox, A.W. (Eds.) Marcel Dekker, New York, 1995, pp. 212–233. With permission.)

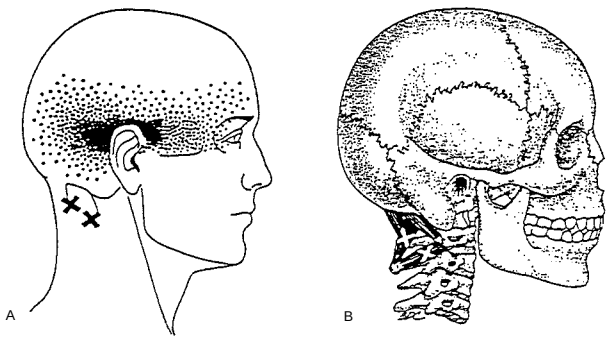

FIGURE 11.8 (A) Referred pain pattern (shaded area) of trigger points (x) in the right suboccipital muscles (B). (From Jay, G.W., in Treating the Headache Patient, Cady, R.K. and Fox, A.W. (Eds.) Marcel Dekker, New York, 1995, pp. 212–233. With permission.)

Finally, the dental literature has been most active in reporting a possible correlation between TMJ dysfunction and TTHA, including PTTHA (Forsell, 1985; Mikail & Rosen, 1980). The relationship appears to be dependent mainly on tenderness of the masticatory muscles, which may have other etiologies and induce TMJ dysfunction, when it exists, on a secondary basis (Langemark, Olesen, Poulsen, & Bech, 1988; Magnusson & Carlsson, 1978a, 1978b). Clinically, in the presence of direct trauma to the TMJ, the incidence of anatomic dysfunction is increased.

NEUROPHYSIOLOGICAL CHANGES

Fewer than 50% of PTTHA patients complain of mild associated autonomic symptoms such as lack of appetite, hyperirritability, dizziness, and increased light sensitivity (photophobia) (Olesen, 1988). Notably, some of these symptoms may be secondary to autonomic changes associated with active myofascial trigger points located in the head and neck.

Although muscle contraction and tenderness may be interpreted as primary symptoms of PTTHA, EMG activity and muscle tenderness increase, in some studies more often during migraine than in TTHA (Cohen, 1978; Olesen, 1978; Tfelt-Hansen, Lous, & Olesen, 1981).

In research comparing TTHA with common migraine patients exposed to auditory stimulation, TTHA patients showed a lower heart rate reactivity than migraine patients experience (Ellertsen, Norby, & Sjaastad, 1987). It was shown that TTHA patients exhibited the greatest cardiovascular arousal during headache (Haynes, 1981). In another study (Bakal & Kaganov, 1977), both migraine and TTHA patients decreased pulse velocity. In a psychophysiological comparison of migraine and tension-type headache, it was found that migraine patients are vasodilated and TTHA patients are vasoconstricted both during and between headache episodes (Cohen, 1978). During another study, administration of ergotamine tartrate, a vasoconstrictor, increased the pain of TTHA, whereas amyl nitrate, a vasodilator, yielded only transient pain relief (Tunis & Wolff, 1954).

Greater sympathetic arousal was found in TTHA patients as compared with controls (Murphy & Lehrer, 1990). Another study reported both TTHA and migraine patients demonstrated cardiovascular sympathetic hypofunction, indicated by low basal levels of norepinephrine (NEP), as well as orthostatic hypotension (Mikamo, Takeshima, & Takahashi, 1989). It has been suggested that TTHA patients have phasic hypersympathetic activity, whereas migraineurs do not differ from controls during psychogalvanic response testing (Covelli & Ferrannini, 1987).

Evidence of pupillary sympathetic hypofunction and subtle anisocoria has been found in both TTHA and migraine patients (Takeshima, Takao, & Takahashi, 1987).

It was suggested that this may have reflected a central bioaminergic system dysfunction. Another study suggested a pupillary sympathetic system imbalance in CTTHA patients, who showed asymmetrical mydriasis after tyramine instillation and in the physiological pupillary tests (Shimomura & Takahashi, 1986). Oculomotor dysfunction in the amplitude and number of corrective saccades during testing of TTHA patients has also been found (Rosenhall, Johansson, & Orndahl, 1987).

Drummond (1986) has reported increased photophobia in TTHA patients as compared with controls. He hypothesized that changes in central neurotransmitter modulation may induce increased sensitivity or hyperexcitability-induced photophobia.

Episodic platelet abnormalities with associated serotonergic dysfunction has been well documented in migraine (D'Andrea, Toldedo, Cortelazzo, & Milone, 1982; Hanington, Jones, Amess, & Wachowicz, 1981). Nonepisodic decreased platelet serotonin in CTTHA patients has also been documented (Rolf, Wiele, & Brune, 1981).

Again, it must be reiterated that the single differentiating aspect between CTTHA and CPTTHA patients is the historical factor of some form of trauma. Findings on examination, treatment techniques, and methodology are the same, with the same outcomes in both entities, if done appropriately. The research noted earlier does not differentiate the TTHA patients from those with PTTHA. Clinically and diagnostically there are few, if any, differences.

NEUROANATOMY AND NEUROCHEMISTRY

The central modulation of pain appears to originate in the brain stem and involves at least two systems. The "descending" inhibitory analgesia system appears to regulate the "gating" mechanisms of the spinal cord. This system includes the midbrain periaquaductal gray region, the medial medullary raphe nuclei, and the adjacent reticular formation, as well as dorsal horn neurons in the spinal cord (Basbaum & Fields, 1984). The "ascending" pain modulation system originates in the midbrain and is projected to the thalamus (Andersen & Dafny, 1983). Both systems utilize biogenic amines, opiod peptides and non-opiod peptides (Anderson & Dafny, 1983; Basbaum & Fields, 1984; Raskin, 1988b).

The ascending system appears to show more relevance to headache disorders. This system has projections from the brain stem to the medial thalamus, which include large numbers of serotonergic and opiate receptors. The midbrain dorsal raphe nucleus, a serotonergic nucleus, projects to the medial thalamus and is associated with pain perception. Serotonergic projections to the forebrain are implicated in the regulation of the sleep cycle, mood changes, pain perception, and hypothalamic regulation of hormone release (Raskin, 1988a).

The endogenous opiate system (EOS) within the central nervous system may act as a nociceptive "thermostat" or "algostat", setting pain modulation to a specific level. As this level changes, an individual's pain tolerance may also change. Fluctuations in pain intensity may be interpreted as being secondary to fluctuations in the function of antinociceptive pathways (Fields, 1988; Wall, 1988). Headache, along with other "nonorganic" central pain problems are thought to be the most common expression of impairment of the antinociceptive systems (Sicuteri, 1982).

The EOS modulates the neurovegetative triad of pain, depression, and autonomic disturbances that are found in only two conditions — CTTH (posttraumatic or otherwise) and acute morphine abstinence (Sicuteri, 1982). The EOS is also implicated as primary protagonists in idiopathic headache (Sicuteri, 1982; Sicuteri, Spillantini, & Franciullacci, 1985). Reduced plasma concentrations of beta-endorphin have been found in idiopathic headache patients, including those with chronic (and posttraumatic) tension-type headache (Facchinetti & Genazzani, 1988; Genazzani et al., 1984; Mosnaim et al., 1989; Nappi et al., 1982).

A primary relationship also exists between the EOS and the biogenic amine systems that are intrinsic to both the pathophysiology of pain modulation and its treatment. Clinical and neuropharmacological information indicates that dysmodulated serotonergic neurotransmission probably generates chronic headache and head pain. It has also been noted that the ordinary, acute or periodic headache may be the "noise" of serotonergic neurotransmission (Raskin, 1988b).

Decreased levels of serotonin (Giacovazzo, Bernoni, Di Sabato, & Martelletti, 1990; Rolf, Wiele, & Brune, 1981; Shimomura & Takahashi, 1990) (with good indications of an impairment of serotonergic metabolism in patients with CTTHA), substance P, an excitatory neuropeptide (Almay et al., 1988; Pernow, 1983) and plasma norepinephrine (Takeshima et al., 1989) are found in CTTHA patients. The latter is also indicative of peripheral sympathetic hypofunction, which may also participate in the etiology or maintenance of central opiod dysfunction (Nappi et al., 1982). Platelet GABA levels are significantly increased in CTTHA patients. This may also act as a balance mechanism to deal with neuronal hyperexcitability and may also be associated with depression (Kowa, Shimomura, & Takahashi, 1992).

The opiod receptor mechanisms appear to be very susceptible to desensitization, or the development of tolerance. In CTTHA patients, opiod receptor hypersensitivity is marked, secondary to the chronically diminished secretion of neurotransmitters. This "empty neuron

syndrome" may involve both autonomic and nociceptive afferent systems, as well as latent, subpathological c- pathological characteristics with spontaneous manifesta tions (Sicuteri, Nicolodi, & Fusco, 1988).

The EOS modulates the activity of monoaminergic neurons. A chronic EOS deficiency can provoke transmit- ter leakage, of both opiod and bioaminergic neurotrans mitters, and lead to neuronal exhaustion and "emptying, as well as compensatory effector cell hypersensitivity. The poor release of neurotransmitter along with cell/recepto hypersensitivity appears to be the most important phenom enon of the hypoendorphin syndromes. It has also bee concluded that CTTHA (and, clinically, PTTHA) may result from dysmodulation of nociceptive impulses, with associated sensitized receptors (Langemark, Jense Jensen, & Olesen, 1989).

CTTHA, including the CPTTHA may be, along with other chronic idiopathic headaches, a "pain disease" directly linked to central dysmodulation of the nociceptive and antinociceptive systems, either latent or pathologica in nature. Research indicates that at least two arms of th main endogenous antinociceptive systems, the EOS ar the serotonergic systems, are involved in the pathogenes of CTTHA. Clinical diagnosis and treatment of PTTHA demonstrates identical findings. This problem appears t be progressive, and the dysfunctions may result from neuronal exhaustion secondary to continuous activation c these systems (Facchinetti & Genazzani, 1988; Sicuter Nicolodi, & Fusco, 1988).

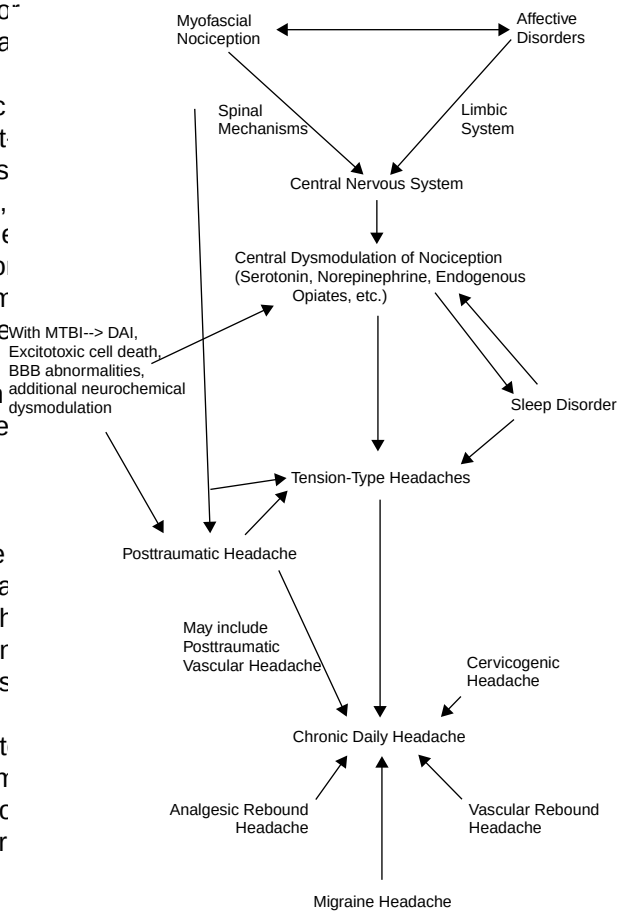

FIGURE 11.9 Headache diatheses found in posttraumatic headache patients.

PATHOPHYSIOLOGY

By looking at the upper portion of Figure 11.9, most of the basics have been mentioned: Continuous peripheral stimulation from myofascial nociceptive input from a MPS, with or without trigger points, may effectively trigger a change in the central pain "rheostat" associated with nociceptive input, secondary to the continuous need for pain-modulating antinociceptive neurotransmitters. The affective aspects of pain —including depression, anxiety, and fear —are secondary to changes in neurotransmitters such as serotonin and NEP, directly influence myofascial nociception, and further reinforce central neurochemical changes.

After 4 to 6 and 12 weeks or so, changes in the CNS central modulation of nociception can occur. Secondary to continuous peripheral nociceptive stimulation, in association with affective changes, the central modulating mechanisms assume a primary instead of a secondary or reactive role in pain perception, as well as antinociception, shifting the initiating aspects of pain perception from the peripheral regions to the CNS.

This intrinsic shift may make innocuous stimuli more aggravating to the pain-modulating systems, the "irritable everything syndrome." The already dysmodulated internal feedback mechanisms may react until central neurochemical mechanisms dominate, secondary to neurotransmitter exhaustion, and receptor hypersensitivity and abnormal biogenic amine metabolism/exhaustion occurs. These neurochemical changes may induce and/or exacerbate a sleep disorder (serotonergic in nature, from the nucleus raphe magnus); by itself this disorder can perpetuate the central neurochemical dysmodulation, which is primarily responsible for CTTHA.

CPTTHA, whether or not it is associated with a MTBI, has the same pathophysiological mechanisms. In the presence of an MTBI, other significant pathophysiological changes occur that can potentiate or exacerbate the mechanisms described earlier.

In the face of dysmodulated neurochemical systems found in CTTHA, add direct myofascial trauma as an initiating event. The effects of diffuse axonal injury from MTBI, which also affects the neurochemistry of the brain as neuronal degeneration and death occurs, can exacerbate the neurotransmitter pathophysiology. This may also explain the initiation of de novo

migraine, because brain stem trigeminovascular mechanisms may obviously be affected. Finally, excitotoxic injury that leads to cell death from the overexuberant production of acetylcholine and glutamate also may induce significant neuropathological "holes" in the primary neurotransmitter systems and exacerbate the headache pathophysiology.

Affective changes follow, with the additional problem of possible cognitive changes resulting from MTBI. The latter may make treatment of PTTHA more difficult.

PTTHA is the most common sequelae of an MTBI. It may also be associated with iatrogenic analgesic abuse. Before treatment or even diagnosis of cognitive deficits is attempted, inappropriate medications must be stopped and the headache ameliorated. Most commonly, for this to be done, the patient must be treated using an interdisciplinary headache treatment protocol. Please see The Headache Handbook: Diagnosis and Treatment for the details of this protocol (Jay, 1999).

The neurochemical factors leading to the perpetuation of PTTHAs appear to be further and more complexly involved than in CTTHA without associated MTBI. Treatment is most appropriately and cost-effectively performed in an interdisciplinary headache rehabilitation program. Tricyclic medications, GABAnergic medications, and nonsteriodal anti-inflammatory drugs (NSAIDs) are appropriate, whereas narcotics, Dilantin, barbiturates, and early generation benzodiazepines are not.

It is worth noting that patients with MTBI who complain of headache do not appear to perceive their headache pain the same way a headache patient without an MTBI does. These patients know that they have headaches. On a scale of 0 (no pain) to 10 (worst pain imaginable— you could not tolerate it for a moment or two), individual patients, when first seen, give you high numbers (e.g., 7 to 10). These numbers are correlated to pathophysiological myofascial findings, including decreased cervical range of motion, muscle spasm, active trigger points, and more. As they go through treatment, you see the patients regain appropriate physical functioning: normal cervical range of motion, amelioration of spasm and trigger points, etc., with a marked associated improvement of function. The patients' appear brighter; they smile, have fewer if any pain behaviors, and resume doing the physical things they enjoy.

Yet, when asked, they continue to state that their headache pain is at the same level of 7 to 10 as when they were first seen. Whether they are perseverating or are just unable to give an accurate subjective pain level (frontal lobe involvement?), their stated pain levels may not change very much at all. Therefore, you must evaluate them on improvements in function, not by self-reported subjective decrements in headache pain levels.

Evaluation and Treatment of Posttraumatic Tension-Type Headache

The neurological examination of migraine patients is, in the absence of complicated aura, negative. The examination of the cluster headache patient may yield signs of a partial Horner's syndrome. The examination of the patient with PTTHA may yield a great deal of information.

Typically, the neurological examination is negative. The musculoskeletal evaluation gives you the facts. Begin by observing the patient's shoulders. In the vast majority of cases, there is an asymmetry of the acromioclavicular joints, with one being higher than the other secondary to greater ipsilateral muscle spasm. The large muscles should be carefully palpated both for general tenderness and the presence of trigger points. These include the trapezius muscles, the deltoids, the scalenes, the rhomboids, the levaeter scapulae, and all associated muscles (including the pericranial musculature). Pay careful attention to the sternocleidomastoid muscles, particularly in patients complaining of dizziness and tinnitus. Palpate the bioccipital and bitemporal insertions. Look for true pericranial muscle tenderness, as well as masseter pain or tenderness. Observe the patient open their mouth: look for the amount of space between the teeth and see if the jaw deviates.

Perform the passive as well as the active cervical range of motion. Observe the patient's head: is it flexed forward? Is it tilted to one side? What about the shoulders: are they rounded or rolled forward? Evaluate the presence and degree of muscle spasm found in the paravertebral muscles over the entire length of the spine. If the patient is a CTTHA sufferer, posttraumatic or otherwise, or if there is a complaint of upper extremity or hand numbness, perform an axillary stretch maneuver as well as the Adson's maneuver to evaluate for a myogenic thoracic outlet syndrome. These are just the basics.

Until you know what you are dealing with physiologically, it is impossible to determine an appropriate treatment plan. Once you know, and are positive about your diagnosis reached by the history and physical/neurological examination, you can begin to formulate a treatment plan.

Treatment of Acute Posttraumatic Tension-Type Headache

The medical management of acute, or episodic PTTHA is relatively simple. Remember that the older nomenclature titled these headaches as "acute muscle contraction headache" or "tension headache." This form of headache is the most common, as previously indicated, accounting for up to 80% of all nonorganic types of headache. It has been estimated that over 90% of Americans experience an acute TTHA, with or without predisposing trauma, at some time. The majority of these headaches are self-treated with over-the-counter medications and therefore never come to the

attention of a physician. This indicates that the statistics are probably low, in that a fairly large number go unnoticed by physicians.

The greatest problem in the treatment of acute PTTHA is the avoidance of the development of analgesic rebound headache, which can easily occur if a patient is overmedicated. This is one step into the development of CPTTHA or daily PTTHA. Physicians should be particularly familiar with the various types of medications that can be utilized for patients complaining of acute PTTHA.

The old adage, that less is better, certainly applies here. Many patients deal with the pain and discomfort by taking two aspirin and relaxing. Exercise is useful, as is a simple glass of wine, on an occasional basis. Any type of relaxation that distracts patients from their headache is useful.

In dealing with the medication management, physicians have a more than ample supply to chose from. It may be therefore tempting to overtreat a minor headache with medications that have a significant risk of dependency.

The simple analgesics are easily chosen by the patient, if not the physician. They are inexpensive and easy to get. They include aspirin and acetaminophen. Like the NSAIDs, aspirin appears to work by inhibiting the synthesis of prostaglandin by blocking the action of cyclooxygenase, an enzyme that enables the conversion of arachidonic acid to prostaglandin to occur. Remember that prostoglandins are synthesized from cellular membrane phospholipids after activation or injury, and sensitize pain receptors.

Aspirin, the prototypical NSAID, has anti-inflammatory and antipyretic properties, along with its pain-relieving properties. The recommended adult dose for treatment of acute PTTHA is 650 mg every 6 h. Taking the aspirin with milk or food may decrease gastric irritation. Aspirin can also double bleeding time for 4 to 7 days after taking 0.65 g. Peak blood levels are found after 45 min. The plasma half-life is 2 to 3 h.

Acetaminophen usage is common. It provides about the same amount of analgesia as aspirin, but does not have the gastrointestinal (GI) side effects. It has been suggested that acetaminophen may work by inhibiting prostaglandin synthesis in the CNS has been suggested. It has much weaker anti-inflammatory activity than that of aspirin. Peak plasma levels occur between 30 and 60 min. The plasma half-life of acetaminophen is 2 to 4 h.

Ibuprofen, an NSAID, is also available over the counter in doses of 200 mg per tablet. It can cause significant GI distress. It has a half-life of 2 to 4 h, with peak plasma levels attained in 1 to 2 h. The adult dosage is 200 to 400 mg every 4 to 6 h, with a maximum of 1200 mg/day.

These medications are frequently sold in combination with other drugs such as caffeine, which exerts no specific analgesic effects, but may potentiate the analgesic effects of aspirin and acetaminophen. There are aspirin–caffeine combination drugs (Anacin), and aspirin, acetaminophen, and caffeine combinations (Excedrin extra-strength, Excedrin migraine, and Vanquish). The recommended dosage is two tablets every 6 h as needed.

The biggest problem is that taking aspirin, acetaminophen, or combination tablets daily or even every other day for a week or more (possibly less) can induce the problem of analgesic rebound headache (which is discussed later).

As with birth control pills, when you ask patients what medications they are taking, they may forget that the birth control pill, aspirin, or acetaminophen are medications; they may forget to tell you, or even be too embarrassed to tell you, because they are taking a large number of pills each day, so you must be certain to ask specifically.

There are a number of NSAIDs that are prescribed. Because of the variability in their efficacy, pharmacokinetics, and side effects, patients may need to be tried on more than one, sequentially, not in combination, to determine the best one for them.

The NSAIDs work, as noted before, by interfering with the action of cyclooxygenase in the synthesis of prostaglandins. GI side effects are common, in up to 15 to 20% of patients; and may include epigastric pain, nausea, heartburn, and abdominal discomfort. A history of GI bleeding or ulcerations should indicate that great caution must be used, if these medications are used at all.

Most Frequently Prescribed Medications

Naproxen sodium (Anaprox) reaches peak plasma levels in 1 to 2 h, and has a mean half-life of 13 h. It can be taken at 275 or 550 mg every 6 to 8 h, with a top dosage of 1375 mg/day. Remember that this NSAID is useful in treating hormonally related migraine.

Ibuprofen (Motrin) is prescribed in dosages of 600 and 800 mg per tablet. The suggested dosage for mild to moderate pain is 400 mg every 4 to 6 h as needed.

Ketoprofen (Orudis) is a cyclooxygenase inhibitor, but also stabilizes lysosomal membranes and possibly antagonizes the actions of bradykinin. Its peak plasma level is reached in 1 to 2 h and has a 2-h plasma half-life. It is now over the counter (12.5-mg tablets), but is best used as 50 to 75 mg capsules. The recommended daily dosage is 150 to 300 mg a day in three or four divided doses. GI side effects are generally mild. Care should be taken when given to a patient with impaired renal function.

Keterolac tromethamine (Toradol) can be given orally or parentally for moderate to severe acute headache pain. Peak plasma levels occur after intramuscular (IM) injection in about 50 min. Its analgesic effect is considered to be roughly equivalent to a 10 mg dose of IM morphine. The typical injectable dose is 60 mg. Because of its potentially significant hepatic/renal side effects, the Food and Drug Administration (FDA) has stated that Toradol should

be given orally, after an IM injection of 60 mg, at 10 mg, every 8 h, for a maximum of 5 days.

The cyclooxygenase-2 (COX-2) inhibitors (celecoxib and rofecoxib) are nonsteroidal anti-inflammatory agents that also have analgesic properties without, for most patients, the typical GI problems associated with NSAIDS. They appear to work by inhibiting prostaglandin synthesis, via inhibition of COX-2, which corresponds to its improved GI side effect profile, while not affecting the COX-1 isozyme, responsible for its anti-inflammatory functions. Celecoxib may be taken twice a day, 100 to 200 mg twice a day, whereas rofecoxib is taken once a day, at dosages ranging from 12.5 to 50 mg.

Muscle relaxants are given for acute TTHA by some clinicians. They are probably best utilized during the first 3 weeks of post-injury-related headache. They are useful in patients with significant muscle spasm and pain, which may be seen in acute PTTHA, but are not usually seen with an episodic TTHA. They are used appropriately after the development of muscle spasm after injury such as a slip and fall, motor vehicle accident, work and athletic injuries, or overstretching.

These medications work via the development of a therapeutic plasma level. Their exact mechanism of action is unknown, but they do not directly affect striated muscle, the myoneural junction, or motor nerves. They produce relaxation by depressing the central nerve pathways, possibly through their effects on higher CNS centers, which modifies the central perception of pain without effecting the peripheral pain reflexes or motor activity.

Carisoprodol (Soma) is a CNS depressant that metabolizes into a barbiturate, which makes it both addictive and particularly inappropriate to use for patients with pain from muscle spasm in addition to MTBI. It acts as a sedative and it is thought to depress polysynaptic transmission in interneuronal pools at the supraspinal level in the brain stem reticular formation. It is short lived, with peak plasma levels in 1 to 2 h and a 4 to 6 h half-life. Dosage is 350 mg every 6 to 8 h. It should not be mixed with other CNS depressants. It is also marketed in two other combined forms (with aspirin as Soma Compound and with codeine) for additional analgesic effects.

Chlorzoxazone (Parafon Forte DSC) is a centrally acting muscle relaxant with fewer sedative properties. It inhibits the reflex arcs involved in producing and maintaining muscle spasm at the level of the spinal cord and subcortical areas of the brain. It reaches peak plasma level in 3 to 4 h, and duration of action is 3 to 4 h. It is well tolerated, and side effects are uncommon. Dosage is 500 mg three times a day.

Metaxalone (Skelaxin) is a centrally acting skeletal muscle relaxant that is chemically related to mephenaxalone, a mild tranquilizer. It is thought to induce muscle relaxation via CNS depression. Onset of action is about 1 h, with peak blood levels in 2 h; and duration of action is 4 to 6 h. The recommended dose is 2400 to 3200 mg a day in divided doses (tablets are 400 mg each). It should be used carefully in patients with impaired liver function, and should not be used at all in patients with significant renal or liver disease as well as a history of drug-induced anemias. Side effects include nausea, vomiting, GI upset, drowsiness, dizziness, headache, nervousness, and irritability as well as rash or pruritis. Jaundice and hemolytic anemia are rare.

Methocarbamol (Robaxin) is a centrally acting skeletal muscle relaxant. It may inhibit nerve transmission in the internuncial neurons of the spinal cord. It has a 30-min onset of action. Peak levels are found in about 2 h, and its duration of action is 4 to 6 h. It comes as 500 and 750 mg tablets. Tablets containing methocarbamol and aspirin (Robaxisal) are also available. The recommended dose of Robaxin is 750 mg three times a day. As with all these medications, it should be taken for 7 to 10 days. It is well tolerated, with initial side effects that resolve over time, including lightheadedness, dizziness, vertigo, headache, rash, GI upset, nasal congestion, fever, blurred vision, urticaria, and mild muscular incoordination. In situations of severe, seemingly intractable muscle spasm, Robaxin may be given intravenously in doses of about a gram every 8 to 12 h.

Orphenedrine citrate (Norflex, Norgesic) is a centrally acting skeletal muscle relaxant with anticholinergic properties thought to work by blocking neuronal circuits, the hyperactivity of which may be implicated in hypertonia and spasm. It is available in injectable and oral formulations. The IM dose of Norflex is 2 mg, whereas the intravenous dosage is 60 mg in aqueous solution. The oral formulation (Norflex) is given in 100 mg tablets — one tablet every 12 h. Norgesic is a combination form, including caffeine and aspirin and should be given 1 or 2 tablets every 6 to 8 h. Norgesic Forte, a stronger combination, is given one half to one tablet every 6 to 8 h. Because of its anticholinergic effects, it should be contraindicated in patients with glaucoma, prostatic enlargement, or bladder outlet obstruction. Its major side effects are also secondary to its anticholinergic properties, and include tachycardia, palpitations, urinary retention, nausea, vomiting, dizziness, constipation, and drowsiness. It may also cause confusion, excitation, hallucinations, and syncope.

Many of these medications are given in combination with other drugs, including barbiturates (butalbatal and meprobamate) and narcotics (codeine, oxycodone, propoxyphene, etc.) This is probably not a good idea, because the barbiturates and narcotics can easily help develop patient dependence.

A good combination utilized by the author is methocarbamol 750 mg three times a day for 10 days in patients with significant spasm, accompanied by ketoprofen, 75 mg every 6 to 8 h as needed, with food as needed. For the acute PTTHA, one tablet of each taken together

every 6 to 8 h for two to three doses works very well. Again, narcotic medications should not be used for the patient with acute PTTHA, because the risk of dependence is too great.

Remember, too, that simple acute PTTHA is a problem that the headache specialists are rarely called to see. The patient's family physician or chiropractor most frequently sees this problem.

Medication Management of Chronic Posttraumatic Tension-Type Headache

The medication treatment of choice is the tricyclic antidepressants (TCAs), or the specific serotonergic reuptake inhibitors (SSRIs).

The TCA medication of choice is amitriptyline, a sedating tricyclic antidepressant. Like all the tricyclics, it works in the synapse to decrease reuptake of serotonin and (depending on the individual medication) NEP. Amitriptyline, unlike the other TCAs, also works to repair the damage in stage 4 sleep architecture. It is the most sedating tricyclic. The typical dosage is between 10 and 50 mg at night. The author has found it rare to need more than 20 or 30 mg at night.

Doxepin is also a very good tricyclic. Anticholinergic side effects such as sedation are reduced (but not by much) when compared with amitriptyline. It does not work on the sleep architecture. It is used at the same dosage levels of amitriptyline.

Notice that the tricyclics are not used in their antidepressant dosages, anywhere from 100 to 350 mg a day. Even though the doses are low, their effectiveness in the treatment of chronic PTTHA is there.

The SSRIs include Prozac, Paxil, and Zoloft. These medications are not typically sedating (although for some patients they may be) and with the exclusion of those patients, they are energizing. They should be given in the morning. Prozac and Paxil should start at 10 to 20 mg a day, and they can be increased to 60 to 80 mg. Zoloft should be given at 25 to 50 mg in the morning, up to 150 mg in divided doses. You should divide the doses, giving one when the patient gets up in the morning (around 7:00 A.M.) and one at noon. Explain to the patients that taking these medications later than noon can, in many cases, give them problems sleeping.

You can also safely combine 10 to 40 mg of Prozac or Paxil, or 50 mg of Zoloft with a small dose of amitriptyline or doxepin (10 to 30 mg) at night. Inappropriate dosages of these two forms of medications can, rarely, induce the serotonin syndrome.

There are other excellent antidepressants such as Wellbuterin, Serzone, and Effexor. These should be considered as needed. Do not combine these medications with the monoamine oxidase (MAO) inhibitors. It is just not a great idea.

Another excellent medication is Clonazepam, a fifth generation form of benzodiazepine. It is GABAnergic in effect. It works at the level of the internuncial neurons of the spinal cord to enhance muscle relaxation. It helps, a bit, with anxiolysis. It has a side effect of sedation. In doses of 4 to 12 mg a day, it works as an anticonvulsant. At smaller doses, 0.5 to 1 mg given at night, it is very useful in the treatment of patients with CTTHA. The sedation lasts for a shorter time than the sedation from tricyclics, and this itself is useful.

If the acute use of muscle relaxant medications is not enough to end the problem, Tizanidine is a good choice of medication after the first 3 weeks or so has gone by and the patient is still exhibiting painful neuromuscular spasm. Tizanidine is an alpha-2-noradrenergic agonist (Coward, Davies, Herrling, & Rudeberg, 1984; Sayers, Burki, & Eichenberger, 1980). It has supraspinal effects by inhibiting the facilitation of spinal reflex transmission by the descending noradrenergic pathways, as it decreases firing of the noradrenergic locus ceruleus (Palmeri & Wiedendanger, 1990). It acts presynaptically in the spinal cord inducing a polysynaptic reduction in released excitatory transmitters (Davies, Johnson, & Lovering, 1983). It also decreases hyperexcitability of the muscle without acting on the neuromuscular junctions or muscle fibers (Wagstaff & Bryson, 1997). Short acting, its maximum plasma concentrations are reached within 1 to 2 h (Wagstaff & Bryson, 1997). It has a large first pass metabolism, with a half-life of 2.1 to 4.2 h (Koch, Hirst, & von Wartburg, 1989). Dosages should be slowly increased, starting at 1 to 2 mg at night and slowly increasing to 20 to 24 mg. Maximum dosage is 36 mg in divided dosages, typically found in patients who need an antimyotonic. Interestingly, this medication appears to decrease muscle pain while providing its antimyotonic effects.

Finally, treating patients with CPTTHA with tricyclics, physical therapy, psychotherapy, etc., Will Not Work if the patient is taking daily or four times a week analgesic medications of any type! In the presence of analgesic rebound headache, nothing shows long-lasting effectiveness until the chronic analgesics are stopped.

Cost-Effective Treatment of Chronic Posttraumatic Tension-Type Headache

Treatment of CPTTHA is best accomplished via an interdisciplinary rehabilitation approach, the main purpose of which is not to "teach the patient to live with the headache", but to properly diagnose and effectively ameliorate, or stop it.

Drug detoxification is the necessary first step, whether the patient is overutilizing simple, over-the-counter analgesics, narcotics, or barbiturates. Chronic daily analgesics appear to prevent appropriate functioning of the EOS (via negative neurochemical feedback loops) and other

associated antinociceptive systems, inducing analgesic rebound headaches, which are secondary problems from the medications that induce headache secondary to pure neurochemical/neurophysiological changes. Vascular rebound headaches from overutilization of vasoconstrictors may also occur and must be stopped before other treatment is applied. Clinically, an effective way to detoxify CTTHA patients is with the repetitive DHE-45 protocol described by Raskin (Raskin, 1988a). Concurrently, prophylactic medications should be started. The use of prophylactic medications, as well as physical therapy and other treatments given while a patient is enduring analgesic rebound headaches, is an ineffectual waste of time and money.

After detoxification, an outpatient interdisciplinary headache rehabilitation program utilizing neuropharmacological therapy (to restore neurochemical homeostasis), physical therapy (Jay, Brunson, & Brunson, 1989), psychotherapy, and stress management (including biofeedback-enhanced neuromuscular reeducation and muscle relaxation) is the most time and cost-effective treatment. Optimal psychotherapy or physical therapy regimes by themselves do not resolve myofascial difficulties or depression if the affective sleep and CNS neurochemical dysmodulation affecting them are not concurrently and appropriately treated. The interdisciplinary treatment paradigm also enables fine-tuning of diagnosis and possible determination of a secondary or "hidden" etiology for a patient's headaches.

Failure to treat the CPTTHA patient with an interdisciplinary, whole-person approach (see Figure 11.9) is responsible for multiple treatment failures as well as monetary waste, because long-term response—headache remediation— is most often not achieved.

POSTTRAUMATIC MIGRAINE

Posttraumatic migraine, which may begin *de novo*— without a previous personal or family history of migraine — may have neurochemical similarities with MTBI, although they are not always found together. These may include increased extracellular potassium and intracellular sodium, calcium, and chloride; serotonergic changes; decreases in magnesium; excessive release of excitatory amino acids; changes in catecholamine and endogenous opiod tonus; decreased glucose utilization; changes in neuropeptides and abnormalities in nitric oxide formation and function (Jay, 1999, pp. 173–2; Packard & Ham, 1997).

Migraine, including posttraumatic migraine, may be associated with a number of neurological symptoms or phenomena. This may include transient global amnesia (TGA), vestibular dysfunction, visual and auditory changes, and possibly increased incidence of seizures (Buchholz & Reich, 1996; Jay, 1999; Leisman, 1990).

The trigeminovascular system is of great importance in migraine (Jay, 1999). In some children who develop posttraumatic neurological deterioration without focal lesions after minor head trauma, there may be an association with an "unstable trigeminovascular reflex" which induces the release of perivascular vasodilatory peptides that can contribute to cerebral hyperemia (Sakas, Whittaker, Whitwall, & Singounas, 1997).

TGA was initially attributed to bilateral temporal lobe seizure phenomena, but more recently attributed to migraine by some (Jay, 1999), and thought to be a totally separate disorder by others, possibly due to a different form of paroxysmal disorder in the brain stem (Schmidtke & Ehmsen, 1998). TGA in the pediatric population is still felt to be secondary to ischemia of the temporo-basal structures induced by an MTBI and associated with a migrainous diathesis (Vohanka & Zouhar, 1988).

Migraine equivalents, transient neurological symptomatology not associated with headache, are not uncommon: proper diagnosis is more difficult to the generalist, as well as the neurologist. In some, possibly more susceptible individuals, minor, even trivial, head trauma can induce a migraine equivalent known as "footballer's migraine" as well as "posttraumatic cortical blindness." This particular migraine equivalent is certainly rare, but transient, total blindness may certainly be cause to call out a total, "full court press" workup (Harrison & Walls, 1990).

Another more common form of transient neurological disturbances associated with migraine are brain stem symptoms including vestibular difficulties such as dizziness, disequilibrium, vertigo, and motion intolerance. These symptoms may also present as a migraine equivalent, between migraine headache episodes or instead of the cephalic pain. Vertigo as a migraine equivalent may occur in about 25% of migraine patients, with the diagnosis made typically by history of familial migraine, because all testing is typically negative. Migraine can also mimic Meniere's disease, with vestibular Meniere's disease being more frequently but still not commonly associated with migraine (Baloh, 1997; Harker & Rassekh, 1988). Also, one should not forget the cervical causes of vertigo and dizziness, secondary to posttraumatic cervical and/or myofascial pathophysiology.

There is also a question of the possible relationship between posttraumatic migraine and posttraumatic benign encephalopathy. The latter, in children, may be associated with cortical blindness, brain stem disturbances, and seizure, lasting from 5 min to 48 h (Vohanka & Zouhar, 1990).

A significant question then arises. Posttraumatic vertigo or dizziness is a very frequent accompaniment to MTBI. It may be secondary to peripheral, labyrinthine disturbance, or brain stem disturbance secondary to trauma; or it may be a migraine equivalent. The importance of this differential is most significant, possibly, when

treatment is attempted. Clinically, this would be an important avenue of treatment to explore.

As noted, trauma may induce the first migraine attack in a possibly susceptible patient or increase the frequency and possibly the severity of preexisting migraine. The etiology of these changes may be secondary to neuronal and/or axonal abnormalities secondary to trauma.

Prophylactic treatment is typically with valproic acid, an anticonvulsant medication. The use of beta-blockers such as propranolol may also be useful, but it may have significant side effects. The same is true for verapamil. The use of a triptan for abortive care is well tolerated, if used appropriately.

Cluster headache has also been seen secondary to head trauma, again possibly secondary to neuronal and/or axonal injury. The incidence ranges from 6 to 10% (Duckro, et al., 1992; Packard & Ham, 1997). Many times, this is seen as a primary chronic, instead of episodic form of cluster, or clusterlike headache. Clinically, this is one of the rarest forms of PTHA seen. Treatment, abortive or prophylactic, has been dealt with elsewhere (Jay, 1999).

OTHER ASPECTS OF POSTTRAUMATIC HEADACHE

An initial trauma may involve soft tissue injury to the scalp or face, which may be followed by an entrapment of a sensory nerve, or the sensory nerve may have been cut during the trauma via laceration. The entrapment may also occur during suturing of a laceration. Such entrapments may induce nerve, or neuropathic pain. This is easily differentiated from other primary headache types. The pain is constant, burning, and relegated to the sensory distribution of the affected nerve. Anticonvulsant medications such as carbamazepine are best for the first-line treatment. Neuronton has been used, but it has different, possibly more significant side effects in some patients, particularly in those with a concurrent MTBI. In some cases, neurolytic procedures such as radiofrequency coagulation or cryoablation may be necessary. Both are good procedures, but have varying durations of benefit, most typically between 6 and 12 months.

Without question, injuries to the cervical spine, the superficial and deep structures of the neck (muscles, ligaments, bone, disks, or nerve roots) may occur. Cervical pain from trigger points in spasmed musculature, as well as from cervical joint dysfunction may be referred to the head.

If the posttraumatic pain is suboccipital with lancinating, electrical-like shooting pain attributes, secondary to involvement of the occipital neurovascular bundle (the occipital nerve, artery, and vein), or secondary to prolonged muscle spasm/contraction or excessive vascular dilatation impinging on the greater occipital nerve of Arnold, this pain is known as occipital neuralgia. It is always in the C2 distribution at the back of the head. Indomethacin may be an effective treatment for this problem. Steroidal injections may also be utilized. Neuroablative procedures should be performed only when all other treatment has failed.

Preexisting arthritis or discogenic disease may also be exacerbated by the initial trauma. An appropriate neurological evaluation helps with these entities.

The dysautonomic cephalalgia of Vijayan (1977) is associated with injury to the anterior aspect of the carotid sheath. The headache is severe and unilateral, in the frontotemporal area and associated with ipsilateral hyperhidrosis and dilatation of the ipsilateral pupil. The role of sympathetic nervous system dysfunction, although it may remain controversial, is shown in many studies, as noted earlier. Also, the signs and symptoms are, of course, similar to cluster headache.

CERVICOGENIC HEADACHE

Just as the community of headache specialty physicians were rather hesitant to accept the fact that the musculature had any role in TTHA, posttraumatic or otherwise, the idea that headache can arise from the structures of the neck still has many detractors.

Dwyer, Aprill, and Bogduk (1990) utilized fluoroscopic control to stimulate joints at segments C2–C3 to C6–C7 by distending the joint capsule with injections of contrast medium. They were able to show that each joint produced a clinically distinguishable, characteristic pattern of referred pain that enabled the construction of pain charts to be used in determining the segmental location of symptomatic joints in patients presenting with cervical zygapophyseal pain.

The diagnostic criteria for cervicogenic headache (CGHA) have been noted by several authors to differ a bit. Bogduk, et al. (1985) defined CGHA as referred pain perceived in any region of the head that was referred by a primary nociceptive source in the musculoskeletal tissues innervated by cervical nerves. Clinical features included pain that was not lancinating, and was dull or aching but could be throbbing — located in the occipital, parietal, temporal, frontal, or orbital regions, unilaterally or bilaterally. There was some indication of cervical spine abnormality such as neck pain, tenderness, impaired cervical motion, aggravation of the headache by neck movements, or history of cervical trauma.

Bogduk's diagnostic criteria included (Bogduk, et al., 1985) identification by clinical examination or by imaging of a cervical source of the pain that is found by valid antecedent studies to be reliably associated with the head pain, or complete relief of the head pain that is seen after controlled local anesthetic blockade of one or more cervical nerves or structures innervated by cervical nerves.

Sjaastad, Fredriksen, and Pfaffenrath (1990) also weighed in with specific criteria. They noted that cervicogenic headaches were one sided, but could also be bilateral "unilaterally on two sides". The duration of a headache or exacerbation ranged from several hours to several weeks. Initially the headache may be episodic, but can later chronically fluctuate. Symptoms and signs were referable to the neck, and included decreased range of cervical motion and mechanical precipitation of attacks with autonomic symptoms such as nausea and photophobia not marked, if at all present. A positive response to appropriate anesthetic blockade is considered essential.

Sjaastad, Fredriksen, and Pfaffenrath (1990) noted several major criteria:

1. Symptoms and signs of cervical involvement
   a. Provocation of an irradiating head pain similar to the spontaneously occurring one
      i. By neck movement and/or sustained awkward head positioning
      ii. By external pressure over the upper neck or head on the side ipsilateral to the pain
   b. Restriction of cervical range of motion
   c. Ipsilateral neck, shoulder, or arm pain of a vague, nonradicular nature, or, on occasion, sharp arm pain in a radicular region

   (Symptoms and signs 1a to 1c are listed in "order of importance". One or more of these must be present for the term cervicogenic headache to be used. Point 1a is itself insufficient criteria, but 1b and 1c are not. Point 2 is a necessary additional point.)
2. Confirmation by diagnostic anesthetic blocks — necessary point
3. Unilateral pain not shifting from side to side
4. Pain characteristics
   a. Nonthrobbing pain, usually beginning in the neck
   b. Episodes of varying duration
   c. Fluctuating, continuous pain
5. Other characteristics of some importance
   a. Marginal or no effect from treatment with indomethacin
   b. Marginal or no effect from treatment with triptans or ergots
   c. Female preponderance
   d. History of head or neck trauma

   (None of the single points under 4 or 5 are essential.)
6. Other descriptions of less importance (various headache-related phenomena that are rarely present, and of only mild to moderate severity when present)
   a. Nausea
   b. Photo- and phonophobia
   c. Dizziness
   d. Blurred vision ipsilateral to the pain
   e. Difficulty with swallowing
   f. Fluid around the eye on the same side as the pain

The anatomic basis of CGHA is thought to be secondary to convergence in the trigeminocervical nucleus between nociceptive afferents from the field of the trigeminal nerve and the receptive fields of the first three cervical nerves. Headache appears to be secondary to structural problems in regions innervated by C1 to C3. These regions include the muscles, joints, and ligaments of the upper three cervical segments, as well as the dura mater of the spinal cord and the posterior cranial fossa and the vertebral artery (Bogduk, 1992).

Other anatomic causation has been identified and includes (Blume, 1997):

1. Disrupted and/or ruptured cervical disks with irritation of the sympathetic sinu-vertebral nerves (in the disk) and nerve roots by mechanical and chemical means at single or multiple levels
2. Irritation of the articular branches to the cervical zygapophyseal joints derived from the medial branches of the cervical dorsal rami
3. Irritation of the peripheral branches and unmyelinated nerve structures to the muscle attachments at the spinous process of C2 supplied by the C2 and C3 nerve roots, including the rectus capitis posterior, major obliquus capitis inferior major, semispinalis cervicis multifidus, semispinalis capitis major and rectus capitis posterior minor and interspinal, muscles at C1 to C2 and C2 to C3
4. Pain from the end fibers of the greater tertiary occipital and sympathetic nerve structures with its C fibers including the periosteum and suboccipital musculature (semispinalis capitis, rectus capitis posterior minor and major, trapezius, and occipitalis)

The treatment of CGHA begins with diagnostic anesthetic blocks that are typically mixed with long-acting steroids such as hydrocortisone. This should temporarily relieve the CGHA for hours to days. If pain relief lasts for weeks to months, blocks should be repeated.

Once a specific targeted joint or disk is identified, the latter with discography if needed, a number of procedures have been utilized for treatment of CGHA. These include

1. Neurolysis of the C2 nerve root via decompressive surgery (Poletti, 1983) as well as partial

denervation of the suboccipital and paraspinal musculature (Pikus & Phillips, 1995)
2. Radiofrequency lesions to the muscle attachments of the spinous process at C2 (Blume, Kakolewski, Richardson, & Rojas, 1982; Rogel, 1995)
3. Radiofrequency neurotomy of the sinuvertebral nerves to the upper cervical disk, as well as to the outer layer of the C3 or C4 nerve root (Sluijter, 1990)
4. Radiofrequency denaturation of the occipital nerve (Blume, 1976; Blume, Kakolewski, Richardson, & Rojas, 1981; Blume & Ungar-Sargon, 1986)
5. Radiofrequency denaturation of the C2 medial rami (Rogal, 1986)
6. Cervical discectomy and fusion
7. C2 ganglionectomy (Jansen & Spoerri, 1985)

The latter procedure is not often performed, although there remain proponents of radiofrequency lesioning vs. the "old" cervical discectomy and fusion.

It is imperative to differentiate CGHA from both migraine headache and PTTHA, because the treatments are completely different. Unfortunately, the literature in general argues the question of cervicogenic headache, although not the idea that headache may be associated with cervical pathology. It should be noted that the International Association for the Study of Pain (IASP) has recognized cervicogenic headache as a pain syndrome (Zwart, 1997). This criteria uses neck mobility as the major indicator of this diagnosis, but both TTHA and migraine have associated decrements in cervical mobility.

The different criteria for the diagnosis of CGHA make other previously recognized primary headache sufferers fall into a diagnostic hole. There appears to be too much overlap in the varying diagnoses. Likewise, patients with the diagnosis of CGHA may also fall into other diagnostic categories, or even multiple diagnostic categories (Leone, 1998; Pfaffenrath & Kaube, 1990; Treleaven, Jull, & Atkinson, 1994).

Not to be forgotten is the fact that the diagnosis specifically may follow an acceleration/deceleration injury or other cervical trauma (Obelieniene, et al., 1998; Treleaven, Jull, & Atkinson, 1994). This makes it imperative to consider the diagnosis of CGHA in patients with PTHA who do not show improvement following appropriate treatment for other diagnosed headache diatheses. On the other hand, clinically, CGHA appears to be found in less than 3 to 5% of the PTTHA population. If a PTHA patient also has an MTBI, the level of difficulty in making the diagnosis and treating that patient increases dramatically.

Psychological factors are there — the neurochemical aspects of depression and anxiety, for instance, are well known. In the presence of an MTBI they become more difficult to tease out and deal with, because the patients may be dealing with pain as well as changes in cognition and behavior, including frontal lobe difficulties such as increased irritability and labile emotionality.

CONCLUSION

Other major problems facing patients and their treating physician(s) are the questions of medico-legal disability secondary to the PTHA syndrome, with or without the question of MTBI. Patients whose injuries involved a skull fracture, subdural hematoma, or severe lacerations and whose gray matter is leaking out of their ears may not have a problem in regard to disability. Unfortunately for patients and their physicians, insurance problems do exist, beginning with getting approval to treat a PTHA syndrome.

Some insurance companies deny that there is such a thing as an MTBI, or PTHAs. They have a number of paid consultants to assure the legal system that this is so. They try to prevent clinicians from even getting involved with treating these patients by refusing to pay them for treatment. It does not matter how devastating a patient's symptoms are; the patient still faces a difficult and totally unjustified legal battle just to get treatment approved, never minding the question of disability compensation.

It is interesting that the vast majority of patients with PTHAs, particularly those with headaches as part of a postconcussion syndrome, present the same way. Maybe they all spoke together on the Internet and planned it out. They are for real and are expressing the same symptomatology from the same causation (head trauma or acceleration/deceleration injuries). This is just like patients with chicken pox who initially present, clinically, in the same way.

Then there is the M word — malingering. This is associated with the idea that settlement of litigation is all that is needed to put a stop to the PTHA syndrome. This is also a favorite theme of the insurance companies. True malingering is almost as rare as hen's teeth. There are published studies that demonstrate that legal settlement has nothing to do with the patient's symptoms ending or encouraging them to return to work (Cicerone, 1992; Elkind, 1989; Evans, 1992; Merskey & Woodford, 1972).

CPTTHAs, with or without the other aspects of the post-concussion syndrome, are extremely common after head trauma and acceleration/deceleration injury. These patients are very consistent in their presentations in their descriptions of their symptoms and sequelae. This consistency is strong evidence that their problems are organic in nature and produced by the trauma.

Most patients with PTHAs have their headaches resolve if they are given appropriate medical treatment.

About 15 to 20% have prolonged difficulties. Correct diagnosis and treatment in the majority of cases should decrease this percentage.

Posttraumatic Headache: Practical Interdisciplinary Approaches to Diagnosis and Treatment

Nathan D. Zasler, M.D., F.A.A.P.M.&R., F..A.A.D.E.P., C.I.M.E., D.A.A.P.M. and Michael F. Martelli, Ph.D., D.A.A.P.M.

INTRODUCTION

The literature on posttraumatic headache (PTHA) appears to be replete with much confusion concerning nomenclature. Oftentimes, clinicians incorrectly assume that because someone has complaints of PTHA, they have sustained some type of insult to their brain. Individuals may develop PTHA and related disability due to a variety of causes including brain injury, cranial or cranial adnexal injury, and/or cervical acceleration/deceleration injury (Zasler, 1999).

Some individuals consider the diagnosis of PTHA to be a so-called "garbage can" diagnosis. The phrase PTHA does not tell patients, family, or other health care practitioners what they did not already know, that is, that they were involved in a trauma and subsequently have suffered from a headache condition. More importantly, many practitioners believe that it is important to specifically identify the pain generators in the context of providing diagnostic labels that may better guide clinical treatment (Zasler, 1996).

Appenzeller (1993) has been noted to have said, "No where is scientific medicine less evident than in the treatment and management of post-traumatic headaches." As practitioners in the field of brain injury care, we could not agree more. There is much confusion in the field across both medical and nonmedical disciplines as to the exact nature of the beast with regard to the diagnostic entity of PTHA. We hope that this chapter provides some edification on the need to assess these patients in a more global manner instead of using what seems to be the traditional Ockham's razor approach. Significant deficiencies in our understanding of PTHA clearly remain which can be seen in the lack of good epidemiological, treatment, and outcomes research. These limitations must be acknowledged in the context of clinical care (Zasler, 1999).

CLASSIFICATION OF POSTTRAUMATIC HEADACHE

Current classification systems for PTHA have much to be desired given their general nature, as well as the empirical basis for the definitional criteria. If one examines the Headache Classification Committee of the International Headache Society's (IHS) (1988) classification for PTHA or the International Classification of Diseases and Related Health Problems, 10th edition (ICD-10) (World Health Organization, 1997) system, it is readily apparent that there are at least some problems with the current taxonomy for PTHA. Refer to Table 12.1 for a conversion chart between ICD-10 and IHS classification systems for PTHA.

The ICD-10 classification system uses criteria that are primarily concerned with the temporal onset and pathogenetic relationship of the headache to the trauma and not with the clinical features of the headache condition. ICD-

0-8493-0926-3/02/$0.00+$1.50

TABLE 12.1
Conversion Table: IHS and ICD-10 Classification Codes

IHS Code		ICD-10 Code: Etiologic Code	ICD-10 Code: Headache Code
5.	Headache associated with head trauma		G44.88
5.1	Acute posttraumatic headache		G44.880
	5.1.1 With significant head trauma and/or confirmatory signs	S06	G44.880
	5.1.2 With minor head trauma and no confirmatory signs	S09.9	G44.880
5.2	Chronic post-traumatic headache		G44.3
	5.2.1 With significant head trauma and/or confirmatory signs	S06	G44.30
	5.2.2 With minor head trauma and no confirmatory signs	S09.9	

10 criteria for PTHA require that headache onset occur within 2 weeks of the traumatic event or regaining consciousness. This temporal onset criterion appears to have been determined only on the basis of empiricism. Clearly, although it tends to be the exception instead of the rule, there are patients who develop headache that is fully apportionable to their original injury beyond the 2-week rule. Another problem with the time designation of 2 weeks is that often patients may have significant multitrauma with other more painful conditions (e.g., neck injury) than their headache, causing them to focus their attention on the more painful body part. Additionally, some may also argue that in more severe brain injury, patients' cognitive status may limit their ability to identify and/or appreciate head pain.

Also of concern is the fact that the ICD-10 criteria for either acute or chronic PTHA require one of the following: a loss of consciousness, a period of antegrade amnesia of at least 10 min, or abnormal neurodiagnostic/neurological exam. Certainly, such inclusion criteria exclude patients with various forms of PTHA including referred pain from cervical injury, as well as direct cranial and/or cranial adnexal injury, among other "posttraumatic" etiologies. Although there are classifications for other types of headache that may be applicable to these patients, they would not by definition fall under the rubric of PTHA by ICD-10 criteria. Of some import is the fact that a separate codification identifies patients with "minor head trauma and no confirmatory signs" under this classification. Acute PTHA by ICD-10 definition resolves within 8 weeks with chronic PTHA being defined temporally as any PTHA lasting longer than 8 weeks (HCCIHS, 1988); this definition is not consistent with common parlance of how chronic pain is typically defined (Zasler, 1999).

The IHS criteria were published (HCCIHS, 1988) to address the lack of operational rules and nonuniformity of nomenclature in the headache field. The classification system defines 13 major categories of headache with two broad categories (primary vs. secondary headaches). The IHS classification system has been endorsed by the World Health Organization (WHO) and the principles of the system have been incorporated into the ICD-10. The IHS criteria use both clinical features and laboratory testing to provide inclusion criteria. As with ICD-10, headache associated with "head trauma" is divided into acute and chronic PTHA. A second edition of the IHS classification was published in 1999. There is fairly good correspondence between the ICD-10 and IHS headache classification systems.

EPIDEMIOLOGY AND OUTCOME

PTHA is clearly the most common symptom following mild brain injury and/or concussion, as well as cervical whiplash (acceleration/deceleration type injuries). Because of the lack of accurate registries and the fact that many persons with these types of injuries are never seen in acute care settings, the true incidence of this disorder in our society at large is unknown.

Surveys examining the number of individuals who develop PTHA as a result of minor head injury range anywhere from 30 to 50% (Evans, 1992; Alves et al., 1986). Additionally, there seems to be a clear, albeit to some extent controversial, correlation between severity of brain injury and incidence of PTHA. The majority of studies, as well as extensive clinical experience by professionals who have seen thousands of persons with cerebral, cranial, and cervical injuries, support the conclusion that persons with milder injury seem to have a higher frequency of headache complaints. To most, this would seem paradoxical based on the anticipated pathoetiology of PTHA. One of the classic studies examining this phenomenon was performed by Yamaguchi (1972) and published in 1992. He found that 72% of persons with mild injury vs. 33% of those with severe injury developed headache. He noted that abnormal findings on cervical radiographs including degenerative changes positively correlated with complaints of more severe headache. Just as interestingly, he noted that abnormalities on mental status testing and static brain imaging were negatively correlated with headache complaints and incidence (Yamaguchi, 1992). In a rather extensive review conducted by Appen-

zeller (1993), he concluded that PTHA incidence was much higher in patients with less severe brain injury.

The whole issue of correlating brain injury severity with extent of subsequent headache complaints seems, in our view, to be "missing the boat," given that there is a significant absence of literature exploring the incidence and severity of associated injury to the cranium and/or cervical spine in PTHA. Both the neck and head may be the source of pain generators in PTHA, either directly or indirectly as a result of referred pain. At the same time, however, one would expect worse cranial and cervical injuries in patients with more severe brain injury, given the magnitude of forces applied to the neural axis and therefore the skull and cervical spine. Thus, one would expect more, not less, headache in patients subjected to more significant forces across the neural and musculoskeletal axes.

Theoretically, the previously mentioned paradox may be explainable by speculating that patients with severe brain injury and/or multitrauma are commonly treated with paralytic agents, as well as prolonged bed rest, as part of their acute neurosurgical care. If one accepts that cervicogenic headache is the most frequent etiologic explanation for PTHA, although this remains controversial, one might also conclude that typically rendered treatment via muscle paralysis or prolonged immobilization may coincidentally be therapeutic for concomitant cervical musculoligamentous injury sustained by patients with more severe brain injury. In fact, this explanation, to a great extent, supports the position that the majority of PTHA may have nothing to do with brain injury per se.

Most studies have been unable to delineate the specific demographic factors related to the incidence of PTHA. The preponderance of data indicate that most individuals who sustain this type of posttraumatic impairment are injured in the context of motor vehicle accidents and most of these individuals are male. In order of frequency, other types of injuries that are associated with head trauma and brain injury include falls, assaults, and sports-related injuries. A rather high incidence of concurrent use of alcohol has been noted in a number of studies examining comorbidities of these types of injuries (Packard, 1999).

There has been very little methodologically sound research looking at preexisting and/or injury-related factors that may predispose to perpetuation of headache symptomatology following concussion. Aside from some literature examining the role of ongoing litigation as a factor in subjective headache complaints, there is no significant body of literature looking at musculoskeletal (including posture), neurological, and/or individual/family history issues plus their potential role in postconcussive headache symptom maintenance. A prime example of a prognostic factor associated with PTHA that is accepted as "gospel" by many physicians is that persons with preinjury headache are more prone to develop PTHA and have a greater risk for chronic PTHA (CPTHA). However, a study by Jensen and Nielsen (1990) found that patients suffering from headache preinjury were no more likely to suffer PTHA than patients without a preinjury headache history.

There is excellent literature with regard to cervical spine acceleration/deceleration injury and chronic pain, although not necessarily involving headache, that must be appreciated by any clinician involved with PTHA management (Freeman & Croft, 1997; Radanov et al., 1993). If one agrees with the experiential data and some research data indicating that cervicogenic referred pain is the primary etiology of PTHA, then it is not surprising to note that the observed higher incidence of PTHA in women instead of men (Jensen & Nielsen, 1990) may in fact have a pathoanatomic basis. Research has shown greater accelerative forces in whiplash injuries in women than in men, deemed to be due to differences in cervical muscle bulk and/or neck length (Siegmund, King, Lawrence, Wheeler, Brault, & Smith, 1997).

PATHOETIOLOGY

The exact pathoetiology of nontraumatic headache continues to be debated. The pain generators and pathoetiology of PTHA are even less well understood. When one considers the anatomic correlates of recurring benign head pain, one can make some general statements that are likely just as applicable for nontraumatic headache as they are for traumatic headache (Packard, 1992).

There are multiple pain-sensitive structures in the head, both intra- and extracranially, that may be pain generators. There are also pain generators more caudally in the neck that may refer pain into the head, either by direct or by indirect means. Pain, in general, is transmitted from the periphery by small myelinated fibers and unmyelinated C fibers that terminate in the dorsal horn of the spinal cord. These fibers also have end terminals in the trigeminal nucleus caudalis. Secondary neurons from the dorsal horn reach the thalamus by the spinothalamic pathways. The upper cervical spine contains pain fiber systems for the entire head/neck region. The trigeminal cervical nucleus is the anatomic structure critical to the concept of cervical headache, as well as head/neck referred pain. Sensory afferents from the trigeminal nerve, as well as the upper three cervical spinal nerves, have been theorized to relay sensory information through the trigeminal cervical nucleus (May & Goadsby, 1999). Bogduk (1982) has proposed that there are overlapping and convergent second-order neurons that serve as the pathoetiologic basis, as well as pathoanatomic basis, for referred pain. Cervical pain can, therefore, be perceived in the territory of the trigeminal nerve, particularly in the ophthalmic division due to epaptic transmission through the proximal portion of the C-2 root. This second-order neuron phenomenon is

also the basis for frequent observation of referred orbital and frontal pain emanating from cervical pain generators.

The exact role that central modulation of trigeminovascular pain plays in headache, in general, and posttraumatic headache, specifically, is yet to be determined, as is the role of so-called central sensitization. This latter phenomenon, which is a well-described event in the animal literature, remains somewhat controversial in the context of various neurological and psychiatric disorders in the human population. It is manifested by increased spontaneous impulse discharges, increased responsiveness to noxious and nonnoxious peripheral stimuli, and expanded receptive fields of nociceptive neurons. So-called "windup" is a short-lasting phenomenon and therefore cannot explain central sensitization that is of longer duration and may involve changes in neuronal plasticity. Windup may, however, be the trigger to longer lasting neuronal sensitization and therefore potentially to chronic headache pain, posttraumatic or otherwise (Sessle, 1999).

In the context of assessment of a patient with PTHA, one must assess pain generators from the face, cranium (including cranial adnexal structures), cerebrum, and neck. There are multiple structures in the neck that have been hypothesized to produce head pain, including zygapophyseal joints of the second and third vertebra, musculoligamentous attachments of the atlantoaxial joints, and upper paravertebral muscles, as well as the muscles innervated by the eleventh cranial nerve (e.g., trapezius and sternocleidomastoid), the spinal dura mater (see later), the vertebral artery, and the C2–3 intervertebral disks (Horn, 1992). There has been some manual medicine literature suggesting that attachments of the ligamentum nuchae exist to the posterior cervical spinal dura and the lateral part of the occipital bone (Mitchell, Humphreys, & OSullivan, 1998). This anatomic discovery may be of significance in terms of understanding the biomechanics and symptomatic sequela of cervical acceleration/deceleration (whiplash) injury, particularly in relation to rotational movements of the head in the sagittal and transverse planes, as related to cervicogenic headache following trauma.

CLINICAL ASSESSMENT

It is important for the examining clinician to keep the different mechanisms of PTHA in mind. Additionally, the mechanism of injury responsible for the initial insult should also be investigated; specifically, inquiry concerning history pertaining to three main phenomena: cerebral, cranial/cranial adnexal, and/or cervical injury.

One of the major clues for the examiner relative to the origin of the headache should come from establishing the symptom profile for that particular headache, as well as the patient's preinjury history of headache. Just because an individual had headache preinjury does not mean that he or she could not develop a different type of headache or a worsening of the preinjury condition following trauma. The major questions relative to the headache profile that need to be asked are expressed in the pneumonic COLDER: character, onset, location, duration, exacerbation, and relief. Additional questions concerning the frequency and severity of headache, time of day of headache, and associated symptomatology (including aura, pain referral patterns, and familial headache history) should be inquired about, among multiple other possibilities. Less common causes of PTHA should always be considered when the obvious ones do not pan out based on the history provided by the examinee. Some of the less commonly seen variants of PTHA include posttraumatic sinus problems, posttraumatic epilepsy, tension pneumocephalus, extraaxial collections such as subdurals and epidurals, cluster headache, paroxysmal hemicrania, dysautonomic or sympathetic headache (anterior and posterior forms), and basilar artery migraine (BAM). Drug use history, whether prescription or recreational, should also be assessed including the potential for drug-induced and/or rebound headache, the latter which is commonly iatrogenic. With the appropriate history and descriptive clues, the clinician is then armed to conduct a clinical examination to allow a more specific conclusion as to the origin of the headache condition (Zafonte & Horn, 1999).

The physical examination of the patient who presents with PTHA should be comprehensive but focused based on a good clinical history. At a minimum, the exam should include a screening neurological and musculoskeletal assessment. The basics of physical examination should be conducted with a focus to the suspected pain generators. The exam should include inspection, palpation, and, as appropriate, percussion and auscultation. Inspection should focus on posture and body asymmetries, among other areas assessed. Musculoskeletal assessment should include an adequate examination of the cranium, cranial adnexal structures, and cervicothoracic spine as deemed relevant to the patient's headache complaints. Palpatory exam might include checking for neuromatous or neuritic pain generators, myofascial trigger points, vertebral somatic dysfunction, sinus tenderness, and/or temporomandibular joint (TMJ) dysfunction (Horn, 1992; Zafonte & Horn, 1999).

MANAGEMENT

Myofascial Pain

Myofascial pain is one of the more common etiologies of PTHA, although to some extent the diagnosis of myofascial pain remains somewhat controversial across medical specialties. Myofascial pain typically presents as a regional pain disorder characterized by localized muscle tenderness in association with discomfort/pain.

It is quite common following cervical acceleration/deceleration injuries, whether of a flexion/extension nature or lateral impulse type of force. Research has shown that referred pain, as well as so-called local twitch response, which are both characteristics of myofascial trigger points, is related to spinal cord mechanisms (Bisbee & Hartsell, 1993). It has been theorized that the taut band of skeletal muscle fibers that contain the myofascial trigger point is produced by an excessive amount of acetylcholine in the abnormal end plate (Hong & Simons, 1998).

A trigger point is defined as a localized deep tenderness in the taut band of skeletal muscles that is responsible for the pain in the zone of reference. Clinicians must differentiate between latent and active trigger points. The zone of reference is defined as the area of perceived pain referred by the irritable trigger point and is usually located over the trigger point or spreads out from the trigger point to a distant site (Travell & Simons, 1983).

Treatment for myofascial pain should be holistic. Muscle exercises should include stretching and strengthening, as well as postural. Trigger point therapy is clearly an important part of the overall armamentarium and may include such techniques as ultrasound, ischemic pressure, accupressure, and massage, among others. Counterstimulation techniques involving Fluori-Methane, diathermy, and heat and/or ice can also be used. Direct current stimulation via such techniques as electroacupuncture, transcutaneous electrical nerve stimulation, and direct current stimulation can also be considered. Acupuncture may serve as an adjutant therapy; however, its role in myofascial pain has not been well studied. Trigger point injections with local anesthetic and/or steroid and dry needling are the most common techniques used to treat this problem. Trigger point injections not only reduce pain and increase range of motion in a muscle that is typically shortened but also improve circulation to the muscle. It is not critical to inject anything into the trigger point for the needling to have a therapeutic effect, because the latter appears to be due to mechanical disruption of the trigger point by the needle, instead of the substance injected per se. Trigger point injections with local anesthetic are generally more effective and comfortable than dry needling or injecting other substances. Some clinicians have reported success modulating myofascial pain symptoms with botulinum toxin injections (Chesire, Abashian, & Mann, 1994). Spray and stretch techniques, as well as other manual strategies including strain-counterstrain, soft tissue mobilization, and myofascial release techniques, have also been found to be quite effective in ameliorating myofascial pain (Travell & Simons, 1983).

Perpetuating factors must be addressed in the treatment of myofascial pain including psychoemotional status, metabolic and hormonal factors, and, most importantly, body asymmetries and postural issues. Additionally, ergonomic issues should be examined in the workplace, as well as at home; included in the latter should be assessment of sleep habits such as use and type of head supports and bed (Travell & Simons, 1983). Therapeutic exercise is a critical component of maintaining pain relief and should include both flexibility and strengthening components. Education concerning the need for compliance with any treatment intervention should be part and parcel of any treatment regimen.

Neuralgic and Neuritic Pain

It is not uncommon after cervical whiplash to find patients with signs of occipital neuralgia, involving either the lesser or greater occipital nerves. This type of problem generally responds well to local anesthetic blockade (sometimes in conjunction with steroids) (Waldman, 1991). Unless associated myofascial dysfunction is also addressed in the context of the overall treatment, occipital nerve irritation may return fairly quickly.

Surgical decompression of the occipital nerve should be considered when entrapment is felt to be the pathoetiologic mechanism responsible for continued pain, although the procedure may not produce complete pain relief. In more intractable cases, consideration can be given for injection of neurolytic agents and/or more aggressive techniques such as destruction of the involved nerve via such procedures as cryoablation and/or open surgical neurectomy (Horowitz & Yonas, 1993). Surgical excision may result in deafferentation pain and/or neuroma formation. Of note, however, is that some experienced clinicians do not recommend the treatment due to the fact that the procedural efficacy remains poorly studied (Bogduk & Marsland, 1986).

Following more significant cranial injuries, it is not uncommon to develop neuromas in the scalp particularly after craniotomies. For more diffuse neuritic scalp irritation, topical capsaicin can be considered. When there is a question of a more focal neuromatous lesion, local anesthetic blockade can be helpful. Enteral medications traditionally used in the treatment of neuropathic pain can also be used for neuritic and neuromatous pain. These medications include nonsteroidal antiinflammatories, tricyclic antidepressants, and anticonvulsants (such as gabapentin, carbamazepine, and phenytoin), among others.

Less commonly, neuralgic problems can be encountered secondary to facial trauma. The nerves that are most commonly involved are the supraorbital and infraorbital nerves. These nerves can be injected locally with good resolution of facial pain and/or dysesthetic symptoms (Waldman, 1991). Sometimes, as with other injections, serial procedures are required.

Migraine

Posttraumatic migraine accounts for up to 20% of CPTHA. It is generally treated similarly to nontraumatic migraine. There are some atypical variants of posttraumatic migraine, such as BAM, that are known to occur more frequently in young females, particularly following whiplash injury (Jacome, 1986). The exact reason for this is unknown. BAM is generally treated with atypical migraine medications such as carbamazepine or valproic acid.

Migraine treatment should include looking at all associated factors that may influence this headache picture, including reduction of so-called trigger factors (this may include certain food groups as well as external and internal stressors). Treatment should be directed at minimizing the functional disability associated with the headache through other interventions including appropriate medication prescription that may be abortive, symptomatic, and/or prophylactic. A small percentage of women who take birth control pills may be exacerbating their migraines and this should be considered in the overall holistic treatment of patients with posttraumatic migraine. Other interventions such as relaxation training and biofeedback may also be used (Bell, Kraus, & Zasler, 1999).

Temporomandibular Joint Disorders

Although true intra-articular pathology is not frequently seen following whiplash-induced temporomandibular joint disorders (TMJD), myofascial dysfunction in the muscles of mastication is frequently noted. Appropriate workup is necessary, however, to rule out intra-articular pathology and, if present, to address it accordingly. In most cases, a referral to an oromaxillofacial surgeon would be warranted. Local treatment as per the discussion of myofascial pain for trigger points involving the muscles of mastication (temporalis, masseter, medial pterygoid, lateral pterygoid) should be aggressively pursued. As indicated, interventions for bruxing should be suggested, for example, intraoral appliances such as occlusal splints (Friction, 1995). Appropriate education concerning minimizing foods that require significant chewing is generally beneficial during the more acute and subacute treatment phase for myofascial pain involving the muscles of mastication. The patient should be instructed in the use of simple jaw exercises including passive jaw opening with the thumb and forefinger and a gentle scissorlike action to a position just short of pain onset. Nonsurgical treatment continues to be considered the most effective way of managing over 80% of all patients who present with symptoms of TMJD in the absence of intra-articular pathology (Dimitroulis, Gremillion, Dolwick, & Walter, 1995).

If and when it is suspected clinically and/or proven by diagnostic testing, such as magnetic resonance imaging (MRI), that there is significant intra-articular pathology, arthroscopic intervention is generally indicated. Rarely, one finds the necessity to proceed to open arthrotomy for disk repositioning and/or arthroplasty. Generally, experience has shown that surgical outcome from the latter type of procedure tends to be guarded. In extreme cases of intracapsular damage, caused by the initial injury, or by failed surgery, condylectomy and costochondral reconstruction of the articulation may be required. When there is significant meniscal injury, an artificial meniscus can be considered.

Cervical Zygapophyseal Joint Pain

Cervical zygapophyseal joint pain can cause both neck pain and referred head pain. Pain from the C2–3 joint is perceived posteriorly in the upper neck extending into the occipital region, whereas pain from the C3–4 joint and any cervical joint caudal to that does not refer into the head. Treatment considerations can include intra-articular injections of local anesthetic at the joint level or blocks of the medial branches of the dorsal rami that supply the joint. Joint blocks should be ideally performed under fluoroscopic control through either a posterior or a lateral approach. Cervical medial branch blocks are a more expedient way to block a cervical zygapophyseal joint in that they are not only easier but also less painful to the patient and provide the same diagnostic information (Lord, Barnsley, & Bogduk, 1993). Other more aggressive modalities for treatment of this type of pain include percutaneous radiofrequency neurotomy via medial branches, although this remains a controversial treatment strategy on several levels (Lord, Barnsley, & Bogduk, 1995).

Somatic Dysfunction

Manual medicine techniques for the treatment of cervical pain remains somewhat controversial. We are quite convinced that craniocervical and cervicothoracic somatic dysfunction following traumatic neck injuries has the potential to generate head pain. There have been numerous studies involving the benefits of mobilization of the cervical spine in chronic headaches, posttraumatic and otherwise, which have shown that cervical mobilization/manipulation can be beneficial in these types of clinical conditions (Jensen, Nielsen, & Vosman, 1990). These procedures are utilized by not only chiropractors but also physical therapists, as well as appropriately trained physicians (both M.D.s and D.O.s). Mobilization with impulse (also referred to as high-velocity, low-amplitude thrust) is based on the principle of overcoming the resistive barrier in the

direction of loss of range of motion. Reduction of hypertonicity in segmentally related paraspinal muscles results through a hypothesized effect on mechanoreceptors and stimulation of the afferent loop of the applicable reflex arc. There are many other techniques in the manual medicine armamentarium. Some of the direct (resistive barrier is engaged) interventions include soft tissue and articulatory muscle energy and myofascial release, as well as craniosacral manipulation. Some of the indirect (resistive barrier is not engaged) interventions include balance and hold, as well as strain-counterstrain (Greenman, 1989). Treatment contraindications, both relative and absolute, must be appreciated by any clinician using these techniques as complications have been reported (Dvorak & Orelli, 1985).

Dysautonomic Headache

Certain nerve fibers in the neck, anteriorly as well as posteriorly, may be damaged from excessive flexion or extension of the neck associated with cervical acceleration/deceleration insult. These types of injuries may produce an uncommon PTHA variant known as dysautonomic cephalalgia. There may be partial or total insult to these nerves that impacts on how the condition is treated relative to medication choices (Vihayan, 1977). Involvement of posterior cervical sympathetic dysfunction (also known as Barre-Lieou syndrome) may produce symptoms of pain in the back of the head, tinnitus (buzzing in the ears), blurry vision, and vertigo (Barre, 1926).

Rare Causes of Posttraumatic Headache

There are multiple rare causes of headache that should also be considered in the posttrauma population. Appropriate neurodiagnostic tests such as computerized tomography (CT) or magnetic resonance imaging (MRI) scanning of the brain, plain X-rays, electrodiagnostic and vascular studies, and laboratory tests should be conducted as deemed appropriate by the treating clinician (Zafonte & Horn, 1999). These tests should not be ordered unless it is felt that the results will alter clinical treatment planning.

Psychological Factors

Chronic pain or pain that persists 6 months or longer after injury: (1) reflects ambiguous pathways between injury sites and the central nervous system, (2) communicates useless information that perpetuates physiological protective responses long after removal of possibility of injury extension and/or despite lack of underlying tissue damage, and (3) poses a liability to postinjury adaptation. Importantly, chronic pain is typically associated with response patterns involving decreases in, and avoidance of, activity. Decreased activity, in response, can prevent normal restoration of function and perpetuate painful experience; and in a cyclic fashion, it reinforces avoidance, inactivity, and increased pain. Finally, the longer pain persists, the more recalcitrant it becomes and the more treatment goals move toward management of pain and coping vs. cure (Penzien, Jeanetta, & Holroyd, 1993).

According to Miller (1993) chronic pain often represents the "weak link" in the cycle of "postconcussion invalidism." Given that PTHA is the most common postconcussive symptom (Packard, 1994; Goldstein, 1991) and hence the most frequent type of posttraumatic pain associated with mild traumatic brain injury (MTBI), it follows that resolution of the postconcussion syndrome, and successful posttraumatic adaptation, may frequently rely on success in coping with PTHA symptomatology. The introduction of biopsychosocial models represents alternative theoretical approaches to dualistic and reductionistic biomedical conceptualizations that explain disease and health primarily in terms of measurable biological variables. A derived stress and coping formulation of postinjury recovery conceptualizes adaptation to injury as a series of stressful demands that require coping. Coping represents an interaction between existing coping resources and injury-related demands. Bolstering of coping resources presumably allows for improved adaptation to stressful life events. PTHA does not occur in a vacuum. Instead, it occurs in a biological system within specific psychological and social contexts. It reflects an interaction of organic and emotional factors.

Although similar to natural headaches in clinical presentation of subtypes and biochemical mechanisms, PTHA is oftentimes resistant to traditional headache treatment. Medication management alone may lead to unwanted side effects (e.g., adverse effects on sleep, mental alertness, sexual functioning, work performance) and certainly does not address adaptation to chronic pain through development of new coping skills (Martelli, Zasler, & MacMillan, 1998). Conversely, PTHA patients have been reported to exhibit minimal response to nondrug (i.e., psychological) treatments alone (Jensen, Nielsen, & Vosmar, 1990). Treatments that are holistic in nature, targeting not only the pain directly but also the patient's reaction to pain within his or her daily life, typically fare better than treatments with a more narrow focus (e.g., medication management or nondrug therapies alone). Understanding vulnerability issues as predictors of poor chronic pain adaptation is also critical in this context (Bennett, 1988) (Table 12). Currently, multicomponent treatment packages are the preferred treatment choice for PTHA (Packard & Ham, 1997).

The assessment phase is the starting point of any psychological treatment protocol. Detailed individual assessment is necessary to consider specific treatment issues (e.g., personality variables, social support) and facilitate the patient–therapist relationship. A thorough

TABLE 12.2
Vulnerability to Disability Rating Scale

Increased Complaint Duration	Complaint Inconsistency/ Vagueness	Previous Treatment Failure	Collateral Injury/Impairment	Pre/Comorbid Medical History	Medication Reliance
0 = < 6 Months 1 = < 12 Months 2 = > 12 Months	0 = Little 1 = Mixed 2 = Mostly inconsistent	0 = Insignificant 1 = Mixed 2 = Mostly or all failures	0 = Insignificant 1 = Mild/moderate 2 = Significant	0 = Insignificant 1 = Mild/moderate 2 = Significant	0 = Little 1 = Moderate 2 = Significant
Especially with expectation of chronicity, poor understanding of symptoms	Multiple, vague, variable sites; anatomically inconsistent; sudden onset without accident or cause; not affected by weather; performing no work or chores, or avoiding easy tasks but performing most hobbies, enjoyments; pain only occasional	Especially with complaint of treatments worsening pain or causing injury, and expectation that future treatments will fail	Especially if silent and involving adaptation reducing impairments	Seizure disorder; diabetes; hypertension; brain injury, stroke or other neurological insult or vulnerability (esp. if undiagnosed); preinjury medication reliance	> 4X/week narcotic, hypnotic or benzo-diazepine tranqulizer; perceived inability to cope without medication

Severity of Current Psychosocial Stress	Psychological Coping Liabilities	Victimization Perception	Social Vulnerability	Illness Reinforcement	Vulnerability Score
0 = Nonsignificant 1 = Mild/moderate 2 = Significant	0 = Few 1 = Mild/moderate 2 = Significant	0 = Little 1 = Mild/moderate 2 = Significant	0 = Little 1 = Mild/moderate 2 = Significant	0 = Little 1 = Mild/moderate 2 = Significant	_____ Total points (Max: 22)
Sum of peronal, social, financial, emotional, identity, activity stresses, life disruption, premorbid coping style disruption, etc. and including injury/ impairment X coping style incongruence; persistent premorbid psychosocial stress levels	Premorbid, comorbid: depression; posttraumatic anxiety; somatization (and repressive) defenses; emotional immaturity/ inadequacy with poor coping skills; hypochondriacal traits (e.g., postinjury MMPI-3 > 85; preinjury > 70); passive coping style; childhood trauma (esp. death of parent; child or sex abuse); anger/resentment; posttraumatic adjustment problems (see "Vulnerability to Disability" tables — psychological impediments); alcohol, substance use/abuse; limited premorbid intellect, education, skills; preinjury psychiatric treatment; poor premorbid work history	Externalized "blame" for accident, disability, etc.; perceived mistreatment; anger, fear, resentment, distrust concerning accident, treatment, understanding (family, employer, doctors, etc. — esp. given characterologic tendencies concerning victimization, resentment, suspiciousness, distrust, etc.)	Lack of family support, resources, romantic support (esp. if recent conflict, divorce); lack of community support/resources/ involvement; lack of employer, co-worker, insurance manager support; etc.	Secondary gain: attention, support in a dependency-prone person; avoidance of stressful or displeasing life or job responsibilities or demands (esp. with recent or imminent job/job duty changes or reorganization); financial compensation (esp. if litigation; or current income = preinjury/ preimpairment)	Preliminary interpretive guidlines Scores of 13 or above suggest high vulnerability to chronic disability

Vulnerability to Disability Rating Scale (VDRS) — General Version. M.F. Martelli, Ph.D. © 1996.

behavioral assessment may include a detailed clinical interview and other assessment instruments such as pain diaries and various standard pain and headache questionnaires. Psychophysiological assessment is an additional option, if feasible, and typically involves examination of muscle tension or electromyogram (EMG) for different muscle groups in the head (forehead, masseter, temporal, occipital) and neck (trapezius, cervical paraspinal) areas. The assessment phase concludes when the results of evaluation have produced a specific case conceptualization that identifies a specifically tailored treatment plan. Feedback to the patient using assessment results provides a framework for the treatment intervention, defines goals and patient/therapist expectations and sequences, and provides the forum for presenting general information concerning PTHA and rationale for treatment and enlisting participation.

Although there is an abundance of headache treatment outcome studies available, there are relatively few studies specifically examining the psychological treatment of PTHA as a distinct subgroup of headaches in general. The literature suggests that PTHA and natural headaches may share common pathways, and clinical presentations are generally very similar if not identical (Haas, 1993). Consequently, standard psychological treatments for headache are presumed to share common mechanisms of action. Although PTHA treatment outcome studies suggest that combined psychological treatments are generally efficacious, evidence suggests that PTHA is often more recalcitrant to standard psychological treatment compared with natural headaches. However, the severity and frequency of pain attacks and chronic pain-related sequelae such as coping abilities, depression, and anxiety may be significantly improved by combined psychological treatment protocols (Miller, 1993; Packard & Ham, 1997; Parker, 1995). Supportive counseling that begins early after trauma and is continuous results in better patient response (Ham & Packard, 1996).

Patient Education

Packard directly asked, "What does the headache patient want?" and detailed the stated treatment priorities of headache patients (Packard, 1979). Education concerning the causes of headaches was listed as a top priority. Information can be individualized for the patient and ideally presented while providing feedback after the behavioral assessment phase. It is especially important as pain professionals to emphasize to patients that their pain is real. Some patients, when told by physicians that medical tests are inconclusive or that their headache pain is due to stress, may interpret this information as "it's all in my head." Anecdotally, many patients are confused or angry when referred to a psychologist for pain treatment. Explaining the cycle of stress and pain and validating their pain may help to gain client trust and commitment.

Biofeedback

Although an abundance of research reports the success of biofeedback for the treatment of tension-type migraine, mixed migraine, and tension-type headaches, many studies listed PTHA among the exclusionary criteria. As a result, few studies have examined the efficacy of biofeedback for PTHA specifically. A number of studies used EMG biofeedback (forehead and neck sites) in combination with other treatment modalities (e.g., cognitive–behavioral treatment, medication) and reported significant improvement in PTHA (Duckro, Tait, Margolis, & Silversintz, 1985; Medina, 1992). Ham and Packard (1996) reported that combined EMG and thermal biofeedback resulted in at least moderate improvement for 53% of 40 chronic PTHA patients, most of whom had previously received medication, physical therapy, chiropractic treatment, and/or trigger point injections without significant success. However, it is difficult to make firm conclusions concerning the efficacy of biofeedback alone for PTHA given the small sample size and the use of other simultaneous treatments in these studies. Although empirical research examining the utility of biofeedback specifically for PTHA is sparse, many clinical researchers feel that biofeedback, when combined with medical treatment and/or psychotherapy, augments the treatment response for many persons with PTHA.

Relaxation Training

Various forms of relaxation training have been used for the treatment of chronic headache (e.g., autogenics, meditation); however, progressive muscle relaxation (PMR) has been most widely studied (Blanchard, 1994). PMR involves the systematic tensing and relaxing of various muscle groups to elicit a relaxation response. Diaphragmatic breathing is generally taught in combination with relaxation exercises. Meta-analytic reviews generally conclude that relaxation training and biofeedback training are equally effective for headache reduction, producing improvement rates between 44.6 and 59.2% for tension-type headaches and migraines (Martin, 1993).

Operant Treatment

Fordyce (1976) pioneered the behavioral approach to psychological assessment and treatment of chronic pain. Although not specifically developed for use with PTHA, the concept follows the operant model to reduce general chronic pain behaviors. That is, the operant model hypothesizes that pain-related behaviors may be positively reinforced by desirable consequences (e.g., sympathy, nurturance), while simultaneously negatively reinforced by

avoidance of aversive consequences (e.g., undesirable work or social obligations). Treatment based on the operant model requires altering environmental contingencies to eliminate pain behaviors (e.g., verbal complaints, inactivity) and reward "well" behaviors (e.g., exercise, increased activity level).

Cognitive–Behavioral Treatments

Cognitive approaches for headache treatment are derived from several cognitive theorists and typically train the headache patient to identify and refute maladaptive beliefs concerning pain. Specific cognitive strategies and skills are taught to replace inappropriate negative expectations and beliefs. Holroyd and Andrasik (1978) have generally led the field in cognitive therapy for chronic headache. Cognitive stress-coping therapy has been successfully applied to tension-type headache patients in group, minimal-therapist-contact, and home-based formats (Tobin, Holroyd, Baker, Reynolds, & Holm, 1988). Cognitive stress-coping therapy proposes that maladaptive cognitive responses are present that contribute to keeping the headache patient stressed/tense by keeping the sympathetic nervous system activated. Pain protocols based on this approach alter the maladaptive beliefs that mediate the stress reaction to presumably alter the stress reaction (muscle tension) leading to increased pain. In essence, the patient with PTHA is trained to shift attention from one aspect of the environment (e.g., internal pain) to another (internal or external).

Social and Assertiveness Skills Training

Miller (1993) recommended social skills training in a group format as an adjunct to standard psychotherapeutic interventions for chronic pain. Assertiveness training, in particular, may help some patients to communicate needs more effectively. This, in turn, increases the likelihood of need fulfillment and more desirable situational outcomes. Subsequent reduction of stressful events, anger, and other distressful emotional states associated with need frustration can reduce associated physiological arousal that contributes to headache pain.

Imagery and Hypnosis

Several studies have reported success with imagery-based treatments for headache in general (Martin, 1993). Procedures vary by study, but training generally includes autohypnosis and suggestions of relaxation and visual imagery. Generally, the patient is instructed to visualize the pain (i.e., give it form) and focus on altering the image to reduce the pain. Imagery-based treatment is recommended following establishment of a good therapeutic alliance to facilitate patient compliance. At least one study documented the application of imagery for PTHA, in particular (Daly & Wulff, 1987).

Biofeedback-Assisted Cognitive–Behavioral Therapy

The efficacy of EMG biofeedback and cognitive–behavioral therapy (CBT), singularly and in combination in multicomponent treatment packages, has been demonstrated for the treatment of various pain disorders (e.g., headache, facial pain). The majority of multicomponent treatment packages in the literature to date utilize distinct techniques for biofeedback and CBT. Grayson (1997) presented a promising single-case research design outlining a multicomponent treatment protocol (biofeedback-assisted CBT; B-CBT) that synthesizes the two in the treatment of chronic posttraumatic pain. The B-CBT protocol combines cognitive, emotional, and physiological (e.g., muscle tension) elements to heighten awareness of self-control. It provides immediate physiological feedback during the cognitive behavior therapy process to heighten awareness of psychophysiological reactions and to facilitate change. Through the process of shaping, patients learn to monitor and control their physiological reactions in conjunction with reviewing and modifying cognitive and emotional aspects of activating stressful events. In addition, a cognitive exposure method can be utilized by having the patient repeatedly relate the activating event, while attempting to maintain physiological responding below a gradually reducing threshold level. Relaxation techniques such as deep breathing and progressive relaxation training may be also used. Initial findings for this procedure have been very encouraging and further research is warranted.

Habit Reversal

In a promising new approach to managing facial pain and tension headaches, Gramling, Neblett, Grayson, and Townsend (1996) used a habit reversal treatment approach. They taught patients with facial pain to detect, interrupt, and reverse maladaptive habits (e.g., suboptimal head/jaw posture, jaw tension, and negative cognitions). The main premise of this program is that participants can learn specific skills to reverse habits as well as reverse stressful thoughts and feelings that precipitate these habits. The treatment program begins by teaching exercises that increase awareness of the habit. Awareness training is facilitated by relaxation training exercises that are taught in conjunction with deep breathing exercises. As pain patients become more aware of maladaptive habits and the situations in which they occur, they are taught to use specific exercises (e.g., facial exercises) and deep breathing as competing responses. A similar process is

used to help pain patients become more aware of habitual stress-inducing thoughts and beliefs.

IMPAIRMENT AND DISABILITY IN POSTTRAUMATIC HEADACHE

Currently, we have poor tools for gauging impairment associated with headache. For example, the American Medical Association (AMA) (1993) does not provide a specific methodology for calculation of impairment related to any type of headache but instead allows the rater to "estimate" the impairment. Pain is therefore rated in qualitative terms relative to frequency and intensity. One must understand, however, that the rating is based purely on patient report and therefore is totally subjective, as opposed to most of the AMA guidelines for impairment determination that are based on objective clinical exam findings. It is also important for readers to understand that the AMA guides were established through an empirical consensus process and would not stand up to current methodologies used in the development of evidence-based standards or guidelines.

The AMA guidelines state, "An individual who complains of constant pain but who has no objectively validated limitations in daily activities has no impairment" (AMA, 1993, p. 309). This statement confuses issues germane to differentiation of impairment from functional disability. That is, impairment should not be gauged by functional ability or disability but by objective examination findings on physical and/or psychiatric examination. It is of utmost importance for clinicians, as well as lawyers, to keep the distinction between impairment (what one finds on examination) and disability (how the impairment impacts on functional abilities) clear and not intermingle and/or analogize these terms.

The AMA guidelines also state, "The vast majority of patients with headache will not have permanent impairments" (AMA, p. 312). First, this statement discusses headache in only a very general sense, and there are clearly differences in headache conditions that affect prognosis, as well as anticipated impairment and disability that are lost when making such a generalization. This statement also has the potential to bias less experienced evaluators and lead to their dismissal of chronic PTHA complaints as "nonorganic", litigious, or attention-seeking behaviors.

Finally, impairment ratings are considered appropriate only after an individual has reached maximum medical improvement (MMI); specifically, this implies that there is no more than a 3% change in whole body impairment rating expected over the ensuing year (AMA, 1993). An individual who has not been adequately assessed (e.g., there is no more specific diagnosis than PTHA) and/or treated should not be labeled, as a rule, as MMI.

Packard and Ham (1993) proposed a reasonable alternative to the AMA impairment rating system using the acronym IMPAIRMENT and a 0 to 2 rating scale. The acronym stands for intensity, medication use, physical signs/symptoms, adjustment, incapacitation, recreation, miscellaneous activity of daily living, employment, number (frequency), and time (duration of attacks). Additionally, there are three physician modifiers scored from 0 to 4 points for motivation for treatment, overexaggeration or overconcern, and degree of legal interest. Although this paradigm for ascertaining an impairment level in PTHA is more cumbersome than the AMA Guides, the Packard and Ham methodology is one viable option that provides a more multidimensional and logical approach to rating impairment in PTHA.

CONCLUSIONS AND RECOMMENDATIONS

There is much to be learned about PTHA conditions. There must be a greater effort at bringing together the multiple disciplines involved with PTHA assessment and treatment to address many of the issues discussed in this chapter, as well as others not discussed because of space limitations. Education concerning PTHA for "frontline" clinicians in the disciplines of emergency medicine, neurology, and family practice is essential if these individuals are to receive appropriate treatment. There must be development of multidisciplinary consensus opinion concerning issues dealing with nomenclature, screening examination, classification, and accepted algorithms for treatment. PTHA classification must be more in depth and specific than that currently provided by ICD-10 or IHS. Better and more objective impairment and disability assessment techniques need to be developed for PTHA, preferably ones that have face validity and good inter-rater reliability with internal "checks" for symptom magnification, as well as response bias. Research efforts should be directed at examining PTHA subtypes in primary not tertiary PTHA patient populations that have been identified relative to historical factors and specific subpopulations (e.g., cerebral, cranial, cranial adnexal, cervical, posttraumatic psychological, or mixed impairments).

Ultimately, there is still much that is not understood about PTHA. Misinformation, lack of information, and incomplete understanding of pathoetiology, as well as natural history of the condition, continue to be problematic issues. We must commit to addressing these deficits in knowledge through multicenter, multidisciplinary, prospective research.

Orofacial Pain and Temporomandibular Disorders

Gary M. Heir, D.M.D.

HISTORICAL PERSPECTIVE

Head and facial pain has plagued mankind throughout recorded history. In ancient times it was believed that the victim's suffering was due to evil spirits and humors that invaded the cranium. Prayers of exorcism and the application of magic potions were often performed to drive away these demons and end the victim's misery.

The search for valid etiologies over those more mystical may have begun with Hippocrates who suggested that noxious vapors from the liver and other poorly understood maladies were the cause of head pain. The release of these vapors was accomplished by the use of leeches, bleeding, and in extreme cases trephination; however, at least according to Hippocrates, these were the remedies of choice. The term *hemicrania* is attributed to the ancient Roman physician Galen, and the origins of the term *migraine* may also be traced back to this period (Kiester, 1989).

During the ensuing centuries there was slow but steady progress in the understanding of head and facial pain. The use of analgesics began in the 13th century and evolved to the use of cocaine and the discovery of other analgesic preparations, but these efforts to relieve pain did not explain its mechanism.

Thomas Willis offered a "vascular hypothesis" in the 17th century (Frank, 1990). He suggested that head pain was due to swelling of blood vessels in the cranium, a theory that was generally accepted within the medical community and became the basis for much of the 20th century pharmacotherapies. In fact, by the 19th century the physician's approach to managing headache and facial pain was almost exclusively pharmacological, and medications were selected based on their efficacy with little understanding of their pharmacodynamics. In modern times it was the work of Wolff (1948) and his contemporaries who continued this pursuit.

While the debate as to the etiology and treatment of migraine headache continued, little effort was made to understand other forms of head and facial pain. Facial pain was thought to be mostly due to dental causes or, in some cases, thought to be of psychogenic origin. Attention was first drawn to facial pain of nonheadache and nonodontogenic origin in 1934 when Costen published his treatise on a syndrome of ear and sinus symptoms dependent on disturbed function of the temporomandibular joint (TMJ).

Now we are in a new era. Science is beginning to understand the mechanisms of pain transduction, transmission, modulation, and perception. With a more clear understanding of pain mechanisms, the healthcare sciences have been able to identify more specific etiologic factors and conditions for our patients' complaints.

For the purpose of this discussion, orofacial pain is categorized by the systems from which it may seem to arise (Merrill, 1997). This discussion reviews head and facial pain of odontogenic, vascular, musculoskeletal, neurogenous, and psychogenic origin. By evaluating symptoms on this basis, the source of the patient's suffering may be identified and appropriate therapeutic measure may be instituted.

OROFACIAL PAIN

Orofacial pain can be acute and related to trauma, dental injuries, dental pathologies, and acute dysfunction of the masticatory system. Acute orofacial pain may include dental pathology, dysfunction of the masticatory musculature, and temporomandibular disorders (TMD). Acute pain is more readily diagnosed and treated, and often there is an identifiable precipitating event associated with the onset of acute symptoms that leads the clinician to the source of the problem.

Chronic orofacial pain is more difficult to diagnose, and the source of the patient's complaint is frequently elusive. The clinician must have the knowledge and clinical expertise to accurately pursue the assessment, diagnosis, and treatment of complex chronic orofacial pain and dysfunction disorders, including oromotor and jaw behavior disorders, chronic head, neck, and facial pain and have knowledge of the underlying pathophysiology and mechanisms of these disorders (American Academy of Orofacial Pain [AAOP], 1998).

Chronic, complex orofacial pain may be of musculoskeletal, vascular, neurogenous, and infrequently psychological origin. There is a clear distinction between complex chronic orofacial pain and acute pain.

ACUTE PAIN

Acute pain is biologically useful. It occurs as a result of a noxious mechanical, thermal, or chemical stimulus. The symptoms and history of the onset of pain help in assessing the problem. A diagnosis for the cause of acute pain is facilitated by an assessment of the location, the duration, and the intensity of the patient's pain. Treatment efforts vary depending on the diagnosis; however, the diagnostic process is usually not difficult.

The acute pain of an infected tooth or an acute dislocation of the TMJ does not present as a significant diagnostic problem. The onset of pain symptoms presents in such a way that the diagnostic process is fairly clear.

The emotional reaction to acute pain is also somewhat predictable. The reaction to the sudden onset of acute pain is anxiety. There is fear that the sudden onset of spontaneous pain represents a life-threatening illness or that pain after trauma is due to a serious injury. However, once the patient understands the source of pain and the clinician acts to alleviate the cause and symptoms, the patient's anxiety dissipates.

CHRONIC PAIN

Unlike acute pain, chronic pain has no biological utility. Chronic pain may not be due to nociception or central neural input. The location of pain does not aid in the diagnosis. The patient may feel as though something is wrong in his or her life. Chronic pain has biological ramifications as well as sociocultural and psychological effects (Grzesiak, 1991).

Chronic pain is both a cognitive and emotional experience and can be destructive. Management may be difficult. Patients develop chronic pain syndromes that rule their lives. Chronic pain patients regularly abuse the healthcare system, overuse medications, and have difficulty with interpersonal relationships. Chronic pain is inevitably depressing, but may be synchronous with depression and not caused by it. The longer pain continues, the deeper the depression may be. Chronic pain monopolizes the patient's attention, compromising behavior and thinking. Expectations for recovery are poor (Wall, 1999).

In practice, the chronic pain patient with psychological affect may be identified by a variety of factors. The duration of their pain is longer than would be expected and, if associated with illness or injury, extends beyond the time required for normal healing or recovery. Chronic pain patients tend to dramatize their complaints. They may exaggerate symptoms verbally or demonstrate compromised functional ability beyond what would be expected. Chronic pain patients provide a history of a variety of diagnostic failures and present as a diagnostic dilemma. There may be a history of excessive use of medications both by prescription or over-the-counter preparations. Chronic pain patients demonstrate dependence on family and friends, become withdrawn, and avoid painful or potentially painful activities. Depression is evident; decision making, antisocial behavior, and rejection by friends and family may also become evident with a carefully elicited history (Rosch, 2000).

Although a psychological diagnosis may be inappropriate if made by a healthcare practitioner not trained in psychology, recognition of the emotional components of chronic pain should prompt an appropriate referral for additional assessment.

ODONTOGENIC PAIN

It is not the purpose of this chapter to discuss odontogenic pain. However, inasmuch as dental pain is the primary etiologic factor in the production of facial pain, a brief discussion is required.

Consider the tooth as a specialized primary afferent nociceptor. A tooth is a hard container composed of enamel, dentin, and cementum. It is firmly attached to the supporting bone by the periodontal ligament. This "hard case" contains the dental pulp. The dental pulp is the principal source of pain within the mouth. This pink, coherent, soft tissue is dependent on the hard tissues of the tooth for its for protection. Once exposed, it is extremely sensitive to all stimuli (Ogilvie, 1969).

Although the dental pulp is often referred to as the nerve, it is not just a mass of raw nociceptive neural tissue. The pulpal tissue of the tooth resembles other loose connective tissues of the body more than it differs from them. There are connective tissue cells of various types, as well as intercellular components made up of ground substance and fibers. Among this lies a complex network of blood vessels, lymphatics, and nerve tissue (Seltzer, 1988). Stimulation of the dental pulp elicits a painful response.

Not all dental pain is a consequence of direct stimulation of the pulpal tissue. Inasmuch as this complex structure has great similarities to other tissues in the body, it responds in a like fashion to injury or trauma. The response is inflammation and/or necrosis.

The classic signs of inflammation — heat, swelling, and, of course, pain — may all be manifest as a result of pulpal pathology or injury (Byers & Narhi, 1999). The endodontist may also bear witness to the fourth sign of inflammation, redness. Erythema is a classic characteristic of an inflamed pulp, which may be observed upon its removal during endodontic therapy. Unlike an injury to any other part of the body, once inflammation of the dental pulp begins, the swelling tissue is trapped in the hard container and, in effect, has no place to go.

An injured or diseased dental pulp may go through several stages, all of which produce pain. These stages of pulpal involvement respond differently to diagnostic testing. The clinically normal pulp is vital to testing procedures, responsive to a variety of excitations, but free of spontaneous symptoms. Histologically, it is free of any inflammatory changes.

Mild irritation of the pulpal tissue, such as caused by thermal, mechanical, or chemical irritants, may cause a dental pulp to become hyperreactive to stimulation. Of these, dental caries or tooth decay is the most familiar. In the case of stronger irritants or more advanced decay, a transitory hyperemia or reversible inflammation may occur (Scimone, 1976). An acute reversible pulpitis may become chronic and lead to pulpal necrosis and pain.

Orofacial pain of dentigerous origin may be referred throughout the face by such inflamed or diseased teeth. Various stages of dental caries may provide adequate etiology for these pulpalgias. Therefore, the patient who presents to the physician or dentist with facial pain must have a complete examination of the dentition.

The periodontal membrane, otherwise known as the periodontal ligament, responds to stimulation in the same manner as any other ligament. In fact the teeth are attached to the supporting bone by the periodontal ligament, forming a synarthrodial joint. Irritation of this generously innervated tissue results in the classic musculoskeletal symptoms of dull, aching pain. This pain is localizable to a general area and may be provoked by percussing the suspected teeth. Increased pressure on a tooth with a periodontal inflammation or infection within the periodontal space produces or increases pain.

The mechanisms of periodontal injuries are either mechanical or chemical (infection). One of the most common sources of periodontal irritation is trauma from occlusion often caused by premature dental contacts or bruxism.

Bruxism may produce pain in the masticatory system, as has been documented experimentally (Christensen, 1971). The pain may arise from muscles, periodontium, and TMJ. Pain produces unbalanced, sustained, abnormal muscle activity, increasing the risk of injury (Arima, Svensson, & Arendt-Nielsen, 1999).

As stated, pain from the periodontal ligament space is musculoskeletal in character. Chronic pain arising from the periodontal ligament has the ability to refer pain to other structures. The pattern of tooth reference pain is well documented in the literature (Simons, Travell, & Simons, 1998).

From the preceding discussion of dental pain, it may be noted that an attempt is made to categorize the various symptoms as arising from vascular, neurogenous, or musculoskeletal origin. This technique is also suggested when considering head and facial pain of nondental causes.

HEADACHE

"Headache has been called the most common medical complaint of civilized man" (Dalessio, 1987). If dental structures are not the primary source of facial pain, vascular head, and facial pain, which includes such entities as migraine and cluster headaches, must be considered next. Familiarity with these entities is important because their region of onset often overlaps dental and masticatory structures.

The evaluation and management of headache disorders are adequately discussed in another section of this text. However, a basic review of various headache disorders that may present as orofacial pain is provided.

The mechanism of headache of vascular origin is currently best explained as a sterile inflammation of the trigeminovascular system (Buzzi & Moskowitz, 1993; Moskowitz, 1993). Pharmacological management of these patients is often possible. Although, it is incumbent on the dental practitioner to have the ability to recognize migraine, as well as other head or facial pains of vascular origin, the responsibility for final diagnosis and treatment of these disorders should be with our medical colleagues.

It should also be remembered that there are a number of painful vascular conditions of the face that either produce pain referred to the teeth or may on occasion affect oral vasculature, thus producing a perception of toothaches or TMD. These include facial migraine, cluster headache, angina pectoris, and temporal arteritis. These

conditions must be recognized and treated (Buxbaum, Myslinski, & Myers, 1989).

Migraine

Included in the classification of vascular disorders that are often confused with masticatory pain are migraine headaches. Migraine is an idiopathic, recurring headache disorder that occurs in attacks that may typically last from 4 hours to as many as 3 days. This headache is usually unilateral, moderately severe, and pulsating in quality. Migraine is generally aggravated by routine physical activity and may be associated with nausea, photophobia, and phonophobia. It is not uncommon for the migraineur to seek a dental consultation for relief from what is perceived to be dental or masticatory musculature pain.

Migraine with aura has similar characteristics, as does migraine without aura. The difference in this case is that the headache is normally preceded by a preheadache neurosensorial disturbance. This may be a series of idiopathic recurring neurological symptoms, which usually develops over a 5- to 20-min period and may last less than 1 hour. "Nausea is the complaint of the vast majority of patients; vomiting, in addition to nausea, occurs in just over one half of the patients. These gastrointestinal disturbances usually start sometime after the onset of the pain but occasionally precede the headache" (Raskin, 1988, p. 44).

A typical aura may consist of visual disturbances, hemisensory symptoms, hemiparesis, dysphasia, or combinations of these phenomena. Gradual development, duration of less than 1 h, and complete reversibility characterized the aura, which is associated with this form of headache. Differential diagnosis of migraine headache includes myalgia, myositis or myofascial pain of the masticatory musculature, TMDs, and tooth pain.

Cluster Headache

The presentation of cluster headache is classic. Cluster headache consists of attacks of severe, strictly unilateral pain in and around the eye and/or temporal region. This temporal, periorbital pain is frequently confused with a masticatory or dental pain. The attacks may last from a few minutes to as much as 3 h. The attacks occur from once every other day up to eight times per day. They are associated with one or more of the following: conjunctival injection, lacrimation, nasal congestion, rhinorrhea, forehead and facial sweating, miosis, ptosis, and eyelid edema. Attacks occur in series lasting for weeks or months. These are the so-called cluster periods. These periods are separated by periods of remission, which may last months or years. Cluster headache predominately affects men in a ratio of 5:1 to women. This is in contrast to migraine, which predominately affects women in a similar ratio. Differential diagnosis of cluster headache includes dental infection and acute pain of the masticatory musculature.

Chronic Paroxysmal Hemicrania

Another benign headache disorder known as chronic paroxysmal hemicrania has characteristics similar to cluster. Whereas cluster headache occurs more commonly in men, chronic paroxysmal hemicrania is more common in women. The attacks are more frequent and of shorter duration but distributed in similar areas as symptoms associated with cluster headache. Between attacks, there may be a continuous, sore feeling in the usually painful areas: the ocular–periocular regions, the forehead and temporal area, neck, and shoulders (Sjaastad, 1987). One diagnostic criterion of this form of headache is that it is invariably relieved by indomethacin. Differential diagnosis of chronic paroxysmal hemicrania is the same as for cluster headache.

Lower-Half Migraine

Other forms of facial pain of vascular origin may include migraine of the midfacial region sometimes called lower-half migraine. Patients with this form of vascular pain report pain in the jaw and neck periorbitally and in the maxilla. There may be tenderness of the carotid artery (Raskin, 1988, Chapter 11); therefore, this disorder is known as carotidynia (Fay, 1932). As with migraine, this condition predominately affects women. The symptoms are of a dull pain with superimposed throbbing that may occur once or several times weekly. Exacerbations may last minutes to hours. Differential diagnosis includes TMD, pain of the myofascial pain, and masticatory musculature and dental pain.

Tension-Type Headache

Tension-type headache is described as recurrent episodes of headache lasting minutes to days. The pain is typically pressing or tightening in quality. Discomfort extends into the face and masticatory musculature. Many individuals describe this sensation as similar to wearing a tight hat. It is of mild or moderate intensity, is bilateral in location, and does not usually worsen with routine physical activity. Nausea is absent, but photophobia and phonophobia may be present.

The patient with tension-type headache may seek the advice of a dentist on the referral of a physician. Chronic, muscle tensionlike headaches such as these may have the capacity to refer pain to the masticatory structures (Simons, Travell, & Simons, 1998). Again, care should be taken to ensure that the patient's complaint is truly a result of masticatory function and not simply referred to the face and jaw from other areas. Differential diagnosis includes myofascial pain and dental pain.

Giant Cell (Temporal) Arteritis

A discussion of cephalgic and facial pain is not complete without some mention of temporal, or giant cell, arteritis. This condition is usually attended by the onset of a new headache in an individual of at least 50 years of age. One or both of the temporal regions are involved. Moderate to severe headache, polymyalgia, and claudication of the masticatory muscles may be present. The occurrence of this symptom is significant, because claudication of the masticatory musculature may be diagnosed as a TMD. There may be a swollen and tender scalp artery, usually the superficial temporal artery, which unless carefully palpated may mimic tenderness of the temporalis muscle. The patient with giant cell arteritis may have an elevated red blood cell count (RBC) sedimentation rate. A temporal artery biopsy is more definitive for giant cell arteritis (Headache Classification Committee of International Headache Society, 1998). This form of headache must not be overlooked because it has a potential for dire consequences. Untreated, temporal arteritis may cause blindness, stroke, or death.

If a patient of 50 years or older presents with a complaint of dull temporal pain, fatigue of the masticatory muscles, and joint pain and reports headache of recent onset, which is chronic, and possibly worsening, temporal arteritis must be ruled out. Differential diagnosis includes myofascial pain and dental pain.

MUSCULOSKELETAL PAIN

As stated, the dentition and supporting structures of the teeth are the primary source of facial pain. If a thorough dental evaluation eliminates the possibility of odontogenic pain, and facial pain of vascular origin has been eliminated as a possibility, pain of musculoskeletal origin should be considered next. Acute muscle pain is easily diagnosed and managed; however, the management of chronic muscle pain can be difficult. Masticatory pain of musculoskeletal origin can arise from the TMJs, the masticatory musculature, or both (Delcanho, 1995).

Temporomandibular Disorders

TMD is defined as clinical problems that involve the masticatory musculature, the TMJs and associated structures, or both. TMDs are considered the most common musculoskeletal disorder causing orofacial pain. Pain may be of muscular origin arising from the muscles of mastication or referred to the masticatory musculature from cervical and/or shoulder structures. Myogenous pain occurs more frequently than articular disorders.

Articular disorders of the TMJs often coexist with masticatory muscle pain. Articular disorders of the TMJs include disk displacement disorders, arthritic and degenerative changes, and neoplasm (AAOP, 1996).

Myogenous pain disorders affecting the masticatory musculature are no different from those that affect other musculoskeletal structures. They include, myofascial pain, fibromyalgia, myositis, myospasm, and local myalgia.

The quality of musculoskeletal pain is deep, constant, dull, and occasionally sharp. The most important features of musculoskeletal orofacial pain are that it is made worse with movement of the jaws and that the pain is provocable. Movement of the affected joint or muscle can reproduce musculoskeletal pain. The intensity of pain is true to the degree of provocation.

In addition to the increase of pain with physical activity, chronic pain of the masticatory musculature can refer to other areas. Referred pain is the phenomenon of perception of pain at a site that is not the source of pain. Referred pain is diffuse and poorly localized. Referred pain is characteristic of myofascial pain.

Myofascial Pain

Myofascial pain is a regional muscle disorder that is the most common cause of persistent pain in the head, face, and neck. It is characterized by one or more hyperirritable sites within the muscle called myofascial trigger points.

A myofascial trigger point is a tender point of localized deep tenderness located in a taut band of skeletal muscle, tendon, or ligament. Myofascial trigger points are approximately 2 to 5 mm in diameter and when provoked can refer pain to another region known as a zone of reference. The zone of reference is distant from the involved muscle and may not be in the same dermatome. The pattern of pain referral is reproducible and consistent, and serves as a guide to locate the source of the myofascial pain.

Myofascial pain is also characterized by increased muscle fatigue and stiffness. The patient may exhibit a mildly restricted range of motion. Pain may be elicited when the muscle is stretched. The patient may also report a sense of subjective weakness in the affected muscle or muscles. Myofascial pain can be localized involving one or two myofascial trigger points or generalized due to muscle injury. It may coexist with other conditions such as cervical or facet joint injuries.

There are two types of myofascial trigger points. A latent myofascial trigger point is painful at the site of palpation but is not associated with referred pain. An active myofascial trigger point is painful at the site of palpation and also causes spontaneous referred pain during palpation and muscle use. Myofascial trigger points cycle between an active and a latent state.

TEMPOROMANDIBULAR JOINT

Intracapsular disorders of the TMJs result from abnormal biomechanics. To appreciate the complexity of intracapsular

disorders of the TMJ, a fundamental understanding of normal anatomy and biomechanics is required.

The TMJ is a synovial joint. That is, it is encapsulated and stress bearing. It is possibly the most complex joint in the body. The articulating surfaces are covered with fibrocartilage. It is a compound joint with four separate articulating surfaces; the superior aspect of the mandibular condyle functions on the inferior surface of the interarticular disk. The superior surface of the disk functions on the posterior slope of the articular eminence of the temporal bone. The disk is unique to this joint. It separates the intracapsular space into an inferior and a superior joint compartment. These are separate and isolated from one another by the disk and anterior and posterior attachment tissue. The retrodiscal tissue, a mass of loosely packed, highly innervated and vascularized connective tissue, occupies the posterior aspect of the joint space. The uppermost layer of this posterior discal tissue is composed of elastic fibers. This elastic layer composes what is called the superior retrodiscal lamina.

The interarticular disk is held tightly to the mandibular condyle by a medial and lateral colateral ligament. These ligaments are intimately incorporated within the capsular ligament. An injury to the capsule is painful.

The position of the disk should be between the condyle and the articular eminence during all mandibular movements. A displacement of the disk, typically anterior to the condyle, is the cause of most of joint sounds perceived during joint function.

Articular Disk Disorders

Intracapsular disorders of the TMJs involve partial or total displacement of the articular disk, inflammation of the retrodiscal tissues, and degenerative changes of the articular surfaces.

NORMAL BIOMECHANICS

The TMJ is a ginglymoid arthrodial joint. It has a rotational as well as translatory movement. The mandibular condyle is ovoid in shape, although the shape of the condyle varies from patient to patient and there may be asymmetrical condyles in the same patient.

The ovoid- or football-shaped condyle functions with the glenoid fossa of the temporal bone. The fossa is a depressed area at the base of the skull that is delineated by the TMJ capsular ligaments. The anterior aspect of the fossa includes the articular eminence, a raised ramplike structure anterior to the depressed area of the fossa. The posterior wall of the glenoid fossa is bounded by thin bone that separates the fossa from the external auditory meatus. The lateral aspect of the joints is enclosed within the capsular ligament and the medial aspect of the joint is osseous.

Interposed between the condyle and fossa is a fibrocartilagenous interarticular disk. This disk is attached to the mandibular condyle by medial and lateral collateral ligaments. This allows the disk to move anteriorly and posteriorly on the condylar head, but does not allow the disk to move away from an intimate contact with the articular surface of the condyle. Attached anteriorly to the superior lateral pterygoid muscle and posteriorly to the fossa, the disk separates the synovial space of the joint into superior and inferior compartments.

During normal function, the mandibular condyle starts its movement from a closed mouth position with the articular disk seated on the posterior slope of the mandibular condyle. Movement begins with a rotation of the condyle against the inferior articular surface of the disk. Translation combined with rotation allows the condyle-disk assembly to slide down the articular eminence to a more forward and downward position. Translation and rotation allow for full maximum opening.

Abnormal Biomechanics

TMDs consist of three basic components: limitation of function, joint pain, and joints sounds. Limited function may result from muscle guarding or contraction following overuse or injury. Contracture, splinting, or spasm of the mandibular elevator muscles result in limited mandibular range of motion. Pain is not always present. Limitation of mandibular range of motion due to disk displacement may also occur in the absence of pain.

NEUROGENOUS PAIN

The face is the most richly innervated structure of the body and represents the majority of input to the somatosensory cortex of the brain. Facial pain is mediated by the trigeminal nerve. Specifically, nociception is transmitted to the central nervous system via two types of nerves or primary afferent nociceptors. These are the thinly myelinated A-delta fibers and the unmyelinated C fibers (Sessle, 1999).

Under normal conditions, primary afferent nociceptors are not responsive to nonnoxious stimuli. To stimulate or transduce an action potential, the primary afferent nociceptive receptor must be activated to threshold by a tissue damaging, or potentially tissue-damaging, stimulus. Such stimuli can be via mechanical deformation of tissue, noxious temperature, or chemical injury.

When an adequate noxious stimulus is encountered, a cascade of events occurs that sensitizes the nociceptive nerve ending, thereby making it receptive to further stimulation and allowing transmission information to the central nervous system. This information is modulated in the dorsal horn of the spinal chord where it is then transmitted to a second-order neuron. The peripheral sensitization is the result of the release of a variety of

excitatory mediators, neuropeptides associated with inflammation, and the endogenous release of additional inflammatory mediators such as substance P. The presence of these neuropeptides in the area of the injury results in the perception of pain for the injured area until healing occurs. Once the tissue damage has resolved or the noxious stimulus has abated, peripheral sensitization ends and pain abates.

NEUROPATHIC PAIN

The mechanisms underlying neuropathic pain differ from those involved in "normal" pain. Neuropathic pain results from a dysfunction of the transmission system that carries nociception from the periphery. Neuropathic pain does not require a noxious stimulus, but may be self-propagating. It is maintained by injury or functional abnormalities of the pain transmission system (Pertes & Heir, 1991). Pain may be severe, have a delayed onset after injury, and persist for years or even decades after noxious stimulation has ceased and the damaged tissue has healed (Benoliel & Sharav, 1998).

Severity and chronicity of neuropathic pain are not clearly related to a specific etiology and may result from a variety of causes. Possible mechanisms for neuropathic pain include continued sensitization of peripheral nociceptive receptors and central neuroplasticity (Sessle, 2000). This suggests the development or activation of aberrant inputs to central, second-order pain transmission neurons. There can be a loss of afferent inhibition known as deafferentation syndrome. In deafferentation syndrome, nociceptive inputs produce an exaggerated response such as seen in postherpetic neuralgia. Neuropathic pain may also include activation of the sympathetic nervous system. In the case of sympathetically maintained pain, dysfunctional pain transmission cells are sensitized to the activity of the sympathetic system and respond with nociception (Sessle, 2000).

Neuropathic pain may be characterized by sensory deficit in the affected region or by pain, which may be bright, burning, and stimulating. Neuropathic pain may also present as dysesthesia or a mild, uncomfortable but nonpainful sensation, paresthesia, and numbness. Care must be taken in evaluating the patient with possible neuropathic pain, because differential diagnosis requires the elimination of myofascial and dental pain as the source of the patient's symptoms.

ATYPICAL ODONTALGIA

Atypical odontalgia (AO) is a poorly understood chronic pain disorder that presents as a persistent pain in apparently normal teeth and adjacent oral tissues. It is generally agreed that the term *atypical odontalgia* does not adequately describe this entity. At the time of the writing of this chapter, a taxonomy committee is hard at work to better define this condition and provide a more descriptive and diagnostic nomenclature. It is postulated that AO is a neuropathic pain disorder (Graff-Radford & Solberg, 1992). Pain, often described as burning and spreading, may occur at the site of tooth extraction. Other concomitant factors may include traumatic injury, various routine dental procedures, endodontic therapy, endodontic surgery on teeth (apicoectomy), periodontal surgery, and dental implants (Vickers, Cousins, Walker, & Chisholm, 1998).

AO can also follow seemingly innocuous dental procedures such as crown preparation, cavity preparation, and periodontal scaling. It is more likely to develop in a tooth that was painful prior to dental intervention.

Most patients are 40- to 50-year-old females. AO is rare in younger age groups. These patients are usually examined and treated by a number of clinicians before being properly diagnosed. They often have a history of many failed dental treatments that serves to perpetuate the pain instead of relieving it. It is not uncommon for a patient with AO to have received multiple endodontic therapies and surgery, as well as multiple extractions.

Clinical characteristics of AO are continuous or almost continuous pain in a tooth or tooth site, with constant, dull, aching pain of moderate to severe intensity. There may be an associated hyperesthesia (tooth is tender to finger pressure). The clinical findings, chief complaints, and fact that pain has been present for more than 4 months with no obvious local dental cause lead to this diagnosis. The patient must have a negative clinical examination, normal radiograph, and no history or evidence of significant psychopathology. Somatic nerve block or local anesthesia does not entirely relieve the discomfort.

There are several theories for the etiology of this condition that include neurovascular, psychological, and neuropathic diagnoses. It is unlikely that AO is related to migraine, because AO is a continuous pain and migraine is episodic.

Scientific support for a psychological basis for AO is lacking. There is no increase in Minnesota Mulitphasic Personality Inventory (MMPI) scales when compared with other chronic pain patients.

Deafferentation is the most likely mechanism. Deafferentation is the partial or total loss of an afferent nerve supply from a particular area. Trauma to a nerve commonly follows dental procedures involving the dentin, pulp, or periodontal tissues. Although this type of injury may be reversible within a short time, in a small percentage of patients (less than 3%) who have undergone a dental procedure, pain persists even after healing has apparently occurred. Pain may not appear for weeks, months, or even a year after the procedure.

There may also be involvement of the sympathetic nervous system. Sympathetically maintained pain (SMP) involves a neuropathology process where the activity of the sympathetic system activates injured primary afferent

nociceptors. Blockade of the sympathetic symptom may provide relief. Diagnosis of AO requires the elimination any odontogenic causes. If a dental source of the pain is not found, no dental treatment should be initiated. Differential diagnosis includes trigeminal neuralgia, facial or midface migraine, myofascial referred tooth pain, maxillary sinusitis, and TMDs.

BURNING MOUTH SYNDROME (BMS)

A review of the medical and dental literature suggests that over 40% of postmenopausal women suffer from symptoms of burning tongue or mouth. On examination, these patients have negative clinical findings for abnormalities or pathology of the oral cavity or mucogingival structures. The only common feature is the history of the onset of their symptoms after menopause.

It has been postulated that the etiology for BMS is a result of changes in estradiol levels that may have a detrimental effect on the function of the special sensory component of CN VII (chorda tympani) (Grushka, Epstein, & Kawale, 2000).

Symptoms of intraoral burning are considered idiopathic. However, a growing body of evidence indicates that BMS it is a neuropathic disorder resulting from disinhibition of nociception regulated by interactions between taste centers in the brain and CN-VII, V, and IX. BMS has also been associated with hormonal imbalance, trauma, nutritional disorders, and positive psychological findings. Conditions that may mimic BMS include denture irritation, infection, oral lesions, xerostomia, and mouth breathing, as well as gastric, rheumatologic, and other disorders. Treatment strategies depend on an accurate diagnosis (Nasri et al., 2000).

SUMMARY

Complex chronic orofacial pain syndromes have multiple etiologies and treatment possibilities. When examining and managing orofacial pain patients, it is important to set goals to achieve an acceptable degree of success. The first goal is to establish a specific diagnosis. This goal can only be achieved if the clinician has a basic understanding of, and familiarity with, those conditions that can lead to orofacial pain. Without knowledge of musculoskeletal and other systemic disorders that may cause orofacial pain, a differential diagnosis cannot be made. Having missed the first goal, diagnosis, the treating doctor cannot logically establish the second goal, management of the disorder. When an accurate diagnosis is made, the correct treatment often becomes apparent (Bell, 1980).

In some cases, despite all our best efforts and scientific knowledge, there are times when we are at a loss to help your patients. Where our skills and knowledge fail us is where our humanity must begin.

"I think that the lives of all people are linked to each other. We are always helping and have been helped by others. We can always do something to help. It is not difficult. Many times it is enough just to say something good, give a little attention, listen a little or just smile" (C. Nasri, personal communication, June 1999).

Chinese Medicine and Acupuncture for Pain Management in HIV/AIDS

Misha R. Cohen, O.M.D., L.Ac.

CHINESE TRADITIONAL MEDICINE IN PAIN MANAGEMENT

Acupuncture and other forms of Chinese traditional medicine have been used for centuries to treat acute pain due to trauma, chronic pain due to injuries, and pain from organic illnesses.

In Chinese traditional medicine, pain is often associated with imbalances within the body that lead to a slowing down or blockage of the body's energy (Qi). This is known as Stagnant or Stuck Qi or with the blockage of Blood (Xue) due to an acute trauma or a worsening of the Stagnant Qi.

Pain can also be related to Damp accumulating in the Channels, to deficient Qi and Xue, to Stagnation of Cold, or to association with Heat or Damp Heat.

For example, peripheral neuropathy can be associated in the early stages with Damp in the Channels (associated with numbness), later with Heat or Cold, and — as it gets worse — Qi and Xue Deficiency-type numbness.

The most commonly used treatment in Chinese traditional medicine and acupuncture is to unblock the Qi or Xue to relieve the pain. However, removing Dampness, clearing Heat, and resolving Damp Heat may also be treatment principles for pain management.

Western science has documented some ways in which acupuncture relieves pain — there are several mechanisms. The most notable is through stimulation of endorphins. Another mechanism is through stimulation of serotonin levels within the brain, which leads to a sense of well-being as well as pain relief.

ISSUES IN HIV/AIDS PAIN MANAGEMENT

In my experience, for the last 17 years of working with people with AIDS, the assembly of a comprehensive care team is central to the treatment of people with HIV/AIDS who are dealing with various pain syndromes. The person in charge is the person with HIV/AIDS, who is the captain of the healing team.

In conjunction with the captain, there is the need to develop a whole and unified team, which may include a number of practitioners as well as caregivers. In pain management in HIV/AIDS, it is important that there be an integrated approach because pain syndromes are often difficult to manage successfully and there is a relationship to the overall treatment plan for HIV/AIDS. If a person with AIDS is in pain, it is difficult to manage other aspects of care, and vice versa.

Therefore, the pain management team would include the person with HIV/AIDS as the captain; at least one Western physician; and then other members would be included such as a licensed acupuncturist and herbalist, a massage therapist, a physical therapist, an occupational therapist, a chiropractor, an osteopathic physician, and a psychologist.

In HIV/AIDS, it is important to always have a Western baseline for ongoing care and treatment. Some pain may be resolved through changes in medications (sometimes added, sometimes subtracted). Often the pain can be associated with opportunistic infections that need to be treated with pharmaceuticals or herbal medicine. Neurological pain, for example, may be mitigated through medication,

0-8493-0926-3/02/$0.00+$1.50

herbs, acupuncture, other modalities, or a combination of several modalities.

CHINESE TRADITIONAL MEDICINE (CTM) EVALUATION AND TREATMENTS

When using Chinese traditional medicine as a main form of treatment in HIV/AIDS related pain syndromes, some or all of the following comprehensive protocols could be adopted:

- Evaluation/diagnosis
- Acupuncture
- Moxibustion
- Chinese herbal medicine
- Qi Gong/other exercises
- Professional massage
- Meditation
- Food therapy

Chinese medicine is a complete medical system with its own forms of diagnosis, treatment, prognosis, and therapies. Chinese medicine treatments address disharmonies using acupuncture, moxibustion, food therapy/diet, herbal remedies, Chinese exercise, and meditation along with Western therapies.

Acupuncture is the art of inserting fine sterile metal needles into certain body or ear points to control the body's energy flow. Acupuncture is relatively painless, often accompanied with a sensation of heaviness, warmth, or movement of energy at the point of insertion or along the energy channels. Acupuncture helps to relieve pain as well as rebalance energy and heal symptoms. Electrostimulation may also be used with acupuncture for pain.

Moxibustion is the burning of the common herb mugwort over areas of the body for stimulation or warmth. Heat packs may also be used during treatment.

Chinese herbal medicine can be used for all types of disease. There are thousands of Chinese herbs. Usually they are put together into formulas to have the most effect.

Exercise includes martial arts as well as more subtle movement such as Tai Ji, Qi Gong, and Yoga. Gym workouts or aerobic exercise are also suggested.

Meditation may include traditional Asian forms as well as relaxation exercises, hypnotherapy, and biofeedback. Massage includes meridian pressure such as Shiatsu, Qi Gong, or Thai massage or muscle massage. Food therapy focuses on improving digestion, increasing energy, and balancing body energy. Food therapy often increases the effect of other treatments.

Acupuncture in HIV Pain Management

Acupuncture is often used in HIV/AIDS for various kinds of pain management.

- Abdominal pain (which may be associated with diarrhea or opportunistic infections)
- Sinus pain/headaches (which may occur as part of chronic sinusitis)
- Peripheral neuropathy (which can include pain and numbness)
- Joint pain (which may be associated both with various viral coinfections or are a result of drug side effects)

HIV Associated Peripheral Neuropathy

Acupuncture is used in the clinic in conjunction with other therapies for treatment of peripheral neuropathy in people with HIV/AIDS. There have been varying studies on its use. Unfortunately, none have been well designed and undertaken long enough to show conclusive results.

However, our clinical observations give us the direction for further study.

The following studies are examples of some research to date.

RESEARCH

A Pilot Study of Acupuncture for the Symptomatic Treatment of HIV Associated Peripheral Neuropathy*

- The objective is to study the outcome of patients receiving acupuncture treatment for the symptomatic treatment of HIV-related peripheral neuropathy, not due to drug toxicity. We evaluated objective and subjective nerve function and quality of life measurements.
- Methods include 39 patients receiving acupuncture twice weekly for 6 months in a nonrandomized observational study. No particular prescription was used, with the treatment choice left to the practitioner's discretion. Neurological and QOL assessments were completed at entry, months 2 and 6.
- In summary, 26 patients returned for the first follow-up at 2 months. The 13 lost to follow-up had more severe neuropathy and lower QOL scores than those who completed the treatment.
- Significant improvement was found for QST of the toe ($p = 0.05$). No trends were found in a subjective symptom list. Five of seven QOL scales showed improved (none were significant).
- In discussion, this study suggests that there may be a role for acupuncture as a treatment

* Jonathan Ammen, AMFAR study 1991–1992, reported at HIV/AIDS and Chinese Medicine Conference 1994.

for peripheral neuropathy future controlled studies may help further define the efficacy of this method.

This 1994 pilot study shows potential to study peripheral neuropathy using traditional Chinese medicine diagnosis and treatment. However, the pilot was too short and uncontrolled to lead to any real conclusion. It is likely that in neuropathy, 8 weeks is too short a time to really see statistically significant differences. However, the conclusion appears to be consistent with this observation.

Chinese Medicine in the Treatment of Peripheral Neuropathy*

- The issue is that peripheral neuropathy in the HIV/AIDS population is a serious and debilitating problem that requires an effective treatment protocol.
- The project at Quan Yin Healing Arts Center — a nonprofit community-based complementary medicine clinic that has delivered Chinese medicine for over 16 years in San Francisco — involved 533 HIV/AIDS clients treated in 1996, which included 66% of its client base. Over 75% of the people with HIV/AIDS at Quan Yin Healing Arts Center presented with peripheral neuropathy, from mild to severely debilitating. All women and men with neuropathy received a combination of treatments including one or more of the following interventions: acupuncture, electroacupuncture, massage therapy, moxibustion (an herbal heat therapy), and herbal medicine. Clients received treatment in time intervals from twice a month to three times a week.
- Results were chart reviews and surveys conducted by the executive director, revealing that over 75% of HIV + clients who were reviewed had reduced symptoms including decreased pain, reduced numbness, and increased mobility (including walking/running when unable to do so previously). Variations in response were related to total number of treatments, number of weeks of treatment, compliance with self-care (such as self-moxibustion), and combination of medications that caused neuropathy. Some patients were able to discontinue treatments for neuropathy after several sessions because they no longer had neuropathy-related complaints. Others needed ongoing care for neuropathy, especially those who continued on drug combinations that are highly likely to cause neuropathy.
- Lessons learned include a combination of Chinese medicine therapies that appears to have a high effect rate in decreasing symptoms in HIV+ people with the serious debilitating problem of peripheral neuropathy. With the apparent rate of clinical success in a large number of clients, a controlled pilot study is recommended as a follow-up to this chart review and collection of surveys.

Body Acupuncture in HIV-Related Pain Syndromes by Condition

- General pain: Liver 3, Large Intestine 4 (Four Gates)
- Abdominal pain: Ren 12, Stomach 25, Liver 5, Zigong, Ren 4, Ren 6
- Epigastric pain: Ren 14, Ren 12, Stomach 34, Spleen 4, Spleen 6
- Sinus pain: Bitong, Yintang, Large Intestine 4, Large Intestine 20, Gallbladder 20, Du 23, Urinary Bladder 2, Stomach 3
- Hand neuropathy: Large Intestine 4, Zhongwan, Bafeng, San Jiao 5
- Foot neuropathy: Liver 3, Stomach 41, Spleen 6, Baxie
- Muscle pain whole body: Spleen 21
- Liver/costal pain: Liver 14, Gallbladder 24, Liver 13, Japanese Mu Points
- Herpes Zoster/Shingles: Liver 2, Liver 5, Surround the Dragon in the local area

Body Acupuncture in HIV-Related Peripheral Neuropathy by CTM Syndromes

- Four Gates for Pain: Liver 3, Large Intestine 4
- Damp in the Channels: Spleen 6, Spleen 9
- Deficient Qi and Xue: Stomach 36, Spleen 6, Kidney 3, Spleen 4
- Stagnant Xue: Spleen 10, Large Intestine 11, Spleen 6
- Stagnant Cold: Ren 6, Kidney 7
- Heat and Damp Heat: Liver 2, Liver 5, Large Intestine 11

Body Acupuncture in HIV-Related Pain Syndromes

- Four Gates for Pain: Liver 3, Large Intestine 4
- Damp in the Channels: Spleen 6, Spleen 9

* Carla Wilson, Executive Director, Quan Yin Healing Arts Center, Poster Session, 12th International AIDS Conference, Geneva, 1998.

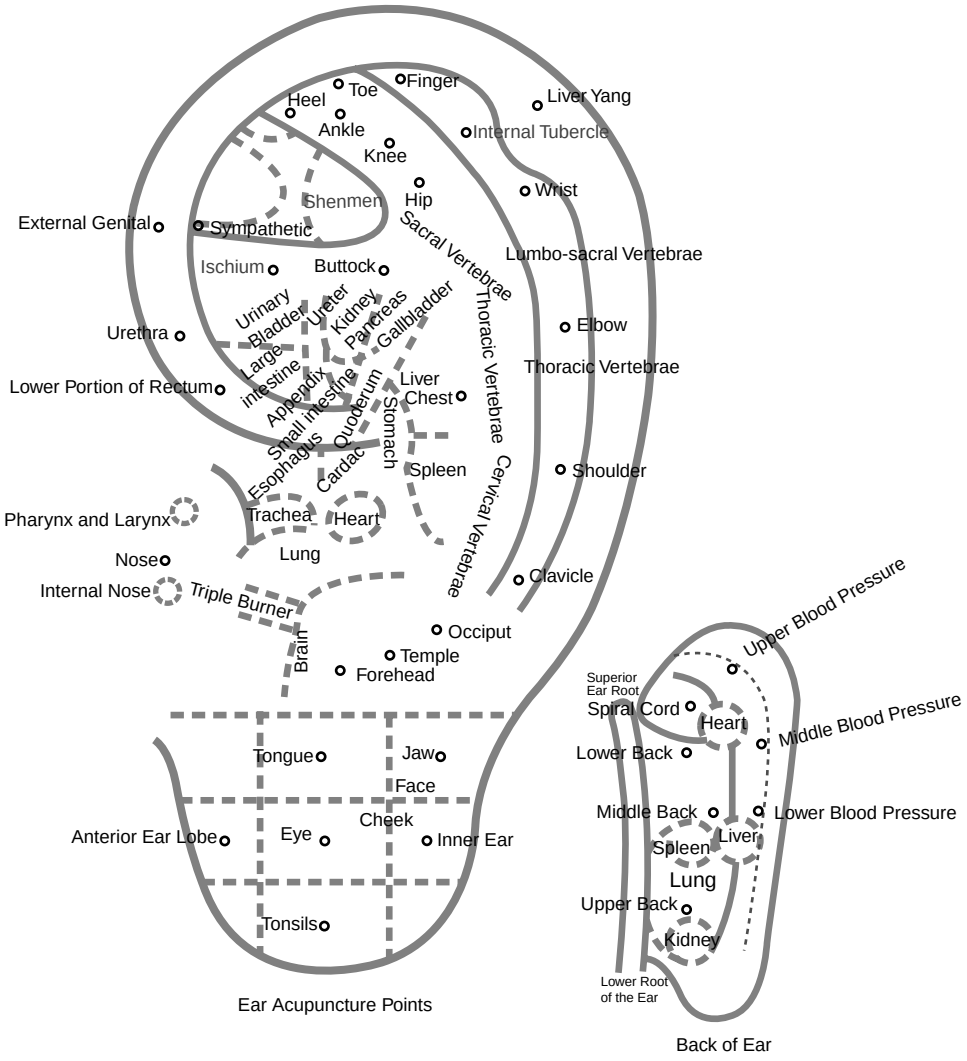

FIGURE 14.1 Ear acupuncture points. (From Cohen, M. (1996). The Chinese Way to Healing: Many Paths to Wholeness. New York: Perigree. With permission.)

- Deficient Qi and Xue: Stomach 36, Spleen 6, Kidney 3, Spleen 4
- Stagnant Xue: Spleen 10, Large Intestine 11, Spleen 6
- Stagnant Cold: Ren 6, Kidney 7
- Heat and Damp Heat: Liver 2, Liver 5, Large Intestine 11

Ear Acupuncture in HIV/AIDS-Related Pain Syndromes

- Overall pain: Ear-Shen-Men, Ear-Sympathetic, Ear-Brain
- Choice of other points according to the area in the ear associated with the organ or body part (Figure 14.1)

Moxibustion (Figure 14.2) can be used in the following ways:

- We can use it over areas of pain.
- We can use moxa on the same points as in acupuncture.
- For abdominal pain, we often use cones of moxa on salt and the herb aconite or ginger over the navel on the point Ren 8. For details, see The Chinese Way to Healing (Perigee, 1996) or The HIV Wellness Sourcebook (Henry Holt, 1998)
- Moxibustion is generally contraindicated with heat or damp heat syndromes, although there are exceptions such as abdominal cramping related to damp heat type of chronic diarrhea because there is always an underlying spleen deficiency (Figure 14.3)

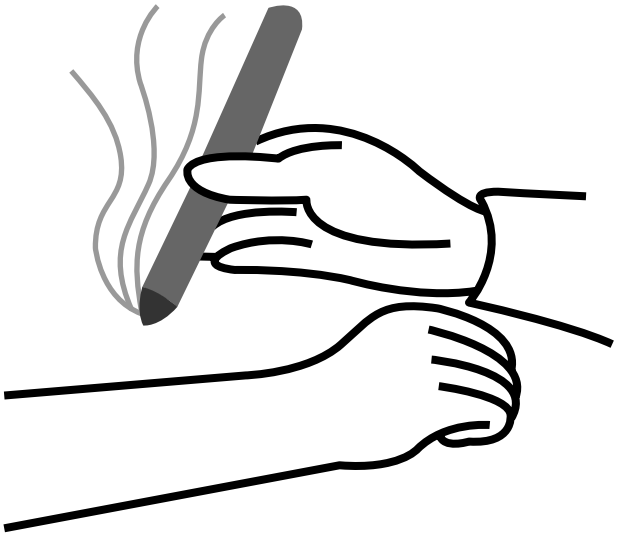

FIGURE 14.2 Moxibustion in HIV-related pain syndromes. (From Cohen, M. (1996). The Chinese Way to Healing: Many Paths to Wholeness. New York: Perigree. With permission.)

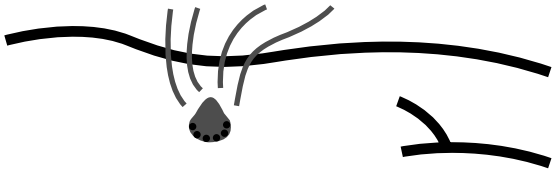

FIGURE 14.3 Abdominal treatment with navel. (From Cohen, M. (1996). The Chinese Way to Healing: Many Paths to Wholeness. New York: Perigree. With permission.)

CHINESE HERBAL MEDICINE FOR HIV/AIDS

The following formulas are examples that we use in the Chinese traditional medicine clinic on a regular basis for regulating the immune system and for differential diagnosis.

Immune Modulation

- Enhancement — tonifies Qi, Xue, Jing; strengthens Marrow and Spleen/Stomach/Kidney; clears Heat and toxins
- Tremella American Ginseng — tones Yin, Qi, Xue, Jing; strengthens Marrow and Spleen/Stomach; clears Heat and toxins
- Cordyseng — strengthens Qi, tones Yin and Yang, and strengthens the Spleen, Stomach, Kidney, and Lung

HERBS FOR PAIN SYNDROMES IN HIV/AIDS

Abdominal Pain

- Channel flow — Qi and Xue Stagnation with Cold
- Source Qi — for diarrhea accompanied by bloating and abdominal pain; used for the Chinese diagnosis of Spleen Qi and Yang Deficiency diarrhea with Cold

Herpes Zoster/Shingles

In this case we treat the underlying condition of Damp Heat or Liver Heat of Heat in the Xue (Blood) with formulas such as:

- Long Dan Xie Gan Tang
- Coptis Purge Fire
- Clear Heat

Peripheral Neuropathy

Cold: Mobility 3 with Channel Flow
Heat: Mobility 2 with Channel Flow
Damp in Channels: Shu Gan Wan
Damp Heat: Long Dan Xie Gan Tan or Coptis Purge Fire
Qi and Xue Stagnation with Cold: Channel Flow
Qi and Xue Deficiency: Eight Precious Pills

MASSAGE/ACUPRESSURE FOR HIV/AIDS PAIN

Ear Acupressure

- Stimulates the specific points that correspond to the areas of the body where there is pain
- Also uses Ear-Sympathetic and Ear-ShenMen

(See Figure 14.1)

Body Acupressure

- For upper back and shoulder problems — Pericardium 6, Small Intestine 11
- For tendons, muscle pain, and tightness — Gallbladder 34
- For pain in the head and abdomen — Large Intestine 4
- To relieve Liver Qi stagnation — Liver 3
- Chest and abdomen pain — Pericardium 6

PATIENT SELF-CARE TREATMENT FOR ACHES, PAINS, AND FIBROMYALGIA

Step One: Stretching Out

- With chronic pain, aerobic or weight-bearing exercise can be overstimulating or aggravating to sore joints and muscles. However, gentle Qi Gong exercises can dispel tension and help you relax.
- It may also help to do mild stretching exercises, head rolls, hamstring stretches, or perhaps the Yoga routine called Bow to the Sun that gently massages each part of the body.
- A mild full-body massage is also a terrific way to relax and extend tense muscles and joints, but be careful not to overstimulate or irritate the nerves and muscles. Avoid intense Shiatsu-style massage.
- If your diagnosis indicates Dampness, Cold, and Deficiency, massage with warming and stimulating oils infused with cinnamon essential oil.
- Meditation and the practice of mindfulness — being in the moment and quieting the mind — keeps the mind from amplifying or fixating on pain.

Step Two: Feel the Warmth

If you have not been diagnosed with a Heat disorder, and do not have a skin rash or fever, you may find hot herbal compresses are very soothing. They come premade at health supply stores and herbal outlets, but you can make them at home.

- Combine one cup fresh rosemary, thyme, and mint.
- Wrap in a double ply piece of cheesecloth. Secure the ends.
- Immerse the cheesecloth package in a pot of boiling water.
- Remove from water and wrap in thick towel.
- Place on your sore joints or muscles until the towel cools.

Step Three: Getting to the Point

Acupressure and moxibustion to ease pain can be done by your practitioner or at home. If you cannot reach these points yourself, use a partner to lend a hand.

Acupressure points follow:

- For upper back and shoulder problems — Pericardium 6; Small Intestine 11
- For tendons, muscle pain, and tightness — Gallbladder 34
- For pain in the head and abdomen — Large Intestine 4
- To relieve Liver Qi Stagnation — Liver 3

For ear acupuncture, stimulate the specific points that correspond to the areas of the body where there is pain. Also use Ear-Sympathetic and Ear-ShenMen. (See Figure 14.1.) Moxibustion can be applied on any area where there is pain without inflammation or redness.

ACUPUNCTURE GUIDE FOR PRACTITIONERS

For all pain, especially Stagnant Qi — Four Gates: Liver 3, Large Intestine 4
For pain related to Damp in the Channels — Spleen 6, Spleen 9
For pain related to deficient Qi and Xue — Stomach 36, Spleen 6, Kidney 3, Spleen 4
For pain related to stagnant Xue — Spleen 10, Large Intestine 11, Spleen 6
For pain related to stagnant Cold — Ren 6, Kidney 7
For pain related to Heat or Damp Heat — Liver 2, Liver 5, Large Intestine 11

MOXIBUSTION IN THE CLINIC AND FOR SELF-CARE

Moxibustion is especially good over areas of pain as well as appropriate points. Moxa on the same points as listed in the preceding acupuncture guide — unless diagnosis is Heat or Damp Heat. Then moxa is not recommended.

Mild Traumatic Brain Injury and Pain

Gary W. Jay, M.D., F.A.A.P.M., D.A.A.P.M.

There are a number of factors that must be considered when one clinically evaluates and treats a patient with a mild or minor traumatic brain injury (MTBI) and pain. The literature is rife with overbroad terminology that when dissected makes little sense. Words are used synonymously when they most probably should not be. Most specifically, in many papers, MTBI is felt to be the same as the postconcussive syndrome. When looking at the etiology of specific problems encountered by these patients, it appears to this author that "lumping," instead of looking more specifically at both nomenclature and what each term entails, and why is extremely important. Therefore, prior to looking at MTBI, specifically its pathophysiology and how that affects pain, we look at the postconcussion syndrome (PCS).

POSTCONCUSSION SYNDROME

The PCS appears to include multiple signs and symptoms consisting of neuropathological, neurophysiological, and neuropsychological as well as physical and psychological or emotional aspects secondary to MTBI (Binder, 1986).

The most common medical problems found in the patient with PCS (and MTBI) include

- Posttraumatic headache
- Posttraumatic musculoskeletal pain syndromes
- Vestibular disturbance
- Visual disturbance
- Fatigue
- Posttraumatic seizure disorder

The most common cognitive, emotional, and behavioral deficits include

- Memory impairment
- Lack of initiative
- Depression
- Problems finding work
- Irritability
- Decreased ability to concentrate
- Anxiety
- Poor impulse control
- Loss of self-esteem
- Slowed behavioral processing
- Job loss/disruption
- Behavioral/personality changes
- Denial
- Perseveration
- Difficulties with social interactions and family relationships

The PCS can be both chronic and disabling, or short lived and benign. A possible explanation for this may be the interaction between organic and psychological factors (Bohnen & Jolles, 1992). It is very difficult to differentiate between the effects of primary neurological, neurophysiological, and neuropathological injury and secondary psychosocial factors. It is thought by some that the typical PCS symptoms, including headache, dizziness, and irritability, result from emotional stress associated with diminished cognitive performance secondary to minor acquired traumatic brain injury (MATBI) (Bohnen, Twijnstra, & Jolles, 1992).

0-8493-0926-3/02/$0.00+$1.50

The influence of accident mechanisms associated with more severe symptoms was studied and it was found that patients with more severe deficits at the time of a motor vehicle accident had been an unprepared occupant, had been in a rear-end collision, with or without subsequent frontal impact; and had a rotated or inclined head position at the moment of impact (Sturzenegger, DiStefano, Radanov, & Schnidrig, 1994).

The postconcussional disorder (PCD) has been accepted into and is found in an appendix of the DSM-IV. A major criterion is loss of consciousness (Anderson, 1996), and it is believed that it would be better to use the Brain Injury Special Interest Group (BISIG) definition from the American Congress of Rehabilitation Medicine (Kay, et al., 1993). This definition states: A patient with mild traumatic brain injury is a person who has had a traumatically induced physiological disruption of brain function, as manifested by at least one of the following (Kay, et al., 1993):

1. Any period of loss of consciousness
2. Any loss of memory of events immediately before or after the accident
3. Any alteration in mental state at the time of the accident (e.g., feeling dazed, disoriented, or confused)
4. Focal neurological deficit(s) that may or may not be transient

The severity of the injury does not exceed:

1. Loss of consciousness of approximately 30 min or less
2. After 30 min, an initial Glasgow Coma Scale of 13 to 15 was found
3. Posttraumatic amnesia of not greater than 24 h

Note that the definition includes patients who experience direct head trauma as well as those who suffer an acceleration/deceleration injury (whiplash) without specific direct head trauma. Loss of consciousness is not a clinical requisite for a classification of MTBI. It is also noted that the symptoms of MTBI (or MATBI) may last varying lengths of time and can consist of persistent physical, emotional, cognitive, and behavioral symptoms that may produce a behavioral disability (Kay, et al., 1993). This is our operational definition of MTBI.

Many researchers have looked for a primary psychological/emotional etiology for the PCS (Karzmark, Hall, & Englander, 1995). Gasquoine (1997) felt that symptom persistence was associated with increased emotional distress. He does note that this fact is also true in patients with severe head injury as well as back injury, and that it relates more to the patient's interpretation of the effect of the trauma than to objective "indicators of brain injury severity."

Landy (1998) looked at the more objective symptoms of headache and cervical pain and found that 70% of patients "get better" within a few weeks post-MVA, whereas about 30% continued to complain of headaches and/or cervical pain. He felt that prolonged management and slow court settlement lead to extensive introspection by the patient and thus prolongation of symptoms. His results also repeat the long-held knowledge that patients with more severe head or neck injury have a lessor incidence of chronic posttraumatic headaches or cervical symptoms.

Barrett, Ward, Boughey, et al. (1994) compared two groups of PCS patients, one of which was hospitalized for observation following a brief loss of consciousness, while the others went to the emergency department, and then home. It was found during follow-up at 2 and 12 weeks that the type and frequency of complaints were similar in both groups. However, at 12 weeks, the number of complaints/symptoms was significantly less in the group of hospitalized patients.

Several groups noted that the PCS was more frequently found after blunt head trauma and other trauma, than would have been predicted (Chambers, Cohen, Hemminger, et al., 1996; Szymanski & Linn, 1992).

By using a questionnaire, Bohnen, Van Zutphen, Twijnstra, et al. (1994) evaluated the longevity of long-term PCS complaints. Their results indicated that MTBI might not, in a percentage of patients, ever resolve.

In an attempt to evaluate the importance of psychological factors in the outcome of whiplash injuries, Mayou and Bryant (1997) utilized interviews at 3 and 12 months postinjury. The majority of the patients in their study continued to complain of persistent cervical symptoms, whereas a "sizable minority" reported specific posttraumatic psychological symptoms, such as intrusive memories and phobic travel anxiety; and this was belived to be "similar to those described by patients suffering multiple injuries." They concluded that travel, social, and psychological morbidity were more prevalent than previously recognized. They did not deal with the issue of the recognized posttraumatic stress disorder (PTSD).

Cicerone and Kalmar (1997) urged clinicians to use a great deal of caution before attributing PCS symptoms or neuropsychological deficits to a preexisting affective disorder. Leininger, Gramling, Farrell, et al. (1990) looked into the idea that MTBI patients do not develop persistent neuropsychological deficits. They found that patients with the PCS/MTBI had measurable neuropsychological deficits and the severity of these deficits was independent of gross neurological status immediately postinjury.

Looking at symptomatic patients 2 years post-whiplash injury, DiStefano and Radanov (1995) evaluated complaints of memory and attentional difficulties with

neuropsychological testing. They found that memory problems were minimal, whereas problems in selective aspects of attentional functioning after whiplash were present, and these could explain the patients' cognitive complaints and induce adaptational problems in daily life.

An interesting study was performed by Parker and Rosenblum (1996) who looked at intelligence and personality difficulties after whiplash or MTBI in adults, an average of 20 months post-motor vehicle accident (MVA). They found a mean loss of 14 points of full-scale IQ from the estimated preinjury baseline (using WAIS-R) with no evidence of recovery. They also found a number of personality dysfunctions including organic or cerebral personality disorder. Of 33 patients, 30 had psychiatric diagnoses including PTSD, psychodynamic reactions to impairment, and persistent altered consciousness. They concluded that cognitive loss was induced by the interaction of brain injury with "distractions" including pain and emotional distress. This report also repeated the fact that the presence of MTBI after MVAs was probably consistently underestimated.

Although the PCS has been thought of as a reflection of the psychological response to injury, there is considerable evidence suggesting that the PCS is primarily a physiological disturbance (Szymanski & Linn, 1992). Reaction time testing, for example, has been used to support a structural, organic etiology for the PCS (Jacobson, Gaasedelen, Gaard, Thomsen, & Henriksen, 1987).

It has been found that cervical injury likely contributes to the symptomatology post-PCS/MTBI and vice versa (Barrett, Buxton, Redmond, et al., 1995). Testing has shown that cervical injuries secondary to whiplash can induce a distortion of the posture control system as a result of disorganized cervical proprioceptive activity (Gimse, Tjell, Bjorgen, & Saunte, 1996). Others note that restricted cervical movements and changes in the quality of proprioceptive information from the cervical spine region affect voluntary eye movements. Acceleration/deceleration (flexion/extension) injury to the neck secondary to whiplash may result in a dysfunction of the proprioceptive system. Oculomotor dysfunction after cervical trauma may therefore be related to disturbances in cervical afferent input (Heikkila & Wenngren, 1998). Patients who have sustained head or cervical trauma appear to exhibit an increased reliance on accurate visual input and are unable to utilize vestibular orienting information to resolve conflicting information from the visual and somatosensory systems (Rubin, Woolley, Dailey, & Goebel, 1995).

Soustiel, Hafner, Chistyakov, et al. (1995) evaluated 40 patients post-mild head trauma using brain stem trigeminal and brain stem auditory evoked potentials (BTEP, BAEP) and middle-latency auditory evoked potentials (MLAEP) within 48 h of injury and again at 3 months. They defined PCS as the presence of at least four of the following: failure to resume previous professional activity, memory deficits, headache, dizziness and vertigo, behavioral and emotional disturbances, and other neurological symptoms. Initially, all three evoked potentials were abnormal, showing prolonged latencies, indicative of disseminated axonal damage. Only the MLEAPs correlated to outcome at 3 months, particularly in its psychocognitive aspects, suggesting that organic diencephalic-paraventricular primary damage may account for the presence of the PCS.

Positron emission tomography (PET), single photon emission computed tomography (SPECT), and magnetic resonance imaging (MRI) studies have been done to attempt to correlate cerebral dysfunction to PCS symptoms. PET looks at glucose metabolism (in these studies), while SPECT looks at cerebral perfusion.

Six patients with PCS and 12 normal controls were tested. The patient group had significant hypometabolism and hypoperfusion in the bilateral parietooccipital regions, as compared with the controls. In some patients there was also hypometabolism found in other regions. It was hypothesized that parietooccipital hypometabolism can be caused by activation of nociceptive afferent nerves from the upper cervical spine (Otte, Ettlin, Nitzsche, et al., 1997).

Another study examined 13 patients with late whiplash syndrome, using PET and SPECT. The authors did not find hypometabolism in the parietotemporooccipital regions. They did find hypometabolism in the frontopolar and lateral temporal cortex and in the putamen. They did not recommend that PET or SPECT be used as a diagnostic tool for routine examination of patients with late whiplash syndrome (Bicik, Radonov, Schafer, et al., 1998).

SPECT was compared with MRI/computerized axial tomography (CAT) scans in 43 patients. The SPECT was found to be abnormal in 53% of patients, MRI was abnormal in 9%, and CAT scan was abnormal in 4.6% of patients post-MTBI/PCS. The SPECT scan appeared to be more sensitive to post-MTBI changes, especially in patients with the persistent PCS (see later) than MRI or CAT scan. No statistical relationships were found between the SPECT scan results and age, previous psychiatric history, history of substance abuse, history of multiple MTBI, or concurrent neuropsychological symptoms (Kant, Smith-Seemiller, Isaac, & Duffy, 1997).

"The truth is out there," but we do not seem to have determined the best method of identifying it. The tests noted earlier were given to patients with the PCS, by author statement. The relationship between the PCS and MTBI is discussed later, and the situation may not be that simple.

Nosologically, it is difficult to determine exactly what constitutes the PCS. Evans (1992) states that the PCS refers to the large number of signs and symptoms found alone or in combination following MATBI, including headache, memory problems, dizziness, fatigue, irritability, anxiety, insomnia, and sensitivity to light and sound.

He further indicates that studies have substantiated the existence of the PCS and that it is common, with resolution in 3 to 6 months, but with persistent symptoms and cognitive deficits persisting for months or years.

Headache, dizziness, and memory deficits are the most common combination of PCS symptoms (Young, 1985). There is no specific symptom complex found in the majority of patients with acute or chronic PCS (Alves & Jane, 1990). The multiplicity of signs and symptoms of the PCS have been well documented (Bohnen & Jolles, 1992; Brenner, Friedman, Merritt, & Denny-Brown, 1944; Brenner & Gillingham, 1974; Hoganson, Sachsy, Desai, & Whitman, 1984; Jones, 1974; Oddy, Humphrey, & Uttley, 1978; Rimel & Jane, 1985; Ritchie, 1974; Rutherford, Merrett, & McDonald, 1977; Symonds, 1965; Young, 1985).

One group has suggested that the PCS should include all the consequences of head injury, regardless of its severity and the nature of the injury (Rutherford, Merrett, & McDonald, 1978–1979).

Berrol (1992) states that the term mild traumatic brain injury (MTBI) is preferable, because it identifies the etiology of the injury, its degree, and the pathological substrate much better than other past terms: minor head injury, traumatic head syndrome, postconcussive syndrome, posttraumatic syndrome, postbrain-injury syndrome, and traumatic cephalgia.

The term postconcussive syndrome (PCS) continues to be frequently used in the literature. The important nosological question is whether the PCS is secondary to the MTBI, or the cognitive/neurological deficits found after MTBI are a separate entity.

The term PCS would then encompass the nonneurological, neurocognitive, and neurophysiological deficits, leaving PCS to be used specifically for the other organ (noncerebral) systems that display posttraumatic signs and symptoms.

Teleologically, it appears to make more sense to separate the etiologies of the problems encountered post-MATBI. A patient with physical findings such as posttraumatic headache may indeed, posttrauma, have a PCS. Patients with neurocognitive deficits and other neurological difficulties have direct evidence of an MTBI. The author believes it is more appropriate to differentiate between the two disorders. This would mean that a patient may indeed have an MTBI as well as a PCS. Both entities must be treated, and, as discussed later, the PCS should be treated first.

Soon after injury, patients have complaints referable to several different organ systems. Alexander (1995) identifies this as the PCS. He notes that the MTBI, which can lead to brain injury, can also cause injury to the head, neck (whiplash and soft tissue damage), vestibular system, and psychological functioning. The initial complaints of deficits in cognition and sleep disorder, Alexander believes, are secondary to neuronal injury, whereas the headache may be secondary to cervical injury, neuronal injury, or a combination; cervical pain secondary to soft tissue problems; dizziness secondary to peripheral vestibular dysfunction or cervical injury; and anxiety, moodiness, and irritability secondary to neurological injury, pain, and/or psychological factors.

The term PCS, in the author's opinion, should not include central nervous system (CNS) deficits. Vestibular dysfunction secondary to brain stem injury should be included in the MTBI, whereas peripheral dysfunction would be a part of the PCS. These differences are most important when planning and executing an appropriate treatment plan/paradigm. This appears to be more important when one encounters the difficulties obtaining insurance approval to treat an ailment (MATBI) that some insurers do not even believe exists.

To the extent plasticity allows, neuronal recovery is certainly taking place at 1 month after injury (Dikmen, McLean, Temkin, et al., 1986; Elson & Ward, 1994; Gentilini, Michelli, & Shoenhuber, 1985; McLean, Dikmen, Temkin, et al., 1984; Stuss, Stethem, Hugenholtz, et al., 1989). Neurological recovery is thought to be "substantial," by some, at 3 months (Levin, Mattis, Ruff, et al., 1987). At this point postinjury, 30 to 50% of patients have continued complaints (Dikemen, Temkin, & Armsden, 1989). Over the next 6 to 12 months (longer than a year postinjury) most patients show continued improvement and "recovery" (McFlynn, Montgomery, Feuton, & Rutherford, 1984).

It has been found that even "well-recovered" patients are still susceptible to periodic impairments secondary to physiological or psychological stress (Ewing, McCarthy, Gronwall, et al., 1980; Gronwall & Wrightson, 1974), which indicates that recovery is most likely the wrong term. That these patients have "compensated" for their injury may be more nearly correct. To say that patients may have a permanent sense of decreased mental or cognitive efficiency (Stuss, Ely, Hugenholtz, et al., 1985) would also be a function of incorrect terminology (i.e., recovered vs. compensated).

PERSISTENCE OF SYMPTOMS

At 1 year, 85 to 90% of patients are felt to be "recovered" but are still symptomatic (Rutherford et al., 1978–1979; McLean, Temkin, Dikmen, et al., 1983), leaving 10 to 15% of patients who are not only "not recovered" but also "not compensated" and still very symptomatic. The literature is replete with studies showing persistence of symptoms after the magic, if not mythical, 3-month period. This literature indicates the symptoms and deficits following MTBI and PCS may last for 6 to 12 months and even longer (Berrol, 1992; Boll & Barth, 1983; Jones, Viola, LaBan, et al., 1992; Katz & DeLuca, 1992; Leininger et

al., 1990; McSherry, 1989; Stuss, et al., 1985; Wrightson & Gronwall, 1989).

Much of the literature equates MTBI and PCS, essentially using the terminology interchangeably. The majority of the literature includes cognitive and other neurological deficits in the PCS. This statement is cautionary, as one must read the literature with great care to see what exactly is being done to exactly what problem or problems.

A survey of rehabilitation specialists who followed patients with MTBI for 6 to 18 months found that 21% of the patients experienced symptoms of the PCS 2 to 6 months after their initial injury, and that 20% of these patients had the "post-MTBI syndrome" (Harrington, Malec, Cicerone, & Katz, 1993). In another survey of 51 patients, where 23 responded, 25% of the respondents reported continued sequelae from their injury. The patients with sequelae after 1 year were found to have reported more symptoms 1 week after injury (Middelboe, Anderson, Birket-Smith, & Friss, 1992).

Cicerone (1992) indicated that there was considerable evidence to show that PCS symptoms persisted in a significant proportion of patients after MTBI, and such symptoms were particularly prevalent in patients who indicated that they needed clinical attention.

Symptoms with organic etiologies, it has been noted, can mimic functional disorders (Russell, 1974). Alves (1992) indicated that as recovery occurred, persistent symptoms could be secondary to an interaction between organic and psychosocial factors. These persistent symptoms are more than would be expected from the initial organic damage alone. Alves further stated that a significant percentage of patients would exhibit persistent problems with symptoms 12 months postinjury. He felt that recovery from MTBI should also be considered in the social context in which it occurred. By recognizing the complexity of the recovery process, we should extend the concept of morbidity to include the specific socioeconomic and emotional sequelae that the patient experienced.

Mateer (1992) found that patients post-MTBI were more acutely aware of their cognitive deficits and difficulties with functional abilities. These patients would go to a physician and be found to have a negative neurological examination. They would be told that there was no organic reason for their problems. They also would be told that they should wait longer for recovery, learn to live with their problems, or seek psychiatric help.

These iatrogenically induced problems (cause and effect) most likely lengthen the patients' symptomatic period, as they begin to feel an ever increasing loss of control, fear of the unknown, and concern that they must be "going crazy."

It doesn't matter what the medical problem is, particularly when, like most patients with MTBI, they look "normal." Physicians with little or no background in the diagnosis of MTBI or PCS, or consultants who are bought and paid for, do a great disservice to MTBI patients. Constant repetition by even well-meaning physicians of the mantra, "There is nothing wrong with you. You look fine. There's no problem here," demonstrably disrupt patients' sense of self, their life, and their feelings that there are indeed people (specifically doctors and insurance companies) "out to get them". This induces iatrogenic exacerbation of their symptoms, as the patients strive, consciously or unconsciously, to prove to someone that they do have a problem. Then, to add insult to injury, this iatrogenically induced problem is used against them both by other physicians and the legal "warriors" who are bound and determined, in the court case after a motor vehicle accident, to prove that there is nothing wrong with them, thus saving their insurance company clients money.

PERSISTENT POSTCONCUSSIVE SYNDROME

Alexander (1992, 1995) has written extensively about the persistent postconcussive syndrome (PPCS). These patients, after 1 year, continue to have symptoms commonly seen in acute PCS, such as headache, sleep disorder, balance problems, dizziness, sensory hyperesthesias, and cognitive symptoms including deficits in attention, memory, and executive functioning. They are also frequently noted to have prominent emotional symptoms including irritability, depression, nervousness, discouragement, and anger.

Alexander (1995) identifies some "predictors" of the development of PPCS, including the female sex, litigation, low socioeconomic status, prior MTBI, headache, and serious associated systemic injury. Although these factors may be implicated, he states that none accounts for more than a small percentage of cases of PPCS.

Other authors identify pain severity postinjury as a predictor of the development of the PPCS post-MTBI (Ettlin, Kischka, Reichmann, et al., 1993; Radanov, Di Stefano, Schnidrig, et al., 1991). Additional data suggests a greater frequency of anxiety and depression months after initial injury (Schoenhuber & Gentilini, 1988).

Dizziness is a frequent symptom of the PCS. It is noted that peripheral vestibular injury with dizziness also has a close relationship with psychiatric disorders, particularly with affective disease and anxiety. Unfortunately, the significant aspects of dizziness secondary to myofascial problems are often ignored. Zasler (1992) discusses cervicogenic dizziness. Dizziness secondary to myofascial trigger points in the sternocleidomastoid muscles is also frequently overlooked. In contradistinction, Alexander (1995) does not appear to anticipate the psychological aspects secondary to this problem, making it seem to be more of a primary psychological problem than one secondary to a true organic problem.

Chronic pain and headache are fairly universal accompaniments of the PPCS. It is also known that patients who experience chronic headache not associated with a PCS have many of the same complaints, including fatigue, sleep disorder, depression, and occasionally dizziness, as well as difficulties with concentration and memory. Psychological factors may aggravate these headaches.

It is recognized that anxiety may decrease concentration and complex mental processes (Binder, 1986; Krapnick & Horowitz, 1981). Depression can cause decreased cognitive functioning, particularly in concentration, memory and executive functions (Cicerone, 1992; Leininger & Kreutzer, 1992; Weingartner, Cohen, Murphy, et al., 1981). The latter problem has also been called "depressive pseudodementia" (Wells, 1979).

Therefore, one cannot assume that if everyone with a PCS/MTBI has impaired concentration, then everyone with impaired concentration after PCS/MTBI has a neurological etiology. The problem is that patients with PCS/MTBI associated with pain and affective difficulties may have impaired concentration for multiple reasons, including post-MTBI neuropathological changes.

Alexander (1995) asks the question: When does the physiogenesis of a clinical problem become psychogenesis? This may be difficult to determine and may have an iatrogenic component. Alexander does indicate that the major issue is physiogenesis transforming to psychogenesis, but he notes that physiogenesis can be very underestimated. He also indicates that there is no single psychological, physiological, or demographic factor leading to the PPCS.

Fenton (1996) attempted to reappraise the PCS. He reviewed data from two U.K. prospective studies of the initial aspects and course of postconcussive symptomatology using parallel psychosocial, neuropsychiatric, quantitative electroencephalogram (EEG or QEEG), and brain stem evoked potentials. Abnormal, prolonged brain stem evoked potentials were seen in between 27 and 46% of patients. Prolonged symptomatology was noted in 13% of patients and was associated with a high percentage of brain stem dysfunction. The degree of QEEG recovery is related to the intensity of early symptom reaction to trauma. Fenton believed that levels of perceived stress at the time of the injury or afterward were not related to symptom formation; however, chronic social difficulties were seen in 21% of patients who initially showed improvement but later, between 6 weeks and 6 months posttrauma, experienced an exacerbation of symptomatology.

Thus, are the PCS and MTBI absolutely two separate entities? I believe that the answer to this question is yes, with an important corollary. Because both problems begin together, after a motor vehicle accident, for instance, the presence of both problems affects each other. The physical problems found in the PCS are affected by the cognitive problems brought on by an MTBI. The affective/emotional problems found in MTBI would also affect the patient with physical problems from a PCS. However, acute and chronic pain engenders affective changes by their presence, on a neurochemical basis as well as secondary to sleep disorders (also a neurochemical problem) and learned behaviors from each patient's past.

This means that there is a lot to dissect or tease out in a patient with the PCS as well as an MTBI. Only by determining and differentiating between the physical/peripheral problems and those from the CNS resulting from an MTBI can a proper treatment plan be created and performed. For example, the author has found that it is best to treat depression and posttraumatic headache first, before endeavoring to treat the MTBI. The patient outcomes, over two decades, appear far superior to those seen when one tries to treat everything at once. Knowing a bit about what happens in the CNS to patients with a MTBI is also important, particularly when attempting to treat these patients.

MINOR TRAUMATIC BRAIN INJURY

Because we are dealing in this chapter with MTBI — the effects of direct trauma-induced focal lesions — contusions, hematomas, edema, hydrocephalus, and so on — are not covered. For those who are interested, they have been well described by Jay (2000).

Diffuse injury to the brain is seen with MTBI and is dealt with here, along with the neurochemical pathophysiology, which is of equal or possibly more importance in the entity called MTBI.

The two categories of diffuse injury important to this discussion are mild concussion and "classical" cerebral concussions (Jay, 2000).

Mild Concussion

- There is no loss of consciousness, but transient neurological disturbance may be seen.
- The patient may be confused, disoriented, and may or may not have amnesia.
- Posttraumatic headache is frequently seen.

"Classical" Cerebral Concussion

- The patient may show temporary, reversible neurological deficits secondary to trauma, associated with a brief loss of consciousness (less than 1 h) with some degree of posttraumatic amnesia.
- A mild or moderate degree of microscopic neuronal abnormalities can be found.

- There may be an associated focal brain injury (contusion).
- Posttraumatic headache, tinnitus, and subtle changes in memory or psychological functioning may be seen.

Caveats— Very Important

- Physiological and (neuro) psychological dysfunction may occur in the absence of anatomic (macroscopic) lesions.
- Functional disruption, which precedes anatomic disruption, is always the greater.
- Clinically, patients with mild concussion syndromes and "classical" cerebral concussion may have physiological dysfunction as well as microscopic anatomic disruptions that may be in contradistinction to the apparent severity of the injury.
- Traumatic brain injury (TBI) deficits are additive.

The neuropathology of TBI is, as with most aspects of the disorder, replete with knowns, unknowns, and variables. Research has established many of the basic facts, but the exact how, when, why, and where are still subject to debate.

Clinical practice indicates that a CAT scan should be performed on patients post-TBI. However, as noted earlier, the timing of the test is important. It is important to repeat a CAT scan on a patient who begins to decompensate neurologically. An acute subdural hematoma or subarachnoid hemorrhage may occur in patients with normal Glasgow Coma Scale (GCS) scores (GCS = 15) typically within 24 h. Other authors believe that when the first CAT scan is performed within 3 h of injury, another should be done within 12 h (Servadei, Nanni, Nasi, et al., 1995).

Quantitative MRI analyses have shown significant differences in TBI patients with unimodal gray matter–white matter histograms, as compared with normals, who demonstrate bimodal gray matter–white matter histograms (Thatcher, Camacho, Salazar, et al., 1997). The MRI is also better than the CAT scan at determining other postinjury pathology including diffuse axonal injury (DAI) and glial scarring. The MRI scan is also useful in morphometric analysis of the brain, showing diffuse neuronal degeneration after TBI with more severe injury. This may include larger ventricle to brain ratios and temporal horn volumes, which may relate to neuropsychological outcome (Gale, Johnson, Bigler, & Blatter, 1995).

DAI is one of the most prevalent and well-acknowledged primary and secondary postinjury pathophysiological phenomenon. The brain tissue, or parenchyma, can be severely injured secondary to axonal shearing forces during acceleration/deceleration and rotational injuries in a closed head injury. The most common locations of DAI include cerebral hemispheric gray–white matter interfaces and subcortical white matter, the body and the splenium of the corpus collosum, the basal ganglia, dorsolateral aspects of the brain stem, and the cerebellum. MRI technology is continually evolving. Nonhemorrhagic lesions can be seen via MRI using fluid attenuated inversion recovery (FLAIR) techniques, proton-density, and T2 weighted images. Old hemorrhagic lesions are best seen with the use of gradient echo sequences (Parizel, Ozsarla, Van Goethem, et al., 1998).

A good tool utilized in the investigation of DAI is beta-amyloid precursor protein (beta-APP). In one series, DAI was seen in 65 to 100% of all cases of closed head injury, fatal cerebral ischemia/hypoxia, and brain death with a survival time of greater than 3 h. Cases with a posttraumatic interval of less than 180 min did not express beta-APP (Oehmichen, Meissner, Schmidt, et al., 1998). The extent and severity of DAI cannot be predicted from biomechanical data alone, such as the height of a fall; total axonal injury in a given patient is a variable mixture of DAI and focal axonal injury from secondary mechanisms. Beta-APP immuno-staining is not able to distinguish between primary and secondary axonal injury (Abou-Hamden, Blumbergs, Scott, et al., 1997). Still another study found beta-APP immunostaining demonstrations of positive axonal swelling 1.75 h postinjury in both mild and severe TBI groups, and demonstrated a spectrum of axonal injury in TBI. The study found that axons were more vulnerable than blood vessels and those axons in the corpus callosum and fornices were the most vulnerable of all (Blumbergs, Scott, Manavis, et al., 1995).

Findings from another study express that neurofilamentous disruption is a pivotal event in axonal injury. The authors studied the progression of TBI-induced axonal change at the ultrastructural level using two antibodies (NR4, to target light neurofilament subunits, and SMI32, to target the heavy neurofilament subunit). Changes noted at 6 h postinjury entailed focally enlarged immunoreactive axons with axolemmal infolding or disordered neurofilaments. By 12 h, some axons showed continued neurofilamentous misalignment, pronounced immunoreactivity, vacuolization, and —on occasion —disconnection. Between 30 and 60 h, further accumulations of neurofilaments and organelles induced further expansion of the axis cylinder and disconnected reactive swellings were recognized. During later times, focally enlarged disconnected axons were observed in relation to axons showing less advanced reactive changes (Christman, Grady, Walker, et al., 1994).

Axonal injury including DAI was noted by several authors in the brains of patients who were victims of blunt head trauma/assault (Crooks, Scholtz, Vowles, et al., 1992; Imajo, 1996; Ramsay & Shkrum, 1995).

Other studies reinforce the fact that neuronal loss after head injury is secondary to both primary and secondary mechanisms. One study also found that microglial activation was a delayed result of TBI (Engel, Wehner, & Meyermann, 1996). Another study that evaluated Purkinje cell vulnerability in mild TBI, found that there was a close anatomic association between activated microglial cells and Purkinje cells, which suggests that Purkinje cell injury is the cause of microglial cell activation (Fukuda, Aihara, Sagar, et al., 1996).

Povlishock's (1992) and Povlishock and Jenkins' (1995) work comes to some of the same conclusions but by a different road. They believe that the TBI itself does not cause axonal disruption. Instead, focal, subtle axonal changes that occur over time lead to impaired axoplasmic transport, continued axonal swelling, and finally disconnection. Povlishock attributes the trauma to altering the axolemmal permeability, direct cytoskeletal damage or disruption, or more overt metabolic and functional disturbances. Trauma may induce axonal change, Wallerian degeneration, and finally deafferentation. Povlishock also thinks that traumatically induced DIA leads to diffuse deafferentation and notes that posttraumatically, the cerebral parenchyma is involved with increased neuronal sensitivity to secondary ischemia. Furthermore, he believes that this increased sensitivity is secondary to the neurotransmitter storm that follows a TBI, which can induce sublethal neuroexcitation. Most importantly, Povlishock (1992) and Povlishock and Jenkins (1995) indicate that the damage noted does not take place immediately posttrauma, but takes place over days or even weeks.

NEUROCHEMICAL ASPECTS OF TRAUMATIC BRAIN INJURY

Abnormal agonist–receptor interactions related to excitotoxic processes may contribute to the pathophysiology of TBI. Activation of the muscarinic cholinergic or N-methyl-D-aspartate (NMDA) glutamate receptors appear to contribute to TBI pathophysiology.

TBI-induced membrane depolarization causes a massive release of excitatory neurotransmitters, particularly acetylcholine (ACH) and glutamate. The posttraumatic overproduction/release of these chemicals may induce abnormal activation of receptors that can produce changes in intracellular signal transduction pathways and thereby induce short-term, long-lasting, or irreversible changes in cell function. Such deficits can occur with sublethal cell disruption or cell death.

Experimental TBI is known to produce widespread neuronal depolarization, which is demonstrated by large increases in extracellular potassium (K+) resulting from neuronal discharges and not neurotransmitter release. Increased neurotransmitter release is recruited to increase depolarization as injury severity increases. The release of these excitatory amino acids (EAAs) significantly contributes to the high levels of K+ release following TBI.

After moderate and most probably mild TBI, tissue deformation may open ion channels resulting in an influx of K+ large enough to induce abnormal levels of excitatory neurotransmitter release and therefore further depolarization.

Mild–moderate TBI induces increases in glutamate and ACH. Increased ACH release and increased cholinergic neuronal activity in some regions of the brain (such as the hippocampus) may persist for hours or longer after injury.

Posttraumatic changes in the blood–brain barrier (BBB) may also contribute to posttraumatic receptor dysfunction by allowing the abnormal passage of blood-borne excitatory exogenous neurotransmitters and neuromodulators into the brain. These additional excitatory neurochemicals may act synergistically with endogenously increased excitatory neurotransmitters (ENTs). Moderate experimental TBI without contusion in the rat leads to acute BBB dysfunction in the hippocampus and the cortex that may last more than 12 h. Other research suggests that dysfunction of the BBB secondary to TBI may allow blood plasma constituents such as ACH (at levels 7 times greater than in the cerebral spinal fluid [CSF]) to gain access to the brain and influence injury processes.

Moderate TBI can induce significant reductions in muscarinic cholinergic receptor binding. Decreased binding by glutaminergic receptors, specifically the NMDA receptors, also occurs following moderate TBI.

The predominant changes seen only in the NMDA receptors suggest that the ENT agonist–receptor interaction secondary to moderate TBI occurs predominately at this receptor subtype. This is supported by the protection given by administration of NMDA antagonists.

Reduced motor and memory deficits can be seen with pharmacological antagonism of NMDA receptors using phencyclidine, MK-801, dextrorphan, and others. This appears to be secondary to their ability to restore Mg^{2+} (magnesium) levels postinjury.

Receptor activation by ENTs may contribute to cellular metabolic alterations after TBI. Further results indicate that EAA neurotransmitters may be involved in injury-induced disruption of ionic homeostasis and ion-induced cytotoxic cerebral edema.

TBI produces widespread neuronal excitation causing prolonged, usually sublethal, pathological changes in neuronal activity that disrupt many functions, including memory. Inhibitory neurotransmitters such as gamma-aminobutyric acid (GABA) and the opiods may also be released with TBI to try to decrease the excitatory state.

Oxygen free radicals (OFRs) may also be important mediators of TBI and cerebral edema. Sources for oxygen

free radicals include catecholamines, amine oxidases, and peroxidases among others. Pharmacological agents being considered to decrease OFR damage include vitamin E, dimethyl sulfoxide (DMSO), and lipid peroxidation inhibitors (lazaroids).

Some conclusions that can be drawn follow.

- Excitotoxic phenomena may render neurons dysfunctional but not necessarily kill them (although that also occurs).
- TBI results in widespread depolarization and nonspecific release of many excitatory and inhibitory neurotransmitters.
- Significant changes in the BBB are found that may last for hours or more.
- The resultant sublethal toxicity appears to be mediated via increases in intracellular calcium levels.
- These processes, including DAI, may begin at the time of an accident, but take days or even weeks until they end.
- There are three subtypes of glutamate receptors: NMDA, quisqualate, and kainate.
- The NMDA receptors may protect against TBI secondary to trauma and cerebral ischemia.
- Cholinergic systems have roles in mediation of TBI and neuronal recovery, including behavioral suppression. Long-term motor deficits may be decreased by the ACH medications blocking release of excitotoxins.
- Catecholamines (especially norepinephrine) appear to help in TBI recovery.
- Alpha-noradrenergic agonists and probably dopaminergic agonists accelerated motor recovery after experimental injury to the sensorimotor cortex. Their antagonists retarded recovery.
- Early postinjury use of benzodiazipines may slow neural recovery and possible restoration of neural recovery.
- Most likely, "therapeutic cocktails" of more than one agent are necessary for appropriate treatment of TBI.

BIOGENIC AMINES AND THE ENDOGENOUS OPIATE SYSTEM

Acute traumatic injury of any type engenders the production of beta-endorphin (BE) as well as other endogenous opiates. One group looked at BE levels in the blood after trauma and found, to little surprise, that there was no correlation between serum BE and pain severity (Bernstein, Garzone, Rudy, et al., 1995). When looking at CSF BE levels, it was found that significant changes in CSF BE levels are found in patients with the full range of TBI, mild to severe. Interestingly, the patients with mild TBI had significantly higher levels of BE than those patients with severe head trauma. The BE levels did not correlate with early prognosis (Pasaoglu, Inci Karakucuk, Kurtsoy, & Pasaoglu, 1996).

Another group of patients had lumbar punctures done on days 1, 4, and 7, head following injury; and the levels of leucine or leu-enkephalin (LENK) and methianine or met-enkephalin (MENK) were determined in the CSF. It was found that MENK levels were constantly elevated, whereas LENK levels decreased in patients with GCS scores of 8 or less, and might provide a poor prognostic factor. It was indicated that LENK and MENK appeared to be linked to different pathophysiological functions (Stachura, Kowalski, Obuchowicz, et al., 1997).

Although endogenous opiates are found in the human gut, BE is produced in the hypothalamus. It is broken down to the smaller forms of endogenous opiates, LENK and MENK. It would therefore be more likely to be found in the CSF, along with enkephalins and dynorphins, which together help mediate the central perception of pain.

Primary metabolites of norepinephrine (methoxyhydroxyphenylglycol [MHPG]), serotonin (5-hydroxyindole-acetic acid [5HIAA]) and dopamine (homovanillic acid [HVA]) were assayed in CSF taken from comatose patients after severe head injury. Samples were taken within days of the injury and again after clinical improvement (13/20 patients) or deterioration (7/20 patients) was seen. Clinical improvement was associated with significant decreases in HVA and 5HIAA. The levels of all three metabolites remained high in patients who deteriorated. These results appeared to indicate that increased turnover of CNS neurotransmitters in severe head injury normalized during recovery (Markianos, Seretis, Kotsou, & Christopoulous, 1996).

In another study, CSF levels of serotonin (5-HT), substance P (SP), and lipid peroxidation (LPx) products were measured in patients with TBI and compared with controls. The levels of SP and 5-HT in patients with head trauma were lower than those found in controls. The CSF LPx products were significantly increased in the TBI patients. There was no correlation between the CSF levels and the GCS at admission (Karakucuk, Pasaoglu, Pasaoglu, & Oktem, 1997).

The loss or decrement of cholinergic neurotransmission has been implicated in both cognitive dysfunction and memory impairment after TBI. One group looked at presynaptic markers related to cholinergic neurotransmission via choline acetyltransferase activity as well as high-affinity nicotinic receptor binding sites in the inferior temporal gyrus, cingulate gyrus, and superior parietal cortex in postmortem brains. They found that the correlation of choline acetyltransferase activity with synaptophysin immunoreactivity revealed a deficit of cholinergic presyn-

aptic terminals in postmortem human brain after TBI (Murdoch, Perry, Court, et al., 1998).

An inverse relationship between plasma norepinephrine and thyroid hormones is found in patients with hyper- or hypothyroidism or severe stress. Head injured patients were found to have low thyroxine (T4), low triiodothyronine (T3), and high reverse T3. When phenytoin was used for seizure control, T3 and T4 were lowered, but thyroid-stimulating hormone was increased. In these patients there was no correlation between NE and T3 (Ziegler, Morrissey, & Marshall, 1990).

A great deal of evidence indicates that dopamine neurotransmission dysfunction after mild to moderate TBI is involved in the induction of posttraumatic memory deficits. By using anesthetized animals that were given MTBIs, it was found that mice were impaired in task performance. They had prolonged latencies for finding and drinking in a retention test and retest. If these animals were injected with haloperidol 15 min posttrauma, they had a shortened latency in both of the tests, which appeared to show that the use of dopamine receptor antagonists was beneficial for recovery of posttraumatic memory dysfunction. For looking closer at the receptor sites, researchers used a D1 receptor antagonist, SCH-23390, and sulpiride, a D2 receptor antagonist, in the same experimental protocol. The use of sulpiride, but not SCH-23390, improved the deficits in task performance, indicating that the D2 receptors were the major site of action. A positive interaction was noted when both D1 and D2 receptor antagonists were given together at individually subtherapeutic levels, indicating that interaction between the two receptors was involved. The dopaminergic mechanisms do appear to contribute to memory dysfunction after TBI (Tang, Node, & Nabeshima, 1997).

MINOR TRAUMATIC BRAIN INJURY AND PAIN: SOME CONCLUSIONS

The various pathophysiological aspects of MTBI and pain therefore appear to encompass several important etiologies:

- At the time of trauma, there may typically be soft tissue injuries, at a minimum. Those patients who experience significant TBI may need to be sedated, and even paralyzed; and therefore may have their perception of pain dealt with on a secondary basis.
- Moderate to severe TBI may make the patient unable to cognitively deal with pain.
- Patients with MTBI may be so overcome with pain immediately postinjury that cognitive changes and problems may not be either relevant or even looked for at that time.
- There are significant neurochemical and neurophysiological abnormalities that occur in MTBI and affect some of the same neurotransmitter systems needed by the nociceptive and antinociceptive systems; these abnormalities can lead to perturbations in the experience, perception, and appropriate recognition of pain and/or pain relief.
- The affective/emotional changes that accompany both chronic pain and MTBI are subserved by the same neurochemical systems, many of which are affected by pain as well as, pathophysiologically, trauma (from both primary and secondary effects).
- The MTBI patient with pain must therefore be dealt with on multiple levels: the soft tissue/musculoskeletal pain problems from the injury; the neuropathological changes, secondary to DAI, excitotoxic cell injury, BBB changes, and the effects of possible neurotransmitter system damage secondary to these factors; and the neurotransmitter system changes that are known to accompany chronic pain, which may be exacerbated or changed secondary to the CNS effects of the MTBI. These factors make treatment more challenging, because medication management, for example, may be more difficult as well as different when looking at a patient with only chronic benign pain.

The pathophysiological changes that occur after an MTBI may last for days or weeks. The resultant deficits may therefore not become manifested for more weeks or months. This leads to an important consideration. What if the patient complains of cognitive or emotional problems within days or several weeks of the initial insult? First, is the patient experiencing all the problems that are going to arise from the injury, or only those that have been detected at that time? Second, can you see a good reason for considering serial neurological examinations?

Somehow it has become an "urban medical legend" that all patients with an MTBI will miraculously be healed within 3 months. This may be true for a simple majority of patients who are not experiencing a significant MTBI. However, as documented earlier, anywhere from 5 to 20% of these patients do not get "all better" in 3, 6, or even 12 months.

As clinicians take the patient's history of cognitive problems, they may also find frequent complaints of posttraumatic myofascial or soft tissue pain problems, including posttraumatic headache, cervical pain, and low back pain, as well as sleep disorder.

If the patient who complains of pain is seen soon after the injury, physical therapy may be all that is needed to stop these problems before the onset of chronicity, with

its attendant affective and neurochemical alterations. The use of narcotic analgesics should be strongly discouraged, because they may further enhance cognitive difficulties. If after 6 to 12 weeks there is no significant diminution of the pain and/or headache, along with depression, consideration of a specialty pain program should be given, as long as the pain practitioner understands the effects of TBI on pain.

There is an interesting dichotomy in the majority of patients with pain and MTBI. Patients in an interdisciplinary pain program are typically taught to rate their pain, on a momentary basis on a 0 (no pain) to 10 or 100 scale. When they begin treatment, the numbers are typically high and correspond with physical findings of muscle spasm, trigger points, and loss of specific function such as decreased range of motion or weakness. As treatment progresses, typically during 4 to 6 weeks, the patients' pain complaints may not change. That is, their identification of their pain level (such as 7 over 10) may not change or change only minimally, whereas functional evaluation reveals a return to a normal range of motion, for example, or absent palpable muscle spasm or trigger points.

It is extremely important to realize that this dichotomy is not a manifestation of malingering, but appears to be more of a learned or even perseverative response. On observation, pain behaviors are diminished and the patients' affect is improved, but they may still claim to endure what appears to be an artificially high pain level. Evaluation must be functional in nature, not subjective.

Even more importantly, in the presence of severe pain, a neuropsychological evaluation or cognitive evaluation is not accurate and should not be performed. This means, MTBI patients with pain should have their pain ameliorated and their depression lifted as much as possible prior to any formal cognitive evaluation and/or treatment

The PCSs as well as the PPCSs are not symptoms or syndromes looking for patients. As indicated earlier, the author believes that the PCS is different from an MTBI. Still, patients from around the country, around the globe, complain of the same symptoms after an acceleration/deceleration injury. There are tests and many studies that show the presence of abnormalities. Again, we do not yet seem to know the best tests, the best window to perform them, or the best way to interpret them.

As clinicians, we also know that we have to listen to our patients. If something they say does not make sense, it is the clinician's medical responsibility to actively investigate what the patient is trying to say.

To be antagonistic to a diagnosis, to not accept the presence of a diagnosis because of preconceived notions or initial thoughts of patient malingering or because your opinion depends on who pays you, puts us back into the era of the Inquisition. That is not our job; "to do no harm" is our responsibility.

Trauma and Soft Tissue Injuries: Clinic and Courtroom

Thomas J. Romano, M.D., Ph.D., F.A.C.P., F.A.C.R.

Astute clinicians have long known that physical trauma, sometimes seemingly trivial, can result in medical conditions characterized by persistent pain (Ashburn & Fine, 1989; Romano, 1990), fatigue (Romano, 1990), frustration, and psychological distress (Aaron, et al., 1997). It is certainly true that most patients who have sustained injuries from motor vehicle accidents, physical assaults, and falls recover fully. At the other end of the spectrum, some individuals die of their traumatically induced injuries. Typically, the clinicians who specialize in pain management do not have the opportunity to treat patients who fall into any of the preceding two categories. It is our responsibility to treat those patients who have neither died as a result of their injuries nor fully recovered. Our patient populations tend not to be composed of cross sections of society but by their very nature are skewed. We treat the patients who have not recovered and probably will not fully recover. Most have already been treated by emergency room physicians, primary care doctors, physical therapists, and other healthcare providers with less than satisfactory results. Our patients complain of chronic pain, headaches, fatigue, and neurological problems, and are often frustrated and angry. This is understandable because many have been injured in either an accident or a physical assault and are often involved in litigation at some level. Although it has been known for many years that numerous individuals suffer persistent pain following trauma (Ashburn & Fine, 1989; Romano, 1990), it is the purpose of this chapter to explain why.

Why do some patients involved in whiplash motor vehicle accident recover fully, while others do not? Why do some patients develop chronic posttraumatic headaches whereas others involved in similar traumas do not? Why do some patients develop fibromyalgia after traumatic events and others do not? The list goes on and on.

Although the answers to these questions will probably never be totally forthcoming, it is useful to think of the problem in the following way. We human beings are highly complex biological systems. We are certainly no less complex than bacteria, goldfish, or zebras. Thus, principles of biodiversity certainly should apply to how each of our individual complex biological systems (i.e., our own bodies) reacts to certain physical stressors such as physical trauma.

I often visit the American Museum of Natural History in New York City. Several years ago a new exhibit hall, the "Hall of Biodiversity," was dedicated. It celebrates the amazing and wondrous variety of plant and animal life on this planet. Not only interspecies variability but also intraspecies diversity is described and catalogued. Certainly all zebras are not exactly the same; neither are all salamanders nor all butterflies. Each individual within a species has its own unique physical and behavioral characteristics, but, of course, there are many characteristics it shares with the remainder of the members of its species.

Dr. Stephen Jay Gould — a frequent contributor to *Natural History Magazine* (a publication of the American Museum of Natural History) and a famed geologist and biologist as well as a prolific author — celebrates biodiversity in his work *Full House* (Gould, 1996). He makes a claim with which I heartily agree. He maintains that if one wishes to describe a complex biological system using

0-8493-0926-3/02/$0.00+$1.50

measures of central tendency such as averages or means, he or she will be wrong. It is interesting to me that he uses the word *will* as opposed to *might*.

We are all distinct individuals. A mere average cannot describe our experiences or predict our future behavior. However, is that not exactly what insurance companies, managed care organizations, and even some members of the legal profession wish for us to do? How often have a patient's medical benefits following an injury been terminated because the insurance adjustor or the physician working for the insurance company has determined that the patient should have recovered?

Although it may be true that most patients with soft tissue injuries totally recover within 4 to 6 weeks, it is unscientific and, dare I say, dishonest to maintain that all soft tissue injury patients do so. Is it then fair to expect that every patient must recover in 4 to 6 weeks or in some other arbitrary length of time and that benefits will be cut off at the end of that predetermined time period regardless of whether the patient and the treating physician maintain otherwise? How frustrating it must be for the clinician and the patient to be told that the injury in question should have healed within a certain period of time, yet knowing that there is still much more to be done to get the patient back on his or her feet. Is the doctor incompetent? Is the patient malingering? Why has the patient not recovered within the specified interval of time? This chapter seeks to answer such questions and perhaps to outline a strategy for the clinician to practice to the best of his or her ability without interference and for the patient to receive whatever damages he or she is entitled to as a result of someone else's negligence.

CERVICAL SPRAIN: AND BEYOND

The scenario of a patient complaining of intense neck pain after a trauma, such as a motor vehicle accident, despite a normal cervical spine X-ray is a common occurrence in our society. What is causing the pain? There is no fracture; the speed of the respective motor vehicles was not great; the physical damage to the vehicles was negligible. Why is the patient still in pain? The answers to these questions probably lie in the ability to more fully appreciate the mechanisms of cervical injuries and the potential for such injuries to evolve into a chronic pain state that for far too long may have been underestimated.

For example, it might seem logical that the greater the impact of two vehicles in a collision and/or the greater the property damage sustained by these vehicles, the more serious and intense is the chronic pain suffered by those injured. However, the conventional wisdom identified by the previous statement seems to be incorrect. A study by Croft (1996) showed that there was no scientifically or empirically sound basis for judging injury potential from the speed of the involved vehicles or from vehicle property damage. This actually does make sense if one remembers there is a large degree of biological variability among accident victims (Radanov & Sturzenegger, 1996). This could help explain why some high-speed impacts may leave some drivers relatively unscathed, whereas some low-impact collisions can be devastating to others.

What about the cervical spine X-ray? The cervical spine X-ray typically taken in the emergency room to rule out a fracture/dislocation of the cervical vertebral bodies probably is not a good predictor of how much chronic pain the patient will have months, and even years, after a particular trauma. One must remember that the emergency room physician is worried about acute spinal cord transection, acute cervical fractures, etc. Having worked in many emergency rooms including Bellevue Hospital in New York City and St. Louis City Hospital, I can assure you that the emergency room doctor's duty is not to concern himself or herself with chronic conditions. The duty is to keep the patient alive, diagnose any acute injuries, and refer to the appropriate follow-up physician.

An Australian study (Taylor & Taylor, 1996) revealed that even though cervical spine X-rays had been read as normal, there was a great deal of damage done to cervical spine structures. Of the 109 cases, 102 or 94% had injuries more often to the intervertebral joints than to the vertebrae. Spinal cord injuries were seen in 25% of cases, and nerve root injuries in 14 to 33% of cases. This is consistent with the findings of an earlier study (Jonssan, Bring, Rauschning, & Sahlstedt, 1991). Is it any wonder that a patient with an occult cervical spine fracture without dislocation would be in intense pain and perhaps not be given sufficient medication … or sufficient respect? After all, the cervical spine X-ray was normal. Would such a sequence of events not make the ground fertile for the development of such chrohnic problems as dizziness (Malison, Longridge, & Peacok, 1996), headache (Lord & Bogduk, 1996), widespread musculoskeletal pain, or even fibromyalgia (Buskila, 1997a)?

Persistent symptoms after whiplash injuries have been the subject of several review articles (Curtis, Spanos, & Reid, 1995; Havsy, 1994a; Havsy, 1994b) and books (Foreman & Croft, 1988; Swerdlow, 1998; Tollison & Satterthwaite, 1992). Various factors have been demonstrated to influence long-term outcome. A statistically significant positive correlation has been shown to exist between poor prognosis (i.e., chronic pain and impairment) and the following findings shortly after the trauma: numbness and/or pain in either arm, sharp reversal of the cervical lordosis as demonstrated on cervical spine X-ray, need for a cervical collar for more than 12 weeks, need for home traction, or need to resume physical therapy more than once because of a recurrence of symptoms (Hohl, 1974). This early study also showed that recovery occurred in only 57% of patients after 5 to 6 years. Degenerative changes developed after the injury in 39%.

A later study (Gargon & Bannister, 1990) with a longer follow-up period (mean 10.8 years) revealed that only 12% of patients who had sustained soft tissue injuries of the neck recovered completely. The authors reported that residual symptoms were "intrusive" in 28% and "severe" in 12%. They further noted that after 2 years from the date of the trauma, symptoms did not tend to alter with the further passage of time. Persistent symptoms posttrauma are not limited to neck pain, stiffness, headaches, etc. Cognitive deficits have been noted in patients with cervical spine injuries (Radanov, Dvorak, & Valach, 1992). These included dizziness, poor concentration, irritability, sleep disturbances, forgetfulness, loss of control, and many others — including, most commonly, headaches.

POSTTRAUMATIC HEADACHES

Many patients complain of rather severe headaches after being involved in traumatic events such as a motor vehicle accident or a fall. The cause of posttraumatic headaches has been known for many years. Often it is a mixed headache disorder developing because of muscle tension and vascular type of headache phenomena. In fact, many patients with cervical spine trauma also have mild traumatic brain injuries (MTBIs) that can result in the patient suffering from chronic headaches resembling migraines in their intensity, characteristics, and frequency. Some neurologists have called such headaches *posttraumatic migraines* I prefer the term *posttraumatic headaches* or *posttraumatic vascular headaches* because these terms tend not to be confused with common migraine headaches, typically idiopathic in nature. Often patients who complain of headaches after an injury are treated symptomatically but little is done to look into the mechanism of the headaches or to validate the patient's complaints with objective testing. Perhaps it is because such patients are not believed or are thought to be exaggerating their pain. Many such patients are involved in litigation, making their motives suspect to the inadequately trained clinician. It must be stressed that there is no medical evidence that faking such symptoms is common.

A study (Packard, 1992) written to put this question to rest consisted of a large series of patients diagnosed with posttraumatic headaches. These patients continued to seek treatment and had persistent symptoms, often severe, despite the resolution of their litigation. That being the case and knowing that certain medications such as calcium channel blockers, beta-blockers, and tricyclic agents can be used prophylactically to prevent vascular headache symptoms (as a vismigraine), then the need to indentify those patients whose posttraumatic headaches have a vascular component becomes obvious.

A method to detect vascular instability in the cerebral circulation (often a harbinger of intense vascular-type headaches) is available. Brain Single Photon Emission Computerized Tomography (SPECT) scanning is a useful, relatively noninvasive (i.e., one intranvenous injection of a radioactive isotope), fairly safe, and sensitive test (Holman & Devous, 1992; Nedd, et al., 1993; Newton, et al., 1992; Wyper, 1993). Although the SPECT scan does not make the diagnosis (the clinician needs to correlate the results with all other aspects of the patient's problem), it can be a very useful tool in making an accurate diagnosis and in directing therapy. If a patient has an imbalance in brain circulation as measured by a brain SPECT scan, the rationale for the use of such prophylactic agents mentioned earlier is obvious and compelling. On the other hand, if the posttraumatic headaches have their origin in muscle tension or intervertebral joint pathology with little, if any, contribution from abnormalities in cerebral circulation, then the treatment plan would weigh more heavily in favor of trigger point therapy, anti-inflammatory/anti-arthritic medication, or physical modalities such as manipulation/adjustment, etc.

Patients with cervical spine injuries who complain of headaches may also have a MTBI that should be evaluated thoroughly. One must not assume that the chronic headache is cervicogenic, although there may be a cervicogenic component. Brain SPECT scanning is a relatively noninvasive and potentially very helpful test and is much more sensitive than magnetic resonance imaging (MRI) or computed tomography (CT) (Tikofsky, 1994) and twice as sensitive as computerized electroencephalography (Romano, 1995) for detecting chronic traumatic brain injury. I must stress that in the initial evaluation of patients suspected of having an acute brain injury, MRI and/or CT can be invaluable. Such problems as subdural hematomas and intracerebral hemorrhage can be promptly identified with the preceding techniques and emergency measures can be taken. Brain SPECT scanning in the context of posttraumatic headaches should be utilized if the patient has persistent headaches and/or cognitive dysfunction months, or even years, after the trauma. At that point intracerebral pathology either had been ruled out or was no longer a realistic consideration.

Many patients who have suffered whiplash injuries also complain of a veritable litany of symptoms including light-headedness, dizziness, vertigo, double vision, blurred vision, ringing of the ears, being hard of hearing, memory problems, trouble concentrating, being easily distracted, fatigue, anxiety, excessive sweating, sadness, trouble sleeping, moodiness, irritability, changes in menstrual periods, impaired vaginal lubrication, impotence, and lack of interest in sex. Do these patients have sufficient injuries to their brains to be considered as suffering postconcussional problems?

Such conditions can arise even if there is only a momentary change in the level of consciousness — and even if no change in consciousness — at the time of the

trauma. Closed head injuries have been associated with depression, anxiety, personality changes, cognitive deficits, and other such symptoms (Kant, 1996). This neurobehavioral morbidity is more common than once believed (Brown, Fann, & Grant, 1994) and, if not treated, can cause severe impairment, resulting in a marked deterioration in the quality of life. This often manifests itself as the loss of one's job, marital difficulties, and the loss of friendships. Economic hardship often accompanies these other problems.

MYOFASCIAL PAIN SYNDROME

The definition and characteristics of myofascial pain syndrome (MPS) have been amply covered in this textbook (Margoles, 1998; Gerwin & Dommerholt, 1998) and other texts (Travell & Simons, 1983; Rachlin, 1994). The diagnosis of MPS is based on the detection of objective abnormalities on careful physical examination. These include the findings of trigger points, taut myofascial bands, local twitch responses of the taut bands (Simons, 1987), and even characteristic electrical activity of trigger points measured by the electromyogram (Hubbard & Berkoff, 1993; Romano & Stiller, 1997).

The role of trauma in the generation and perpetuation of trigger points, long known to be the hallmark physical findings of MPS, was perhaps most succinctly stated by Rachlin (1994): "Injuries and surgical procedures may lead to the formation of trigger points causing repeated episodes of pain".

The worst cases of MPS seem to be the result of traumatic events such as an automobile accident or fall. Simons (1987) noted that such patients "suffer greatly and are difficult to help". He went on to write, "They exhibit a posttraumatic hyperirritability of their nervous system and of their trigger points". The trauma in question, according to Simons, is "severe enough to damage the sensory pathways of the central nervous system". In a study of Israeli trauma victims (Buskila, Neumann, Vaisberg, Alkalay, & Wolfe, 1997a), the authors suggested that the reason fibromyalgia syndrome (FS) followed neck injury 13 times more often than lower extremity injury was because of this very mechanism. The involvement of the nervous system probably is very important in the perpetuation and prolongation of the pain, thus preventing full recovery. Simons (1987) opined that damage to the nervous system "... apparently acts as an endogenous perpetuating factor susceptible to augmentation by severe pain, additional trauma, vibration, loud noises, prolonged physical activity, and emotional stress". In describing the patients who developed such severe MPS, Simons noted, "From the date of the trauma, coping with pain typically becomes the focus of life for these patients who previously paid little attention to pain. They are unable to increase their activity substantially without increasing their pain level." Once the nervous system exhibits "posttraumatic hyperirritability" or other perpetuating factors exist and are left untreated, "an acute myofascial pain syndrome characteristically becomes chronic".

When I first read the preceding description, I immediately knew that Dr. Simons and I had something in common. We both saw numerous chronic pain patients and we both took the time to analyze their situations. He could have easily been describing patients I see and treat every day. He and I know these patients are suffering and in trouble. They did not choose to be injured; they need our help.

The concept of perpetuating factors has been known for many years (Travell & Simons, 1983), yet many patients who have severe, chronic MPS (often posttrauma) are met with skepticism and even disbelief. Bayer (1999, p. 171) wrote, "It is amazing if not amusing that insurers and their attorneys cannot believe that a patient who has suffered an injury can continue to experience symptoms of pain months or years after the injury".

However, the reality of the situation can be summed up as follows: (1) some patients develop severe, chronic MPS and even FS as the result of an injury; (2) some of these patients are treated unfairly and are not evaluated thoroughly because they may not be believed, especially when personal injury litigation is pending; and (3) the pain management specialist must rely on medical knowledge and scientific validity in formulating diagnoses and prognoses— not on bias or innuendo.

Stress plays a role in the severity of illness — any illness, not just musculoskeletal or neurological. What sane physician would encourage a patient with high blood pressure, heart disease, or ulcers to continue a stressful and unhealthy lifestyle? Thus, in treating the patient with chronic MPS, the clinician needs to help minimize stress — not contribute to it. The evaluation and treatment must be done honestly and professionally, realizing that the vast majority of patients diagnosed with posttraumatic MPS (PTMPS) are in a great deal of pain; they also are probably anxious, depressed, and frustrated due to the severity and longevity of their pain as well as probably having previously been given "short shrift" by a system that is supposed to help them. If patients with PTMPS are not treated promptly or if their pain cannot be controlled, they may even develop FS.

POSTTRAUMATIC FIBROMYALGIA SYNDROME

FS is a soft tissue rheumatic disorder characterized by widespread musculoskeletal pain associated with a deficiency of deep (i.e., stage 4, non-rapid eye movement, delta wave) sleep, headaches, fatigue, decreased stamina, and other symptoms (Romano, 1990). A committee appointed by the American College of Rheumatology (ACR) published FS criteria (Wolfe, et al., 1990) that are

still in use today, not only in the United States but also throughout the world.

The concept of posttraumatic fibromyalgia syndrome (PTFS) has been discussed in another chapter in this book (Romano, 1998a). However, additional remarks concerning the validity of a PTFS diagnosis need to be stressed. There have been numerous reports and book chapters in which the authors link trauma and FS (Bennett, 1989; Greenfield, Fitzcharles, & Esdaile, 1992; Moldofsky, Wong, & Lue, 1993; Rice, 1987; Saskin, Moldofsky, & Lue, 1986; Smythe, 1989). Despite this wealth of information, most doctors at a conference in Vancouver, British Columbia, in 1994 could not link trauma to FS in a cause–effect relationship. They concluded that at the time "…data from the literature are insufficient to indicate whether a causal relationship exists between trauma and FM (fibromyalgia)" (Wolfe, 1996). Many of the conference attendees opined that based on only four studies published up to that time (Greenfield, Fitzcharles, & Esdaile, 1992; Moldofsky, Wong, & Lue, 1994; Romano, 1990; Saskin, et al., 1986) they did not have enough evidence to conclude that trauma could cause FM. The committee chairman, Dr. Wolfe, was quick to add that the absence of evidence "…however, does not mean that causality does not exist, rather that appropriate studies have not been performed." Since the Vancouver conference, subsequent articles have been published (Aaron, et al., 1997; Alexander et al., 1998; Waylonis & Perkins, 1994) linking trauma and FM including a case report (Wolfe, 1994) and a controlled study of 161 cases of traumatic injury (Buskila, et al., 1997a) — both authored by Wolfe. In the latter study, Wolfe and the other authors conclude that FM was 13 times more frequent following neck injury than following lower extremity injury. Furthermore, the article ends with the following two sentences: "Thus, trauma may cause FMS (fibromyalgia syndrome), but it does not necessarily cause work disability. These findings have important implications for many industrialized countries."

Despite these new data, the Vancouver conference proceedings continue to be quoted out of context and sections of the text have been unfairly used to discredit patients who have developed PTFS. As an attendee of the Vancouver FS Conference and a participant in the discussions, I did not initially appreciate that this academic endeavor would be used for purposes unintended by most, if not all, participants. When I returned from the conference, I witnessed firsthand how attorneys and even medical evaluators have incorrectly stated the findings of the Vancouver conference to gain an advanatge in such medico-legal proceedings as depositions and even trials.

Such misrepresentations, often blatant, of what happened at that meeting motivated some attendees to publish a report to correct any misconceptions about the Vancouver conference (Yunus, Bennett, Romano, Russell, et al., 1997). These authors correctly state that the Vancouver Consensus Report is likely to be used in the legal setting and further aptly remark that in such a setting "…causality entails only 51% certainty, usually stated in terms of reasonable medical probability." They go on to state that "…it seems more than 51% likely that trauma does play a causative role in some FMS (fibromyalgia) patients…". They cite articles on clinical patterns (Bennett, 1993; Moldofsky, et al., 1993; Pellegrino, 1996; Romano, 1990; Wolfe, 1994), other case studies (Bengtssom, et al., 1986; Buskila, et al., 1997a; Greenfield, et al., 1992; Yunus & Alday, 1993), and biological plausability concerning central nervous system plasticity (Coderre, Katz, Vaccarino, & Melzack, 1993; Dubner & Ruda, 1992; Yunus, 1992) as the basis of that statement.

FS does not develop after all, or even most, traumatic events but it can evolve after such traumas as physical assaults, motor vehicle accidents, and/or falls. FS takes at least 3 months to evolve according to ACR criteria (Wolfe, 1990). Thus, FS does not occur at the exact time of the trauma, but instead can develop weeks to months later as a direct consequence of the trauma. The real question confronting the clinician and about which he or she may need to offer legal testimony is whether a specific trauma caused a specific FS in a specific patient at a specific time. To determine that, a careful record review, a thorough medical history, and a physical examination must be obtained so that a conclusion can be reached based on the facts as opposed to prejudice or bias.

Infections can also trigger or precipitate the development of FS. An association between infections and FS has been known for a long time (Beetham, 1979). There have been numerous case reports of patients developing FS as a result of certain infections. For example, FS has been reported to have been caused by hepatitis virus (Buskila, et al., 1997b), human immunodeficiency virus (HIV) (Simms, et al., 1992), *Borrelia burgdorferi* (Lyme disease) (Dinerman & Steere, 1992), and coxsackie virus and parvovirus (Leventhal, Naides, & Freundlich, 1991). Goldenberg (1993) attempted to explain how infections trigger FS by theorizing that such infections may "promote a maladaptive behavior pattern which secondarily leads to fibromyalgia". Other explanations, including a disruption of normal sleep pattern and/or endocrine abnormalities, may be equally valid.

Regardless of how infections trigger FS, they can and do cause FS in some patients. Considering that the presence of FS diminishes the quality of life (Burckhardt, Clark, & Bennett, 1993; Martinez, Ferraz, Sato, & Atra, 1995; Turk, Okifuji, Sinclair, & Starz, 1996), the development of FS as a result of an infection is an important component of the patient's medical history. If the infection comes about as the result of negligence or even malice, the clinician may be called on to render an expert opinion concerning causation, severity, and prognosis.

If asked to testify in court concerning soft tissue injuries, the healthcare professional must remember that the court needs to know (1) what the patient is suffering from, (2) whether the medical problem (e.g., FS or MPS) could have been precipitated or caused by trauma, (3) whether the problem was indeed precipitated or caused by the accident/incident in question (i.e., if the trauma had not occurred, would the patient have this problem), (4) whether the problem is temporary or permanent, and (5) what the cost of future care will be for the patient for the injuries sustained in the accident/incident. The court needs to know these facts to a reasonable degree of medical probability or certainty. The physician's education, training, and experience, as well as his or her knowledge of the particular patient in question, should be the basis for giving such opinions.

There is no cure for FS and it does not decrease longevity. Therefore, the use of standard actuarial/mortality tables such as those provided by government agencies (Vital Statistics of the United States, 1992) is a reasonable way to determine the number of additional years a given patient is expected to live.

With that information and the knowledge of what the individual PTFS patient would need for his or her future care, the practitioner would be in a good position to render an opinion as to the cost of future medical care for the treatment of the injuries in question. Typically this treatment would include office visits, oral medications (e.g., muscle relaxants, analgesics), topical preparations (liniments), local injections, physical modalities (e.g., massage therapy, manipulation, or adjustment), and blood tests to determine whether the oral medications were causing side effects, etc.

The treatment of FS can result in diminution of symptoms with resultant clinical improvement, albeit temporary. A cure, thus far, has not been forthcoming (Kennedy & Felson, 1996; Wolfe, et al., 1997a; Wolfe, et al., 1997b). It has been reported that cost of treatment of FS patients is substantial (White, Speechley, Harth, & Ostbye, 1999; Wolfe, 1995), in part due to the chronicity of this syndrome. Often the cost of future treatment for the remainder of a patient's life is in six figures, especially if the patient is under the age of 40, and therefore is likely to live another 30 to 40 years (Vital Statistics, 1992), or if the patient in question requires a large number of medications or procedures. Of course, these projections must be tailor-made for each individual patient.

An even greater challenge to the pain practitioner is the task of estimating the relative contribution of each of several traumas to the patient's chronic pain state. Although the clinician must call on his or her years of education, training, and experience to perform such an apportionment, a method to help do this using mathematical formulas has been published (Romano, 1998b). This method can be applied to patients with either PTFS, PTMPS, or both. However, the author notes that there is no substitute for clinical acumen and that these formulas must not be used as a substitute for sound clinical judgment.

DISABILITY

The assessment of impairment and disability can be a difficult task, especially when the patient in question has chronic pain (Teasell & Merskey, 1997) with little or no skeletal deformity as is the case with soft tissue rheumatic syndromes such as FS and MPS (Bennett, 1996; Crook, Moldofsky, & Shannon, 1998; Monsein, 1994; Reilly, 1998). Because the issues are varied and complex, only clinicians with sufficient knowledge and experience in the evaluation and treatment of such patients should render opinions concerning disability (Bennett, 1996).

The majority of patients who suffer from painful soft tissue problems remain in the workforce. However, some are so impaired that they need to seek disability benefits. For example, patients with FS caused by trauma or illness are more disabled than other FS patients (Greenfield, et al., 1992). FS is as disabling as rheumatoid arthritis (Bombardier, et al., 1986; Cathey, Wolfe, & Kleinheksel, 1988; Russell, Fletcher, Tsui, & Michalek, 1989). The FS patient can be disabled because of not only pain but also inability to perform repetitive muscular tasks (Bennett, 1993); the disability is probably because of fatigue, abnormal hormone production, and other factors including lesions in muscle that result in low levels of high-energy phosphates and altered microcirculation. Some FS patients can remain employed only if there are significant workplace modifications. These include reverting to part-time status, freelancing if possible, and alteration of the patient's workstation itself including the provision of special ergonomically suitable aids. When these fail or are impractical, FS patients often enlist the aid of their doctors in obtaining disability benefits.

What is meant by the term *disability*? The Social Security Administration (1998) defines disability as, "An inability to perform any substantial gainful activity because of a medically determinable physical or mental impairment which can be expected to last for a continuous period of not less than 12 months." Of course, there are numerous other sources of potential disability benefits ranging from private insurance disability policies to benefits offered by companies and state agencies. The definition of disability by these other entities must be ascertained by reading the individual policies. Consequently, a discussion of this topic must of necessity be limited to the Social Security system's definitions and procedures. To that agency, "substantial gainful activity" means work that "(a) involves doing significant and productive physical or mental duties; and (b) is done (or intended) for pay or profit."

There are several reasons why a person would not be eligible for Social Security disability benefits. If a person is working (except in a "sheltered" setting) even if chronically ill or if he or she has recovered within 12 months of the onset of a potentially disabling illness, benefits are not granted. Furthermore, benefits are denied if the claimant is judged not to have a medically determinable impairment. That is where the patient's treating physician becomes a part of the disability process.

The role of the physician in the disability process is a crucial but often frustrating one. Often the patient does not understand that the determination of partial or total disability does not rest in the hands of the doctor. In truth, the physician may be able to rate impairment but disability is usually determined by a board that not only takes into account the patient's impairment but also considers other factors such as the individual's age and education, job opportunities, and local economy. Although the doctor may be convinced that the patient is disabled, he or she often is put in the unenviable position of having to explain the vagaries and intricacies of this system to the patient who has just been denied disability benefits.

This turn of events is especially likely for the patient with FS. The reasons for this are numerous. Despite the establishment of FS criteria by the ACR in 1990 and in subsequent studies showing that FS patients have numerous objectively measurable abnormalities (e.g., low magnesium levels (Romano and Stiller, 1994); decreased growth hormone levels (Bennett, Clark, Campbell, & Burkhardt, 1992)), the very existence of FS is doubted by those who have not kept up with the medical literature. Furthermore, the physician may have a difficult time in rating impairment and justifying that rating to disability boards because the American Medial Association Guides to the Evaluation of Permanent Impairment does not address FS. In fact, this publication needs revision for a number of different reasons (Cocchiarella, Turk, & Anderson, 2000; Speiler, Barth, Burton, Himmelstein, & Rudolph, 2000). Finally, the FS patient typically does not look ill.

However, despite all these apparent disadvantages, the FS patient who cannot work should apply for disability benefits with the expectation that fairness and reason will prevail. For this to happen, a collaborative effort between patient, physician, and — in most instances — attorney is necesary (Potter, 1992).

The treating physician's medical report is essential for the awarding of disability benefits, but the doctor must take care to provide detailed and clear (and, of course, honest) statements concerning the patient's impairments. Terse opinions that the patient cannot work or is disabled are insufficient. The narrative report should follow a familiar forensic format with a detailed history, a thorough physical examination, an enumeration and explanation of relevant test results, and a discussion that directly addresses itself to the patient's pain and the credibility of the patient. Where applicable the physician should also indicate that he or she has expertise in FS and has treated many such patients. Because of the nature of FS and unfounded bias against this diagnosis, it is worthwhile for the doctor to state emphatically that the patient is not exhibiting secondary gain or is not a malingerer. It is essential to state that the patient's symptoms are consistent with the findings and diagnosis of FS.

The Social Security system tends to be slow and somewhat reluctant in granting disability benefits in general. Therefore, if the initial application is rejected, the truly disabled FS patient needs to follow an orderly and logical process to obtain disability benefits. There are several steps ranging from a request for reconsideration to a hearing before an administrative law judge to an appeal through the U.S. District Court. An attorney, of course, is necessary for these latter two steps in the disability process. Paradoxically, even the denials can be helpful to the applicant, because they usually contain suggestions for alternative work possibilities (practical or not) and may suggest changes in strategy.

For example, because there is no specific listing for FS (as is also the case with newly described diseases and syndromes) and if the patient is denied disability benefits on the basis of FS, the physician may be able to find "acceptable" disease entities (i.e., those that are listed) that could explain the patient's symptoms. Many FS patients exhibit, in addition to musculoskeletal pain and fatigue, many psychiatric symptoms such as anxiety, and/or depression (listing 12) or may be considered to have a somatoform disorder (listing 12.07). This is not to suggest that FS is a psychiatric disease but the ravages of FS with its concomitant chronic pain, sense of loss, and economic hardship certainly can predispose one to psychological problems. Another tactic is to attempt to get disability benefits based on organic brain dysfunction (i.e., diffuse impairment of cerebral tissue function), which is listed as 12.02. Many FS patients have significant cognitive problems that have been correlated with brain abnormalities detected by cranial SPECT imaging (Romano & Govindan, 1996), an objective neurodiagnostic test. Although this may not be the most ideal way to obtain benefits, it may be the only recourse for some FS patients, especially under the present circumstances.

The FS patients who are denied disability benefits frequently ask me to explain why they were not granted what they felt they deserved. I cannot answer this question fully because I am not privy to the machinations and workings of the disability boards. However, I have a good idea why FS patients frequently run into problems. It stems from how the FS patient is perceived. There are many different ways the FS patient may be viewed depending on the nature and/or bias of the observers. For example, managed care and health maintenance organizations claim that healthcare costs must

be curbed. That translates into the very real possibility that doctors are to be limited in what they can do for their patients — FS and MPS sufferers included. If chronic soft tissue problems such as FS and MPS are perceived to be less important than other disorders, these patients may go undiagnosed, untreated, or undertreated. It certainly seems that it is in the best interest of the health insurance industry to withhold or delay issuing funds for care. Anyone who doubts this statement has only to read articles that appeared in *American Medical News* (Jacob, 1998; Mitka, 1996) describing the high salaries of managed care executives. Governmental agencies, moreover, experience budgetary constraints. This has been especially true as the national debt has risen. Thus, patients whose problems are not immediately life-threatening make handy scapegoats for the health-care providers who treat them.

What is the answer? How is the FS patient to proceed? If the FS patient is truly unable to work, he or she must become thoroughly familiar with the disability determination process and proceed accordingly. The treating physician's report is a very important part of this process. The FS patient, however, must not be unduly discouraged by a system that is less that ideal. It is only through dogged determination and persistance that justice is truly served, not only for the individual FS patient presently seeking disability benefits but also for all FS patients who ultimately need respect and understanding from our society in addition to medical treatment.

Even more frustrating and challenging is the task of rendering an opinion as to the extent of partial disability or impairment. How does one give such an opinion for FS patients, for example, whose symptoms wax and wane depending on such variables as weather changes, stress, and severity of concomitant illnesses? One way to perform such an analysis is to do so by having the patient fill out pain and activity questionnaires (Callahan, Smith, & Pincus, 1989; Meenan & Pincus, 1987; Pincus, Summey, Soraci, Hummon, & Wallston, 1983; Wolfe, 1995) on multiple occasions or keep a daily diary of symptoms and activities. If, for example, half the time a particular patient is totally incapacitated (even bed-bound) due to severe FS pain, fatigue, or excrutiating headaches, but the remainder of the time, normal activities can be pursued, then it is reasonable to assign that particular patient a 50% impairment of the "whole person." There is no easy formula to estimate impairment and/or disability for the patient with FS or other forms of painful soft tissue rheumatic problems. That is where the skill and experience of the clinician truly comes into play.

Bennett (1996) noted that for FS patients a biopsychosocial model of disease must be used in their disability evaluations and that opinions need to be expressed in terms of reasonable probability. He further states that some physicians feel "uncomfortable" in the assessment of chronic pain and "others will not have acquired the broad knowledge base necessary for understanding the biopsychosocial concept of disease." I heartily agree with his opinion that it is "preferable that both (those) groups exempt themselves, from the disability evaluation process." One can but hope … and dream.

THE CLINICIAN IN THE COURTROOM

The pain management clinician should take an active role in the legal process. First, as a member of the community he or she should get involved in community matters, especially those that affect his or her patients. Obviously this may include the medical/legal arena. If the clinician has knowledge concerning a patient's medical condition that would benefit the court, the practitioner has a duty to present that knowledge at the proper time whether it be in the form of a deposition or as an expert witness giving testimony in a courtroom. I am not alone in this opinion. As a member of the American Medical Association (AMA) and as a Fellow of the American College of Physicians, I have reviewed the ethics manuals for each group (American College of Physicians, 1998; American Medical Association Council on Ethical and Judicial Affairs, 1996–1997). Both publications clearly state that if the physician has knowledge that can be useful to the court, it is his or her duty to present such knowledge when asked.

I have participated in hundreds of trials and depositions mostly as a witness giving expert medical testimony concerning patients that I am actively treating. Some attorneys have wrongly intimated that because of this, I cannot be objective, that I have an interest in the outcome of the case, and/or that I am being less than truthful in my responses because the plaintiff in question is my patient. These are common tactics used to undermine the credibility of expert witnesses. However, despite the innuendo I willingly testify at trials because I believe it is the right thing to do, especially considering my unique perspective as a pain management specialist. This is even more so if the patient in question is being treated by me and I have examined him or her on numerous occasions. When I perform a medical evaluation for the purpose of rendering an opinion only, I strive to be objective, relying on established criteria for FS and MPS as well as testing with a dolorimeter and a tissue compliance meter (Smiley, Cram, Margoles, Romano, & Stiller, 1992).

The court is not interested in "may be" or "could be." The court wants to know whether a patient has a particular condition as a result of a particular trauma "to a reasonable degree of medical probability." That means is it more likely than not that the trauma in question caused the patient to develop a medical problem for which he or she is being treated. For example, did the motor vehicle accident of 3 years ago cause the patient to develop FM? One does not need to know with 100% certainty that a given trauma caused a patient's medical problem in question;

however, based on the clinician's education, training, and experience he or she often can given an opinion "to a reasonable degree of medical probability" whether the trauma in question caused a patient's injuries. This is an important concept and one that is often lost on academicians and scientists who are used to expressing their thoughts to a degree of certainty approaching 95 to 100%.

The court is especially interested in the objective findings that help form the bases for the opinions rendered. After performing a range of motion and/or a trigger point examinations, the clinician in the role of expert witness must stress that such findings on physical examination are objective. Other objective findings include muscle spasm, jump signs, swelling, discoloration, especially reticular skin changes, taut myofascial bands, muscle atrophy, asymmetry of muscle size or strength, and deep tendon reflex abnormalities. The greater the skill of the examiner, the more likely such abnormalities will be observed and recorded. Most neurologists and orthopedists do not have the required expertise to perform an FS tender point count or an MPS trigger point exam. According to Simons (1987), the diagnosis of FS and/or MPS "…would probably be missed on routine conventional examination. The examiner must know precisely what to look for, how to look for it, and then must actually be looking for it." Is it any wonder that patients who have been diagnosed with either FS and/or MPS are sent by insurance companies to doctors with little or no experience in the diagnosis of these disorders? Is it not in the best economic interest of such corporations to muddy the waters, so that the true extent of the patient's injuries are not appreciated?

However, absence of proof is not proof of absence. It is beyond the control of the pain practitioner to alter the view of the insurance industry that invididuals who claim not to have recovered from an injury and therefore suffer resultant chronic painful conditions are exaggerating their pain, malingering, or suffering from mental problems.

However, it is within the expertise of the knowledgeable clinician to be diligent in taking a medical history, circumspect in reviewing pertinent medical records, and thorough in performing a physical examination so that he or she can make an accurate diagnosis in the case and explain the salient findings in legal proceedings. What is wrong with the best trained and most skilled examiners testifying in court? It appears to be in the best interest of the insurance companies to place blame on the patient and to ignore important facts about MPS and/or FS as well as other important details about those individuals suffering from disorders stemming from a traumatic event.

The clinician as an expert witness must not take sides in a personal injury lawsuit. He or she must be honest, truthful, and professional at all times. However, having sworn to tell the whole truth, he or she must point out to the court if and how insurance company adverse medical evaluations were either inadequate, inappropriately performed, or lacking in scientific/medical validity. Doing so does not make the clinician an advocate in court, but instead it helps the court make a decision based on sound medical principles as opposed to ignorance and/or misrepresentations.

It should be remembered that medicine is an art that uses scientific principles, but an art, nonetheless. Some medical experts are more skilled than others. The clinician who specializes in pain and has particular expertise in evaluating individuals claiming chronic painful problems posttrauma deserves to have his or her opinions regarded carefully and with respect. So, too, do our patients deserve our respect and that of the courts.

Neuropathic Pain: Mechanisms and Management

Mark V. Boswell, M.D., Ph.D., Samuel K. Rosenberg, M.D., and Thomas C. Chelimsky, M.D.

INTRODUCTION

Neuropathic pain is a common cause of chronic pain. Neuropathic pain is a challenge to clinicians because it is difficult to diagnose and often is resistant to analgesics, such as opioids (Arner & Meyerson, 1988; Dellemijn, 1999; Portenoy, Foley, & Inturrisi, 1990). Classic examples of neuropathic pain include trigeminal neuralgia, postherpetic neuralgia, diabetic neuropathy, phantom limb pain, and pain associated with plexopathy and radiculopathy (see Table 17.1). Neuropathic pain often complicates the treatment of cancer pain. For example, brachial plexopathy occurs in approximately 15% of patients with cancer and pain is the most common complaint associated with brachial plexopathy (Foley, 1987). Thus, successful management of cancer pain frequently requires management of neuropathic pain.

From a theoretical standpoint, neuropathic pain is relatively simple to define. It is an abnormal pain state that arises from a damaged peripheral nervous system (PNS) or central nervous system (CNS) (Merskey & Bogduk, 1994). Indeed, peripheral neuropathies, particularly those associated with diabetes, are a frequent cause of neuropathic pain (Galer, 1995). However, from a clinical perspective, neuropathic pain may be difficult to diagnose with certainty, because its clinical characteristics are rather nonspecific. Neuropathic pain may be hard for some patients to describe, but frequently is characterized as burning or stabbing, descriptors that are not unique to neuropathic pain. Indeed, neuropathic pain may be similar to the pain ascribed to common injuries not considered neuropathic in nature, such as burns and sprains. This ambiguity in character may simply reflect the relatively limited number of ways that pain can be encoded by the nervous system.

A peculiar property of the nervous system is its plasticity. Damage to nerves often results in alteration or amplification of the signal encoded by the nerve. For example, peripheral nerve ablation, performed with good therapeutic intentions, may result in a pain syndrome that is worse than the one originally being treated. When dealing with the nervous system, "shooting the messenger" (the nerve) often intensifies and distorts the message. The new pain syndrome may be more severe, and associated with allodynia, hyperalgesia, and spontaneous and paroxysmal pain, all in the presence of mild to moderate cutaneous numbness. This complex of signs and symptoms is paradoxical to the patient and confusing to the clinician, but quite typical of neuropathic pain.

The ambiguity notwithstanding, it is important to consider neuropathic pain in the differential diagnosis of chronic pain, because neuropathic pain may be treated with some success using adjuvant analgesics, medications not traditionally considered to be pain relievers (Hegarty & Portenoy, 1994). Adjuvant analgesics, such as tricyclic antidepressants and anticonvulsants, do not have strong antinociceptive analgesic properties in experimental or clinical studies, but have been shown to be helpful in neuropathic pain states (McQuay, et al., 1996; Swerdlow, 1984). Indeed, the mainstay of treatment of neuropathic,

Modified from B.S. Galer, 1995, Neurology, 45 (Suppl. 9), S17–S25.

pain is pharmacologic, and effective regimens often require multiple medications. In addition, the possible effectiveness of opioids for neuropathic pain should not be overlooked, although doses may be considerably higher than typical antinociceptive doses. The clinician should also keep in mind that successful management of chronic pain often requires treating neuropathic pain as well as pain associated with tissue injury, because both conditions may coexist and interact to maintain the painful condition.

MECHANISMS OF NEUROPATHIC PAIN

Neuropathic pain may result from a pathological process occurring at any level of the nervous system, from the nociceptor, the distal nerve, the plexus level, the dorsal root ganglion, the root entry zone, the dorsal horn of the spinal cord, and higher levels in the CNS, particularly the medulla and thalamus. It has become popular to contrast neuropathic pain with typical postinjury, nociceptive pain. Nociceptive pain, typically thought to indicate a properly functioning nervous system, is considered physiological because it results from activation of nociceptors, specialized nerve endings that respond to high threshold noxious stimuli and generally serve a protective function. In contrast, neuropathic pain may be thought of as pathophysiological, because it arises from a damaged PNS or CNS and provides no obvious protective benefit (Bennett, 1994; Tanelian, & Victory, 1995). However, from a clinical perspective, this distinction is seldom straightforward, because physiological pain often is associated with early clinical findings generally considered neuropathic in nature, such as allodynia and paresthesias (tingling sensations). Moreover, chronic neuropathic-like pain occasionally may follow an injury that did not appear to involve nerve damage, such as a simple soft tissue injury. On the other hand, pain associated with peripheral neuropathy may be maintained by sustained peripheral nociceptive input (Gracely, Lynch, & Bennett, 1992). Strong nociceptive input often produces central sensitization, an abnormal pain amplification process in the CNS. Therefore, the definitional borders of neuropathic pain are becoming more diffuse, not more distinct, as we gain a better understanding of the remarkable plasticity of the nervous system and its close association with the various tissues that it innervates.

Neuropathic pain may be classified as stimulus-evoked or stimulus-independent pain. Stimulus-evoked pain can result from stimulation of nervi nervorum present in connective tissue surrounding otherwise intact nerves. Painful stimuli that activate nociceptors around nerves include inflammation and tissue injury from tumor or trauma (Woolf & Mannion, 1999). Stimulus-independent neuropathic pain may result from damage to afferent sensory fibers in the PNS or CNS. In this case, ongoing inflammation is usually absent. Days to months after peripheral nerve injury, persistent abnormal primary afferent activity from the periphery may arise from hypersensitive nerve terminals or nerves (Price, Mao, Mayer, 1994).

There is substantial pharmacological evidence that abnormal nerve activity is an important mechanism underlying the spontaneous pain typical of neuropathic pain states (Devor, 1994, 1995; Tanelian & Victory, 1995). It is hypothesized that sites of ectopic foci develop on injured or regenerating nerves in the periphery, at the level of the nociceptor, neuromas, or segments of injured nerves; at the dorsal root ganglion; and in the dorsal horn of the spinal cord. Indeed, after nerve transection, increased sensitivity occurs, followed in a few days by spontaneous activity. These abnormal ectopic foci may be thought of as spontaneous pain generators, resulting in paroxysmal and spontaneous pain. Precise pathophysiology is unclear, but pharmacological evidence suggests that ectopic activity is due to an increased number of sodium channels, or more likely an abnormal subtype of sodium channel, resulting in unstable sodium channel activity (Chaplan, 2000). Pharmacological evidence supporting this hypothesis is the effectiveness of local anesthetics and some anticonvulsants (sodium channel-blocking drugs) in

neuropathic pain. These drugs presumably produce frequency and voltage-dependent blockade of sodium channels on damaged neurons (Devor, 1995). The abnormal sodium channel involved in neuropathic pain states may be a tetrodotoxin-insensitive subtype, found only in neural tissue (Novakovic, et al., 1998). Accumulation of atypical as well as tetrodotoxin-sensitive sodium channels (responsible for normal nerve conduction) may explain the often inadequate therapeutic benefit of current sodium channel blocking drugs.

Work in animal models demonstrates that voltage-dependent calcium channels may also be important in modulating neuropathic transmission. Unfortunately, the currently available calcium channel blockers are cardioselective, and are not particularly effective in neuropathic pain. There appear to be at least six calcium channel subtypes, and studies with novel N-type calcium channel blockers are promising in animals (Chaplan, 2000). Preliminary studies with conotoxin (SNX-111) are positive, although the drug must be administered spinally.

Gabapentin, a novel anticonvulsant, appears to bind to the $\alpha 2\delta$ subunit of a voltage-dependent calcium channel. Work by Chaplan (2000) and colleagues demonstrates that messenger RNA and protein for the $\alpha 2\delta$ subunit are increased more than 10-fold in dorsal root ganglia following nerve injury, but are not changed after tissue injury. Blockade of a retrograde signal from the injury site (which may involve nerve growth factor) prevents upregulation of the $\alpha 2\delta$ subunit. Chaplan points out that the $\alpha 2\delta$ subunit does not seem to play a role in normal channel kinetics but may effect calcium channel assembly and insertion into the neuronal membrane. Thus, the subunit may act as a drug-binding site and secondarily modify channel kinetics.

Following peripheral nerve injury, concomitant alternations may be evident in dorsal root ganglia, including transmitter changes and increased density of sympathetic nerve terminals (McLachlan, Janig, Devor, & Michaelis, 1993). Tyrosine hydroxylase positive cell terminals that produce norepinephrine, migrate from vessels supplying the dorsal root ganglion to nerve ganglion cells following sciatic nerve injury. The dorsal root ganglia then expresses α-adrenergic receptors. This may be a putative link between peripheral tissue injury, nerve injury, and sympathetically maintained pain states, such as reflex sympathetic dystrophy and causalgia (complex regional pain syndromes Type 1 and 2, respectively). In the periphery, sprouting nerve terminals may exhibit sensitivity to prostaglandins, cytokines, and catecholamines. These kinds of changes further increase the complexity of the neuropathic pain picture and blur the distinctions between nociceptive and neuropathic pain.

It should be noted that not all stimulus-independent pain is mediated by spontaneous activity in primary sensory neurons. Loss of normal inhibitory mechanisms, whether segmental, supraspinal, or both, may also cause neuropathic pain (Woolf & Mannion, 1999). After deafferentation injury, particularly following loss of C fibers, arborization of $A\beta$ fibers into the substantia gelatinosa of the dorsal horn may result in central sensitization and allodynia (Woolf, Shortland, & Coggeshall, 1992). Available evidence supports the contention that tactile allodynia is mediated by large myelinated $A\beta$ afferents with input that is modulated at supraspinal sites in the dorsal columns (Ossipov, Lai, Malan, & Porreca, 2000). This may explain why transcutaneous electrical nerve stimulation (TENS) and spinal cord stimulation, which produce a low threshold, tingling sensation, characteristic of large fiber afferent activation, may be effective in chronic pain states, particularly neuropathic pain. Tactile allodynia should be differentiated from thermal allodynia, which appears to be mediated by nonmyelinated C fibers and amplified by pathological spinal dynorphin (discussed later).

Various studies suggest that stimulus-evoked neuropathic pain is more sensitive to opioids than stimulus-independent pain (Dellemijn, 1999). Opioid responsiveness may be maintained in some forms of stimulus-evoked pain, because opioid receptors in the substantia gelatinosa are preserved. On the other hand, segmental loss of presynaptic central opioid receptors occurs following injury or loss of C fibers, typically seen after deafferentation injury. However, the magnitude of receptor loss is minimal and largely segmental, and only partly explains the diminished opioid-responsiveness characteristic of neuropathic pain (Ossipov, et al., 2000).

Supraspinal facilitative mechanisms may also be involved in maintenance of neuropathic pain and opioid resistance. Evidence suggests that sustained afferent drive induces facilitation of spinal cord pain transmission involving a descending pathway from the rostroventral medial medulla (RVM) (Ossipov, et al., 2000). Tonic facilitation may involve supraspinal cholecystokinin (CCK), traditionally thought of as a visceral hormone that regulates emptying of the gallbladder. CCK antagonists injected into the RVM in animals reverse tactile and thermal allodynia produced by spinal nerve ligation (Kovelowski, Ossipov, Sun, Malan, & Proecca, 2000). Mechanistically, these antiopioid and pronociceptive actions may occur at spinal and supraspinal sites. Spinal CCK may antagonize opioid effects at the level of the primary afferent terminal in the spinal cord. Both CCK and opioids colocalize on primary nociceptive afferent neurons in the dorsal horn. In addition, CCK may act on supraspinal opioid-dependent pathways in the RVM to reduce opioid responsiveness, and thus impair descending inhibition, an important mechanism involved in opioid pain relief. Ultimately, CCK antagonists may prove useful for treating neuropathic pain states.

The phenomenon of reduced opioid responsiveness in neuropathic pain has prompted extensive studies in

animals, particularly the effects of intrathecal opioids on pain associated with thermal and tactile stimulation. The similarities between opioid tolerance and neuropathic pain are also an area of active study (Vanderah, et al., 2000). It is well known that N-methyl-D-aspartate (NMDA) antagonists appear to minimize the development of opioid tolerance. Spinal dynorphin may be a common link between NMDA, central sensitization, and reduced opioid responsiveness. Following spinal nerve ligation, dynorphin levels in the spinal cord increase, suggesting that dynorphin may act as a pronociceptive mediator (Ossipov, et al., 2000). Although, under certain circumstances, dynorphin appears to have analgesic properties, it is becoming increasingly clear that dynorphin also has nonopioid, antianalgesic properties. Antiserum to dynorphin blocks thermal hyperalgesia after nerve injury in rats. Moreover, antiserum to dynorphin or MK801, an NMDA antagonist, restores normal spinal morphine analgesia following spinal nerve ligation. Furthermore, both agents restore morphine synergy between the brain and spinal cord (Ossipov, et al., 2000), which is required for the full clinical analgesic effects of morphine. Therefore, current evidence suggests that the pain-promoting effect of dynorphin is mediated by the NMDA receptor. Although the full clinical ramifications of dynorphin are far from understood, it is clear that sustained nociceptive drive from the periphery maintains elevated levels of spinal dynorphin, which in turn, may have toxic effects on the spinal cord. Thus, reducing sustained peripheral nociceptive input into the spinal (i.e., pain relief) may be an important way to reduce the incidence of neuropathic pain (Caudle & Mannes, 2000).

Currently, NMDA antagonists, such as ketamine, have only limited indications because of significant side effects. Ultimately, however, medications such as NMDA antagonists may become available that can reduce the effects of pathological spinal dynorphin.

MANAGEMENT OF NEUROPATHIC PAIN: GENERAL CONSIDERATIONS

Management of neuropathic pain is a complicated endeavor and often is frustrating to patient and physician alike. This stems from our relatively poor understanding of mechanisms and the limited efficacy of currently available analgesics. Therapeutic approaches vary greatly among physicians, which reflects the paucity of randomized clinical trials, particularly those comparing different drug regimens. Given our current level of understanding of neuropathic pain mechanisms and the limitations of available drugs, nonpharmacological methods may be as effective as pharmacological approaches. Recalcitrant chronic pain syndromes warrant an interdisciplinary approach, which may include attempts to treat the underlying disease (e.g., causes of the peripheral neuropathy), as well as formulation of a rational approach to medications, interventions such as nerve blocks, and psychological and physical therapies.

The nature, duration, and severity of pain should be evaluated in detail, including appropriate physical and neurological examinations. For example, performing a neurological examination looking specifically for evidence of nerve injury, such as the presence of hypoesthesias or reflex changes, may suggest neuropathy or radiculopathy, and help guide treatment. It is crucial that psychosocial and emotional factors be explored, because there is a high comorbidity of depression and anxiety disorders in patients with chronic pain. Moreover, given the similarities between the pharmacology of mood and depression and pain transmission (e.g., serotonin and norepinephrine), patients with concomitant systemic illness and stress may be at risk for depression and development of an abnormal chronic pain state. Pharmacological management of depression may improve neuropathic pain by addressing overlapping, but distinct mechanisms.

After multiple medication trials in which there has been minimal therapeutic benefit and perhaps significant drug-related side effects, patients may believe that they have little recourse but to undergo invasive, ablative procedures in attempts to relieve their pain. Specific treatment modalities aimed at the underlying pathophysiology are usually not possible in most neuropathies, particularly with chronic sensory polyneuropathies. In general, ablative procedures are not warranted, because of the high probability of long-term worsening of pain. Except for patients with advanced cancer-related pain, nerve ablation is likely to provide only temporary benefit, leaving the patient with sensory and perhaps motor deficits. Exceptions to this phenomenon appear to be ablation of sympathetic fibers, visceral plexi, and medial branch nerve blocks, which denervate painful facet joints in the spine. In cases of nerve entrapment, where ongoing nerve compression is likely to be responsible for pain, neurolysis or transposition of the nerve may provide benefit, as long as pain is not due to irreversible underlying nerve damage. In all cases of neuropathic pain, even when neuropathy is evident, it is appropriate from time to time to reevaluate the presumed etiology of the neurological problem.

When a medication trial proves to be ineffective, a multidimensional or interdisciplinary approach should be considered. Again, this includes an attempt to treat the underlying disease, as well as specific pharmacological, psychological, and physical therapy interventions. The outcome measure for successful treatment should include increased activity as well as decreased subjective pain ratings and improved patient satisfaction. The treatment goal in chronic neuropathic pain is different from that in acute pain. In the usual acute pain setting, the goal is nearly complete relief of pain, to allow recovery of normal function during the healing process. With chronic

neuropathic pain, limitations of current analgesics usually make complete pain relief a very unrealistic goal. Therefore, attention to increasing function and comfort and treating associated problems, such as depression, become paramount. Reducing dependence on opioid medications may or may not be an important goal. The objectives to consider with chronic opioid therapy include determining whether nonopioid approaches have been tried, whether the pain syndrome is opioid responsive, and whether the patient demonstrates appropriate improvement in function, without undo side effects or evidence of abuse of medications.

Nonpharmacological approaches to treating neuropathic pain include the use of a TENS unit, although relief may be poor when burning pain is a prominent complaint. This may be explained by the fact that burning pain is a C-fiber-mediated sensation, whereas TENS units probably modulate large fiber input into the dorsal horn.

Spinal cord stimulation may be efficacious for chronic pain, including neuropathic pain (North, Kidd, Zahurak, James, & Long, 1993) and reflex sympathetic dystrophy (Kemle,r et al., 2000). Mechanisms involved are poorly understood, which reflects current understanding of neuropathic pain states in general. However, central effects may include alteration in dorsal horn processing and transmission in the tract of Lissauer (Iacono, Guthkelch, & Boswell, 1992) and suppression of sympathetic outflow from the intermediolateral gray column of the spinal cord. The latter effect may explain improved peripheral blood flow in patients with chronic peripheral vascular insufficiency. The CraigPENS technique, a novel application of electroacupuncture (percutaneous neural stimulation [PNS]) has been shown effective in herpes zoster, diabetic peripheral neuropathy, and sciatica (Ahmed, et al., 1998; Ghoname, et al., 1999; Hamza, et al., 2000).

Available evidence indicates that nonpharmacological approaches such as TENS and CraigPENS can provide an initial rational therapeutic strategy, and may obviate the need for potentially toxic medications, improve the effectiveness of current analgesic regimens, or reduce the amount of medications required. Spinal cord stimulation still tends to be a treatment of last resort, although judicious use earlier in the course of treatment is probably warranted in carefully selected patients. Considering the current high cost of medication, alternative approaches, if efficacious, may prove to be cost effective.

PHARMACOLOGY OF NEUROPATHIC PAIN

From a practical standpoint, medications remain the pillar of pain management strategies, despite their limitations. From a conceptual standpoint, adjuvant analgesic drugs may be categorized into two broad classes, membrane stabilizing agents and medications that enhance inhibitory mechanisms in the dorsal horn. This classification system may provide a simple framework with which to approach therapy; however, it should be kept in mind that most of these drugs have multiple mechanisms of action, and their effects often may overlap. Given the limitations of our current drugs, pain management often becomes an exercise in polypharmacy, where the clinician uses multiple medications to target different symptoms. This strategy may optimize the chances for success, but complicates management issues when side effects develop.

Membrane stabilizing agents include local anesthetics such as lidocaine and some anticonvulsant drugs, including carbamazepine, phenytoin, and valproic acid (Tanelian & Victory, 1995). Their molecular mechanism of action involves blockade of frequency and voltage-dependent sodium channels on damaged or regenerating neuronal membranes (Devor, 1994, 1995). It appears that minimal doses of suppressive drugs may inhibit ectopic discharges without interfering with normal neuronal function. It is also possible that the sodium channel targets are atypical and not involved in normal neuronal conduction. Although the evidence is less substantial, corticosteroids also appear to have effects on membrane conductance (Castillo, et al., 1996; Devor, Govrin-Lippmann, & Raber, 1985). In addition, tricyclic antidepressants, such as amitriptyline, have effects on sodium channels (Pancrazio, Kamatchi, Roscoe, & Lynch, 1998), an action that is distinct from their effects on the reuptake of serotonin and norepinephrine. The latter are traditionally thought to be responsible for their effects on depression and pain.

Conventional wisdom maintains that the adjuvant analgesics, particularly the tricyclic antidepressants, and clonazepam and baclofen, modulate inhibitory mechanisms in the spinal cord and brain. Inhibitory pathways descend from the periaqueductal gray, reticular formation, and nucleus raphe magnus in the dorsolateral funiculus to the dorsal horn. These pathways mediate antinociception by adrenergic, serotonergic, GABAergic (γ-amino butyric acid), and opioid mechanisms (Yaksh, 1979). Although the putative mechanisms are complex and poorly understood, serotonergic effects are mediated in part by action on GABAergic interneurons (Alhaider, Lei, & Wilcox, 1991). For example, facilitory effects of large myelinated afferent fibers may be suppressed by tonic GABAergic activity, removal of which results in allodynia (Yaksh & Malmberg, 1994).

As noted earlier, tricyclic antidepressants alter monoamine transmitter activity at neuronal synapses by blocking presynaptic reuptake of norepinephrine and serotonin, thereby modulating descending inhibitory spinal pathways. However, additional mechanisms include effects on membranes, interaction with NMDA activity (Eisenach & Gebhart, 1995), and sodium channel blockade (Pancrazio, et al., 1998).

TABLE 17.2
Adjuvant Analgesics for Neuropathic Pain

Drug Class	Mechanism of Drug Action
Anticonvulsants	
Carbamazepine	Sodium channel blockade
Phenytoin	Sodium channel blockade
Valproic acid	Sodium channel blockade
Gabapentin	Calcium channel binding
Clonazepam	GABAegic mechanism
Antidepressants	
Amitriptyline	As a group Norepinephrine and serotonin reuptake effects, possible NMDA effects, and sodium channel blockade
Nortriptyline	
Imipramine	
Desipramine	
Fluoxetine	Serotonin selective effects
Paroxetine	Serotonin selective effects
Venlafaxine	Adrenergic and opioid receptor binding effects
Antiarrhythmics	
Lidocaine	As a group sodium channel-blocking effects
Mexiletine	
EMLA cream	
Miscellaneous	
Corticosteroids	Antiinflammatory and membrane stabilizing effects
Baclofen	GABA-B agonist
Capsaicin	Vanilloid agonist and C-fiber neurotoxin

From a practical standpoint, it helpful to consider the various medications useful for neuropathic pain in terms of their traditional pharmacological indications (eg, anticonvulsants and antidepressants). However, it is necessary to keep in mind that all these drugs have incompletely understood mechanisms of action, and the drug categories are more conventional than mechanistic (Table 17.2).

Anticonvulsants

Anticonvulsants are useful for trigeminal neuralgia, postherpetic neuralgia, diabetic neuropathy, and central pain (Hegarty & Porteny, 1994; Swerdlow, 1984). Although anticonvulsants have traditionally been thought of as most useful for lancinating pain, they may also relieve burning dysesthesias. Chemically, anticonvulsants are a diverse group of drugs, are typically highly protein bound, and undergo extensive hepatic metabolism. At present it is uncertain whether anticonvulsants or antidepressants are better for neuropathic pain, because similar results have been obtained with both types of drugs (McQuay, et al., 1996). Indeed, the choice of a particular drug, whether anticonvulsant or antidepressant, may be based more on a clinician's experience with the drug, the expected time to therapeutic benefit, or a drug side effect profile, instead of theoretical mechanisms of action.

Carbamazepine has a long history of use for neuropathic pain, particularly trigeminal neuralgia. Trigeminal neuralgia is an FDA-approved indication for the drug. Carbamazepine is chemically related to the tricyclic antidepressant imipramine, has a slow and erratic absorption, and may produce numerous side effects, including sedation, nausea, vomiting, and hepatic enzyme induction. In 10% of patients, transient leukopenia and thrombocytopenia may occur, and in 2% of patients hematologic changes can be persistent, requiring stopping the drug (Hart & Easton, 1982; Sobotka, Alexander, & Cook, 1990; Tohen, Castillo, Baldessarini, Zarate, & Kando, 1995). Aplastic anemia is the most severe complication associated with carbamazepine, which may occur in 1:200,000 patients. Although requirements for hematologic monitoring remain debatable, a complete blood cell count, hepatic enzymes, blood urea nitrogen (BUN), and creatinine are recommended at baseline; and these are checked again at 2, 4, and 6 weeks, and every 6 months thereafter. Carbamazepine levels should be drawn every 6 months and after changing the dose to monitor for toxic levels and verify that the drug is within the therapeutic range (4 to 12 µg/cc). Patients with low pretreatment white blood cell counts are at increased risk of developing leukopenia (WBC < 3000/mm^3). Because toxicity is entirely unpredictable, it is important to instruct patients to recognize clinical signs and symptoms of hematologic toxicity, such as infections, fatigue, ecchymosis, and abnormal bleeding, and to notify the physician if they develop. To improve compliance, carbamazepine should be started at a low dose (e.g., 50 mg twice daily) and increased over several weeks to a therapeutic level (200 to 300 mg four times a day).

Phenytoin also has well-known sodium channel-blocking effects and is useful for neuropathic pain (Swerdlow, 1984). However, carbamazepine is more effective than phenytoin for trigeminal neuralgia (Blom, 1962). Phenytoin has a slow and variable oral absorption. Toxicity includes CNS effects and cardiac conduction abnormalities. Side effects are common and include hirsuitism, gastrointestinal and hematologic effects, and gingival hyperplasia (Brodie & Dichter, 1996). Allergies to phenytoin are common, and may involve skin, liver, and bone marrow. Phenytoin doses in the range of 100 mg twice or three times a day may be helpful for neuropathic pain; therapeutic blood levels are in the range of 10 to 20 µg/ml. There are numerous potential drug interactions, including induction of cytochrome P450 enzymes, which may accelerate the metabolism of other drugs. Because of side effects and toxicity, phenytoin is not a first-line drug for neuropathic pain.

Valproic acid appears to interact with sodium channels but may also alter GABA metabolism. The principle use of valproic acid for neuropathic pain is for the prophylaxis of migraine headache (Matthew, et al., 1995). Potential

toxicity includes hepatic injury and thrombocytopenia, particularly in children on multiple antiepileptic medications, although valproic acid is generally considered safe for adults.

Divalproex sodium is better tolerated than valproic acid. The recommended starting dose is 250 mg twice daily, although some patients may benefit from doses up to 1000 mg/day. As a prophylactic drug, valproic acid can reduce the frequency of migraine attacks by about 50% (Matthew, et al., 1995). Although there is little published information on the efficacy of valproic acid for other neuropathic pain syndromes, based on its mechanism of action it may be useful alone or in combination with other adjuvant drugs.

Clonazepam may be useful for radiculopathic pain and neuropathic pain of a lancinating character. Clonazepam enhances dorsal horn inhibition by a GABAergic mechanism. The drug has a long half-life (18 to 50 h), which reduces the risk of inducing an abstinence syndrome on abrupt withdrawal. The major side effects of clonazepam include sedation and cognitive dysfunction, especially in the elderly. Although the risk of organ toxicity is minimal, some clinicians recommend periodic complete blood count (CBC) and liver function tests for monitoring. Starting doses of 0.5 to 1.0 mg at bedtime are appropriate to reduce the incidence of daytime sedation.

Gabapentin is a popular anticonvulsant for neuropathic pain. Gabapentin was released for use in the United States in 1994, for the treatment of adults with partial epilepsy. Almost immediately after its release, physicians began to use gabapentin for various neuropathic pain disorders, such as diabetic peripheral neuropathy and postherpetic neuralgia. The structural similarity of gabapentin to GABA suggested that the drug might be useful for neuropathic pain. Although tricyclic antidepressants have been proven clinically effective for neuropathic pain for years, they often fail to provide adequate pain relief or cause unacceptable side effects. Therefore, when gabapentin became available, its benign side effect profile quickly made it very popular among physicians. Although initial enthusiasm for the drug was based largely on word of mouth, anecdotal published reports, and discussions at clinical meetings, animal studies have substantiated the efficacy of gabapentin in various types of neuropathic pain. Over time, a growing consensus concerning the usefulness of gabapentin has emerged.

It is clear that gabapentin is not a direct GABA agonist, although indirect effects on GABA metabolism or action may occur. A leading hypothesis suggests that gabapentin interacts with a novel receptor on a voltage-activated calcium channel (Chaplan, 2000; Taylor, et al., 1998). Inhibition of voltage-gated sodium channel activity (such as occurs with classical anticonvulsants, e.g., phenytoin and carbamazepine) and amino acid transport, which alters neurotransmitter synthesis, may also occur. Although gabapentin is not an NMDA antagonist, there is evidence that gabapentin interacts with the glycine site on the NMDA receptor (Jun & Yaksh, 1998).

Ligation of rat spinal nerves L5 and L6 (the Chung model) produces characteristic pain behaviors, including allodynia, which are typical of neuropathic pain. Chapman, Suzuki, Chamarette, Rygh, and Dickenson (1998) demonstrated that gabapentin reduces pain in the Chung model. Gabapentin appears to act primarily in the CNS, in contrast to amitriptyline, which seems to act centrally and peripherally (Abdi, Lee, & Chung, 1998). Gabapentin also is effective in reducing pain behavior in phase 2 of the formalin test, a model of central sensitization and neuropathic pain (Shimoyama, Shimoyama, Davis, Inturrisi, & Elliott, 1997). Gabapentin reduces spinally mediated hyperalgesia seen after sustained nociceptive afferent input caused by peripheral tissue injury. Gabapentin also enhances spinal morphine analgesia in the rat tail-flick test, a laboratory model of nociceptive pain (Shimoyama, Shimoyama, Inturrisi, & Elliott, 1997).

Gabapentin is effective in reducing painful dysesthesias and improving quality of life scores in patients with painful diabetic peripheral neuropathy (Backonja, et al., 1998). Of patients randomized to receive gabapentin, 56% achieved a daily dosage of 3600 mg divided into three doses per day. The average magnitude of the analgesic response was modest, with a 24% reduction in intensity at the completion of the study compared with controls. Side effects were common. Dizziness and somnolence occurred in about 25% of patients, and confusion occurred in 8% of patients.

Morello, Leckband, Stoner, Moorhouse, and Sahagian (1999) compared gabapentin with amitriptyline for diabetic neuropathy and found both equally effective. Although gabapentin probably has fewer contraindications than tricyclic antidepressants, it is considerably more expensive.

Postherpetic neuralgia (PHN) is another difficult neuropathic syndrome. PHN affects approximately 10 to 15% of patients who develop herpes zoster, and is a particularly painful syndrome associated with lancinating pain and burning dysesthesias. The incidence of PHN is age-related, with up to 50% of patients older than 60 years of age developing persistent pain after a bout of herpes zoster. Pain relief usually requires pharmacological therapy. Unfortunately, most medications are not very effective. For example, only about one half of patients obtain adequate relief with antidepressants.

Rowbotham, Harden, Stacey, Bernstein, and Magnus-Miller (1998) evaluated the efficacy of gabapentin for the treatment of PHN. Of patients taking gabapentin, 65% achieved a daily dosage of 3600 mg. Although the average magnitude of pain reduction with gabapentin was modest, with approximately a 30% reduction in pain compared with controls, statistically pain reduction was

highly significant. In addition, gabapentin improved sleep parameters and quality of life scores. Adverse effects that occurred more commonly in the gabapentin group included somnolence (27%), dizziness (24%), ataxia, peripheral edema, and infection (7 to 10%). Based on the data of Rowbotham and colleagues, it is reasonable to consider gabapentin as first-line therapy for postherpetic neuralgia. Gabapentin probably is at least as effective as antidepressants, with fewer contraindications. Gabapentin may be used as monotherapy or adjunction treatment.

Although gabapentin can be started at 300 mg three times a day with most patients, giving the drug three times a day with meals and again at bedtime may be more effective. Use of a bedtime dose may assist with sleep and prevent pain from developing at night. With some patients, a more gradual titration may be better tolerated. In addition, this reduces the risk of patients stopping the drug because of side effects, before a therapeutic dose is achieved (David Longmire, personal communication, 2000). For example, start with a bedtime dose of 100 mg and then increase the daily dose to 100 mg twice a day with meals and at bedtime, for 2 days. Thereafter, the dose can be increased to three times a day with meals and at bedtime. Further titration every 3 to 7 days can be continued until pain relief, side effects, or a maximum daily dose in the range of 2400 to 3600 mg/day is reached. An instruction sheet for the patients is helpful in clarifying the dosage schedule and explaining possible side effects.

Gabapentin is generally well tolerated, even in the geriatric population, and has a safer side effect profile than tricyclic antidepressants. In the PNH study, the majority of patients were titrated to 3600 mg/day, and the median patient age was 73 years. The kidneys excrete gabapentin, and the dosage must be reduced for patients with renal insufficiency (Beydoun, Uthman, & Sackellares, 1995).

Antidepressants

Tricyclic antidepressants have been used for years for the management of neuropathic pain syndromes, including diabetic neuropathy, postherpetic neuralgia, and migraine headache (Max, 1994; McQuay, et al., 1996; Onghena & van Houdenhove, 1992). However, pain relief is often modest and accompanied by side effects. Controlled studies indicate that approximately one third of patients will obtain more than 50% pain relief, one third will have minor adverse reactions, and 4% will discontinue the antidepressant because of major side effects (McQuay, et al., 1996). Fortunately, some patients obtain excellent pain relief.

Because comparisons between tricyclic antidepressants have not shown great differences in efficacy (Max, 1994; McQuay, et al., 1996), the choice of which antidepressant to use often depends on the side effect profile of a given drug. For example, when a patient is having difficulty sleeping because of pain, a more sedating drug, such as amitriptyline, may be indicated. On the other hand, desipramine, which is less sedating, may be better tolerated in elderly patients.

The tricyclic antidepressants are generally highly protein bound with large volumes of distribution and long elimination half-lives. They undergo extensive hepatic first-pass metabolism and typically have active metabolites. Although effective doses may be lower than typically used for depression, this is often not the case. Patients must be warned of potential side effects including sedation, cognitive changes, and orthostatic hypotension from α-adrenergic blockade. Anticholinergic side effects are common and include constipation, urinary retention, and exacerbation of glaucoma. Antihistaminic effects may cause sedation. Because of their long half-lives, these drugs may be given as a single bedtime dose. To minimize side effects, small doses (e.g., 10 to 25 mg) are used initially and increased over several weeks to a therapeutic dose, generally in the range of 50 to 150 mg/day. An electrocardiogram (ECG) is recommended if there is a history of cardiac disease. ECG changes such as QRS widening, PR and QT prolongation, and T wave flattening can be induced by these agents. Tricyclic antidepressants may have quinidine-like actions, consistent with their sodium channel-blocking effects, particularly in patients with underlying ischemic cardiac disease or arrhythmias (Glassman, Roose, & Bigger, 1993). Because abrupt discontinuation of antidepressants may precipitate withdrawal symptoms, such as insomnia, restlessness, and vivid dreams, a gradual taper over 5 to 10 days is recommended. Occasional blood levels are recommended, as well as CBC and hepatic studies to monitor for organ toxicity.

Amitriptyline is a tertiary amine that inhibits norepinephrine and serotonin reuptake equally (American Medical Association Drug Evaluations Annual, 1993). Amitriptyline is probably the most commonly used tricyclic agent for neuropathic pain. Amitriptyline also is the most sedating of the tricyclic antidepressants and has the most potent anticholinergic effects. A starting dose of 25 mg at bedtime is recommended.

Amitriptyline is metabolized into nortriptyline, a secondary amine with twice as much inhibition of norepinephrine reuptake, compared with serotonin. Nortriptyline is less sedating than amitriptyline with less anticholinergic side effects. A starting dose of 10 mg at bedtime is generally well tolerated.

Imipramine is a tertiary amine with equal inhibition of norepinephrine and serotonin uptake. This drug is moderately sedating and has average anticholinergic effects. The suggested starting dose is 25 mg at bedtime. Because of unpredictable metabolism, occasional blood levels are suggested. Imipramine is metabolized to a secondary amine,

desipramine, which is a much more selective inhibitor of norepinephrine uptake. Desipramine is less sedating and has fewer anticholinergic effects than imipramine or amitriptyline, is at least as effective for pain control, and is better tolerated by elderly patients.

Compared with tricyclic agents, serotonin selective reuptake inhibitors (SSRIs) for neuropathic pain have been relatively disappointing. In addition, they are more expensive than the older generic agents. Nonetheless, at relatively high doses, (e.g., 60 mg) paroxetine is effective for diabetic neuropathy (Sindrup, Gram, Brosen, Eshj, & Morgensen, 1990). Fluoxetine may also be useful in the treatment of rheumatic pain conditions, many of which have neuropathic components (Rani, Naidu, Prasad, Rao, & Shobhar, 1996). SSRIs are better tolerated than tricyclic antidepressants and should be considered as a first-line drugs in patients with concomitant depression. In this group they may serve double duty.

Venlafaxine is a novel phentylethylamine antidepressant that is chemically distinct from the older tricyclic antidepressants and the serotonin selective uptake inhibitors. Although venlafaxine blocks serotonin and norepinephrine reuptake, its analgesic actions may be mediated by both an opioid mechanism and adrenergic effects (Shreiber, Backer, & Pick, 1999). The drug may be at least as well tolerated as tricyclic agents and more effective for pain than standard doses of serotonin-selective drugs. Indeed, an initial report suggests that venlafaxine is effective for neuropathic pain (Galer, 1995). Venlafaxine should be started at one half of a 37.5 mg tablet twice daily and titrated weekly to a maximum of 75 mg, taken twice a day. Nausea appears to be the most common side effect.

Antiarrhythmics

Antiarrhythmics block ectopic neuronal activity at central and peripheral sites (Chabal, Jacobson, Mariano, Chaney, & Britell, 1992). Lidocaine, mexiletine, and phenytoin — type I antiarrhythmics — stabilize neural membranes by sodium channel blockade. Lidocaine suppresses spontaneous impulse generation on injured nerve segments, dorsal root ganglia, and dorsal horn wide dynamic range neurons (Abram & Yaksh, 1994; Sotgiu, Lacerenza, & Marchettini, 1992). Lidocaine infusions have been used to predict the response of a given neuropathic pain disorder to antiarrhythmic therapy (Burchiel & Chabal, 1995). Lidocaine may be effective at subanesthetic doses, and following nerve blocks analgesia may outlast conduction block for days or weeks (Burchiel & Chabal, 1995; Chaplan, Flemming, Shafer, & Yaksh, 1995; Jaffe & Rowe, 1995). It has been reported that patients with PNS injury experience better pain relief than those with central pain syndromes (Galer, Miller, & Rowbotham, 1993). If a trial of infusion of lidocaine is effective, a trial of oral mexiletine is worth considering.

Prior to starting mexiletine, a baseline ECG is recommended if the patient has underlying ischemic heart disease. Dosages may be increased from 150 to 250 mg three times a day over several days. Taking the medication with food may minimize gastric side effects, which are common and a major reason for discontinuing the drug. Other side effects of mexiletine are nervous system effects such as tremor and diplopia. Once on a stable dose, a serum level should be obtained (the therapeutic range is between 0.5 and 2.0 μg/ml).

Topical preparations of local anesthetics may be effective for neuropathic pain when there is localized allodynia or hypersensitivity. Topical blockade of small- and large-fiber nerve endings should reduce mechanical and thermal allodynia. A topical lidocaine patch (Lidoderm 5% lidocaine) has become available, which can be applied to painful areas in shingles (herpes zoster). Up to three patches may be applied at one time to the painful area. The patches can be worn for up to 12 h a day. A topical cream, eutectic mixture of local anesthetic (EMLA cream), a mixture of lidocaine and prilocaine, may also be useful for cutaneous pain. The cream may be applied three or four times a day to the painful area.

Corticosteroids

Corticosteroids are clearly useful for neuropathic pain, particularly in stimulus-evoked pain such as lumbar radiculopathy. The anti-inflammatory effects of corticosteroids are well known, which may partly explain their efficacy for pain. When administered epidurally for treatment of discogenic radiculopathy, corticosteroids inhibit phospholipase A2 activity and suppress the perineural inflammatory response caused by leakage of disk material around the painful nerve root (Saal, et al., 1990). However, corticosteroids also act as membrane stabilizers by suppressing ectopic neural discharges (Castillo, et al., 1996; Devor, Govrin-Lippmann, & Raber, 1985). Therefore, some of the pain-relieving action of corticosteroids may be due to a lidocaine-like effect.

Depot forms of corticosteroids injected around injured nerves provide pain relief and reduce pain associated with entrapment syndromes. Corticosteroids are also effective if given orally or systemically. In cancer pain syndromes, steroids such as dexamethasone may be first-line therapy for neuropathic pain. The potential side effects of corticosteroids are well known and may be seen whether given orally, systemically, or epidurally.

Baclofen

Baclofen is useful for trigeminal neuralgia and other types of neuropathic pain (Fromm, Terrence, & Chattha, 1984),

particularly as an add-on drug. Baclofen is a GABA-B agonist and is presumed to hyperpolarize inhibitory neurons in the spinal cord (Yaksh & Malmberg, 1994), thereby reducing pain. This GABA effect appears to be similar to benzodiazepines, such as clonazepam. Side effects of baclofen can be significant and include sedation, confusion, nausea, vomiting, and weakness, especially in the elderly. A typical starting dose is 5 mg three times a day. Thereafter, the drug can be increased slowly to 20 mg four times a day. Abrupt cessation may precipitate withdrawal with hallucinations, anxiety, and tachycardia. The drug is excreted by the kidneys and the dosage must be reduced in renal insufficiency.

Capsaicin

Capsaicin is a C-fiber-specific neurotoxin and is one of the components of hot peppers that produces a burning sensation on contact with mucous membranes. Topical preparations are available over the counter and are widely used for chronic pain syndromes. Capsaicin is a vanilloid receptor agonist and activates ion channels on C fibers that are thermotransducers of noxious heat (>43° C) (Caternia, et al., 1997). With repeated application in sufficient quantities, capsaicin can inactivate primary afferent nociceptors. For patients with pain due to sensitized nociceptors, capsaicin may be effective, if they can tolerate the pain induced by the medication. The drug causes intense burning, which may abate with repeated applications and gradual inactivation of the nociceptors. However, in patients with tactile allodynia, which is probably mediated by large fibers, capsaicin may not be as effective. Capsaicin extracts are available commercially as topical preparations, containing 0.025 and 0.075% and should be applied to the painful area three to five times a day. The preparation may be better tolerated if it is used after application of a topical local anesthetic cream.

SUMMARY AND RECOMMENDATIONS

Neuropathic pain is a common cause of chronic pain and tends to be resistant to usual doses of traditional analgesic medications. Classic examples of neuropathic pain include trigeminal neuralgia, postherpetic neuralgia, and diabetic neuropathy. Neuropathic pain is often described as lancinating or burning in nature. Both types of pain may be present at the same time, often accompanied by allodynia.

Neuropathic pain may be manageable with one or more adjuvant analgesic drugs, often prescribed as part of a comprehensive treatment plan. From a theoretical point of view, it may be helpful to categorize adjuvant analgesics into two broad classes of drugs, agents that act as membrane-stabilizing agents and drugs that enhance dorsal horn inhibition. Membrane-stabilizing drugs may act by blocking sodium and calcium channels on damaged neural membranes. Medications that enhance dorsal horn inhibition appear to act by augmenting spinal biogenic amine and GABAergic mechanisms. From a clinical standpoint, given the paucity of our understanding of neuropathic pain mechanisms and how the medications actually work, it is probably more useful to classify adjuvant drugs according to their traditional therapeutic indications (e.g., antidepressants and anticonvulsants). This point of view is strengthened by the fact that most drugs appear to have multiple mechanisms and sites of action, making further subclassification arbitrary and probably inaccurate.

Anticonvulsants, particularly carbamazepine (and more recently gabapentin), are useful for neuropathic pain. Although conventional wisdom suggests that anticonvulsants may be most effective for lancinating pain, anticonvulsants also are useful for burning dysesthesias. The mechanism of action of gabapentin is poorly understood, but the drug has been demonstrated to bind to a novel voltage-dependent calcium channel receptor. Gabapentin reduces the pain due to diabetic peripheral neuropathy and postherpetic neuralgia; and the overall safety record with gabapentin is good, making it an attractive alternative to carbamazepine and tricyclic antidepressants, particularly for elderly patients.

Clonazepam is another option and also poses minimal risk from the standpoint of organ toxicity. Clonazepam may be useful for radicular pain and pain associated with tumors, such as plexopathy. In addition, clonazepam may be used to supplement other adjuvant drugs. When given at bedtime, the mild sedating effect of clonazepam can be helpful for patients who have difficulty sleeping because of pain.

Antidepressants have been used effectively for years in the management of multiple pain syndromes, including diabetic neuropathy, postherpetic neuralgia, rheumatoid arthritis, osteoarthritis, migraine headache, low back pain, and fibromyalgia. However, pain relief is often modest and accompanied by side effects. Studies indicate that only one third of patients obtain more than 50% pain reduction. However, some patients obtain dramatic pain relief.

The choice of which antidepressant to use for neuropathic pain often depends on the particular side effect profile of a given drug, because comparisons of individual tricyclic antidepressants have not shown great differences in efficacy. When a patient is having difficulty sleeping because of pain, a more sedating drug, such as amitriptyline is appropriate. On the other hand, desipramine, which is considerably less sedating and has fewer anticholinergic effects, may be much better tolerated in elderly patients.

Serotonin-selective reuptake inhibitors for neuropathic pain have been disappointing, although paroxetine at relatively high doses is useful for diabetic neuropathy. Fluoxetine may be useful in the treatment of rheumatic

pain conditions, many of which have neuropathic components. As with the tricyclic agents, the SSRIs are probably interchangeable. However, SSRIs are better tolerated than tricyclics and may be extremely effective in treating patients with chronic pain and concomitant depression.

It remains unclear whether anticonvulsants or antidepressants should be first-line therapy for neuropathic pain. Similar results have been obtained with both, and current evidence concerning drug efficacy does not support the use of one drug over another. In many cases, selection of a particular drug may depend more on expected side effects (e.g., sedation) or the clinician's experience with the drug, than theoretical considerations about mechanisms of drug action. It must be remembered that treatment of neuropathic pain remains largely empirical. In addition, for maximum analgesic benefit, more than one drug may be necessary. Until more effective medications become available, polypharmacy will remain the rule instead of the exception. This is probably understandable, given the multiple mechanisms involved in the pathophysiology of neuropathic pain.

In general, for neuropathic pain either gabapentin or amitriptyline (or a similar tricyclic antidepressant) should be first-line therapy. When considering issues such as time to effective analgesic action and toxicity, gabapentin is more attractive. In our clinic, gabapentin often is our first choice, followed by a tricyclic antidepressant, such as nortriptyline. Both drugs must be started slowly and titrated to effect, perhaps to rather high levels, for full benefit. However, tricyclics have many potential side effects that must be considered, particularly anticholinergic and cardiac interactions and organ toxicity. Clearly, gabapentin is a safer drug, but may cause sedation or dysphoria in some patients. Occasionally, patients complain of weight gain and nonpitting edema. Other disadvantages of gabapentin include its cost (approximately ten times the cost of a generic tricyclic antidepressant at usual starting doses) and the need to take the drug three or four times a day. Keep in mind that the dosage of gabapentin must be reduced appropriately for patients with renal insufficiency. A comparison of gabapentin with tricyclic antidepressants is provided in Table 17.3.

When an appropriate medication trial has been ineffective, an interdisciplinary approach should be considered. With chronic neuropathic pain, limitations of current analgesics usually make complete pain relief a very unrealistic goal. Therefore, improving function and comfort and treating associated problems, such as depression, become important goals. Reducing dependence on opioid medications may or may not be a primary goal, depending

TABLE 17.3
Comparison of Gabapentin and Generic Tricyclic Antidepressants: Dosages, Side Effects, and Cost

Drug	Dosage	Side effects	Approximate Cost to Patient
Gabapentin (Neurontin)	Starting dose: 300 mg b.i.d. to t.i.d. (patient may start with bedtime dose) Elderly patients: 100 mg twice a day Effective dose: 1800 to 2400 mg/day (25 mg/kg/day); e.g., 600 mg with meals and at bedtime) Note: studies used doses as high as 3600 mg/day Titrate by increasing daily dose every 3 to 7 days, patient instruction sheet helpful	Somnolence, dizziness, ataxia, and peripheral edema. Reduce dosage in renal insufficiency	300 mg capsules t.i.d.: $106/month ($118/100 capsules) No laboratory studies needed to monitor therapy.
Amitriptyline	Starting dose: 25 mg at bedtime; elderly patients: 10 mg at HS Effective dose: 25 to 150 mg/day Titrate by increasing daily dose every 7 days; patient instruction sheet helpful	Sedation, cognitive problems, anticholinergic side effects, weight gain, orthostatic hypotension, arrhythmias; rare hepatic injury	25 mg tablets at bedtime: $7.80/month ($26/100 tablets) Laboratory studies needed to monitor therapy; consider baseline ECG
Nortriptyline	Starting dose: 10 mg at HS; effective dose: 10 to 100 mg/day Titrate by increasing daily dose every 7 days; patient instruction sheet helpful	Less sedation, fewer anticholinergic effects than amitriptyline; otherwise same effects as amitriptyline	10 mg tablets at bedtime: $12/month ($40/100 tablets) 25 mg tablets at bedtime: $24/month ($80/100 tablets) Lab studies, ECG
Desipramine	Starting dose: 25 mg at bedtime; elderly patients: 10 mg HS Effective dose: 25 to 150 mg/day Titrate by increasing daily dose every 7 days, patient instruction sheet helpful	Less sedation, less anticholinergic effects, otherwise same effects as amitriptyline	25 mg tablets at bedtime: $9/month ($30/100 tablets) Lab studies, ECG

on whether the pain syndrome is opioid responsive, the patient is demonstrating appropriate improvements in function, and there are not undo side effects or evidence of drug abuse.

Current evidence indicates that nonpharmacological approaches may be reasonable, obviate or reduce the need for potentially toxic medications, and improve the effectiveness of analgesic regimens. Spinal cord stimulation may reduce pain in selected patients. Less invasive techniques, including TENS units and percutaneous nerve stimulation, are also beneficial.

Effective management of neuropathic pain requires patience on the part of the clinician and the patient, and the willingness to evaluate different treatment approaches, including trials of various medications. This may be a time-consuming process. Insofar as possible, it is helpful to target specific symptoms, for example, burning pain with tricyclic antidepressants and lancinating pain with anticonvulsants. However, from a practical standpoint, pharmacological choices are often based on physician comfort with a given drug and expected side effects. Moreover, the high cost of newer drugs may make the older tricyclic antidepressants, such as amitriptyline, the only cost-effective alternative for some patients. Until more effective drugs become available, the pharmacological approach remains largely one of trial and error. In the meantime, nonpharmacological strategies may assume a larger role in clinical practice.

Primary Headache Disorders

R. Michael Gallagher, D.O., F.A.C.O.F.P., F.A.H.S.

MANAGEMENT OF PRIMARY HEADACHE DISORDERS

Introduction

Headache disorders are an exceedingly common patient complaint that have been described throughout recorded medical history. Symptoms of head pain were noted as early as 7000B.C. (Lyons & Petrucelli, 1978), and Neolithic trepanned skulls suggest the extreme measures once taken to relieve head pain that was attributed to evil spirits (Venzmer, 1972, p. 19). Currently, the National Headache Foundation (2000) reports that more than 45 million Americans have chronic, recurring headaches. Each year, U.S. businesses lose approximately $50 billion to absenteeism and medical expenses caused by headache, and headache sufferers spend in excess of $4 billion on nonprescription analgesics (NHF, 2000). Headache is responsible for approximately 10 million physician consultations per year (Linet & Stewart, 1987), and it is the fourth most common reason for emergency room visits in the United States.

Although the last two decades of the 20th century produced significant advances in our understanding of headache, the precise pathophysiology of the primary headache disorders remains unknown. For many years, primary headaches were classified symptomatically, as eithervascular headaches (migraine and cluster) or nonvascular headaches (tension type). Technological advances in the 1980s allowed researchers to see for the first time that changes in cerebral blood flow during headache episodes, particularly in migraine, did not occur exclusively in areas defined by vascular boundaries.

The Headache Classification Committee of the International Headache Society (IHS) ([ACCIHS], 1988) published a classification system for headache disorders. Although they were designed to help diagnose patients for clinical trials, the IHS criteria reflect international expert consensus and, unlike earlier headache diagnostic criteria (Friedman, Finley, & Graham, 1962), they outline the specific characteristics necessary to confirm and to exclude a broad range of headache disorders. According to the IHS, most chronic or recurring head pain can be classified as one of the "primary headache disorders": tension type, migraine, or cluster. Each of these headache types, as the descriptor suggests, can occur without the presence of an underlying disorder. The IHS system classifies all other types of headache as "secondary headache disorders," because they can always be attributed to one of hundreds of indirect causes of head pain (e.g., fever, trauma, subarachnoid hemorrhage, medication). This chapter reviews the diagnosis and treatment of the three primary headache disorders.

Overall Approach

The vast majority of headache patients can be successfully treated. When therapy is successful, the management of headache can be extremely rewarding for the patient and for the physician. Therapy can be time consuming and difficult in some cases, however. When it does not succeed, or it succeeds only partially, the challenge can quickly become frustrating. Help for headache sufferers rests with the empathetic, knowledgeable medical professional who is willing to establish an honest partnership that aims at relieving symptoms, restoring function, and reducing disability, not toward "curing" their "problem". In many cases, a clinician's ability to educate patients is key; all headache patients should clearly understand the goals of their treatment plan. Unfortunately, many headache

0-8493-0926-3/02/$0.00+$1.50

patients seek medical attention during severe attacks, which demand immediate attention and prevent the evaluation necessary to making an accurate diagnosis. The most productive time for assessment is when the patient is headache free or not so debilitated as to interfere with a complete history taking and examination. After the diagnosis is made, the clinician and patient can develop a realistic, achievable treatment plan.

There are two main elements of headache treatment. Abortive treatment aims at relief once a headache attack has begun, and prophylactic treatment is used to prevent or reduce the likelihood of headache episodes before they occur. Abortive treatment is used for patients whose headaches are infrequent and for those headaches that break through in spite of prophylactic therapy. When headaches are frequent or unresponsive to abortive medication, prophylactic measures should be taken. Many clinicians begin prophylaxis when a patient has more than three severe headache attacks per month.

Whether preventive or abortive therapy is indicated, management should follow a definite plan incorporating the physician and the patient into a team that works actively to reduce the frequency and/or severity of headaches. The physician's impressions and physical findings should be completely explained to the patient no matter what level and pace are required to ensure complete understanding. The headache condition should also be explained, emphasizing the fact that the disorder is real, not imagined, and that it is controllable, not curable. Once a plan is developed, follow-up and continuing care are important elements in a successful outcome.

TENSION-TYPE HEADACHE

In the 1988, IHS classification of headache, a headache type once known as "muscle contraction headache" was renamed "tension-type headache" (TTH) (HCCIHS, 1988). Traditionally, it was believed that TTH was caused by sustained muscle contraction of the neck, jaw, scalp, and facial muscles. It has since been learned, however, that the sustained contraction of pericranial muscles associated with TTH may occur as an epiphenomenon to possible central disturbances, not as a primary process. Alterations in the levels of serotonin (5-HT), substance P (SP), and neuropeptide Y in the serum or platelets have been shown in patients affected by TTH, leading to speculation that these neurotransmitters are involved in the genesis and modulation of pain in the condition (Ferrari, 1993; Gallai, et al., 1994; Nakano, Shimomura, Takahashi, & Ikawa, 1993; Rolf, Wiele, & Brune, 1981; Schoenen, 1990; Shukla, Shanker, Nag, Verma, & Bhargava, 1987; Takeshima, Shimomura, & Takahashi, 1987). Without concrete evidence of central activity, however, the cause of TTH remains unknown.

TTH is the most common type of headache and is considered to have episodic (ETTH) and chronic (CTTH) variants. One-year period prevalence estimates using the IHS criteria indicate that as many as 93% of the general population have at least one tension-type headache per year (Rasmussen, Jensen, Schroll, & Olesen, 1991), although some investigators have found ETTH rates as low as 14.3% (Lavados & Tenhanun, 1997). CTTH sufferers (more than 180 headache attacks per year) are far less common than ETTH sufferers; the highest 1-year period prevalence ever recorded for CTTH was 8.1% (Tekle Haimanot, Seraw, Forsgren, Ekborn, & Ekstedt, 1995).

Both ETTH and CTTH are characterized by intermittent or persisting bilateral pain, often described as a squeezing pressure or a tight band around the head. Some patients experience pain in the temporal or occipital regions, the forehead, or the vertex. The location of symptoms can vary from attack to attack, and associated tightness of the neck and shoulders is common. Unlike migraine, TTH is not preceded by prodromal symptoms, and TTH are not episodes typically associated with nausea or vomiting. The intensity of pain in TTH varies widely, but it is not usually incapacitating. TTH can last from hours to days and, in some cases, persist for months. The IHS diagnostic criteria for ETTH and CTTH are listed in Table 18.1 (HCCIHS, 1988).

Precipitating Factors

TTH frequently occurs during periods of stress or emotional upset. Some CTTH patients may display evidence of anxiousness, as well as poor coping and adaptation skills. If headaches are frequent or near daily, depression may be involved and should be considered, even in the absence of obvious signs, such as mood changes, crying spells, or loss of appetite. Organic processes may also be involved in the precipitation of TTH. When the cause is organic instead of psychogenic, the pain may also be resistant to usual treatment modalities. Organic causes can be numerous, but the more commonly encountered in clinical practice include degenerative joint disease of the cervical spine, head or neck trauma, temporomandibular joint dysfunction, or ankylosing spondylitis.

Treatment

ETTH can be resolved with nonpharmacological measures, analgesic medications, or some combination of these modalities. Nonpharmacological options for TTH include manipulation, massage, exercise, cold or warm compresses, stress avoidance, and relaxation techniques (Table 18.2) (Stevens, 1993). When these approaches do not provide adequate relief, simple analgesics, such as acetaminophen (APAP), aspirin (ASA), or ibuprofen (IB), often relieve the symptoms of ETTH. If simple analgesics

TABLE 18.1
IHS Diagnostic Criteria for Episodic Tension-Type Headache

A. At least 10 previous headache episodes fulfilling criteria B to D listed next; number of days with such headache < 180/year (< 15/month)
B. Headache lasting from 30 min to 7 days
C. At least two of the following pain characteristics:
   - Pressing/tightening (nonpulsating) quality
   - Mild or moderate intensity (may inhibit, but does not prohibit activities)
   - Bilateral location
   - No aggravation by walking stairs or similar routine physical activity
D. Both of the following:
   - No nausea or vomiting (anorexia possibly occurring)
   - Photophobia and phonophobia are absent, or one but not the other is present
E. At least one of the following:
   - History, physical, and neurological examinations not suggesting one of the disorders listed in groups 5 to 11
   - History and/or physical and/or neurological examinations suggesting such disorder, but ruled out by appropriate investigations
   - Such disorder present, but tension-type headache not occuring for the first time in close temporal relation to the disorder

fail, caffeinated combination analgesics often provide effective relief. In TTH studies, it has been shown that it takes about 40% more of a simple analgesic to equal the analgesic potency of the simple analgesic plus caffeine (Laska, et al., 1984; Migliardi, Armellino, Friedman, Gillings, & Beaver, 1994). If a prescription is required to provide adequate relief, some patients with ETTH benefit from the combination of isometheptene, acetaminophen, and dichloralphenazone. Other options include the alpha-agonist tizanidine, ASA combined with the muscle relaxants orphenadrine or carisoprodol, or APAP added to chlorzoxazone. In some patients, the symptoms of TTH can be extremely severe and require potentially addictive analgesic combination drugs containing butalbital, meprobromate, or an opioid. These drugs provide analgesia and reduce the anxiety often associated with pain (Table 18.3). As with any potentially addicting drug, however, limit the amounts prescribed and make sure that patients understand that they should contact you about a change in prescription instead of beginning daily or near-daily use of a medication with a high risk of addiction.

Patients with CTTH require a different approach. Prescribing the stronger medications in this patient subset greatly enhances the risk of abuse. Prophylactic treatment may be needed for CTTH patients or for those whose attacks are caused by organic abnormalities. Pharmacological treatment of CTTH can include the judicious use

TABLE 18.3
Selected Prescription Medications for Tension-Type Headache

Drug	Brand Name	Dose — Prn
Aspirin	Bayer	650 mg every 4–6 h
Acetaminophen	Tylenol	500–1000 mg every 4–6 h
Aspirin/acetaminophen/caffeine	Excedrin	2 tablets every 4–6 h
Ibuprofen	Advil/Motrin	400 mg every 4–6 h
Naproxen	Aleve	275–550 mg every 6–8 h
Orphenadrine/aspirin/caffeine	Norgesic	2 tablets every 4 h
Isometheptene/dichloralphenazone/acetaminophen	Midrin	2 tablets at onset followed by 1 tablet hourly (up to 5 tablets)
Carisoprodol/aspirin	Soma compound	2 tablets every 4 h
Chlorzoxazone	Parafon Forte	1 tablet every 4–6 h
Butalbital/aspirin/caffeine	Fiorinal	1 tablet every 4 h
Butalbital/acetaminophen/caffeine	Fioricet/Esgic	1 tablet every 4 h
Tizanidine	Zanaflex	2–4 mg every 4 h

of sedatives or muscle relaxants, but most patients who respond do so only temporarily, and the risk of habituation is significant.

The nonsteroidal anti-inflammatory drugs (NSAIDs) and antidepressants appear to be the most useful in preventing TTH (Gallagher & Freitag, 1987b). Most CTTH patients who improve with NSAID treatment do so in 2 to 3 weeks. Side effects of the NSAIDs include fluid retention, nausea, diarrhea, dizziness, and gastric and duodenal irritation. Renal function monitoring must be done periodically to avoid renal injury in patients who take NSAIDs regularly. Antidepressants, in a single bedtime dose, may also be effective in reducing the frequency of CTTH pain. Therapeutic response can take as long as 4 weeks. The regimen should begin with a low dose and gradually be titrated to the individual patient's needs. Side effects vary depending on the agent and the patient, but they most frequently include drowsiness, postural hypotension, weight gain, constipation, and dry mouth.

Nonpharmacological options for CTTH include manipulation and soft tissue massage techniques to the scalp, cervical, or thoracic areas, reduction of stress and muscle tension, and biofeedback. Consider psychotherapeutic interventions for patients whose headaches are related to significant emotional conflict or are treatment refractory. Choices can range from supportive to long-term and may involve the family physician, psychiatrist, or psychologist.

MIGRAINE

An estimated 28 million Americans, about 18% of women and 6% of men, suffer from migraine (Stewart, Lipton, Celentano, & Reed, 2000). This chronic, neurologic disorder is characterized by periodically recurring attacks of head pain that are accompanied by gastrointestinal, visual, and auditory disturbances (HCCIHS, 1988). Although the intensity and severity of attacks tend to vary throughout the migraine population, as well as within the same migraineur over a series of episodes, estimates suggest that pain and disability are mild in approximately 5 to 15% of attacks, moderate to severe in 60 to 70% of attacks, and incapacitating in 25 to 35% of attacks (Stewart, Schecter, & Lipton, 1994). The disorder occurs most frequently among persons aged 25 to 55 (Stewart, Lipton, Celentano, & Reed, 1992), concentrating its burden on those who are typically in their most productive years. Migraine patients consistently report lower mental, physical, and social well-being than do unaffected controls (Terwindt, et al., 2000; Lipton, et al., 2000).

According to the IHS, migraine is an "idiopathic, recurring headache disorder manifesting in attacks lasting 4–72 hours. Typical characteristics of headache are unilateral location, pulsating quality, moderate to severe intensity, aggravation by routine physical activity, and association with nausea, photo-, and phonophobia" (HCCIHS, 1988). Migraine does not occur on a daily basis; typical frequency is one to four per month. In some patients, the migraine may occur once yearly or as often as 15 to 20 times per month.

Migraine pain typically affects one side of the head, and may switch sides. The headache can become generalized. Many patients report that their pain localizes around or behind the eye, or in the frontotemporal area. The pain may radiate toward the occiput or upper neck during an attack. The shoulder and lower portion of the neck may also be involved. In some cases, the pain radiates to the face.

A number of associated symptoms can accompany the pain of an acute attack. Nausea or vomiting, in addition to either photophobia or phonophobia, are required for the diagnosis of migraine (HCCIHS, 1988). However, dizziness, lightheadedness, blurred or double vision, anorexia, constipation, diarrhea, chills, tremors, cold extremities, ataxia, and dysarthria may also be present. Some patients may experience lethargy and fatigue for several days following an attack.

A prodrome or aura often precedes migraine attacks. Aura symptoms are usually visual, typically start just before the acute headache, and continue for less than 1 h. Prodromal symptoms include scotomata, teichopsia, fortification spectra, photopsia, paresthesias, visual and auditory hallucinations, hemianopsia, and metamorphopsia (Diamond, 1997). Despite the absence of visual and other prodromal characteristics, migraine without aura sufferers have also described premonitions of impending migraine attacks. These symptoms are usually vague and can occur from 2 to 72 h before an attack. The list of painless warnings includes hunger, anorexia, drowsiness, depression, irritability, tension, restlessness, talkativeness, excess energy, and euphoria. Table 18.4 lists the complete IHS criteria for migraine with aura and migraine without aura (HCCIHS, 1988).

Precipitating Factors

Certain factors, known as "triggers," can play a precipitating role in the onset of migraine attacks. Migraine triggers can be categorized as physiological, psychological, or external stimuli. Although they are highly individualized, some of the most common migraine triggers appear in Table 18.5.

Physiological

Migraine sufferers can be particularly sensitive to changes in eating and sleeping patterns. Fasting or missing a meal is a known headache trigger. All migraine patients should be encouraged to maintain a regular meal schedule. Over- or undersleeping can also precipitate a migraine. Migraine attacks that occur on weekends, on

TABLE 18.4
IHS Diagnostic Criteria for Migraine without Aura and Migraine with Aura

Migraine without Aura

A. At least five attacks fulfilling B–D
B. Attack lasts 4–72 h (untreated or unsuccessfully treated)
C. Attack with at least two of the following characteristics:
   - Unilateral location
   - Pulsating quality
   - Moderate or severe intensity (inhibits or prohibits daily activities)
   - Aggravation by walking stairs or similar routine physical activity
D. During attack at least one of the following:
   - Nausea and/or vomiting
   - Photophobia and phonophobia
E. At least one of the following:
   - History, physical, and neurological examinations not suggesting a secondary disorder
   - History, physical, and/or neurological examinations suggesting such disorder, but ruled out by appropriate investigations
   - Such disorder present, but migraine attacks not occurring for the first time in close temporal relation to the disorder

Migraine with Aura

A. At least two attacks fulfilling B
B. At least three of the following four characteristics:
   - One or more fully reversible aura symptoms indicating focal cerebral cortical and/or brain stem dysfunction
   - At least one aura symptom developing gradually over more than 4 min or, 2 or more symptoms occuring in succession
   - No aura symptom lasting more than 60 min, if more than one aura symptom present, accepted duration is proportionally increased
   - Headache following aura with a free interval of less than 60 min (may also begin before or simultaneously with the aura)
C. At least one of the following:
   - History, physical, and neurological examinations not suggesting a secondary disorder
   - History, physical, and/or neurological examinations suggesting such disorder, but ruled out by appropriate investigations
   - Such disorder present, but migraine attacks not occurring for the first time in close temporal relation to the disorder

TABLE 18.5
Recognized Migraine Triggers

Physiological	Psychological	External
Fasting, missing a meal, or other changes in eating patterns	Stress (external or unconsciously created by patient)	Bright or flickering lights
Over- or undersleeping	Repressed hostility	Loud noises
Oral contraceptives in migraine patients	Depression	Strong odors
Cyclical hormonal changes; hormone replacement therapy in postmenopausal women	Fear	Rapid changes in barometric pressure; travel to areas with different altitudes
Food triggers including: Alcoholic drinks, Coffee, tea, and cola, Aged cheese, Chocolate, Cured meats, Chinese food, Smoked fish, nuts, and pickled or marinated foods	Anger	Airline flights
Drugs: Atenolol, Caffeine (and caffeine withdrawal), Danazol, Diclofenac, H2 receptor blockers, Hydralazine, Indomethacin, Nifedipine, Nitrofurantoin, Nitroglycerin, Oral contraceptives, Reserpine	Anxiety	Allergens

holidays, or during vacations have been linked to oversleeping (Wilkinson, 1986). To avoid "weekend" headaches, patients should be instructed to go to bed only when they are tired and to arise at the same time each day. Lack of sleep and fatigue may also provoke an acute migraine attack.

A relationship between the menstrual cycle and migraine attacks is well documented and partially accounts for the higher prevalence of migraine in women. Among female migraineurs, 60 to 70% note a menstrual link to their migraine attacks, with severe attacks occurring immediately before, during, or after their period (Diamond, 1997). Many report a remission of migraine after the first trimester of pregnancy. Many female patients see a reduction in frequency or complete remission of their headaches after menopause (Honkasalo, Kaprio, Heikkilä, Sillanpää, & Koskenvuo, 1993). Oral contraceptives should be used judiciously in migraine patients, because these drugs have long been known to increase the frequency, severity, duration, and complications of migraine (Whitty, Hockaday, & Whitty, 1966). Also, hormone replacement therapy (HRT) should be avoided in postmenopausal migraineurs, because these hormones can exacerbate or restart migraine attacks. However, side effects have been reduced with the patch delivery system and lower doses of estrogen, as well as with progesterones.

The link between diet and migraine depends on the individual patient. The amines, including tyramine and

phenylethylamine, nitrates, monosodium glutamate (MSG), and alcohol, have all been implicated as triggers. Tyramine is found in aged cheese, pickled foods, fresh-baked yeast breads, and marinated foods. Another amine, phenylethylamine, is contained in chocolate. The nitrates, which promote vasodilation, are found in cured meats. Many food additives and Chinese foods contain MSG, which has been associated with headache. Alcohol has both central and direct vasodilating properties, and, in some patients, migraine attacks can be precipitated, especially with wine. Other possible triggers for migraine include caffeine, nicotine, ergotamine, hypoglycemia, allergy, ingestion of ice cream, and monoamine oxidase inhibitors (MAOIs). Migraineurs who are sensitive to dietary triggers should be instructed to avoid the substances to which they are susceptible whenever possible.

Psychological

Stress is probably the most readily identified psychological trigger of an acute migraine attack. However, many migraine patients remain headache free during a stressful period only to experience a severe headache when the stress has resolved. Depression, fear, anger, anxiety, and repressed hostility may also be associated with migraine. Although avoiding stress is difficult, reducing stress is not, and instruction on coping methods may be beneficial for "overloaded" patients. Other psychological triggers may require additional counseling, concomitant treatment, or both.

External Stimuli

Some migraine patients describe a relationship between their headaches and weather. Rapid changes in barometric pressure as well as extreme variations in weather have been shown to provoke a migraine attack in certain patients (Diamond, Nursal, Freitag, & Gallagher, 1989). During or subsequent to travel to an area with an altitude substantially different from the patient's norm (i.e., the mountains for those who live at sea level and vice versa), a patient may report an increase in headache frequency. A diuretic, such as acetazolamide, used on the day of a flight may help to prevent these headaches. Other external migraine triggers include bright or flashing lights, loud noises, and strong odors (such as smoke, perfume, or cleaning fluids).

Treatment

With a confirmed diagnosis of migraine, the clinician and patient should begin to devise a treatment plan that accounts for the practical realities of the patient's lifestyle. Migraine treatment plans usually involve some combination of behavioral change (avoiding triggers, increasing exercise, and relaxation) and pharmaceutical and nonpharmaceutical pain management approaches (prophylactic or abortive medications, manipulation and massage, cold compresses, or warm baths). Determining the relative value of these strategies for each patient shapes the course of both acute and long-term therapy.

Behavioral changes and nonmedicinal treatments can be valuable, particularly in patients with frequent or severe migraine attacks. Most treatment plans incorporate behavioral modification in the form of avoiding foods, beverages, or situations that trigger attacks; each patient is unique in this regard. Similarly, the use of cold compresses, warm baths, or massage for migraine should be governed by the nature of the individual's disorder.

If medication is a part of the treatment plan, the selection can be tailored to the migraine patient's needs. Before recommending or prescribing any medication for migraine, however, it is crucial to determine all remedies the patient may have already tried before consulting, because detailed information in this area may reveal important therapeutic limitations and opportunities. Familiarity with the wide range of options for migraine pharmacotherapy can increase the likelihood of meeting an individual patient's needs.

Standard Migraine Medications

Pharmacological therapy is often the main component in migraine therapy. There are three broad categories of pharmacological treatment of migraine: prophylactic, abortive, and symptomatic. If migraine attacks occur four or more times per month, or if attacks are incapacitating, many clinicians consider prophylactic therapy. If a patient has three or fewer migraine attacks per month, abortive treatment may be indicated. When acute pain does not respond to abortive measures, symptomatic therapy can be employed as a backup.

Prophylactic Treatment

Prophylactic medications are used to prevent the onset of migraine attacks and to reduce their frequency and severity. The decision about which class to use generally depends on comorbidities and interactions with concomitant medications. Beta-blockers, for example, could be used in patients with hypertension but are contraindicated in those with asthma (Rapoport & Adelman, 1998); a depressed patient taking a selective serotonin reuptake inhibitor (SSRI) should not take an MAOI for migraine because of dangerous interactions. Drugs currently approved for long-term use in migraine prophylaxis include propanolol, timolol, divalproex sodium, and methysergide (Diamond, 1997).

Propanolol, an adrenergic blocker, one of the most frequently used drugs in the prophylactic therapy of migraine, must be given carefully in patients with coronary heart disease and thyrotoxicosis. It may exacerbate

coronary ischemia and can produce unstable angina or myocardial infarction (Diamond, 1997). Propanolol is contraindicated in patients with asthma, chronic obstructive lung disease, congestive heart failure, or arterioventricular conduction disturbances. In some patients, administration may cause depression, nightmares, lethargy, fatigue, sexual dysfunction, and weight gain (Rapoport & Adelman, 1998). Patients being treated with insulin, oral hypoglycemia drugs, or MAOIs should not be treated with propanolol. Propanolol is administered from 60 to 240 mg/day in a simple, long-acting dosage or in divided doses. If propanolol is not tolerated, timolol, another beta-blocker, can be used in doses of 5 to 30 mg/day. Other beta-blockers, such as nadolol, atenolol, and metoprolol, have been used with varying degrees of success.

The alpha agonist, clonidine, may be useful for migraineurs who are sensitive to cheeses and other foods containing tyramine (Diamond, 1997). Side effects are usually mild and include drowsiness, dry mouth, constipation, and occasional disturbance of ejaculation. Mild orthostatic hypertension and depression may also occur.

Divalproex sodium is FDA approved for migraine prevention and is particularly indicated for migraineurs with epileptic seizures, bipolar disorder, and possibly head trauma (Rapoport & Adelman, 1998). An extended-release formulation of divalproex, which produces less fluctuation in plasma concentrations than the standard therapy, is also available. The recommended starting dose for the extended-release formulation is 500 mg daily and can be increased to 1000 mg daily. Divalproex sodium should be avoided in any patient with a history of hepatitis or abnormal liver function; it is contraindicated in pregnancy, because it is associated with neural tube defects. Divalproex sodium can be effectively combined with tricyclic antidepressants in patients with chronic recurrent migraine.

Closely related (and similar in some long-term effects) to ergotamine and its derivatives, methysergide promotes serotonin inhibition and mild vasoconstriction. This agent is usually prescribed in doses of 2 mg three times a day (t.i.d.) and should not be used for more than 4 consecutive months, after which a minimum 1-month hiatus is required before resuming therapy. Approved by the FDA for migraine prophylaxis, the drug's sustained use is contraindicated because of the potential for cardiopulmonary and retroperitoneal fibrosis (Diamond, 1997). During the treatment period, the patient should be examined at regular intervals to detect the development of fibrotic conditions, murmurs, or pulse deficits.

Topiramate, a polysaccharide anticonvulsant with several mechanisms of action, has also been assessed in an open label study of migraine. With an average daily dose of 325 mg/day in two divided doses, investigators noted an average decrease in attack frequency of 72% and an average decrease in the severity of attacks of 55% (Kruszynski & Scott, 1999). Among migraine prevention medications, a unique side effect of topiramate is that it may cause some patients to lose weight during a course of therapy. With a positive efficacy and safety profile, topiramate appears to be a promising treatment option for patients with refractory migraine.

Abortive Treatment

Abortive medications used in the treatment of migraine include the nonprescription agents, IB and APAP/ASA/CAF, as well as a range of prescription-only medication (including isometheptene mucate, ergotamine preparations, prescription-strength NSAIDs, dihydroergotamine mesylate (DHE) and DHE nasal spray), and the 5-HT_{1D} receptor agonists (including sumatriptan, naratriptan, rizatriptan, and zolmitriptan). Selected abortive agents are reviewed next.

APAP/ASA/CAF — Lipton, Stewart, Ryan, Saper, Silberstein, and Sheftell (1998) published the results of three studies comparing the nonprescription combination of APAP 250 mg, ASA 250 mg, and CAF 65 mg with placebo. A single two-tablet dose of this nonprescription compound was highly effective in relieving both migraine pain and associated symptoms. There were no serious side effects.

Ergotamine preparations — The utility of these medications in arresting migraine attacks is due to their ability to counteract the dilation of some arteries and arterioles, primarily the branches of the external carotid artery. Nausea is a common side effect of ergotamine-treated patients. Once used, ergotamine should not be repeated for 4 days to avoid the possibility of ergotamine rebound headache, a relatively prevalent side effect characterized by a self-sustaining cycle of daily or almost daily migraine headaches coupled with the irresistible use of ergotamine tartrate to alleviate them (Gallagher, 1983). Ergotamine and its derivatives should be avoided in elderly and, because of their ability to induce labor, in pregnant patients. Dihydroergotamine, which was developed as an improvement over ergotamine tartrate, has a better safety profile. It is available in parenteral and nasal formulations. A 2-mg dose of the nasal spray formulation of this agent has a rapid onset of action, a low recurrence rate, and completely resolves a migraine attack in up to 70% of patients within 4 h (Gallagher, 1996).

NSAIDs — In prescription doses, NSAIDs have been shown to be superior to placebo and equivalent to other reference drugs in the abortive treatment of migraine (Pradalier, Clapin, & Dry, 1988). Two nonprescription formulations of IB have also been approved for the treatment of acute migraine. Although fewer side effects are reported with NSAIDs than with ergotamine preparations, the gastrointestinal, renal, and hepatic risks linked with NSAID use are well documented (Rapoport & Adelman, 1998).

Isometheptene — This sympathomimetic with vasoconstrictive effects is found in combination with acetami-

nophen 325 mg, and dichloralphenazone 100 mg. The combination can be effective in migraine without aura. It is taken orally, two capsules at onset and one each hour thereafter, to a maximum of five capsules in 1 day. Side effects include drowsiness and nausea, and it is contraindicated in patients with hypertension and renal disease, as well as those taking MAOIs.

Selective serotonin reuptake inhibitors — Sumatriptan, an SSRI, is a mainstay in migraine therapy. A single subcutaneous dose of 6 mg relieves the majority of migraine attacks successfully (Subcutaneous Sumatriptan Study Group, 1991); oral and nasal preparations are also available. However, because of sumatriptan's low oral bioavailability, significant headache recurrence (Goldstein, 1996), and contraindication in large subgroups of patients, newer agents have been developed and introduced.

The migraine drugs being marketed as "next generation" agents are similar to sumatriptan, 5-$HT_{1B/1D}$ receptor agonists. As of this writing, there are six new compounds, only three of which have been approved for marketing by the FDA: naratriptan, rizatriptan, and zolmitriptan. Three others, almotriptan, eletriptan, and frovatriptan, should be available in the near future.

Reports of clinical experience with the approved medications suggest that, although they are effective, response to them is highly individualized. For instance, Freitag, Diamond, Diamond, Urban, & Pepper (2000), in a retrospective study of clinical experience with naratriptan, rizatriptan, and zolmitriptan, found that all the newer acute treatments for migraine were highly effective, but they observed no clear differences between the 5-HT medications that might distinguish one agent as the "best." However, one trial comparing zolmitriptan with sumatriptan found that zolmitriptan (2.5 mg) was significantly more effective than sumatriptan (50 mg) in terms of headache response at 2 and 4 h posttreatment (Gallagher, Dennish, Spierings, & Chitra, 2000). In other work, investigators compared rizatriptan 10 mg with zolmitriptan 2.5 mg and reported that patients treated with rizatriptan were 31% more likely to be pain free and 23% more likely to have pain relief sooner than patients who were treated with zolmitriptan (Diener, Pascual, & Vega, 2000).

It has been suggested that naratriptan may have the lowest rate of headache recurrence of the 5-HT oral agents (Ryan, 1998), but headache recurrence remains a problem for all the triptans. Up to one third of patients taking almotriptan (Pascual, et al., 2000), 40% of patients taking sumatriptan, 28% taking naratriptan, 40 to 47% taking rizatriptan, about 30% taking zolmitriptan have experienced recurrence of their migraine symptoms within 24 h (Goldstein, Keywood, & Hutchinson, 1999). Preclinical data indicate, however, that frovatriptan may have a prolonged duration of action, and pharmacokinetic studies show that the elimination half-life is the longest in the class (Buchan, 1998). This characteristic may be responsible for the low rate of headache recurrence seen in frovatriptan-treated patients (Goldstein, Keywood, & Hutchinson, 1999). Eletriptan effectively relieves the symptoms of an acute migraine attack at both the 40 and 80 mg doses. In clinical trials, therapeutic response to eletriptan is generally superior to sumatriptan, and the rate of headache recurrence among eletriptan-treated subjects is low (19%) (Pryse-Phillips, 1999). More investigations and additional clinical experience with the 5-$HT_{1B/1D}$ class are needed to determine how the use of these medications can be optimized across the wide range of migraine patients.

Symptomatic Treatment

When first-line nonprescription and second-line prescription abortive agents fail, symptomatic treatment is indicated. Symptomatic agents are sometimes referred to as rescue medications. Transnasal butorphanol, a nasal preparation, is one of the more useful drugs in patients with infrequent attacks. Pain relief has been demonstrated within 15 min (Goldstein, Marek, & Winner, 1998), and the nasal formulation is particularly convenient for patients who are suffering from severe nausea or vomiting. Other options for rescue therapy include injectable NSAIDs and butalbital combinations, opioids, and opioid-like combinations. Because of their abuse potential and the possibility of rebound effects, precautions must be observed when using symptomatic medications.

Intractable Migraine

Episodic migraine may become incessant and refractory to standard care (Mathew, Reuveni, & Perez, 1987). For many of these patients, drug dependence is a factor; for others, disabling headaches continue, unabated, seemingly indefinitely. In such cases, clinicians should be aware of several approaches to the management of intractable migraine. DHE, administered in a protocol developed by Raskin, can produce a headache-free state in 90% of intractable migraine patients within 2 days (Raskin, 1986). Metoclopramide is used adjunctively with DHE to suppress withdrawal symptoms (Ramaswamy & Bapna, 1987). Alternative treatments for intractable migraine include dexamethasone (4 mg intravenously) (Gallagher, 1986), ketorolac (30 to 60 mg intramuscularly or intravenously), chlorpromazine (0.1 mg/kg intravenously every 6 to 8 h) (Newman, 2000).

CLUSTER HEADACHE

Cluster headache is a devastatingly severe type of recurrent vascular headache. It also sometimes is referred to as histaminic cephalalgia, histaminic headache, Horton's cephalalgia, Horton's headache, Horton's syndrome, or migrainous neuralgia. Its clinical constellation of symptoms with the characteristic patient behavioral tendencies

during attacks should make it easy to recognize and distinguish from migraine or TTH. Of the recurrent headache syndromes, it is probably the most distressing and brutal to the afflicted.

A cluster attack is characterized by severe unilateral pain, often described as a burning, boring, or stabbing sensation in the area of the eye, temple, or forehead with radiating to the jaw, ear, or neck. During attacks, sufferers often pace or become extremely active, similar to patients experiencing renal colic. Frequently associated with the pain are ipsilateral lacrimation, eye injection, rhinorrhea, congestion, facial droop, or sweating. The pain usually builds quickly over several minutes and lasts approximately 30 to 90 min.

Cluster headache attacks can occur numerous times daily, sometimes at the same hour each day. Early morning awakening with headache 2 to 3 hours after retiring is common. In its typical form, episodic cluster, the headaches cluster or group for periods of weeks to months and mysteriously disappear for months to years; thus the name "cluster headache." In its chronic form, which affects approximately 10 to 15% of sufferers (Ekbom & Olivarius, 1971), the headaches continue to occur indefinitely, affording the patients few headache-free days. The IHS criteria for cluster headache are shown in Table 18.6 (HCCIHS, 1988).

The typical onset of cluster headache is in the third or fourth decade of life although cluster attacks have been reported from as early as 1 to 3 years to the late 60s (Lance, 1993). Unlike migraine, cluster is more prevalent in men; its gender ratio favors men by 5:1. The etiology remains poorly understood. However, it has been proposed that vasomotor, hypothalamic, or neurohormonal disturbances may be involved (Moskowitz, 1984; Saper, 1983; Kudrow, 1983).

Unlike migraine, diet does not seem to precipitate cluster, although an occasional patient reports that chocolate can be a factor. The one exception, however, is the consumption of alcohol during cluster periods. Most, but not all, cluster patients are heavy smokers and drinkers. During remission periods when patients are not on preventive medications, alcohol appears to have no provoking effect.

TABLE 18.6
IHS Diagnostic Criteria for Cluster Headache

A. At least five attacks fulfilling B–D
B. Severe unilateral orbital, supraorbital, and/or temporal pain lasting 15 to 180 min untreated
C. Headache associated with at least one of the following signs that have to be present on the pain side:
   1. Conjunctival injection
   2. Lacrimation
   3. Nasal congestion
   4. Rhinorrhea
   5. Forehead and facial sweating
   6. Miosis
   7. Ptosis
   8. Eyelid edema
D. Frequency of attacks: from one every other day to eight per day
E. At least one of the following:
   History, physical, and neurological examinations not suggesting a secondary disorder
   History, physical, and/or neurological examinations suggesting such disorder, but ruled out by appropriate investigations
   Such disorder present, but cluster headache not occurring for the first time in close temporal relation to the disorder

Treatment

The preferred approach to the treatment of cluster headache patients is prophylactic. The tremendous pain and relatively short but frequent attacks makes symptomatic treatment less practical and often ineffective. Appropriate pharmacological prophylactic regimens can reduce the frequency and severity of attacks in most patients. When treating cluster patients, the benefits of therapy should be weighed against the hazards of taking medication. Patients should be monitored closely, because some of the medication prescribed in treatment can potentially cause problems. Ergotamine and DHE preparations, methysergide, calcium channel blockers, corticosteroids, and lithium are commonly used. Other agents, such as cyproheptadine, indomethacin, chlorpromazine, antidepressants, and ergonovine have been used with limited success.

For cluster patients, ergotamine tartrate is administered orally in divided doses throughout the day and often limits the severity and frequency of cluster attacks. The daily dose should be kept as low as possible (1 to 2 mg daily), and additional ergotamine for breakthrough headaches should not be permitted. Individual tolerance and sensitivity varies greatly, and patients should be followed closely for untoward reactions and complications.

Methysergide, an ergotamine derivative, may also be used to treat cluster headache patients. It is administered orally in divided doses not to exceed 8 mg/day. On initiation of therapy, some patients experience transient mental confusion, nausea, vomiting, muscle cramps or takes, and insomnia. If the symptoms persist for more than 3 days or the patient develops evidence of peripheral vasoconstriction, claudication, or angina, the medication should be stopped. Methysergide is contraindicated in patients who have peripheral vascular or cardiovascular disease, hypertension, active ulcer, cardiac vascular disease, and hepatic or renal dysfunction; or who are pregnant.

Corticosteroids, alone or in combination with methysergide, are frequently effective for difficult patients. Their mechanism of action is not completely understood, but it is thought to involve suppression of hormonal mechanisms. This treatment is more suited for patients with

episodic cluster headache, because its long-term use could be hazardous. However, because of the extreme distress and suffering of some chronic cluster patients, corticosteroids can provide temporary relief whereas other drugs are being introduced.

Prednisone or triamcinolone are commonly prescribed, although others are effective. The steroids are given in divided doses that must be titrated to the individual. The average daily starting dose is 60 mg of prednisone or 16 mg of triamcinolone. The medication is then tapered over 2 to 4 weeks with adherence to usual steroid precautions. Side effects include fluid retention, weight gain, gastrointestinal disturbances, lethargy, and Cushing's syndrome. Contraindications are hypertension, diabetes, peptic ulcer disease, infection, active immunization, or pregnancy.

Calcium channel-blocking drugs have been helpful to many patients, especially those with the chronic form of cluster. It is believed that they alter smooth muscle tone of cerebral arteries by interfering with calcium ion function (Gallagher & Freitag, 1987a). Verapamil is generally well tolerated and more frequently utilized. It has been suggested as a first-line pharmacological treatment for the prevention of cluster headache, although weeks of therapy may be required before control of the condition is established (Saper, 2000, pp. 76–77). It is given in divided doses with an average daily dosage of 360 mg/day. The most frequent side effects with verapamil are constipation and fluid retention. Verapamil is contraindicated in hypotension, cardiac conduction disease, and significant renal or hepatic disease. Other calcium channel blockers sometimes used are nifedipine (40 to 280 mg/day) and nimodipine (30 to 60 mg/day).

Lithium carbonate is reported to be affected in reducing frequency and severity of attacks in the treatment of patients suffering with chronic form of cluster headache. Its mechanism of action has been debated, but it may involve its effect on cyclic changes in serotonin and histamine (Gallagher & Freitag, 1987a) or electrical conductivity in the central nervous system (Diamond & Dalessio, 1980). It is administered orally in divided doses with a daily dosage of 600 to 1200 mg. Serum lithium level monitoring is necessary to avoid toxicity. Effective therapeutic ranges vary greatly, but generally should not exceed 1.2 meq/l. Nonsteroidal anti-inflammatory drugs and thiazide derivatives should be used with caution; when used concomitantly, these agents raise the potential risks of toxicity. Side effects include fatigue, tremor, sleep disturbance, diarrhea, decreased thyroid function, goiter, and fluid retention. Lithium is contraindicated in the presence of significant renal or cardiovascular disease.

Abortive therapy for cluster patients is a limited effectiveness because of the relatively brief headaches and the time necessary for medication absorption. Few nonpharmacological measures are helpful to cluster patients. However, the complete abstinence from alcohol during cluster periods is imperative. Drinking alcohol, without question, interfere with prophylactic therapy. Reducing cigarette smoking and caffeine consumption (Gallagher & Freitag, 1987a), as well as avoidance of daytime napping (Stensrud & Sjaastad, 1980), may benefit some patients. The inhalation of oxygen during a cluster attack is a relatively safe and effective treatment. In the majority of sufferers, oxygen aborts attacks within 12 min (Kudrow, 1981). Oxygen is administered at a rate of 7 l/min by facial mask at the onset of attack continued for up to 15 min. The main drawback to the use of oxygen is cumbersome equipment, which makes it difficult to transport for patients whose attacks are unpredictable.

For patients who experienced longer headaches and those who are not sufficiently controlled by preventive medication, abortive medication may be needed. This is generally limited to ergotamine or analgesic/sedatives. Ergotamine and its derivatives can be administered early in a cluster attack, sublingually, intramuscularly, or by inhalation. This may give relief to some, whereas simply delaying the completion of the headache in others. The usual ergotamine limitations must be observed, which limit the amount that can be taken and the number of headaches that can be treated. Analgesics and sedatives are a limited help, but they aid certain patients psychologically and reduce the anxiety associated with cluster attacks. Unmonitored use of these medications should be avoided, because potential habituation or toxicity can develop.

MIXED HEADACHE SYNDROME

Most headache patients experience one or possibly two distinct headache types, with pain-free periods between attacks. However, there is a group of patients who experience intermittent migraine attacks superimposed on a daily or near daily, less intense headache similar to that of the tension type. This pattern is characteristic of the mixed headache syndrome. The mixed headache syndrome is one of the most difficult headache patients to manage.

The typical mixed headache patient, in many cases, has a long history of evaluations and failed therapeutic attempts. Their constant fear of the daily or near-daily headaches worsening sometimes leads to self-treatment and excessive medication use. The frequent use of any immediate-relief medication for head pain can cause rebound headache, which perpetuates the problem and often renders other treatments ineffective until all medications are stopped. Psychogenic factors, such as chronic stress, anxiety, burnout, or depression, are often present and further contribute to the ongoing problem.

The patient–doctor relationship is critical in the management of mixed headache patients. An effective,

comprehensive treatment plan that addresses each element of the patient's problem must be developed and supervised by a single physician. The patient must be educated as to the nature of his or her headaches and how each aspect of treatment is expected to contribute to the control of the headaches. Once a plan is begun, continuity of care with regular follow-up visits is vital.

The treatment of the mixed headache syndrome usually requires prophylactic medications in addition to nonpharmacological measures, such as diet, exercise, stress reduction, biofeedback, social adjustments, and counseling. Because these patients, in effect, experience coexisting tension-type and migraine headache, each individual component requires its own appropriate therapy. The management of tension-type and migraine headache has been described earlier in this chapter. Patients who do not respond to outpatient therapy or who are unable to withdraw from frequent analgesic or ergotamine use may benefit from hospitalization at dedicated in-patient, tertiary care facilities (Diamond, Freitag, & Maliszewski, 1986).

Muscular Parafunction of the Masticatory System: Headache, Face, Jaw, and Sinus Pain (Temporomandibular Disorders)

James P. Boyd, D.D.S.

Some of the most difficult diagnoses to make are those that are without objective signs, that is, conditions that present with subjective symptoms only. Some of the most common pain complaints: headache, face, jaw, and sinus pain, usually present with no objective signs, and treatment is based on the patient's subjective report. The diagnosis of parafunction of the masticatory musculature falls into this category (Figure 19.1).

Before parafunction of any muscle can be addressed, one must become familiarized with the function of that muscle. As with all skeletal muscles, the form of the muscle dictates its function, and the function of the muscle follows its form. This chapter specifically addresses only two of the muscles of mastication: the temporalis and the lateral pterygoid.

TEMPORALIS

The temporalis origin covers the entire side of the skull and resides within the temporal fossa. With the anterior portion of the temporal fossa being deepest, the anterior portion of the temporalis is thickest, and therefore the strongest portion of the muscle. With the insertion of this muscle as the coronoid process of the mandible, the sole function of the temporalis is to elevate the mandible. Anthropologically speaking, the temporalis functions closely with the canine teeth. Carnivores who typically have prominent canine teeth also have well-developed temporalis muscles. Following the opening of the mouth (to capture prey), the role of the temporalis is to forcibly attempt to elevate the mandible (close the mouth) through the objects that are engaged with the canine teeth. Conversely, the herbivores have much less developed temporalis muscles and canine teeth, instead having better well-developed masseters, which work together with flattened occlusal patterns of the teeth, to facilitate mastication.

LATERAL PTERYGOID

In 90° opposition to the orientation of the temporalis (i.e., the alignment is horizontal instead of vertical) is the lateral pterygoid muscle. The name is derived from its origin, which is the lateral side of the pterygoid (winglike) plate of the sphenoid bone (which houses the maxillary sinuses). The insertion (of its inferior belly) is at the neck of the condyle (the superior belly attaches to the articular disc, which rides on top of the condyle). During unilateral contraction, the lateral pterygoid pulls the condyle in the anterior-medial direction of its fibers (form dictates function), with the overall effect of the mandible shifting laterally. For example, when the right lateral pterygoid contracts, the mandible moves to the left, and vice versa. When both lateral pterygoids contract simultaneously, the mandible is advanced and the mouth opens as the condyles slide down the articular eminence of the temporal bone.

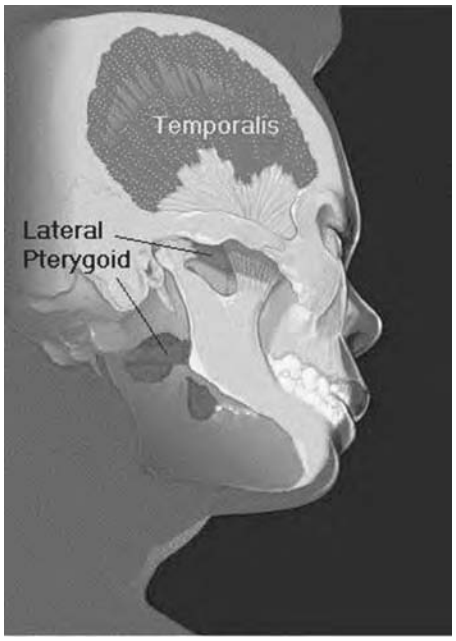

FIGURE 19.1 Masticatory musculature.

FUNCTION VS. PARAFUNCTION

In humans, these two pairs of muscles work together to bite and tear food, and to position the mandible while chewing. Once the jaws have come together and the teeth have occluded, the particular arrangement of the teeth is referred to as the *occlusion*, or occlusal scheme. It is important to make the distinction between the *occluding* of the teeth (a muscular act) and the scheme of *occlusion* (the relationship of the teeth following their occluding). During mastication, there is no purpose in having the teeth in occlusion (food is supposed to be in between the upper and lower teeth) for anything more than a fraction of a second. In fact, the instant the teeth occlude with each other, an opening stroke is initiated. Other than chewing and swallowing, any muscular act that occludes the teeth (provided by the temporalis) is considered parafunctional. Symptoms and signs that may develop depend on the intensity, frequency, and duration of the parafunctional muscular contraction.

ETIOLOGY

The field of dentistry has obviously been assigned to treat conditions of the masticatory system. Dentistry typically acknowledges that the activity synonymous with muscular parafunction is *bruxism*, which had traditionally been defined as "teeth grinding". However, although the current standard treatment for bruxism (an intraoral splint or "night-guard") may prevent against the signs of teeth grinding (worn and loose teeth), it may not be entirely effective at resolving the symptoms. The problem lies not in dentistry's mistreatment, but in its misconception of the diagnosis and definition of bruxism. This lack of understanding of the true nature of bruxism has resulted in the current standard of care for chronic temporomandibular disorder (TMD): management of symptoms (McNeil, 1990; Okeson, 1989, p. 160). By using a traditional interocclusal splint, the practitioner has succumbed to the patient's intensity of occluding, which plays the largest etiologic role in his or her symptoms (regardless of the patient's occlusal scheme). Unfortunately, dentistry has stipulated that treatment with an interocclusal splint results in one of three scenarios: the patient may improve (the intensity of parafunction is disrupted and decreases), remain unchanged (intensity is unaffected), or get worse (Clark & Solberg, 1987, p. 130; Dao, et al., 1994; Hansson, 1991) (muscle contraction activity intensifies). Without a full understanding of the nature of bruxism's destructive forces, the practitioner cannot inform the patient of the outcome potential when using a traditional interocclusal nightguard/splint (Figure 19.2).

One of the problems with treating muscular parafunction has been where to start. Due to the unpredictability of the outcome of a traditional intraoral splint (which is intended to reduce muscular parafunction, but may not), varying opinions of TMD treatment have developed within dentistry. Two basic philosophies have evolved: the patient's jaw orientation is inappropriate and therefore must be altered, or the patient's occlusal scheme is inappropriated and therefore must be altered. However, an individual with an ideal jaw relationship (the way the condyle of the mandible seats into the temporal fossa) and/or ideal occlusal scheme may suffer from chronic debilitating headaches and/or face and jaw pain (TMD), whereas another with a less-than-ideal jaw relationship and/or "improper" occlusal scheme may be completely asymptomatic. (Okeson, 1989, p. 160). When it comes to

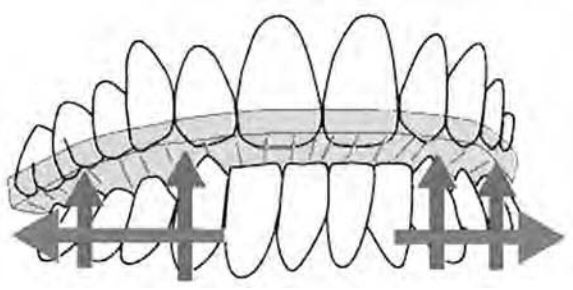

FIGURE 19.2 A flat and smooth surface reduces the efforts of the lateral pterygoids (green arrows). Eliminating the resistance of occluding cusps reduces the strain on the origins of the lateral pterygoid (the pterygoid plate of the sphenoid bone resulting in a reduction of facial symptoms) and insertions (the neck of the condyle resulting in a reduction of TMJ strain and symptoms). However, the same surface provides a more efficient resistance to the effort of the temporalis at clenching, therefore increasing the clenching intensity (red arrows).

TMD, etiologic research continues to show that, essentially, it does not matter what a person has or where it is (the occlusal scheme and jaw relationship) (Kahn, et al. 1999; McNamara, Seligman, & Okeson, 1995; Rodrigues-Garcia et al, 1998). What matters is what one does with what one has (the nature of the muscular activity—the occluding) (Israel, 1999; Ito, et al., 1986).

Understanding Bruxism

To gain an upper hand on bruxism, a new understanding of the term, and therefore the condition itself, is necessary. Bruxism is not a condition of the teeth. Teeth do not cause an activity, they are merely being affected by an activity. (Okeson, 1989, p. 160). Dentistry is essentially the art and science of how healthy teeth occlude with each other. Therefore, dentistry has been reactively treating a condition by addressing the health of the teeth and their occlusal scheme (Wilkinson, 1991). However, signs and symptoms of bruxism do not result simply from the creation of an occlusal scheme; they result from the intensity of the occluding of the teeth. The resulting scheme of occlusion may modify and direct the forces generated during the occlusion, but it may not alter the intensity of the occluding.

Bruxism is best described as a function of clenching. The intensity of clenching dictates the severity of grinding. There is no teeth grinding unless the jaws are first clenched together to some degree. The jaws must be clenched together intensely enough to provide adequate resistance to alternating lateral pterygoid activity, which then grinds the teeth in excursive movements. As the intensity of temporalis contraction (clenching) increases, resistance to lateral mandibular movement increases. The required increased efforts of the lateral pterygoids to translate the condyles (pull them down the articular eminence of the temporal bone) provide the strain on the temporomandibular joints (TMJs), which is a major source of joint pathology (Israel, 1999).

As the intensity of clenching approaches maximum, the lateral pterygoids ability to move the mandible laterally (i.e., translate the condyles) decreases or is prevented entirely. Ultimately, the most intense clenching would prevent any movement of the jaw or grinding of the teeth. Clenching in a centered position, with a balanced occlusal scheme, would provide the most stable and protected environment for the TMJs. With this observation, the appropriate definition of bruxism becomes apparent: "Jaw-clenching, with or without forcible excursive movements". The patient who presents with severely worn teeth, obviously a result of vigorous grinding, may have no symptoms to report because he or she never exerts adequate clenching intensity to become symptomatic (but enough to vigorously rub the teeth together). Another patient with no indication of occlusal wear, but who complains of severe headaches and neck pain and has no facial

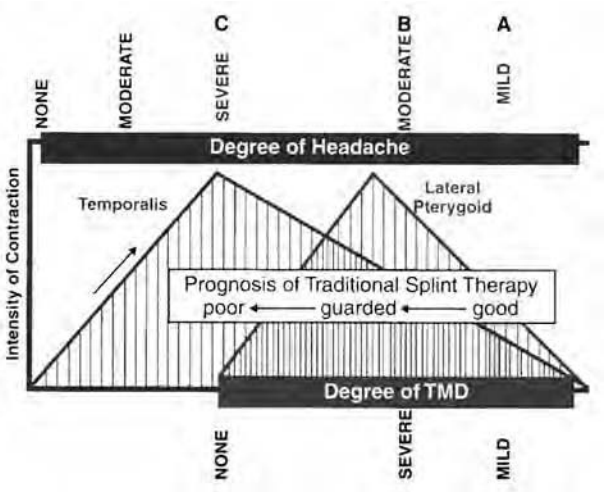

FIGURE 19.3 As temporalis contraction increases to maximum, lateral pterygoid ability to translate the condyle for potential joint strain is eliminated. As temporalis contraction intensity reduces, the opportunity for the lateral pterygoid to translate the condyle increases, thereby increasing signs and symptoms of TMD. A: In this example, minimal lateral pterygoid intensity produces mild TMD, and minimal temporalis intensity produces mild headache. Traditional splint therapy has a good prognosis. B: Intense lateral pterygoid contractions resulting from significant occlusal resistance, provided by moderate to severe temporalis intensity, allow for severe TMD. C: Intense temporalis clenching (nonexcursive) stabilizes the condyles, which presents with tension-type headache without typical signs or symptoms of TMD.

or TMD signs or symptoms, may be clenching intensely in centric position. Only by recognizing bruxism as a function of clenching can these patients be accurately diagnosed and treated (Figure 19.3).

In a study of chronic tension-type headache patients without signs or symptoms of TMD, clenching during sleep was shown to be, on average, 14 times more intense than in asymptomatic control subjects (Clark, 1997). Clenching in centric and balanced position maintains a stabilized TMJ environment. However, the typical patient with chronic TMD (headaches, face and jaw pain, tooth wear) forcibly grinds his or her teeth to an excursive position, and then clenches in that position ("grinding to clench"), placing severe and often damaging strain on the TMJs (Hannam, 1991). If both lateral pterygoids were to maintain an isometric contraction during a centric clench, or even more significantly, with the jaw slightly advanced, a strain is placed on the pterygoid plates of the sphenoid bone (the origins of the lateral pterygoids), thereby generating sinus symptoms (in the absence of objective disease). There exists a dynamic relationship between the temporalis and lateral pterygoids, from which signs and/or symptoms may result. The intensity of the temporalis activity combined with the degree of lateral

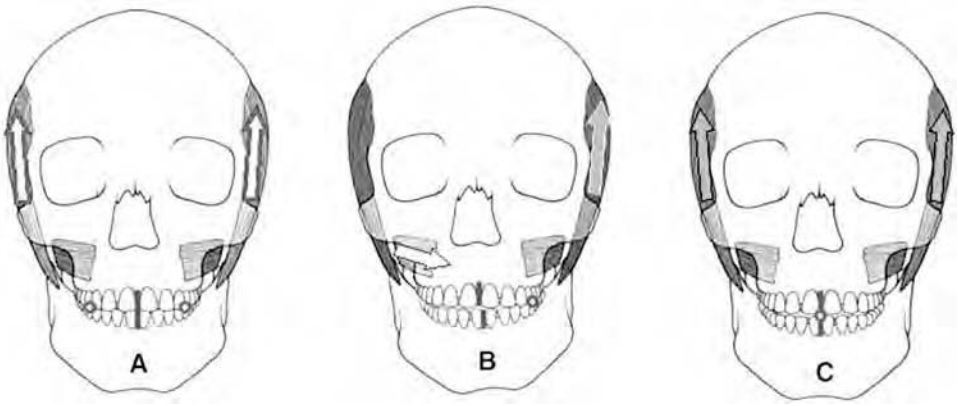

FIGURE 19.4 The relationship between occlusal scheme, joint strain, and muscle contraction intensity. A: Bilateral, posterior equal contact (red dots) allows for maximal clenching (and headache) without joint strain. B: Unilateral posterior contact (maintained by the same side temporalis) provides the opposite lateral pterygoid with resistance to its contraction in a medial direction, straining the joint. Even with a well-adjusted splint, the contortion of the mandible in excursive movement can create this scenario. C: With anterior midline point contact, there is minimal temporalis contraction intensity. Resistance to lateral pterygoid contraction is minimal (therefore minimal contraction intensity) and in an anterior/superior direction, thereby seating the condyle into its optimal orientation.

pterygoid activity (if possible), dictates the presentation of headache, TMD, or tooth wear (Figure 19.4).

Treating and Preventing Bruxism

Ultimately, to treat and prevent bruxism, clenching intensity must be suppressed. Unfortunately, the traditional interocclusal splint, while decreasing resistance to lateral movement (thereby relieving lateral pterygoid contraction and TMJ strain), provides ideal (or in some cases, enhanced) resistance to the temporalis, allowing clenching to persist or intensify (Clark, Beemserboer, & Rugh, 1981).

The success or failure of the traditional interocclusal splint is a function of the intensity of clenching. If clenching intensity persists or increases after using a splint, bruxism/TMD treatment becomes bruxism/TMD management. Therefore, to treat and prevent bruxism/TMD, clenching suppression must be addressed. This is achieved by exploiting the nociceptive trigeminal inhibition (NTI), reflex also known as the jaw-opening reflex (Okesan, 1989, p. 160; Stohler & Ash, 1986), and by creating an occlusal scheme for the least efficient muscular contraction (i.e., least intense). NTI is created by direct pressure stimulation of the mandibular incisor periodontal ligament (PDL), activating a reflex loop, which suppresses the contraction intensity of the temporalis (conversely, anesthetization of the mandibular incisor PDL allows clenching intensity to increase) (Hannam, 1991).

Historically, an anterior deprogrammer (such as a Lucia jig) or an anterior point stop (Clark, Beemsterboer, & Rugh, 1981) has been advocated to establish and record optimal condylar position (CR) and to suppress acute muscular symptoms on a short-term basis. These are effective for clenching suppression in a jaw-centered position, but are contraindicated for therapeutic use because of the complications caused by excursive (protrusive, retrusive, lateral) movements of the mandible. During an excursive movement of the mandible, deprogramming jigs can allow a mandibular canine to contact the device, resulting in ipsilateral near-maximal clenching (Stohler & Ash, 1986) and joint strain. Protrusive movement of the mandible with the simple anterior point stop allows for occluding of the posterior teeth, again allowing for high-intensity clenching. All mandibular excursive positions, not just centric, must be considered when attempting to suppress temporalis clenching in a dynamic environment (Figure 19.5).

To accommodate for parafunctional, protrusive, and retrusive movements, an anterior midline point stop can be extended anteriorly and distally, providing clenching suppression in all mandibular movements. A prefabricated, retrofitted device is available commercially through NTI-TSS).* Used primarily during sleep, a modified anterior midline point stop (AMPS) reduces voluntary clenching intensity to one third of maximum (Becker, et al., 1999). A modified AMPS design allows for the best "musculoskeletally stable" (CR) position of the condyles, while suppressing hyperactive musculature. In addition, by providing for no unilateral canine or posterior contacts (as can happen with a full-coverage splint when the mandible contorts during excursive movement [Clark & Solberg, 1987, p. 130]), the modified AMPS allows for the least destructive clenching.

Two misconceptions of a modified AMPS are not uncommon: posterior teeth may supraerupt, and mandibular

*NTI Tension Suppression System. FDA marketing allowance, July 1998: "For the prevention of chronic tension and temporal mandibular joint syndrome that is caused by chronic clenching of the posterior mandibular and maxillary teeth by the temporalis muscle. The device is custom made for the individual." NTI-TSS, Inc., Mishawaka, IN.

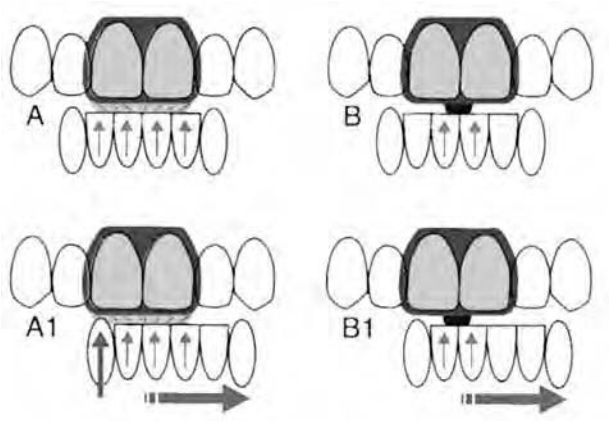

FIGURE 19.5 Both the anterior deprogrammer (A) and a modified AMPS (B) allow for minimal muscular contraction intensity and optimal seating of the condyle. An excursive movement (A1) allows an opposing canine to contact the deprogrammer, thereby providing an opportunity for intense temporalis contraction on the same side as the translated condyle, resulting in significant joint strain. The same excursive movement with a modified AMPS (B1) reduces the possibility of canine contact, thereby allowing the modified AMPS to be used therapeutically.

incisors may intrude. However, for a posterior tooth amount of potential joint strain in any excursive or protrusive movements, thereby allowing for optimal joint healing and remodeling (Schames, Boyd, Schames, & King, 2000).

To supraerupt, it must go unopposed without any contact for at least 8 days (Kinoshita, et al., 1982). With a modified AMPS in place, mastication is impossible because of the trauma experienced by the incisors opposing the device. Therefore, because an AMPS must be removed whenever the patient eats, the daily masticatory stimulation of the molars prevents their supraeruption (Kinoshita, et al., 1982).

As for incisor intrusion, there is no opportunity without a constant apical force, which is required to intrude teeth (clenching efforts last minutes, and are suppressed). Even in the case of a clinician's oversight, where the discluding element of the modified AMPS (which provides the point stop) is not perpendicular to the long axis of the mandibular incisor, the patient reports a tenderness to the tooth immediately after the first night of use. The patient resists wearing the device until the dentist addresses the problem, long before there is any orthodontic tipping movement.

Although the modified AMPS device itself does not cause any orthodontic movement, it does allow for optimal (re)positioning of the condyle, thereby potentially changing the occlusal scheme. By providing for the most musculoskeletally stable condylar position, a change in occlusal scheme is most noticeable in patients whose condyles seat more posteriorly and superiorly in the fossa as symptoms resolve. For example, as chronic tension of the lateral pterygoids resolves, the condyles may seat more posteriorly and superiorly (a tensed lateral pterygoid may have maintained the condyles in a position anterior and inferior to the optimum). Therefore, the mandible may rotate at the last molars, with the anterior mandible rotating inferiorly and posteriorly, possibly resulting in a degree of anterior open bite (depending on the original degree of incisal overlap). After any repositioning of the condyles, some degree of occlusal equilibration or restoration may be necessary.

A modified AMPS requires less fabrication and adjustment time than the traditional methods of splint fabrication and delivery (which typically requires impressions, models, laboratory fees, and potential for several adjustment appointments). The commercially available prefabricated devices require one simple chairside procedure where the device can be retrofitted and delivered (in most cases by a supervised auxiliary) in a 20-min appointment and one follow-up appointment. Compared with the bulky and often irritating traditional splint and the unpredictable outcome, the relatively smaller size of a modified AMPS and secure fit make for excellent patient compliance. The clinical efficacy of a modified AMPS makes it a viable treatment alternative for the treatment and prevention of occlusal trauma, bruxism, and TMD.

Complex Regional Pain Syndrome, Types I and II

Nelson H. Hendler, M.D., M.S.

CLINICAL SIGNS AND SYMPTOMS

Complex regional pain syndrome, type I (CRPS I) (formerly known as reflex sympathetic dystrophy [RSD]) and complex regional pain syndrome, type II (CRPS II) (formerly known as causalgia) are symptom complexes that evoke a great deal of confusion. Very often, physicians do not recognize that these are separate and distinct entities, and commonly assume that they are disorders of the same etiology, as well as responsive to the same treatment. Clinically, this has not proven accurate. CRPS, type I is a group of symptoms and clinical signs that usually follows a minor injury to a limb. In contradistinction, CRPS, type II is usually associated with peripheral nerve injury, classically from a bullet wound or some other partial nerve damage. Throughout this chapter, for the sake of consistency, earlier references that used the terms of reflex sympathetic dystrophy (RSD) are referenced or quoted as CRPS, type I despite the original nomenclature. This same approach is used for references using the term causalgia, which are changed for the sake of continuity, to CRPS, type II. In a very fine review article, Payne (1986) clearly defined the distinction between CRPS, type I and CRPS, type II, although at the time he called them RSD and causalgia, respectively. This has been further expanded by the International Association for the Study of Pain in a supplement edited by Merskey (1986) (Table 20.1). A further expansion of this comparison is offered by Baron, Blumberg, and Janig (1996) (Table 20.1A).

Clinically, one can make the distinction between the two disorders on the basis of signs and symptoms.This is a more important set of criteria than results of laboratory tests or response to treatment, because test results for this disorder are highly variable, and the accuracy of diagnosis of this disorder is low. If a disorder is misdiagnosed, then how can a physician rely on the response to treatment as a way of establishing a diagnosis? However, sometimes physicians establish a diagnosis based on a response to treatment. This circular logic predicts that all disorders respond equally well to a given treatment, and those who do not are the fault of the patient. This ego-protective trap is a convenient one into which an unsuspecting physician might easily fall. However, there is valuable information that can be derived from a patient's response to treatment, from both a retrospective and a prospective research position. Obviously, the variables in clinical research are legion, and include the variable responses patients have to a single pathological etiology; the similar manifestations patients have to diseases of multiple etiologies; the variability of accurate diagnosis; the variability of the skill of the physician performing a procedure; and the variable response to a single, well-performed procedure. Without much trouble, five variables have already been mentioned, giving rise to a 5-factorial analysis, or 120 possible combinations of factors. Therefore, in analyzing the results of clinical research in humans, one has to be very circumspect. This is certainly true for CRPS, type I and CRPS, type II.

TABLE 20.1
Comparison between CRPS Type I and Type II

	Complex Regional Pain Syndrome Type II (Causalgia)
Definition	Burning pain, allodynia, and hyperpathia, usually in the hand or foot, after a partial injury to a nerve or one of its major branches
Site	In the region of the limb innervated by the damaged nerve, not around the entire limb
Main features	Onset usually immediately after partial nerve injury or, may be delayed for months; CRPS, type II of the radial nerve very rare; the nerves most commonly involved are the median, the sciatic and tibial, and the ulnar; spontaneous pain; pain described as constant, burning, exacerbated by light touch, stress, temperature change or movement of involved limb, visual and auditory stimuli (e.g., a sudden sound or bright light, emotional disturbances)
Associated symptoms	Atrophy of skin appendages, secondary atrophic changes in bones, joints and muscles Cool, reddish, clammy skin with excessive sweating; sensory and motor loss in structure innervated by damaged portion of nerve
Signs	Cool, reddish, clammy, sweaty skin with atrophy of skin appendages and deep structures in painful area
Laboratoryfindings	Galvanic skin responses and plethysmography revealing signs of sympathetic nervous system hyperactivity, roentgenograms possibly showing atrophy of bone
Usual course	If untreated, the majority of patients having symptoms that persist indefinitely; spontaneous remission occurring
Relief	In early stages of CRPS, type II (first few months) sympathetic blockade plus vigorous physical therapy usually providing transient relief; repeated blocks usually leading to long-term relief; when a series of sympathetic blocks not providing long-term relief, sympathectomy indicated; long-term persistence of symptoms reducing the likelihood of successful therapy
Social and physical disabilities	Disuse atrophy of involved limb; complete disruption of normal daily activities by severe pain; risk of suicide, drug abuse if untreated
Pathology	Partial injury to major peripheral nerve; actual cause of pain unknown; peripheral central and sympathetic mechanisms involved in an unexplained way
Essential features	Burning pain and cutaneous hypersensitivity with signs of sympathetic hyperactivity in portion of limb innervated by partially injured nerve
	Complex Regional Pain Syndrome Type I (Reflex Sympathetic Dystrophy)
Definition	Continuous pain in a portion of an extremity after trauma that may include fracture but does not involve a major nerve, associated with sympathetic hyperactivity
Site	Usually the distal extremity adjacent to a traumatized area; all around the limb
System	Peripheral nervous system; possibly the central nervous system
Main features	The pain follows trauma (usually mild), not associated with significant nerve injury; the pain described as burning, continuous, exacerbated by movement, cutaneous stimulation, or stress; onset usually weeks after injury

TABLE 20.1 (CONTINUED)
Comparison between CRPS Type I and Type II

Associated symptoms	Initially there is vasodilatation with increasing temperature, hyperhidrosis, edema, and reduced sympathetic activity also occurring; atrophy of skin, vasoconstriction and appendages, cool, red, clammy skin variably present; disuse atrophy of deep structures possibly progressing to Sudeck atrophy of bone; aggravated by use of body part, relieved by immobilization; sometimes follows a herniated intervertebral disc, spinal anesthesia, poliomyelitis, severe iliofemoral thrombosis or cardiac infarction; may appear as the shoulder–hand syndrome; later vasospastic symptoms becoming prominent with persistent coldness of the affected extremity, pallor or cyanosis, Raynaud phenomenon, atrophy of the skin and nails, and loss of hair, atrophy of soft tissues and stiffness of joints; without therapy these symptoms possibly persisting; not necessary for one patient to exhibit all symptoms together; an additional limb or limbs possibly affected as well
Signs	Variable; may be florid sympathetic hyperactivity
Laboratoryfindings	In advanced cases, X-rays possibly showing atrophy of bone, and bone scan changes over time
Usual course	Persists indefinitely if untreated; small incidence of spontaneous remission
Relief	Sympathetic block and physical therapy; sympathectomy if long-term results not achieved with repeated blocks; may respond in early phases to high doses of corticosteroids (e.g., Prednisone, 50 mg daily)
Complications	Disuse atrophy of involved limb; suicide and drug abuse if untreated; sometimes spreads to countralateral limb
Social and physical disabilities	Depression, inability to perform daily activities

	CRPS I	CRPS II
Pathology	Unknown	Partial nerve lesion
Essential features	Burning pain in distal extremity usually after minor injury without nerve damage	Nerve damage
Differential diagnosis	Unrecognized local pathology (fracture, strain, sprain)	Posttraumatic vasospasm, nerve entrapment syndromes radiculopathies, or thrombosis

TABLE 20.1A
Criteria for Differential Diagnosis of Complex Regional Pain Syndromes (CRPS) Types I and II

	CRPS I	CRPS II
Etiology	Any kind of lesion	Partial nerve lesion
Localization	Distal part of extremity, or entire limb; independent from site of lesion	Any peripheral site of body; mostly confined to territory of affected nerve
Spreading of symptoms	Obligatory	Rare
Spontaneous pain	Common, mostly deep and superficial orthostatic component	Obligatory, predominately superficial, no orthostatic component
Mechanical allodynia	Most of patients with spreading tendency	Obligatory in nerve territory
Autonomic symptoms	Distally generalized with spreading tendency	Related to nerve lesion
Motor symptoms	Distally generalized	Related to nerve lesion
Sensory symptoms	Distally generalized	Related to nerve lesion

Note: From Merskey, H. (Ed.). (1986). *Pain*, 3 Suppl., pp. 28–29. Reprinted with permission.

COMPLEX REGIONAL PAIN SYNDROME TYPE I (CRPS I) (REFLEX SYMPATHETIC DYSTROPHY)

Following the distinction drawn by Payne (1986), one considers CRPS, type I as the result of minor trauma, inflammation following surgery, infection, or lacerations resulting in some degree of swelling in the affected limb; infarctions; degenerative joint disease; frostbite; and burns. One should add to this list the possibility of any compression, such as casting or swelling due to injury, that may cause prolonged pressure on peripheral nerves. As an example of this, we have seen at least two or three cases per year of CRPS, type I brought about from arthroscopy. The probable etiology is not injury to the nerve from the use of the arthroscope, but instead from using the tourniquet for a long period of time to create a bloodless operating field. A differential diagnosis between nerve entrapments and CRPS I is critical and based on the distribution of the pain, which follows nerve pathways for nerve entrapments, and is circumferencial for CRPS I.

According to Schwartzman and McKellan (1987), there seem to be three phases to CRPS, type I. Additionally, physicians should recognize that CRPS, type I is a symptom complex that is a cluster of symptoms and signs, and that patients do not present with all signs and symptoms during the course of their disease. In fact, very often they may have only one or two of the signs and symptoms of the disorder.

As described by Payne (1986) and by Schwartzman and McKellan (1987), the acute stage of CRPS, type I is characterized by spontaneous pain, usually aching or burning, that follows the distribution of blood vessels or peripheral nerves. The acute stage may manifest as "hyperpathia" (this is described as a painful syndrome of overreaction to a stimulus or after-sensation following a stimulus) and may include hypesthesia or hyperesthesia (described as a decreased or an increased sensation to pain stimulation, respectively), or dysesthesia (described as an unpleasant abnormal sensation). Associated with these tactile sensations are usually a warm, dry, red skin, or cold, blue, sweaty skin, with some swelling; and, surprisingly, increased hair and nail growth. A number of authors have interjected the notion of allodynia, or a painful response to a normally nonpainful stimulus. (Chaplan, Bach, Pogrel, Chung, & Yaksh, 1994; Kim & Chung, 1995; Lee, Kayer, Desmeules, & Guilbaud, 1994). Additionally, the patient has dependent redness and reduced motion in the damaged extremity. This summarizes the acute stage of this disorder, which may last several weeks, and may begin immediately or several days after the onset of the injury. However, it is possible for CRPS I to remain in this stage, and never progress to stage II or stage III. This is a highly individualized response.

The second stage of CRPS, type I, which usually begins about 3 to 6 months after the injury, is called the dystrophic stage by Payne (1986). During this stage, the patient experiences a burning type of pain, which radiates either above or below the site of the injury, and increased hypersensitivity or hyperalgesia (an exquisite sensitivity to touch or temperature—in counterdistinction to allodynia, a painful response to a normally nonpainful stimulus—a most important distinction that is discussed later in the chapter). The patient has changes in the nails on occasion, as well as decreased hair growth. This seems to be a variable finding, and certainly is not a sine qua non of the diagnosis of CRPS, type I. Joints may become stiff, with decreased range of motion, and possible thickening, associated with some degree of muscle wasting. Edema may be present, as well as bullous skin lesions, that are not related to an autoimmune disease (Baron, et al., 1996). Osteoporosis may be noted, with proper testing (Payne, 1986). Movement disorders may begin at this stage, with either dystonias, or contractures noted (Schwartzman & Kerrigan, 1990; Webster, Schwartzman, Jacoby, Knobler, & Uitto, 1991). Symptoms may vary, and fluctuate from individual to individual.

The third stage described by Payne is the atropic stage, which usually occurs 6 months or longer after the injury. According to Payne, the patient experiences pain, decreased skin temperature, trophic changes in the skin associated with a smooth glossy skin, stiff fixed joints associated with contractures, increased or decreased sweating in the affected extremity, and demineralization of the bone associated with wasted muscles and reduced strength (Payne, 1986). Again, the progression to this stage is highly variable, and may progress, in a rapidly fulminating case, in less than 2 to 3 months. As always, in medicine, there are only guidelines, but no hard and fast rules. (A summary of many of the clinical symptoms is shown later in Table 20.2.)

COMPLEX REGIONAL PAIN SYNDROME, TYPE II (CRPS, TYPE II)(CAUSALGIA)

CRPS type II, is usually associated with peripheral nerve injury and severe pain. According to Payne (1986), pain occurring in CRPS, type II follows an injury to a nerve trunk, usually a major proximal nerve branch, and is described as a persistent burning pain, but does not necessarily have to be burning in quality. It is unrelated to associated damage from surrounding tissue, and seems to be worsened by emotional or environmental stimuli. Most importantly, the pain seems to persist more than 5 to 6 weeks, which seems to be the length of time needed for surrounding tissue to recover from injury. Typically, the injury is due to damage by a bullet, a knife, sharpened rocks or parts propelled by a

TABLE 20.2
Clinical Symptoms Associated with CRPS, Type II and CRPS, Type I

Clinical Symptoms	Mechanism	Diagnostic Studies	Treatment
		CRPS, Type II	
a. Burning pain[a,b]	a. Unmyelinated C fibers[a]	a. Rarely have cold hyperalgesia (2/7) or heat hyperalgesia (0/9)[b]; do have mechanical hypersensitivity[b]; use a drop of acetone and Von Frey hairs to test	a. Phenoxybenzamine DREZ sympathectomy 12% to 97% effective[a], clonazepam[a], gabapentin[a]
b. Paroxysms of pain[a]	b. Nerve stretch and axon disruption[a]	b. Clinical reports	b. None
c. Partial motor paralysis (70%)	c. Peripheral nerve injury, proximal nerve trunk[a,b]	c. EMG/nerve conduction velocity studies	c. No relief with sympathetic blocks[b]; no success with beta-blockers[d]
d. Worse with stress	d. Lots of theory, no proof	d. Clinical reports	d. Clonidine
e. Vasomotor changes, but rare trophic change[b]	e. Unknown	e. Clinical observation	e. Sympathetic blocks
		CRPS, Type I	
Hyperalgesia and Allodynia			
a. Mechanical-hypersensitivity to light touch[a]	a. Ectopic alpha-adrenergic chemosensitivity[a], sensitization of WDR neurons in the spinal cord[a], central nervous system mediated[a], intact low-threshold mechanoreceptor with A-delta afferents[a]	a. All patients have mechanical hypersensitivity use Von Frey hairs to test[a]	a. Sympathectomy possibly relieving it[c] sympathectomy not relieving it[c], low-dose naltrexone possibly working[a] nifedipine[a]? gabapentin[a]?
b. Thermal-hypersensitivity	b. No mechanism delineated	b. Patients having either cold[b] either heat or cold[b,k] hyperalgesia (3/4), and/or heat hyperalgesia (4/5); use a drop of acetone to test[b]	b. 6/6 receiving relief with sympathetic blocks or sympahtectomy[b] nifedipine?
Dystrophy Phase			
a. Osteoporosis[a]	a. No mechanism delineated	a & b. X-ray did not correlate well with clinical symptoms, but bone scan did[a] (abnormal flow images, 83% abnormal static images[a]) (also true for clinical features c. and e.[a]); if clinically had CRPS, Type I, 22/23 had positive delay image bone scan[a]	a. & b. Maybe calcitonin[a,o,p,p]
b. Diffuse or patchy, bony demineralization[a,o,p]	b. No mechanism delineated	b. X-ray and bone scan[a]	b. Calcitonin[a,o,p,r]
c. Molted skin[a,b,r]	c. No mechanism delineated	c. Themography[a,p]	c. Prednisone 60 to 80 mg, tapering[r]
d. Hair loss[a,n]	d. No mechanism delineated	d. Clinical observation[a]	d. Steroids[a,r]
e. Vasomotor instability	e. No mechanism delineated	e. History or longitudinal observation	e. Sympathetic blocks[a], steroids[a]

machine, or other such objects. When the injury is associated with a high-velocity missile, one must consider not only actual damage to the tissue itself, but also hydrostatic effects caused by shock waves. When one takes into account the fact that the body is made up largely of water, it is easy to see how a high-velocity missile can cause damage not only to the actual tissue that has been penetrated by the missile but also to surrounding tissue as a result of hydrostatically transmitted shock waves. If the reader desires additional information concerning the hydrostatic effects of high-velocity missiles, he or she is referred to a most amazing book titled Split Seconds (Dalton, 1984). Photographs in the book clearly illustrate the hydraulic effect in soft tissue caused by a bullet.

Typically, patients with CRPS, type II report an onset of pain within several hours to a week after the injury, and describe the pain using words such as stinging, aching, burning, or tingling. Superimposed on the regular pain, patients may experience paroxysms of deep pain (Payne, 1986).

Long (1982) clearly made the distinction between CRPS, type II and CRPS, type I. CRPS, type II is secondary to partial injury to major mixed nerves, caused by low- or high-velocity missiles; and manifests as trophic changes in the distribution of the nerve

associated with extreme hypersensitivity. The pain is diffuse and burning, and true CRPS, type II almost always responds to sympathectomy. Long suggested performing three or more sympathetic blocks, sometimes every day for up to a week or longer, with the expectation that longer relief should follow each subsequent block. With positive responses to sympathetic blocks, Long would suggest a sympathectomy; on the other hand, CRPS, type I usually follows a minor injury and does not involve a major nerve root. Frequently, the site of injury is the knee, ankles, or wrist; and the pain seems to get worse with cold but not with emotional upset, unlike CRPS, type II. Demineralization of the bone occurs, with fibrosis of tendons and sheaths and spasm of the muscle. Dysesthesia suggests that there will be less success with sympathectomy.

SYMPATHETICALLY MAINTAINED PAIN

This term has come into use in an effort to further define diagnostic accuracy, which would then allow better selection of treatment methods, and have some predictive value in terms of outcome. Raja and Hendler (1990) report clinical features of sympathetically maintained pain to be (1) spontaneous pain, (2) hyperalgesia to both mechanical and cooling stimuli, (3) soft tissue swelling, (4) vasomotor disturbances, (5) trophic skin changes, (6) diminished motor function, and (7) pain relief after sympathetic blockade. By using these criteria, one can have sympathetically maintained pain that could have features of either CRPS, type I or CRPS, type II because either of these conditions could have features of sympathetically maintained pain.

Hendler (1982) originally described the use of oral phentolamine to treat CRPS, type I using the rationale that this drug was a postsynaptic alpha-1-blocker. Raja and his co-workers (1991) later described the use of intravenous phentolamine as a diagnostic test to confirm whether or not the pain a patient had was sympathetic in origin, that is, "sympathetically maintained." There is evidence that the mechanism of sympathetically maintained pain is present not only in CRPS, type I but also in some cases of CRPS, type II, however, because various authors have reported the benefit of sympathetic blocks in both disorders (Long, 1982; Ghostine, et al., 1984; Hannington-Kiff, 1979). Perhaps the best conceptual framework to use is one that takes into account both neurophysiologically (i.e., the presence or absence of major peripheral nerve injury documented by electromyography [EMG], nerve conduction velocities [NCV] studies, and the somatosensory evoked potential [SSEP]) and response to pharmacological intervention (i.e., response to IV phentolamine testing, or sympathetic blocks). A physician might consider six separate types of disorders, as shown in Table 20.3.

USING THE CLINICAL HISTORY AND SENSORY EXAMINATION FOR DIFFERENTIAL DIAGNOSIS

A number of authors have advanced the notion that there are other types of sensory mechanism, other than hyperalgesia evident in CRPS I and II (Chaplan, et al., 1994; Kim & Chung, 1995; Lee, et al., 1994; Lee & Yatsh, 1996). Unfortunately, the vast majority of the research reports are in animal models, using animals fairly low on the phylogenetic scale. There is always a danger in extrapolating from animal models to clinical work in humans, because there are species-specific differences, and some of the sensory values assigned to a rat reveal more about the creativity of the researcher than they do about the sensory experience of the rat. However, bearing these caveats in mind, clinicians should be aware of the research observations that may have significant value for their patients. A sensation called allodynia has been described, which is a painful response to a normally nonpainful stimulus. It is important to make a distinction between this sensation and hyperalgesia, which is a more intense response to a normally painful stimulus. This distinction bears reemphasis, for this is the most commonly confused terminology in the hands of inexperienced clinicians. Clinically, hyperalgesia, a more intense response to a normally painful stimulus, is seen in the early phases of nerve entrapments, and radiculopathies. In counterdistinction, allodynia, a painful response to a normally nonpainful stimulus, is seen in CRPS, types I and II.

Also, it is important to make a distinction between cold hyperalgesia, heat hyperalgesia, and mechanical hyperalgesia. Both cold and heat hyperalgesia are rarely seen in CRPS II (Meyer, Campbell, & Raja, 1985; Raja, et al., 1986). Moreover, it is important to make a distinction between cold allodynia, and mechanical allodynia. Cold thermal allodynia is most often seen in CRPS, types I and II, whereas mechanical allodynia is seen commonly in CRPS, types I and II; nerve entrapment syndromes; and radiculopathies (Hendler & Raja, 1994). This clinical distinction has led to the use of the Hendler alcohol drop and swipe test to make a distinction between CRPS, types I and II, with cold allodynia (which has a painful response to an alcohol dropped on an affected limb [allodynia]); and CRPS, types I and II, nerve entrapment syndromes, and radiculopathies, with mechanical allodynia, demonstrated by lightly stroking the affected limb with the used swab (Hendler, 1995). Concisely stated, mechanical allodynia is of less use diagnostically, because it may be present in CRPS, types I and II, nerve entrapment syndromes, and radiculopathies; whereas thermal allodynia is a more useful clinical feature, usually being limited mostly to CRPS, type I and occasionally to CRPS II (Meyer et al, 1985; Raja, et al., 1986).

TABLE 20.3
Diagnostic Considerations

Response to IV	Positive Response to Phentolamine IV	No Response to Phentolamine IV	Partial Response to Phentolamine IV
EMG/nerve conduction velocity/somatosensory-evoked potential: all negative	CRPS, type I sympathetically maintained pain (SMP)	Microvascular damage with swelling and mechanical hyperalgesia; sympathetically independent pain (SIP)	Mixed injury
EMG/nerve conduction velocity/somatosensory-evoked potential: at least one positive	CRPS, type II	Neuroma or nerve entrapment at site of injury; SIP	Mixed injury
Positive response to alcohol drop test	CRPS, type I, SMP	Too low a dose phentolamine	Too low a dose phentolamine
Positive response nerve to a local nerve block (radial, ulnar, median, peroneal, saphenous, tibial) with 100% relief of all symptoms	Nerve entrapment syndrome with sympathetic component	Nerve entrapment syndrome without any sympathetic component	Nerve entrapment syndrome with sympathetic component
Positive response to sympathetic block or (a warm limb and 100% relief of all symptoms)	CRPS, type I, SMP	Too low a dose of phentolamine, or too slow an infusion	Too low a dose of phentolamine; too slow an infusion
Partial relief of pain with local nerve block	Mixed injury	Poor nerve block	Mixed injury

Additionally, a cool limb is not diagnostic of CRPS I and II, despite many reports in the literature to that effect (Hannngton-Kiff, 1979; Prough, et al., 1985). First and foremost, for a clinician to hold an affected limb in one hand, and a normal limb in another, and pronounce that the temperatures are either equal or different is a demonstration of arrogance, more than clinical skills. The ability to detect temperature differences varies due to the ambient temperature of the clinical setting, and the "physiological zero" of the organism sensing the temperature change, which lowers the "threshold of detection for thermal sensation of the opposite quality" (Geldard, 1962, p. 137). In an extensive report, by Uematsu, Hendler, Hungerford, Ono, and Long (1981), reviewing 803 cases at Johns Hopkins Hospital, the authors found that (as expected) patients with CRPS I and II had cold limbs most of the time, with ranges of 0.5°C to more than 3.0°C coldness being reported for over 79% of the cases diagnosed with CRPS I. However, in 89% of the cases in which there were abnormal EMG or nerve conduction velocity studies, the affected limb was also cold, although not to the same severity as the patients with CRPS I. These figures included cases of CRPS II, as well as patients with radiculopathies, and nerve entrapment syndromes.

The anatomic distribution of the pain is another important feature to consider. Sympathetic fibers travel with the sensory nerves, so an injured sensory nerve may have a component of sympathetic damage reported, such as coldness, or hyperalgesia. However, the actual location of the pain is a critical factor. If the pain is in the distribution of a peripheral nerve, even if all the sensations for CRPS, type I are present, then the clinical syndrome is really a nerve entrapment, with the sympathetic sensory components of it coming from the sympathetic fibers traveling with the sensory nerve. CRPS, type I has a circumfrencial pain distribution (i.e., it is all around the limb, in the pattern of the blood flow, not in a discrete nerve distribution or in a radicular distribution). Failure to recognize this distinction has lead to the misdiagnosis of a number of nerve entrapment syndromes, which get mistakenly called CPRS, type I (Hendler & Kozikowsku, 1993; Hendler, Bergson, & Morrison, 1996). In an article in preparation, Hendler and colleagues will report that 70% of the patients sent to Mensana Clinic with the diagnosis of CRPS, type I actually have nerve entrapment syndromes.

TREATMENTS

Appropriate treatments for CRPS, type I and type II have been described in Consensus Report, sponsored by the International Association for the Study of Pain (IASP) (Stanton-Hicks, et al., 1998). In this report, the participants emphasized the need for functional restoration, and psychological counseling, as well as medical intervention. Not only is there disuse as the result of a painful limb, creating multiple disabilities and atrophy but there is also evidence that once the disorder of CRPS, type I spreads, that there may be a centrally mediated muscle disorder, resembling dystonia (Schwartzman & Kerrigan, 1990). Therefore, the prob-

lem of a painful limb in CRPS, type I and type II is compounded by a real motor disorder.

The psychological problems associated with both CRPS, type I and type II have been well described for chronic pain patients in general. Hendler (1982, 1984) has long reported that patients with both chronic pain and depression really have become depressed as the result of their chronic pain. The earlier psychiatric "wisdom" of feeling that depression manifests as chronic pain has not been supported by more care observations (Hendler & Talo, 1989). Therefore, the use of group therapy seems to be the most efficient and productive way of providing support for patients with all types of chronic pain problems, and certainly is applicable to patients with CRPS, type I and type II (Hendler, Vierstein, Shallenberger, & Long, 1981). Family counseling and patient education is also of great use, when available.

The pharmacological management of CRPS, type I and type II is complicated (Hendler, 2000). The treatments shown in Table 20.2 are meant to deal with the specific symptoms associated with CRPS, type I and type II. However, there is a role for a more generalized pharmacological approach, especially dealing with the issue of depression and pain relief. Antidepressants, in and of themselves, provide relief of many of the symptoms by (1) reducing depression, (2) reducing anxiety, and (3) promoting natural sleep; and actually have some limited pain-relieving properties (Max, et al., 1991; Watson, et al., 1991; Watson, et al., 1981). For symptomatic relief in CRPS, type I and type II, narcotics are problematic. A number of authors have reported reduced efficacy, or variable effects, of narcotics in the palliative treatment of pain in patients with CRPS, type I and type II (Arner & Meyerson, 1988; Lee, Chaplan, & Yaksh, 1995; Portenoy, Foley, & Inturrisi, 1990). The variability and usual lack of efficacy of narcotics for CRPS, type I and type II may be explained by recent elegant research, which shows only a kappa-2 opioid agonist blocks the pain of hyperalgesia and allodynia seen with peripheral neuritis and neuropathy, by inhibiting the activity of the *N*-methyl-D-aspartate (NMDA) receptor in the spine (Eliav, Herzberg, & Caudle, 1999). Although this research is in animals, with all the attendant problems of translating to human use, this avenue seems to hold a great deal of promise, because the formulation of a kappa-2 opioid agonist is a feasible endeavor for major drug companies. However, as of the date of writing this material, there is no practical kappa-2 agonist available for human use; thus the use of narcotics in CRPS, type I and type II for allodynia and hyperalgesia is of limited usefulness. Opioids may help pain caused by other symptoms of CRPS, type I and type II, such as muscle spasm and pathological fractures. A review of other pharmacological approaches for the management of pain can be found in several chapters by the author (Hendler, 1997, 2000).

Sympathetic blocks have always been the mainstay of diagnosis and treatment. The important feature of these blocks is to be certain of the efficacy of the block, before interpreting the result. The clinical criterion that best correlates with an efficacious block is the report of total limb warming. This tells the clinician that the sympathetic block did what it was supposed to do (i.e., blocked the sympathetic input to a limb, thereby producing warming of the limb). At this point, the next question to ask the patient is, "What do you feel?" If the patient has a warm limb, and 100% total absolute relief of all pain, then one may consider that the block was (1) effective and (2) appropriate for pain relief. From this, a clinician may conclude that the pain is sympathetic in origin. If, however, the block did not warm the limb, then the clinician must conclude that the block was not effective; and no information of any value can be determined from this type of block, except that another block, at a later date, is needed. If the block produces a warm limb, but only partial relief of the symptoms, then the question is, "Where do you still have pain?" If the remaining pain is reported in a nerve distribution, then the patient has both CRPS, type I and a nerve entrapment syndrome, which coexist, or a nerve entrapment syndrome, with a sympathetic component. If the limb is warm, and the patient has no relief, then the chances are the patient has a pure nerve entrapment syndrome (see Table 20.3).

After a clinician determines a block is effective, then the patient should have a series of six to ten blocks. After this series of blocks, several results are possible: (1) the CRPS, type I or II may go away, (2) the CRPS, type I or II may temporarily go away for weeks or months, only to return; or (3) the CRPS, type I or II may temporarily go away for hours or days, after the blocks, only to return. If scenario (1) occurs, the diagnostic blocks have also provided the cure. If scenario (2) or (3) occurs, then the patient is a candidate for sympathectomy. This author favors the surgical sympathectomy, because direct visualization of the sympathetic chain, and pathology reports on the tissue are more reassuring than a blind ablation techniques. Moreover, the author has seen disastrous results in patients, in which phenol was used for a neuroablative procedure. Despite the obvious benefit of direct visualization for sympathectomy, there are still some physicians, mostly anesthesiologists, who continue to use blind chemoablative techniques, with neurolytic agents, such as phenol, or radiofrequency lesions (Stanton-Hicks, et al., 1998).

In extreme cases, the use of epidural stimulation has been reported efficacious, although there are only a small number of cases in the literature (Barolat, Schwartzman, & Woo, 1989; Peuschl, Blumber, & Lucking, 1991; Robaina, Dominguez, & Diaz, 1989). The epidural infusion of SNX-111 has been suggested as a possible treatment for CRPS, type I or II, as has the infusion of

baclofen. SNX-111 is a conotoxin that works on specific calcium channels to block the message of pain, whereas baclofen is a gabaminergic muscle relaxer. Epidural opioid infusion has been reported (Broseta, Roldan, & Gonzales-Darder, 1982), but the absence of a kappa-2 agonist may have reduced the potential results (Eliav, et al., 1999). Clonidine actually seems more effective than morphine in humans, for deafferentation pain, after spinal cord injury (Hassenbusch, Stanton-Hicks, & Covington, 1995). Other researchers have explained this difference, based on the independence of the opioid and noradrenergic pathways of the spinal cord (Glynn, Dawson, & Sanders, 1988). Opioid receptors exist in only a small group of neurons in the dorsal horn, and have various subsets, of which only the kappa-2 subset seems to be effective in reducing the allodynia of CRPS, type I (Eliav, et al., 1999). On the other hand, clonidine has multiple sites of action, such as inhibiting pain transmission in the dorsal horn of the spinal cord, and inhibiting norepinephrine release, due to its alpha-2 partial agonist effect, which inhibits the release of norepinephrine.

THEORY

With the clinical descriptions from Table 20.3 in mind, one can then make an effort to define the various anatomic, neuroanatomic, and physiological bases for these two disorders. Ghostine and colleagues (1984) have suggested multiple etiologies for CRPS, type II. Various considerations include ephapse, in which there seems to be an erosion of the insulation between nerve fibers, allowing for short-circuiting between somatic afferent fibers and sympathetic efferent fibers; and experimentally produced neuromas, with resultant ephapses occurring both acutely and chronically between myelinated fibers. Because of the delay in developing the ephapses, which does not correspond to the clinical observations of a relatively rapid onset of CRPS, type I and type II, however, the theory of ephapses as the etiology of CRPS, type II has fallen from favor. To replace this theory, the concept of nerve sprouts or free nerve endings that are sparsely myelinated seems feasible. Axonal sprouting has been noted to occur early after an injury, with a high frequency and without total axonal disruption. The possibility that causalgia is produced by these sparsely myelinated fibers is supported by evidence that the blood–nerve barrier, which is similar to the blood–brain barrier, has been destroyed in the injured nerve.

Perhaps the most comprehensive review of the neurophysiological basis of CRPS, type I and type II has been advanced by Roberts (1986). In his extensive review article, Roberts dealt with the neural mechanisms associated with pain of CRPS, types II and I. He called these disorders SMP. His hypothesis concerning SMP is based on two assumptions: "(1) that a high rate of firing in spinal wide dynamic range (WDR) or multireceptive neurons results in painful sensation and (2) that a nociceptor response is associated with trauma which can produce long-term sensitization of the WDR neuron." Furthermore, his theory postulates that SMP is mediated by low-threshold, myelinated mechanoreceptors, and that these impulses, which carry messages to the brain, are the result of sympathetic fibers carrying messages from the spine and brain to act on the receptors, or to act on the fibers carrying messages to the brain. The most important part of this hypothesis is the fact that Roberts does not postulate the need for nerve injury or for dystrophic tissue. Before one can more fully appreciate Roberts' theories, however, one has to explore the basic anatomy of the sympathetic chains.

Bennett (1991) at the National Institute of Health has advanced a brilliant theory that integrates clinical observations with basic neurophysiology. Bennett synthesizes three theories that show that damaged nerves, when they regenerate, have sprouts that are sensitive to norepinephrine; they will discharge on exposure to norepinephrine; there is enough norepinephrine produced by sympathetic fibers to trigger firing of damaged nerves; damaged nerves actually produce norepinephrine receptors at the damaged end; and nociceptors (pain receptors) in intact nerves fire more in response to norepinephrine. All of these mechanisms may be operating in the case of patient nerve damage due to physical trauma, he says; and these events are likely to sensitize surviving afferent terminals, perhaps to the point of inducing an ongoing discharge …". Bennett further differentiates between the type of injury: constriction or entrapment vs. partial destruction of a major peripheral nerve. The former injury (constriction) does not seem to respond to sympathetic blocks 1 to 2 weeks after the injury, and this is attributed to the loss of noradrenergic vasomotor innervation, which takes several weeks to develop. The latter injury (partial nerve destruction) becomes painful within hours of the injury, remains painful for months, and responds to sympathetic blocks even months after the injury. Other researchers have expanded on a purely neuron-mediated mechanism, and have suggested that autoimmune factors may be involved. The Schwartzman group, at Thomas Jefferson University School of Medicine, Philadelphia, found inflammatory skin lesions in the late stages of CRPS, type I, and attribute these lesions to a deposition of immune complexes in the skin. They believe the skin lesion supports the concept that cytokines and lymphokines such as interleukin-2 (IL-2) are produced as the result of the activation of complement; this in turn is excited by the progression of events beginning with local injury causing nerve growth factor release, thus activating sympathetic neurons and causing recruitment of neutrophils and monocytes, which in turn activate complement (Webster, et al, 1991). Interestingly, IL-2 has been found to selectively stimulate sympathetic

neurons, whereas nerve growth factor (NGF) is produced in high concentrations after injury, which stimulates inflammation and in turn activates complement. Knobler (1996) has expanded on this, and advanced the notion of aberrant immunologic mechanism, as a cause for CRPS, type I. He traces trauma, as the cause for the release of NGF, which then stimulates inflammation and activates the complement components of the immune response, "promoting the expansion of antibody-producing B cells of the immune system." He reports that substance P and the lymphokine IL-2 are released in response to NGF, with both of these factors acting on the sympathetic nerves to activate it. As research progresses, the various factors described earlier need to be explored, with rigorous controls for (1) the type of lesion (crush vs. cut), (2) the stage of the disease, correlating with anatomic and neurohumoral changes over time, and (3) the attempt to correlate the clinical symptoms with response to various treatments.

In a discovery that led to her Nobel Prize, Rita Levi-Montalcini described the effect of NGF on sympathetic nerve (Levi-Montalcini, Skaper, Toso, Petrelli, & Leon 1996). In response to an injury or lack of innervation, the end organ, sensory receptor, releases NGF, which chemotaxically stimulates a nerve to grow toward the newly denervated receptor. This chemotaxic agent was found to be NGF. Clearly, sympathetic ganglion grow profusely in response to the addition of NGF to their growth medium. This is not limited to just sympathetic nerves. Skin and sensory nerves also have sprouted after injury (Inball, Rousso, Ashur, Wall, & Devor, 1987).

A study by Ro, Chen, Tang, & Jacobs (1999) shows that this process can be reversed, in rats, by the administration of anti-nerve growth factor antibodies. Previous work shows that anti-NGF antibodies prevented collateral sprouting of dorsal root ganglion in rats (Mearow & Kril, 1995). Ro and others (1999) studied the specific sensory response to anti-NGF, which showed that, in a dosage and time-dependent fashion, heat and cold hyperalgesia can be reduced, as well as collateral sprouting.

Finally, one of the most seminal concepts to emerge from animals studies is the idea of plasticity of the central nervous system (i.e., its ability to change in response to stimuli). Nowhere is this more important than for the understanding of CRPS, types I and II. In response to a chronically painful stimulus, the cells of the dorsal horn of the spinal cord actually alter their cytoarchitecture (the structure of the chemistry of the cell). Hyperalgesia and allodynia are largely created by the enhancement of NMDA receptor activity in the spinal cord, and treated by blocking the NMDA receptor (Ren & Dubner, 1993). The central role of NMDA receptor activity in the creation of allodynia must be emphasized. Unfortunately, there is not a practical way to modify the NMDA receptor in man, so the treatment of hyperalgesia and allodynia remains elusive. Therefore, mechanisms other than NMDA inhibition need to be explored.

To briefly summarize the material presented earlier, three sensations are associated with CRPS, types I and II: (1) pain, which is a sensation usually experienced when tissue damage occurs; (2) hyperalgesia, which is an increased response to a normally painful stimulus; and (3) allodynia, which is a painful response to a normally non-painful stimulus. This can be hot, cold, mechanical, or even chemical. The message of pain is initiated at two receptor sites: (1) a nosioceptor, which is usually a free nerve ending, or unmyelinated C fiber, which detects tissue damage such as temperature or chemical changes; (2) a mechanoreceptor, which is sensitive to pressure, like a Pachinian corpusle. When tissue is damaged, it produces a primary hyperalgesia, which is a sensitivity to pain, at the site of the pain; and a secondary hyperalgesia, surrounding the zone of primary hyperalgesia, in the absence of tissue damage. A sensitized nosioceptor has a lower threshold to pain, and produces hyperalgesia, whereas a sensitized mechanoreceptor transmits a message of pain, to a normally nonpainful stimulus (i.e., allodynia). Both hyperalgesia, and allodynia are the result of spinal dorsal horn body sensitization. The afferent fibers carry the sensory message to the brain, and the efferent fibers modify the sensory input from the brain back to the periphery. They have their origins in the brain stem, medulla, and periaquaductal gray; and are called descending afferent pathways. These pathways modify sensation. At the spinal cord level, increased sensory input from the peripheral nosioceptor actually changes cell functioning in the spinal cord, by altering chemical mediators, and receptor activity. The persistent sensory stimuli activates NMDA at certain cells of the dorsal horn of the spinal cord, called WDR neurons or NS. Phosphorylation of the NMDA receptor is the result of constant sensory input, which then activates the NMDA receptor, and this creates central sensitization of the receptor ion channel. Mg^{2+} is removed, so Ca^{2+} enters the channel, which causes cell sensitization. This spinal cord change produces allodynia in the peripheral nerves. Therefore, tissue damage produces damage to the nosioceptor in the periphery, causing sensitization, or hyperalgesia; and the result of this chronic increase in activity at the spinal cord level produces central sensitization. Likewise, damage to the nerve causes growth hormone to produce nerve sprouts; these are very sensitive, which cause continued input the spinal cord, producing central sensitization. This increased sensory input, which produces central sensitization, actually changes the cells in the dorsal horn of the spinal cord, which results in allodynia. The damaged nerve produces sprouts, as the result of NGF stimulation. These sprouts have alpha-2 adreno-receptors on them, which are sensitive to norepinephrine circulating in the bloodstream.

GROSS ANATOMY

The most startling finding, and one that flies in the face of commonly held beliefs, is a report by Kleinman (1954) in which sympathetic chains were found to have communication between them, in up to 80% of cases. This is an important finding, because this anatomic consideration is rarely, if ever, discussed in surgical textbooks or clinical papers. This finding also explains why some cases of CRPS, type I do not respond to sympathetic denervation, and why, paradoxical as it may seem, some cases do respond to countralateral blocks (i.e., if a patient has pain in the left leg, blocking the right lumbar sympathetic chain may produce relief).

Additional anatomy has been described by Allen and Morety (1982). When one traces the pathway of the sympathetic nerves, cell bodies are located in the lateral columns of the cervical, thoracic, and lumbar spinal cord. Cell bodies then give off axons, which form the preganglionic fibers of the sympathetic nervous system. From C7 to L2, these fibers are associated with the anterior spinal nerve roots, and leave the spinal cord in this pathway. They then separate from the nerve root and become the white rami communicantes, which then continue on to the paravertebral ganglia, forming a chain running from the skull to the coccyx. From the ganglia themselves postganglionic fibers run back to nerve roots, or become separate nerves supplying various organs.

It is important to note that some ganglion cells are found in the anterior roots, as well as the white and gray rami. By the same token, some pre- and post-ganglionic fibers do not pass through sympathetic trunks, which again indicates that there is residual sympathetic innervation due to either normal variants or aberrant fibers that bypass the sympathetic trunk. This anatomic finding explains the failure of some ganglionectomies, and suggests that one might need to do anterior nerve root sections and preganglionic rami sectioning (Smithwick procedure) in patients in whom ganglionectomy has failed.

Cervical outflow, coming from the upper portion of the cervical chain, sends fibers to the pupils and the eyelids. These fibers radiate from the upper stellate ganglion, which also supplies various fibers in the head and face. The upper thoracic sympathetic chain receives preganglionic input from upper thoracic roots, and supplies the upper extremity through postganglionic fibers that pass through the brachial plexus. The lower extremities receive input from the T11 to L3 nerve roots, forming ganglia; and from the lower two lumbar and upper sacral nerve roots, with gray rami (postganglionic) to the lumbosacral plexus.

MICROANATOMY

As described earlier in the gross anatomy portion, there are various sites along the sympathetic chain where damage can occur to a nerve. Additionally, there are several sites where chemical intervention is possible, notably at the synapses that occur along the sympathetic pathways. Additionally, the various fibers that carry sympathetic messages are important. It has been widely held that C fibers, which are small unmyelinated fibers carrying sensory messages, are responsible for the transmission of pain. Some theories consider that SMP is mediated by activity in A fibers, however, because C-fiber blockade fails to eliminate pain in patients with SMP (Roberts, 1986). Therefore, one must start at the very beginning of the onset of pain (i.e., the receptor itself) to fully understand SMP and CRPS, types I and II. Originally, it was thought that nociceptor afferents (nerves that carry the message of pain from the periphery to the cord and the brain) were responsible for the continuous pain of SMP and CRPS, type I and CRPS, type II (Bonica, 1970; Devo & Janig, 1981; Roberts, 1986). In Roberts (1986) article, however, he adheres to a theory first advanced by Loh and Nathan (1978) that indicates low-threshold mechanoreceptors are responsible for SMP. Roberts takes this position because nociceptor afferents, which are typically considered unmyelinated C fibers, do not have appropriate responses to sympathetic activity; therefore, both practically and conceptually cannot be included as the receptors that mediate SMP. Roberts (1986) reported that mechanoreceptors do respond appropriately to both touch and sympathetic activity, however. For CRPS, type II, others have proposed a neuroma formation as the cause of pain. Roberts believes that the sympathetic action of a neuroma is not capable of explaining why treatments that occur distal to the injury (in the form of either a nerve block or guanethidine infusion) are able to ameliorate CRPS, type II, however; even so, Roberts (1986) used the summation theory, or convergence theory, to say that both the peripheral receptors (in this case, mechanoreceptors) that arise in the neuroma and those that arise in the skin itself are transmitting painful messages to the cord, and that distal blocks eliminate only the mechanoreceptors from the skin, which is not enough to trigger responses in the WDR neurons in the spinal cord. Additionally, the concept of a neuroma causing prolongation of CRPS, type II-type pain does not fit the clinical observation that SMP may occur even in cases in which the nerve is not injured.

Ochoa, et al. (1985) advanced the theory that mechanical A-delta nociceptor endings become sensitized to multiple sensory inputs. This gives rise to the thermal hyperalgesia that is seen in CRPS, type I. On the other hand, Ochoa believes that there are abnormalities in distal nociceptor fibers that seem to have a low threshold. These low-threshold mechanoreceptors reside within large myelinated fibers, and are nonsympathetic dependent, because they transfer their information to nociceptor pathways proximal

to the site of injury. These fibers may account for the mechanical hyperalgesia, manifesting as sensitivity to light touch. The previously mentioned receptors, which are the source of the hyperalgesia seen in CRPS, type I, are different than the burning pain receptors seen in CRPS, type II. Ochoa and colleagues (1985) believe that the burning pain of CRPS, type II is mediated by unmyelinated C fibers, whereas Payne (1986) believes that this pain is due to nerve stretch and axon disruptions. Another consideration is the fact that such pain may be mediated by nerve fascicles where all three types of fibers exit (Ochoa, et al., 1985). Therefore, in summary, the current thinking seems to suggest that sparsely myelinated or C fibers carry the message of burning pain found in CRPS, type II, whereas sparsely myelinated afferents or the A-delta nociceptors may be responsible for pain in CRPS, type I.

SYNAPSES

Both synaptic considerations and axonal considerations have been raised as possible factors controlling both CRPS, types I and II. Ephapses, or artificial synapses, have been demonstrated in normal peripheral nerves. The concept of synaptic factors in CRPS, types I and II pain was first advanced by Granit, Leksell, & Skoglund (1944) when they found that stimulating the motor root of a damaged mixed motor sensory nerve also produced recordable electrical events in the sensory root. According to the review by Payne (1986), the formation of ephapses after nerve injury may allow a short circuiting or shunting of current from sympathetic fibers coming from the cord to the peripheral nerve into somatic fibers arising at the site of injury, carrying the message of pain back to the cord. Unfortunately, these cross-connections between fibers coming from the cord to the periphery, and conversely coming from the periphery to the cord, have been demonstrated in animal models, but not in humans (Payne 1986). Another consideration is the possibility of an ectopic impulse resulting from alterations in calcium, sodium, and potassium channels (Payne, 1986). In effect, the damaged nerve becomes "epileptic," and the spontaneous discharges from the sensory nerve may give rise to the episodic pain noted in some individuals. This could be due to lowered threshold or heightened mechanical sensitivity.

Neurosynaptic mediation of CRPS, types II and I, holds great promise for the future. When reviewing the synapses that are present within the sympathetic chain, it is apparent that these provide a potential site of mediation for sensory input. To understand synaptic mediation, one must review the anatomy of a synapse per se. By borrowing heavily from Roberts (1986), one can define the functional neuroanatomy, and delineate the location of various synapses. First, the trauma occurs, with receptors in the skin detecting various components of the trauma. Initially, the C-fiber nociceptors carry the message to the dorsal root ganglion, and then back to the spinal cord neuron, where they synapse. After synapsing with the neuron in the spinal cord, these multiple neurons transmit information to the WDR neurons, which then send messages, via their axons, to the central nervous system or higher levels of the spinal cord. With use of Roberts' model, additional light touch activates the mechanoreceptors, which travel in the A fibers instead of the C fibers. Because the WDR neurons are already sensitized by the C fibers nociceptors, they respond to what is usually subthreshold stimuli to the A fiber mechanoreceptors. These mechanoreceptors travel in the A fiber, reaching a neuron within the spinal cord, which again impinges on the WDR neuron; this, in turn, again sends messages up the spinal cord to the brain. Sympathetic fibers exist within the lateral portions of the thoracic cord, sending efferent messages to the sensory receptor. These efferent messages (i.e., messages traveling from the cord to the periphery, mainly to the sensory receptors) may occur in the absence of cutaneous stimulation. According to Roberts' theory, however, the sympathetic efferent activity requires no cutaneous stimulation, and is the cause of the SMP. In response to this efferent activity, the WDR neurons fire, again sending messages to the spinal cord and brain. The key to Roberts' theory is the fact that the WDR neurons in the spinal cord remain sensitized, and they give a vigorous response to mechanical stimulation of A-fiber mechanoreceptors even after healing has occurred. In this schema, multiple synapses occur within the spinal cord, at the WDR neuron, and in the sympathetic ganglion. Therefore, synaptic regulation can occur at the spinal cord level or at the sympathetic ganglion level. When reviewing the actual synapse, one must conceptualize a presynaptic area wherein various chemicals are formulated, becoming neurosynaptic transmitters. The two synaptic transmitters that are of most interest to the study of CRPS, types I and II are the indolamines, of which serotonin is an example; and the catecholamines, of which norepinephrine, epinephrine, dopa, and dopamine are examples. In the presynaptic area of the nerve, precursor substances are manufactured into neurosynaptic transmitters, which confer a degree of specificity on nerve transmission. L-Tryptophan becomes 5-hydroxytryptophan, which becomes 5-hydroxytryptamine (serotonin); dopa becomes dopamine, which can be converted to norepinephrine and epinephrine.

The specific type of the neurosynaptic transmitter determines whether it will occupy a specific postsynaptic receptor site. Biogenic amines, such as the indolamines and catecholamines, are constantly being formulated and broken down by monoamine oxidase (MAO). Thus, chemically, the presynaptic area may be described as an area of high flux, with formulation and degradation of the same chemical occurring in the relatively steady state. As electrical impulses travel down the axon, pore diameter

changes, altering the permeability of the membrane and causing the release of neurosynaptic transmitters. These synaptic transmitters flow across a minute gap between nerves and occupy postsynaptic receptor sites. The gap, of course, is called the synapse. The postsynaptic receptor sites determine the strength and duration of the electrical impulse that the synapse propagates. This is done by the degree of specificity that the neurosynaptic transmitters have for a particular receptor site. It also depends on the affinity that a specific neurosynaptic transmitter has for a particular receptor site, and whether it is easily displaced or forms a tight bond. Almost all neurosynaptic transmitters have their activity ended by presynaptic reuptake; that is, the chemical that occupies the postsynaptic receptor site is then taken back into the presynaptic area. Acetylcholine is an exception, being degraded on the postsynaptic receptor site by acetylcholinesterase. Additionally, some small amount of degradation of biogenic amines occurs in the synapse itself by catechol-O-methyltransferase (COMT). It is thought that less than 5% of the chemical degradation of synaptic transmitters occurs in the synapse by COMT, and 95% of the degradation occurs presynaptically, by MAO. Of course, there is constant rebuilding of the neurosynaptic transmitter presynaptically, creating the steady state mentioned earlier.

Obviously, there are multiple ways to modify the synapse. One can inhibit MAO, thereby enhancing the buildup of a monoamine neurosynaptic transmitter, such as the indolamines or the catecholamines. In fact, a class of drugs called MAO inhibitors do exactly that. By the same token, certain drugs can function as MAO exciters, which facilitate the degradation of biogenic amine neurosynaptic transmitters, such as the indolamines (serotonin) and the catecholamines (epinephrine, norepinephrine, dopamine, and dopa). Because the majority of the neurosynaptic transmitters have their activity ended by presynaptic reuptake, one can enhance the synaptic transmission by blocking presynaptic reuptake. This is how tricyclic antidepressants work. Conversely, one can diminish synaptic transmission by facilitation of presynaptic reuptake. Finally, one can work at the receptor end by using drugs that mimic the action of the presynaptic transmitters and occupy receptor sites, thereby triggering them as if the actual chemical had been released. By the same token, other drugs can be used that occupy the receptor sites but have no pharmacological activity other than to inhibit the presynaptic transmitter from occupying the receptor site. For example, curate effects a total blockade of the acetylcholine receptor. In this sense, these drugs become inhibitors of neurosynaptic transmission. Receptor sites are found not only postsynaptically but also presynaptically, very often for the same presynaptic neurosynaptic transmitter. As the number and sensitivity of these receptors change, so does the response to the neurosynaptic transmitter itself.

DIAGNOSIS OF COMPLEX REGIONAL PAIN SYNDROME, TYPE II

With the foregoing theoretical information, the clinical components of CRPS, types I and II should be more readily differentiated by appropriate diagnostic studies. According to both Raja, et al. (1986) and Payne (1986), CRPS, type II manifests as a burning pain, which is not a consistent finding of CRPS, type I. Additionally, CRPS, type II patients may experience paroxysms of pain, especially after stress, whether it be emotional or environmental. In an elegant study, Raja, et al. (1986) found that patients with CRPS, type II rarely have cold hyperalgesia (two of nine), and they do not have heat hyperalgesia (none of nine). Additionally, these patients obtain no relief from sympathetic blocks. Raja, et al. (1986) differentiated various types of hyperalgesia using sensory testing with either Von Frey hairs for touch, a drop of acetone for cold, or laser thermal stimulation for heat. Ochoa, et al. (1985) believe that CRPS, type II is not always sympathetically mediated, and instead is mediated by unmyelinated C fibers. Stretch injuries to the nerve or axon disruption of a major nerve branch is one explanation favored by Payne (1986). Usually, the CRPS, type II patient has a history of a nerve injury to a peripheral nerve, or surgery, that has damaged the proximal portion of the nerve trunk (Payne, 1986; Raja, et al., 1986). The CRPS, type II may be related to damage of nerve fascicles where all three types of C fibers exist (Ochoa, et al., 1985).

TREATMENT OF COMPLEX REGIONAL PAIN SYNDROME, TYPE II

Various authors have reported that sympathetic blocks are or are not effective, with efficacy for sympathectomy being reported to be between 12 and 97% (Payne, 1986). No relief with sympathetic blocks was reported by Raja, et al. (1986; 1991). Payne has suggested that a dorsal root entry zone (DREZ) procedure may prove effective. Ghostine, et al. (1984) have suggested the use of phenoxybenzamine. They reported 40 consecutive cases of CRPS, type II, all of which involved nerve injuries from bullet or shrapnel wounds. The Ghostine group noted partial motor paralysis in the distribution of the damaged nerve in 70% of the cases. Over time these deficits resolved in many of the cases, however. They also noted vasomotor changes, usually severe vasodilatation and sweating and less often vasoconstriction (Dalton, 1984). Rarely were trophic changes noted. The majority of the cases involved the sciatic nerve, median nerve, brachial Plexus, cauda equina, and occipital nerve, in descending order. The treatment that Ghostine, et al. (1984) used was phenoxybenzamine, which is a postsynaptic alpha-1-blocker and a presynaptic alpha-2-blocker. As mentioned earlier under the etiology of CRPS, type II, nerve sprouts, which are one of the theoretical

origins of this disorder, seem to be highly excitable on the administration of norepinephrine; these can be reversed with alpha-blocking agents such as phentolamine but which are unaffected by beta-blocking agents. The dosage of the drug used by Ghostine, et al. initially was 10 mg three times a day, although this varied from patient to patient. Eventually maximum dosages of 40 to 120 mg/day were reached, with treatment lasting 6 to 8 weeks. Common side effects were orthostatic hypotension in about 45% of the patients and reduced ejaculatory ability in about 8% of the patients. In some instances, treatment lasted as long as 16 weeks. It is important to note that the patients were all treated within 2 to 70 days after the onset of their injury, however.

For this treatment to be effective, it is most important that rapid diagnosis and institution of treatment occur. Another possibility for the pharmacological treatment of CRPS, type II would be the use of clonazepam, which has been reported by Bouckoms and Litman (1985) to be effective for "burning" pains.

Surgical sympathectomy has been recommended as a treatment for CRPS, type II, after repetitive sympathetic blocks. Additionally, guanethidine, which is a ganglionic blocking agent, has proved effective in treating some forms of CRPS, type II. Guanethidine must be used with caution, however, because it causes the release of norepinephrine prior to occupying the receptor sites itself, and the time course of the cessation of activity is variable. The fact that one may occlude an affected limb below the site of the CRPS, type II and still achieve effective blocks with guanethidine suggests that its activity is not at the ganglion but instead on the peripheral sensory nerves, which produces its effect on CRPS, type II (Hannington-Kiff, 1979). Surgical intervention, in the form of surgical sympathectomy, has been used to treat CRPS, type II with variable cure rates, ranging from 12 to 97%. The variability may be ascribed to lack of precision and diagnosis, with an overlap of CRPS, type I with CRPS, type II, or CRPS, type I mistakenly diagnosed as CRPS, type II; varying skills in performing blocks; collateral reinnervation of postganglionic sympathetic fibers; and delay in performing a sympathectomy (Payne, 1986). For CRPS, type II that is not responding to sympathectomy, the possibility of a contralateral sympathectomy has been raised (Kleinman, 1954).

DIAGNOSIS OF COMPLEX REGIONAL PAIN SYNDROME, TYPE I

The clinical diagnosis of CRPS, type I is more complicated than that of CRPS, type II. Some authors believe that there is a very definite set of criteria to establish the diagnosis, whereas other authors think that only several symptoms from a whole list of symptom complexes need be present to establish the diagnosis of CRPS, type I. Kozin, et al. (1981) have established the criteria for CRPS, type I as a patient presenting with pain and tenderness in an extremity associated with vasomotor instability (particular temperature or color changes) and generalized swelling in the same extremity. The second group of patients they consider are those with pain and tenderness associated with a vasomotor instability or swelling in an extremity; they call this group "probable CRPS, type I." This system lacks precision, however, because it does not take into account the particular type of pain that patients with CRPS, type I experience.

Raja, et al. (1986) define patients as having CRPS, type I if they have pain associated with signs of sympathetic hyperactivity (i.e., lower skin temperature, skin discoloration, increased sweating, and some trophic changes) and symptomatic relief after sympathetic blocks; they found that those with CRPS, type I also had thermal hyperalgesia either to cold or to heat. In contrast, their patients with CRPS, type II did not experience thermal hyperalgesia to heat, and only two out of seven experienced hyperalgesia to cold. Both the CRPS, type II and CRPS, type I patients experienced hyperalgesia to mechanical stimulation (Raja, et al., 1986). On the other hand, Ochoa, et al. (1985) found mechanical hyperalgesia, which they called allodynia, in their patients with CRPS, type I. Additionally, hypersensitivity to temperature was also found in patients with CRPS, type I, whether it be to heat or to cold (Meyer, Campbell, & Raja, 1985; Ochoa, 1985; Raja, et al., 1986).

One proposed mechanism for mechanical hypersensitivity is ectopic alpha-adrenergic chemosensitivity (Devor, 1983). Another consideration is a secondary abnormality in distal nociceptor fibers that escaped injury, or intact low-threshold mechanoreceptors with large myelinated fibers that are not sympathetic dependent because of transfer of information to nociceptor pathways proximal to the site of injury (Ochoa, 1985). Additionally, Ochoa, et al. (1985) advanced the concept of alpha-receptor sensitization, whereas others believe that the hypersensitivity of the mechanoreceptors could possibly be a central nervous system event (Meyer, Campbell, & Raja, 1985).

TREATMENT OF COMPLEX REGIONAL PAIN SYNDROME, TYPE I

Treatments for the mechanical hypersensitivity or hyperalgesia of CRPS, type I have been advanced by several authors, without clear-cut definition. One group of authors believes that sympathectomy may relieve mechanical hyperalgesia, whereas another group of authors reports that sympathectomy does not (Meyer, Campbell, & Raja, 1985; Hoffert, et al., 1984). Another group has advanced the notion that nifedipine, a calcium channel-blocking

agent, may prove effective (Prough, et al., 1985). Finally, a group from South Africa suggested that low-dose naloxone, and possibly longer acting naltrexone, may prove effective for reducing mechanical hyperalgesia, because of the existence of a hypergesic kappa system of opiate receptors (Gillman and Lichtigfeld, 1985). Again, the area of mechanical hyperalgesia is quite muddy, because all the patients with either CRPS, type II or CRPS, type I had mechanical hypersensitivity (Raja, et al., 1986).

Thermal hypersensitivity to either heat or cold (hyperalgesia) has been reported by several groups (Meyer, Campbell, & Raja, 1985; Ochoa, et al., 1985; Raja, et al., 1986). The mechanism behind the thermal hypersensitivity is not well elucidated, but one can clinically differentiate mechanical from thermal hypersensitivity by the use of a drop of acetone. Patients with CRPS, type I in the series studied by Raja, et al. (1986) had hyperalgesia to cold (three of four, as tested by acetone drop) or to heat (four of five, as tested using a laser thermal stimulator). Some patients had hypersensitivity and hyperalgesia to both heat and cold; however, these patients did not have CRPS, type II, but instead CRPS, type I. Of the group of patients with hyperalgesia to temperature change, six of six got relief with sympathetic blocks or sympathectomy (Raja, et al., 1986). Other authors have reported that nifedipine is effective for treating hyperalgesia (Prough, et al., 1985). Specifically, in 13 patients with pain having a burning character, dysesthesia, and cold intolerance, nifedipine beginning at 10 mg three times a day, and increasing to 30 mg three times a day, proved effective in 7 of 13 patients. Nifedipine is a calcium channel-blocking agent, and as such may work by dilating blood vessels and antagonizing the effects of norepinephrine on arterial and venous muscle (Payne, 1986). Also, nifedipine may interfere with ectopic impulse formation that occurs in regenerating nerves, by blocking calcium channel protein.

The dystrophic component of CRPS, type I is more difficult to delineate. Some authors have reported a diffuse or patchy bony demineralization (Kozin, et al., 1981), whereas others have reported frank osteoporosis late in the disorder (Schott, 1986). A number of authors have reported molted skin, again late in the disorder (Kozin, et al., 1981; Payne, 1986; Raja, et al., 1986). Some authors have reported hair loss, yet again late in the disorder (Raja, et al., 1986; Schott, 1986). Vague terms such as vasomotor instability have also been reported, as well as trophic skin changes (Kozin, et al., 1981). The etiology for these components is not well defined, but the consensus seems to be reduced blood flow to the various involved organs.

A more precise diagnostic assessment was advanced by Holder and MacKinnon (1984). They evaluated patients with CRPS, type I, which they defined as diffuse hand pain, diminished hand function, joint stiffness, and skin and soft tissue trophic changes with or without vasomotor instability. They also used three other control groups, including patients with diffuse pain, focal pain, or vascular disease. Holder and MacKinnon (1984) found that 22 of the 23 patients who met their criteria for diagnosing CRPS, type I had positive delayed image bone scans, 12 of the 23 patients had positive blood pool images, and 10 of the 23 patients had positive radionuclide angiograms. Approximately half the patients with CRPS, type I had positive early phase bone scans, whereas almost all patients with CRPS, type I had positive delayed image bone scans.

This study compared favorably with work done by Kozin, et al. (1981), who found that radiography is not a useful tool for diagnosing CRPS, type I (Bonica, 1970). Kozin, et al. (1981) did find that 83% of the patients with CRPS, type I had positive static (delayed) bone scans, however, whereas 69% of the patients had positive flow studies. Therefore, it is apparent that between 50 and 60% of patients with CRPS, type I will have positive early phase bone scans, but between 83 and 96% of patients will have positive delayed image bone scans (Holder & Mackinnon, 1984; Kozin, et al., 1981). Treatment for this component of CRPS, type I is difficult to assess. Kozin, et al. (1981) reported that 90% of patients with a positive bone scan had good to excellent steroid response, beginning with steroids at the level of 60 to 80 mg/day and tapering the dosages.

Schott (1986) has reported a variety of therapeutic modalities, including steroids, nonsteroidal anti-inflammatory drugs, alpha- and beta-blocking agents, griseofulvin, calcitonin, transcutaneous electrical nerve stimulation, physical therapy, sympathetic blocks, and intravenous guanethidine. None of these treatments has been studied in a systematized fashion, however.

Nail brittleness has been reported by Schott (1986) and Payne (1986) late in the disorder. The etiology of this is not clear and there is not any clear-cut treatment. Muscle spasm has been reported by a number of authors (Kleinman, 1954; Long, 1982; Schott, 1986), again without a clear-cut mechanism describing the etiology (Payne, 1986). Interestingly, electromyography (EMG) nerve conduction velocity studies seem to be relatively negative in CRPS, type I (Uematsu, et al., 1981). The treatments that seemed most effective for muscle spasm were trigger point injections (Payne, 1986) and the use of baclofen. Baclofen is a gamma aminobutyric acid (GABA)-minergic drug that centrally reduces muscle spasm. The inhibition of substance P may be implicated as part of its mechanism for reducing spasm and the pain associated with spasm (Gillman & Lichtigfeld, 1985). Soma and quinine have also been tried, with only limited success (Hendler, unpublished observations). Contractures, usually in the hand, have also been reported (Payne, 1986; Schott, 1986). The etiology of this is unclear, but is probably related to disuse.

Again, there is an absence of positive EMG-nerve conduction velocity studies (Uematsu, et al., 1981), and the only treatment seems to be preventative, by the use of passive range-of-motion exercises and physical therapy.

Contralateral involvement has been reported by several authors (Kleinman, 1954; Schott, 1986). The etiology for this may be quite direct. In approximately 80% of examined cadavers there is cross-communication between the sympathetic fibers and the sympathetic chains (Kleinman, 1954). Countralateral blocks and denervation have been recommended (Kleinman, 1954). Edema of the affected limb (Payne, 1986; Schott, 1986), as well as swelling of a specific joint (Kozin, et al., 1981), has been reported. Again, the etiology is unclear. The diagnosis is established by measuring the proximal interphalangeal joint, which averages 12.9 mm larger in the affected hand than in the control hand (Kozin, et al., 1981). No treatment has been advanced for this, although nifedipine is suggested to be effective (Prough, et al., 1985). At Mensana Clinic, Stevenson, MD, we have observed some benefit from the use of spironolactone, or carbonic anhydrase inhibitors, but not on a consistent basis.

Lower skin temperature has been reported by a variety of authors (Hendler, Uematsu, & Long, 1982; Payne, 1986; Raja, et al. 1996), but it does not seem to be due to vasospasm (Janof, Phinney, & Porter, 1985). Reflex contraction due to altered activity within the afferent and efferent nerves is proposed as the etiology (Janoff, et al., 1985). Thermography is an excellent diagnostic tool to document the reduced skin temperature (Hendler, et al., 1982; Uematsu, et al., 1981). In fact, very often patients with CRPS, type I are diagnosed as having psychosomatic disorders, and thermography can be a most convincing diagnostic tool to confirm the otherwise subjective complaint (Hendler, et al., 1982). However, nerve entrapments and radiculopathies can also lower limb temperature (Uematsu, et al., 1981).

Treatment for lower skin temperature associated with pain is best effected using regional sympathetic blocks employing reserpine. It is important to note that these reserpine blocks, or Bier blocks, are not effective for vasospasm, but specifically seem to function best for treating CRPS, type I. Therefore, vasospasm does not seem to be the etiologic mechanism for the coldness noted in the limb in CRPS, type I (Janoff, et al., 1985). Stiffness (Holder & MacKinnon, 1984; Payne, 1986) and tenderness (Kozin, et al., 1981) of the joints have been reported; again, the etiology is not clear (Payne, 1986). Very often, the involvement of the joint leads to misdiagnosis and confusion with other diseases that can affect the joint, notably infective arthritis, rheumatoid arthritis, Reiter's syndrome, systemic lupus erythematosus, and arthritides (Kozin, et al., 1981). In one series, 71% of the patients with joint tenderness and stiffness had a poor response to stellate ganglion blocks. Steroids, notably prednisone (60 to 80 mg) for 2 to 4 days, then 40 to 60 mg for 2 to 4 days, and then 30 to 40 mg for 2 to 4 days, in four equally divided doses, were the initial therapy. Subsequently, the dose was rapidly tapered using a single morning dose of 40 mg, then 30 mg, 20 mg, 10 mg, and 5 mg over 2 or 3 days at each dose. By using this regimen, 82% of the patients with joint stiffness and tenderness obtained good or excellent relief.

An unusual complication of CRPS, type I is the appearance of pathological fractures subsequent to minor trauma. In patients complaining of persistent pain in the limb that seems to be bony in origin, instead of part of the CRPS, type I, it would be imperative to obtain bone scanning to confirm the presence or absence of an undetected break. In our experience, one patient with long-standing CRPS, type I received a minor trauma (i.e., bumping her ankle while walking in a train) that resulted in a chronic intense worsening of pain in the heel. Radiographs of this area were within normal limits, but the pain persisted for several days after the event, and a bone scan was obtained. Only on bone scan did the break in the calcaneus appear, which had been totally missed by routine radiograph. Of any breaks present, 95% will have a positive bone scan after 72 h (Matin, 1979). Interestingly, after the fracture is healed, 90% of the bone scans have returned to normal 2 years from the date of the injury. Therefore, in patients with CRPS, type I who have minor injuries and complain of bony pain, it would be prudent to obtain a bone scan, and not rely on radiographs.

Payne (1986) has enumerated many attempted treatments for CRPS, type I. Unfortunately, there seems to be a lack of systematic investigation for these treatments, and most are based on clinical reports instead of systematized trials. Reported pharmacological interventions that may work for CRPS, type II are the use of propranolol, a beta-blocking agent; prazosin, an alpha-1-adrenergic-blocking agent; phenoxybenzamine, both an alpha-1- and an alpha-2-blocker; and guanethidine, a drug that produces a chemical "sympathectomy." Physical therapy has been advanced for the treatment of CRPS, type I, specifically to minimize muscle contractures and joint stiffness. It is never a definitive treatment, however, and should not be considered such. Electrical stimulation of the central nervous system, using either electrodes centrally implanted into the periaqueductal or periventricular gray or epidural stimulators, may prove effective, as might transcutaneous electrical nerve stimulation. Tricyclic antidepressants, nonsteroidal anti-inflammatory drugs, narcotics, and anticonvulsants have all been reported as treating some components of CRPS, type I, with varying degrees of success.

Surgical intervention is a treatment that is reserved until all other modalities of treatment have been attempted. In all cases, the criterion for surgical intervention would

TABLE 20.4
Recommended Treatment Flow Sheet

Treatment	Dosage	Time Course	If Ineffective, Next Step
1. Prednisone	80 mg to start and taper by 10 mg q.i.	8 days	Go to 2
2. Physical therapy	3 times a week	2 weeks	Go to 3
3. Transcutaneous electrical stimulation	Wear constantly	1 week	Go to 4
4. Sympathetic blocks	3 times a week	2 weeks	If lasting relief, stop; if 100% pain relief but temporary, go to 5
5. Sympathectomy	-—	1-week recovery	If lasting relief, stop; if no relief, go to 6
6. Contralateral blocks	3 times a week	2 weeks	If lasting relief, stop; if 100% pain relief but temporary, go to 7, if no relief, go to 8
7. Contralateral sympathectomy	—	1-week recovery	If relief, stop; if no relief, go to 8
8. Epidural spinal cord stimulator	—	1-week recovery	If relief, stop; if no relief, go to 9
9. Epidural pump	Start with clonidine (Rauck, et al., 1993)	1-week recovery	If relief, stop; if no relief, try other meds in combination or alone, go to 10
10. Psychotherapy (supportive)	Use antidepressants	6 months to 2 years	Maintenance

be repetitive successes with repeat sympathetic blocks. The most commonly employed surgical interventions are resection of the lower third of the stellate ganglion and resection of the upper two thoracic ganglia; however, some surgeons resect the second through fifth thoracic ganglia in an attempt to treat upper-extremity difficulties. There are four surgical approaches to upper extremity sympathectomies (Allen & Morety, 1982):

1. Above the clavicle (anterior cervical approach)
2. Posterior resection of the transverse processes of ribs 2 and 3, and proximal section of ribs 2 and 3
3. Anterior transpleural entry through the pectoralis muscle to the third intercostal space, pressing the lung, to reach the operative area
4. The axillary approach, which is through a transaxillary incision over the second intercostal space

Also, a lumbar approach can be made through the external and internal obliques, and then the transversalis muscle, below the twelfth rib, behind the kidney; others have suggested a thoracolumbar presacral neurectomy. Side effects of surgical approaches are postsympathectomy neuralgia, beginning 7 to 10 days after surgery, and postsympathectomy dysesthesia that may last 2 to 14 weeks, and is described as continuous, severe, and worse at night. Anticonvulsants, such as diphenylhydantoin or carbamazepine, may be used to treat this (Allen & Morety, 1982). Medication, such as valproic acid and gabapentin may be useful (Mellick & Mellick, 1995). Dorsal root entry zone procedures, which produce lesions in the dorsal root interrupting the nociceptive pathways in the tract of Lissauer and in laminae I-V of the dorsal horn of the spinal cord, may prove to be an effective modality for treating CRPS, type II for stretch injuries (Payne, 1986). A treatment guideline is shown in Table 20.4.

CONCLUSIONS

In summary, it is quite apparent that a great deal of confusion has arisen concerning the diagnosis of CRPS, type I and CRPS, type II. This is evidenced by the lack of uniformity in clinical criteria for establishing the diagnosis. Because of this lack of uniformity, assessment of various articles detailing treatment of CRPS, type I and/or CRPS, type II is difficult. What some clinicians take as symptoms of CRPS, type I are not always present in their entirety. Unfortunately, if one adheres rigorously to these criteria, proper diagnosis, and more importantly proper treatment, may be withheld. The various clinical symptoms that have been reported as associated with CRPS, type I and CRPS, type II are shown in Table 20.2. A patient should be considered to have CRPS, type I if he or she has at least one type of hyperalgesia (either mechanical or thermal), lower skin temperature, and the sensation of pins and needles. However, the presence of allodynia is a more consistent finding. At a minimum, diagnostic studies that would facilitate the diagnosis of CRPS, type I would be thermography, sympathetic blocks, and bone scan. Clinical diagnostic studies that would prove important would be testing with a drop of acetone for cold hyperalgesia and allodynia, and testing using Von Frey hairs for mechanical hyperalgesia and

allodynia. All patients suspected of having CRPS, type I should have at least three sympathetic blocks. After that, one should use various diagnostic and treatment techniques, including pharmacological intervention, depending on the patient's type of complaints.

To make the diagnosis of CRPS, type II, one certainly should establish that the symptoms of burning pain are constantly present, in association with a partial peripheral nerve injury. Electromyographic and nerve conduction velocity studies should be conducted to detect whether there is an associated nerve injury. Certainly, patients should receive a peripheral nerve block; sympathetic blocks; and a trial with phenoxybenzamine, valproic acid, and gabapentin.

Regardless of whether a patient has CRPS, type I or CRPS type II, one must be aware of the need to make a distinction between the two diagnoses, because the treatments vary. More importantly, if the patient has even a single symptom of CRPS, type I, a diagnostic assessment involving the previously recommended modalities would be warranted, and further diagnostic studies should be pursued if the diagnosis of CRPS type I is not confirmed. Kozin, et al. (1981) clearly defined a number of overlapping conditions that may originally be misdiagnosed as CRPS, type I. Of the patients who were found not to have CRPS, type I, 25% had peripheral neuropathy or trapped peripheral nerves, and half the patients misdiagnosed as having CRPS, type I had inflammatory arthritis (Kozin, et al., 1981). Therefore, laboratory studies, including erythrocyte sedimentation rate, antinuclear antibody, rheumatoid factor, Lyme disease, HIV, and the like, should be conducted in patients thought to have CRPS, type I but in whom the diagnosis is not complete. In any event, CRPS, types II and I require clinical acumen to establish the diagnosis, and persistence to effect appropriate treatment. Aggressively pursuing all the diagnostic studies available, as well as relying on clinical judgment, provides better care for these patients.

Treatment of Myofascial Pain Syndromes

Robert D. Gerwin, M.D. and Jan Dommerholt, P.T., M.P.S.

INTRODUCTION

The treatment of persons with myofascial pain syndrome (MPS) follows the general principles that apply to all medical disorders. The nature of the pain problem first must be understood through developing an appropriate differential diagnosis and evaluating the contributions of coexisting disorders, until a single working diagnosis emerges. Following the initial assessment and formulation of diagnostic hypotheses, new data are collected. A regular review at each encounter and modification of the hypotheses facilitate a more efficient and effective management of patients with MPS and dictate the actual program components (Higgs & Jones, 1995; Jones, 1994). After addressing the issue of diagnosis, the practitioner must determine the structural or biomechanical functioning of the patient and the contribution that any dysfunction may have to the individual's pain. Medical and psychological disorders that may alter the presentation of MPS or that may predispose to its becoming chronic are assessed. Treatment of persons with MPS addresses each of these issues specifically (Figure 21.1). There must be relief of pain by the direct inactivation of the myofascial trigger point (MTrP) itself. The mechanical and structural factors that affect or overload the muscle and aggravate the pain must be resolved or alleviated. The medical and psychological problems that affect muscle function, including those that alter and impair intracellular metabolism, must be identified and corrected where possible. Inactivation of the MTrP may occur with direct intervention at the MTrP itself, through correction of the mechanical factors that produced it or through improvement in the underlying medical disorders that predispose to the development or maintenance of the MTrP.

DIAGNOSIS

The diagnosis of MPS should be suspected when there is a nonneuropathic pain complaint almost anywhere in the body, including headache. At first glance, such a statement may seem to be so nonspecific as to be meaningless, but it emphasizes the need to be aware of the role of soft tissue or muscle in all types of pain. Indeed, MPS has been reported as the most common diagnosis responsible for chronic pain and disability (Fricton, 1990; Masi, 1993; Rosomoff, et al., 1989; Skootsky, Jaeger, & Oye, 1989). MPS is often thought of as a regional pain syndrome in contrast to fibromyalgia as a widespread syndrome; however, as many as 45% of patients with chronic MPS have generalized pain in three or four quadrants (Gerwin, 1995b). Patients with widespread MTrPs should be diagnosed with MPS and not with fibromyalgia, even though the classification criteria for fibromyalgia suggested making the diagnosis of fibromyalgia "irrespective of other diagnoses" (Wolfe, et al., 1990). In clinical practice the diagnosis of fibromyalgia should not be made without considering all differential diagnoses (Dommerholt, 2001; Gerwin, 1999). A survey of members of the American Pain Society showed general agreement with the concept that MPS exists as an entity distinct from fibromyalgia (Harden, et al., 2000).

Muscle pain tends to be dull, poorly localized, and deep, in contrast to the precise location of cutaneous pain. The diagnosis of MPS is confirmed when the MTrP is identified by palpation. Systematic palpation differentiates between myofascial taut bands and general muscle spasms (Janda, 1991). An active MTrP is defined as a focus of hyperirritability in a muscle or its fascia that causes the patient pain (Simons & Travell, 1984). The key features

0-8493-0926-3/02/$0.00+$1.50

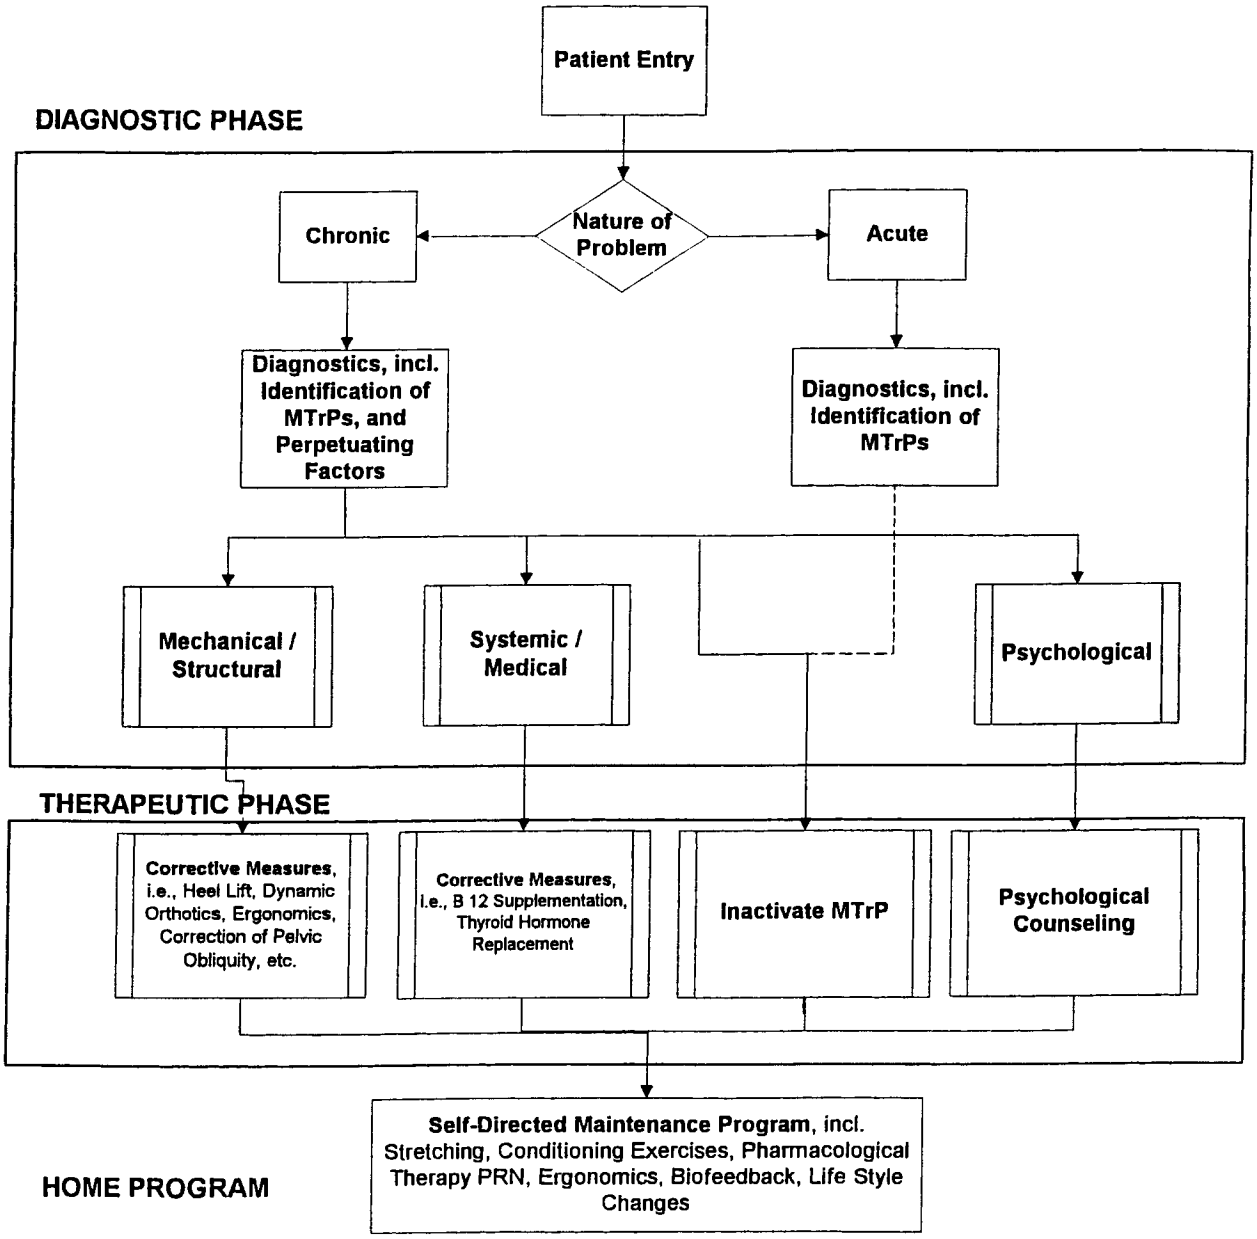

FIGURE 21.1 Treatment program example.

of the trigger point have been established by Simons, Travell, and Simons (1999) and are listed in Table 21.1. The interrater reliability of the clinical examination has been established by Gerwin, et al. (1997) for the five major features of the trigger point. Individual features of the trigger point are differentially represented in different muscles. For example, the local twitch response is easier to obtain and therefore more commonly found in the extensor digitorum communis than in the infraspinatus muscle. One should not expect to find each feature of the trigger point in every muscle by physical examination. The minimum criteria that must be satisfied in order to distinguish an MTrP from any other tender area in muscle are a taut band and a tender point in that taut band. The presence of a local twitch response, referred pain, or reproduction of the person's symptomatic pain increases the certainty and specificity of the diagnosis.

Making a diagnosis of MPS may be therapeutic in itself and may constitute the first step in treatment, because many patients may not have been given a correct diagnosis previously. Patients are often depressed, confused, or frustrated, as they may not have been given an appropriate explanation of their pain in previous evaluations. They often appear relieved when the practitioner can literally

TABLE 21.1
Myofascial Trigger Point Characteristics

1. Focal exquisite tenderness in a taut band of muscle
2. Referral of pain to a distant site upon activation of the trigger point
3. Contraction of the taut band (local twitch response) upon mechanical activation of the trigger point
4. Reproduction of the person's pain by mechanical activation of trigger point
5. Restriction of range of motion
6. Weakness without muscle atrophy
7. Autonomic phenomenon such as piloerection or changes in local circulation (regional blood flow and limb temperature) in response to trigger point activation

put the finger on the source of the pain, which usually results in instant rapport between patient and clinician.

The introduction of pressure algometers has improved the assessment of sensitivity significantly (Fischer, 1986c; Keele, 1954); however, only recently have pressure algometers been applied to the assessment of MTrPs (Fischer, 1984, 1986a,b). Several studies have confirmed the reliability of pressure measurement for the assessment of pain sensitivity (Jensen, et al., 1986; Merskey & Spear, 1964), for pressure sensitivity of MTrPs, and for the detection of their location (Delaney & McKee, 1993; Jaeger & Reeves, 1986; Ohrbach & Gale, 1989; Reeves, Jaeger, & Graff-Radford, 1986). Tenderness and the presence of a taut band in muscle may be quantified by pain pressure algometry and tissue compliance measurements (Fischer, 1986a,c, 1993). Fischer (1997) discussed the role of algometry and tissue compliance testing in the diagnosis of MPSs. He incorporated the two main criteria for the diagnosis of MTrPs, local point tenderness (as quantified by algometry) and recognition of patient's symptoms, into his concept of segmental sensitization, radiculopathy, and paraspinal spasm.

Hubbard and Berkoff (1993) identified a characteristic electrical discharge emanating from the trigger point and unique to it. Simons, Hong, and Simons (1995) have further studied this activity, whereas Chu (1995) has reported finding it in the trigger points of persons with lumbosacral radiculopathy. Phentolamine infusion reduced the average integrated signal of the spontaneous electrical activity by about one third in the experimental animal model. This result shows that there is a modulating effect of the sympathetic nervous system on the motor activity of the trigger point (Chen, et al., 1998). Thus, an objective electromyographic (EMG) signature of the trigger point is now available for diagnostic and research purposes.

PRINCIPLES OF TREATMENT

The ultimate goal of treatment of persons with MPS is restoration of function through inactivation of the trigger point, restoration of normal tissue mobility, and elimination of pain (Dommerholt, 2001; Miller, 1994). The patient and the clinician need to identify appropriate goals and develop the means to implement them through therapy. Inactivation of the trigger point is a means to achieve relief of pain, to improve biomechanical function, and thus to improve the ability of the patient to better perform whatever desired tasks have been selected as goals. Relief of pain or increased range of motion, both of which can be the result of trigger point inactivation, are not in themselves the final goals of treatment. For some individuals, an initial goal may be to simply sleep through the night. For another patient, it may be eating out of bed at a table, or fastening a bra behind the back. For yet another, it may be regaining sexual ability, or returning to work or to a recreational activity. Reasonable goals that can be achieved and measured as being reached or not, are more important to focus on than simply the inactivation of a tender point or an increase in the range of a particular movement (Gerwin, 2000).

Inactivation of the MTrP can be achieved manually, by correcting structural mechanical stressors, by direct injection of a local anesthetic into the muscle, or by dry needle intramuscular stimulation of the MTrP. Treatment of the patient with MPS can be very effective when used in the context of a comprehensive diagnostic and treatment spectrum (Yue, 1995). After establishing an accurate medical diagnosis with identification of systemic, mechanical, and psychological perpetuating factors, the patient with chronic MPS is best treated through an interdisciplinary team approach (Turk & Okifuji, 1999). The term interdisciplinary is preferred to multidisciplinary because it reflects the coordinated working relationship between members of the treatment team (Melvin, 1980; Turk & Rudy, 1994). Essential members of the interdisciplinary team include the patient, physicians, psychologists, clinical social workers, occupational therapists, physical therapists, ergonomists, massage therapists, and others actively involved in patient care (Ghia, 1992; Khalil, et al., 1993). Not every MPS patient necessarily requires such an extensive collaboration. For example, patients with acute MPS may only require treatment by physicians and physical therapists. The treatment plan can be divided into a pain control phase and a training or conditioning phase (Saal & Saal, 1991). During the pain control phase, the most essential components are manual therapy, trigger point injection, dry needling, and elimination of mechanical perpetuating factors. Throughout the treatment process, much attention should be paid to educating the patient concerning the etiology, perpetuating factors, and self-management. Patients must learn to modify their behaviors and avoid overloading the muscles without resorting to total inactivity (Simons & Simons, 1994). Following the pain control phase, patients should be introduced to therapeutic exercises, movement reedu-

cation, and overall conditioning. Too often, patients with chronic myofascial pain dysfunction are introduced too soon to isotonic training and conditioning, causing further aggravation of active trigger points and increase of pain and dysfunction. Likewise, work hardening programs should never be conducted during this phase of treatment. This can lead to further discouragement and depression, as well as an increase in pain. On the other hand, the pain control phase must be time limited, and patients must understand that progressing to the conditioning phase is imperative. If they do not move beyond the pain control phase, patients can be restricted in their functional abilities and be at greater risk of reinjury (Saal & Saal, 1991). In daily practice, the various aspects of the rehabilitation process are addressed simultaneously and not treated as separate entities.

MANUAL THERAPY

Manual therapy is one of the basic treatment options for MPS. In conjunction with manual therapy approaches, Simons, Travell, and Simons (1999) advocate the stretch and spray technique, which combines use of a vapocoolant spray with passive stretching of the muscle. Application of vapocoolant spray stimulates thermal and tactile A-beta skin receptors, thereby inhibiting C-fiber and A-delta fiber afferent nociceptive pathways and muscle spasms, MTrPs, and pain when stretching. Prior to applying the stretch and spray method, the patient is positioned comfortably. The muscle involved is sprayed with a few sweeps of a vapocoolant spray, after which the muscle is stretched passively. With the muscle in the stretched position, the spray is applied again over the skin overlying the entire muscle, starting at the trigger zone and proceeding in the direction of, and including, the referred pain zone. Following the stretch and spray, the area is heated with a moist heat pack for 5 to 10 min. The patient is encouraged to move the body part several times through the full range of motion. The stretch and spray technique can be used in physical therapy as a separate modality or following MTrP injections. In the United States, Fluori-Methane (Gebauer Chemical Co., 9410 St. Catherine Avenue, Cleveland, OH 44104) has been used, whereas in Europe the use of liquid nitrogen or ethyl chloride is the norm (Dejung, 1988a). Fluori-methane is being replaced due to its potentially damaging effects on the ozone layer. An environmentally safe substitute is being prepared.

Lewit (1991) suggests using the stretch technique for short or taut muscles and fascia, while promoting post-isometric relaxation for treatment of trigger points. Post-isometric relaxation is also known as muscle energy technique (Mitchell, 1993) or hold–relax technique (Knott & Voss, 1968) and can easily be combined with stretch and spray techniques either in the clinic or as part of the patient's home program. The muscle is gently lengthened, taking up the slack until a barrier is reached. The patient is then asked to contract the muscle isometrically against resistance for about 10 s at approximately 10% of maximal effort. Because it is difficult for patients to gauge a level of effort, the clinician presents a force against which the patient pushes. The patient is instructed, "Meet my force, but do not exceed it." Thus, the clinician is in complete control of the effort exerted by the patient, and an appropriately slight contraction of muscle is achieved. Then the patient relaxes the muscle. Once total relaxation is achieved, the slack is taken up again and the process is repeated for three to five times (Lewit, 1991; Lewit & Simons, 1984; Simons & Simons, 1994). Respiratory facilitation of muscle relaxation utilizes the contraction of antirespiratory muscles that occurs with inspiration and the relaxation of the same muscles during expiration. During the relaxation phase, the patient is asked to exhale and look down to facilitate muscular relaxation (Lewit, 1988). A variation on Lewit's approach combines isometric contractions, reciprocal inhibition, and stretch (Fischer, 1995).

Soft tissue mobilization is an essential component of the treatment. Soft tissue biomechanics including stress–strain patterns; the normal inflammatory, repair, and remodeling stages following soft tissue injury (Carlstedt & Nordin, 1989; Nolan & Nordhoff, 1996; Soderberg, 1992); the reactivity of the tissues; and tolerance level and comfort of the patient are considered (Ellis & Johnson, 1996). The intratissue (muscle tone) and intertissue mobility (muscle play) of the structures involved and of the adjacent muscles, fascia, and joints must be evaluated and treated as well. Myofascial adhesions may develop with secondary or "satellite" trigger points in nearby muscles. MTrPs appearing in muscles that are part of a functional unit must be treated together. Muscles that work together as agonists, or that work in opposition to each other as antagonists, constitute a functional muscle unit. The same muscles can be related to each other both as agonists and antagonists, depending on the action being performed. For example, the muscles that move or stabilize the shoulder form a functional unit. The trapezius and levator scapula muscles display this relationship well. These two muscles work together as agonists in elevation of the shoulder, but are antagonists in rotation of the scapula, the trapezius rotating the glenoid fossa upward and the levator scapula rotating it downward. When one of these two muscles contracts to rotate the scapula, the other must relax. If these or some other shoulder muscles become dysfunctional, because of the presence of MTrPs that weaken or shorten them and restrict their range of motion, excessive loading on other muscles in the shoulder functional unit may occur. Trigger points in the levator scapula limit upward rotation of the lateral border of the scapula, thereby placing a greater load on the trapezius, which is unable to accomplish the movement with usual

effort, or perhaps is not able to accomplish the movement at all, causing a compensatory lifting of the entire shoulder to raise the arm.

The functional relationships of muscles may differ at each end of the muscle, because the agonists and antagonists for each muscle may be different at the proximal and distal ends of the muscle. MTrPs may spread from one region to another because of these relationships. Bilateral axial muscles like the trapezius, sternocleidomastoid, quadratus lumborum, and iliopsoas act as both agonists and antagonists to each other, facilitating the spread of MTrPs across the midline. Muscles that bridge regions, like the latissimus dorsi, and those that influence posture like the effect of the iliopsoas or quadratus lumborum muscles on scoliosis, also facilitate the spread of MTrPs. Thus, MPS can involve a single region of the body or it can spread to involve all four quadrants of the body. Effective treatment should address all the affected areas. Otherwise, remaining dysfunctional muscle units may lead to the recurrence of active or spontaneously painful MTrPs.

Myofascial release techniques and gentle, sustained pressure may soften or elongate shortened or hardened muscles. The principle of the least possible force is applied, instead of applying high stress to the muscle. Effective myofascial release techniques include strumming, perpendicular and oscillating mobilizations, tissue rolling, and connective tissue massage, among others (Cantu & Grodin, 2001; Ellis & Johnson, 1996). Deep muscle massage consisting of effleurage (stroking massage technique) and pétrissage (kneading massage technique) is also recommended (Lehn, 1990; Vis, Raats, & Van der Voort, 1987). After the introductory superficial approach over the entire muscle and adjacent muscles, massage therapy can be applied directly to the taut band and trigger points. Massage and exercise were found to be effective in reducing the number and intensity of trigger points, but the addition of therapeutic ultrasound did not improve the outcome (Gam, et al., 1998).

Soft tissue mobilizations may result in improved local circulation, normalization of muscle tone and muscle play, and reduction of reflex activity and pain (Vis et al., 1987; Wells, 1994). By combining gentle approaches with more aggressive techniques, the Swiss physician and psychologist Dejung (1988a) has developed a seven-step treatment approach to myofascial dysfunction. Dejung's approach combines sustained compression, stretch and spray techniques, myofascial release, restoration of muscle play, active and passive movements, and dry needling (Dejung, 1987a, 1988b; Grosjean & Dejung, 1990). As part of Dejung's protocol, the patient actively moves the involved muscle, while the physician or therapist maintains constant pressure over the trigger point (Dejung, 1987b, 1994).

Simons, et al. (1999) also describe direct manual compression of the trigger point to inactivate trigger points. Although it previously has been described as ischemic compression, it is now termed trigger point pressure release or trigger point compression. The patient can apply direct compression for self-treatment using a Thera Cane® (Thera Cane Co., P.O. Box 9220, Denver, CO 80209; Phone 800–947–1470) or a similar device. Acupressure may be another form of direct compression of trigger points (Kodratoff & Gaebler, 1993). Following the Simons et al. protocol or using acupressure guidelines, compression of trigger points is moderately painful. In contrast with these relatively gentle compression techniques, Tsujii (1993) suggests using at least 10 to 20 kg of force over the trigger point and 50 to 60 kg in chronic cases with a strong elbow pressure technique. He presumes that successful treatment of chronic muscle pain is dependent on opioid-induced analgesia and that only intermittent painful stimuli for more than 30 min produce such analgesia. Because Tsujii's approach results in tissue damage, treatments are scheduled with at least 10 days in between appointments to allow the tissues involved to heal prior to the next application.

Trigger points may also be directly related to underlying articular dysfunction (Ellis & Johnson, 1996). In the treatment of myofascial pain, the practitioner must evaluate and, when indicated, treat both soft tissue and joint dysfunction. Muscular and joint dysfunction are closely related and should be considered as a single functional unit (Janda, 1994). Restrictions in joint capsules inhibit muscle function for those muscles overlying the particular joint. Conversely, muscle dysfunction results in joint capsule restrictions (Dvořák & Dvořák, 1990; Warmerdam, 1992). Zygopophyseal joints may have referred pain patterns similar to MTrPs (Bogduk & Simons, 1993; Dwyer, Aprill, & Bogduk, 1990; McCall, Park, & O'Brien, 1979). In addition, Butler (2000) suggests that impaired mechanics and physiology of the nervous system may be another contributing factor in the overall etiology of various pain problems, including myofascial pain. Somatic dysfunction affecting muscle and joint may result in restricted range of motion and weakness that can be rather quickly reversed by manual therapy.

INVASIVE INACTIVATION OF THE MYOFASCIAL TRIGGER POINT

Inactivation of the MTrP by injection appears to be the result of the mechanical action of the needle in the trigger point itself, because it can be successfully accomplished by dry needling without the use of local anesthetics or other materials (Chu, 1995; Gunn, Milbrandt, Little, & Mason, 1980; Hong, 1994b). When using injection needles, the use of a local anesthetic is more comfortable for many patients and results in a longer lasting reduction in trigger point pain (Hong, 1994b; Travell, 1976). The use

of solid acupuncture needles vs. injection needles has not been examined at this time. After identifying and manually stabilizing the tender area in the taut band with the fingers, the needle is quickly passed through the skin and then into the trigger zone. A local twitch response or a report of referred pain indicates that the trigger zone has been entered. A small amount, usually 0.1 or 0.2 ml, of local anesthetic may be injected into the trigger zone. The needle is withdrawn to just below the skin, the angle of the needle is changed, and the needle is again passed through the muscle to another trigger zone. A conical volume of muscle can thus be examined for active trigger points without withdrawing the needle through the skin. The trigger zone is explored in this manner until no further local twitch responses are obtained. At this point, the taut band is usually gone, and the spontaneous pain of the trigger point has subsided. Patients who have previously undergone treatment can tell when trigger points remain and when they have been sufficiently inactivated. A knowledgeable patient urges the clinician to continue in an area until a key trigger point is inactivated, at which time there is a noticeable decrease in pain. The process is repeated until the symptomatic MTrPs are treated throughout the functional muscle unit (Hendler, Fink, & Long, 1983; Hong, 1993, 1994a).

Trigger point injections can be performed without anesthetic, so-called dry needling, or with a local anesthetic (Hong, 1994b). Historically, procaine has been used for this purpose, although lidocaine is also commonly used today. Procaine, in a dilute solution of 0.5%, has a short half-life, which is an advantage if the anesthetic solution spreads between tissue planes and produces a nerve block. Other local anesthetics, such as bupivicaine and etidocaine, are also used, but no study has been conducted to determine whether the longer duration of action of these latter drugs offers any therapeutic advantage. Glucocorticosteroids and ketorolac have also been used in MTrP injections, but they too have not been the subject of controlled studies comparing their effectiveness against either local anesthetic or dry needling. Steroids have the disadvantage that they are locally myotoxic and that repeated administration of steroids can produce all the unwanted side effects associated with them. Saline or dry needling can be performed on persons allergic to local anesthetics. Botulinum toxin has been tried successfully in MTrP inactivation, although it can cause a flulike myalgia lasting days to a week, and occasionally weakness beyond the area of injection (Cheshire, Abashian, & Mann, 1994; Childers, 1999; Childers, et al., 1998; Yue, 1995).

There is no limit to the number of MTrP that can be needled. Common sense and patient comfort dictate restraint. Nevertheless, when treating a regional MPS, a sufficient number of muscles in the region must be treated to resolve the problem and allow effective postneedling stretching. All the muscles in a functional muscle unit must be released and returned to full length, if possible, either by needling or by trigger point compression and stretching. Inadequate treatment that leaves critical trigger points within a functional muscle unit usually results in the recurrence of trigger points throughout the muscles of the functional unit. Five to ten different MTrP sites can readily be treated per session, and some physicians skilled in MPS management treat considerably more in one session. Repeat injections or dry needling into the same area are best done after an interval of 1 week to allow the muscle to recover. Muscles of the affected functional unit must always be stretched, to their full length if possible, after MTrP needling. Moist heat is applied to the muscle to improve the local circulation and to reduce postinjection soreness. Otherwise, MTrPs recur because of residual significant muscle dysfunction. Local anesthetic patches can be applied to reduce the superficial or cutaneous soreness from needling. Complications of MTrP injections are listed in Table 21.2.

Trigger point injections or dry needling are a highly effective way to reduce the local pain and contraction of the taut band. This does not, however, constitute the whole treatment of MPS. The causes that led to the condition must be corrected, when possible. Mechanical, medical, and psychological perpetuating factors must also be eliminated or alleviated to reduce the chance of recurrence. Inadequate attention to these aspects of treatment leads to failure to relieve the pain (Table 21.3).

TABLE 21.2
Complications of Trigger Point Injections

1. Local hemorrhage into muscle
2. Local edema
3. Painful contraction of a taut band from inadequate MTrP inactivation (missing the MTrP)
4. Infection
5. Perforation of a viscus, most commonly the lung
6. Nerve injury from direct trauma by the needle
7. Transient nerve block
8. Syncope
9. Allergic reaction from the anesthetic

TABLE 21.3
Causes of Trigger Point Injection Failure

1. Missing the trigger point
2. Injecting the secondary or satellite trigger point and not the primary trigger point
3. Inadequate stretching of the muscle following the injection in the clinic
4. Inadequate stretching of the muscle by the patient at home
5. Failure to correct perpetuating factors

Acupuncture is used to treat many different types of pain, including myofascial pain (Baldry, 1993). Acupuncture can be performed by the traditional method of using predetermined acupuncture points along set meridians or by the more recently developed method of placing the needle close to the point of pain (Liao, Lee, & Ng, 1994). Japanese acupuncture (shallow needling) reduced the pain of chronic myofascial neck pain in one study (Birch & Jamison, 1998). Baldry (1993) has developed a technique of subdermal needling over the trigger point, while Gunn, Milbrandt, Little, and Mason (1980) and Gunn, Sola, Loeser, and Chapman (1990) use a method of dry needling called intramuscular stimulation (IMS). IMS involves the insertion of the needle into the taut band without necessarily considering the actual trigger point. It may be combined with electrical stimulation delivered through the needle (percutaneous electroneural stimulation).

MECHANICAL PERPETUATING FACTORS

Biomechanical perpetuating factors have long been known to cause persistent musculoskeletal pain (Simons et al. 1999; Travell & Simons, 1992). Major mechanical factors to be considered in the management of MPS include anatomic variations, poor posture, and work-related stress (Simons & Simons, 1994).

Correction of Anatomic Variations

According to Simons et al. (1999), the most common anatomic variations are leg length discrepancy and small hemipelvis, the short upper arm syndrome, and the long second metatarsal syndrome.

The leg length inequality syndrome produces a pelvic tilt that results in a chronic shortening and activation of a chain of muscles in an effort to straighten the head and level the eyes. Any asymmetrical position of the pelvis or spine requires a regulatory adjustment of the neck muscles to maintain equilibrium and an appropriate head position (Janda, 1994). The quadratus lumborum and paraspinal muscles contract to correct the deviation of the spine caused by the pelvic tilt. This correction in turn causes a tilt of the shoulder in the direction opposite to that of the pelvic tilt when a simple C-shaped scoliosis occurs. The shoulder and neck muscles then chronically contract and shorten to correct the subsequent neck tilt. Excessive loading perpetuates MTrPs and may result in low back, head, neck, and shoulder pain (Gerwin, 1995a). Trigger points in these chronically shortened and constantly contracted muscles are not readily inactivated until the muscles are unloaded. The combination of trunk muscles that undergo shortening as they constantly pull the spine toward one side or the other is more complex in an S-shaped scoliosis, but the problem is the same. A similar loading of trunk, shoulder, and neck muscles occurs when one hemipelvis has a diminished height relative to the other or in the presence of pelvic obliquity. According to Grieve (1994), the quadratus lumborum may be less likely to develop trigger points during the teenage years, and typically, unilateral low back pain is located on the side of the shorter leg, because of early attenuation of the annulus fibrosis on that side. In adults, it occurs on the side of the longer leg, due to later arthrotic and spondylotic changes and shortening of the quadratus lumborum. A true leg length discrepancy is corrected by placing a heel lift on the shorter leg. The asymmetry caused by a small hemipelvis is corrected by placing an ischial or “butt” lift under the ischial tuberosity.

A distinction must be made between a true and an apparent leg length discrepancy. An apparent leg length discrepancy or functional shortening may be caused by a pseudo-scoliosis where the legs are actually of equal or nearly equal length, by hip adductor contractures, by hip capsule tightness, or by posterior innominate rotation, because the acetabulum is anterior to the iliosacral rotation axis (LeVeau, 1994; Mitchell, 1993; Reid, 1992). The cause must be identified and then corrected where possible. If the problem is an ilial rotation, the rotation should be corrected. If it is combined with a sacroiliac joint dysfunction, that should be corrected as well. Quadratus lumborum or iliopsoas muscles shortened by trigger points, a cause of pseudo-scoliosis, must be inactivated by stretching or by other means, such as MTrP injections. Placing a heel lift under an apparent shorter leg may increase the leg length discrepancy. Functional shortening, pseudo-scoliosis, and pelvic obliquity can be corrected via osteopathic mobilizations and muscle energy techniques (Fowler, 1994; Greenman, 1991).

When clinical determination by physical examination is uncertain, a radiographic study of the pelvis and lumbar spine utilizing a plumb line can be useful (Travell & Simons, 1992). A functional scoliosis can be corrected or reduced by a heel lift, even if it has been present for years. A fixed skeletal cause of scoliosis does not correct with a heel or butt lift. Functional scoliosis must be distinguished from those asymmetries that cannot be corrected before attempting to use a heel or butt lift. Relief of pain in the neck, shoulder, low back, and legs can result from the complete or partial correction of leg length inequality and scoliosis.

Saggini, et al. (1996) describe the incomplete resolution of pain in persons with peroneus longus MTrPs and leg length inequality corrected only by a heel lift. The peroneus longus has an increased shear force in the medial-lateral plane when loading, which increases eccentric muscle involvement, leading to muscle injury. Correcting abnormal loading associated with leg length discrepancy with a dynamic insole eliminated both the pain and the trigger points.

Short upper arms result in forward shoulder roll, pectoral muscle shortening, and abnormal loading of neck and trunk muscles, as the individual attempts to find a comfortable position when seated. Another cause of biomechanical stress on muscles that can lead to the persistence of MTrPs is a long second metatarsal bone. In this situation, the normal, stable tripod support of the foot created by the first and second metatarsal bones anteriorly and the heel posteriorly may not be present. Instead, in some individuals with this foot configuration, weight is carried on a knife edge from the second metatarsal head to the heel, overloading the peroneus longus that attaches to the first metatarsal bone. Diagnostic callus formation occurs in these individuals in the areas of abnormal loading, under the second metatarsal head, and on the medial aspect of the foot at the great toe and first metatarsal head. Correction is accomplished with support under the head of the first metatarsal, restoring the normal tripod support of the foot (Travell & Simons, 1992).

Posture Correction

In addition to postural deviations due to anatomic variations, muscle imbalances and altered movement patterns play an extremely important role in the etiology and management of poor posture. The clinician should become familiar with Vladimir Janda's extensive research in posture and muscle dysfunction. Janda distinguished "tonic or postural" muscles from "phasic or dynamic" muscles. Postural and phasic muscles are physiologically different in their oxidative ability and their ability to contract over a specific time period. Tonic muscles are slow twitch (Type I) muscles. Phasic muscles are fast twitch (Type II) muscles. MTrPs can develop in both tonic and phasic muscles. Tonic muscles include the hamstrings muscles, rectus femoris, iliopsoas, quadratus lumborum, erector spinae muscles, pectorals, sternocleidomastoids, descending trapezius muscles, and levator scapulae. Phasic muscles include the rectus abdominus, serratus anterior, rhomboids, ascending and transverse trapezius, deep neck flexors, suprahyoid, and mylohyoid (Cantu & Grodin, 2001; Carriere, 1996; Janda, 1983, 1993, 1994). Tonic muscles have a tendency to tighten in response to abnormal stress or dysfunction, whereas phasic muscles have a tendency to become weak. These typical response patterns result in the "upper and lower crossed syndromes" (Janda, 1993, 1994). The upper crossed syndrome or forward head posture is the most common postural deviation in patients with MPS (Fricton, et al., 1985; Janda, 1994; Mannheimer, 1994).

In the forward head posture, total body alignment is severely affected. There is posterior cervical rotation with hypomobility of the upper cervical and subcranial motion segments and hypermobility of the mid and lower cervical spine. Muscle imbalances occur between the anterior and posterior cervical muscles and between the anterior and posterior shoulder muscles. The shoulder girdle protracts, and there is an increase in thoracic kyphosis, a loss of lumbar lordosis, and an increase in posterior pelvic rotation. Muscular imbalances may lead to abnormal afferent input and MTrPs (Cantu & Grodin, 2001). There is a statistically significant relation between the degree of forward head posture, posterior cervical rotation, and pain (Haughie, Fiebert, & Roach, 1995). Poor body alignment, forward head posture, and muscle imbalances predispose and perpetuate chronic pain problems including MPS.

Correcting poor body posture and alignment is an important component of treating patients with MPS, even when posture seemingly may not be directly related to the region of musculoskeletal pain. Core (trunk) stabilization as part of a closed kinetic chain rehabilitation allows optimal control of the lumbopelvic complex and improves the recovery of persons with a kinetic chain dysfunction manifest as a postural stress syndrome (Clark, Fater, & Reuteman, 2000). Good posture minimizes stress and improves efficiency in the use of muscles (Sahrmann, 1988). The physical therapist needs to determine on an individual basis whether manual therapy procedures should precede postural corrections or vice versa. In some instances, joint and myofascial restrictions must be removed prior to any postural corrections. Without the mobilizations, shortened muscles may restrict movement so much that treatment to correct postural abnormalities may not succeed. In other cases, patients may be able to alter their posture prior to or even without any manual therapy (Dommerholt & Norris, 1996).

Correction and prevention of abnormal postures requires a comprehensive program that includes exercises to restore normal dynamic pelvic and vertebral stabilization and mobility, motor control, muscle balances, strength, endurance, and breathing patterns. Certain activities of daily living may predispose a patient to chronic musculoskeletal overload, increasing the risk of myofascial dysfunction. A dynamically stable trunk in neutral position is essential, as is normal pelvic mobility (Carriere, 1996). Paradoxical breathing should be corrected with functional abdominal breathing. Paradoxical breathing is a common cause of overload of the auxiliary breathing muscles, most notably the scalene muscles (Travell & Simons, 1983; Carriere, 1996). To improve posture, the individual components must be integrated into total motor patterns (Walpin, 1994). Both the Alexander technique (Barlow, 1973; Jones, 1992; Knebelman, et al., 1994) and the Feldenkrais method (Feldenkrais, 1977; Rywerant, 1983) aim to restore function to body awareness and movement retraining and can be used in combination with physical therapy (Dommerholt, 2000).

Although posture is usually described in terms of relative alignment of body parts, it is important to realize that a person's posture reflects more than just biomechan-

ical principles. Buytendijk (1964) states that "posture is an individual's innermost means of expression." People express their emotions, feelings, and overall well-being through their posture. Therefore, posture must be viewed as a physiological, biomechanical, and psychological phenomenon. Addressing biomechanical issues without consideration of a more phenomenological approach to posture reduces the treatment approach to strict mechanistic intervention.

Work-Related Stress

Certain jobs and work-related activities are associated with an increased risk of developing cumulative trauma disorders or work-related musculoskeletal disorders (Kuorinka & Forcier, 1995). In certain instances, MPS may be associated with work exposures (Grosshandler & Burney, 1979). In the ergonomics literature, the term tension neck syndrome is preferred over MPS (Viikari-Juntura, 1983). Ergonomics is a broad profession and incorporates knowledge from anatomy, physiology, and psychology. More specifically, ergonomics includes anthropometry and biomechanics, work and environmental physiology, and skill and occupational psychology (Singleton, 1972). Thompson (1991) defines ergonomics as "the application of the human physical and behavioral sciences together with the engineering sciences in the study of humans working with machines and tools." Ergonomics is based on the so-called human-machine system. In designing the ideal human-machine system, ergonomics recognizes four strategies, namely, stress reduction, machine and task design, match between the job demands and human abilities, and education and training (Ayoub, 1994; Khalil, et al., 1993). Pheasant (1991) summarizes the field as "the science of matching the job to the worker and the product to the user."

Awareness of generic risk factors in work-related musculoskeletal disorders is important. They include awkward postures, musculoskeletal loading, task invariability, cognitive demands, and organizational and psychosocial work characteristics (Kuorinka & Forcier, 1995). Prolonged static postures, awkward postures, excessive force, and repetitiveness are the most likely specific risk factors for MPS (Armstrong, 1986a). Several studies have found that occupational groups with repetitive arm movements and constrained work postures have high rates of MPS (Amano, et al., 1988; Bjelle, Hagberg, & Michaelsson, 1979; Hünting, Läubli, & Grandjean, 1981). Awkward postures include wrist flexion and extension, ulnar and radial abduction, forearm supination and pronation, extended reaches beyond the shoulder-reach envelope, and pinch grips that are either too wide or too narrow (Armstrong, 1986b; Feuerstein & Hickey, 1992). For example, the intramuscular pressure in the supraspinatus muscle exceeds 30 mmHg at 30 degrees flexion or abduction, resulting in impairment of blood circulation, mechanical overload of the muscles and adjacent muscles, and increased risk for myofascial pain (Järvholm, et al., 1988). Particular occupational groups at increased risk include data entry operators, typists (Hünting, et al., 1981), musicians (Norris & Dommerholt, 1996), teachers and nurses (Onishi, et al., 1976), and industrial and assembly line workers (Amano, et al., 1988; Silverstein, 1985).

Considering work-related aspects of myofascial pain enhances treatment outcomes. Modifying the workplace or the patient's work habits is critical. If a patient continues to be exposed to certain workplace stress factors without modification of the conditions, the potential cause of myofascial dysfunction may not be addressed adequately. Physical therapists and occupational therapists can contribute significantly to integrating basic ergonomic principles into therapeutic practice, although specific training in ergonomics is indicated (Berg Rice, 1995). More complicated ergonomic problems require the assistance of ergonomists (Ayoub, 1994; Khalil, et al., 1994).

SYSTEMIC MEDICAL FACTORS

The problem of unresolved or persistent MTrPs can be the result of systemic medical factors that affect muscle metabolism primarily or affect muscle function secondarily. These factors can be categorized broadly as nutritional, hormonal, metabolic, infectious, autoimmune, etc. An important principle that Janet Travell often emphasized in her lectures is that insufficiency states impair the ability of stressed or overloaded muscle to respond adequately to therapy. Levine and Hartzell (1987) have applied this concept to vitamin C insufficiency. They propose that the optimum concentration of an enzyme cofactor (vitamin or mineral) is that which allows each enzymatic reaction to proceed maximally (not rate limited) when required. For example, many vitamin or mineral enzyme cofactors, such as ascorbic acid (vitamin C) or iron, participate in a number of different enzymatic reactions that are not all equally active at any one time. However, if a limited concentration of an enzyme cofactor becomes rate limiting, then the products of the associated reaction may be insufficient, like the underproduction of high-energy organic phosphates for certain iron-dependent enzymes or the underproduction of serotonin or norepinephrine for certain vitamin-C-dependent enzymes. It is postulated that the needs of the body under physical stress are different than when unstressed and what may be an adequate concentration of enzyme cofactor under normal conditions may be insufficient at times of physical stress. Hence, the concept of nutritional insufficiency states is distinguished from that of disease-producing deficiency states like scurvy, the disease associated with vitamin C deficiency. Vitamin C taken in the amount of

10 mg/day prevents scurvy, but 250 mg/day is considered the optimum daily intake for good health.

Four nutritional or hormonal factors have repeatedly been found to be low or in the lower quartile of the normal range in persons studied in our clinic who have persistent myofascial pain, namely, iron insufficiency, folic acid insufficiency, vitamin B12 insufficiency, and thyroid hormone insufficiency. Of women with a chronic sense of coldness and chronic myofascial pain, 65% have a low normal or below normal serum level of ferritin, largely from an iron intake insufficient to replace menstrual iron loss. Other causes of low serum ferritin include blood loss associated with chronic intake of mixed cyclooxygenase (COX)-1 and -2 nonsteroidal anti-inflammatory drugs, and gastrointestinal blood loss associated with parasitic disease. Ferritin represents the tissue-bound nonessential iron stores in the body that supply the essential iron for oxygen transport and iron-dependent enzymes. Serum levels of 15 to 20 ng/ml mean that muscle and other storage sites for iron (liver and bone marrow) are depleted of ferritin. Anemia is common at levels of 10 ng/ml or less. The disease of iron deficiency is anemia. Symptoms of iron insufficiency are fatigue, muscle cramps, and coldness. The association between iron insufficiency and chronic myofascial pain suggests that iron-requiring enzymatic reactions like reduced nicotinamide adenine dinucleotide (NADH) dehydrogenases and the cytochrome oxidase reaction may be limited in such persons. This may in turn produce an energy crisis in muscle when it is overloaded and thereby produce metabolic stress. MTrPs may not easily resolve in such circumstances. Iron supplementation in persons with chronic MPSs and serum ferritin levels below 30 ng/ml prevents or corrects these symptoms.

Vitamin B12 and folic acid metabolism are closely related. They function not only in erythropoiesis but also in central and peripheral nerve formation. Studies have shown that in a subset of patients, serum levels of vitamin B12 as high as 350 pg/ml may be associated with a metabolic deficiency manifested by elevated serum or urine methylmalonic acid or homocysteine and may be clinically symptomatic (Pruthi & Tefferi, 1994). Preliminary studies show that 16% of patients with chronic MPS either were deficient in vitamin B12 or had insufficient levels of vitamin B12, and that 10% had low serum folate levels (Gerwin, 1995b). Replacement of vitamin B12 is lifelong, either orally, transmucosally, or intramuscularly.

Hypothyroidism is suspected clinically in chronic MPS when there is a complaint of coldness, dry skin or dry hair, constipation, and fatigue. Hypothyroidism occurred in 10% of chronic MPS subjects in one study (Gerwin, 1995b). The MTrPs tend to be widespread in hypothyroid persons. The thyroid-stimulating hormone (TSH) level may only be in the upper range of normal, but, as shown by thyroid-releasing hormone (TRH) stimulation tests, may still be abnormal for a given individual. Thyroid hormone supplementation to restore the thyroid state may resolve many myofascial complaints and allow resolution of the problem by the usual means of physical therapy and trigger point inactivation. Thyroxine (levothyroxine) is generally used to treat hypothyroidism. However, not all tissues are equally able to convert thyroxine to triiodothyronine, the active form of thyroid hormone. The addition of triidothyronine to thyroxine has been shown to result in an improved sense of well-being; an improvement in cognitive function and mood; and an increase in serum levels of sex-hormone-binding globulins, a sensitive marker of thyroid hormone function (Bunevicius, et al., 1999; Toft, 1999).

Other less commonly associated medical problems that are found in patients with chronic MPS and that act as perpetuating factors include recurrent candida yeast infections, particularly in women who have been given courses of antibiotic therapy for recurrent urinary tract infections. Persons with myofascial pain dysfunction syndromes affecting the temporal mandibular joint often complain of sore throat or earache and may be given antibiotics, thereby predisposing them to candida overgrowth. Women who present with widespread MTrPs resistant to usual treatment should be investigated for candida infection. If the history is very suggestive, treatment is indicated even if the organism cannot be implicated by hanging drop examination or culture. Men and postmenopausal women who have elevated uric acid levels may also have persistent MTrPs. Parasitic infections can also be associated with widespread MTrPs, often complicated by fatigue and an often nonspecific sense of discomfort, and occasionally gastrointestinal distress. Amoebiasis is the most common parasite encountered in MPS in the United States, but giardia, trematode, and nematode infection have also been found. Treatment of these infections results in an overall improvement, and often in a diminution of the extent of trigger point involvement of muscle. Of course, persons with osteoarthritis, rheumatoid arthritis, Sjögren's syndrome, carpal tunnel syndrome, or peripheral neuropathy caused by diabetes mellitus are more prone to develop MTrP. The postlaminectomy syndrome is frequently caused by MTrP. Treatment is always directed toward the underlying condition, as well as the trigger point where possible.

Sleep disturbance can be a major factor in the perpetuation of musculoskeletal pain. Pain is magnified in the presence of insomnia, whether the insomnia is caused by pain or by other factors. There is the rare case in which chronic musculoskeletal pain is eliminated by the restoration of normal sleep when caffeine was reduced or eliminated from the diet. More often, however, sleep must be addressed directly, noting that sleep disturbance is increased in persons with chronic pain. Attention is paid to pain control at night, to sleep apnea, and to mood disorders like depression or anxiety. Management is both

pharmacological and nonpharmacological. Pharmacological treatment utilizes drugs that promote a normal sleep architecture, induce and maintain sleep through the night, and do not cause daytime sedation. Nonpharmacological treatment emphasizes sleep hygiene, such as using the bed only for sleep and sex, and not for reading, television viewing, and eating (Menefee, et al., 2000).

Psychological stress may aggravate MPS and activate MTrP (Lewis, et al., 1994; McNulty, et al., 1994). Trigger point EMG activity has been shown to increase dramatically in response to mental and emotional stress, whereas adjacent nontrigger point muscle EMG activity remained normal. Thus, the effect of stress on the trigger point can be highly selective, instead of generalized throughout the muscle. MPS may be the major symptomatic expression of psychological distress. In addition, pain-related fear and avoidance can lead to the development of a chronic musculoskeletal pain problem (Vlaeyen & Linton, 2000). Treatment directed toward reducing stress has been shown to diminish MPS symptoms (Banks, et al., 1998). The clinician must be sensitive to this possibility and refer the patient for psychological counseling when appropriate.

SUMMARY

In summary, treatment of MPS begins with the identification of the MTrP as a source of the pain or as a contributing factor, and a delineation of the extent of the problem. The problem may be confined to a few muscles or may be more widespread, regional, or generalized. Direct inactivation of the MTrP is accompanied by correction of mechanical and systemic medical factors that contribute to the development of the syndrome. Exercise to restore physical conditioning reduces the chances of recurrence. Persons with chronic MPS who have not responded as expected to appropriate therapy must be evaluated for further mechanical, medical, or psychological problems that have been associated with persistent MPS. Attention to the postural and physical stresses of work and awareness of the effect that psychological stress has on muscle pain identify those areas that need to be addressed. These problems must be corrected or alleviated to effectively treat the MPS. Effective treatment can be provided through the application of a variety of manual techniques, by invasive inactivation of the trigger point, and by carefully identifying and correcting the factors that interfered with recovery.

Chronic Pelvic Pain

Andrea J. Rapkin, M.D. and Julie Jolin, M.D.

INTRODUCTION

Chronic pelvic pain is, by definition, pain that persists for more than 6 months. In its various forms, chronic pelvic pain affects an estimated 12 to 15% of women in the United States, accounting for more than $881 million spent each year on outpatient visits associated with this chronic pain (Mathias, Kupperman, Liberman, Lipschutz, & Steege, 1996). It is one of the most common but taxing problems in gynecologic practice. Even after a thorough workup, the etiology may remain obscure, and the relationship between certain types of pathology and the pain response may be inconsistent and often inexplicable. In the patient who has no obvious pathology, it may be tempting to remove pelvic structures for their physiological variations. Approximately 12% of all hysterectomies are performed for pelvic pain and 30% of patients who present to pain clinics have already had a hysterectomy (Chamberlain & La Ferla, 1987; Reiter, 1990a).

The purpose of this chapter is to outline the anatomy and physiology of pelvic pain and to explore the differential diagnosis and management of chronic pelvic pain, including the role of surgery, psychotherapy, and the multidisciplinary pain clinic.

Neuroanatomy and Neurophysiology of Pelvic Pain

The pelvic viscera receive afferent (sensory) innervation by way of the autonomic nerve trunks (Kumazawa, 1986). The major neural pathways for visceral pain from the female pelvic organs travel with the sympathetic nerve bundles and have cell bodies in a thoracolumbar distribution. Sensory afferents that travel with the parasympathetic (sacral) fibers are probably of secondary importance for pain transmission from the pelvic organs. These latter nerves have their cell bodies in the sacral dorsal root ganglia (Kumazawa, 1986). The innervation of the female pelvic viscera and somatic structures is depicted in Figure 22.1.

The lower abdominal wall and anterior vulva, urethra, and clitoris are innervated by mixed (motor and sensory) somatic nerves deriving from lumbar 1 and 2 (L1 and L2) (Renaer, 1981). The dorsal rami derived from L1 and L2 innervate the lower back, often a region of referred pelvic pain. The anus, perineum, and lower vagina are innervated by somatic branches of the pudendal nerve, which is derived from the second through fourth sacral root ganglia (S2 to S4) (Renaer, 1981).

Pain impulses from the upper vagina, cervix, uterine corpus, inner one third of the fallopian tube, broad ligament, upper bladder, terminal ilium, and terminal large bowel travel with the thoracolumbar sympathetics via the vaginal, uterine, and hypogastric plexes to the hypogastric nerve, through the superior hypogastric plexus and to the lower thoracic and lumbar sympathetic chain (Kumazawa, 1986). The afferents then pass through the dorsal roots of thoracic 11, 12 and lumbar 1 (T11, T12, L1) and enter the spinal cord at this level. There is some duplication of afferent fibers in the thoracolumbar and sacral regions and there are probably some pain impulses from the upper vagina, cervix, and lower uterine segment that travel in the pelvic nerve (nerve erigentes) via pelvic parasympathetics (sacral autotomics) to spinal segments sacral 2 through 4 (S2 to S4) (Kumazawa, 1986). Urogenital sinus structures including the lower vagina, rectum, and lower bladder are innervated by both thoracolumbar and sacral afferents (Kumazawa, 1986).

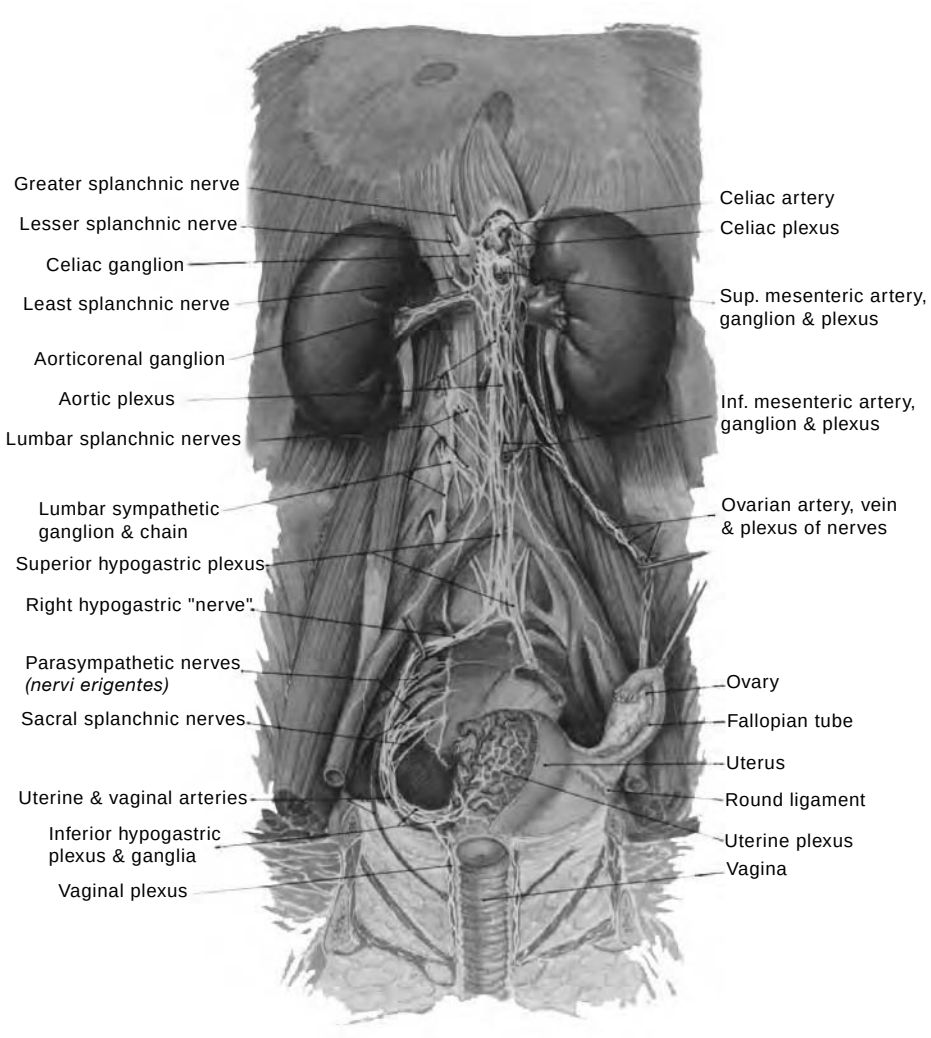

FIGURE 22.1 The innervation of the female pelvic viscera.

Afferents from the ovary, outer two thirds of the fallopian tube, and upper ureter travel along the ovarian artery entering the sympathetic nerve chain at lumbar spinal segment 4 (L4) ascending with the chain to penetrate the cord at T9 and T10 (Kumazawa, 1986). The superior hypogastric plexus carries no afferents from the ovary that accounts for the failure of presacral neurectomy (the transection of the superior hypogastric nerve) to diminish lateralizing pain or pain of adnexal origin. In sum, the transmission of painful stimuli from the pelvic organs relies on an intact sympathetic nervous system (Cervero & Tattersall, 1986). However, the parasympathetic (sacral) system is crucial for micturination, defecation, and reflex regulation of the reproductive organs (Kumazawa, 1986). The role of the sacral autonomics in the genesis of pelvic pain remains to be delineated.

A large proportion of the sacral afferents from the colon and urinary bladder are usually silent. Only 5% of colon afferents and 2.5% of bladder afferents can be activated by mechanical distension. A proportion of the nonmechanosensitive unmyelinated sacral afferents are chemosensitive and can develop nouveau mechanosensitivity (Janig, Haupt-Schade, & Kohler 1993). These usually "silent" fibers may be activated by and sensitized by inflammation or unusually strong mechanical stimulation and may play a role in pelvic pain of urinary tract or gastrointestinal etiology and theoretically from the internal reproductive organs as well.

The cell bodies of the afferent axons from the pelvic organs are located in the dorsal (sensory) ganglia of the spinal nerves (Fields, 1987). Before entering the spinal gray matter of the dorsal horn, branches of these afferent axons may extend for two or more segments beyond the level at which the original axons entered the cord. Much of neuronal modulation occurs in the dorsal horn. Evidence from animal studies indicates that supraspinal factors interact at the level of the dorsal horn to modulate the sensory perception of pain from the pelvic viscera (Berkley & Hubscher, 1995; De Groat, 1994).

The dorsal horn is an important site of modulation of afferent input (Cervero & Tattersall, 1986). The second-order neurons are subjected to excitatory and/or inhibitory interactions. For example, if a visceral structure and a cutaneous (somatic) structure transmitting to the same second-order neuron in the dorsal horn are stimulated simultaneously, the second-order neuron response may be greater than either the cutaneous or the visceral stimulus would evoke on its own. These viscero-somatic neurons tend to have larger receptive fields than the somatic neurons. There are also many more somatic second-order neurons than there are viscero-somatic neurons (Cervero & Tattersall, 1986). Both of these facts may account for the vague, poorly localizable quality of visceral pelvic pain.

General Considerations of Visceral Pain

The neurophysiology of pain transmission from the viscera (internal organs such as bowel, bladder, rectum, uterus, ovaries, and fallopian tubes) differs from that of somatic structures (cutaneous elements, fascia, muscles, parietal peritoneum, mesentery, external genitalia, anus, urethra). Nociceptors receive pain evoked at somatic nerves, whereas a plentitude of nonspecific receptors receive pain induced in the viscera (Berkley, 1994; Cervero, 1994). Visceral pain, in contrast to somatic pain, is usually deep; difficult to localize; and frequently associated with various autonomic reflexes such as restlessness, nausea, vomiting, and diaphoresis (Procacci, Zoppi, & Maresen, 1986). Early surgical studies performed under local anesthesia have shown that cutting, crushing, or burning the bowel, for example, evokes no pain, whereas distension of muscular organs or hollow viscera, stretching of the capsule of solid organs, hypoxia or necrosis of viscera, production of algesic (pain producing) substances, rapid compression of ligaments or vessels, and inflammation may cause severe pain. In contrast, cutting or crushing a somatic structure produces exquisite pain that is well localized (Procacci, et al., 1986).

PERIPHERAL CAUSES OF CHRONIC PELVIC PAIN

Adhesions

The differential diagnosis of the peripheral component of pelvic pain is listed in Table 22.1. Laparoscopic studies for the evaluation of chronic pelvic pain, would suggest that adhesions play a prominent role. However, when these studies were performed, nonobvious sources of pelvic pain such as abdominal wall pain, irritable bowel syndrome, and interstitial cystitis (IC) were often not excluded prior to laparoscopy. Adhesions were present in 16 to 44% of the patients undergoing laparoscopy for chronic pelvic pain (depending on the series) (Rapkin, 1986; Kresch,

Seifer, Sachs, & Barrese, 1984; Lundberg, Wall, & Mathers, 1973; Liston, Bradford, Downie, & Kerr, 1972; Renaer, 1981). Do adhesions actually cause pelvic pain? Of 100 patients Kresch laparoscoped for chronic pelvic pain, 38% had adhesions and 10% had bowel adhesions. However, of 50 asymptomatic patients undergoing laparoscopy for sterilization, only 12% had adhesions and only 2% exhibited adhesions involving the bowel. These differences were highly significant (Kresch, et al., 1984). Keltz, et al. in a combined retrospective/prospective study found colon to side-wall adhesions in a higher proportion of patients (93 vs. 13%) with pelvic pain than the control group (sterilization) (Keltz, Peck, Liu, Kim, Arici, & Olive, 1995).

In comparison, Rapkin (1986) noted that many infertility patients with severe adhesions had no pain and compared the results of laparoscopies performed on two groups of patients — the first group complained of chronic pelvic pain and the second group had infertility, without complaints of pain. When evaluating both the site and density of adhesions, it was notable that there were no significant differences between the group with chronic pelvic pain and asymptomatic patients in the infertility group. The results of this study question the role of pelvic adhesions as a common cause of chronic pelvic pain (Rapkin, 1986). If adhesions cause pain, then lysis of adhesions should relieve pain. A prospective noncontrolled nonrandomized study of lysis of adhesions did not show significantly lower postoperative pain ratings (Steege & Scott, 1991). However, post hoc analysis consisting of separation of the subjects into those with and without psychosocial dysfunction revealed a significant improvement in pain scores in the group without psychosocial dysfunction. The only prospective randomized study of adhesiolysis in the literature revealed no differences in the pain scores between the groups (adhesiolysis vs. no adhesiolysis). Again, post hoc analysis of the data suggested there was a significant improvement (although only on two of the three methods of pain assessment) in pain scores in the subgroup of patients with dense vascular adhesions involving small bowel (Peters, Van Dorst, Jellis, VanZuuren, Hermans, & Trimbos, 1991). Advances using a 3-mm laparoscope have enabled development of "conscious pain mapping" whereby patients under local anesthesia and conscious sedation guide in determining which adhesions are those associated with pain (Palter, 1999). In an observational pain mapping study of 50 women under local anesthesia, manipulation of appendiceal and pelvic adhesions was observed to contribute significantly to pelvic pain (Almeida & Val-Gallas, 1997). Though adhesions may be prevalent in patients with chronic pelvic pain, these adhesions may or may not be the cause of pain. No prospective studies of adhesiolysis and outcome based on pain mapping have been published.

ENDOMETRIOSIS

Another "peripheral" cause of chronic pelvic pain is endometriosis. The actual incidence of endometriosis is unknown because many individuals undoubtedly have endometriosis without sufficient symptomatology to warrant surgical intervention. It seems that the incidence of endometriosis is increasing. However, this apparent increase in prevalence may be a reflection of the more liberal use of laparoscopy and of the recognition of atypical forms of endometriosis. Endometriosis is noted in patients undergoing laparoscopy for chronic pelvic pain in anywhere from 5 to 37% of the cases (Kresch, et al., 1984; Liston, et al., 1972; Lundberg, et al., 1973).

The diagnosis of endometriosis is usually made in the third or fourth decade; however, it has been noted to be a prominent diagnosis in adolescents and women in their twenties who are evaluated for chronic pelvic pain (Chatman & Ward, 1982). In fact, endometriosis has been suggested by one study to be the etiology in up to 70% of adolescents with chronic pelvic pain unresponsive to medical treatment (Probst & Laufer, 1999).

The most common symptoms of endometriosis are dysmenorrhea, dyspareunia, infertility, and abnormal uterine bleeding, usually from a secretory endometrium (Kitchen, 1985). Pelvic pain in women with endometriosis may occur at any time in the menstrual cycle, though dysmenorrhea is the most classic symptom. Dysmenorrhea may be so prolonged that the patient may complain of what seems like acyclic, continuous pain; beginning 7 to 10 days before the onset of the menstrual period and

persisting until 1 week or so after the bleeding has ceased. The patient often describes pressurelike pain and aching in the lower abdomen, back, and rectum. There may be radiation of pain into the vagina, thighs, or perineum. Dyspareunia is common when the disease involves the cul-de-sac (pouch of Douglas), uterosacral ligaments, or rectovaginal septum. Pain with defecation (dyschezia) may also be present even in patients without direct bowel wall involvement. These symptoms may be due to endometrial implants near the rectum. Urinary urgency, frequency, and bladder pain may also be associated with urinary tract involvement. Because endometriosis may be present in unusual locations, the manifestations of endometriosis are protean (Kitchen, 1985). Usually the previously noted common symptoms and signs are present but, rarely, patients may complain of rectal bleeding, symptoms similar to bowel obstruction, suprapubic pain, and/or urinary symptoms (such as frequency, dysuria, or hematuria). If ureteral involvement is present, there may be flank pain, backache, or hypertension. Signs and symptoms of an acute abdomen occur infrequently and are usually related to rupture of an endometrioma.

Examination of patients with endometriosis may reveal tenderness and nodularity on the rectovaginal examination of the uterosacral ligaments and posterior cul-de-sac (Kitchen, 1985). Progressive disease results in findings of obliteration and fibrosis of the cul-de-sac, and fixed retroversion of the uterus. Enlarged ovaries (endometriomas) with decreased mobility may be noted.

Laparoscopy is necessary for definitive diagnosis of endometriosis though the diagnosis may be suggested by history and pelvic examination. A study by Ling (1999) for the Pelvic Pain Study Group reported the efficacy and safety of medical treatment with depot leuprolide before laparoscopy based on empirical, clinical diagnosis. Ultrasound is not diagnostic and cannot differentiate an endometrioma from a benign or malignant ovarian neoplasm, scattered small implants are not detectable by ultrasound. Laboratory studies are usually not specific. CA 125 and erythrocyte sedimentation rate (ESR) can be elevated in women with endometriosis.

Endometriosis can be treated hormonally using androgenic hormones (Danocrine®), progestins, or gonadotropin-releasing hormone analogs to create pseudomenopause and to atrophy ectopic endometrial implants. For those undergoing long-term therapy (12 month or greater), hormonal add-back therapy, norethindrone acetate with or without estrogen, prevents long-term hypoestrogenic side effects such as bone loss (Hornstein, Surrey, Weisberg, & Casino, 1998). Laparoscopic electro- or laser surgery or laparotomy with resection of disease often is reserved for treatment of severe endometriosis. However, in a prospective randomized double-blinded study of 63 women with minimal to moderate endometriosis, laparoscopic laser treatment was noted to benefit 90% of those women who initially responded at 1-year follow-up (Sutton, Pooley, Ewen, & Haines, 1997). Patients who do not desire fertility may opt for radical surgery for endometriosis, which consists of a total abdominal hysterectomy with bilateral salpingo-oophorectomy as well as removal of any residual gastrointestinal (GI), genitourinary (GU), or peritoneal disease. It should be noted that patients with endometriosis, who have failed hormonal or conservative surgical therapy, may still benefit from the pain management approach (Rapkin & Kames, 1987). At least 30% of patients with recurred pain after treatment of endometriosis do not have residual disease at the time of repeat laparoscopy.

Endometriosis is a common finding in reproductive aged women, but it is clear that in many women with chronic pelvic pain and endometriosis the latter may not be the cause of the pain and may be only a contributing factor. There is no significant correlation between the amount of disease and pain severity although higher stage disease tends to be associated with a greater prevalence of and increased intensity of pain. Additionally, there is no correlation between location of pain and site of endometriotic lesions (Fukaya, Hoshiai, & Yajima, 1993) and as many as 30 to 50% of patients regardless of stage have no pain. However, deeply infiltrating lesions, particularly of the uterosacral ligaments, are strongly associated with pain (Cornillie, Oosterlynck, Lauweryns, & Koninckx, 1990). Vaginal and uterosacral endometriosis has been associated with complaints of deep dyspareunia (Vercellini, Trespedi, De Giorgi, Cortesi, Parazzini, & Crosignani, 1996).

Clinically it is possible to determine whether there is a relationship between pain and endometriosis in a specific patient because of the hormonal sensitivity of the disease and the potential to surgically cure disease. Clearly, pain that does not respond to adequate surgical and medical management of endometriosis should be reevaluated for another source, pain, or other contributing central factors.

PELVIC CONGESTION

For the last 100 years there has been waxing and waning interest in the role of pelvic congestion in the genesis of chronic pelvic pain without obvious pathology. The concept of autonomic nervous system dysfunction leading to a vascular disorder affecting the uterine and ovarian veins was outlined by Taylor (1954). Taylor suggested that emotional stress could lead to smooth muscle spasm and congestion of the veins draining the ovaries, uterus, and vulva. Taylor's series of 100 cases consisted of women in their reproductive years with the chief complaint of lower abdominal pain. Subjects also complained of secondary dysmenorrhea, low back pain, dyspareunia, infertility, and menorrhagia. Their pain was usually bilateral, lower pelvic in distribution, and was exacerbated

with the menstrual period. Two thirds of the patients also complained of nervous tension, chronic fatigue, breast tenderness, and spastic colon, as well as symptoms similar to the premenstrual syndrome. Personality characteristics noted by Taylor included immaturity and decreased sexual drive.

On exam, patients manifested tenderness over the uterus. The fundus of the uterus and cervix were often bulky and the ovaries often enlarged with multiple functional cysts. The parametria, especially the uterosacral ligaments, were noted to be tender and indurated. At laparotomy, the uterus was usually soft, enlarged, and purplish or mottled. There was increased fluid in the cul-de-sac and edema of surrounding subserosal connective tissue and occasionally ovarian varicosities were prominent (Taylor, 1954).

The concept of pelvic congestion has been resurrected to explain chronic pelvic pain (Hobbs, 1976). Beard, Highman, Pearce, and Reginald (1984) performed the only blinded study of venograms in patients with chronic pelvic pain. Larger mean ovarian vein diameters, delayed disappearance of contrast medium, and ovarian plexus congestion were present in a significantly greater proportion of women with chronic pelvic pain without pathology than those with pathology or controls. Other diagnostic means include transvaginal ultrasound, which may reveal uterine enlargement, thickened endometrium, cystic ovaries, and dilated pelvic veins (Adams, Reginal, Franks, Wadsworth, & Beard, 1990; Stones, Rae, Rogers, Fry, & Beard, 1990), or more recently for more detailed visualization of structures, magnetic resonance imaging (MRI) (Gupta & McCarthy, 1994).

Because many patients were noted to have polycystic ovaries, and all were of reproductive age, hormonal suppression consisting of a hypoestrogenic environment was considered as a mode of treatment for pelvic congestion. Medroxyprogesterone acetate (MPA) given in doses of 30 mg daily for 3 months was administered in a randomized, placebo-controlled treatment trial for women with chronic pelvic pain with pelvic congestion (abnormal venograms) (Farquhar, Rogers, Franks, Pearce, Wadsworth, & Bland, 1989). A study of 84 subjects included four separate groups: MPA alone, MPA and psychotherapy, placebo plus psychotherapy, and placebo alone. MPA was significantly more effective after the 3-month treatment period than psychotherapy or placebo. Patients reported a 50% reduction in pain in the MPA group and 33% reduction in pain score after receiving placebo. However, pain returned in the MPA group after stopping treatment but did not return in the placebo group. Psychotherapy did not reduce pain in the short term, but there was a positive interaction between MPA and psychotherapy 9 months after the treatment was concluded. However, 9 months posttreatment, improvement was reported irrespective of the treatment group. This response coupled with a strong placebo response reaffirms central factors in this condition. It also suggests that hormonal suppression with MPA or gonadotropin-releasing hormone (GnRH) agonists with or without low-dose estrogen and progestin hormone add-back may be therapeutic. A few small non-controlled studies have assessed the more invasive technique of transcatheter embolotherapy of the ovarian and internal iliac veins to treat pelvic congestion, with results revealing good short-term success (Capasso, Simons, Trotteur, Dongelinger, Henroteaux, & Gaspard, 1997; Sichlau, Yao & Vogelzang, 1994; Tarazov, Prozorovskij & Ryzhkov, 1997). Long-term efficacy remains to be evaluated (Venbrux & Lambert, 1999).

Salpingo-oophoritis

Salpingo-oophoritis can cause chronic pelvic pain, though patients usually present with symptoms and signs of acute or subacute infection before the pain becomes chronic. More commonly, a patient will present with frequent recurrent infections.

Sweet and Gibbs (1985) proposed criteria for making the diagnosis of salpingitis on clinical grounds. Patients should have a history of lower abdominal pain as well as lower abdominal tenderness (with or without rebound), cervical motion tenderness, and adnexal tenderness. In addition, they must have one of the following: temperature greater than 38°C, leucocytosis (greater than 10,500 white blood cells per cubic millimeter); culdocentesis fluid containing white cells and bacteria on Gram stain; presence of an inflammatory mass; elevated ESR; a Gram stain from the endocervix revealing Gram-negative intracellular diplococci; or a monoclonal smear from the endocervical secretions revealing chlamydia (Sweet & Gibbs, 1985).

Patients may complain of having had numerous episodes of pain associated with fever and may have been given the diagnosis of pelvic inflammatory disease. When these episodes become recurrent, the patient is often considered to have chronic salpingo-oophoritis, though it is not clear that a chronic inflammatory condition exists. Instead, subacute or subclinical disease with recurrent acute infections may be present. An additional possibility is that the patient may not have salpingitis at all. In all these situations, laparoscopy with peritoneal fluid cultures is diagnostic, though an experienced clinician can often make the diagnosis on the basis of clinical criteria. Broad spectrum antibiotics and anaerobic coverage represent the standard treatment of acute or recurrent salpingo-oophoritis. Only rarely is hysterectomy and salpingo-oophorectomy required.

OVARIAN REMNANT SYNDROME

Chronic pelvic pain in a patient who has had a hysterectomy and bilateral salpingo-oophorectomy for severe

endometriosis or pelvic inflammatory disease may be caused by the ovarian remnant syndrome. Ovarian remnant syndrome results from residual ovarian cortical tissue that is left in situ after a difficult dissection in an attempt to perform an oophorectomy (Steege, 1987). Often the patient has had multiple pelvic operations with the uterus and adnexa removed sequentially.

The diagnosis is suspected on the basis of history and physical examination (Price, Edwards, & Buchsbaum, 1990). The patient usually complains of pelvic pain that is often cyclic and may be accompanied by peritoneal signs. The patient may have a history of flank pain and frequent urinary tract infections; and there is on occasion intermittent, partial bowel obstruction. The painful symptoms usually arise 2 to 5 years after surgery. Pelvic exam may reveal a tender mass in the lateral region of the pelvis and ultrasound following ovarian stimulation with 50 mg daily for 5 days of clomiphene usually confirms a mass with the sonographic characteristics of ovarian tissue. In a patient who has had bilateral salpingo-oophorectomy and is not on hormonal replacement, estradiol and follicle-stimulating hormone (FSH) assays reveal a characteristic premenopausal picture, though on occasion the remaining ovarian tissue may not be active enough to suppress FSH levels. Laparotomy and removal of residual ovarian tissue is necessary for treatment (Pettit & Lee, 1988). Importantly, it has been shown that those who have achieved pain relief with GnRH-agonist hormonal therapy prior to surgery, are usually those who also receive relief with surgical removal of the remnant (Carey & Slack, 1996).

CYCLIC PELVIC PAIN

Cyclic pelvic pain consists of primary and secondary dysmenorrhea but also includes atypical cyclic pain, such as pain beginning 1 week prior to menses and lasting for up to 1 week following the cessation of menstrual flow with occasional midcycle pain as well. Atypical cyclic pain is a variant of secondary dysmenorrhea. The diagnosis of cyclic pain often depends on the review of a daily pain diary that patients should be asked to maintain. With the availability of nonsteroidal anti-inflammatory agents and compounds that alter the female sex steroids, cyclic pelvic pain has become significantly more manageable.

Dysmenorrhea or "difficult monthly flow" is a common gynecologic disorder affecting up to 50% of menstruating women (American College of Obstetricians and Gynecologists, 1983). Primary dysmenorrhea refers to pain with menses when there is no pelvic pathology, whereas secondary dysmenorrhea is painful menses with underlying pelvic pathology. Primary dysmenorrhea usually appears within 1 to 2 years after menarche, with the establishment of ovulatory cycles. The disorder primarily affects younger women with ovulatory cycles, especially teens, but may persist into the forties. The pain of primary dysmenorrhea begins a few hours prior to or just after the onset of menstrual flow and usually lasts for 48 to 72 hours. The pain is laborlike with suprapubic cramping that may be accompanied by lumbosacral backache, pain radiating down the anterior thighs, nausea, vomiting, and diarrhea.

Secondary dysmenorrhea, on the other hand, usually, though not always, occurs years after menarche and may occur with anovulatory cycles (ACOG, 1983). The most common cause of secondary dysmenorrhea is endometriosis. Other common causes, listed in Table 22.1, include vaginal, cervical, uterine, fallopian tube, adnexal, and peritoneal pathology. The differential diagnosis of secondary dysmenorrhea includes primary dysmenorrhea and noncyclic pelvic pain and entails ruling out primary dysmenorrhea and confirming the cyclic nature of the pain. The etiology of primary dysmenorrhea has been established to be increased uterine prostaglandin production (Filler & Hall, 1970). Prostaglandin synthetase inhibitors are effective for the treatment of primary dysmenorrhea in 70 to 80% of the cases (The Medical Letter, 1979). For the patient with primary dysmenorrhea who has no contraindications to oral contraceptive agents and desires contraception, the birth control pill is the agent of choice (Chan & Dawood, 1980). More than 90% of women with primary dysmenorrhea have relief with birth control pills.

If the patient does not respond to prostaglandin synthetase inhibitors and does not desire oral contraceptive pills for contraception, or if either of them are contraindicated, narcotic analgesics should be administered for 2 to 3 days per month. Prior to the addition of narcotic medication, psychological factors and other organic pathology should be ruled out. Other modes of hormonal menstrual suppression include high dose progestins (oral or depo intramuscular injection) continuous oral contraceptive pill administration, or GnRH agonists with or without continuous low-dose hormone (menopausal dosage) add back. Breakthrough bleeding and associated pain are potential problems with these regimens.

A patient with dysmenorrhea who does not respond to prostaglandin synthetase inhibitors and/or birth control pills and in whom organic disease has been ruled out may also respond to the pain management approach and, in particular, acupuncture or transcutaneous electrical nerve stimulation (Helms, 1987; Mannheimer & Whaler, 1985). In one study, Kaplan, et al., (1994) reported a 30% marked pain relief, 60% moderate pain relief, and 10% no pain relief in women with primary dysmenorrhea undergoing transcutaneous electrical nerve stimulations (TENS). To more fully evaluate the evidence for treating primary dysmenorrhea with TENS or acupuncture, a forthcoming study by the Cochrane Library aims to analyze all prospective randomized controlled trials comparing those modalities with medical treatment or placebo (Wilson, Farquhar, Kennedy, & Jin, 2000).

The distinction between primary and secondary dysmenorrhea requires a thorough history as to the nature and onset of the pain, the duration of pain or symptoms, and a pain diary (if on first query the pain does not appear to be cyclic). A complete physical and pelvic examination is important, with focus on the evaluation of the size, shape, and mobility of the uterus and adnexal structures and for nodularity and fibrosis of the uterosacral ligaments and rectovaginal septum. Genital cultures for gonorrhea and chlamydia and a complete blood count (CBC) with ESR are usually warranted. If no abnormalities are found, a tentative diagnosis of primary dysmenorrhea may be made and the patient started on oral contraceptive pills and/or prostaglandin synthetase inhibitors. Having made a diagnosis of primary dysmenorrhea, a 4- to 6-month trial of oral contraceptives and/or prostaglandin synthetase inhibitors is warranted before laparoscopy is performed to rule out secondary dysmenorrhea and, in particular, endometriosis. A strong family history of endometriosis and any clinical signs of endometriosis on exam may suggest that laparoscopy be performed sooner.

Surgical approaches to dysmenorrhea include laparoscopic uterine nerve ablation, presacral neurectomy, and, in selected cases of secondary dysmenorrhea, hysterectomy (Malinak, 1980). The uterosacral ligaments carry the main afferent supply from the uterus, and if complete, the uterosacral ablation should be as effective as the presacral neurectomy, though Doyle (1955) described a 70% success rate. Long-term or controlled studies of the neurectomy procedures are lacking. The management of secondary dysmenorrhea involves treatment of the underlying pathology.

GASTROENTEROLOGIC CAUSES OF CHRONIC PELVIC PAIN

Many of the patients referred to gynecologists with chronic pelvic pain actually have GI pathology (Rapkin & Mayer, 1993; Reiter, 1990b). Because the cervix, uterus, adnexa, lower ileum, sigmoid colon, and rectum share the same visceral innervation, with pain signals traveling via the sympathetic nerves to spinal cord segments T10 to L1, it is often difficult to determine whether lower abdominal pain is of gynecologic or enterocoelic origin (Hightower & Roberts, 1981). In addition, as is true with other types of visceral pain, pain sensation from the GI tract is often diffuse and poorly localized. Skillful medical history and examination are usually necessary to make the diagnosis.

Irritable bowel syndrome (IBS) is one of the more common causes of lower abdominal pain and may account for as many as 7 to 60% of referrals to a gynecologist for chronic pelvic pain (Reiter, 1990b). The predominant symptom of irritable bowel syndrome is abdominal pain (Ritchie, 1979). Other symptoms include excessive flatulence and alternating diarrhea and constipation. The pain is usually intermittent cramplike and predominantly left lower quadrant in location but, occasionally the pain is constant. Pain is often improved after a bowel movement. The pain may last for only a few minutes, but 50% of patients may have pain for hours to days, and 20% of patients may complain of pain for weeks or longer. Symptoms are usually worse during periods of stress tension, anxiety, depression, and with the premenstrual and menstrual phases of the cycle (Ritchie, 1979).

The diagnosis of the IBS is usually made on the basis of the history but cannot be made without first excluding other conditions. Sigmoidoscopy or barium enema is often necessary and is routinely negative though there may be mucosal hyperemia on sigmoidoscopy and increased haustral contractions or loss of haustration on barium enema (Hightower & Roberts, 1981). IBS is a waxing and waning disorder and treatment consists of reassurance, education, stress reduction, and antcholinergic or other antispasmodic pharmaceutical agents. Bulk-forming agents such as Metamucil® and high-fiber diet are also usually added as well (Ritchie, 1979). Low-dose tricyclic antidepressants are also useful.

Patients with chronic diarrhea must be evaluated carefully, often with a gastroenterologist in consultation. Though symptoms may have become chronic, it is possible that the patient may have contracted infectious diarrhea due to any one of a number of bacteria or parasites including Shigella, Escherichia coli, Salmonella, Campylobacter, or Amoeba (Hightower & Roberts, 1981).

Though appendicitis is a common cause of abdominal pain, the abdominal pain of appendicitis is severe enough that the patient presents to the physician within 12 to 48 h after the onset of the symptoms. The practitioner treating a patient for chronic pelvic pain should be cautious when the patient suddenly has an increase in abdominal pain, especially if it is accompanied by localized right lower quadrant pain, as well as anorexia, nausea, vomiting, and peritoneal signs on exam. It is not uncommon that a patient under treatment for chronic pelvic pain develops acute appendicitis or other acute pelvic condition while in the process of evaluation for the chronic pain problem. Chronic appendicitis is a controversial entity, but in the opinion of Lee, Bell, Griffen, & Hagihara (1985), it does exist.

Another cause of chronic enterocoelic pain is diverticular disease of the colon (Young, Alpers, Norland, & Woodruff, 1976). Of the adult population over 40, 5% have been noted to have diverticulae (Painter, 1970). This percentage increases to 40% in individuals over the age of 70 although most patients never develop diverticulitis. Though diverticulosis is usually asymptomatic, diverticulitis results in severe pain. Diverticulitis results from perforation of one or more of the diverticula and usually leads

to the formation of a pericolonic abscess. The principal symptom of diverticulitis is left lower quadrant abdominal pain. A tender mass may be palpable on exam. Fever and leukocytosis are usually present. Sigmoidoscopy is diagnostic. These symptoms and signs, however, are usually those of an acute pathological pain process bringing the patient to a physician early in the course of pain.

Inflammatory bowel disease such as ulcerative colitis or granulomatous disease (Crohn's disease) similarly do not usually present as chronic pelvic pain because their presentation is usually more acute with diarrhea, fever, vomiting, and anorexia (Hightower & Roberts, 1981). A sigmoidoscopy or barium enema is diagnostic.

Tumors of the GI tract can cause chronic lower abdominal pain in women (McSherry, Cornell, & Glenn, 1969). The most frequent and early symptoms of bowel carcinomas are change in bowel habits (74% of patients) and abdominal pain (65% of patients). Rectal bleeding and weight loss may be signs of advanced disease (McSherry, et al., 1969). Most rectal tumors can be palpated on rectal examination. Sigmoidoscopy and biopsy as well as barium enema are diagnostic.

Included in the differential diagnosis of lower abdominal pain is hernia though there is a relatively low incidence of hernia in females (Hightower & Roberts, 1981). Anterior and posterior perineal hernias, usually limited to cystocele, rectocele, or enterocele, may cause lower abdominal/perineal pain in women though the pain is usually not severe. This type of pain usually responds to a pessary though the management is surgical.

UROLOGIC CAUSES OF CHRONIC PELVIC PAIN

Chronic pelvic pain of urologic origin may be related to recurrent cystoureteritis, urethral syndrome, interstitial cystitis (IC), infiltrating bladder tumors, ectopic pelvic kidney, or various ureteral causes of pelvic pain such as ureteral obstructions or endometriosis (Vereecken, 1981; Summit, 1993).

The patient with cystitis presents with complaints of suprapubic pain, dysuria, frequency, urgency; has pyuria on urinalysis; and has a positive urine culture (Vereecken, 1981). The symptoms usually respond to adequate antibiotic therapy. Relapses and reinfection can be diagnosed with the aid of history, urinalysis, and culture. The antibiotic and duration of therapy may have to be adjusted and on occasion, if the patient has recurrent cystoureteritis, antibiotics may have to be administered postcoitally possibly for a prolonged period of time (Vereecken, 1981).

The urethral syndrome is a common condition in women and may present as chronic pelvic pain (Bodner, 1988). Symptoms of dysuria, urinary frequency, suprapubic pain, and dyspareunia are prominent and the diagnosis is one of exclusion. A negative urine analysis, urine culture, and urethral cultures, as well as negative evaluation for vulvovaginitis, increase the suspicion for the diagnosis of urethral syndrome. Treatment consists of a trial of antibiotics, preferably tetracycline for 2 to 3 weeks; and, if without success, urethral dilatation in reproductive aged women and vaginal estrogen for peri- and postmenopausal women (Bergman, Karram, & Bhatia, 1989). Attention should be paid to psychological factors as well.

When a patient complains of symptoms of urinary frequency, urgency, and suprapubic pain but laboratory studies are negative, the patient may actually have IC (Karram, 1993; Messing & Stamey, 1978). The evaluation of patients with the preceding symptoms should include urinalysis and culture, urethral culture for chlamydia, mycoplasma, and gonorrhea, and cystoscopy with hydrodistension and possible biopsy. The consensus criteria for the diagnosis of IC include at least two of the following: pain or bladder filling relieved by emptying; pain in suprapubic, pelvic, urethral, vaginal or perineal region, glomerulations on endoscopy; or decreased compliance on cystometrogram (Karram, 1993). Therapy consisting of intravesical distension with dimethylsulfoxide, intravesical instillation of analogs of glycosaminoglycan, TENS and biofeedback including pelvic floor muscle biofeedback training have all reduced pain in uncontrolled studies of patients with IC. Because treatment of the condition remains empiric and less than optimal, oral drugs such as anticholinergics, antihistamines, antispasmodics, nonsteroidal anti-inflammatories, tricyclic antidepressants, narcotics, and pentosan polysulfate sodium (which is Food and Drug Administration [FDA] approved for IC treatment) (Sant, 1998) have all been utilized with some success.

Very severe chronic suprapubic pain may be caused by infiltrating carcinomas of the bladder, cervix, uterus or rectum (Vereecken, 1981). These conditions should be apparent after performing the history, pelvic examination, urine analysis, and cystoscopy, though intravenous pyelogram (IVP) or CT urogram may be necessary.

NERVE ENTRAPMENT OR INJURY

Abdominal cutaneous nerve entrapment or injury should always be considered in the differential diagnosis of chronic lower abdominal pain, especially if no visceral etiology is apparent. The syndrome most commonly occurs months to years after Pfannenstiel skin or other lower abdominal and even laparoscopic incisions (Sippo, Burghardt, & Gomez, 1987) but can also follow trauma or exercise. Commonly involved nerves include ilioinguinal (T12 and L1), iliohypogastric (T12 and L1), and genitofemoral (L1 and L2).

Symptoms of nerve entrapment include pain that is typically elicited by exercise and relieved by bedrest (Hammeroff, Carlson, & Brown, 1981; Sippo, et al., 1987). The pain is described as stabbing, colicky, and sudden; and is usually judged as coming from the abdomen and not from the skin. The pain is located along the line of the lateral edge of the rectus margin and may be associated with a burning pain radiating horizontally or diagonally toward the linea alba and back to the flank or sacroiliac region. Nausea, bloating, menstruation, and full bladder may exacerbate the pain of nerve entrapment (Sippo, et al., 1987).

On exam, the pain can usually be localized with the fingertip (MacDonald, 1993). The maximal point of tenderness is the neuromuscular foramen at the rectus margin medial and inferior to the anterior iliac spine or, in the case of spontaneous nerve entrapment, at the site of exit from the aponeurosis of the other thoracic/abdominal cutaneous nerves. A maneuver that helps to make the diagnosis is to ask the patient to tense the abdominal wall by raising shoulders or raising and extending the lower limbs in a straight leg raising maneuver. The outer side of the rectal muscle is then pressed with a single finger. The pain is exacerbated if nerve entrapment syndrome is present. With the abdominal wall relaxed, the pain is relieved and becomes more diffuse. The tentative diagnosis is confirmed with a diagnostic nerve block consisting of injection of 2 to 4 ml of 1% lidocaine or 0.25% bupivocaine. Patients usually report immediate relief with symptoms after injection and many patients require no further intervention, though some patients require 2 or 3 weekly injections. Only as a last resort should patients be considered for surgical removal of the involved nerves if no other psychological factors predominate and if visceral pathology can be ruled out. Deafferentation pain is a probable sequel to surgery and there are no long-term studies of nerve excision. Medications such as low-dose tricyclic antidepressants and anticonvulsants are also useful for pain control. Physical therapy may be necessary to educate the patient concerning strengthening other muscles to prevent reinjury.

MUSCULOSKELETAL CAUSES OF CHRONIC PELVIC PAIN

Women complaining of lower back pain without complaints of pelvic pain rarely have gynecologic pathology as the cause of their pain; however, low back pain may accompany pelvic pathology. Back pain may be caused by gynecologic, vascular, neurological, psychogenic, or spondylogenic (related to the axial skeleton and its structures) pathology (Morscher, 1981). Musculoskeletal abnormalities commonly contribute to the symptoms of chronic pelvic pain (Baker, 1993).

MYOFASCIAL PAIN

Myofascial pain is defined as "pain and/or autonomic phenomena referred from active myofascial trigger points, with associated dysfunction" (Travell, 1976). Reports of the prevalence of the syndrome vary, but only two papers assessing chronic pelvic pain patients for trigger points have been published. Reiter and Gambone found myofascial syndrome in 15% of their patients with somatic pathology (Reiter, 1990b). [Patients with somatic pathology represented 47% of all patients referred to their pelvic pain clinic (Reiter, 1990b).] Slocumb (1984), in comparison, noted trigger points in most women presenting to the pain clinic with chronic pelvic pain irrespective of underlying pelvic pathology. Clinically, myofascial pain is exacerbated by activity within the muscle or muscle group and, in the case of abdominal wall trigger points and pelvic floor muscle, is exacerbated by activity in deeper visceral structures (bladder or rectal fullness, menses, and cervical motion and intercourse), which share the same dermatomal innervation (Slocumb, 1984; Slocumb, 1990; Travell, 1976). On digital exam of dermatomas of abdomen, back, or vagina, pressure on the trigger point evokes local and referred pain. Pain is exacerbated by the straight leg raising maneuver described earlier. Treatment of myofascial trigger points includes injecting the trigger points with local anesthetic, as well as treating any physical and psychological factors such as depression, anxiety, and learned behavior patterns that may accompany and exacerbate the condition (Travell, 1976; Slocumb, 1984). Medications such as tricyclic antidepressants and anticonvulsants or physical therapy may also be useful.

CENTRAL (BRAIN) FACTORS IN CHRONIC PELVIC PAIN

Descending pain modulating mechanisms, including those originating in the brain or spinal cord, probably involve various chemicals such as classical neurotransmitter, endogenous endorphin and nonendorphin analgesic systems, and excitatory amino acids. Anxiety, depression, and other psychological states may be facilitators or inhibitors of neurological transmission. Wall (1988) has suggested that it is "necessary to consider the lability of central transmission pathways as well as seeking peripheral pathology in all painful conditions." From a psychological perspective, there are various factors that may promote the chronicity of pain. Described as a "diathesis-stress" model of pain, a woman is more susceptible in certain social contexts to develop chronic pain based on her preexisting vulnerabilities including those related to cognitive, affective, biological, and behavioral functioning (Jacobs, 1997).

Studies on women with chronic pelvic pain have documented a high level of psychological disturbance. The Minnesota Multiphasic Personality Inventory (MMPI) conversion "V" profile (elevated scores on the hypochondriasis, hysteria, and depression scales) was described by Castelnuova-Tedesco and Krout (1970) in a survey of 40 women with pelvic pain. Gross, Doerr, Caldirole, Guzinski, and Ripley (1980) reported high levels of psychopathology in women with pelvic pain, as well as a past exposure to childhood sexual abuse in 90% of their sample. Studies using the MMPI have failed to find a correspondence between psychological and physiological findings. Renaer, Vertommen, Nijs, Wagemans, and Van Hemelrijk (1979) compared MMPI profiles of women having chronic pain without obvious pathology with those of women having pain arising from endometriosis and a control group. They found the two pain groups differed from controls but not from each other. Interestingly, treatment resulting in subjective improvement in pain severity and increased activity level produces a significant improvement in personality profile (Duleba, Jubnyik, Greenfield, & Olive, 1998).

Other studies have focused on the specific diagnosis of depression and pain (Magni, Salmi, deLeo, & Ceola, 1984; Walker, Katon, & Harrop-Griffiths, 1988). Magni, (1984) examined the role of depression and found higher depression scores for women with chronic pelvic pain without pathology compared with women found to have chronic pelvic pain and pathology as established by laparoscopy. They also found a higher likelihood of depressive disorders in the family histories of women whose pain could not be attributed to organic pathology. A comparison of women with pelvic pain of unknown etiology and a pain-free control group revealed the pain group to have a significantly higher prevalence of episodes of major depression. In 12 of the 16 women with a past history of depression, the depression preceded the onset of the pain (Magni, et al., 1984; Walker, et al., 1988). It has been suggested that pain may reflect a masked depression, in view of the common neurotransmitter pathways mediating both pain and mood.

Studies have also examined the role of sexual abuse as a specific risk factor for chronic pelvic pain. Gross and associates (1980) reported a high prevalence (90%) of sexual abuse in their sample. A sample of 25 women with chronic pelvic pain of mixed etiology showed no differences in psychological functioning when divided according to presence or absence of organic findings (Harrop-Griffiths, et al., 1988). However, when compared with a control group of gynecologic patients without pain, there was a higher prevalence of prior substance abuse, functional dyspareunia, inhibited sexual desire, higher scores on the SCL-90, and greater prevalence of sexual abuse both as youths prior to age 14 and as adults. The authors identified a history of sexual abuse as a child, along with a past history of depression, as strongly related to the subsequent persistence of pelvic pain.

The association between prior abuse and pelvic pain was studied by Rapkin, Kames, & Darke (1990). The study was designed to assess whether prior abuse is more likely in pelvic pain patients than in women with chronic pain in other sites or a painful control group, and whether the abuse was specifically sexual or extended to physical abuse as well. The prevalence of childhood sexual abuse did not differ significantly between the three groups: 19% of pelvic pain, 16% of other pain patients, and 12% of controls. There was a significant difference in the prevalence of physical abuse: highest for the pelvic pain patients (39%), compared with 18 and 9% in the other two groups. This study suggested abuse of any kind is linked to chronic pain. Walling and colleagues (1994) compared women having chronic pelvic pain with women having nonpelvic chronic pain (headache) and pain-free women, finding that women suffering pelvic pain reported a higher lifetime prevalence of major sexual abuse (56%) and physical abuse (50%). By drawing on the learned helplessness model for depression, abuse may predispose to chronicity of pain because it increases the vulnerability to depression and helplessness in the face of adversity (Abramson, Seligman, & Teasdale, 1978). Toomey et al. reaffirmed the importance of obtaining sexual and physical abuse histories in chronic pelvic pain patients (Toomey, Hernandez, Gittelman, & Hulka, 1993).

Renaer (1980) has suggested the diagnosis "chronic pelvic pain without obvious pathology" refers to patients who lack somatic pathology. Often these patients have been considered to have psychogenic pain. As noted in the previous discussion, the majority of patients with chronic pain have abnormal psychogenic profiles, but those patients without pathology do not appear to be psychologically different from those with organic disease (Harrop-Griffiths, et al., 1988; Renaer, et al., 1979). Furthermore, the potential role of as yet unknown neurophysiological mechanisms on the brain and spinal cord in the maintenance of chronic pain cannot be ignored. Abdominal wall, lower back, and pelvic floor muscle trigger points; nerve entrapment in surgical scars; IBS; and IC represent the most common sources of nonreproductive system chronic pelvic pain (Reiter 1990a), all of which probably entail alterations of central processing. Interestingly, these patients also have a high incidence of concurrent psychopathology (somatoform pain disorder), somatization, or depression (Reiter 1990a; Wood, Weisner, & Reiter, 1990). It may be reasonable, therefore, to suggest that chronic pelvic pain without, or even with, pathology is likely to involve all levels of the neuraxis and to direct management approaches accordingly.

DIAGNOSIS AND MANAGEMENT OF CHRONIC PELVIC PAIN

Successful diagnosis and management of patients with chronic pelvic pain requires a meticulous yet compassionate, multidisciplinary approach. As with the investigation of any other physical symptom, a thorough history should be obtained, and often must be acquired in stages. The nature of the pain, location and radiation, aggravating and alleviating factors, timing, effect of menses, exercise, work, stress, intercourse, and orgasm should be queried. The context in which the pain arose should be ascertained. Did the pain begin postpartum, postabortal, or postrape? Have there been previous episodes of pain or inability to perform one's occupation. Is there pending litigation or worker's compensation? Other somatic symptoms should be noted: genital tract (abnormal vaginal bleeding, discharge, mittelschmerz, dysmenorrhea, dyspareunia, infertility); enterocoelic tract (constipation, diarrhea, flatulence, tenesmus, blood, changes in color or caliber of stool); musculoskeletal system (predominant low back distribution, radiation down posterior thigh, association with injury, fatigue, postural changes); and urologic tract (dysuria, urgency, frequency, suprapelvic pain). Historical questions specific to all the peripheral pathologies noted in Table 22.1, should be queried. Past history including medical, surgical, gynecologic, obstetric, medication intake, and prior evaluations for the pain should be documented. Operative and pathology reports are important if the patient has had surgery.

Current and past psychological history — including psychosocial factors; history of past (or current) physical, sexual, and/or emotional abuse; history of hospitalization; suicide attempts; and chemical dependency — should be asked. The attitude of the patient and her family toward the pain, resultant behavior of the patient or family with respect to the pain, and current upheavals in the patient's life should be discussed. The part of the history addressing sensitive issues may have to be reobtained after establishing rapport with the patient.

Symptoms of an acute process such as fever, anorexia, nausea, emesis, significant diarrhea or constipation, abdominal distension, uterine bleeding, pregnancy, or recent abortion should alert one as to the possibility of an acute condition requiring immediate medical or surgical intervention. This is especially called for if accompanied by orthostasis, peritoneal signs, pelvic or abdominal mass, abnormal CBC, positive genital or urinary tract cultures, or positive pregnancy test.

One should perform a complete physical examination, with particular attention to the abdominal, back vaginal, bimanual, and rectovaginal examination. The exam should include evaluation of the abdomen with muscles tensed (head raised off the table or with straight leg raising) to differentiate abdominal wall and visceral sources of pain. Abdominal wall pain is augmented and visceral pain is diminished with the preceding maneuvers. The patient should be examined while standing for hernias, abdominal (inguinal and femoral) and pelvic (cystocele, enterocele). An attempt should be made to locate by fingertip palpation of the tissues (abdominal, pelvic, external genital, and lower back) that reproduce the patient's pain. The patient should be evaluated by, or in concert with, a gynecologist.

Laboratory studies to obtain the first visit include CBC, ESR, urine analysis and culture, cervical and urethral cultures (gonorrhea and chlamydia), wet mount of vaginal secretions, pap smear, stool guaiac, and — if diarrhea is present — stool culture. If the pelvic or abdominal exam is confusing or suggestive of a mass, ultrasound evaluation is indicated. If symptoms and signs are suggestive of other system involvement, barioptic or other appropriate imaging studies of other organ systems should be considered (e.g., upper and lower intestinal barium studies or computerized axial tomography [CAT] scan, intravenous pyelogram, and MRI of the spine).

The patient should be given a daily pain diary in which to note the onset and intensity of pain. Medication intake and aggravating and alleviating factors should be noted in the diary. A simple diary utilizes a visual analog scale from 1 (no pain) to 10 (most severe pain ever). The diary should be maintained for at least 2 months. Previous medical records, surgical and pathological reports or scans, should be requested at the time of, or prior to, this first visit. The second visit should be scheduled for approximately 2 weeks later.

During the second visit, one should again pursue the psychosocial and sexual history. The pain diary, laboratory results, and previous records should be reviewed with the patient. Subacute conditions should be treated (e.g., cervicitis, salpingo-oophoritis, urethritis, cystitis); and the abdominal, back, and pelvic exam should be repeated with thorough evaluation for abdominal, lumbosacral, and vaginal trigger points if not performed on the first exam. A description of the evaluation and treatment of trigger points is provided by Slocumb (1984).

At the time of the second visit the patient should be evaluated by a psychologist familiar with the evaluation and management of chronic pain. The psychologist should preferably be located within the same office or clinic suite.

Psychological referral accomplishes both evaluation, as well as opens the possibility for introducing cognitive behavioral pain management. The assessment should be designed to evaluate the pain complaint, its impact on life circumstances, and the controlling factors and coping mechanisms. Assessment in a chronic context involves a broader range of measures, reflecting social and psychological influences and sequelae, than may apply in the acute setting.

Assessment must evaluate the impact of the pain on the woman's lifestyle. Pelvic pain is likely to affect sex-

ual functioning, which may have additional repercussions in terms of the quality of the patient relationship and self-esteem. As with mood, a careful history is needed to establish whether the sexual problems existed before the pain or developed subsequently. Previous sexual abuse or trauma should be evaluated, as well as the impact of the pain on day to day functioning. Standardized psychological testing is helpful to determine if affective disturbance is present, as well as to establish a baseline against which to measure treatment response and guide treatment approaches.

If somatic pathology is suspected or confirmed, workup and management should proceed as per treatment of the somatic condition (see Table 22.1). Consultation with a urologist, gastroenterologist, orthopedist, or neurologist should be requested if indicated.

The third visit should be scheduled for 1 or 2 weeks later. This visit should include another review of the pain diary. Patients with cyclic or atypical cyclic pain should be evaluated for primary or secondary dysmenorrhea.

Evaluation of pelvic pain, especially cyclic pain, may require a diagnostic laparoscopy. Pelvic ultrasound or transuterine venography may be indicated if pelvic congestion is suspected, but treatment can proceed on the basis of clinical suspicion. If trigger points were injected and pain has persisted, injection should be repeated weekly or biweekly up to five injections. In addition, consideration should be given to a physical therapy consultation, especially if activity increases the pain or if low back pain is prominent.

A follow-up appointment (fourth visit) should be scheduled for 1 or 2 weeks later. Before the third and fourth visits, the "pain manager," the gynecologist (if not the pain manager), and psychologist should consult.

If pain persists, the patient should initiate cognitive behavioral pain management and various centrally acting pharmaceutical agents should be tried. Tricyclic antidepressants and anticonvulsants have been used successfully in pelvic pain patients. To date, only one randomized controlled trial assessed the effect of selective serotonin reuptake inhibitors on pelvic pain, and the short 14-week trial of 23 women failed to show significant difference in measures of pain and functional disability (Engel, Walker, Engle, Bullis, & Armstrong, 1998). The patient should continue to have scheduled visits with the gynecologist on a regular basis.

MANAGEMENT OF CHRONIC PELVIC PAIN: SURGICAL

Diagnostic Laparoscopy

Diagnostic laparoscopy has become a standard procedure in the evaluation of patients with chronic pelvic pain. Between 14 and 77% of patients have no obvious pathology and two thirds of patients have findings of adhesions that may or not play a role in their pain. Furthermore, nonsurgical management of chronic pelvic pain (multidisciplinary pain clinics or trigger point injections) is successful in 65 to 90% of patients regardless of presence of minimal pathology (Rapkin & Kames, 1987; Reiter, Gambone, & Johnson, 1991; Slocumb, 1984). Laparoscopy should probably be reserved for patients in whom other pathology has been ruled out; and for those with signs and/or symptoms of endometriosis, cyclic pelvic pain, or infertility. Some retrospective and prospective evidence suggests that laparoscopy provides pelvic pain patients a positive psychological impact (Elcombe, Gath, & Day, 1997); however, it is costly and not without surgical and anesthetic risks.

Lysis of Adhesions

The role of pelvic adhesions in the genesis of pain is unclear. Lysis of adhesions at laparotomy is frequently undermined by a high incidence of adhesion reformation (Holtz, 1984). Laparoscopic lysis of adhesions may be less likely to result in significant reformation of adhesions; however, 20 to 90% of adhesions reform or form de nouveau after an adhesiolysis procedure. It is not unreasonable, therefore, to lyse adhesions at the time of diagnostic laparoscopy, but controlled studies have yet to be definitive.

Hysterectomy

Hysterectomy has long been performed to cure pelvic pain. In fact, up to 19% of hysterectomies are performed for the sole indication of chronic pelvic pain (Reiter, 1990a). However, 30% of patients presenting to pelvic pain clinics have already undergone hysterectomy without experiencing relief of pain (Chamberlain & La Ferla, 1987). Reiter and associates (1991) noted a decline in the incidence of hysterectomy for the indication of chronic pelvic pain from 16.3 to 5.8% after the initiation of a multidisciplinary approach to the diagnosis and treatment of chronic pelvic pain. A prospective cohort study, the Maine Womens Health Study, revealed 18% of women had a hysterectomy for chronic pelvic pain with significant improvement in pain and associated symptoms. Their underlying diagnoses, however, were not described (Carlson, Miller, & Fowler, 1994). Hillis, Marchbanks, and Peterson (1995) studied a prospective cohort of 308 women who underwent hysterectomy for chronic pelvic pain, thought to be of uterine origin. The outcome revealed a 74% response rate, with observed persistent pain associated with multiparity, prior history of pelvic inflammatory disease (PID), lack of pathology, and Medicaid payer status (Hillis, et al., 1995). Hysterectomy remains an option for appropriately selected

patients with pain of uterine origin. In recognition of the fact that hysterectomy treats at best only some women, the American College of Obstetricians and Gynecologists (1998) established criteria to be met prior to performing such invasive surgery for pelvic pain. The criteria include that no remediable pathology is found on laparoscopic examination and that a 6-month presence of pain occurs with negative effect on the patient's quality of life.

Presacral Neurectomy

Presacral neurectomy or sympathectomy (PSN) was first described by Cotte (1937) for the indication of dysmenorrhea. As is apparent from the discussion of the neuroanatomy of the pelvic organs, the presacral nerve, which is actually the superior hypogastric plexus, receives the major afferent supply from the cervix, uterus, and proximal fallopian tubes. Afferents traveling with the sympathetic nerve supply from the bladder and rectum also pass through the superior hypogastric plexus. Normal micturition and defecation are dependent on an intact sacral autonomic nerve supply and are relatively unaffected by resection of the superior hypogastric plexus. The nerve supply to the adnexal structures bypasses the hypogastric plexus, as the afferents from the ovary travel with sympathetic fibers accompanying the ovarian artery to the superior mesenteric plexus to enter the spinal cord at T9 and T10. These autonomic relationships constitute the rationale for Cotte's (1937) emphasis on differentiating dysmenorrhea with the maximum intensity of the pain localized to the uterus with radiation to the sacrum from lateralizing pain radiating to the lumbar region.

PSN has been studied in the management of central pelvic pain in the setting of both cyclic and noncyclic pain (Ingersoll & Meigs, 1948; Lee, Stone, Magelssen, Belts, & Benson, 1986; Polan & DeCherney, 1980). Though most studies of PSN are uncontrolled, Polan and DeCherney's (1980) study did include a control group of patients who had infertility surgery without PSN. In the latter group, only 26% experienced relief of pain as compared with 75% of patients who also underwent PSN. In another randomized controlled study by Tjaden, Schlaff, Kimball, and Rock (1992), the study was prematurely terminated due to the overwhelming response to PSN compared with resection of moderate to severe endometriosis (Tjaden, et al., 1992). However, when Candiani, Fedele, Vercellini, Bianchi, and DiNola (1992) studied PSN vs. resection of moderate or severe endometriosis, initial central pain was reduced though 6-month follow-up revealed no significant difference in pain. The value of PSN remains controversial.

MULTIDISCIPLINARY PAIN MANAGEMENT

Multidisciplinary Pain Management

Multidisciplinary pain management is an excellent approach to chronic pelvic pain. Peripheral factors are managed by the pain manager. Spinal cord and central factors related to possible abnormalities of modulation of pain impulses are addressed with trigger point injections, centrally acting medications, acupuncture, or TENS (Helms, 1987; Mannheimer & Whaler, 1985; Rapkin & Kames, 1987; Slocumb, 1984). Cognitive behavioral and other psychological factors are addressed by the psychologist.

One program was successful in reducing pain by at least 50% in 85% of the subjects (Rapkin & Kames, 1987). Other studies have suggested that similar results may be obtained with a multidisciplinary team (Milburn, Reiter, & Rhomberg, 1993; Pearce, Knight, & Beard, 1982; Peters, et al., 1991; Reiter, et al., 1991; Wood, et al., 1990). In a prospective randomized study, the multidisciplinary approach was found to be more effective than traditional gynecologic (medical and surgical) management (Peters, et al., 1991).

Section IV

Specialty Approaches to Pain Management through Team Management

23

Pain Medicine and the Primary Care Physician

Uday S. Uthaman, M.D., F.A.C.F.P. and Pierre L. LeRoy, M.D., F.A.C.S.

> Pain is a more terrible lord of mankind than even death itself.
>
> Albert Schweitzer

This chapter is dedicated to John J. Bonica, M.D., for his outstanding contributions to pain medicine and humanity.

INTRODUCTION

The dynamics of the present health care system has forced many patients to seek managed care. This has not provided the anticipated results or satisfied the expectations of many to offer individualized care. The current system is largely a pharmacological system-based treatment program that does not address etiology or causation.

New State of the Art

Due to five new considerations, these and other shortcomings can be remedied:

1. New advances in the field of clinical pain medicine
2. Recent advances in diagnoses
3. New and diversified treatment programs
4. Progress in laboratory studies
5. Availability of focused integrated studies

Individually and collectively, these provide a new frontier and opportunity for primary care physicians (PCPs) to diversify their clinical practice and acquire advanced certifications and degrees.

Mission Statement for Clinicians

We offer the following ten considerations:

1. Reduce human pain and suffering
2. Individualize patient care
3. Reduce economic and psychosocial losses
4. Concurrently treat co-morbidity and social productivity
5. Reduce loss of workforce skills
6. Reduce healthcare expenditures
7. Reduce occurrence of preventable disease and injury
8. Pursue educational resources
9. Communicate with the patient with empathy
10. Never give up hope for the patient

How can these goals be accomplished?

The professional, annual continuing education of physicians is now mandated by licensing Medical Boards, but the focus on personal selection of pain medicine is elective. Some state Medical Boards are already identifying pain medicine as a subspecialty.

The Role of Specialty Associations

Some specialty scientific societies have long recognized the need for additional specialties in the field of pain medicine. For example, the American Association of Neurological Surgeons (AANS) has organized several divisions, of which there is a section on pain management that concentrates on both the medical and surgical treatment of pain. Anesthesiology, orthopedic, and other

0-8493-0926-3/02/$0.00+$1.50

societies have also followed this trend, offering educational course material, conferences, seminars, certification, and accreditation. The world medical community, led by Dr. John J. Bonica, in the 1970s recognized the need for further research and professional interaction and founded the International Association for the Study of Pain (IASP). Dr. Bonica and several others realized at the first IASP meeting in 1975 in Florence, Italy, that there was no American Pain Society. Thus, it was quickly organized and became known as the APS. Others followed, but remained exclusive in their membership, focus, and formulated regional sections. Realizing that these organizations were primarily for specialties, the American Association of Pain Management (AAPM) was organized to be more inclusive, recognizing the need to bring together all health professionals that expressed interest in the complex field of pain medicine, a multidisciplinary approach that brings diversification, interaction, expanding education, and credentialing to the field of pain medicine.

The purpose of this chapter is to bring together a syllabus for the PCP and other interested health professionals, providing a clinical overview of the field and referring to other specific chapters for additional information.

THE DEFINITIONS OF PAIN

This subject has been a Herculean task and was assigned to Professor Mersky, on whose committee the co-author (Pierre LeRoy) was privileged to be a member. For 5 years, the Taxonomy Committee of the IASP struggled for a definition that would satisfy the somatic and psychologic criteria and be translatable into other languages to clarify the existing Babylonian confusion.

Mersky

> Pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.

Since then, other concepts have emerged.

Mount Castle

> Sensory experience evoked by stimuli that injure or threaten to destroy tissue, defined introspectively by every man as that which hurts.

Arnoff

> Operational definition of pain is that of a complex, personal, subjective and unpleasant experience which may or may not have any correlation with bodily injury or tissue damage.

Later, other definitions evolved to show the definitive progress that has been provided by the basic scientist and technology in neuroanatomy and physiology, which act as the foundation for the improved clinical management of pain medicine.

The fundamental nociceptive stimuli for pain can provoke irritation, which is reversible, or can produce tissue damage that is not reversible and accounts for chronic spontaneous pain perception, which eventually may be interpreted by the limbic-forebrain system as "it hurts"; and becomes associated with psychological discontent and depression. If the inflammatory response, the reaction of tissue to an irritation continues, is associated with the classic, long-known, four characteristics of Dolore, Calor, Temor, and Rubor (or pain, heat, swelling, and redness). These are discussed later in this chapter and in more detail by Richard S. Materson, M.D., in Techniques for Assessing and Diagnosing Pain

THE INCIDENCE OF PAIN

Actual, accurate data is not yet available but many estimates have been made that recognize an enormous human and economic burden in society. It is felt by many colleagues that the incidence of pain is underreported. Data banks have now been established to correct this. An estimate by The Information Specialists of Tampa, Florida, is that "pain costs the U.S. economy about 100 billion dollars a year, including 515 million workdays lost and about 410 million office visits to doctors." It is estimated that one in every five adult Americans experiences chronic pain and seeks relief from a doctor.

These staggering estimates are addressed in more detail in Pain and Its Magnitude, by Barry Fox, Ph.D.

THE CLASSIFICATION OF PAIN

Many classification systems have been proposed, but the acute, chronic, cancer, and psychogenic pain divisions appear practical for clinicians.

- Acute: From onset in time of perception, it may be variable, lasting from seconds to months.
- Chronic: A consensus is developing that after 6 months, it is considered to be chronic and frequently associated with varied emotional responses.
- Cancer: Initially, many malignancies have no symptoms and are silent. Pain perception due to tumefaction, vascular, cytochemical, and pathophysiological changes may develop insidiously

with symptoms of cancer. Special pain management is needed for this patient population.
- Psychogenic pain syndromes: These can be diagnosed when the patient complains of pain, but no physical assessment or laboratory test can corroborate the complaint. It can be considered a symptomatic response, however, that can be managed.

No classification is yet considered complete but Drs. Thienhaus and Cole address this in detail in this text.

PATHOPHYSIOLOGY FOR THE CLINICIAN

> He who understands pain, knows medicine.
>
> Sir William Osler

Basic anatomical and physiological considerations can be simplified. We will review current concepts of incoming pain signals. They are referred to as afferents or arrival sensations. We can identify four fundamental divisions that can be classified as sensory receptors, peripheral nerve networks, spinal modulation, and central brain discrimination and affective correlates.

Receptors for Pain

Receptors for pain are thought to be free nerve endings, but Meissner's corpuscles and bulbs of Krause, for example, have thresholds for pressure and cold temperature changes, as do many other receptor organelles. Such receptors can act like a symphony orchestra and transmit specific sensory information, but can also relay to pain networks when the stimulus becomes nociceptive. In the normal resting state, receptors are on "call," but do not "talk" unless certain thresholds are reached. This is true for neuropathic, myofascial, vascular, scleral, and visceral pain.

Peripheral Sensory Nerves

Some peripheral sensory nerves are named but the vast majority remain unnamed. These networks are more complex than previously realized because they are not only composed of somatic and autonomic afferents, but also efferent outgoing motor neurons transmitting electrochemical action potentials that regulate many forms of interactive ionic channel electrolytes such as calcium, sodium, and potassium — thus conducting a propagation action potential wave of millivolt energy similar to a small battery, but which eventually must be recharged. In addition, we now know that the ganglion cells produce neuropeptides, such as catecholamines, bradykinin, histamine, cytokines, and many other modulating substances that influence the nerve impulse. These can also be sensitized in injury area cross-talk, interact with other nerves, and produce hyperalgesia. This also explains how a light-touch stimulus can exacerbate a previously injured area that has not healed, and explains why an acute pain can become chronic and produce regional allodynia. In addition, the autonomic nervous system can produce a transmitted substance under nociceptive stimulation. This helps to explain the sensitization to allodynia in patients with reflex sympathetic dystrophy (now being called Complex Regional Pain Syndrome), in which patients avoid touch or clothing contacts that produce dysesthesias or disagreeable painful sensations.

The Spinal Level

At the spinal level, further modulation takes place prior to sending the messages proximally as well as distally. Incoming afferent peripheral nerve impulses moving at speeds recorded in milliseconds, from low or high thresholds, neurons such as A-beta, A-delta, and C-fibers, or from sensitized receptors separating the dorsal horn of the spinal cord into zones called Rexed layers. The outermost layer is called Lissauer's tract or Substantia Gelatinosa. Here, unmyelinated C- and A-delta high-threshold nerve fibers transmit specific sensations that have burning, touch, and pressure characteristics. Other A-beta fibers go deeper into the Rexed layer five and transmit non-nociceptive sensations. These fibers integrate with marginal neurons and cross-talk when nociception occurs so that a network discriminates localizing intensity and transmits centrally, temporal-based impulses through the cord proportionate to the input stimulus. These clinical characteristics of the sensory pain signal can be identified by the patient and communicated to the physician. These deeper second-order neurons are called wide dynamic neurons (WDN). These also ascend and descend, forming the main pain tract known as the spinothalamic tract — the main pain pathway to the brain for further modulation.

The Brain

The spinothalamic tract ends superiorly in the basal thalamus. This main tract carries pain and temperature sensory signals and also has a homunculus, layered localization within the thalamus itself. Non-nociceptive A-beta fibers may now trigger pain perception and help explain central sensitization. It is this tract — the main pain highway — that neurosurgeons interrupt by carefully cutting or heating with controlled radio-frequency lesions in order to relieve intractable pain. Over the years, neurosurgeons and other scientists realized that pain symptoms temporarily improved symptoms but the pain sensation returned. It was then realized that other pathways and tracts must be carrying pain sensations to perceptions not previously

realized. Basic scientific research then demonstrated that other tracts, such as in the posterior section of the spinal cord, the medial and lateral tracts ending in gracilis and cuneate nucleus, not only transmit light touch, vibrations, and proprioception, but also pain. Moreover, they too cross in the sensory decussation in the brain stem. In addition, the reticular formation and spinal–spinal tracts also transmit pain sensation. Other homologous tracts transmit facial head and neck pains through the extremely complex trigeminal network.

Thereafter the thalamic afferents relay to the primary somatosensory and secondary cortical centers organized in a homunculus for localization and lateralization. An example is provided in identifying the left great toe's medial aspect as a source of pain. This tract integrates with the limbic lobe to generate the discriminatory and affective emotions components of the pain, from which the objective anatomic and physiologic basis for nociception pain and suffering is expressed as "I hurt."

In summary, we have reviewed and elucidated the basis for anatomic, discriminatory, and affective psychologic responses associated with the the nociceptive, peripheral, central, and psychological components for your consideration. The types of pain, intensity, duration, and localization due to a focal injury or disease process can have a spreading component by convergence, facilitation, inhibition, cross-talk, or sensitization responding to an inflammatory process. For example, when one has sunburn and steps into a warm shower, the pain response is exaggerated and is called hyperalgesia. These responses are compensated in addition by complex ionic and molecular neurochemical systems providing a self-adjusting, discriminatory-affective defense system. Sometimes, depending on the type of mechanical, thermal, or chemical stimulus, the intensity can not be modulated sufficiently; and when self-care fails, the patient seeks medical attention.

The pathophysiology of chronic pain perception can also shift from a relatively high threshold stimulus needed to produce pain sensation to a low mechanical, chemical, or temperature threshold stimulus of any kind to cause increased pain to be felt and lays the foundation for the sensitization and explanation of pain after injury when the stimulus has left; this has been referred to as spontaneous pain. The reader is referred to other chapters for additional information. As technology advances and clinical informational data banks develop, the progress will continue to close our gap of ignorance so that improvements in the diagnosis and treatment of pain syndromes can be achieved. This basic science provides the foundation of home care, pharmacology, physical therapy, modality, treatment, and improved rehabilitation.

DIAGNOSIS OF PAIN

The diagnosis of pain can vary from simple to complex, but is based on a thorough history, physical and basic neurologic examinations, correlation of appropriate laboratory tests, specialty consultations when needed, and the outcomes of medical, surgical, and alternative treatment programs.

In more complex pain syndromes, especially those associated with co-morbidity, the diagnosis cannot be made immediately but may require serial follow-up consultations and this should be communicated to the patient and documented in well-kept medical records. It should also be remembered that no medical information should be sent to requesting agencies without the patient's express written permission.

TREATMENT OF ACUTE, CHRONIC, AND CANCER PAIN

For successful pain management, individualization by diagnosis, personality traits, intellect, age, and outcome of prior treatments must all be seriously considered.

Based on prior educational/training experience, the PCP is in an excellent position to not only know the patient, but also the patient's family and supporting friends and groups, all of which have assistive value.

Administrative managed care and third-party reimbursement programs, however, may place barriers on a model individualized treatment plan and alternatives must be sought, but documentation for the clinical changes must be kept due to the utilization and legal considerations addressed in other chapters.

Treatment programs have at least twelve areas to consider:

1. Self-care
2. Pharmacology
3. Physical modalities
4. Surgery
5. Alternative medicine
6. Psychological/psychiatric assessment
7. Physical medicine and rehabilitation
8. Management of co-morbidity
9. Specialty consultations
10. Occupational and vocational evaluations
11. Disability evaluation
12. Medical/legal considerations

Self-Care

In self-care, is important to involve the patient's cooperation, compliance, and motivational initiatives to get well.

Lacking these, the treating physician is hard-pressed to achieve a successful outcome.

Pharmacologic Treatment

Pharmacologic treatment is usually sought when self-care fails. Pain medicine has four pillars of treatment; however, when sensitivities, untoward reactions, or complications occur in each class of drugs prescribed for the patient, caution must be exercised.

Analgesics

Analgesics are employed for symptomatic pain relief. They include (1) non-narcotic, aspirin-type salicylate compounds; and (2) opioids. Opoids are controlled substances and require special handling, based on two principles: to benefit the patient and to be in compliance with regulatory agencies. Pharmacologic drug selection and dosage schedules must be individualized.

Anti-inflammatories

Anti-inflammatories have made significant advances in becoming more receptor specific therapy, moving from (COX) cyclooxygenases (with 14 subclasses) to the new (COXII) generation with reportedly less undesirable side effects, targeting gastrointestinal, renal, hepatic, and pulmonary organ systems. These individuals still require close monitoring because adverse effects can occur at any time in a treatment program to any patient.

Antispasmodics

Antispasmodics are prescribed when there is sufficient clinical/objective evidence of involuntary muscle spasm that itself causes pain and limitation of function. The three classes act: (1) peripherally at myoneural junctures; (2) at the spinal cord level, influencing afferent-efferent modulation; and (3) central inhibition at cortical and possibly subcortical levels.

Antidepressants

Antidepressants can play a major role in pain management because they are a class of medications that result in several synergistic effects: (1) antidepressant-serotonergic, (2) antispasmodic, and (3) analgesic. These three effects vary depending on the type of selective serotonin reuptake inhibitor (SSRI) prescribed.

These four classes of medicine can be prescribed singularly or in combination. Frequently, polypharmacy results and careful trials of various compounds must be made to produce an optimum treatment plan.

This is far from an exhaustive review, but serves as an outline for more detailed chapters in pharmacotherapeutic, psycho- and immunopharmacology.

Laboratory Testing for Pain Medicine

Laboratory testing for pain medicine includes hematopoietic, serologic, imaging, and electrodiagnostic tests. Frequently, functional tests that evaluate impairment and related ergonomics that cannot be evaluated by the above are necessary and reasonable to assist in determining medical impairment and serve as a foundation for legally determined disability ratings. Functional testing comes in two categories: (1) physical or somatic, and (2) emotional or psychological. It should be noted that the latter has gained increased credibility because federal mandates direct that disability be determined by physical or mental impairment, or both.

The reader is referred to various chapters that relate more specifically to these concerns. Recall that clinical judgment is necessary because, to paraphrase Albert Einstein, "All that is important cannot be measured and all that is measured is not necessarily important." The test for clinicians is that they be able to provide a basis for their ordered tests (i.e., that the tests be reasonable and necessary) because they may be challenged or adjudicated by the legal community.

Modalities

Modalities are gaining increased use in medical pain management because of the lack of complete efficacy of selected chemical compounds we call pharmaceuticals. We are in no way being critical of the pharmacologic approach to pain medicine, but there are limitations of dosage schedules, intolerance reactions, and lack of efficacy that must be recognized. Some patients are averse to take medicine. Modalities offer an alternative.

Two types of modalities are recognized:

1. Mechanical
2. Electrical

Both prescribed therapies require individualization and outcome documentation.

Mechanical or physical modalities include self-care, rubbing massage, pressure, ultrasound, stretching, traction, hydrotherapy, and heat and cold techniques. These can be self-administered, or provided by trained assistants and professionally experienced physical therapists, and also manual medicine techniques performed by osteopathic and chiropractic physicians. These offer a variety of options and combinations to assist in the healing process. All, in various ways, have the potential to accel-

erate the normalization of the pathophysiology of disease and injury processes.

Electrical modalities are gaining wider acceptance as our basic knowledge of physics as applied by medical researchers and bio-engineering has progressed. This progress then lends itself to the clinical practitioner.

Electrical energy used as a therapy has long been recognized as beneficial. As we move from a pharmacologic-allopathic and homeopathic system of care, we are using more electronically based therapies. Based on the classic research of Gibert, Faraday, Nordenstrom, Becker, Avery, Sheely, Kirsch, and so many others, many clinical applications are now available to the PCP.

Transcutaneous electrical nerve stimulation (TENS) has been available by prescription since the Medical Service Act passed in 1975. There are now probably 100 types of devices on the market, but great care should be exercised in selecting the most suitable model with special attention given to the electrode placement pattern, electrical settings of waveform, pulse width, and individual tolerance requirements before prescribing a unit. In over 40 years of experience, we recommend a trial of four to six treatments in the office setting with physician and clinical assistant supervision before prescribing home-use units that cost between $200 and $800. A rental trial is often desirable for home care to see if the patient understands how to use the device. When effective, we found that TENS provided a substantial savings (in oral medication) when individualized frequency and pulse settings and optimal electrode pad placement were employed. Care must be taken not to prescribe TENS during first and second trimesters of pregnancy, or with cardiac pacemaker patients. Never place the electrode adhesive pad over the cervical region of the carotid sinus, due to the possibilities of affecting the cardiac rhythms.

Electromedicine has made other significant clinical advances in providing relief of physical pain by, probably, closing the spinal gate that hinders the perception of pain by stimulation of the A-beta fibers but also causing a mild vasodilation (not yet reported in the literature). This Alpha-Stim type of stimulation is different from TENS in that it provides a somatic as well as an emotional modulation pattern mediated by the serotonergic system.

Microcurrent electrical therapy (MET) reported by Kirsch and Mercola, is based on bio-electric data and provides, for the first time, a combination therapy for the modulating the perception of somatic pain and its emotional affective symptoms. It has been approved by the FDA.

Using probes or clip electrodes applied to the ear lobes, selected patients can use the alpha-stim device for office or home care applications. Not all patients benefit from these modalities, but they do offer a variety of options for patients who do not, will not, or cannot take medication.

The reader is referred to chapters that address these subjects in more detail, permitting the PCP to enter a new field of electromedicine therapy that we call medical energetics.

Physical Medicine and Rehabilitation

Physical medicine and rehabilitation are recommended for therapies of acute, chronic, and cancer pain because they provide more than modality treatment. For the PCP, it supplements the therapy program in the patient who continues to have symptoms and impairments of daily activities involving personal and work tasks. It provides a second opinion for the PCP, and it enhances the patient's probability of improving while documenting progress or lack thereof. We refer the reader to the appropriate chapters on ergonomics by Dr. Sella and others.

The psychological and psychiatric assessment and management of the pain patient presents a special field for consideration. Because the discriminatory-affective component is complex and is superimposed on a preexisting emotional character profile, diagnosis of personality characteristics can be identified as pre- and post-disease and/or injury. Attitude and behavioral components can be evaluated and managed in conjunction with the PCP's treatment of pain syndromes and co-morbidity. Special consideration is made for energizing stress, anxiety, and depression. Reflective care can be offered for lack of complaint; lifestyle and drug abuse without symptom magnification must be evaluated very carefully, with further consideration of secondary gain but also secondary losses. Munchausen's syndrome and psychogenic pain patients should be seen in conjunction with specialists in the field. The reader is referred to appropriate chapters in this text for further reference.

Occupational and Vocational Rehabilitation

Occupational and vocational rehabilitation are important aspects of pain management for the PCP because they can be made part of the necessary therapy, especially for those with chronic and cancer pain symptoms. Resource services are available from both private and state-supported programs, the latter of which have no service fees. This allows the PCP to be captain of a multidisciplinary team to coordinate diagnosis, treatment, and rehabilitation plans and to assist the patient in returning to an economically productive lifestyle. Insurance programs frequently do not pay for job retraining but are ready to support job modification services in returning the patient to work, thereby reducing their monetary outlay.

The reader is referred to other chapters that address the challenges and barriers faced by patients returning to the workplace.

Medical/Legal Aspects of Pain Medicine

The medical and legal aspects of pain medicine present a different sort of challenge because they are based on the adversarial approach to medical management, in which the PCP is frequently not as experienced as the clinical medicine physician. Simply stated, the PCP is in a position to provide both factual and expert witness reports, and, when needed, testimony as the treating physician who has consulted with the patient many times. PCPs are able to provide credible history, physical examination, treatment, pertinent laboratory findings, outcome, and diagnosis. They can also provide estimates for future medical care, prognosis, and disability determination by documentation or oral testimony. These are all subject to challenge by opposing counsel as well as the medical testimony of physicians retained by opposing counsel. These retained physicians often render reports that tend to minimize findings, testifying about the co-morbidity, preexisting disease or injuries, or a contributing cause of the plaintiff (patient's medical and psychological problems) from a retrospective point of view.

The treating PCP, however, can provide evidence-based opinion and testimony that the diagnosis, treatment, and related services being addressed are, in fact, reasonable and necessary. The treating physician should also charge for the medical/legal services performed, based on a usual and customary fee schedule that can be made available to requesting agencies prior to rendering these administrative services. Because the rules of testimony and evidence change and vary from state to state, the reader is referred to the medical/legal chapters of this text to update further information.

DISABILITY DETERMINATION

Disability determination is a legal concept and has become the purview of the legal community and state and federal agencies. The PCP, however, is in an eminent position to determine functional impairment. How is this determined? By clinical experience, medical literature, and consultation, an impairment rating can be determined quantitatively based on mild, moderate, and severe impairment classifications. When mild, the patient can perform home, self-care, return to usual occupational work and need not have professional treatment or see a physician, except on occasion. In the moderate category, the patient has impairment that interferes with activities of daily living (ADLs) and must modify these; professional treatments are needed and physician care is important. Return to work must be modified. In severe impairment, the patient has continued symptoms and needs continued treatment and ongoing professional medical care. He or she is not able to return to work and is considered totally and permanently disabled as determined by Social Security Disability Entitlement Programs. Periodic reevaluation visits are performed to verify the continuing disability. The reader is referred to the chapters on disability in this text for more information.

In conclusion, we are of the opinion that:

1. PCPs are in an eminent position to become specialists in pain medicine.
2. Educational resources are available for in-office, local, regional, and national services offering continuing education credits, certification, and advanced degrees.
3. The PCP can become coordinator and captain of the ship in pain medicine, providing an individualized, humanized treatment program for the patient.
4. Specialty consultations are available to offer second opinions in complex pain syndromes available locally or at academic university centers.
5. The PCPs can concurrently manage co-morbidity while practicing pain medicine.
6. The PCP's office staff can be trained in special techniques for in-office care at substantial cost savings.
7. The PCP can provide a supportive and counseling role in the areas of pain medicine in conjunction with psychological and psychiatric consultations.
8. The PCP can refer the patient with special behavior, abuse, compliance or lifestyle impairments to specific evaluation and treatment programs and to share the care of difficult patients.
9. The PCP can provide medical testimony that is evidence-based and provide impairment ratings for further disability determination.

To paraphrase Hypocrites: The future is bright, but fraught with difficulty. We will be trained beyond our intelligences, so the real test for physician is at the bedside. The ball is in your court. Primary care physicians should consider the following value concepts in medical decision making.

1. Clinical: Accumulate as much relevant medical information as possible, employing acceptable services to benefit the patient. Less than that is not acceptable.
2. Educational: Every patient encounter provides an accumulation of data contributing to clinical experience, but can also be shared with others through anecdotal or published peer review literature.
3. Research: Evaluation of unconventional approaches to unusual problems adds to the total fund of knowledge and should be shared.

4. Administrative: Simplify documentation; it has created a burdensome task for clinicians and staff as well as significantly escalating the cost of medical care. How can this be accomplished? The PCPs' help is needed.
5. Fiscal: Cost constraints instituted by third-party payors have inhibited medical programs. What other options are available?
6. Regulatory affairs: Agencies mandated by legislative actions to maintain and control health care delivery systems often go beyond the spirit of the legislation and are dismantling the best health care system in the world. Together, can PCPs make a difference by acting in an advisory capacity due to the significant advances that produce the gaps in agency updating?
7. Political: Correctness creates a trend toward mediocrity. Having served, can PCPs take a leadership position?
8. **Medical/legal:** Responsibilities have grown complex and costly, developing an adversarial system in which many health professionals and patients have lost confidence. It still is considered the best we have. How can PCPs help regain credibility?
9. Personal: Has this entire effort of dedicating one's life and career to the care of others been of value?

The Impact of Pain on Families

James H. Ballard, D.Min., C.R.T.

INTRODUCTION: THE IMPACT OF PAIN

From the moment actor Christopher Reeve suffered his accident riding horseback, not only was his life changed, but also the lives of his wife and family. Whether one's pain is the result of an accident or an illness of spirit, soul, or body, its impact is like a rock dropped into a pond … it has a ripple effect.

Phyllis was referred to me by a local physician. The victim of a serious automobile accident, she had spent months in physical recovery. In the later phases of her physical therapy, she experienced pain in her body that could not be traced to any physical cause. She had begun to have flashbacks to a very painful and abusive past. After sessions dealing with spiritual and psychological issues, I remarked that she had not mentioned the physical pain for which she had entered counseling. Her remark was, "It's gone!" Relief of pain in spirit and soul had brought about physical healing. These sessions took place several years ago and there has been no recurrence of her pain.

After years of counseling from a Christian perspective, I am finding many whom I counsel to be in physical or psychological pain. Very often, such pain comes from deep spiritual and psychological issues that have not been faced and resolved. Rejection, abuse, and abandonment often result — not only in spiritual or psychological crises, but physical ones as well.

The victim does not stand alone. Family structures are also vitally involved and affected. Treatment of pain not only impacts the victim but all those who are part of his or her world.

A number of years ago, my wife, two children, and I lived in South Brazil where we served as missionaries. While there, I came down with extreme pain in the abdomen. The attempt to diagnose its origin led to deep depression on my part. All of that resulted in an emergency medical furlough and 6 weeks of hospitalization. At the end of that time the doctor recommended that we not return to Brazil because of the possibility of the disease returning. Needless to say, my physical and psychological pain resulted in emotional and relational pain for my wife and our two preschool-aged children. The trauma of all that took place sent shock waves through our family at the time and for several years after our return to the U.S.

I agree with Carl McNeely (2000) when he states that patients, along with family members, may frequently have adjustment difficulties because of changes in roles and limitations of the functioning of the patient. Look with me at the impact of pain on families in the following areas.

PAIN IS INTERGENERATIONAL

Karl, in his mid-fifties, has had both heart catherization and bypass surgery. He is presently separated from his wife due to repeated martial infidelities on his part. The probability of reconciliation is very slim. His family of origin gives evidence of heart trouble for several generations. Emotional, relational, and physical dysfunction has carried over into his generation and it has become clear that, with each succeeding generation, the toxicity has increased. There have been boundary violations within the family of origin structure. Karl is not the first to commit adultery. He is carrying into his generation the lifestyle of earlier generations. Such behavior ensures that familial pain from the past is carried forward. Karl has two sons. It is Karl's perspective, however, that his separation and divorce from their mother will not affect his boys because

0-8493-0926-3/02/$0.00+$1.50

"they are adults." It is difficult to move beyond denial. Often, hurts go deeper in adult children of divorce than in those who experience that trauma in their earlier years. There is a probability that Karl's sons will continue his behavior for another generation or else emotionally separate themselves from their father's irresponsible actions.

I have spent more time counseling George and his fourth wife, Nora, than most of my other clients. There was deep-seated anger and personality conflicts between them. Nora has a very co-dependent personality. Her record of failed marriages closely resembles George's. They both brought a child into their marriage. These children witnessed the pain and anger that permeated their parents' relationship. Both of these children are now approaching their teenage years. I am very concerned that the past irresponsibility of their parents may wash over into their lives, thus carrying the toxicity of the past into the present and drastically affecting their futures.

After a number of sessions with George, there was a breakthrough. He admitted that much of his anger, which surfaced frequently, was the result of the sexual molestation and abuse he had experienced as a child.

Sexual molestation between the ages of birth and 18 years is affecting one out of four women and one out of five men. The trauma of these events, often many violations over a period years, has devastating effects on the victim and those around him or her. The pain of guilt and shame exacts a high price on the victim. Scars remain with them for years, whereas the perpetrator often does not remember actions toward the victim.

Traumas from past violations of one's personhood can have a devastating effect upon one's self-esteem. It can affect the victim's approach to personal intimacy. Evidence of the negative effect of such traumas can be seen in many victims of rape. Marriage bonds are strained and often broken because of this violation of one's person. Although violation of one's physical being may not be evident in many cases, it can be in other areas.

PAIN IS INTERRELATIONAL

When a family is healthy in its relationships, it allows appropriate boundaries and personal privacy. There is a clear distinction between adults and children. Children are allowed to be who they are … children. When there is dysfunction and enmeshment, children are often the major source of affirmation and affection for the adults. I frequently hear from clients that they were never allowed to have a positive, happy childhood. They had to continually replenish their parents' sense of well-being. The child in such a relationship often becomes a parent to the parent (or parents). When children grow up in such a toxic environment, they experience relational pain. The consequence of having to meet parental emotional needs can result in low self-esteem and burnout, or in a perfectionism that is self-destructive. These traits can develop in young children as well as in older ones. Unconditional love and care within families of origin are extremely vital for healthy relationships to form. Where conditional love or absence of any type of deep, parental caring is evident, there is pain within one's personhood.

Unmet parental needs often find children going into professions of parental choosing rather than those of their own choice. Dennis was such a person. His future was laid out for him by his doctor father who wanted his son to follow in his footsteps. Dennis went to medical school and through medical residency, much to the delight of a doting dad. After Dennis completed his residency and set up a medical practice, his father died. Freed from his father's shadow, Dennis left medicine to become a musician, something he had desired to do since childhood.

Warren was the son of a woman who had risen rapidly in governmental service. She was perfectionistic and controlling in her family. Warren's father left the marriage because of the mother's dominating personality. Warren, unable to escape the power of his mother took out his anger and rage on four different wives. As of this writing, he is allowing his mother to continue to "bail him out." He does not tell his mother where to go; rather, he chooses another woman to become a victim of his dysfunctional relationship with his mother. Warren's failed marriages have caused much pain, not only for his ex-wives, but also for their immediate families.

In the procession of pain within families, whether that pain is spiritual, psychological, or physical, there are other dimensions to consider.

THE TRAUMA OF THE TEMPORARY

Whether it is a broken bone because of an accident or a broken heart that is the result of a failed relationship within teen years, there is trauma that impacts the family structure.

Our knowledge and discernment tells us that this, too, shall pass. Yet, during the disconcerting days of its happening, schedules are interrupted and the focus of attention is shifted with the victim leaving other important tasks undone. Stress often becomes the order of day, particularly if it involves the victim's hospitalization. Life often seems to be filled with times of temporary paining. One knows there will come an end to the hurts, but the journey through the valleys of pain are real while the family member is in crisis. There is often a toll on the health of the family.

THE CRISIS OF THE CHRONIC

The processing of pain within families of Alzheimer's patients can be ongoing and often debilitating. The decline of mental and physical faculties of the patient are often years in duration. Alice was a strong independent woman who, with her husband Glenn, had a good life on a farm

in Piedmont, North Carolina. After Glen's death, Alice began to show signs of early Alzheimer's and began a slide into its depths over an 8-year period. Judy, Alice's daughter, took care of Alice at home for the duration of Alice's life. During that time, Judy worked full-time as a nurse in a regional hospital and spent most of her time away from work caring for her mother. Alice's decline, slow at first, began with Alice's constant wandering around the community and progressed more rapidly with time. When living with Judy, Alice often set off the house alarm at night while attempting to leave the premises. The possibility of a normal life between Judy and her husband and children became secondary and often nonexistent because of the demands of Alice's illness. Alice was a large woman and incontinence became an increasing problem that necessitated much lifting and changing. Outside help was difficult to obtain because few people were physically able to manage Alice. The strain of years of dealing with Alzheimer's had its effect on every family member.

Cancer is another chronic disease that takes its toll on family members. The Wards were a close-knit family. Lowell and Ruth, elderly in years, were deeply distressed when their daughter Carole, with a family of her own, came down with cancer of the pancreas. For several years Carole endured an endless series of chemotherapy treatments. With each treatment, the quality of Carole's life decreased. Lowell and Ruth spent much of their time and energy caring for her.

I recall, during one of my pastoral visits, watching Ruth massage Carole's back as the cancer spread within her body. I do not believe the touching alleviated much pain, but the tenderness of her mother's massage had a soothing effect on Carole's mind and spirit. Six weeks after that scene, Carole died. Just a couple of months later, Ruth was diagnosed with a rapidly growing cancer. Refusing any treatment, she died within weeks. The pain of a double loss so close together had its impact on Lowell, who was 80 years old. The stress of watching his daughter and wife deteriorate, and the grief following their deaths, took a fatal toll on Lowell. He experienced kidney failure and died within weeks of his diagnosis. The impact of such chronic pain exacted the ultimate price on the family.

Similar to Alzheimer's, AIDS takes it toll on family members, often not just psychologically, but physiologically. I visited John's hospital room often and every time I went, Mary was there sitting beside her son John who was critically ill with AIDS. As John deteriorated, the strain of his illness became more evident on Mary's demeanor. There were two victims of this terrible disease in that room. When John died, I conducted his funeral. Not only John's companion, but members of the gay community who had been John's friends, gave evidence of their pain from the loss of his life.

Genetics often play a tragic role in the family structure. Increasingly, bipolar disorders have a devastating effect on the family structure. With the severe mood swings of the victim, there often comes a breakdown of the family structure. Aberrant behavior often causes strains in a breakup of marriages. Trace this disease back and one often finds genetic links. The same can be true with schizophrenia. With both bipolar disorder and schizophrenia, entire families can be affected by the disease of one member. Grace and Harry have a son, Clarence, in his early twenties, who has been diagnosed with schizophrenia. When Clarence is on his medication, his behavior is stabilized; but like some, he periodically thinks he can do without his medication. When this takes place, the chronicity of this psychiatric problem takes its toll on the family structure. Henry and Grace do not have to tell me when Clarence is not taking his medication because I can see the pain on their faces and in their eyes.

PAIN AND PERSONALITY

Dick is the older of two boys. William, his younger brother, is 9 years his junior. In his teen years and early twenties, Dick acted very immaturely and irresponsibly, causing his parents to spend an abnormal amount of time in rescue mode – devoting time they should have been spending with William – coping with Dick's continuing crises.

Dick got involved in the drug and alcohol scene and almost lost his life in a wreck. Seeing the actions of his brother, William withdrew into himself and became a very private person, not expressing his feelings to family or friends. Extremely brilliant, he chose to rebel in another way. He refused to attend college and he became extremely critical of societal institutions, particularly in the areas of education, politics, and religion. William chose a track opposite to that of his brother. He became fiercely independent, hardworking, and sought to free himself from causing any financial drain on his parents. The pain of the problems in the lives of these young men had a long-lasting effect on both parents. At one time, the strain was so great that the parents contemplated separation and divorce. The parents' approaches to the concerns of their children caused them to act in opposite ways. One parent became over-controlling and the other passive-aggressive.

PAIN AND PERSONHOOD

In I Thessalonians 5:23, Paul the apostle prayed that the Christians at Thessalonica would be preserved complete in spirit, soul, and body at the coming of Christ (NASV). Both the Old and New Testaments use separate words in describing these three entities of who we are.

Whenever we experience pain in one aspect of our being, it affects the other areas. There is often spiritual or

psychological pain before physical pain is evident. Stresses within one's personality often cause the body to fall victim to diseases it otherwise has the capability to overcome.

We are now living in a time where the body is looked at as more than a free-standing mechanistic instrument that allopathic medicine can fix. Psycho-spiritual entities must be brought into play as well.

Emotional dysfunction that has been a pattern for several generations may ultimately express itself through physical symptoms. In a conference sponsored by The National Institute of Clinical and Behavioral Medicine, Dr. Paula Reeves (1994) presented a paper dealing with the effect of somatic belief patterns on emotional, physiological, and behavioral change. She stated that our biography is our biology, beginning with conception. Her belief is that all disease is psychosomatic, with symptoms being one-tenth instinct and nine-tenths metaphor. The majority of physical illnesses are the result of emotional and spiritual crises that occur in lives that experience a lack of love and family involvement.

Core messages that spring from family concerns result in illnesses. Dr. Reeves offers these examples:

Core Message	Illnesses
Don't feel	Phobias, depression
Don't think	Headache; ear, neck, throat problems
Don't be a child	Eating disorders, substance abuse, kidney and bowel problems
Don't exist	Respiratory/circulatory problems, sexual dysfunction, allergies
Don't be yourself	Skeletal: facial and balance problems
Don't be a bother	Muscle problems, nerve disorders (multiple sclerosis, muscular dystrophy)

All of the above involve pain. Such pain causes family concerns and pain as well. Anyone experiencing the above, according to Dr. Reeves, needs to trust that symptoms have meaning for one spiritually, emotionally, physically, and mentally.

THE ASSISTANCE OF THE FAMILY

Carl McNeely (2000) states that positive interaction between family members and the person with chronic pain is crucial. Often, when pain levels are high and the dependency of the patient is great, things can be very difficult as well as frustrating. As much as possible, clear, open communication is vital to keep at bay the mounting resentments and counterproductive emotions and reactions.

The establishment of routines and goals is vital to both the patient and family, whether the pain is physiological, psychological, or spiritual. Family help and assistance are crucial in up to 70% of patients experiencing pain.

Not only is the assistance of the family crucial for the patient, but the family itself has needs that cannot be ignored. Caregivers need to have time and energy for their other varied roles within the structure of family.

Boundaries must be visible. There must be a differentiation between caregiving (which has boundaries) and caretaking (where boundaries are nonexistent). It is crucial that goals be established concerning family involvement. Being proactive rather than reactive in this area can be of assistance in the ability of the patient to get better.

It is unwise to treat a complex, chronic pain patient separately from his family and social network. This approach could doom or, at best, retard the treatment process.

FACING THE FAITH FACTOR

In the Old Testament, Job, from the depths of pain that encompassed his whole being, states that "… I know that my Redeemer lives … even after my skin is destroyed, yet, from my flesh I shall see God" (Job 19:25–26). In the midst of traumatic testing, Job's faith was not destroyed, but refined. Several years ago, I visited a lady who was in the terminal stages of cancer. She remarked, "I am so glad I have cancer." Taken aback by that statement, I asked, "Why?" Her reply was that through the pain of cancer she had met many wonderful Christians whom she otherwise would never have known. Although her body was wasting away, due to the disease, her soul and spirit were at peace.

Allopathic medicine seeks the cure and alleviation of pain. There can be healing of soul and spirit without a cure for the body. You see, we are eternal beings in soul and spirit who live in temporal bodies.

A number of years ago, my grandmother developed pancreatic cancer. Her disease progressed slowly. My father remarked toward the end of her life that, up until that point, he had emotionally held on to her. When he was able to release her, my grandmother died within a short time.

And history repeated itself with my father. He almost died of kidney failure. At that time, my mother prayed, "Lord, whatever it takes, let Harold live." Dad lived for 6 more years. My mother, during those years, administered peritoneal dialysis every other day. As his condition worsened, mother one day remarked to me, "I am ready for your dad to go on home now." Dad died a short time later. I believe that God, in His mercy, allows loved ones to live until that time of emotional release by relatives.

STRATEGIES FOR POSITIVE ACTION

All of the illustrations set forth in this chapter have a common thread: the faith factor. Christians are not perfect;

they are pilgrims. Through painful traumas, both the victim and family members indicated that their faith was often deepened.

Andrew knew that he was losing his battle with cancer. His family had put his hospital bed in the living room so that he could see outside. On one of my visits, near the end of his life, Andrew told me that the night before had been a long and painful one. As he lay awake in the midst of his pain, he had begun thinking of how blessed he was with both his family and his faith. And in the midst of the darkness of the night, he had burst out singing. I recalled the scripture from Job 35:10b, "He (God) gives us songs in the night".

A friend of mine, Dr. Ronna Fay Jevne, has Crohn's disease. Yet in the midst of her pain, she has ministered to many cancer patients in Edmonton, Alberta, Canada. She is the author of several books centered around the theme of hope. She is also the founder of The Hope Foundation. She shares the following from her book, The Voice of Hope, Heard across the Heart of Life (Jevne, 1994):

"The Voice of Illness"

> Illness is an introduction to the fragility and sacredness of life. With illness we learn we are not immune. Nor are those whom we love. We learn that our sense of invulnerability is an illusion. Illness is the great equalizer. We come to understand that life and death are intimately and ultimately connected. For everyone.
>
> Illness comes with a formidable invitation to notice the sacredness of life. It is a wake-up call to life's preciousness. A call to notice the everyday, to be present to "here" and "now." To place our lives in perspective to others, to our universe. To accept the place we have in infinity and eternity. To ask the "big" questions and enjoy the "simple" answers. To do this, we must find a rightful place for suffering. A perspective that allows room for hope. Serious illness is a journey, a hopeful journey, an unknown destination. In illness the dichotomies are vivid. Hope is the space between symptoms and diagnosis, between diagnosis and prognosis. It is the wrestling match between science and compassion, between body and spirit, between pain and relief. It is the dilemma between fearing to be alone and hungering for privacy.
>
> Hoping is waiting: for test results, for appointments, for the organism to heal and the spirit to rekindle. Hoping is walking the line between tolerating constant probing and invasions, and declaring "no more, not now." The hope for survival is not the only hope; many days, not even the overriding hope. The real hope is not to be healed."
>
> Hoping is knowing that someone is making an effort to help. That family is never far away. That the system cares. That what happens is the best of technology and the best of humanness. Hoping is being attended by people who understand that caring makes a difference. An immeasurable difference.
>
> Hoping is being treated, not as another case of a particular disease, but as a person. By people who understand, this could happen to them. It is knowing there are no secrets. Being a partner on the treatment team. Being encouraged to do as much as possible for oneself. Hoping is trying again. Moving against the odds. Knowing everything that can be done is being done. Knowing the caring will go on when the limits of science are reached.
>
> Hoping is denying the statistics. Reaching beyond the traditional. Keeping open the possibility of being the exception. Hoping is listening to the unconscious. Having dreams in the world of sleep and dreams in the world of the consciousness. Wondering if there are miracles. Being fascinated with the little miracles: the words that heal, the memories that let us forget.
>
> Hoping is having passion for life. Noticing life. Wanting life. Inching toward life. Being willing to embrace life despite the risks. Hoping is recognizing that death is not the enemy — never living is.
>
> Suffering humbles us; hoping takes us forward. We come to understand that we are among many who are ill. Among many who hurt and fear. And who need. We come to trust the unusual experiences we cannot explain. The experiences for which we have no words. There is a knowing that accompanies suffering; a knowing that emerges from deep within us. That speaks from another dimension to life.

Pain affects not only individuals and their family structure, but impacts the human family. We, despite our many differences, are fellow pilgrims on this planet. Perhaps the one thing that is a common factor is pain.

The Apostle Paul, writing to the Corinthians, made a statement regarding not only the physical body, but the body of Christ, the Church: "… members should have the same care for one another … if one member suffers, all the members suffer with it; if one member is honored, all the members rejoice with it" (I Corinthians 12:25-26, NASV).

During my years in the ministry, my family and I have experienced periods of pain, either relational or physical. During those times, I questioned why. I now know that those times of trauma were to better equip us to understand and minister to ones trapped in prisons of pain. May it be so with you as well.

The Impact of Nursing on Pain Management

Chris L. Algren, R.N., M.S.N., Ed.D. and Mary Romelfanger, R.N., M.S.N.

INTRODUCTION

Pain is the most common reason patients seek out healthcare professionals. The National Institutes of Health (NIH, 1987) published a consensus statement in 1987 that stressed the "caring" and "curing" role in pain management. Since that time, great strides have been made in the assessment and understanding of the multiple dimensions of pain. Advances have been made in both the pharmacologic and nonpharmacologic methods of treating pain. The number of multidisciplinary pain centers has grown rapidly. Comprehensive, holistic pain management using a multidisciplinary team of health professionals with an integrated approach has gained wide acceptance.

The NIH consensus statement expressed concern that the education of many professionals — including nurses, physicians, dentists, and physical therapists — did not put sufficient emphasis on contemporary pain assessment and management. The need for communication and collaborative approaches among professionals was noted (NIH, 1987).

The U.S. Congress created the Agency for Health Care Policy and Research (AHCPR) in December 1989 as the federal government's focal point for health services research. The agency's mission is to enhance the quality of patient care services by generating knowledge that can be used to meet society's healthcare needs. The AHCPR is responsible for developing and updating guidelines that will be used to manage clinical conditions. To meet these challenges and others, agency activities include database development, effectiveness and outcome research, and dissemination of research findings and guidelines to providers, policy makers, and the public (Acute Pain Management Guideline Panel, 1992).

Pain-related guidelines were among the first sets developed by interdisciplinary expert panels representing medicine, nursing, pharmacology, psychology, rehabilitation therapy, ethics, and consumers/patients. Nurse clinicians, educators, researchers, administrators, and professional nursing organization representatives provided input. The first edition of the Acute Pain Management Guidelines was published by the AHCPR in February 1992 (Acute Pain Management Guideline Panel, 1992). The American Society of Anesthesiologists promulgated guidelines for acute pain management in the perioperative setting in 1995 (Ready, 1995).

Most recently, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) published Pain Standards for 2001 (JCAHO, 2001). These new standards are effective for surveys conducted after January 1, 2001. Aspects of pain management are covered in six of the eleven chapters of functions or activities required of accredited healthcare organizations. Organizations — including ambulatory care, behavioral healthcare, home care, hospice, hospitals, and long-term care facilities — now have a mandate to address pain management.

The integration of the pain management team's knowledge and skill is enhanced through an understanding of the perspective and scope of practice of each discipline. Pain manuals specific to nursing practice are available (McCaffery & Pasero, 1999).

Because "patient" is used by pain management practitioners from many disciplines and because "patient" is used in a majority of settings where nurses practice in the world, "patient" rather than "client" is used in this chapter. The rights and responsibilities associated with the use of "client" are intended.

THE NURSE'S ROLE IN PAIN MANAGEMENT

Nurse decision-making is performed step by step using the nursing process, including assessment, diagnosis, planning, implementation, and evaluation (Gordon, 2000). Based on the establishment of a trusting relationship and a good rapport with the patient and family, this systematic process provides a framework for nurses to provide care for patients with pain in all settings.

The move to multidisciplinary planning and plans of care is supported by accrediting bodies such as the JCAHO and the American Academy of Pain Management Pain Program Accreditation. Current hospital and home health JCAHO standards require coordination, collaboration, and continuity of services to each patient by all disciplines through an established plan of care. Critical pathways are a means of organizing patient care that relate care and services by disciplines and time frames to costs and measurable outcomes. Critical pathways are population specific and provide a database for performance improvement, including outcome-driven, competency-based staff development. Sample diagnosis-related critical paths are available in the literature (Aspen Reference Group, 1995; Cronin & Bahrke, 1996; Ignatavicius & Hausman, 1995).

Nurses play an essential role in the assessment of a patient's pain. The information the nurse obtains from assessing the patient's pain is used to identify goals for managing that pain. The goals for the patient can be accomplished using a combination of both pharmacologic and nonpharmacologic means. Assessing the effectiveness of interventions and monitoring for adverse effects are important aspects of the nurse's role. The nurse serves as an advocate for the patient when the intervention is not effective in relieving pain. The nurse also serves as an educator to the patient and family. Teaching about pain and measures to relieve it lessens anxiety and gives the patient and family a sense of control.

NURSING MANAGEMENT OF CHRONIC NONMALIGNANT PAIN

One of the most widely accepted definitions of pain is that "pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (IASP, 1979). Pain is not determined by tissue damage alone. Patients with chronic nonmalignant pain (CNP), pain not associated with a neoplastic process, may have pain for which little or no tissue damage can be found.

Pain is subjective and personal. McCaffery's (1968) definition — "Pain is whatever an individual says it is, and it occurs whenever he says it does" — seems especially relevant for the patient with CNP. The practitioner can only observe signs and obtain information about symptoms. The pain belongs to the patient, not to the practitioner. The person with pain is the best judge of the existence, duration, and severity of the pain and the success of pain management treatments.

The patient as expert rather than the healthcare practitioner can be difficult for the practitioner to accept. Until recently, pain has been viewed as a symptom, not as a diagnosis. Pain was thought to be something the healthcare provider could cure, or at least control. Many times, the cause of chronic pain is not discovered quickly or easily. The healthcare provider as well as the patient becomes frustrated.

Many healthcare providers had and still have little training about pain, particularly chronic pain, and the relief of pain. Often times, pain management is not considered a priority.

The nurse is a key player on the chronic pain management team, regardless of the setting. Nurses who work in community settings are likely to regularly help patients and families manage chronic as well as acute pain. Table 25.1 outlines how home health standards for practice and reimbursement can be applied to a diagnosis of pain (Marrelli, 1994).

The nurse, as well as everyone caring for the patient, needs to know the meaning that pain has for the patient. No chemical or neurophysiological tests exist that can accurately measure pain. Because the question of whether

TABLE 25.1
Home Care Pain Management

- Documentation Guidelines
- General considerations
- Need for initial visit
- Potential diagnoses and codes (medical-surgical)
- Associated nursing diagnoses (e.g., home maintenance management, impaired)
- Skilled services (e.g., RN to implement nonpharmacological interventions, titrate medication dose to achieve outcome with acceptable level of side effects)
- Other services (e.g., home health aide to assist with activities of daily living; MSS to assess financial ability to comply with pain treatment plan; physical therapist to teach energy conservation, apply heat or cold)
- Homebound status factors
- Short-term goals by discipline (e.g., RN to daily control pain and other symptoms)
- Long-term goals by discipline (e.g., RN, patient, and/or caregiver knowledgeable about pain management measures)
- Discharge plans
- Education needs: patient/family/caregiver
- Reimbursement tips

the patient has "real pain" cannot be answered, healthcare providers must accept the patient's report of pain. The nurse must determine what the patient thinks is needed in order to deal with chronic pain. Nurses, particularly those who are discharge planners or who work in the community, need to know what resources are available to patients in pain. Support groups established to assist individuals in pain and referral services for patients are needed. One such group in the United States, with chapters throughout the country, is the National Chronic Pain Outreach Association. Nurses and physicians often serve as advisers or as coordinators for local chapters. If the practitioners are certified in pain management by the American Academy of Pain Management, they bring valuable knowledge and expertise that might not otherwise be available to many members of the group.

Regardless of the setting, the nurse functions as patient advocate, educator, counselor, provider, and coordinator of care.

NURSING MANAGEMENT OF PAIN IN THE ELDERLY

For purposes of the discussion that follows, the term "elderly" refers to those persons 65 years of age or older. However, it is important to note that many of the physiological changes associated with the aging process have an onset as early as the fourth decade. Therefore, although this discussion focuses on an age-related cohort, individual variation is a hallmark of any investigation of the sequelae of human aging.

The axiom that "aging is not for sissies" may have found its origin in the many factors of aging that support the nursing diagnosis "alteration in comfort." Carpenito (1999) states unequivocally that pain is omnipresent in the elderly. This is a particularly startling revelation in view of Wolanin's (1976) observation that pain is primary and, until it is relieved, no person functions adequately. This discussion explores these concepts in more detail and addresses other factors that combine to make the elderly a population uniquely vulnerable to pain.

The myriad physiologic and pathophysiologic changes of human aging that result in either acute or chronic pain may manifest themselves in a variety of ways in the elderly. Some of these manifestations are obvious and accompanied by typical signs and symptoms of a specific problem, while others are subtle, atypical, or even paradoxical (Caird, Dall, & Williams, 1987). Although the mechanisms of pain have been well described (Thompson, 1984), variation in pain perception in the elderly remains an area of contradictory subjective opinion and objective data (Caird et al., 1987; Corso, 1971; Matteson, 1988). However, it is generally accepted that pain threshold increases with age (Carpenito, 1999; Charleton & Buckley, 1984; Jacox, 1977; McConnell, 1988). In addition to an increased pain threshold, other factors are known to alter pain perception in the elderly. These include peripheral and central nervous system impairments, drug therapies, cognitive impairments, co-existing pathologies, individual psychophysiological or cultural experiences, and adaptation (Caird et al., 1987; Carpenito, 1999; McConnell, 1988; McCue, 1987).

Whether a result of increased pain threshold or other factors, certain conditions are reported to be less painful in older adults than in younger persons. Conditions frequently presenting with significant pain in younger persons but with only mild discomfort in the elderly include peptic ulceration, appendicitis, pneumonia, and mesenteric infarction (Charlton & Buckley, 1984). In the elderly, these events may be heralded only by vague signs such as restlessness or confusion.

Another factor confusing the symptom pattern in the elderly is the tendency for pain to be referred to other sites in the body. Chest pain may be referred from abdominal or esophageal pathologies (Charlton & Buckley, 1984; Dymock, 1985), while abdominal pain may arise from musculoskeletal or spinal problems or abdominal wall entrapment syndromes. Back pain may be the presenting symptom of a host of pathologies, including disc degeneration, arthritis, osteoarthritis, metastatic disease, and Paget's disease. These conditions may present as lower limb pain (Charlton & Buckley, 1984). Spondylosis of the cervical vertebrae may present as pain, muscular spasticity, or paresthesia in one upper limb (Grahame, 1985; Pathy, 1985).

Perhaps the most frequently cited clinical manifestation of paradoxical pain perception in the elderly is cardiac pain. Although elderly persons experiencing angina pectoris report the same need to cease exertion and similar dyspnea and pain radiation patterns as younger persons, they also report much less severe pain. It is postulated that the modified severity of pain results from either the presence of afferent denervation of the heart or the occurrence of disease in the smaller coronary vessels which produces less pain than disease in the larger vessels (Caird et al., 1987).

In addition to modified chest pain, it is not unusual for the elderly patient with clinically severe ischemic heart disease to present totally absent of pain. One study found that 31% of the elderly patients who experienced myocardial infarction reported no pain, while 40% reported clinically atypical symptoms (Caird et al., 1987; Charlton & Buckley, 1984). This phenomenon may be the result of the presence of multiple pathologies that severely limit activity, such as arthritis, parkinsonism, blindness, or hemiplegia. The presence of other pathologies may also present the patient with other symptoms so noxious that chest pain is not noticed (Caird et al., 1987).

Clearly, determining the origin of pain in the elderly presents a challenge to the healthcare practitioner and patient alike. Pain is a subjective phenomenon. Variables

such as coexisting chronic pathologies, underreporting of pain, and the increased incidence of cognitive impairment all combine to make pain evaluation much more difficult among the elderly than among other adult populations (Ferrell & Ferrell, 1987). Although practitioners observe the elderly for behavioral manifestations of pain such as facial grimacing, positional guarding, etc., such observations, or even the perceptions of the experienced practitioner, are not reliable assessments of whether pain is present and, if so, how severe that pain may be. As is the case with nonelderly patients presenting with pain, the elderly patient's report of pain must be accepted as the most reliable clinical description. This requires that the patient with pain be trusted (Wright & Gal, 1987). It has been reported that the inability of an elderly patient to walk on a broken thigh was ascribed to hysteria (Pitt, 1982).

Although this is an extreme example of failure to trust, attributing pain to psychogenic origin may occur in those circumstances where no clear-cut etiology for the pain is found. In reality, it is not always possible to discover an etiology for the discomfort experienced by patients. This reality can lead to frustration or guilt on the part of the clinical practitioner, which in turn can lead to avoidance of the patient or minimization of the patient's pain by the practitioner, neither of which benefits either party (McConnell, 1988). Compounding the difficulty of establishing trust and gathering accurate data from the patient is the fact that older persons tend to be more reluctant to report pain than younger persons (Charlton & Buckley, 1984; Matteson, 1988; McConnell, 1988). Additionally, due to increased pain tolerance and adaptation, the elderly individual also does not tend to demonstrate expected objective signs of pain as readily as a younger person (Carpenito, 1999). While this adaptive behavior by the elderly patient may be necessary for continued survival, particularly in the presence of chronic pain, it may lead to inaccurate assessment by the practitioner, ineffective pain management, reduced comfort and mobility, and increasing dependence and isolation, anger and frustration, and, in some cases, confusion on the part of the patient (Pitt, 1982).

Clearly, an individual touched by pain experiences that perception across the broad spectrum of physical, emotional, and spiritual aspects of human experience. The experience also includes the human diminishments pain evokes in the individual, both organically and spiritually. This view of the integrated wholeness of the human person experiencing life events is reaching new awareness in a healthcare environment and era that had found comfort in the high-tech-low-touch approach to problem solving. During the past decade, however, the traditional philosophies and healthcare practices of Western society have become increasingly receptive to a cultural renewal of the ancient and Eastern philosophies of holistic health. This openness is resulting in increasingly active interest in the modalities associated with those traditions. As a result, it appears that we are witnessing the emergence of sociocultural legitimacy of a holistic health paradigm, perhaps best described as a renaissance moment. A singular outcome of this ongoing trend is without doubt the consciousness-raising constellation of external and internal variables integral to the individual and personal experience of health/illness events, such as pain.

Seaward (1994) posits that the primary reason for this readiness to transition originates from the socioeconomic reality that the "American healthcare system is crumbling under its own economic weight." The burgeoning recognition that Eastern traditions and Western traditions are in fact not mutually exclusive but rather complementary is perhaps best illustrated by recent activities at the federal level of healthcare policy. The NIH is transitioning the Office of Alternative Medicine (OAM) into the mainstream by funding and staffing the office to serve as the primary agency to engage in and support research in the area of complementary and alternative medicine, or CAM (Villaire, 1995). The evolution of this new emphasis is reflected in the creation of six to eight additional research centers devoted to specific clinical problems, including, but not limited to, stroke, women's health, and pain issues.

The readiness of the healthcare community to learn and share new realities and awareness of the power of integrating East and West and high-tech and high-touch has found a common ground in the search for higher clinical efficacy and healthcare cost savings. These were also the discussion triggers for the participants in the OAM-sponsored Conference on Technology Assessment during the fall of 1995. The two specific clinical foci of that conference were treatment modalities for insomnia and chronic pain, and the outcome recommendations give new direction for plausible and efficient modalities for efficacious interventions (Chilton, 1996). By nature of the everyday adaptations these realities demand of the older adult, the outcome recommendations of this panel have benchmark implications for healthcare providers serving this population.

For example, Garner and Kinderknecht (1993) address the responsibility of healthcare workers to empower clients in pain by teaching them coping skills that will allow clients to actively engage in the process of ameliorating pain. In their discussion of the gate theory of pain perception, the authors provide an overview of pain management and coping modalities designed to insert self-control back into the equation of health status, even in the face of the reality of illness. This is a most powerful and appealing idea. The concept is a natural evolution of the psychological theory of "self-efficacy." This theory, in turn, is giving rise to the model of self-efficacy training, which is reportedly being proven as an intervention for indigenous peoples in Canada, Latinos in California, and those with chronic co-morbid conditions (Chilton, 1996).

Results of scientific investigation into the phenomenon of pain experienced by the elderly may assist the elderly in achieving the best possible quality of life. Although instruments have been developed to quantify and qualify pain experienced by the elderly and non-elderly (Kane & Kane, 1984; Wright & Gal, 1987), this remains an area of need for additional nursing research. Unfortunately, until recently, pain research in the elderly has received limited attention. This is despite the fact that the special vulnerability to pain experienced by this cohort is commonly reflected in the literature as a given. For example, the Clinical Practice Guideline for Management of Cancer Pain states: "The elderly should be considered an at-risk group for the undertreatment of cancer pain because of inappropriate beliefs about pain sensitivity, pain tolerance and ability to use opioids. Elderly patients, like other adults, require aggressive pain assessment and management"(Agency for Health Care Policy and Research, 1994).

Some of the factors that singly and in combination explain why the elderly population is at high risk for the nursing diagnosis alteration in comfort are presented in Table 25.2.

THE LOCUS OF ASSESSMENT: THE PATIENT

Gratefully, the past decade has brought important changes in both the knowledge and performance parameters of pain management across all health professions. The most crucial change in thinking is the clinical foci of control of pain residing with the patient, rather than the individual professional whose capacity to address subjective symptoms may be biased by a host of intellectual, cultural, professional, and personal variables which influence effective treatment interventions for the elderly.

The awareness of pain and its influence on the quality of life has garnered the attention of the graying American public. Thanks to the influences of communications media from print to the Internet, the level of healthcare consumer knowledge today is more sophisticated than in previous generations. Concurrently, the health industry, with its renewed focus on quality assurance, has found the focus of care delivery once again returning to the patient. Performance expectations, measurable behavioral outcomes of patient care, and other outcome performance tools are all examples of the shifting model of healthcare service delivery. The shift is consonant with a heightened awareness of the criticality of pain management throughout the clinical professions.

The clinical discourse on quality assurance of pain control has also translated into a new organizational awareness. Policy and standard-setting institutions such as the Agency for Healthcare Research and Quality, and the JCAHO are developing new pain management standards (Acute Pain Management Guideline Panel, 1992; JCAHO, 2001). Significantly, the JCAHO developed new standards for pain control with a radical change in thinking — that pain management is the responsibility of healthcare organizations. In introducing the new standards (effective January 2001), which include the elderly in all care delivery settings, the quality of pain management is addressed through a systematic assessment of pain using a 10-point scale. More detail regarding the specific revisions in the six standards chapters (Rights and Ethics; Assessment of Persons with Pain; Care of Persons with Pain; Education of Persons with Pain; Continuum of Care, and Improvement of Organization Performance) is available on the JCAHO Web site (http://www.jcaho.org) (Phillips, 2000).

TABLE 25.2
Risk Factors Associated with Nursing Diagnosis: Alterations of Comfort in the Elderly

- Pain threshold increases with age.
- Physiologic/pathophysiologic changes may alter perception of pain.
- Pain in the elderly may be referred from site of origin.
- Physiologic changes of aging give rise to chronic pain.
- Multiple pathologies may result in the paradoxical absence of pain.
- Severe pain and chronic discomfort in the elderly may manifest as confusion.
- Cultural/psychological expectations may diminish reporting of pain.
- Concern for overmedication may result in insufficient pain management modalities.
- Societal acceptance of pain in the elderly leads to avoidance or minimalization of pain.
- Depression is present and most frequently associated with chronic pain.
- Constellation of symptoms in chronic pain states includes behavior commonly associated with maladaptation to the aging process, including sleep disturbances, appetite disturbances, decreased libido, irritability, withdrawal of interests, weakening of relationships, and increased preoccupation with ill health.
- Underreporting of symptoms occurs frequently.
- Communication difficulties increase history-taking problems.

NURSING MANAGEMENT OF PAIN IN INFANTS AND CHILDREN

Although pain relief is a primary goal of nurses, pain management in children has often been ignored and has received limited attention in the literature. In 1977, Eland and Anderson documented the undertreatment of pain in children. Following this study, subsequent research findings supported the idea that pain in children is an ignored dimension of care (Wong & Hockenberry-Eaton, 2001). Recently, significant advances in the management of children's pain have been facilitated by the development of clinical practice guidelines for pain (Acute Pain Management Guideline Panel, 1992) management from the federal

TABLE 25.3
Myths Associated with the Undertreatment of Pain in Children

- Infants and children are unable to perceive and experience pain.
- Children have no memory of pain.
- Pain produces no harmful effects.
- Children become easily addicted to narcotics.
- Children are more likely to experience respiratory depression.

AHCPR and the development of acute pain services in hospitals.

Experts have proposed many explanations for undertreatment of pain in children (Table 25.3). The inability to assess children's pain, however, has presented the biggest challenge for pediatric nurses. Preverbal infants, intubated patients, and developmentally challenged children are not able to verbally describe their pain. Pediatric nurses must be able to assess pain and understand that infants and children respond to pain with reactions based on age and cognitive processes. Because of the problems associated with the measurement of pain in children, assessment requires a multifaceted approach.

Research findings indicate that infants and children do experience pain and respond to that pain both physiologically and behaviorally (Deshpande & Anand, 1996; Jorgensen, 1999). These pain cues may be more subtle than those expressed by adults. Observation of these responses provides the basis for nursing assessment. Other assessment parameters include: (1) obtaining a thorough history from the child and/or parents; (2) using a self-report tool, if appropriate; and (3) eliciting parental input about the child's pain.

Behavioral changes may indicate pain in children who are unable or unwilling to verbally report pain. Behavioral responses associated with children's pain include:

- Vocal communication, such as moaning, whimpering, or crying
- Facial expressions, such as a grimace
- Body language, such as positioning, posturing, splinting, pushing away, or kicking
- Emotional responses, such as withdrawal, depression, irritability, and unusual quietness
- Changes in daily routines, such as loss of appetite and disturbed sleep patterns

Behavioral responses modulate over time and require careful assessment throughout a child's illness. Parents are often the first to detect these subtle behaviors, and their input is essential.

Physiological parameters that demonstrate the presence of pain include changes in vital signs, skin color, sweating, and nausea and/or vomiting. Flushed skin, increased temperature, pulse, and blood pressure; poor tissue perfusion; and dilated pupils may be associated with pain. These signs of autonomic nervous system arousal and the body's stress response are self-limiting. The body cannot continue the response. Adaptation occurs and a state of homeostasis follows, although the child is still in pain. These physiological responses, therefore, are only helpful when they are combined with other assessment data.

Assessment tools offer a systematic approach to the evaluation of pain. A valid and reliable tool reduces bias. Various tools exist, and one tool is not appropriate for all children. The selection of an assessment tool should be based on the child's age and developmental level (Wong & Hockenberry-Eaton, 2001).

A specific assessment form should be used to document assessment findings. Documentation should include the location and intensity of the pain, the type of assessment tool used, observed behavioral manifestations, physiological parameters, the pain intervention, and the response to that intervention (Lux, Algren, & Algren, 1999).

The AHCPR publication, "Clinical Practice Guideline for Acute Pain Management" (Acute Pain Management Guideline Panel, 1992), provides information for the assessment and management of pain in infants, children, and adolescents. The goal for pediatric pain management is preventing or relieving pain as much as possible using pharmacological or nonpharmacological strategies, or a combination of the two.

Pharmacological agents used to manage pain in children include both opioid and nonnarcotic analgesics. The ideal analgesic should be easy to administer, have a rapid onset, and produce the desired degrees of analgesia. Physiological parameters and respiration should be minimally altered. The discussion of specific pharmacological agents is beyond the scope of this chapter. Extensive information can be found in Chapter 39 on the "Management of Procedural and Perioperative Pain in Children."

A variety of routes of administration are now being utilized in pediatric pain management. Oral and rectal administration are less traumatizing than intramuscular injection. In fact, injections are strongly discouraged in most pediatric institutions. Topical anesthetics, regional anesthesia and analgesia, and epidural analgesia have also become commonplace in treating children's pain (Algren & Algren, 1994; Wong & Hockenberry-Eaton, 2001).

In most children's hospitals, patient-controlled analgesia (PCA) is the mainstay of pediatric pain management. Pain resulting from etiologies such as surgery, trauma, sickle cell crisis, and cancer can be successfully managed by PCA. Using an infusion pump, patients can self-administer a preset amount of opioid, usually morphine, by simply pressing a button. The patient, however, cannot repeat a dose before a specified period of time, usually

8 to 15 minutes. PCA gives the patient control over pain management, permits individual titration, and provides superior analgesic effect (Lux et al., 1999).

Patient-controlled analgesia was first used in adolescents, but its use has quickly spread to younger children. Children as young as 5 years of age can safely and effectively control their own analgesia (Yaster et al., 1997). A degree of safety is maintained by the patients when they no longer feel the need to "push the button" or when they become sedated. The key to successful use of PCA in children is adequate patient and parent education. The control of PCA pumps by a surrogate such as a parent or nurse is controversial because it compromises the inherent safety of PCA. If parents or nurses control the PCA system, frequent assessment and conservative dosing is desirable (Lux et al., 1999).

Nonpharmacological strategies may be very helpful in the management of mild to moderate pain and procedural pain. These techniques are noninvasive, inexpensive, and offer some control to the child and parent. Strategies such as distraction, guided imagery, and relaxation techniques decrease anxiety, reduce pain perception, and enhance the effectiveness of analgesics (Vessey & Carlson, 1996). Guided imagery, such as imagining being at the beach, can be used in children who are capable of abstract thinking. Relaxation activities such as holding, rocking, reading stories, and listening to music may reduce the stress associated with pain and thus provide pain relief.

Cutaneous stimulation can also be used as a noninvasive pain relief measure. Activities such as stroking or rubbing an injured area stimulate the large A-alpha peripheral fibers and block the transmission of noxious impulses at the spinal cord. Applications of heat and cold may also promote analgesia.

In summary, nurses play a vital role in pediatric pain assessment and management. Health professionals must create a climate that makes effective pain management a priority. Developmentally appropriate pain assessment tools must be utilized in evaluating children's pain. Clinical practice must be evaluated through research and quality improvement programs. Finally, all practitioners must be advocates for the child and the family for effective pain management.

NURSING MANAGEMENT OF CANCER PAIN

Approximately one million Americans are diagnosed with cancer each year. In the early and intermediate stages, 30 to 45% experience moderate to severe pain. In the advanced stages of cancer, 75% of patients experience pain; 25 to 30% of these patients describe their pain as severe. Good to excellent pain relief is possible in 95% of these patients if adequately treated with pharmacological therapy (Jacox et al., 1994). The majority of cancer patients in the U.S. receive inadequate pain management. The literature suggests that healthcare providers continue to have misconceptions about cancer pain (Pargeon & Hailey, 1999). Patients may hamper their own treatment due to misconceptions about pain and fears about opioids.

Cancer pain is multifaceted and is generally classified as pain from direct tumor involvement, invasive diagnostic and therapeutic procedures, infection, or toxicity of chemotherapy and radiation therapy. Because cancer most often occurs at ages when other maladies causing pain develop (e.g., arthritis and chronic back problems), the practitioner must attempt to identify the source of the pain and intervene appropriately. Cancer-related pain may be difficult for the patient to explain. Thorough and accurate nursing assessment is paramount to the diagnosis and management of cancer pain.

The Standards of Oncology Nursing Practice emphasize the systematic and continuous collection of data to plan appropriate interventions with the patient (ANA, 1996). Cancer patients may underreport pain if they think pain indicates their disease is not responding to treatment. Some patients simply do not want to complain even if analgesics are available to relieve the pain because they think it is part of the fate of the disease. Other variables such as financial concerns, anxiety, and limited family support may add to the perceived pain experienced. The absence of standardized assessment tools makes it difficult for nurses to consistently and effectively assess the extent of pain, evaluate the efficacy of the intervention, and accurately communicate this information. Lack of knowledge about the cause of cancer pain, as well as attitudes toward pain and its management, can be barriers to adequate assessment.

The Oncology Nursing Society has long recognized the need for a consistent approach to cancer pain management and barriers to that management. In a recent revision of its Position Paper on Cancer Pain Management (Oncology Nursing Society, 2000), emphasis is placed on multidisciplinary management that is collaborative and involves ongoing assessment, planning, intervention, and evaluation of pain and pain relief.

The site of the cancer and the stage of the disease factor into the incidence and prevalence of pain. As the disease progresses, patients with metastatic disease are more likely to experience pain, particularly those with bone involvement from primary infiltration or metastasis. Interference with organ function or structure or nerve invasion intensifies pain. Terminal patients report significant increases in pain. It is evident that the management of cancer pain may need to be multimodal secondary to the many dimensions of its etiology. However, the treatment of acute and chronic cancer pain continues to remain primarily within the realm of pharmacologic management.

Effective cancer pain management has been described in practice guidelines by organizations such as the AHCPR (Jacox et al., 1994). While advocating a team approach, details such as assessment, pharmacological management, adjuvant therapy, and psychological interventions are outlined in the guidelines.

Analgesics are extremely effective in most patients when used correctly. In 1986, the World Health Organization recommended a three-step "analgesic ladder" that emphasizes the use of standard drugs classified as nonopioids, weak opioids, and strong opioids. Sequential use of the drugs is advocated with the addition of a weak opioid in combination with the nonopioid, or a strong opioid should relief not be obtained. Adjuvant drugs are added if required for specific indications, and they are often needed in patients with pain secondary to nerve injury. Nonopioid drugs such as the nonsteroidal anti-inflammatory drugs interfere with peripheral receptors by inhibiting prostaglandin release, thus reducing pain from resulting inflammation. Opioid drugs (narcotics) bind to receptors that interfere with the transmission of painful stimuli. Because of the difference in action, a combination of the two types of drugs results in efficacious pain management. Adjuvant drugs are used to treat specific types of pain and to alleviate other symptoms that may occur in cancer patients. Anticonvulsants, antidepressants, and corticosteroids are used to reduce anxiety and depression, which often exacerbate cancer pain and interfere with other activities of the patient.

Other interventions may be useful, particularly for pain that is not responsive to analgesics. Nerve blocks, transcutaneous nerve stimulation, and neuroablative techniques may benefit cancer patients.

Nurses in acute and chronic pain settings can add a unique perspective to the assessment and care of each cancer patient. Changes in a patient's comfort that occurs every 24 hours can be observed and reported and interventions evaluated more closely because of the increased contact with the patient. Combining nursing therapies with behavioral therapies and pharmacotherapies offers a broader approach to pain management. Comfort measures helpful for patients with cancer pain are summarized in Table 25.4.

TABLE 25.4
Nursing Therapies for Cancer Pain

- Rest and sleep
- Adequate nutrition
- Daily elimination
- Activities of daily living
- Encourage movement
- Environmental control
- Encourage independence
- Medications
- Thermal therapy
- Communication
- Therapeutic touch
- Relaxation techniques
- Distraction
- Emotional support
- Availability of spiritual support

The Oncology Nursing Society (2000) supports nurse design of individualized physical and psychosocial interventions that are intended to achieve stated outcomes and are prioritized according to the patient needs. The nurse also collaborates and communicates with appropriate members of the multidisciplinary team in designing the plan of care.

It is imperative that information be as complete as possible and be available to all practitioners involved in treating the patient's pain or discomfort. Outcome criteria for the patient, in relation to comfort, state that the patient will:

1. Communicate alterations in comfort level
2. Identify measures to modify psychosocial, environmental, and physical factors that increase comfort and promote the continuance of valued activities and relationships
3. Describe the source of discomfort, the treatment, and the expected outcome of the proposed intervention
4. Describe appropriate interventions for potential or predictable problems such as pain

To do so requires a comprehensive approach to pain control for the cancer patient. Accountability and responsibility of the professionals involved with the care are demanded and advocated. The challenge is for the nurse to identify, assess, treat, evaluate at specific intervals, make alterations if necessary, and further evaluate. It is the professional and ethical responsibility of caregivers to assist the patient and family in identifying and managing factors that promote comfort.

SUMMARY

In conclusion, the AHCPR and other major organizations have widely disseminated pain guidelines. The absence of knowledge is no longer a factor in caring for patients with pain. Pain management as a multidisciplinary, collaborative practice is still too new for many practitioners to be competent, confident members of the team. In Seizing the Future, Zey (1994) addresses mentoring as an effective developmental tool routed in caring and individualized learning that provides the emotional sup-

port often missing in society's high-tech cognitive approach to solutions.

To assist patients with pain and to help them integrate its management into their life, practitioners need cognitive, affective, and psychomotor practice skills. Formal pain mentoring programs established in hospitals and other settings (Kachoyeanos, 1966) and less-formal mentoring through the American Academy of Pain Management, the American Society of Pain Management Nurses, and other pain organizations can develop practitioners to better serve patients and mentor other colleagues in the future.

Nurses are ubiquitous, just as pain and the need for pain management is ubiquitous. Nurses have more contact with patients in pain than any other practitioner. Nursing practice, research, and mentoring are vital components of pain management practice, and nurses are valuable participants who help determine how the health care systems in the U.S. and throughout the world deal with pain management.

The Psychiatrist's Role in Pain Diagnosis and Management

Nelson H. Hendler, M.D., M.S.

INTRODUCTION

The role of a psychiatrist in chronic pain management is multiple. He or she must be a diagnostician, a pharmacologist, a sociologist, a psychotherapist, and even, on occasion, patient advocate. Therefore, by definition, the psychiatrist must have an eclectic orientation, and be broadly schooled in all forms of diagnostic and therapeutic interventions.

There are at least three approaches to chronic pain that a psychiatrist can use. Each has its own advantages and disadvantages.

The medical model. Using this paradigm, pain is defined as a manifestation of a disease. This approac lends clarity to the problems of pain, and offers predictive capabilities for outcome. It may offer a cure where none existed before. As an example, "pain in the back and the leg" is a description, but "a herniated disc with radiculopathy" is a diagnosis. Surgery on the disc may cure the pain. However, should the surgery not work, or should there be psychological problems or social problems compounding the recovery, response to surgery may not be as predicted.

The psychiatric model. Using this approach, a psychiatrist tries to establish a psychiatric diagnosis to explain the behavior of a pain patient who is troublesome or not responding in the predicted fashion. Using this tack, personality disorders, affective disorders, or anxiety traits that might be the source of a patient's complaints are identified and treated. Unfortunately, the use of psychiatric intervention in this fashion very often leads to an "either-or" type of thinking, with psychiatric diagnosis being established to the exclusion of medical diagnosis. A person with a histrionic personality disorder, who has surgical excision of a disc and does not get well, may run afoul of the system. His or her lack of recovery is ascribed to "secondary gain" or "dependency needs," but not to retained disc material missed by the first surgery.

The integrated response model. Using this model, the psychiatrist tries to establish both medical and psychiatric diagnoses, not only from the point in time at which a patient is seen, but also based on the historical perspective of the patient, that is, the "pre-morbid" or "pre-pain" personality. In this fashion, one can determine the appropriateness of response to pain, and to treatment. This approach is time-consuming and involves a multidisciplinary approach, with multilevel diagnoses and integration of material. In this model, both medical and psychiatric diagnoses can exist.

Medical Model

Adherence to the medical model is often found within pain treatment centers or in clinical practices that utilize only medical evaluation of the patient. The absence of a psychiatric or psychological professional to assist in evaluation and diagnosis limits the evaluation of the chronic pain patient to only medical assessment. It disregards the possibility that a patient may have psychiatric problems, the result of chronic pain, which can lead to diagnostic oversight. Indeed, some authors believe that the incidence of depression, in dissociation with chronic pain, is remarkably high (Hendler, 1984b; Krishnan, et al., 1985; Pilowsky & Bassett, 1982). Other authors have advanced the theory that chronic pain may be a manifestation of an underlying

0-8493-0926-3/02/$0.00+$1.50

depression (Engel, 1959; Maruta, Swanson, & Swanson, 1976). Therefore, the medical assessment of chronic pain without psychiatric assessment (to determine the preexisting personality characteristics and motivations that may lead to an exaggerated response to chronic pain, or may, in fact, lead to the expression of psychiatric disease as a chronic pain process) would compromise any medical diagnostic endeavor. By the same token, severe and chronic illness certainly produces depression, and perhaps other psychiatric disorders, which would benefit from therapeutic intervention. The use of a purely medical model cannot be endorsed.

Likewise, the purely psychiatric model suffers from many of the same problems. In a most thorough review of the problem, Dr. Charles Ford (1986) discusses what has been called "somatizing disorders." In this article, Ford discusses the concept of the sick role, which allows the ill person to be released from regular duties and obligations. He further differentiates illness from disease, describing the latter as objectively measured, while illness discusses the change in functioning of an individual. He further clarifies the point, indicating that disease can occur in the absence of illness, while conversely, illness can occur in the absence of disease. Dr. Ford further describes somatization as "the process by which an individual uses the body, or bodily symptom, for psychological purpose or personal gain." However, Ford does concede that somatization can occur in the presence of demonstrable physical disease, with amplification of the response to a real physical disorder. Ford then lists nine reasons why people somatize:

1. To avoid unpleasant tasks, or to achieve primary or secondary gains, in the form of payment
2. To solve family problems
3. To allow an individual to focus on physical symptoms rather than psychological problems
4. As a form of communication of displeasure
5. As a way of expressing oneself when they are not capable of expressing themselves otherwise
6. A culturally determined response
7. Using a physical symptom because is it more culturally acceptable than a psychiatric one
8. Focusing on physical problems that are manifestations of underlying stress
9. Utilizing the fashionable diagnosis to explain underlying/psychiatric disease, such as hypoglycemia

Ford further feels that patients may utilize somatic symptoms instead of expressing depression, and further indicates that these depressions are unrecognized. Anxiety may also manifest as a somatic complaint, which he also believed could go undiagnosed. According to Ford, "chronic pain syndromes are one of the more common forms of somatization." He also includes disability syndromes under the description of somitizing disorders. He describes hard-working individuals who have an accident, and then fall apart. This inability to function allows the individual to have support and secondary gains, and allows an underlying dependency to manifest itself.

Psychiatric Model

In a superb review article, Drs. Turk and Flor (1984) reviewed the psychological models contributing to chronic back pain. In this article, they discuss theoretical constructs, which explain the transition from acute to chronic back pain, with the exception of the psychoanalytic approach. In this approach, unexplained back pain is considered a conversion neurosis, a manifestation of underlying tension, and manifess as increased muscle activity and spasm. Using this model, various authors have suggested that pain of unexplained origin should be treated as depression with the use of antidepressant drugs. Another explanation for unexplained back pain advances the family system theory. In this approach, the basic idea is that "symptoms of the patient fulfill the emotional needs of other family members." They suggest that the sick role is used for conflict avoidance. Another theory that is advanced is the observational learning theory based on cognitive behavioral assumptions. In this model, the patient expresses feelings of helplessness aand hopelessness, and loss of control over his or her environment. Another theory, originally advanced by Flor, discusses the diathesis-stress model of chronic back pain. In this model, interactions lead to the development of chronic back pain. This is an attempt to integrate the physical, psychological, and social factors that lead to the development of illness. In this diathesis-stress model, hyperactivity of the back muscles may be due to (1) the existence of a response stereotypy (diathesis) involving the back muscles, (2) recurrent or very intense adverse situations perceived as stressful, and/or (3) inadequate coping abilities of the individual.

Another attempt to explain pain of unknown etiology utilizes the diagnostic manual of the American Psychiatric Association (1994). Reich, Rosenblatt, and Tupin (1983) have attempted to explain the use of this diagnostic system for chronic pain patients. They indicate that attempts to categorize chronic pain patients "merely in terms of the prime physical complaints has obvious shortcomings." They describe the prime physical complaints as having five categories, or axes, the Diagnostic and Statistical Manual of Mental Disorders (DSM-III), that correspond to five major areas of concern:

Axis I: used to describe thought disorders, such as schizophrenia and manic depressive disease, and drug abuse;

Axis II: used to describe personality characteristics

Axis III: used to describe medical diagnoses, or physical complaints;
Axis IV: used to describe the severity of psychosocial distress
Axis V: used to describe the highest level of functioning during the past year

Reich and colleagues (1983) feel that an entire category of diagnoses, "the somatoform disorders," can be used to categorize chronic pain patients, in whom there is a strong psychological component that could explain a pain unexplained by physical diagnosis. The major diagnosis within this group is "psychogenic pain disorder." The criteria for utilizing this diagnosis are (1) the absence of appropriate physical findings, and (2) the presence of psychological factors that may explain the etiology of the complaint. Attendant to this diagnosis are a variety of subjective assessments, such as the severity of the pain, the inability of the pain to conform with anatomical distribution, and, perhaps the most subjective assessment of all, that the severity of the pain be out of proportion to what one might anticipate. Further diagnostic categories under the somatic disorders include hypochondriasis and conversion disorder. In the former, the patient is concerned with the development of a severe, debilitating illness, despite the lack of objective findings. In this instance, the patient's concerns are considered inordinate because the organic condition was not substantiated. In conversion disorders, the physical condition suggests an underlying organic disease, but the basis of the illness is purely psychological. The authors then offer several examples of DSM-III diagnoses, in which the predominate features are highly subjective, and the use of words "inconsistent with physical findings" or "pain, etiology unknown," and prior surgeries with residual pain. The authors advocate the use of DSM-III taxonomy because it has achieved better reliability than previous psychiatric diagnostic systems.

With the advent of the Diagnostic and Statistical Manual of Mental Disorders, fourth edition, which was published in 1994, there have been some modifications to the approach to pain, with a wide range of options. At one extreme, there is a group of patients who actually fabricate symptoms for subconscious psychological, but not financial gain. These patients have factious disorders, with predominantly physical signs and symptoms (DSM-IV code 300.19) or with combined psychological and physical signs and symptoms (DSM-IV code 300.19). An entire chapter is devoted to "Somatoform Disorders," and contains a wide-ranging list. Included are Hypochondriasis (DSM-IV code 300.7), Somatization Disorder (DSM-IV code 300.81), Undifferentiated Somatoform Disorder (DSM-IV code 300.81), Conversion Disorder (DSM-IV code 300.11), Pain Disorder with several subtypes: Pain Disorder Associated with Psychological Factors (DSM-IV code 307.80), or Pain Disorder Associated with both Psychological Factors and General Medical Conditions (DSM-IV code 307.89). Most noteworthy is the addition of a concept of Pain Disorder Associated with a General Medical Condition, divided into acute (less than 6 months) or chronic (greater than 6 months). This category is not considered a mental disorder and is coded under Axis III to facilitate differential diagnosis, and then uses the ICD-9 codes of the medical disorder to classify the diagnosis. This is a major advance in psychiatric thinking; it advances the notion that chronic pain can produce psychiatric disorders, rather than the reverse. (APA,1994).

Integrated Response Model

The third approach to diagnosing chronic pain patients, utilizing an integrated response model, avoids the diagnostic dualism of the previous two models. In this model, an attempt is made to study the normal response to chronic pain in a previously well-adjusted individual, and then using these responses as a benchmark against which other responses can be measured. Only by thoroughly understanding the normal patterns of response can one determine what is abnormal. It is for this reason that a medical student studies anatomy before he or she studies pathology, physiology, or pathophysiology. This approach also attempts to integrate responses, taking into account physical, psychological, and environmental factors, including sociological and legal considerations. One such attempt at integration has been advanced by Richard Black, M.D. (1982). Black asserts that a patient with a chronic pain syndrome must be assessed simultaneously for physical, mental, and environmental factors. He believes that sociological and economic factors rarely get considered, except when litigation is involved.

In an effort to further clarify this issue, Hendler and Talo (1989a) offer a diagnostic system that takes into consideration (1) the pre-morbid (pre-pain) adjustment of the individual (pathological or well-adjusted), (2) the response to the pain (pathological or appropriate), and (3) the actual physical diagnosis (the presence or absence of objective findings). Central to this formulation are two basic concepts:

1. Chronic pain can create psychological problems in a previously well-adjusted individual
2. Regardless of the pre-morbid (pre-pain) personality characteristics, if a person has a normal response to chronic pain, then the chances of a valid organic basis for the complaint of pain are quite high. This would be true even in the absence of objective laboratory studies or physical finding. Restated for emphasis, if a patient's response to pain is appropriate but there are no objective physical findings, it is incumbent upon the physician to keep looking for the organic basis of the patient's complaints.

Hendler (1981) has divided chronic pain patients into four groups, based on the three factors mentioned previously; that is: (1) pre-morbid adjustment, (2) response to pain, and (3) the presence or absence of objective upon physical findings in laboratory studies or physical examination. These four categories are:

1. Objective pain patient, defined as an individual with:
   a. Good pre-morbid adjustment,
   b. Normal response to chronic pain
   c. A definable organic lesion
2. Exaggerating pain patient, defined as an individual with:
   a. Pathology as part of a pre-morbid adjustment
   b. An unusual response to pain, in that there might be an absence of anxiety, or depression
   c. Minimal organic findings
3. An undetermined pain patient, defined as an individual with:
   a. Good pre-morbid adjustment
   b. A normal response to pain
   c. An absence of objective physical findings or physical examination (it is this individual who warrants further investigation)
4. Affective or associative pain patient, defined as an individual with:
   a. A poor pre-morbid adjustment
   b. An unusual response to chronic pain
   c. A total absence of objective physical findings or positive laboratory studies

By studying the normal response to chronic pain, one can then compare any patient against a known standard. In this case, the objective pain patient serves as the "normal" model against which all other responses to chronic pain should be judged. The objective pain patient has a good pre-morbid adjustment, which can be defined (Hendler, 1982a) as:

1. A good work record
2. A stable family background
3. A negative psychiatric history, with no previous suicide attempts or depression
4. The absence of alcohol or drug abuse
5. A good marital history
6. Lack of financial difficulties prior to the pain
7. A good sexual adjustment
8. No sleep difficulties
9. No radical changes in weight, other than conscious attempts to change it
10. The absence of any anti-social or sociopathic behavior

Hendler (1982b) further expands upon the objective pain patient, indicating that this individual goes through four stages in response to the chronic pain:

1. The acute stage, anywhere from 0 to 2 months, is when the individual expects to get well and has no psychological problems. Psychological testing administered during this time is within normal limits.
2. The subacute stage, which occurs anywhere from 2 to 6 months, is when the individual begins to experience somatic concerns and may have elevated Scales 1 and 3 on the Minnestoa Multiphasic Personality Inventory (MMPI).
3. The chronic stage of chronic pain occurs anywhere from 6 months to 8 years after the acquisition of the pain. The previously well-adjusted individual then develops depression and has elevated scales 1, 2, and 3 on the MMPI, with Scale 2 depression being higher than Scales 1 and 3 (hypochondriasis and hysteria).
4. The subchronic stage of chronic pain occurs anywhere from 3 to 12 years after the acquisition of the pain, during which time the depression resolves, but hypochondriacal and hysterical Scales of the MMPI remain elevated as one might expect, because the patient still has somatic concerns.

If all of the above occurs in an individual with a definable organic lesion and with positive objective testing, then one categorizes this type of patient as an objective pain patient. If all of the above psychological features are present, but no objective testing is positive, then one considers this individual an undetermined pain patient who still needs further medical investigation (Hendler, 1981).

To facilitate diagnosis using the four categories described previously, Hendler and co-workers (1985b) have devised the Mensana Clinic Back Pain Test. Using a simple, 15-question screening test, chronic pain patients can be divided into the four diagnostic categories, as described by Hendler. The screening test had good predictive values because women scoring in the objective pain patient category (17 points or less) had positive findings on electromyogram (EMG), nerve conduction velocity studies, thermography, CT scan, myelogram, or X-ray 77% of the time. If women scored in the exaggerating pain patient category (21 points or greater), none of the 53 women studied had objective physical findings, which is in counter-distinction to the MMPI, which had a great deal of scatter, with only the Depression Scale correlating with all with the absence or presence of physical findings. Hendler, et al., (1985a) also published results for the predictive volume of the test for men, showing that in 31 men there was a 91% chance of organic pathology if the patient

scored in the objective pain patient range. Overall, the predictive value of the test was 85% (Hendler, Mollett, Talo, & Levin (1988). The usefulness of the four diagnostic categories for chronic pain patients is highlighted by the ability to predict the presence or absence of objective physical findings, based on the pre-morbid adjustment to the response to chronic pain and the description of the pain itself. The fact that the MMPI, which measures personality traits, was not a useful predictor of organic pathology lends support to the belief that personality characteristics and physical abnormalities are independent events, which reduces the accuracy of the DSM-III diagnostic manual, for validating the complaints of pain (Hendler and Talo, 1989a).

Patients with chronic pain are often misdiagnosed. This is neither a local nor regional phenomenon. Data from research reports from the Mensana Clinic, in Stevenson, Maryland, reflect a national picture because 75% of the referrals to the Clinic are from 42 states and 8 foreign countries. Hendler and Kozokowski (1993) and Hendler, Bergson, and Morrison (1996) found that 40 to 67% of the patients referred to Mensana Clinic arrived with overlooked physical diagnoses, which were later diagnosed and treated at Mensana Clinic. Failure to have a diagnosis for medical conditions, and even worse, having a psychiatric diagnosis assigned to a patient to explain the symptoms, leads to frustration, resentment, and certainly a well-justified psychological response in a previously well-adjusted individual. In these instances, chronic pain certainly leads to depression, as described previously. Moreover, after the proper diagnoses are found at Mensana Clinic, 50 to 55% of the patients are referred for surgery. Finally, once proper diagnosis and treatment are obtained, the patients get better. This is amply demonstrated by objective measures such as return to work rates. Liberty Mutual, one of the largest workers' compensation insurance carriers in the U.S., reports that when a claimant is out of work for 2 years or more on a workers' compensation claim, the return-to-work rate is less than 1%. At Mensana Clinic, for the same group of patients, the return-to-work rate is 19.5% for workers compensation patients and 62.5% for auto accident cases (Hendler, 1989). This is in stark contrast to the results of the more psychologically and behaviorally oriented pain treatment centers, very few of which have any published statistics on these outcome measures.

The preceding lengthy preamble regarding the psychiatric diagnosis is critical in defining the role of a psychiatrist in treating chronic pain patients. It is essential to have a diagnosis of an individual before instituting the therapy. By offering a clinician a variety of diagnostic systems from which to choose, the selection of appropriate therapy becomes a less formidable task. Whether one strictly adheres to DSM-IV diagnoses or less conventional diagnostic systems is a matter of which system gives the best results in the hands of a particular practitioner. This should facilitate selection of an appropriate therapy. Although many types of psychotherapy are available, treatment results are not well documented for any of the forms of therapy. This chapter deals with the more conventional modalities, such as

1. Individual psychotherapy
2. Biofeedback
3. Family therapy
4. Group psychotherapy
5. Pharmacotherapy
6. Narco-synthesis
7. Hypnosis.

PSYCHOTHERAPY

Very few reports in the psychiatric and medical literature support the contention that individual psychotherapy is a useful treatment for chronic back problems, or pain of any sort. For the purpose of definition, one should consider psychotherapy as an individual session, conducted between a patient and a therapist without the use of specialized techniques, such as hypnosis, biofeedback, or narcosynthesis. Likewise, group psychotherapy (or conditioning therapy) is separate and distinct from individual, insight-oriented, dynamic psychotherapy. When one imposes these parameters on the definition of psychotherapy, reports on its efficacy are sparse indeed. However, some components of individual psychotherapy have therapeutic benefits, although it is difficult to substantiate their efficacy. Prutrick (1981) reports that psychotherapy can be effective if the therapist directs his or her activity toward understanding the 'psychosomatic' personality, which is described as those individuals who (1) have difficulty with psychological thinking, (2) have difficulty expressing emotion, and (3) are impulsive.

Very often, psychotherapy is administered in conjunction with other modalities of therapy. As such, eclectic studies employing numbers of interventions provide some evidence for the usefulness of comprehensive treatment programs. However, the lack of control groups, the lack of a comprehensive pain assessment, and the uncertainty about the effective component do not allow definite conclusions to be drawn. Here too, a wide variety of patients have been treated with a lack of or widely divergent sample descriptions. It needs to be determined which patients profit from what treatment. Component analysis of eclectic and cognitive behavioral treatments are needed to determine the effective interventions and thus reduce cost and treatment time and enhance the effectiveness of the treatment (Turk & Flor, 1984).

One element of psychotherapy, which is present whether an individual therapist recognizes it or not, is the component of modeling. This process occurs when

patients observe another person with chronic pain who is functioning despite their physical damage. This other individual serves as a model for the patient's behavior and straddles the bridge between individual psychotherapy, and behavioral therapy. Some therapists have used videotapes of patients in pain coping with their problem, while others have used a directive approach, actually instructing a patient about which behaviors are acceptable and which are not (Webb, 1983).

BIOFEEDBACK

The use of biofeedback as a modality for assisting patients with chronic pain has created much controversy. Some authors feel that biofeedback does not offer any advantage over relaxation techniques, and attributed its efficacy to its placebo effect (Webb, 1983). Other authors have conducted a more comprehensive review and concluded that EMG biofeedback may be a promising treatment modality for chronic back pain (Turk & Flor, 1984). In their most evenhanded review of biofeedback techniques, Turk and Flor report only the results of EMG biofeedback. This modality seems to have the most usefulness for patients with muscle tension-type pain. Turk and Flor found that there were three types of reports in the literature: (1) anecdotal or systematic case studies, (2) group outcome or comparison studies, and (3) controlled group studies. The efficacy of EMG biofeedback was further complicated by the fact that in a review of over 20 articles, all researches — save one — utilized concomitant medication, and not biofeedback exclusively. In the two controlled studies reviewed by Turk and Flor, both showed strong effects of EMG biofeedback on reducing pain and tension levels. In one study, a decrease of 60% in pain intensity and duration, as suffered by the patients, was noted. As expected, as muscle tension levels drop, pain intensity also drops. However, interestingly, at 3-month follow-up, although muscle tension increased, pain reduction was maintained. In the other study reviewed, EMG biofeedback was compared to medical treatment and "psychotherapy". In this study, conducted by Flor and coworkers, they found that EMG biofeedback was more efficacious than psychotherapy and control groups receiving just medical treatment alone. They noted that EMG readings decreased and the patients sought less medical attention when utilizing EMG biofeedback. Turk and Flor concluded that muscle relaxation alone does not necessarily contribute to the beneficial effects of EMG biofeedback, but rather that a cognitive process is important. Hendler, et al. (1977) attributed EMG biofeedback effectiveness to other factors. In their study, they found two groups of patients: (1) those who responded to biofeedback and (2) those who did not respond to biofeedback. In this study, 13 patients were evaluated using EMG biofeedback. Six of the 13 reported that they had less pain in at least 4 out of 5 days of EMG biofeedback training, but 11 of the 13 were unable to alter EMG biofeedback in the affected muscle group. EMG relaxation consisted of reduction of muscle tension in the forehead. Therefore, one might conclude that specific muscle relaxation was not the therapeutic component of the EMG biofeedback. There were no significant differences between either the starting EMG muscle tension levels or the final levels between the two groups. However, the response rate (i.e., 6 out of 13) was double what one might expect from a placebo response alone on a consistent basis (Hendler & Fernandez, 1980). The difference between the two groups was thought to be due the stage at which the patient was in his or her chronic pain process; that is, whether they were in the acute stage, subacute stage, chronic stage, or subchronic stage. The difference between the patients who responded and those who did not respond was the presence of depression in the responders. Those who did not respond did not have elevated depression scales, using the SCL-90.

Another component that might contribute to the efficacy of biofeedback therapy is the issue of the patient's motivation or preparedness for change (Large, 1985). Large utilized a measure for "illness attitudes" in an effort to determine which patients might respond to therapeutic interventions. He used an illness behavior questionnaire, developed by Pilowsky and Spence, and expanded upon this by using a repertory grid technique, which has been described by Bannister and co-workers. Seven of the 18 patients did not experience overall relief of symptoms, while 11 did. In this report by Large (1985), 48 ratings were analyzed to determine the discrepancy between how patients perceived themselves, and how patient wished they would be. Correlating these findings with response to biofeedback showed that people who were dissatisfied with their condition (i.e., chronic and persistent pain) were more likely to respond well to biofeedback.

FAMILY THERAPY

The role of the family in the maintenance of chronic pain behavior may be one factor to consider when dealing with treatment failures. The poorest outcome among patients with chronic pain was found in families with the greatest degree of agreement when rating the severity of the patient's pain (Webb, 1983) Webb interprets this as "tertiary gain", indicating that the pain is maintained because of the psychological importance to other family members. A more likely explanation is the fact that a person with severe debilitating disease would have difficulty concealing the deficit from the family members and that they would be in agreement with his assessment of the pain. Webb describes family studies in which it is clear that the spouse and children of patients with chronic pain experi-

ence distress, as might be expected. This is particularly true in families where the patient is unemployed, while less so in families where the patient is retired. Webb (1983) feels that families can reinforce the pain and worsen the prognosis.

A more empathetic study involved that of the spouses of chronic pain patients. Two nurses (Rowat & Kna 1985) studied the impact of pain on 40 spouses of chronic pain sufferers (21 males and 19 females). They found that 60% of the spouses were uncertain as to the cause or persistence of the pain in their partners. Additionally, 83% of the spouses reported experiencing emotional, physical, or social disturbances that they directly attributed to the pain in their spouses. And 69% of the spouses felt that they were experiencing emotional difficulties as a result of their partner's pain. The most frequent forms of emotional disturbance were sadness or depression, fear, irritability, and nervousness; 40% of the spouses reported that there was a sense of helplessness because they were unable to effect any change in their partner's pain, and they were uncertain about how to proceed in doing so. They expressed feelings of loss of control. Some 75% of the spouses felt that they could delineate which factors influenced their mate's pain, such as increased activity that reduced or increased the pain, and medications reducing the pain.

In a very fine review article, Payne and Norfleet (1986) examined the factors influencing family relationships and believe that certain family characteristics and behaviors contribute to the problem of chronic pain, as well as influencing outcome. In their review, Payne and Norfleet found that some authors believe that there might be a relationship between the maintenance of pain and large family size. The rationale for this is obvious. In a large family, one of the only ways to get attention and reduce tension would be the expression of disability or invalidism. Some authors have reported that the majority of their patients come from families with four or more children. Birth order was also considered as a factor influencing the complaint of pain. One author found that the youngest or the oldest child complained, while another author found that the complaint of pain might even effectively reduce tension for younger children in large families. These findings have not been supported by other authors.

Socioeconomic status may also influence the expression of pain. The fact that a majority of pain patients are blue-collar workers has been interpreted as the inability of working-class people to express emotional conflict, thereby using somatizing terms. Of course, one must take into account that there are probably more blue collar workers than there are professionals, and it is the blue-collar workers who have the physically strenuous jobs that put them at higher risk. Other equivocally substantiated theories have been offered, such as the quality of relationships with parents, early loss of a family member, maintenance of pain or illness in the family, and location of the pain corresponding to that of the family member. Depression in the family member has also been explained in psychodynamic terms, which are equally as difficult to substantiate. No doubt, patients with chronic pain have reduced sexual activity and poor sexual adjustment, which may contribute to poor marital relationships. Unfortunately, the majority of studies in this area discuss only the patient, and they appear at the time that they are seen by the physician, without an adequate historical perspective. One questions whether or not marital difficulties develop as the result of the chronic pain, or if marital difficulties predated the chronic pain and if the chronic pain became a convenient excuse to avoid further sexual contact. When chronic pain patients with depression were compared to patients with just depression, the former group had a more disturbed marital relationship than the latter. In another study, pain patients with no documented organic lesion were found to have more frequent "upsets, blows, conflicting interests, or separation" than those patients with definable organic lesion. Payne and Norfleet (1986) further report that 91% of couples interviewed at the Chronic Pain Treatment Center reported sexual problems and a decline in their social lives since the onset of their pain problems. This was confirmed by other researchers. The authors conclude that studies on marital relationships involving chronic pain patients consistently indicate high rates of sexual and marital maladjustment, even in previously stable relationships. However, they also advance the notion that the family can maintain the pain of an individual patient. Based on Payne and Norfleet's review of the literature, they feel there are four factors that contribute to the persistence of chronic pain in a patient:

1. The patient's pain is an expression of dysfunction within the family system, and it is easier to utilize the complaint of pain rather than say there are difficulties with the relationships.
2. The family acts as a reinforcer for pain behavior by nurturing and caring for the injured member.
3. The patient may use the symptom of pain to control his or her family members and is reinforced when this works.
4. The stresses of family life may produce physiological effects that predispose an individual to stress and disease.

The review article considers the three approaches to family therapy: (1) behavioral, (2) transactional, and (3) systems approach of structural family therapy. The behavioral approach has been discussed in previous chapters in this volume. The transactional approach tries to make family members aware of the ways a patient can use pain for psychological "payoffs" and how they might foil these attempts. The systems approach deals with the family as

an organization and tries to change the structure so that no one family member has to be in the sick role. Most articles report that family therapy is a combination of behavioral, transactional, and systems approaches. Unfortunately, it is quite difficult to assess the efficacy of family therapy. However, follow-up studies designed to reassess the recurrence of symptoms are the best way to determine efficacy. One study, conducted at the Northwest Pain Center, compared 25 successful patients with 25 patients who did not maintain gains made at the pain treatment center. Interestingly, they found that there were more divorced or separated people in this success group, while the failure group had done little to change the patterns of behavior in their environment. They concluded that the role of the family in maintaining pain behavior contributed to the failures. Payne and Norfleet (1986) concluded that family members contribute to treatment outcome by reinforcing or not reinforcing pain behavior. They suggested that if a patient has a family that is appropriately supportive, and has learned not to reinforce pain behavior, the chance of success with pain treatment is greatly improved. If family members have not participated in the program, or resist change to their own behavior, then the family member with pain will probably persist. When compared to these resistant family groups, a single (unmarried) pain patient will probably have a better chance at success although they do not have family support.

GROUP PSYCHOTHERAPY

Group psychotherapy has been an adjunctive treatment for patients with terminal disease, rheumatoid arthritis, and chronic, intractable benign pain. These three groups of patients share four common features (Hendler, Viernstein, Shallanberger, & Long, 1981):

1. They have not had success with conventional therapy.
2. They feel isolated and burdensome to their family and friends.
3. They are angry at physicians and disappointed about treatment failure.
4. They have reactive depressions, frustration, and reduced physical activity.

Group therapy can be utilized on both an inpatient and outpatient basis, although the structure and format for these two groups is somewhat different (Hendler, 1981). In the inpatient setting, the patient is involved in group therapy for a relatively short period of time, usually 8 to 12 sessions. In this context, the group psychotherapy format more closely resembles a mixture of educational and free-interaction group psychotherapy, with more of a focus on the depressive components of the chronic pain process. The most common themes of inpatient groups deal with depression and frustration including (Hendler, et al., 1981):

1. The feeling that treatment in a pain treatment center is a last resort
2. Expression of displeasure and anger toward physicians for not helping
3. A willingness to do anything to get rid of the pain
4. A feeling of helplessness and guilt, compounded by feelings of inadequacy and frustration because of an inability to function with the pain
5. Indications about the relationship between the patient and his or her family that clearly indicate whether the family is supportive of the patient behavior, or in conflict with it
6. A questioning of religious faith and the selection process (why me?)
7. Explorations regarding feelings of dependency,
8. Resentment towards the disbelief of family members, physicians, and associates
9. A fear about the origin of the pain and its progression

These same authors then described outpatient group therapy that was more protracted and allowed exploration of different themes including:

1. Feelings of physical inability or handicaps
2. Resentment toward vocational rehabilitation
3. Difficulty in readjusting life goals
4. Concern about other group members
5. Frustration regarding the slowness of the process of rehabilitation
6. Fear regarding the loss of a spouse because of the chronic pain

As with all forms of psychotherapy, it is difficult to access the efficacy of group treatment. However, Ford (1984) utilized an objective measure of efficacy (i.e., the amount of medical care sought by patients prior to and after group psychotherapy) and reviewed the literature on this topic. Ford offers a cogent argument for psychotherapy — if it able to reduce the number of medical visits, on a cost-effective basis, if for no other reason. Various authors have reported between a 50 and 75% reduction in medical clinic visits while patients with somatic illness were undergoing group psychotherapy concomitantly. Ford's own experience was not quite as dramatic, but he attributes this to patients belonging to a low socioeconomic group, and underscores the need for very long-term group treatment before any benefit was noted. The most important patient benefit appeared to be in the area of gaining control over his or her life. Other authors have advanced the notion that "peer modeling" and "interaction with other group members" allow patients to more freely

express their emotions, to learn new coping methods, and to be more verbal when soliciting help (Gamsa, Braha, & Catchlove, 1985). Although these authors conclude that group psychotherapy is a useful adjunct to their chronic pain treatment program, they do not offer any objective evidence. Hendler, et al. (1981) studied patients assigned to group therapy or individual therapy. In their study, 8 of the 11 patients assigned to group therapy had remained in therapy, and 7 of the 8 had abstained from narcotic and hypnotic use. This was contrasted with a group of 12 patients, 7 of whom continued to use hypnotics, narcotics, or benzodiazepines prescribed by other physicians. At the end of 3 months, 6 of the 12 had discontinued sessions. A much more comprehensive report (Hall, Hall, & Gardner, 1979) compared the efficacy of combined group therapy and tricyclic antidepressants vs. supportive individual therapy, analytically oriented therapy, and management by surgical specialists, using narcotics or antidepressants. Using the Zung Rating Scales as an indication of the severity of depression, Hall's group found that group psychotherapy combined with tricyclic antidepressants was the most efficacious modality of therapy, while individual psychotherapy and surgical management, using narcotics or antidepressants, were least effective.

Although it is difficult to accurately assess the efficacy of group therapy, and many reports do not have objective measures of outcome, the technique is cost-effective and provides a degree of modeling and social reinforcement that is not available from other forms of therapy. The effectiveness of other self-help groups, such as Alcoholics Anonymous, would lend credence to the contention that group therapy is an effective modality for treating chronic pain patients.

NARCOSYNTHESIS

Several recent articles in the psychiatric literature, as well as in the chronic pain literature, suggest that many undiagnosed chronic pain problems are really conversion reactions or hysterical conversion disorders. Most of these articles are unsubstantiated, or deal with single cases or a few cases, after which the authors attempt to apply their limited experience to the broad range of chronic pain patients. In reality, the number of conversion disorders presenting as chronic pain problems is probably very small. In this author's experience (more than 25 years), after treating over 7000 chronic pain patients at the Chronic Pain Treatment Center of Johns Hopkins Hospital, while under the direction of the Department of Neurosurgery, and at the Mensana Clinic, the incidence of hysterical conversion disorders was three cases. Of course, these cases are quite memorable and represented enormous therapeutic challenges.

One must be quite careful in making the diagnosis of hysterical conversion reaction. In one of the classic studies, Slater (1965) did a 9-year, follow-up study on 85 people originally diagnosed as having hysterical conversion reaction, who had been seen at the Queens Square Hospital in London. At the time of follow-up, only 19 of the 85 patients were free of symptoms. Of these 85 patients, 7 were found to have recurrent endogenous depression, 2 were schizophrenic, 3 had undetected neoplasms, and of the 4 who committed suicide, 2 had atypical myopathy and disseminated sclerosis. Each died of natural causes. Two of the patients were found to have trigeminal neuralgia and one woman was finally diagnosed as having thoracic outlet syndrome. Three people were finally diagnosed as having early, previously undetected, dementia, while one woman, who had pain in the right shoulder and arm, was later diagnosed as having Takayasu's syndrome. The remainder had a multiplicity of organic diseases, including epilepsy, vestibular lesions, and total block of the spinal cord. Of the 85 patients with the original diagnosis of "hysteria" meaning conversion reaction, only 7 were really found to have an acute psychogenic reaction resulting in formation of a conversion symptom, while 14 were diagnosed as having Briquet's syndrome, which is a polysomatic hysterical neurosis more compatible with hypochondriasis, or somatizing disorders.

In a most thorough review of the literature, encompassing nearly a 50-year period of time, Stephens and Kamp (1962) found that the incidence of hysterical conversion reaction at a psychiatric hospital (Phipps Clinic of Johns Hopkins Hospital) was approximately 2% of all psychiatric admissions. Therefore, one must be quite cautious in assigning the diagnosis of conversion neurosis, or hysterical conversion disorder. Additionally, many clinicians have difficulty differentiating between histrionic personality disorders, and hysterical personality disorder resulting in many somatic complaints, which has been called Briquet's syndrome. These two disorders are different from a hysterical conversion reaction because the last of these three disorders can occur in a previously well-adjusted individual subjected to extreme stress (Hendler, 1981). A review of histrionic personality disorders vs. hysterical, polysomatic Briquet syndrome vs. hysterical conversion reactions vs. malingering can be found in Hendler's book (Hendler, 1981). Also, Hendler and Talo (1989a) published a chapter in which the differential diagnosis of these disorders is summarized.

If hysterical conversion reaction is suspected in the differential diagnosis, amobarbital narcosynthesis can be quite useful in assisting in the diagnosis. One of the leading proponents of this technique, Dr. Walters (1973), of the University of California School of Medicine, has recommended dosages between 200 and 500 mg, taking a patient through the surgical pains of anesthesia, including loss of corneal reflex, which produces full relaxation of "psychogenic tissue pain." Indeed, using too small a dose of amobarbital may contribute

to many of the failures associated with the lack of effectiveness of this technique (Hendler, Filtzer, Talo, Pantzetta, & Long, 1987). In fact, Hendler and co-workers specifically found that a diagnostic failure, using amobarbital narcosynthesis, was directly related to an inadequate dosage of amytal (dosage range 200 to 250 mg). When the dosage was increased to between 450 and 600 mg, effective narcosynthesis was obtained.

HYPNOSIS

When considering hypnosis for the patient in pain one must make a distinction between acute pain and chronic pain. There is no question that hypnosis is an effective treatment for acute pain problems. Scott (1974) has discussed the usefulness of hypnotic techniques for treating badly burned patients and for surgical candidates. However, even Scott admits that the effectiveness of this technique is variable and unreliable. In theory, hypnosis can be used to treat the patient with acute pain, by altering his or her perception of the amount of time the pain is experienced. In this fashion, Teitelbaum (1965) has proposed that hypnosis can be used for hypnoanalgesia and calls this phenomenon "time distortion".

For chronic pain states, generalized relaxation therapy as described by Jacobson (1964) seems to be quite useful. As with biofeedback, hypnotic relaxation techniques seem to work best with chronic pain patients who have myofascial pain or chronic muscle tension. Unfortunately, it is difficult to assess the efficacy of hypnosis, especially in chronic pain states, and the technique does not lend itself to controlled studies. The question of the efficacy of hypnosis with chronic back pain awaits controlled empirical research (Turk & Flor, 1984). The major objection to hypnosis lies in the fact that it might provide temporary relief for the patient with chronic pain, but long-term relief has not been adequately documented. However, hypnosis may be a useful diagnostic tool for uncovering underlying hysterical conversion reactions, although it may be less than narcosynthesis, as previously discussed.

DIAGNOSIS AND TREATMENT OF DEPRESSION

No discussion about the psychotherapy of chronic pain patient would be complete without a thorough understanding of the depression associated with chronic pain. One of the major difficulties one encounters in diagnosing chronic pain patients with depression pertains to the etiology of the depression. France and Krishnan (1985) make a distinction between despondency, or grief reaction in response to serious physical disease, and depression, stating that despondency is similar to grief reaction and must be differentiated from depression in chronic pain states (Krishnan, et al., 1985). France and co-workers believe that one can differentiate various subtypes of depression in chronic low-back pain patient, and distinguish between (1) major depression, (2) minor depression, (3) intermittent depression, (4) chronic low back pain patients without depression. One way of making this distinction is the use of the dexamethasone suppression test. The former chairman of the Department of Psychiatry at Duke University, Bernard Carroll, first advanced the notion of elevated plasma cortisol, resistant to suppression by dexamethasone, in severe depressive illness (Carroll, Martin, & Davies, 1968). Subsequent to this original article in 1968, Carroll and co-workers published extensively about the use of the dexamethasone suppression test. Randall France, formerly of Duke University, and later the University of Utah, studied a group of 80 chronic back pain patients, with and without depression, using the dexamethasone suppression test (DST) (France & Krishnan, 1985). France and co-workers selected a uniform group of chronic low-back pain patients, that is, those with chronic low-back pain associated with organic pathology, and divided them into two groups based on the presence or absence of major depression, using DSM-III criteria. They then examined the cortisol response to dexamethasone in each group. Of this group of 80 patients, 35 patients were diagnosed as having major depression, while 45 patients did not satisfy the criteria for major depression. However, of the 45 patients who did not have major depression, 10 satisfied the criteria for dysthymic disorder. In the group of patients with the diagnosis of major depression, 14 of the 35 had a positive dexamethasone suppression test, while none of the 45 patients who did not have major affective disorder had a positive dexamethasone suppression test. Again, of this group of 45 patients, 10 were diagnosed as having a dysthymic disorder, which might be more appropriately described as reactive depression. France very appropriately concluded that the abnormal dexamethasone suppression test is in response to a major depressive disorder, and not to chronic pain itself. Additionally, France noted that the incidence of anormal cortisol response to dexamethasone is higher in depressed patients without organic findings. As a conclusion, France and co-workers stated that the "difference in the rate of non-suppression in chronic back pain patients with and without depression suggests that the notion of conceptualizing chronic back pain as a variant of depression or as a marked (sic) (masked) depression might be an oversimplification" (France & Krishnan, 1985).

In another study of 63 patients, conducted at the University of Washington Pain Clinic, 49% of the sample met the DSM-III criteria for major depression (Haley, et al., 1985). In this study, depressed patients did not differ significantly from nondepressed patients in the ratio of male vs. female, use of narcotics, use of sedative-hypnotics or antidepressant medication, number of years in chronic

pain, age, or number of surgeries. However, for women, depression was more closely related to subjective reports of pain; while in men, depression was more closely related to impairment of activity. In a review of 454 chronic pain patients at Columbia-Presbyterian Medical Center, Department of Anesthesiology Pain Treatment Service, NewYork, 100 patients were selected at random, and eventually 82 patients were contacted by telephone for long-term follow-up of a sub-sample of the original number of patients (Dworkin, Richlin, Handlin, & Brand, 1986). In evaluating the original 454 chronic pain patients, 79 of these patients were found to be depressed, while 375 were not considered depressed. Between the two groups, there was no significant difference in the percentage of males, females, age, marital status, education, or compensation. The only significant differences existed between the percentage of patients undergoing litigation or being employed. The depressed patients had a higher percentage of litigation and a lower percentage of employment when compared with nondepressed chronic pain patients. When compared with pain-related characteristics, chronic pain patients with depression more often had constant pain, and a higher self-reported scale of pain than the non-depressed patients. In non-depressed patients, significant variables contributing to the ability to predict treatment outcome were number of treatment visits, compensation, number of previous therapies, and the location of pain. In depressed patients, the predictors of treatment outcome were employment and duration of pain.

Atkinson and his group in San Diego have defined three subgroups of chronic pain patients based on MMPI scores and the type of depression they experience (Atkinson, Ingrani, Kremer & Saccuzzo, 1986). Using Research Diagnostic Criteria, Atkinson, et al. found that 44% of the 52 patients examined had major depression, 19% had minor depression, 13% had other psychiatric disorders, and 22% had no mental disorder. Patients with a major depression were found to have a discrete MMPI profile, with Scales F, Hs, D, Hy, Pd, Pa, Pt, Sc, Ma, and Si being significantly higher, and Scale K being significantly lower than the other three groups. The best predictors were Scales Sc, Pt, and D. When the patients were divided by clinical characteristics of somatization, depression, or hypochondriasis, patients with major depression fell into three depression MMPI profile groups (2, 1, 3, for rank order elevation of MMPI scales, or D, Hs, Hy). Despite these distinctions, there was an even distribution of objective evidence for pain across all MMPI subgroups. This supports the contention that Hendler, et al. (1985a,b) have long maintained, that is, the MMPI cannot predict the validity of the complaint of pain, and patients with psychiatric problems can also have real physical problems at the same time.

By using a psychiatric diagnostic system for delineating the various types of depression in chronic pain patients and adhering rigorously to DSM-IV diagnostic criteria, one can identify a group of chronic pain patients who will respond to interventions for depression. There is no doubt that the use of antidepressant medication in the chronic pain patients with major depression will prove the most efficacious modality of therapy. To appropriately prescribe medication, physicians should understand the pharmacological contributions to normal sleep, pain perception, anxiety, and depression. A review of the literature, Hendler (1982a) describes the common pharmacological substrate of normal sleep, pain perception, and antidepressant activity within the central nervous system as being elevation of serotonin levels. Therefore, drugs that enhance serotonin activity within the central nervous system are beneficial, and these include tricyclic antidepressants as well as the newer bicyclic and tetracyclic antidepressants. Thus, an antidepressant given at bedtime may promote natural sleep, reduce the perception of pain, and reduce anxiety and depression. Unfortunately, the selective serotonin reuptake inhibitors (SSRIs), which would be thought to be ideal for augmenting the treatment of pain, have not been as effective as the tricyclic antidepressants (Hendler, 2000). Moreover, there seems to be a paradoxical worsening, or even creation of anxiety with the use of certain SSRIs, in certain sensitive individuals (Hendler, 2000).

Antidepressant dosage should be individually tailored to suit the patient's age and tolerance for medication, but as a starting dose, one might recommend 50 to 100 mg amitriptyline, or doxepin, in patients who are both anxious and depressed, while one might consider using nortriptyline or desipramine at dosages between 25 and 75 mg in patients who are depressed and report lack of energy or a feeling of sluggishness. Dosage can be escalated in 25- to 50-mg increments, depending on the patient's response to the medication. It should be noted that the anti-anxiety effects of medication usually occur within the first 2 days, as does enhancement of sleep. However, it usually take 2 to 4 weeks before the antidepressant effect of these medications are fully appreciated. This seems to correlate well with the amount of time it takes for the down-regulation of the post-synaptic serotonin receptors (Hendler, 2000). If the use of antidepressants does not prove productive by the end of 4 weeks, therapeutic monitoring, using serum levels, will allow adjustment of the dosage into the proper range.

The use of specialized treatments for depression, such as monoamine oxidase inhibitors or electroconvulsive therapy, is best left in the hand of psychiatrists, and the selection of patients for these types of therapies should be done only after psychiatric consultation has been obtained.

RESULTS

Describing a pain patient can be likened to the famous fable of the five blind men describing an elephant for their king.

Each clinic, each physician, and each hospital sees a different type of patient. Therefore, to assess results properly, the demographics of the chronic pain patient population under study must be defined. On this point, the literature is in shambles. Even more chaotic is the reporting of results.

Few, if any, individual psychiatrists have published any results documenting the efficacy of their intervention. Reporting is hampered by the absence of objective criteria for improvement. What parameters should be measured to determine if a patient has benefited from the intervention of a psychiatrist? How do you measure pain? Is pain relief or improved activity the desired goal? Can they exist independently? How long has the patient had pain? Is litigation involved?

Hendler and Talo (1989) reviewed the literature of chronic pain clinics that had published results of treating their pain patient population. Most clinics were either multidisciplinary or behavior modification clinics. Of note, 1 year after discharge from the clinic, most clinics reported that only 25% of their patients had maintained the improved level of activity they had experienced at discharge from the clinic. Pain relief ranged from slight to great in only 33 to 63% of the patients. That is, only about half the patients experienced any relief, even slight relief, and only 25% maintained any improvement in their level of activity (Hendler & Talo, 1989a). Using a more objective set of criteria, Hendler (1989) reviewed 60 patients who had been diagnosed and treated at the Mensana Clinic. All 60 patients were involved in litigation and had been out of work an average of 4.9 years. By all accounts, this group of patients was considered to be difficult to treat because of the involvement of litigation and the chronicity of their problem. Although 90% of the patients had no difficulty discontinuing narcotics, hypnotics, and/or tranquilizers, only 50% had pain relief, but 91% improved their sleep and levels of activity. However, the most startling statistic was the number of undiagnosed surgical problems; 50% of the patients were referred on for further surgery (one to four additional operations) because they had not been properly diagnosed before referral (Hendler, 1989). Subsequent reports by Hendler and colleagues show that 40 to 67% of the patients are misdiagnosed, and the referral to surgery rate is 50 to 55% (Hendler & Kozokowski, 1993; Hendler, et al., 1996). Referral diagnosis was very often a vague or descriptive one in 41% of the cases (25/60), with such terms as "psychogenic pain," "pain neurosis," "low-back pain," "chronic muscle strain," etc. being used instead of any attempt at diagnosis. Because 96% of the referrals came from orthopedic or neurosurgeons, internists, rheumatologists, and physical medicine and rehabilitation medicine physicians, the failure to diagnose surgically correctable lesions is especially troubling. This was not a local or regional phenomenon because 75% of Mensana Clinic patients came from around the country (43 states and eight foreign countries, as of the year 2000. Therefore, the need to accurately diagnose patients, both medically and psychiatrically is of paramount concern for the psychiatrist. The psychiatrist cannot rely on the medical diagnosis of nonpsychiatric physicians. If he or she feels the patient merits further diagnostic evaluations, it is incumbent upon the psychiatrist to order additional diagnostic studies and to obtain consultation with top-quality surgical colleagues.

THE PSYCHIATRIST AS EDUCATOR

Patients with chronic pain are frightened because, very often, they do not know or understand what is wrong with them. Once an accurate diagnosis has been established, the psychiatrist should explain in simple and concise terms—the anatomic origin of the pain problem, the options for treatment, the expected treatment outcome, and alternatives to treatment. Chronic pain is a devastating problem; but once a patient is fully informed about his or her options, anxiety is reduced and the patient has been given an active role in the decision-making process. Patients appreciate this involvement and respond in a positive fashion. Little has been written about the educator role for a psychiatrist; but in the author's opinion, it is one of the most beneficial interventions that he or she performs.

PSYCHOLOGICAL TESTS

Simply put, if a psychiatrist wants to measure personality traits, then he or she should use the MMPI or the Millon. If one wishes to measure psychological states, then the SCL-90, Beck Depression Test, Stress Vector Analysis, and Holmes-Rahe Life Events tests should be used. To measure the validity of the compliant of pain, only the Mensana Clinic Back Pain Test is designed to do so, independent of preexisting personality traits or psychological states (Hendler, et al., 1979, 1985a, b, 1988). The fact that not one single scale of the MMPI ever correlates with the presence or absence of organic pathology clearly illustrates the need to use the proper test to measure the pathology of interest.

SUMMARY

Psychotherapy of chronic pain patients is a difficult task at best. In part, the process is complicated by the lack of precision of diagnosis within the realm of psychiatry, but also within the realm of medicine. For this reason, chronic pain patients engender controversy. Improved treatment can be achieved by improved precision of diagnosis, both in the medical and psychiatric realms. Unfortunately, the efficacy of psychotherapy is difficult to establish, but

improved levels of functioning, less depression, better family relationships, and improvements in sleep and pain levels can all be achieved with appropriate interventions. Most important, the psychiatrist should serve as an objective observer and recorder of patient complaints and be a diagnostician. Without accurate diagnosis, all treatments are doomed to fail.

A Rheumatologist's Perspective on Pain Management

Thomas J. Romano, M.D., Ph.D., F.A.C.P., F.A.C.R.

INTRODUCTION

Pain can be defined as an unpleasant sensation that is thought to originate from a particular body part and which is usually associated with processes that are capable of causing damage to body tissue. Pain can be acute, such as one might experience in the case of a fractured bone. If pain persists beyond the customary time it takes the affected part to heal or recuperate, the pain is termed "chronic." Acute pain typically occurs when a noxious stimulus activates sensitive peripheral endings of primary afferent nonciceptors. The noxious stimulus is then turned into a form of electrochemical energy by a process called transduction, whereupon the message is then transmitted via peripheral nerves to the spinal cord and then on to the brain, where the inputs are modulated and pain is consciously perceived (reviewed in great detail by Fields, 1987). It is clear that pain is more than just a sensation. It has two components: sensory and affective. Regardless of the cause of the pain, both components must be considered.

No greater interplay between the sensory and affective aspects of pain can be found than in the rheumatic diseases. Not only is the central nervous system of a patient suffering from arthritis bombarded by afferent signals from inflamed swollen tissue, but the conscious (or unconscious) interpretation of the significance of the painful stimuli (perhaps the harbinger of crippling, loss of independence, etc.) may influence pain perception, as can other factors such as the development of a secondary fibromyalgia syndrome or psychiatric/psychological problems that may complicate the course of a patient with chronic (i.e., incurable and probably progressive) disease.

Rheumatologists are concerned with many problems and/or potential problems that affect the clinical course of the patients under their care. Patients need to be kept ambulatory, if possible, or at least their ability to care for themselves must be maximized to prevent progressive joint and spine deformity. Physicians want to minimize or eliminate the chance that the patient's underlying disease (e.g., systemic lupus erythematosus, rheumatoid arthritis) will affect their internal organs (e.g., nephritis in systemic lupus erythematosus, Felty's syndrome [splenomegaly and neutropenia] in RA), and optimize the length and quality of the patient's life.

When the vast majority of patients first present for consultation and treatment, it is the complaint of pain, above all other symptoms, that dominates the initial patient-physician encounter. Certainly, the fear of having a potentially crippling disease or of not being able to perform certain tasks because of weakness, stiffness, or loss of dexterity comes to the forefront after the impact of the illness is explored. However, it is the worsening of pain or the fear of increased pain that has brought the patient for treatment at that particular time, although other symptoms may have been present for months or even years.

To better appreciate how the rheumatologist approaches the problem of pain, and to gain an understanding of the role of pain control in the rheumatic diseases, one must first know what a rheumatologist is, how he/she was trained, and what concerns him/her when con-

0-8493-0926-3/02/$0.00+$1.50

fronted with a patient who is in pain and who often has other symptoms/problems. Frequently, the rheumatologist's patient is confused as to the diagnosis and prognosis, often having seen numerous other health professionals before contacting the rheumatologist.

A rheumatologist typically treats many types of musculoskeletal diseases. The spectrum of rheumatologic disease is vast, and classifications are constantly being updated. The most recent classification can be found in the latest *Primer on Rheumatic Diseases* (Schumacher, 1997). In his/her day-to-day practice, the rheumatologist typically encounters patients with inflammatory conditions such as rheumatoid arthritis (RA), systemic lupus erythematosus, and the like, or degenerative joint disease such as osteoarthritis and myofascial pain syndromes of both the regional and generalized (i.e., fibrositis/fibromyalgia) forms. Quite frequently, he/she is also confronted with musculoskeletal problems that arise out of or complicate other diseases. Infectious diseases (e.g., AIDS, tuberculosis, rheumatic fever), endocrine abnormalities (e.g., diabetes mellitus, thyroid disease, hyperparathyroidism), malignancy, and other pathologic conditions may first manifest themselves as neuromuscular or musculoskeletal problems. Therefore, the rheumatologist must use his/her acumen as an internist to understand and treat patients thus afflicted.

It would be easier to understand the treatment of rheumatologic diseases if general categories were established and analyzed separately. For purposes of clarity and trying to follow general pathophysiologic guidelines, I propose dividing rheumatologic diseases into four main groups:

1. Degenerative diseases
2. Inflammatory conditions
3. Myofascial pain syndromes
4. Other (e.g., infectious, neoplastic, endocrine, congenital) conditions

Naturally, there may be considerable overlap, and any one patient may have several of the above conditions, but these distinctions should prove useful in systematically analyzing and treating patients with either simple or complex problems. Conspicuous in its absence in the above format is the impact of psychological forces that may play a part in the suffering of rheumatologic disease patients. Although rheumatologists do not primarily treat psychological disease, its presence is recognized in some patients. Therefore, problems such as depression and anxiety will be discussed in terms of their impact on specific diseases, as opposed to creating a separate category.

DEGENERATIVE DISEASES

The category of degenerative diseases contains, but is not limited to, degenerative joint disease; degradation of joint, bone, and other connective tissue by repeated trauma or inflammation; and low back pain that usually arises from a combination of factors.

TABLE 27.1
Possible Causes of Secondary Osteoarthritis

A.	Joint damage due to:
	• Infectious (septic arthritis)
	• Hemophilia
	• Neuropathy (Charcot joint)
	• Gout and other crystal-induced arthritis
	• Rheumatoid or other inflammatory arthritis
B.	Multiple epiphyseal dysplasia
C.	Congenital dislocation of the hip
	• Slipped capital epiphysis
D.	Inherited metabolic disorders
	• Wilson's disease
	• Hemochromatosis
	• Alkaptonuria
	• Morquio's disease
E.	Paget's disease of bone
F.	Acromegaly
G.	Other processes that damage articular cartilage

Degenerative arthritis or osteoarthritis (OA) (osteoarthrosis in Great Britain and The Commonwealth) is probably the most common rheumatic disease affecting bones and joints (Creamer & Hochbery, 1997). It may be primary (idiopathic) or secondary to other diseases (Table 27.1). It is characterized by the narrowing of joint space by progressive loss of articular cartilage, usually accompanied by reactive changes at the joint margins and underlying subchondral bones. Many patients describe a "bone-on-bone" sensation in weight-bearing joints, such as the knees and/or hips, especially during exercise or simply upon ambulation. It must be remembered that OA is a disease of the joints and it has no systemic component (Bergstrom, 1985; Forman, Malamet, & Kaplan, 1983).

The prevalence of OA increases with age and some form of OA is present in almost all patients 65 or older. Many times, the patient experiences transient and/or mild to moderate discomfort and does not see a rheumatologist. Often, over-the-counter analgesics, combined with resting of the affected area, tend to provide significant relief. Other patients have more prolonged symptoms or have more severe pain than they can control themselves, so they initially seek relief from their family doctor. Many such patients obtain relief with the chronic use of nonsteroidal anti-inflammatory drugs (NSAIDs) such as prescription-strength aspirin preparations (Zorprin, Easprin), nonsalicylate medications such as ibuprofen (Motrin, Rufen), diclofenac (Voltaren), naproxen (Naprosyn), flurbiprofen (Ansaid), ketoprofen (Orudis), piroxicam (Feldene), indomethacin (Indocin, Indocin SR), and many others. These have been amply reviewed (Fowler and Arnold,

1983) and their effectiveness has been established. A word of caution: if a patient with OA on an NSAID obtains objective improvement (e.g., decreased swelling, redness, warmth) but still complains of pain, a secondary myofascial pain or fibromyalgia syndrome should be considered (Romano, 1996). Many OA patients also suffer from regional (e.g., anserine bursitis) or generalized (e.g., fibromyalgia) soft tissue myofascial pain syndromes. Unless these are addressed separately and treatment initiated, the patient will continue to complain of pain — which is the primary reason he/she sought medical attention in the first place— despite a good response to OA treatment. These are the types of patients whom the rheumatologist is apt to see. These OA sufferers who do well with NSAIDs or other therapy prescribed by their family doctor have no reason to visit a rheumatologist's office. While NSAIDs are excellent medications, they should not be used in a cavalier fashion, due to potentially severe and even life-threatening side effects. The potential gastrointestinal toxicity of these medications is very well-known (Huskisson, Woolf, Balme, Scott, & Franklin, 1976), as are the effects of these drugs on renal plasma flow (Brezin, Katz, Schwartz, & Chintz, 1979) and platelet aggregation (Roth & Majerus, 1975). These effects are the result of prostaglandin inhibition and seem to affect patients in a direct proportion to their age and the presence of other disease (e.g., peptic ulcer disease, liver disease, kidney disease).

One way to prevent the untoward effects of prostaglandin inhibitors is the use of anti-inflammatory medications that are selective prostaglandin inhibitors, such as salsalate (Disalcid, Salflex, Monogesic) or choline magnesium trisalicylate (Trilsate). Misoprostol (Cytotec) can be introduced to prevent NSAID gastropathy (Graham, Agranval, & Roth, 1988) because it is a synthetic prostaglandin E analog that allows the stomach to proceed with its endogenous cytoprotective mechanisms even in the presence of NSAID-induced prostaglandin inhibition. It is generally prescribed for patients who are elderly or who have had upper gastrointestinal problems in the past. Patients using nonacetylated salicylates do not need to use misoprostol. Recently, a new class of NSAIDs has been approved for use for arthritis sufferers (Osiris & Moreland, 1999). Celecoxib (Celebrex®) (Simon, et al., 1999) and rofecoxib (Vioxx®) (Langman, et al., 1999) selectively inhibit cyclooxygenase-2 (COX-2), thus minimizing potential adverse effects on the gastrointestinal tract. Furthermore, topical capsaicin (McCarthy, & McCarthy, 1992) and topical preparations of NSAIDs (Russell, 1991) (Ginsberg & Famaey, 1991) have been shown to be effective in relieving symptoms in OA patients.

Often, topical and NSAID therapy is not enough to relieve the pain in a particular joint. In such cases, the use of intra-articular injections of a local anesthetic-corticosteroid mixture can provide prompt, dramatic relief (Hollander, 1972). While the relief is usually temporary, lasting from weeks to months, it can aid the patient in taking advantage of exercise or physical therapy that previously may have been difficult to endure. More recently, viscous/elastic intra-articular preparations composed of mixtures of hyaluronic acid and saline such as sodium hyaluronate (Hyalgan®) (Altman & Moskowitz, 1998) have been employed to treat painful knee OA. While these visco-supplementation medications are superior to oral NSAID treatment alone, their role in the long-term management of OA remains to be determined. Other regimens to help reduce pain and relieve mechanical stress on affected (especially weight-bearing) joints are weight loss, muscle strengthening, use of orthotics (e.g., cane, walker, crutches), and local heat/massage.

A word of warning: NSAIDs should be given with great caution in patients taking oral anticoagulants, sulphonylurea anti-diabetes medication, or other highly protein-bound drugs because NSAIDs compete with such medication for plasma protein binding sites and often displace a sufficient amount of the drug in question to cause untoward effects (e.g., a further prolongation of the prothrombin time or an exaggerated hypoglycemic response). In addition, NSAIDs can interfere with diuretic therapy, and adjustments in type or dosage of these medications may need to be made (Day, Graham, Champion, & Lee, 1984).

When the pain or deformity of OA become overwhelming, consideration should be given to orthopedic consultation, especially if the patient has symptoms involving a weight-bearing joint like the hip or knee. The technology for the replacement of these joints is superior than for other joints, and orthopedists generally have more experience with this type of replacement. However, not every patient with recalcitrant knee OA needs total knee replacement. High tibial osteotomy and other corrective procedures may be more appropriate in selected patients.

Often, patients with OA develop associated painful conditions, such as carpal tunnel syndrome, fibromyalgia, or a local myofascial pain syndrome, all of which need to be identified and treated.

Joints under increased mechanical stress would seem to be likely candidates for the development of OA, although the medical literature is far from clear on this issue, as illustrated in recent papers regarding runners (Lane, et al., 1986; Panush, et al., 1986).

Some studies have found that there is a relationship between prolonged stress and OA (e.g., spine OA in coal miners [Schlomka, Schroter, & Ocherwal, 1955] and shoulder OA in bus drivers [Lawrence, 1969]), while other studies have not found this to be the case (Burkle, Fear, & Wright, 1977; Puranen, Ala-Ketola, Peltokallio, & Saarela, 1975).

Each patient's problem must be evaluated individually, and aggravating factors minimized or removed if and

when they are identified. This is particularly true for patients with back problems.

Back pain may come from a single problem or a combination of pathologic processes. Spinal OA is a disease of the apophyseal joints. It is frequently associated with disc disease and the terms degenerative disc and joint disease, or spondylosis, are often used. While anatomic changes may be well-defined by an X-ray or CT scan showing osteophytic lipping and sclerosis, often these correlate poorly with the clinical picture. The development of spondylosis is probably inevitable in most patients with microtrauma where everyday activities contribute to the symptoms. However, preventive measures, such as the maintenance of ideal weight, good posture, moderate exercise, and proper methods of lifting and carrying, can do much to ease symptoms. The use of NSAIDs, as well as adequate rest and the use of heat or cold applications to the affected areas, may be helpful. In some patients, traction and/or bracing may be needed (Lee, et al., 1989). If the cervical spine is involved, the use of a cervical pillow (preferably a four-in-one cervical pillow or Wal-Pil-O [Roloke Co., 8919 Sunset Blvd., Los Angeles, CA 90069]), which prevents neck flexion and hyperextension, is helpful in relieving night pain. Using chairs with a headrest and avoidance of reading or watching television while recumbent can also help. Posterior neck muscles can be strengthened by isometric exercises (Thiske, 1969). The patient tightens the muscles in the back of the neck and makes a double chin (military posture) to the count of five; this is repeated 10 times. Patients are encouraged to do this four or five times per day.

As far as the lumbar area is concerned, pain in the buttocks, thighs, and legs is caused by a combination of entrapment of nerve roots by discs, apophyseal joints, and adjacent soft tissue. There is often a long-standing history of recurrent low back pain related to a congenital narrowing of the neural canal. Aging and degenerative changes bring on further narrowing and the clinical syndrome of spinal stenosis.

Spinal stenosis, especially of the lumbar spine, most commonly occurs in elderly patients with spondylosis with encroachment of osteophytes into the spinal canal or exit foramina. This causes a phenomenon known as neurogenic claudication in which the patient experiences calf and/or thigh/buttock pain while walking. Relief typically occurs when the patient sits down, which helps to differentiate the problem from vascular claudication. The symptoms of vascular claudication are often alleviated when ambulation ceases, but sitting down is not usually necessary for relief. The presence of the above history in an elderly patient (or one who suffers from Paget's disease) with strong distal pulses, should make the clinician very suspicious. A CT scan of the spine should be taken and, if stenosis is present, orthopedic or neurosurgical consultation should be obtained. Corrective surgery often gives dramatic relief. Age alone should not be a deterrent in cases of spinal stenosis, especially since medical management of this condition is far from ideal and the quality of life can be greatly enhanced by a relatively safe and effective procedure.

INFLAMMATORY CONDITIONS

Unlike degenerative diseases such as OA, inflammatory conditions, such as systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), and vasculitis (e.g., polyarteritis nodosa, giant cell arteritis, or cryoglobulinemia), are not only painful conditions, but can be life-threatening. The musculoskeletal manifestations of these systemic diseases can be quite severe, and can affect the nervous system directly through the deposition and activity of immune complexes.

Rheumatoid arthritis (RA) is a chronic inflammatory connective tissue disease that can be potentially crippling and even life-threatening (Harris, 1990). It typically affects diarthrodial joints, but can also cause such extra-articular manifestations as scleritis, pericarditis, lymphadenopathy, arteritis, nodulosis, splenomegaly, neutropenia, anemia, and pleural effusions/pleuritis. The systemic nature of RA is reflected by the presence of an increased erythrocyte sedimentation rate, the presence of rheumatoid factor, antinuclear antibody, other autoantibodies, anemia (usually chronic disease, but iron deficiency anemia may also be present), or low plasma albumin in some, but not necessarily all patients.

Rheumatoid arthritis is found worldwide and is extremely common (approximately 1% of the U.S. population is believed to be affected) with a female to male ratio of 3:1. Peak incidence is between the ages of 40 and 60. Mild cases are usually treated symptomatically by patients using over-the-counter preparations, while more seriously afflicted individuals seek the services of their primary care doctor. Rheumatologists usually see more severe cases, especially when disease-modifying antirheumatic drugs (DMARDs) or remittive agents are needed in addition to NSAIDs and/or oral glucocorticosteroids. DMARDs are slow-acting agents whose function is to prevent RA from crippling and are also helpful in controlling systemic problems (Furst, 1990). Gold salts (injectable or oral), d-penicillamine, and hydroxychlorogorine have been used in the past, over a decade ago, with some success; but recently, immunosuppressive agents such as methotrexate, azathioprine, and cyclosporin have been successful in halting the ravages of RA. However, even the immunosuppressive agents were less than ideal, either due to unacceptable side effects (e.g., bone marrow failure, hepatotoxicity, nephrotoxicity, etc.) or the lack of efficacy. More recently, leflunomide (Arava®), etanercept (Enbrel®), and infliximab (Remicade®), have been introduced. Each works differently but all have been shown to

be effective in treating many RA patients already on methotrexate (Smolen, et al., 1999; Weinblatt, Kremer, & Bankhurst, 1999; Maini, Breedveld, & Kalder, 1998). Leflunomide inhibits pyrimidine synthesis while etanercept blocks the action of tumor necrosis factor (TNF), a substance necessary for the autoimmune inflammatory synovitis in RA. Infliximab, a monoclonal antibody, neutralizes the activity of TNF, thus reducing disease activity.

For patients with particularly severe RA that is unresponsive to various combinations of one NSAID and a single DMARD, combinations of DMARDs have been used with success (McCarty, Harman, Grassanovich, Qian, & Klein, 1995b). The treatment pyramid for RA is shown in Figure 27.1.

Lately, many rheumatologists have chosen to treat RA much more aggressively, initiating treatment with NSAIDs plus DMARDs earlier rather than later (Wiske & Healey, 1990). Suffice it to say, the rationale regarding RA therapy has undergone some changes recently (Mikuls & O'Dell, 2000). Each patient is unique and, given the variety of medications and techniques now at our disposal, it is more likely than ever that a safe, individualized treatment can be designed to fit each patient.

A word of caution: DMARDs with NSAIDs tend to have potentially more serious side effects than NSAIDs used alone. Alopecia, lowering of blood count (red blood count and/or white blood count and/or platelet count), hepatotoxicity, gastrointestinal upset, and oral ulceration are common to all DMARDs. Gold salts can cause renal problems and rashes, as can d-penicillamine, which can also cause such bizarre problems as polymyositis (a myasthenia gravis-type syndrome) and obliterative bronchiolitis. Cyclosporin use can cause renal failure.

Leflonamide can cause hepatotoxicity and other side effects such as rash, diarrhea, and reversible alopecia. Etanercept must not be given to patients at risk for serious infection because it is immunosuppressive and may exacerbate infectious processes. One disadvantage in using etanercept is that it needs to be injected subcutaneously (25 mg) twice a week. Another is cost—the wholesale price for 6 months of treatment would be $6000 to $7000. For severe refractory RA, intravenous infliximab has been given in multiple administrations. The cost of three doses for a 70-kg patient would easily cost several thousand dollars. This cost must be weighed against the potential benefit, of course, potential life-threatening side effects.

Like OA, RA can involve weight-bearing joints in addition to its capacity to involve the small joints of the hands, wrists, feet, ankles, and elbows in a symmetrical manner. Often when knees are involved, large effusions result and aspiration and injection can be dramatically effective (McCarty, Harman, Grassanovich, & Quin, 1995). Analysis of synovial fluid generally shows an elevated white cell count (usually 10,000 to 50,000 per microliter) with a predominance of polymorphonuclear

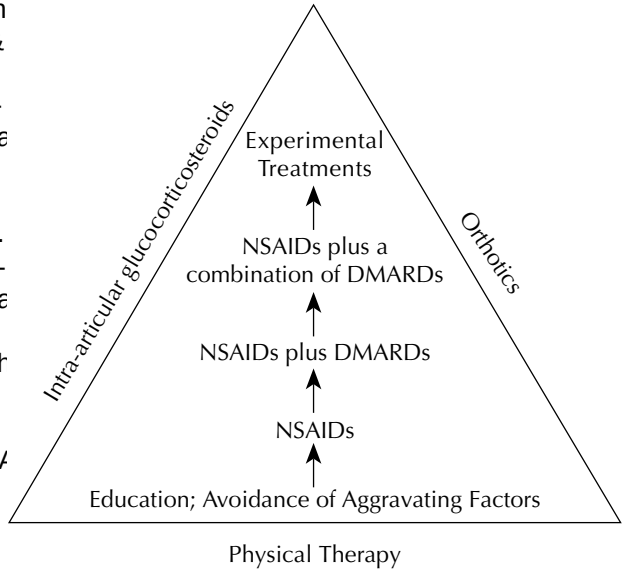

FIGURE 27.1 Treatment pyramid for RA.

leukocytes. Complement levels in RA synovial fluid are generally low and rheumatoid factors are often found; however, this testing tends to be of only limited benefit as it usually does not affect the course of treatment. A more dramatic, convenient, and inexpensive test is the observation that RA synovial fluid is watery compared to the more viscous fluid found in joint fluid from OA patients and normal controls. This is because the hyaluronic acid and other macromolecular synovial fluid components have been degraded by the inflammatory mediators (e.g., superoxides, enzymes, lymphokines) present in the affected joint.

If an inflamed RA knee develops a large effusion that becomes chronic, a popliteal or Baker's cyst may develop. Most of the time, the communication between the joint space and the cyst is one-way and this valve effect can cause high pressures in the popliteal space. Because fluid is incompressible, a rupture of the cyst can occur. The release of a large volume of fluid that contains inflammatory mediators posteriorly between the medial head of the gastrocnemious muscle and the tendinous insertion of the biceps muscle can cause the affected calf to become swollen, red, and intensely painful. The patient thus involved can present to the physician with a problem that resembles acute thrombophlebitis. The Homan's sign is frequently positive, thus causing some confusion. A positive arthrogram (with or without a negative venogram, depending on the circumstances) can confirm the presence of a Baker's cyst. Treatment with intra-articular steroids, rest, elevation, and attention to the underlying rheumatological conditions should be effective in the vast majority of cases. Surgical synovectomy may occasionally be necessary. A word of caution: treating a patient with a Baker's cyst using an intravenous anticoagulant, such as heparin (the

preferred treatment for acute thrombophlebitis), is not only ineffective, but may be counterproductive, causing painful ecchymoses in the calf tissues that have become hyperemic from the inflammation.

Although many reports of improved and "unorthodox" treatments for RA are sprinkled throughout the lay press and touted by some health care professionals, it is important to remember that testimonials and endorsements are not a substitute for sound scientific research. However, one must keep an open mind regarding new RA therapies. Three recent studies offer examples of the utility of treatments not ordinarily thought of as antirheumatic but have been shown to be effective in treating RA: fish oil (Kremer, et al., 1995) and the antibiotic minocycline (Kloppenburg, Breedveld, Terwiel, Mallee, & Dijkmans, 1994; Tilley, et al., 1995). The clinician must weigh what he/she feels is the potential benefit vs. the possible risks/toxicities of each therapeutic intervention and prescribe accordingly. RA may be unpredictable and often periodic reassessments of the patients' conditions need to be made with attendant adjustments in therapeutic regimen changes in therapy.

Other painful problems that can occur in RA are the development of fibromyalgia, severe metatarsalgia (often helped by wearing 3/8-in. metatarsal bars on the outside of the shoes), carpal tunnel syndrome (median nerve compression neuropathy), chest pain due to either pleuritis or pericarditis, and Sjogren's syndrome (a chronic autoimmune/inflammatory disorder that results in keratoconjunctivity sicca and xerostomia). The dry eyes associated with the latter condition are painful and annoying, and other mucous membranes can also become affected. The lack of vaginal secretions can make sexual intercourse painful. If food is not chewed well and eaten with frequent sips of water, it may become lodged in the throat. The paucity of saliva (with its attendant antibacterial activity) can lead to painful dental caries and frequently loss of teeth. Other complications of RA are legion but their enumeration and description fall outside the scope of this chapter.

MYOFASCIAL PAIN SYNDROME

It is important for the rheumatologist to realize that, in terms of the general population, the majority of patients with musculoskeletal complaints do not have arthritis. The pain usually results from problems (i.e., disease or injury) in structures near or around the joint, such as nerves, muscles, tendons, fascia, ligaments, bursae, bones (Simons, 1990). This section focuses on pain caused by these non-articular areas. The problem may be localized or generalized (reviewed in Fricton & Awad, 1990). Localized myofascial pain syndromes have plagued man since the beginning of time. These syndromes are characterized by complaints of regional pain (e.g., neck, shoulder, hip) that can be reproduced by palpation of specific trigger points that may be present at a site distant from the painful area and often possess taut myofascial bands which may even restrict movement. These are amply illustrated (Travell & Simons, 1983; Sheon, Moskowitz, & Goldenberg, 1982) (see Figure 27.2). The trigger point has been shown to have a characteristic pattern on needle electromyographic testing (Hubbard & Berkoff, 1993; Romano & Steiller, 1997). Furthermore, some patients with myofascial pain syndrome have been shown to have magnesium deficiency (Romano, 1994). Trauma, especially sustained repetitive trauma, can bring on these syndromes, and part of therapy is to avoid aggravating conditions.

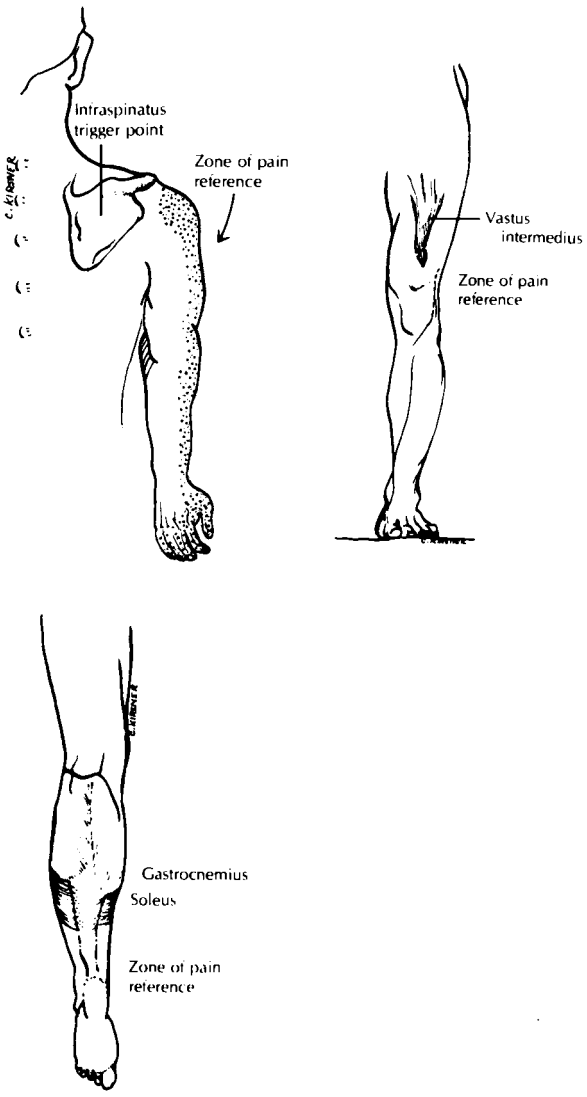

FIGURE 27.2 Zones of reference: Upon palpating the trigger point, pain is produced at some distant point. This zone is quite characteristic for each trigger point. (From Shoen, R.P., Markowitz, R.W., & Goldberg, V.M. (Eds.) (1987). Soft tissue rheumatic pain: Recognition, management and prevention (p. 224). Philadelphia: Lea & Febiger. Copyright ©1987. Reprinted by permission.)

Men and women appear to be affected equally. Treatment usually consists of local trigger point injections with a local anesthetic —long-acting corticosteroid preparation followed by massage of the affected area. This can cause a dramatic response with prompt relief and better range of motion. The use of a moist heating pad several times a day for 5 to 15 minutes is encouraged as is trying to get family members involved in the treatment scheme, because recurrences may be preempted with easily learned acupressure techniques (Prudden, 1980) before the pain becomes unbearable. Education and reassurance are extremely helpful and usually result in fewer visits and a diminished requirement for trigger point injections.

For the patient with chronic myofascial pain that is recalcitrant or recurrent (and for the generalized myofascial pain patient), a counselor/psychologist trained in biofeedback, relaxation techniques, and a cognitive-behavioral approach to pain may prove invaluable. Often, such patients benefit from treatment by a physical therapist with interest and training in myofascial release techniques or spray and by a chiropractor who is able to manipulate certain muscle groups that are in spasm or very taut. In so doing, pain can be relieved and postural problems corrected.

TABLE 27.2
The American College of Rheumatology 1990 Criteria for the Classification of Fibromyalgia

1. History of widespread pain
Definition: Pain is considered widespread when all of the following are present: pain in the left side of the body, pain in the right side of the body, pain above the waist, and pain below the waist. In addition, axial skeletal pain (cervical spine, anterior chest, thoracic spine, or low back) must be present. In this definition, shoulder and buttock pain is considered as pain for each involved side. "low back" pain is considered lower segment pain.

2. Pain in 11 of 18 tender point sites on digital palpation.
Definition: Pain, on digital palpation, must be present in at least 11 of the following 18 tender point sites:
- Occiput: Bilateral, at the suboccipital muscle insertions
- Low cervical: Bilateral, at the anterior aspects of the intertransverse spaces at C5-C7
- Trapezius: Bilateral, at the midpoint of the upper border
- Supraspinatus: Bilateral, at origins, above the scapula spine near the medial border
- Second rib: Bilateral, at the second costochondral junctions, just lateral to the junctions on upper surfaces
- Lateral epicondyle: Bilateral, 2 cm distal to the epicondyle
- Gluteal: Bilateral, in the upper outer quadrants of buttocks in anterior fold of muscle
- Greater trochanter: Bilateral, posterior to the trochanteric prominence
- Knee: Bilateral, at the medial fat pad proximal to the joint line

Digital palpation should be performed with an approximate force of 4 kg. For a tender point to be considered "positive," the subject must state that the palpation was painful. "Tender" is not to be considered "painful."

Adapted from Wolfe, et al., 1990, Arthritis and Rheumatism, 33, 160–172.

Fibromyalgia Syndrome

The epitome of a widespread soft tissue pain syndrome is fibromyalgia (previously termed fibrositis) syndrome (FS). Intense research efforts over the past decade have provided good evidence that FS is a distinct rheumatological disorder, and widely accepted definitive criteria for its diagnosis were published in early 1990 (Wolfe, et al., 1990). The 1990 criteria are given in Table 27.2. FS occurs predominantly (80 to 90%) in women from their teens to mid-thirties, but in the Upper Ohio Valley area, the female:male ratio is 3:1 (Romano, 1988b). Children have also been diagnosed as having FS (Yunus & Masi, 1985; Romano, 1991a).

FS is a very common problem, and it confronts rheumatologists on a daily basis (Bohan, 1981; Mazenac, 1982). FS patients usually complain of musculoskeletal pain, stiffness, and easy fatigability, often linked to non-restful sleep. Generalized achiness and diffuse musculoskeletal pain are very common and, although joint swelling cannot be documented, it is often a complaint. Feelings of weakness cannot be documented, but are commonly encountered. They cannot be correlated with the usual tests of muscle strength and routinely available tests (e.g., blood muscle enzyme levels, routine muscle biopsies, and electromyographic studies) are normal. However, more sophisticated testing has demonstrated abnormalities in histochemical (Awad, 1990), immunological (Caro, 1986; Romano, 1991b), and neurological (Romano & Stiller, 1988; Cohen, Arroyo, & Champion, 1990; Romano & Govindan, 1996) testing. This may help explain the presence of such neuritic complaints as paresthesias, lancinating pains, and headache that affect over 50% of FS sufferers (Wolfe, et al., 1990). Fatigue is an extremely common symptom in FS patients and many have been shown to have FS and chronic fatigue syndrome (Goldenberg, Simms, Geiger, & Komaroff, 1990). Fatigue may be the major reason why some FS patients are impaired. A defect in stage 4, non-REM, delta-wave sleep is often present (see Figure 27.3) leading to a nonrestorative sleep after which the FS patient feels as tired, or more tired, upon arising than when he or she retired. Nocturnal myoclonus has been found to be very common in FS patients (Romano, 1999). This disturbing symptom often responds to clonazepam (Klonopin®) taken at bedtime.

Patients with FS are reported to have a poor quality of life (Burkhardt, Clark & Bennett, 1993; Bernard, Price, Edsoll, 2000) and may become so impaired that

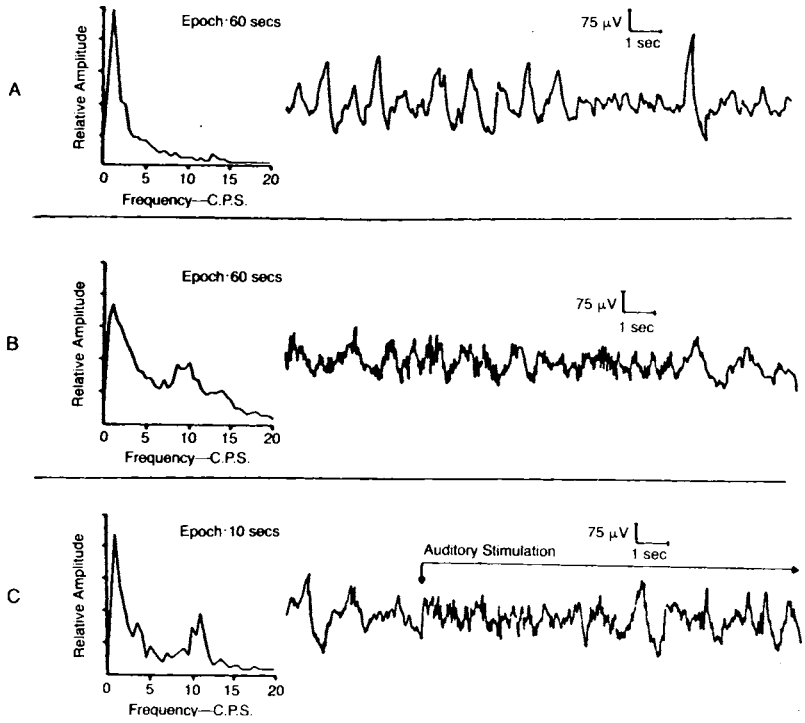

FIGURE 27.3 (A) Frequency spectra and raw EEG from non-REM (stage 4) sleep in a healthy 25-year-old subject. The spectrum shows that most amplitude is concentrated at 1 cps (delta). (B) Non-REM sleep in a 42-year-old "fibrositis" patient. The spectrum shows amplitude at both 1 cps (delta) and 8–10 cps (alpha). (C) Non-REM sleep of a healthy 21-year-old during stage 4 sleep deprivations. In the EEG, there is a clear association between the external arousal (auditory stimulation) and alpha onset. Again, the frequency spectrum (obtained by 10-second analysis from stimulus onset) shows amplitude concentrated in the delta and alpha bands. (From Primer on the rheumatic diseases (9th ed.). Copyright ©1988. Used by permission of the Arthritis Foundation.)

they are disabled from gainful employment (Bennett, 1993). This may be because the central nervous system is affected. Yunus (1992) postulated a pathophysiological model of FS that described aberrant central pain mechanisms with peripheral modulation. Recent studies lend support to this hypothesis. Abnormalities of regional cerebral blood flow have been demonstrated in FS patients (Mountz, et al., 1995; Romano & Govindan, 1996). Cognitive difficulties have also been demonstrated in patients with FS (Clauw, Morris, Starbuck, Blank, & Gary, 1994), as has abnormal central processing of nociceptive stimuli (Bradley, et al., 1995).

Many modulating factors affect the FS sufferer. Most FS patients report worsening symptoms due to cold damp weather, loud noises, emotional stress, anxiety, and/or overexertion. Patients seem to report improvement in symptoms in warmer, dryer months, and after hot baths, mild to moderate activity, and/or vacations. Often, numerous medications (e.g., NSAIDs, analgesics) have been tried without success. Many patients report that chiropractic help gives relief, albeit temporary. A complete history should help the clinician in making diagnosis of FS in that the physical examination would chiefly include a tender point count, as well as good general examination. The hallmark of the FS patient examination is the presence of typical tender points at characteristic locations (Wolfe, et al., 1990). A dolorimeter examination is not necessary for diagnosis, but helps in achieving more objectivity in the analysis of tender points (Campbell, Clark, Forehand, Tindall, & Bennett 1983; Fischer, 1987). Not all FS patients are aware of the presence of many of these discrete points of tenderness and often express surprise when the trained physician seems to locate these points with relative ease. The examination of the primary FS patient often does not reveal any other abnormalities. There is no synovitis or joint swelling. Range of motion of all appendicular joints is usually normal, and edema is absent. Neurological examination reveals no abnormalities in gait or station (although poor posture may be present). There is normal sensation to pinprick and vibratory sense, and reflexes are normal. If a localized myofascial pain syndrome also afflicts the FS patient, then a trigger point or constellation of trigger points is usually present. As opposed to a tender point that causes local pain when palpated, pressure on a trigger point causes pain to be referred to nearby regional sites. The rheumatologist needs to be aware that many conditions may present with FS-like symptoms. These include, but are not limited to, early SLE or RA, polymyalgia rheumatica, polymyositis, Sjogren's syndrome, metabolic

myopathies, regional myofascial pain syndromes, hypothyroidism, hyperparathyroidism, and widespread generalized OA.

Before initiating treatment, the physician needs to stress that patients must be actively involved in their treatment and not just a passive recipient of health care (Bennett, 1986; Romano, 1988a). Patients need to understand that FS does not kill or cripple; it can nonetheless be very painful, and they must minimize stress in their lives and be compliant with the treatment plan.

The treatment of FS consists of prompt symptomatic relief, along with a plan for long-term management. NSAIDs are not very useful, except as analgesics. Because of a paucity of potential adverse reaction (especially important in those FS sufferers who also have irritable bowel syndrome, irritable bladder, tension headaches, temporomandibular joint syndrome, migraine, and dysmenorrhea), use of one of the nonacetylated salicylates (salsalate: Disalcid, Monogesic, Salfex; choline magnesium trisalicylate: Trilisate) prescribing up to 3 g/day in divided doses is preferred. FS patients may get temporary benefit from heat therapy, massage, acupuncture, spray-and-stretch techniques, injection of tender points with local anesthetic (such as 1% procaine or 1% xylocaine with or without a corticosteroid preparation), transcutaneous nerve stimulation, physical therapy, and/or postural correction. Medications that help restore normal sleep patterns, such as amitriptyline, nortriptyline, chlorpromazine, doxepin, trazodone, or cyclobenzaprine, can be very useful if taken in the evening. The dosages may need to be individualized to each particular patient, but typical starting doses are: amitriptyline (Elavil), 10–50 mg; nortriptyline (Pamelor), 10–25 mg; chlorpromazine (Thorazine), 25–100 mg; doxepin (Sinequan), 10–50 mg; trazodone (Desyrel), 50–150 mg; and cyclobenzaprine (Flexeril), 10–20 mg. Gabapentin (Neurontin®) (Neville, 2000) at 100 to 3600 mg/day in divided doses helps many FS patients who have prominent neuritic symptoms. Tramatol (Ultram®) 50 mg q 4–6 h prn) has been reported by many FS researchers to be helpful as a safe and effective analgesic. Other strategies, including the use of narcotic analgesics and growth hormones have been reviewed by Bennett (1999). Brand-name medications instead of generic drug preparations are preferred, despite the cost savings. Too many questions have been posed concerning the quality control and bioavailability of generic drugs to have confidence in them, and therefore, their use is discouraged. Narcotic preparations that provide moderate analgesic effect may be helpful in some patients, but the need for their use should diminish with time. Recent studies have demonstrated a deficiency of magnesium in some FS patients (Clauw, Blank, Hewitt-Moulman, & Katz, 1993; Romano & Stiller, 1994) and dietary supplementation has been suggested (Abraham & Flechas, 1992) as an important treatment for these patients. As FS is still incompletely understood and treatment far from ideal, successful management of FS patients requires a good physician-patient relationship, with the realization that progress can be made through mutual trust and effort. As is the case with other rheumatic diseases, a "cookbook" approach has little chance of success and shortchanges both the physician and the patient.

TRAUMA AND SOFT TISSUE RHEUMATISM CONDITIONS

It is important to realize that there are three types of FS. The first is idiopathic FS or FS that occurs for a reason but one that cannot be readily identified. Another form of FS is called secondary or concomitant FS, where the FS comes as a direct consequence of a chronic medical condition, such as rheumatoid arthritis, chronic lung disease, chronic heart disease, etc. The third type of FS, known as post-traumatic FS, comes as a result of an accident, such as a motor vehicle accident or fall. In terms of severity, a recent study has shown that reactive FS (either post-traumatic FS or secondary/concomitant FS) is more severe and more disabling than the idiopathic variety (Greenfield, Fitzcharles, Esdaile, 1992). There is no doubt that fibromyalgia (also known as fibrositis) can be caused by trauma (Bennett, 1989; Smythe, 1989). The question is whether a specific trauma caused a specific FS in a specific patient at a specific time. To determine that, a careful history and physical examination must be obtained so that a conclusion based on the facts as opposed to prejudice or bias can be reached. However, because many physicians are unfamiliar with FS and/or myofascial pain syndromes, their relationship to a traumatic event can be overlooked. Dr. David Simons (1987) wrote, "Myofascial trigger points are one of three musculoskeletal dysfunctions that are commonly overlooked and deserve particular attention. The other two are fibrositis/fibromyalgia and articular dysfunction. None has a diagnostic laboratory imaging test at this time. All three conditions presently require diagnosis by history and physical examination alone. In each case, the diagnosis would probably be missed on routine conventional examination. The examiner must know precisely what to look for, how to look for it, and then must carefully be looking for it." Since this was written, techniques such as dolorimetry, tissue compliance testing, etc., have aided the pain practitioner, but it is ultimately the "hands-on" examination by an experienced examiner that can correctly diagnose a given situation. This is incredibly important in dealing with patients who suffer from these nonarticular or soft tissue rheumatism conditions especially when such patients and their advocates are criticized for maintaining that these patients are in a great deal of pain when diagnostic studies

such as MRI, CT, etc., are negative or normal. An article in a law journal (Smiley, Cram, Margoles, Romano, Stiller, 1992) underscores the importance of obtaining a good history, performing a methodical and accurate physical examination, and obtaining the appropriate tests to allow the pain practitioner to determine the presence or absence of one or another soft tissue pain syndrome. The injury can then determine the extent of compensation based on the manner in which these tools are used to describe the patient's injuries (or lack of them). Once a patient is diagnosed as having post-traumatic FS, he/she is likely to return for treatment even when litigation is over (Romano, 1990), a phenomenon that has also recently been observed in patients with post-traumatic headache disorder (Packard, 1992).

To understand how a local injury can cause FS, one needs to understand that most patients with soft tissue trauma, and even with fractures, recover uneventfully after a reasonable period of time, usually several months. However, some patients do not recover and have widespread pain that seems to get worse with time. Several noted rheumatologists have described the connection between trauma and FS. Smythe (1989) wrote, "Trauma may initiate a chronic fibrositis syndrome with a frequency of 25% in one study of 92 patients." In addition; "injury to the neck was described in 40% before the onset of symptoms and in the low back in 31%." More recently, several rheumatologists described an increased incidence of FS after cervical spine injury as opposed to injuries to the lower extremity (Buskila, Neumann, Vaisberg, Alkalag, & Wolfe, 1997). Bennett (1989) described how a sequence of events can take place to generate a widespread FS from a local myofascial pain syndrome.

FS can be as painful and disabling as rheumatoid arthritis (Russell, 1990). It can adversely affect lifestyle (Burkhart, Clark and Bennett, 1993), so much so that FS patients consistently scored among the lowest in all domains measured compared with patients with RA, OA, permanent ostomies, chronic obstructive pulmonary disease, insulin-dependent diabetes, and health controls. This may be a surprising finding for the uninitiated, but this is absolutely true and is something that is seen on an almost-daily basis.

Because traumatically induced FS usually starts as a local myofascial pain syndrome (Bennett, 1989) or "regional fibromyalgia" (Yunus, 1993), and then spreads to involve other areas of the body, possibly as the result of expanded receptive fields (Dubner, 1992) and neuroplasticity of the nervous system (Mense, 1994), it is no surprise that the resultant FS is intensely painful and difficult to treat. These "persistent pain syndromes can dramatically affect the patient's life, leading to long-term disability and a significant decrease in quality of life." (Ashburn & Fine, 1989).

If asked to testify in court regarding soft tissue injuries, the physician must remember that the court needs to know (1) what the patient is suffering from; (2) if the soft tissue problem (e.g., FS, myofascial pain syndrome, etc.) could be precipitated or caused by trauma; (3) if the problem was precipitated or caused by the accident/incident in question (i.e., if the trauma would not have occurred, would the patient have this problem); (4) if the problem is permanent; and (5) the cost of future care for the patient for the injuries sustained in the accident/incident. The court needs to know these things to a reasonable degree of medical probability or certainty. How this standard applies to testimony given by a rheumatologist was outlined in a paper authored by several prominent FS researchers (Yunus, et al., 1997). A method to assess the contribution of several different traumas regarding patients' painful medical problems has been determined (Romano, 1998). Ultimately, however, the physician's education, training, and experience, as well as his knowledge of the particular patient in question, should be the basis for giving such opinions.

MISCELLANEOUS CONDITIONS

Perhaps in no other area is the skill of the rheumatologist (vis-à-vis internist) put to more of a test than in the realm of such miscellaneous conditions as endocrine, metabolic, infectious, or neoplastic diseases that present with musculoskeletal signs and symptoms. The patient with a disease that fits into one of the above categories has more than a muscle, joint, bone, or soft tissue problem, but this may not be obvious early in the course of the disease, less so if the condition behaves in an atypical manner. One must remember, however, that FS can coexist with any of these disorders (Hudson, Goldenberg, Pope, Keck, & Schlesinger, 1992). In fact, FS has even been described in patients infected with human immunodeficiency virus (Simms, et al., 1992).

The musculoskeletal problems attendant to certain endocrine diseases may be the first clue that an endocrinopathy is present. The rheumatological signs and symptoms are often eminently treatable and even curable if the underlying endocrine abnormality is rectified (Bland, Frymoyer, Newberry, Revers, & Norman, 1979). If the patient presents with myofascial pain (especially fibromyalgia), carpal tunnel syndrome, shoulder capsulitis (i.e., periarthritis), crystal deposition disease (e.g., pseudogout due to calcium pyrophosphate deposition disease), proximal myopathy, or osteopenia (osteoporosis and/or osteomalacia), the presence of an underlying endocrine disorder should be strongly considered. Endocrine problems including, but not limited to, parathyroid disease (both hypo- and hyperparathyroidism), adrenal disorders, and diabetes mellitus can be causative or contributing to the development of the above rheumatologic problems.

The patient suffering from hyperparathyroidism often presents with back pain and even vertebral fractures that mimic osteoporosis senilis (Dauphine, Riggs, & Schlotz, 1975). Generalized muscular aching and stiffness, joint laxity (and accompanying arthralgia from hypermobility), erosive OA (Resnick, 1974), spontaneous tender avulsion/rupture, and neuromyopathy (Patten, et al., 1974) can also raise the suspicion of the presence of hyperthyroidism, especially if serum calcium determinations are elevated. Some 35% of hyperparathyroidism patients have chondracalcinosis (Pritchard & Jessop, 1977). Acute arthritis in the setting of an acute myocardial infarction or postoperatively may be due to gout or pseudogout. A synovial fluid analysis, which includes a crystal examination, helps establish this diagnosis.

At the opposite end of the spectrum, the patient with hypoparathyroidism may present with signs and symptoms (typically back pain) of ankylosing spondylitis (Chaykin, Frame, & Sigler, 1969), carpopedal spasm with tingling due to the low serum calcium, as well as muscle cramps.

Musculoskeletal complaints seem to be associated with adrenal overactivity and adrenal underactivity, the latter condition (Addison's disease) frequently manifesting itself as severe muscle cramping.

Cortisol excess (Cushing's syndrome) can be idiopathic or due to treatment with glucocorticosteroids, and in severe osteoporosis may ensue with compression fractures of the spine and ribs, proximal muscle wasting, and possible aseptic necrosis of bone (especially the femoral head). When exogenous corticosteroids are withdrawn, pseudorheumatism (diffuse muscle, joint, and bony aching) may occur. It is imperative to be aware of this, as such a problem can have the same symptoms as a flare of certain types of arthritis for which the medication may have been prescribed. When and if such symptoms occur, their interpretation in light of the patient's clinical course is crucial for optimal management, because pseudorheumatism usually abates gradually with a slowing down of the steroid tapering schedule and the administration of mild non-narcotic analgesics. However, a flare of RA, for example, could entail a much more thorough reassessment and revision of the treatment plan.

Thyroid disease often affects the musculoskeletal system and its manifestations are protean. Hypothyroidism often presents with a myopathy, with profound muscle weakness and elevated serum muscle enzymes. It can be confused with inflammatory disorders of muscles, such as polymyositis or dermatomyositis. The peripheral joints of hypothyroid patients with myxedema may be swollen in a symmetrical fashion much like the joints in rheumatoid arthritis (Dorwart & Schumacher, 1975).

In contrast to the joint fluid from RA patients, the synovial fluid aspirated from the joints of hypothyroid patients is definitely not inflammatory (i.e., it is thick and highly viscous, with white cell counts of 1000 cells/mm^3 or less). Thyroid replacement often results in dramatic resolution of the above rheumatic problems.

If a patient has an overactive thyroid, rheumatic problems often manifest. Diffusely swollen and painful hands and feet associated with periositis (thyroid acropachy) can be seen in Graves disease, as can thyrotoxic myopathy, bone pain caused by osteopenia, shoulder periarthritis, and shoulder-hand syndrome complicating adhesive capsulitis (Wohlgethan, 1987). Musculoskeletal pain may also occur with Hashimoto's thyroiditis. This disorder has been seen with increased frequency in association with RA and possibly other connective tissue disease (Smiley, Husain, & Indenbaum, 1980; Gordon, Klein, Dekker, Rodnan, & Medsger, 1981). Ironically, one of the treatments of hyperthyroidism, the administration of propylthiouracil, has been reported to cause such rheumatic diseases as SLE (Amrheim, Kenney, & Ross, 1970) and vasculitis (Houston, Crouch, Brick, & DiBartolomeo, 1979).

Diabetes mellitus, probably the most common endocrine disease, also has numerous rheumatologic manifestations (Gray & Gottlieb, 1976). Painful neuropathy may first bring the diabetic patient to the attention of the pain specialist. Other problems, such as Charcot joints (Sinha, Munichoodappa, & Kozak, 1972) (often not completely painless and confused with osteomyelitis, another condition to which diabetic patients are susceptible), shoulder periarthritis (Bridgman, 1972), carpal tunnel syndrome and palmar flexor tendinitis (Jung, et al., 1971), and a scleroderma-like digital sclerosis (Seibold, 1982), can plague the diabetic patient. The rheumatologist often encounters patients with both adult and juvenile onset diabetes who have painless contractures of the proximal and distal interphalangeal joints; recognition of these conditions is important because such microvascular complications as nephropathy and retinopathy may parallel the development and progression of these contractures (Fitzcharles, Duby, Waddell, Banks, & Karsh, 1984).

Excess pituitary secretion of growth hormone, which causes acromegaly, can result in a characteristic arthropathy that mirrors the enhanced action of this hormone on bone, cartilage, and periarticular soft tissue. With regard to the diarthrodral joints, early cartilage hypertrophy causes the joint space to be abnormally wide, as seen on X-ray. This cartilage tends to break down more easily than normal cartilage and such patients develop OA at a relatively early age. Carpal tunnel syndrome is also common. The spinal pain and polyarthritis have been reported to respond dramatically when the underlying pituitary disorder is treated successfully (Lachs & Jacobs, 1986). This principle (i.e., the importance of the identification and treatment of the underlying endocrine problem) is crucial in alleviating the pain and suffering of patients with endocrine disease in whom musculoskeletal manifestations may be severe.

TABLE 27.3
Differential Diagnosis of Generalized Osteopenia in Adults

Osteoporosis	Parallel loss of mineral and matrix Predisposing factors include aging, menopause, female sex, white or Asian race, immobilization, low physical activity, inadequate dietary calcium, smoking, alcohol, corticosteroid therapy, family history
Osteomalacia	Inadequate mineralization of bones, matrix Differential diagnosis includes: • Vitamin D deficiency: Inadequate intake, low sunlight exposure, drug-induced catabolism of vitamin D, intestinal malabsorption • Phosphate-wasting syndrome: Acquired renal tubular defects, with isolated phosphate loss, combined tubular defects (Fanconi syndrome), renal tubular acidosis, antacid abuse
Osteitis fibrosa	PTH-induced increase in mineral and matrix reabsorption Differential diagnosis includes: • Primary hyperparathyroidism • Secondary hyperparathyroidism: Vitamin D deficiency states, primary decrease in intestinal calcium absorption with age, reduced renal mass (chronic renal insufficiency)
Glucocorticoid-induced osteopenia	Differential diagnosis includes: • Iatrogenic • Adrenal corticosteroid overproduction: Indiopathi (Cushing's syndrome)
Other disorders	• Hyperparathyroidism • Diffuse osteolytic malignancies (e.g., multiple myeloma) • Congenital disorders: Osteogenesis imperfecta tarda, vitamin D–resistant rickets

From Seminars in Arthritis and Rheumatism.

It should be noted that FS often coexists with endocrine problems (Crofford, 1996; Griep, Buersmat, & de Kloet, 1993), necessitating even more vigilance and circumspection on the part of the clinician. Clearly, the most common metabolic disease that causes musculoskeletal pain in the general population is osteopenia. The scope of this problem is enormous and the differential diagnosis lengthy (see Table 27.3). Acute bone fracture can result from osteopenia, and thousands of patients suffer from hip fractures annually, making it a major public health problem with high morbidity and mortality. Metabolic bone disease can also cause muscular pain and weakness, symptoms of which are often confused with other musculoskeletal conditions. Osteopenia can also occur in patients who have other rheumatic diseases, especially those receiving long-term glucocorticosteroid treatment (Hahn & Hahn, 1976). The scope of the problem is so vast that a chapter devoted to it could not even begin to outline the problem and discuss therapy. However, some major factors need to be considered. The patient with osteopenia usually has osteoporosis (loss of bone mineral and matrix in parallel), osteomalacia (accumulation of unmineralized matrix after loss of bone mineral), hyperparathyroidism with osteitis fibrosa (replacement of bone by fibrous tissue), or cortisteroid-induced osteopenia. The last problem is often unavoidable due to the patient's need for such medication, but the ability of steroids to interfere with calcium absorption from the intestine may be partially overcome by the administration of calcium and vitamin D supplementation (Hahn, Halstead, Teitelbaum, & Hahn 1979). The use of these medications is recommended for patients with osteoporosis senilis, as is estrogen, fluoride, calcitonin, or a combination of these agents based on the individual patient's needs. The best method of treating osteoporosis is prevention, if feasible. Patients at risk (typically sedentary, small-framed women approaching menopause who smoke and drink alcohol and who have low calcium and vitamin D intake) should use preventative measures such as regular exercise, adequate intake of calcium and vitamin D (Matkovic, et al., 1979; NIH Consensus Conference, 1984), and consultation with a physician who may feel that other measures, such as estrogen therapy, are necessary.

The most common causes of osteomalacia in adults are decreased absorption of vitamin D due to intestinal or biliary tract disease, accelerated catabolism of vitamin D due to drug-induced increases in hepatic oxidase activity, and acquired renal tubular defects with phosphate wasting. Correcting the cause of the metabolic problem is necessary for reversal of the osteomalacia.

While not as common as osteopenia, Paget's disease of bone is a frequent cause of bony pain, and is estimated to affect 1 to 3% of people over the age of 45 in the U.S. It is usually polyostotic, and men tend to predominate. While the cause of Paget's disease (osteitis deformans) is unknown (late manifestation of viral infection has been suggested), it is characterized by excessive bone resorption followed by excessive bone formation, culminating in a bizarre mosaic pattern of lamellar bone associated with increased local vascularity and increased fibrous tissue in adjacent marrow (Smiger, et al., 1977). The disease is a focal disorder as normal bone exists even in patients severely affected. The sites most commonly involved are the pelvis, skull, femur, tibia, and spine. In addition to pain, gross deformity, compression of neural structures, fracture of involved bone, and alteration of joint structure/function, often result. Increased serum alkaline phosphatase and urinary hydroxproline reflect the increased bone turnover in

this disease. An infrequent (<1%), but dreaded, complication of Paget's disease is osteosarcoma; other associated neoplasms include non-neoplastic granulomas and giant cell tumors. Paget's disease can be asymptomatic with little clinical disability and, therefore, no therapy may be necessary (Altman & Singer, 1980). However, specific therapy is available for patients who are suffering. While NSAIDs help control pain, they do not affect the biochemical abnormalities. Disodium etidronate, a diphosphonate compound (Krane, 1982), decreases bone resorption, but this oral agent should be given for no longer than 6 months at a time. Bone pain usually responds to this medication, but a temporary paradoxical increase in bone pain may occur in some patients. Subcutaneous injections of synthetic salmon calcitonin are also used to provide pain relief and help prevent deformity. Clinical improvement usually occurs within a month or two. Some patients may become refractory to this medication if they produce neutralizing antibodies to this salmon protein.

Joint pain can be caused by a variety of pathophysiological mechanisms. While disorders such as RA, OA, and SLE are chronic and incurable causes of arthritis and arthralgia, infectious agents can cause an acute arthritis which, with early detection and proper management, can be cured with little or no permanent sequellae.

While any infectious agent can cause septic arthritis, pyogenic bacterial arthritis causes the most rapidly destructive form of infectious arthritis. Bacterial arthritis is usually divided into two groups, that caused by *Neisseria gonorrhea* and that caused by other bacteria (e.g. staphylococci, enteric organisms, etc.). Most cases of bacterial arthritis are the result of hematogenous spread to the affected joint(s). Other causes include direct infection from a puncture wound or skin infection. Once inside the joint space, the infectious agent multiplies rapidly, and the inflammatory response can become very severe, causing so much joint swelling and intense pain that the patient can neither actively extend nor flex the affected joint. Usually, such patients are febrile with high peripheral white blood cell counts. If untreated, the infection can cause destruction of cartilage and bone, as a result of a direct toxic effect of the bacteria and enzymatic destruction from purulent inflammatory exudates (Goldenberg & Reed, 1985). *Staphylococcus aureus* and Gram-negative bacilli often destroy joints rapidly, whereas other organisms, such as *Streptococcus pneumoniae* and *Neisseria gonorrhea*, cause damage much more slowly. To make a correct diagnosis, an aspiration of the affected joint needs to be performed under aseptic conditions and the fluid sent for cell count, differential, and culture. A septic joint typically has a white cell count in excess of 50,000 cells/mm^3, with a predominance (often 90%) of polymorphonuclear leukocytes. It may take several days for the offending organism to grow in culture, and therapy should not be delayed. The prompt initiation of intravenous antibiotics (the exact nature of which depends on the likelihood of having a particular organism under certain clinical conditions) may be critical. Periodic joint aspiration and reassessment need to be performed while the patient is hospitalized. Depending on the organism, intravenous antibiotics need to be administered for 2 to 6 weeks. Some patients can be managed with home intravenous therapy at the discretion of the physician. Patients at risk for the development of septic arthritis include patients taking systemic or locally injected corticosteroids, immunocompromised patients, and patients with hemarthroses. Among otherwise young, healthy patients, disseminated gonococcal infection is the most common cause of septic arthritis in the urban population. Increasing in prevalence (Veasy, et al., 1987), although still considered uncommon, is acute rheumatic fever, an inflammatory disease induced by an antecedent group A beta-hemolytic streptococcal pharynigitis. The most common features are carditis and polyarthritis. The Jones criteria enable the physician to establish the diagnosis (Stollerman, Markowitz, Toronta, Wannamaker, & Whittemore, 1965) and act as a guide in the evaluation of patients with polyarthritis of unknown etiology.

Patients with neoplastic diseases often are seen by a rheumatologist for musculoskeletal symptoms. Primary neoplasms of bursae, joints, and tendon sheaths are uncommon (Jaffe, 1958). Most arise from the synovium and are benign. Tumor-like swelling in and around a joint most likely is the result of inflammatory and traumatic lesions and which hence should not be considered true neoplasms. However, tumors can occur (see Table 27.4).

TABLE 27.4
Types of Tumors of Joint, Tendon Sheaths, and Bursae

Benign

Neoplasms and tumoral conditions
- Pigmented villonodular synovitis
- Synovial chondromatosis (osteochondromatosis)
- Other benign tumors: lipoma including lipoma arborescens, chondroma, hemangioma, fibroma

Tumor-like lesions
- Ganglion, bursitis, synovial cyst, parameniscal cyst, nodules

Malignant

Primary
- Synovial sarcoma (malignant synovioma); biphasic and monophasic
- Clear cell sarcoma
- Epithelioid sarcoma
- Synovial chondrosarcoma

Secondary
- Metastatic carcinomatous arthritis
- Joint invasion by leukemia, lymphoma, myeloma
- Continuous spread of malignant bone tumors

More often, secondary neoplastic involvement of joints occurs as a complication of contiguous spread of primary bone sarcomas, invasion by hematologic malignancies (e.g., leukemia, lymphoma, myeloma), or carcinomatous metastases (Schajowica, 1982).

Most subtle involvement of the musculoskeletal system with malignancy manifests itself as the group of disorders termed *paraneoplastic syndromes*. True paraneoplastic syndromes include myopathies, arthropathies, and other conditions such as hypertrophic pulmonary osteoarthropathy, amyloidosis, and secondary gout. Polyarthritis resembling RA may be the presenting sign of malignancy (Calabro, 1967). The cause is unknown, but the action of circulating immune complexes and alterations in cellular immunity have been offered as explanations (Robins & Baldwin, 1978; Awerbuch & Brooks, 1981). In addition, a syndrome similar to SLE has been reported in association with underlying malignancies (Wallack, 1977; Pierce, Stern, Jaffe, Fullman, & Talan, 1979). Unfortunately, other rheumatic conditions, such as polymyalgia rheumatica, scleroderma, necrotizing vasculitis, cryoglobulimenia with Raynaud's Phenomenon (seen most commonly with metastatic malignancy), and reflex sympathetic dystrophy have also been associated with various malignancies. This confusing picture often requires much in the way of energy and expertise to understand and properly treat the specific condition(s).

ROLE OF THE RHEUMATOLOGIST IN THE MULTIDISCIPLINARY APPROACH TO THE TREATMENT OF THE PAIN PATIENT: THE RHEUMATOLOGIST AS "TEAM PLAYER"

To paraphrase the eminent poet John Donne: no physician is an island, especially when it comes to the treatment of the pain patient. Often, the physician needs to coordinate the efforts of several health care professionals (e.g., orthopedists, neurologists, anesthesiologists, counselors, psychologists, physical therapists) and educate his/her colleagues regarding the special requirements of such patients. Physical therapy, for example, is an extremely useful adjunct in the treatment of many patients who require specialty (e.g., rheumatological) care. However, the approach of the physical therapist needs to be individualized to each and every patient he or she sees. Most physical therapists see patients with such varied disorders as strokes, arthritis, post-surgical states, sports injuries, and myofascial pain syndromes. The stroke victim has a different pathology and hence different needs than the patient with RA or adhesive capsulitis of the shoulder. While general principles of physical therapy usually are the same for all patients, the practical application of these principles can vary greatly from patient to patient, depending on the problem. The patient with arthritis of the knees, for example, who requires quadriceps muscle strengthening therapy to combat atrophy of the thigh muscles due to disuse requires different management if a concomitant myofascial pain syndrome (MPS) is also present. The same is true for work-hardening programs. If the deconditioned patient with a regional MPS enrolls in a standard program, he/she will be unable to tolerate the strengthening exercises because they will exacerbate the condition (Janet Travell, personal communication). It is only when the rheumatologist or other pain specialist treats the MPS successfully that work-hardening can proceed. The physical therapist can play a pivotal role in treating MPS with spray-and-stretch techniques, massage, acupressure, local heat, or ultrasound. In fact, the therapist often can alert the referring physician to the possibility that the patient may have a regional MPS if the patient in question has a paradoxical response to correctly applied physical therapy modalities. As mentioned above, if work-hardening causes increased pain, one should suspect a regional MPS. The same principle holds true for cervical traction, a very useful treatment for chronic cervical radiculopathy(ies). If, in addition, the patient has a regional MPS in the vicinity of the occiput or cervical musculature or trapezius/rhomboid areas, the force of the correctly applied traction applied to taut muscles usually results in more pain rather than less. Such a scenario should alert the therapist to the possibility of a regional MPS, and this information should be shared with the referring physician. If the MPS persists, rheumatologic consultation should be obtained.

Often, FS patients with bothersome neuritic symptoms need the expertise of a neurologist to help determine if peripheral neuropathy, nerve entrapment, or another neurological problem exists. Tests such as electromyograms (EMGs), nerve conduction studies, and radiographic studies (e.g., CT scans, MRI scans) may need to be done to complement the neurological examination and more precisely define (or rule out) a particular problem. FS sufferers tend to have an exacerbation of their symptoms after EMGs, probably due to their abnormal perception of pain and aberrant central processing. In fact, the first clue that a patient may have FS is often the observation that the patient in question, who is being treated or evaluated by a neurologist for numbness, tingling, or lancinating pain, behaves quite differently than other patients with similar symptoms. The patient may report that the EMG was very painful and may, in fact, terminate his/her participation in the study before it is completed due to unbearable pain. The neurologist can be of great help to the patient referred for neuritic symptoms but for whom no definable neurological abnormality can be found. As mentioned earlier, gabapentin may be helpful in the management of neuropathic pain. These patients may be

suffering from FS and should be referred to a rheumatologist for further evaluation.

The orthopedist is frequently called upon to help the rheumatologist when medical management of rheumatologic conditions fails. As mentioned, patients with end-stage osteoarthritic or rheumatoid arthritic changes in knee or hip joints often require total joint replacement. It is up to the rheumatologist to help select suitable candidates for such procedures. The ideal surgical candidate not only has failed conservative measures but is not overweight (the heavier the patient, the more likely the prosthesis may loosen or dislodge), is motivated and intelligent (so as not to take undue risks after the procedure is performed [i.e., avoid activities that put increased mechanical stress on the prosthetic joint]), and is sufficiently advanced in years such that, statistically speaking, the life span of the prosthesis should exceed that of the patient. Conversely, many practicing orthopedists evaluate patients with joint pain who, inspired by media hype, self-refer themselves for total joint replacement. Some need the procedure, but many others do not. Their arthritis can be managed quite well with a program of anti-inflammatory drug therapy, weight reduction, physical therapy, and orthotic use (e.g., a cane, if necessary). Conservative medical management of this type can often help patients avoid premature and possibly unnecessary surgery while adequately controlling their pain.

The rheumatologist is most likely to call upon the services of his/her colleagues in anesthesiology when a patient requires a nerve block for such diverse conditions as occipital neuralgia (as the cause of some chronic headache conditions) and reflex sympathetic dystrophy (which can often complicate arthritic conditions). Many "failed back" patients benefit from lumbar nerve root blocks, which often give effective, albeit temporary, relief from severe pain. Other modalities (outlined in Chapter 23) can be extremely effective, especially if timely referrals are made.

Frequently, the orthodontist and the rheumatologist need to work together in the treatment of FS patients with temporomandibular disorders, as these two entities frequently coexist in the same patient and one can exacerbate the symptoms of the other (see Chapter 15).

A valuable ally in treating patients in pain is the psychologist or counselor. Often, patients with chronic painful states such as RA, fibromyalgia, and/or OA are anxious, depressed, or lack coping skills necessary to deal with their pain. Cognitive behavioral approaches to pain such as pain imaging, for example, may be very useful tools in helping patients take an active role in controlling their pain level and not just become a victim of their disorder. Biofeedback training may help some patients, especially those afflicted with myofascial pain states. Families whose members have painful diseases are often under a great deal of stress and become dysfunctional. Family counseling and/or marital counseling can go a long way in aiding the patient and those around him/her in coping with chronic illness. The patient suffering from chronic pain must avoid the feelings of helplessness and despair that can occur, especially when the patient feels that he/she is a victim and has no control over his/her pain. Overcoming such obstacles is essential for optimal care of the patient with chronic painful states. Insight into how certain aspects of a patient's lifestyle can aggravate the underlying painful condition can also be attained through counseling, thus further benefiting patients and conceivably lessening their need for analgesics and other medications.

While multidisciplinary pain clinics have been a great boon in the treatment and further understanding of the pain patient, they are beyond the reach of many — probably most — patients. However, that does not mean that such an approach to patients in pain cannot be attempted at the community level. Such an endeavor, however, requires that the professional caring for the patient strive to cooperate and communicate with each other in order to provide the most conducive atmosphere for encouragement and eventual improvement.

CONCLUSIONS

For the patient who comes to the rheumatologist with a complaint of pain, it is not sufficient for the physician to offer only symptomatic relief. As an internist, as well as a specialist in rheumatic diseases, the rheumatologist needs to accurately pinpoint the cause of the pain and take appropriate measures to minimize associated morbidity. Investigations necessary for the accurate and prompt identification of the scope of the patient's illness may be costly in terms of time and money, but the advantages of an accurate, early diagnosis and prompt effective treatment far outweigh these other considerations. Patients trust their physicians to care for them when they are suffering. That trust must never be betrayed; patients deserve no less.

The Role of the Neurologist in a Multidisciplinary Pain Clinic

Jacob Green, M.D., Ph.D.

INTRODUCTION

It has been said that many of the multidisciplinary pain clinics take on the characteristic interests of their director. True to this comment, as neurologist–director of a large multidisciplinary pain clinic, I place a significant emphasis in our institution on the evaluation of the nervous system. We never lose sight that pain is "an experience," and our approaches to the individual patient are always pluralistic, multidisciplinary, and multifaceted in character. We evaluate the patient as a whole and do, in fact, always use the traditional multidisciplinary approach, including those beneficial aspects of both behavioral and organic approaches to each person in our consideration of their pain problems.

This chapter is a synopsis of the various neurodiagnostic studies commonly employed in our multidisciplinary pain clinic in order to ascertain the state of function of the nervous system as used in the day-to-day approach to any patient. These diagnostic studies typically include an analysis of peripheral nerve and spinal cord functions.

Newer studies such as electronic brain imaging ("brain mapping") that ascertain the cerebral mechanisms involved in the "appreciation" of pain are now coming online. Our very preliminary research shows a potential side-to-side difference in the brain mapped somatosensory input tests in chronic unilateral pain patients. The brain map study helps us to evaluate the way the cerebrum handles nociceptive (sensory) incoming information. Technical change is certain, ongoing, and ever-present. Needless to say, we will probably be rewriting this chapter on these newer aspects of central-brain neurophysiology tests in the future. Surely, future assessments of the cerebral influences will be included in a physiologic assessment study of the appreciation of the pain experience. The study of the brains' ongoing adaptation to chronic pain states will also be included in future considerations of the clinical neurophysiology (neurology) studies of pain. Such a compilation has been accomplished by Chen (1993).

The physician can objectively evaluate the chronic pain patient with concomitant peripheral nerve and/or spinal dysfunction using various diagnostic methods that are currently available in most neurodiagnostic laboratories and affiliated pain clinics and that are truly multidisciplinary and multitasking.

More information can now be gained with motor nerve conduction studies using late responses, which provide data concerning the most proximal course of the motor nerve. Sensory nerve conductions via computer averaging techniques now make information concerning sensory complaints alone more easily understandable. Thermography (high resolution infrared imaging), using the electronic infrared technique, indicates when the autonomic nerves are dysfunctional. All of this information aids in our interpretation of dysfunctional mixed peripheral nerves. Cerebrally recorded, peripherally stimulated evoked potentials provide a method of determining the input pathways from the sensory tracts through the spinal cord into the cerebral cortex and give a measure of the cerebral processing of nociceptive information.

Often, the physician who is treating a patient suffering radicular pain must assess all the information available

0-8493-0926-3/02/$0.00+$1.50

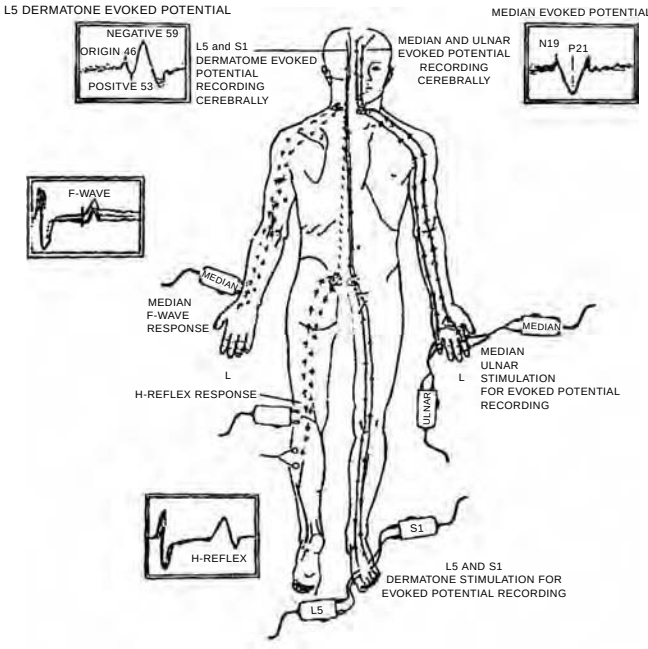

FIGURE 28.1 Schematic demonstrating recording of information obtained in neurophysiological evaluation. (From Contemporary Orthopaedics, Nov. 1987, Vol. 15, No. 5. Reproduced with permission.)

and obtainable by all the neurodiagnostic studies performed. Electromyography (EMG) tests only the motor component of the mixed peripheral nerve. EMG gives no information about the sensory component (nociception), which frequently is involved when the patient presents with a chronic pain complaint. Electromyography is simply a needle study to assess damage to only motor nerves or muscles. It is incumbent upon the physician to have a working knowledge of all the neurodiagnostic methods currently available for thoroughly testing the peripheral nervous system, spine, and brain when evaluating chronic pain patients.

NEUROPHYSIOLOGIC STUDIES

The term *clinical neurophysiological evaluation* involves the assessment of a patient using various available electrodiagnostic methods to detect relevant changes that may correlate with the clinical pain condition. In addition to traditional EM), these diagnostic tests include electroneurography (motor and sensory nerve conduction velocity studies), evoked potential studies, and high-resolution infrared imaging.

Electroneurography

By definition, electroneurography is an electrical stimulation study of the peripheral nerves. In addition to studying the motor nerve from a point proximal to one more distal, now it also is possible to evaluate "late responses." In these late responses, the neural message travels down to the electrode recording pick-up placed over a designated muscle belly, and it also travels proximally (upward) into the central (spinal cord) neuraxis and then back out (again) to the final recording site, arriving later. Computerized averaging techniques make these tiny voltage neurophysiological events (late responses) useful evaluative tools in patients suffering chronic radicular pain from proximal nerve lesions. The sensory component of the mixed peripheral nerve is also tested using direct nerve stimulation techniques.

Motor Nerve Conduction Studies

In motor nerve conduction velocity studies, a recording electrode is applied on the skin over the active belly of a selected distal muscle, with a reference electrode placed distally over a nonactive area (Figure 28.1). Stimulation of the motor fibers of the mixed peripheral nerve is then carried out, and the time it takes to create the muscle contraction is recorded.

An example of this technique is the placement of a recording electrode over the abductor pollicis brevis muscle, with a reference electrode placed distally over the thumb (Figure 28.2). The median nerve and its motor components are then stimulated in sequence at the supraclavicular region, forearm, and wrist (8 to 10 cm above the muscle). By varying these stimulation points and dividing the time elapsed at each stimulus site into the distance to the muscle stimulated, a conduction "velocity" is determined on a segmental basis for the motor nerve from the supraclavicular region point to point down to the hand (Buchthal & Rosenfalck, 1966; Hodes, Larrabee, & German, 1948; Jebsen, 1967; Melvin, Harris, & Johnson 1966).

A similar strategy is used for the ulnar nerve (Figure 28.3), proceeding sequentially from the supraclavicular

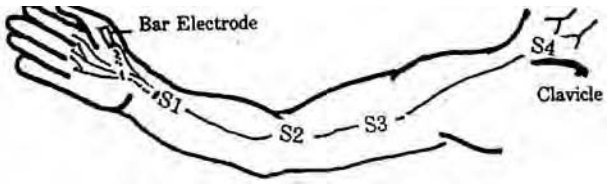

FIGURE 28.2 Placement of recording electrodes in a motor nerve conduction velocity study. Median nerve (C6, 7, 8, T1): Bar electrode over abductor pollicis brevis muscle (ABD). S1—10 cm, directly over carpel tunnel. S2—Elbow (antecubital fossa)—medial to the palpable brachial artery. S3—Axilla—groove between muscles (must be 10 cm from elbow stimulator). S4—Supraclavicular—approx. 5–6 cm from clavicular notch. F-wave—supramaximal stimulator (take shortest wave of ten trials). (From Contemporary Orthopaedics, Nov. 1987, Vol. 15, No. 5. Reproduced with permission.)

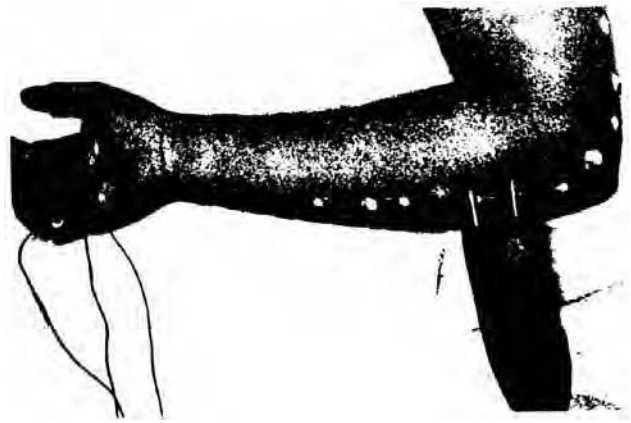

FIGURE 28.3 Use of inching technique to accurately determine the site of a nerve block (ulnar nerve). (From Contemporary Orthopaedics, Nov. 1987, Vol. 15, No. 5. Reproduced with permission.)

area to the axillary region, to the elbow, to a pick-up over the abductor digiti minimi muscle in the hand (Kimura, 1974).

In the lower extremity, typically a stimulus is sent from the popliteal fossa down the peroneal nerve to the lateral portion of the foot and similarly down the posterior tibial nerve to the medial portion of the foot (Figure 28.4), where recordings are made over the selected muscles.

For the peroneal nerve, these recordings are made over the extensor digitorum brevis; for the posterior tibial nerve, the recordings are made over the abductor muscles (Hodes et al., 1948; Jimenez, Easton, & Redford, 1970; Lamontagne & Buchthal, 1970). Under special circumstances, magnetic or needle stimulation of the sciatic nerve can be carried out in the lumbosacral area, with recordings obtained distally over any point of the sciatic innervated muscles (Yap & Hirota, 1967).

FIGURE 28.4 Stimulation applied to the posterior tibial nerve at the ankle. (From Contemporary Orthopaedics, Nov. 1987, Vol. 15, No. 5. Reproduced with permission.)

Late Response Studies

Late response studies (F-times) are carried out by stimulation of a motor nerve and recording the response from the muscle distally, with the averaging computer looking for a sufficiently long period of time for the stimulating neural impulse to climb up the motor nerve in retrograde antidromic fashion (Eisen, Schomer, & Melnod, 1977a, b; Kimura, 1983; Mayer & Feldman, 1967; Panayiotopoulos & Scarpalezos, 1977). There is then a synapse in the internuncial neuronal pool of the spinal cord, and a subsequently generated neural impulse, which comes back down in an orthodromic fashion to be recorded over the muscles of the hand or foot. This F-wave late response uses supramaximal current (Figure 28.5A) and shows a somewhat variable responses (Kimura, 1974).

The quickest of ten supramaximal shocks for each nerve studied is the designated F-time (latency for this activity). A significantly prolonged F-time (2 msec or more), compared to the reading for the opposite side, may well correlate with a typical proximal motor nerve deficit.

In the lower extremities, in addition to the F-time determination, posterior tibial nerve stimulation may be conducted using a submaximal current (Figure 28.5B), with a late response phenomenon recorded over the soleus muscle. This is known as the Hoffmann reflex or H-reflex (Braddom & Johnson, 1974; Cook, 1968; Magiadery, Porter, Park, & Teasdale, 1952). This action potential denotes the time taken for the stimulus at the popliteal fossa to climb in a normal orthodromic fashion, up the 1-A sensory input fibers, which usually are used by the muscle spindles to send messages into the spinal internuncial neuronal pool; then these neural impulses subsequently go down the motor component of the sciatic-posterior tibial nerve. H-reflexes are quite accurate. In an adequate study performed in a controlled setting, a 2-msec delay in a side-to-side comparison may well indicate a proximal lesion of the S1 nerve root (i.e., a herniated disc) or other proximal peripheral nerve lesion.

Magnetic Motor Nerve Stimulation

The magnetic motor system stimulating coil device can be used at the skin surface to painlessly "excite" both the central neuraxis (brain and spinal cord) and the peripheral motor nerves. Pending FDA release for cerebral study, we chose to utilize only the peripheral motor nervous system alone. All neural structures within the entire intra- and extraspinal course of the motor component of the peripheral nerve are accessible for this magnetic (motor) study.

Several practical advantages of this new noninvasive motor nerve stimulation technique are apparent. The magnetic stimulator is placed directly over the spinal column (on the skin) in the neck and also in similar fashion over

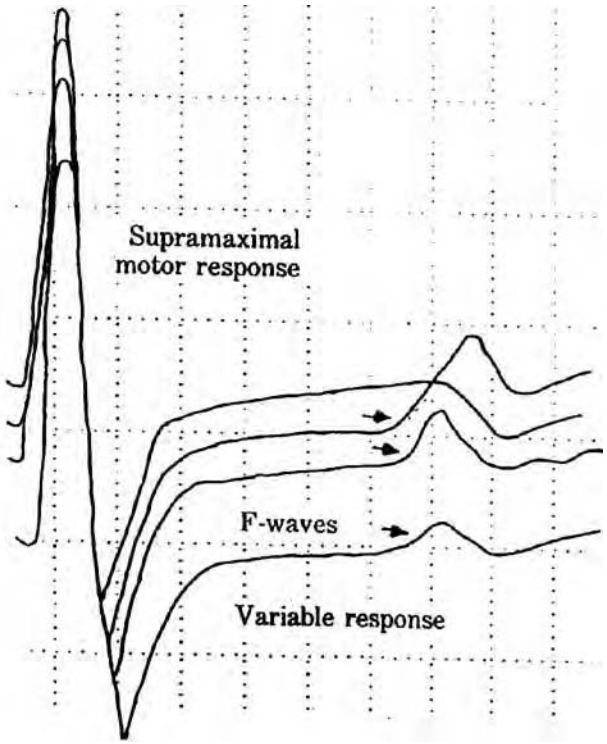

FIGURE 28.5A (Recording of supramaximal shock wave to provide F-time for comparison with opposite side. (From Contemporary Orthopaedics, Nov. 1987, Vol. 15, No. 5. Reproduced with permission.)

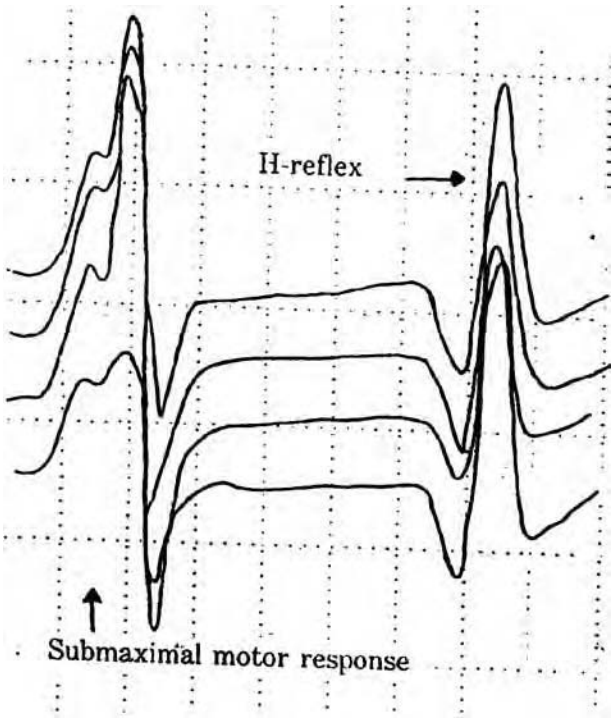

FIGURE 28.5B (Use of submaximal current for posterior nerve stimulation to record late phenomenon over the soleus muscle. (From Contemporary Orthopaedics, Nov. 1987, Vol. 15, No. 5. Reproduced with permission.)

the skin of the low back area (both in the midline) to symmetrically study the activity of the final motor neuron's entire pathway.

In the past, one of two methods of spinal motor nerve root exit zone evaluation was to insert deep needle electrodes within the paraspinal muscles in order for the stimulator to become juxtaposed to the emerging (cervical and lumbosacral) motor nerve roots as they exited from the spinal column. The relatively invasive (direct) motor nerve needle stimulations were done to obtain physiologic information from the motor nerve roots near their origin. The deep needle stimulation procedure was typically quite painful.

The only other previously available method utilized to obtain clinically relevant information from this important paraspinal area (i.e., the motor spinal root exit zone) was the use of "late response" nerve conduction studies previously described. This "F-time" neurophysiologic technique typically called for the "cocheting" of an antidromic (nerve) message up the motor nerve into the spinal internuncial neuronal spinal pool. This intraspinal neuronal pool would then, in turn, respond to the generated incoming stimulus with an outward-bound elicited motor nerve response. Clinically, the F-time was obtained by the repetitive use of supramaximal (painful) electrical shocks applied to the distal peripheral nerve to be tested. This F-time late response technique typically required the repetitive use of 10 to 20 of these supermaximum shocks delivered to each mixed peripheral nerve. This repetitive shock study was done to ascertain the quickest F-time of the motor transmission times for each of the nerves studied. This late response information was used to compare, in side-to-side (symmetry) fashion, the motor root entry and exit zone functions of each spinal-accessible nerve pair.

This new magnetic stimulation technique, utilizing a painless skin surface magnetic coil stimulation system, allows for a positive patient evaluative experience. The central neuraxis (C-spine and LS-spine) to peripheral motor system transmission information is measured by recording the motor responses at the hand muscles and similarly at the foot muscles. This information (nerve function values) is now readily derived in a painless manner from the most proximal part of the motor nerve. Central motor (CNS, brain, and spinal cord) conduction times have been recorded in this manner (Pascual-Leone, et al., 1993).

Sensory Nerve Condition Studies

Sensory nerve conduction velocity studies depend on the ability to record messages transmitted from purely sensory nerves. Sensory nerve action potentials (SNAP) are of low

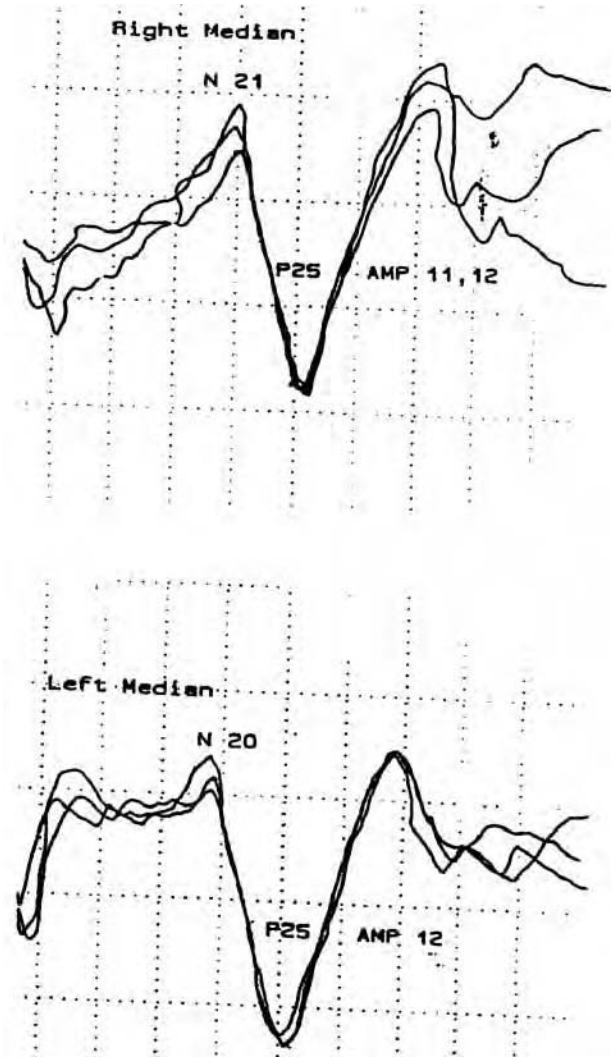

FIGURE 28.6 Cerebrally recorded peripherally stimulated median nerve potentials obtained for comparison between the affected and unaffected extremities (normal study). (From Contemporary Orthopaedics, Nov. 1987, Vol. 15, No. 5. Reproduced with permission.)

voltage (15 uV) compared to motor potentials (5 to 15 mV). SNAPs are well observed by the averaging techniques now widely used in modern-day clinical neurophysiology laboratories equipped with microprocessing computers (Behse & Buchthal, 1971; Buchthal & Rosenfalck, 1966; Ludin & Beyeler, 1977).

A sensory nerve conduction study can provide information concerning the competency of the sensory portion of the mixed peripheral nerves (Burk, Skuse, & Lethlean, 1974; Lefebvre-D'Amour et al., 1979). Testing of the sensory components of a peripheral nerve (e.g., median, ulnar) is conducted in a fashion similar to that for motor nerves. The stimulus is applied starting at the axillary region and proceeding to the elbow and wrist, while a recording of an "antidromic" sensory conduction velocity is made from the fingers (Kimura, 1974; Lachman, Shahani, & Young 1980). Similar timing of the response from point to point can provide segmental sensory nerve conduction velocity, a study that can be used for comparison with the opposite, clinically "unaffected" side (Figure 28.6).

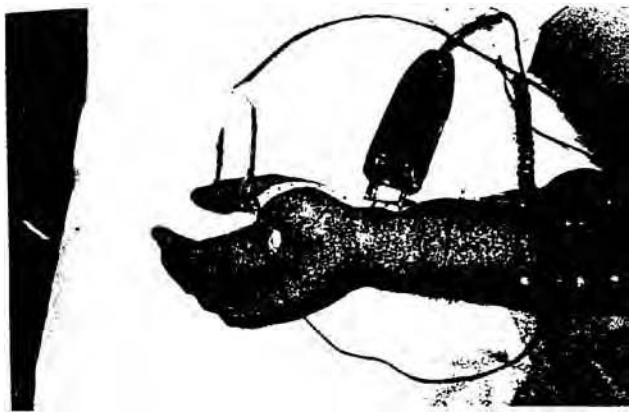

FIGURE 28.7 Radial nerve orthodromic sensory study. (From Contemporary Orthopaedics, Nov. 1987, Vol. 15, No. 5. Reproduced with permission.)

Noting that the fingers contain only sensory nerves, the recording can be made in an orthodromic manner, coming upward from the fingers as the impulses reach the wrist, elbow, axillary, and supraclavicular regions (Figure 28.7).

These sensory techniques can also be used to stimulate at the dorsal thumb region and a more proximal site in order to record the sensory potentials of the radial nerve.

In the lower extremities, sensory nerve conduction studies can be used to gain information concerning the integrity (or lack thereof) of the sural nerve. The sural nerve is a combination of branches from the peroneal and posterior tibial nerves that carries purely sensory impulses from the foot and lower leg up to the spinal cord. The sensory latency of the sural nerve is tested by applying stimulation in an antidromic (outward) fashion.

Specific information as to the individual components of the sensory nerve C, 1A, and 1D fibers can be obtained via neurometer testing. This test is the most sensitive measure of sensory nerve function, in my opinion (Green, et al., submitted; Katims, et al., 1991).

Evoked Potential Cerebral Recording Studies

Evoked potential studies are a further offshoot of biomedical computer averaging techniques. In these painless and fully reproducible studies, stimuli are applied at the peripheral nerves, that is, the median and ulnar nerves in the hand and the posterior tibial and peroneal nerves in the foot (Bergamini, Bergamasco, & Fra, 1969; Green, Gildmeser, & Hazelwood, 1983; Hume & Cant, 1978). The dermatomes of the foot (L5, S1, etc.) can also be stimulated to send sensory messages in an orthodromic

(inward) manner to the spinal cord and subsequently to the brain. These tiny electrical messages are continually conducted up the neuraxis to be recorded as the impulses arrive at the cranial vault (Magiadery & McDougal, 1950).

Dermatomal stimulation of the lumbar roots by stimulating patches of skin known to be innervated by a specific nerve root has been helpful in the diagnosis of lumbar disc disease. Examples of this include stimulation over the dorsum of the foot between the first and second interspaces to test an L5 dermatome, and stimulation of the lateral plantar surface of the foot to test an S1 dermatome. Patients having herniated lumbar discs may demonstrate significant delay or distortion of the signals from these dermatomes.

Because of the interlacing of the cervical nerve roots within the brachial plexus, less specific information is gained on a dermatomal basis in the upper extremities. However, information from anatomic areas subserved by the radial, median, and ulnar nerves occasionally can be detected by a distortion of the cerebrally recorded signal generated by dermatomal skin stimulation.

There are a number of proponents of intraoperative monitoring of evoked potentials during spinal surgery. Most operative formats suggest bilateral stimulation of specific nerves by placement of indwelling subcutaneous needle electrodes near the nerve being evaluated. Stimulation from the upper extremity is part of the paradigm for ensuring that recording apparatus is intact. Halogenic anesthetics must be avoided because of the distortion of the cerebrally recorded evoked signal. Meticulous recording techniques are typically performed throughout the operative procedure. In some cases, reversible spinal pathway abnormalities have been detected with these testing methods, preventing spinal cord damage during surgical procedures for scoliosis and other conditions.

Electromyography

In the technique used to obtain an electromyogram, the actual EMG, a thin Teflon-coated needle is inserted into the various muscles being studied (Figure 28.8) (Buchthal, 1975).

In a pure radiculopathy, among the first EMG changes noted following injury (at approximately 10 days) often will be electrographic signs of unstable muscle cell membrane potentials in the paraspinal areas alone. Within 3 weeks or so, more peripheral changes can usually be found in the extremity muscles of the involved limb. The earliest EMG changes seen also include reduction of motor unit potential amplitudes (Petajan & Philip, 1969).

Motor nerve root irritation may also be evidenced by the finding of unstable muscle cell membrane potentials (fibrillations and positive sharp waves, previously called denervation potentials) in the various groups of extremity muscles.

Decreased recruitment of motor unit action potentials elicited during EMG testing also is a reliable sign of neuropathic dysfunction (Petajan, 1974; Sacco, Buchthal, & Rosenfalch, 1962; Wexler, 1983a).

In long-standing neuropathic changes, renervation can occur and high-voltage prolonged motor unit action potentials with many positive and negative turns can be found.

A careful study of multiple sites in multiple muscles in the back is essential in ascertaining whether a motor nerve root, individual nerve, or a group of nerves (i.e., brachial plexus, L-s plexus) is involved.

On some occasions, perplexing data can occur at the C5–6 level even in myelographically verified root lesions (Uyematsu, 1983; Wexler, 1983b). For example, positive sharp waves may be found in the deltoid and bicep muscles, both innervated by C5–6, but not in the cervical paraspinal muscles, as expected. In some nerve root abnormalities, findings of unstable muscle cell membrane potentials and decreased recruitment may be discovered. As an example, occasional abnormalities may be found in the medial gastrocnemius and soleus muscles of the leg, while other muscle groups, which are not innervated by S1, are spared.

Findings of positive sharp waves and fibrillations in the multifidus muscles alone (deep paraspinal muscles) may be a good indication of motor root nerve irritation via the motor root primary dorsal ramus. Motor abnormalities alone may not be associated with pain per se unless the sensory nerve fibers also are involved.

Thermography (High-Resolution) Infrared Imaging

The newest neurophysiologic examination technique is high-resolution (electronic) infrared thermography, also known as neurothermography or HRI. This technique depends on the use of a highly sensitive electronic infrared scanning camera to ascertain the autonomic sympathetic peripheral nerve output.

Normalcy is manifested by showing little or no side-to-side variations in skin surface temperatures. When the individual is equilibrated and repetitive infrared scanning photos are taken, damage to the autonomic nerve component is revealed by the persistence of abnormality. These thermographic abnormalities in the extremities and related areas of the back have been correlated with a high degree of accuracy with other neurophysiological studies (Green, Noran, Coyle, & Gildemeister, 1985). According to reports in the literature, the correlation between thermographic findings and myelography may be as high as 90%. Ochoa, a student of basic pain mechanisms, has stated that it is the best test of the autonomic peripheral system (Ochoa, 1990).

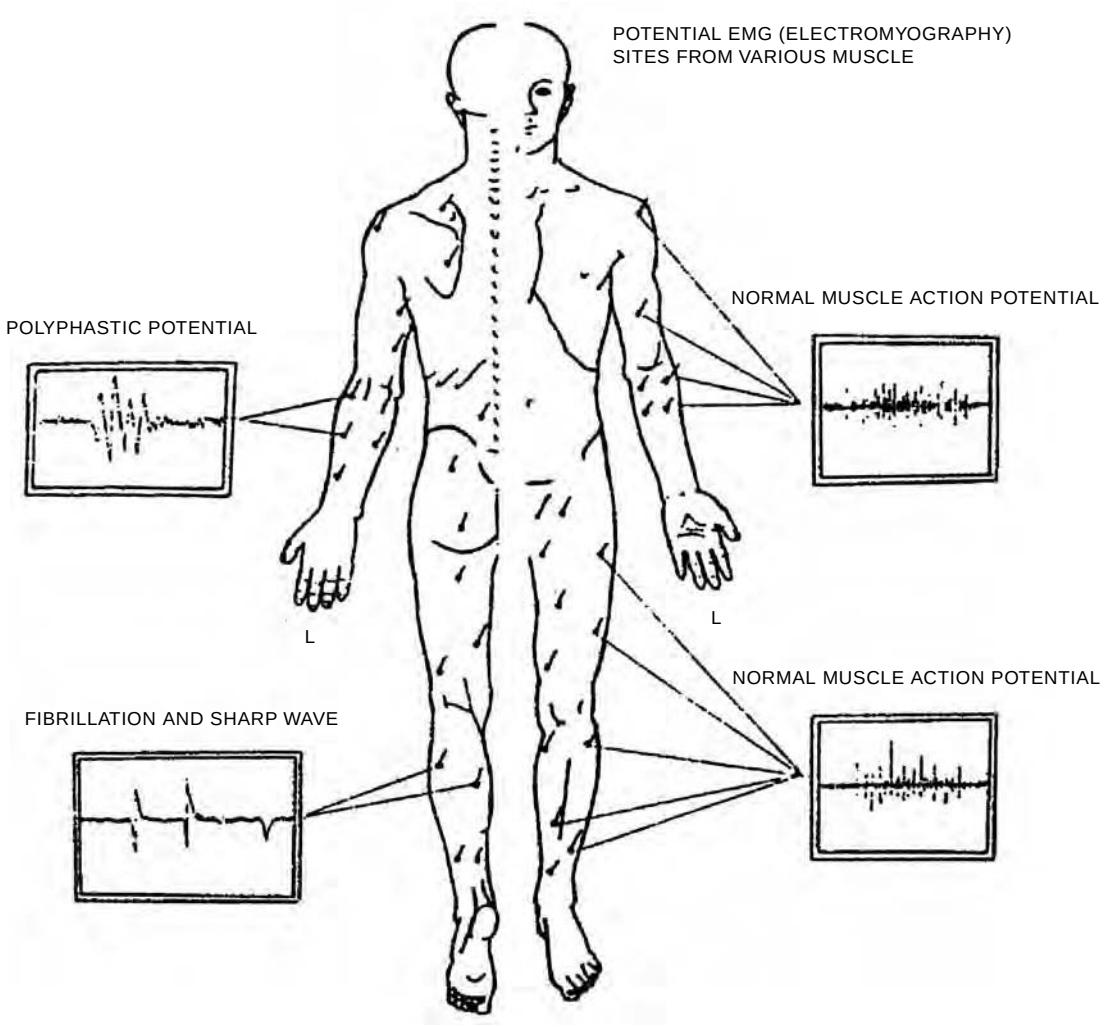

FIGURE 28.8 Potential EMG sites for various muscles. (From Contemporary Orthopaedics, Nov. 1987, Vol. 15, No. 5. Reproduced with permission.)

Comments

Comments concerning the use of thermography (HRI) include:

- "Thermography, a culminate temperature mapping achieved by this procedure allows delineation of the territory of the skin affected by dysfunction of peripheral nerves. The fibers types evaluated with telethermography are sympathetic C-fibers" (Pulst & Haller, 1981). At present, thermography is the most valuable test available for evaluationg the autonomic nervous system" (Ochoa, 1990).
- "Thermography is a safe, noninvasive test which does not involve the use of ionizing radiation. It is a test of physiological function and may aid in the interpretation obtained by the other tests. Thermography can be useful in diagnosis of selective neurological or musculoskeletal conditions. "Thermography is useful in the diagnosis of reflex sympathetic dystrophy syndrome" (American Academy of Physical Medicine and Rehabilitation, 1990).
- "There is absolutely no diagnostic method more specific for cutaneous autonomic dysfunction than thermography. Thermography is the only means by which initial signs of vasomotor instability occurring in sympathetic dysfunction may be observed. The value of this in diagnosis, prognosis and treatment cannot be achieved by any other laboratory or clinical diagnostic device at present available to medicine" (Stanton-Hicks, 1990).
- "Many cases of SMP/RSD are less than obvious and may require adjunctive diagnostic tests, which may include an assessment of surface temperature, particularly by infrared

thermography"(Harden, 1990). In an editorial response to his comments, he stated that the term SMP should be used whenever an autonomic abnormality is detected by thermograms (Brenna, 1990).

CASE REPORTS

Case 1

A 38-year-old male who was working as a brick mason fell 6 feet from a scaffold and landed on his buttocks. The patient initially had severe pain in the buttocks that resolved within 3 weeks. Continual pain radiated down his right leg in a sciatic distribution. Conservative therapy, including 2 weeks of bed rest, analgesics, and antiinflammatory medication, reduced the pain by 50%. During the following 3 months, the patient worked 4 days per week.

Based on the slow clinical improvement in a patient whose neurological examination, including reflex, motor, and sensory nerve tests, was normal, a decision was needed regarding whether to proceed with myelography. Noting that the patient had experienced a reaction to IVP dye one year previously, it was decided to continue with additional conservative therapy and to perform comprehensive neurophysiological testing.

The EMG showed no paraspinal or peripheral muscle signs of denervation such as fibrillations, positive sharp waves, or decreased recruitment pattern. Cerebrally recorded, peripherally stimulated dermatomal evoked potentials showed no delay or distortion of the evoked responses. Motor and sensory nerve conduction studies were normal with the exception of the right H-reflex, which was 4 msec slower than the left. According to laboratory criteria, this is an abnormal finding. Electronic infrared thermography showed a deviation of the midline heat stripe to the right on the back, with a persistent decreased temperature on the right calf, suggestive of S1 radiculopathy.

Based on the positive thermogram and delayed H-reflex, a myelogram was performed, which showed a large S1 disc herniation. The patient experienced no adverse effects from the myelography and was referred for surgery and not included for long-term pain management services.

Case 2

A 47-year-old female patient complained of severe pain in the back, radiating down the right leg for approximately 1 month. Four months previously, the patient had undergone a lumbar laminectomy for a myelographically demonstrated L4–5 disc protrusion on the right.

Examination showed a reduced right ankle jerk reflex compared to the left. Right Lasegue's test was positive at 30E. Physical examination revealed no other motor or sensory changes. The patient was hostile toward the orthopaedic surgeon who had performed the laminectomy and had considered obtaining legal redress.

Neurophysiological investigation showed needle EMG findings of positive sharp waves and fibrillations within 3 cm of the midline of the low back. Fibrillations, positive sharp waves, and decreased recruitment were found in the right medial gastrocnemius muscle. It should be noted that permanent changes within 3 cm of the midline of the low back can occur following laminectomy and have no clinical significance.

Dermatomal level evoked potentials showed the S1 dermatome to be delayed by 4 msec and decreased in amplitude by 40% compared to the opposite side. Motor and sensory nerve conductions were normal, and no delays in the H-reflex or F-times were noted.

Electronic infrared thermography showed an increase in the midline heat stripe at the area of the laminectomy scar. Decreased temperature was noted in the area of the right calf. This was a positive thermogram strongly suggestive of an S1 abnormality.

The patient was told that another myelogram was indicated, noting there could be a recurrence of the previous disc abnormality or that another disc could be ruptured. The patient confessed that 1 month following her previous laminectomy, she had fallen down a flight of stairs. The onset of her current symptoms had in fact appeared after her postoperative fall. A myelogram was performed, and a huge S1 right herniated disc was identified, suggestive of surgical intervention in the immediate future.

Case 3

A 29-year-old male who had been employed as a railroad worker for 1.5 months stated that he had slipped and fallen backward on grease that had leaked from an engine. The patient had been off work for 90 days, complaining of severe back pain with numbness in his right foot and right testicle.

Neurologic examination showed no motor or reflex asymmetries and a varying sensory examination. Needle electromyography of the back and legs and a thermogram were also completely normal.

After being informed of this series of normal studies, the patient was more accepting of our psychiatrist's and our rehabilitation team's advice without further medical intervention that might reinforce the notion that he had been "seriously" injured on the job.

Case 4

A 38-year-old male was seen because of pain in the back running down both legs, with some occasional numbness of the posterolateral aspect of the left leg. There was no numbness or pain in the anterior thigh or the area of the

saphenous nerve. There was an occasional weak feeling and giveaway of the left leg over the right. The patient had fallen on the job. Knee jerks were diminished as were ankle jerks. An MRI-myelogram was done and was indicative of a lumbar disc. Noting the newness of the technique, the MRI-myelogram, the patient also had a lumbar Metrizamide invasive myelogram that showed, in essence, a less significant picture of the same lesion that was much better demonstrated on the MRI and myelogram alone. This indicates a new technique that is not invasive, which corroborates the patient's history and physical findings of back pain with radiation into the leg.

Epidural Steroid Injection: A Review of Indications, Techniques, and Interpretation of Results

W. David Leak, M.D., D.A.B.P.M. and A. Elizabeth Ansel, R.N.

INTRODUCTION

This chapter is written with the specific focus as an applied clinical tool for practitioners of pain management. Acute applications for epidural injection, such as labor and delivery and elective surgical regional anesthesia, are not within the parameters of this chapter. The information imparted is directed to clinicians with a basic understanding of normal and pathologic anatomy, physiology, pharmacology, and basic physics.

The placement of chemicals for diagnostic, prognostic, and therapeutic purposes in the epidural space is widely practiced and published. More than 447 references are available from the National Library of Medicine for the search phrase *epidural injection* and 20,471 for the keyword *epidural*. The practice of medicine has become more complicated not by the nature of disease, but by the maze of authoritative yet illogical denial "rationale" by third-party payers. The use of epidural injection, although a very useful clinical tool, is also underappreciated and thus undervalued relative to associated risk. This chapter assists not only in the clinical application of epidural injection, but the administrative practice as well.

The key clinical pearl: Epidural injection is not experimental or investigational.

HISTORICAL BACKGROUND

Clinical reports of the earliest epidural anesthesia have been credited to James Corning. Corning used intraspinal cocaine on two subjects: a dog, to stop the animal from masturbating, and a human with "spinal weakness and seminal incontinence". These were classified as neurological illnesses. The results were reported in the fall of 1885 in the *New York Medical Journal*. European urologists Cathelin and Sicard of France documented epidural placement via the sacral route in the early 1900s. Epidural injection to treat sciatica was described by Viner in 1925. Edwards and Hingson reported continuous caudal epidural anesthesia in 1942 (Kafiluddi & Hahn, 2000). Interventional procedures can be partitioned into three major purposes: (1) diagnostic, (2) prognostic, and (3) therapeutic. Historically, epidural steroid injection has been viewed as therapeutic, applied in many cases to sciatica. Epidural injection with various agents may be diagnostic. Injection of epidural steroids yielding relief suggests inflammatory disease. Injection of epidural local anesthetics with lower extremity pain relief well beyond the duration of the local anesthetic suggests autonomic dysfunction. If pain does not return after diagnostic epidural injection, the procedure is therapeutic. Should pain return after a short duration of relief (hours, days, weeks), the procedure is prognostic for future interventions.

The key clinical pearl: Epidural injection and infusion are neither new nor investigational.

ANATOMY

The epidural space is confined to the cranial and spinal canal. The most common reference is the space between the walls of the vertebral canal and the dura mater of the spinal cord (Stedman, 1999). It extends from the most cephalad aspect of the cranium surrounding the brain with compartmental interruption at the formen magnum. In the spinal canal, it extends caudally to the sacrococcygeal junction. Thus, epidural therapies and pathology may occur from the cranium to the caudal canal. Accessing the epidural space in the spinal column had been traditionally taught as a "blind technique," palpating surface anatomy and advancing the needle using proprioceptive feedback. Numerous terms have been used to describe the sensation one should appreciate during various phases of this "blind procedure". The terms include words such as give, pop, release, and loss of resistance. When taught by experts an appreciation of these mystical sensations can be regarded as universal truths that guarantee proper procedural performance. Numerous tissue plains that are below the skin have give, and will pop, release, and lose resistance but will direct a needle far away from the epidural space. The advent of fluoroscopic guidance for spinal injection procedures has revealed that massive amounts of misinformation existed relative to the anatomy, proprioception, and behavior of infusions into the epidural space.

Leak demonstrated that board-certified anesthesiologists who routinely performed blind epidural injections could not reliably identify spinal levels when surface anatomy identification techniques were used alone. When compared to fluoroscopy, vertebral interspaces (specifically the L3-4) could not be identified using conventional anatomy surface landmarks in patients in the prone position. Clinicians and researchers have published significant prospective studies demonstrating the essential need for fluoroscopy when performing epidural blocks for painful diseases (Bogduk, Aprill, & Derby, 1995; Manchikanti & Bakhit, 1999). Derby and White published a missed target rate of over 30% using blind techniques for epidurals. The traditional teachings suggested that the spread of injection solutions in the epidural space could be calculated. Teaching that the volume of an anesthetic solution would cover predictable anatomic areas has been proven erroneous by numerous clinical reports (Bogduk, et al., 1995). Figure 29.1 demonstrates the alignment of an epidural needle in the midline of an adult male patient. Attempts to maintain anatomic symmetry are demonstrated. Equal distance of the pedicles from the spinous process in a true anterior posterior radiographic projection should yield midline needle placement. Figure 29.2 demonstrates a unilateral flow of an 8-cc water-soluble contrast injection in the thoracic epidural space. Despite midline needle placement, the contrast migrated to the right side of the patient's spinal canal. The flow is not uniform in the cephalad caudad direction either.

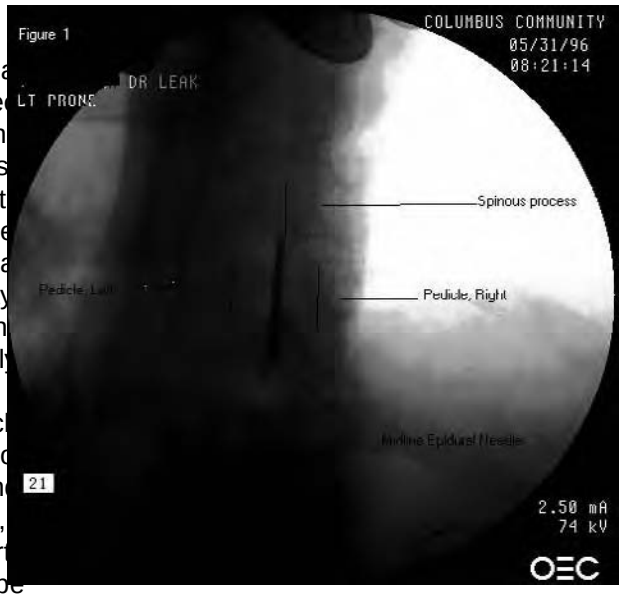

FIGURE 29.1 The alignment of an epidural needle in the midline of an adult male patient.

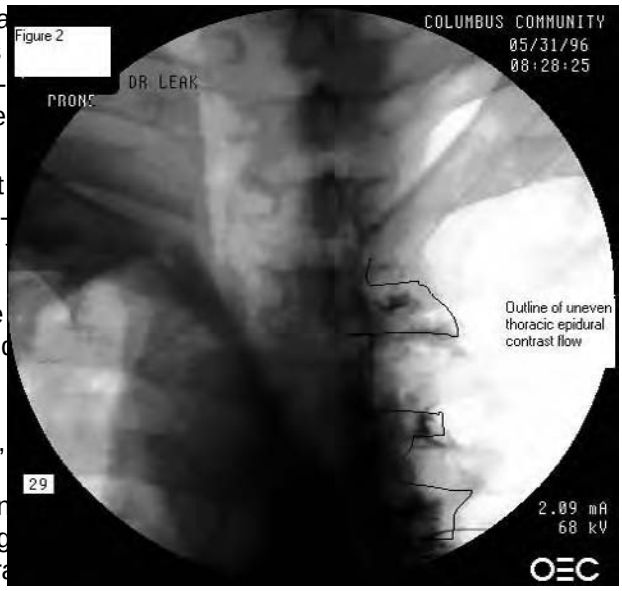

FIGURE 29.2 A male patient injected in the prone position via midline epidural needle placement with 8 cc of contrast agent.)

Figures 29.1 and 29.2 demonstrate a single aberrancy that could lead to misinterpretation of the effectiveness of an epidural injection. If the patient's multilevel neuritis was left sided the clinical conclusion might be that the patient was disingenuous with his pain complaint because the epidural failed to relieve his pain. This anatomic mishap could lead to catastrophic events for the patient, including behavioral modification in the face of unrelieved organic pain. A missed diagnosis could lead to a medical liability judgment against the physician.

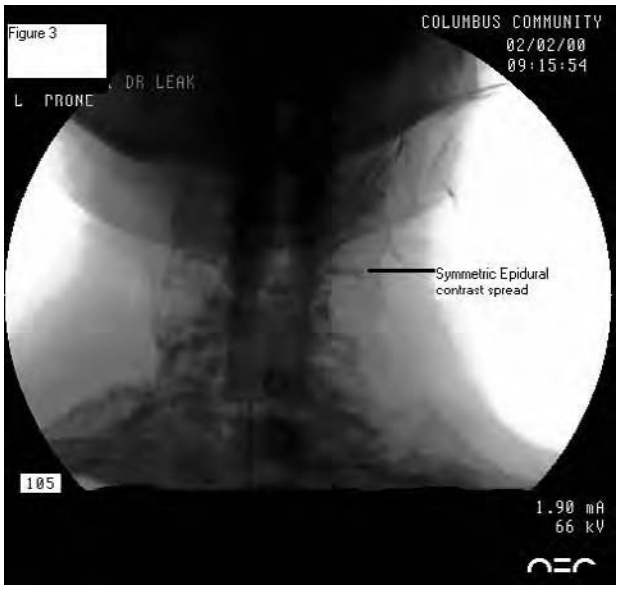

FIGURE 29.3 Normal-appearing anatomy of the cervical spine.

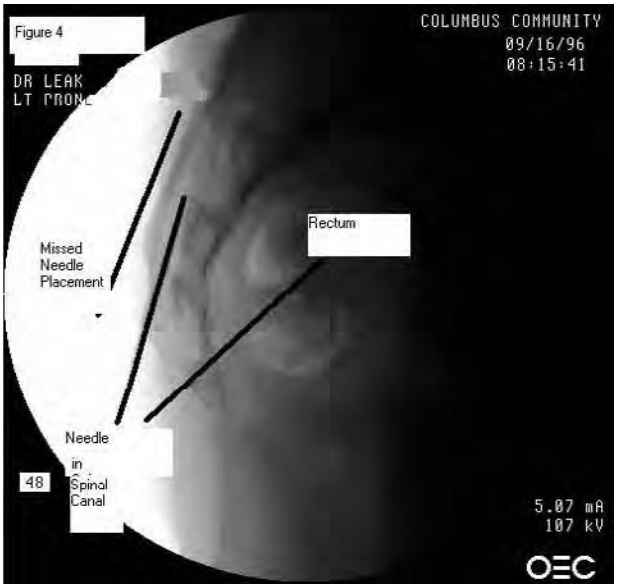

FIGURE 29.4 A needle placed in the caudal canal using direct fluoroscopic guidance.

Headaches of cervical origin have been reported as often as 50% of the time. Knowledge of cervical spinal anatomy for injection is paramount (Dwyer, Aprill, & Bogduk, 1990). Reportedly, one of the most frequently missed spinal injections is the blind caudal approach. Knowledge of anatomy is critical, but there is no substitute for direct fluoroscopic visualization. Figure 29.3 demonstrates the normal-appearing anatomy of the cervical spine. A misplaced needle in the cervical region can have rapid and irreversible aberrant results. Avoidance of the spinal cord, dome of the lung, and carotid and vertebral arteries is easier said than done using blind techniques. Figure 29.4 shows a needle placed in the caudal canal using direct fluoroscopic guidance. The hazards are not insignificant. Interosseous injection, rectal injection, bladder injection, and simple missed blocks can have catastrophic effects.

The key clinical pearl: Knowledge of radiographic anatomy and the use of radiographic guidance is the standard of care for diagnostic, prognostic, and therapeutic spinal injection procedures.

THE WORK-UP

Although mastery of anatomy for execution of the epidural injection is required, the most important component of the procedure is performing it correctly. The right physician should do the right procedure on the right patient for the right reason. Standard requirements for epidural injections are not widely known, although they do exist from several sources. Guidelines have been written by The American Society of Anesthesiologists (ASA), the International Spinal Injection Society (ISIS), and the Pain Net, to name a few. There is variation between the "guidelines" of the various organizations.

Patient history and physical examination should generate substantial subjective and objective evidence for the procedure. The impressions and plan should be consistent with the history and physical. Avoidance of being the "itinerant surgeon" is of paramount importance. A patient may be referred for a series of epidural injections for back pain or sciatica. The performance of a transient palliative procedure that masks or delays diagnosis of cancer, discitis, or other progressive and deadly diseases is below the standard of care. Thus, a review of records, history, and physical examination, and a review of relevant laboratory and radiographic studies constitute the minimum standard prior to performance of the procedure.

Work-Up Components

The specific components of the work-up should cover the following general standard:

History

1. Chief complaint.
2. History of present illness (include other work-ups and treatment for the current problem).
3. Past medical and surgical history (e.g., age is an important factor in the work-up of complaints of low-back pain from a 20-year-old subject).
4. Social history (e.g., work, smoking, substance abuse, and secondary gain factors should be explored).

5. Family history (rheumatoid disease, coagulopathy, cancer, etc.).
6. Allergies and specific reactions and where the events are documented:
   a. Beware of patients who are allergic to "all nonsteroidal anti-inflammatory drugs."
   b. Supplementation of pain relief with scheduled drugs may not excuse the practitioner from contributory negligence or malpractice claims in the event of drug-related morbidity or mortality.
   c. When total classes of nondependency producing agents are reported without any healthcare professional's objective documentation, consider allergy testing.
7. Medication history (a copy of all pharmacy printouts from the previous 12 months is recommended).
8. Review of systems.

Physical Examination

1. Vital signs:
   a. They will change in association with performance of epidurals.
   b. Noxious stimulation associated with traumatic introduction of a trochar into an already hyperalgesic area may produce a potentially fatal change in a patient who is already hyperdynamic.
   c. A patient rendered "normotensive" by antihypertensive agents may be volume deficient and suffer fatal consequences from epidural infusion and associated vasodilation.
2. Cardiovascular exam:
   a. Mortality associated with epidural injection in the face of uncompensated aortic valvular stenosis is a preventable circumstance. The epidural may cause massive vasodilatation that may not be adequately compensated for in an individual with severe aortic valvular stenosis, resulting in profound and irreversible hypotension.
3. Neurologic exam:
   a. Sensory, motor, and reflex findings normal and aberrant should be documented prior to commencing a procedure with the capacity to cause neurologic damage.
4. Musculoskeletal exam:
   a. Tenderness pre- and post-procedure.
   b. Noxious range of motion.
   c. Pain-alleviating range of motion.
   d. Documentation of range of motion.
5. Integument:
   a. Infectious lesions of the skin in the path of the epidural are direct contraindications to performing the procedure.
   b. Psoriatic lesions should not be traversed if in the path of an epidural injection:
      i. Displacing keratinotic and possibly nonsterile tissue into the epidural space may be hazardous.
   c. Bruises may suggest coagulation problems:
      i. Epidural hematomas are associated with severe morbidity and mortality.

Laboratory

1. Complete blood count (CBC):
   a. Evidence of infection or, more important, absence of infection should be documented.
   b. Leukopenia that may risk serious infection.
   c. Anemia that may become clinically significant with required volume expansion.
   d. Thrombocytopenia resulting in insufficient clotting.
2. Coagulation profile:
   a. Prolonged bleeding times may result in bleeding and anemia.
   b. Prolonged coagulation times may result in paralyzing intraspinal hematomas.
3. Electrolytes plus calcium and magnesium:
   a. Sodium has been observed to drop after exposure to anesthetics.
   b. Sodium, potassium, calcium, and magnesium may be low in association with chronic painful diseases via renal elimination.
   c. Glucose may have dangerous fluxes in susceptible individuals, such as diabetics, when epidural steroids are administered.
4. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP):
   a. Inflammatory processes, both infectious and noninfectious, may yield elevated ESR and CRP.
   b. The CRP can be followed to determine whether the inflammation is progressive because it responds very quickly to circulating pyrogens and complement complexes.
5. Urinalysis:
   a. Provides a broad snapshot of endocrine, immune, and metabolic functions.
   b. Specific gravity may indicate volume depletion or overload.
   c. Glucose level may indicate risk for undiagnosed diabetes.
   d. Infectious processes revealed in the urine are a relative contraindication to epidural injection

Radiographic Studies

1. Plain radiographs:
   a. The target region must be imaged in the anterior/posterior and lateral views to eliminate the presence of dangerous anatomic anomalies that may create complications in an otherwise uncomplicated procedure.
   b. Spina bifida presence should be known prior to needle introduction.
   c. Hypertrophic spinous processes and facets may impede successful injection.
   d. Calcification of interspinous ligaments may wreak havoc with an intraspinal approach.
2. Scintillation scans:
   a. Primary metastatic oncologic disease may be revealed.
   b. Discitis or osteomyelitis may be discovered.
3. Computerized axial tomography (CAT):
   a. Depending on the history and physical examination, a CAT scan may be indicated.
   b. With a history of cancer, a CAT scan is a must due to the potential for metastatic or recrudescent disease.
4. Magnetic resonance imaging (MRI):
   a. Prior to embarking on an invasive therapeutic trial, comprehensive information concerning soft tissue structures of the spine should be known.
   b. Discovery of damage or destruction of tissue after an invasive procedure, such as an epidural injection, subjects the procedure and the physician performing the procedure to being considered pathologic etiology.

Electrophysiologic Studies

1. Somatosensory evoked potentials (SSEP):
   a. Measures sensory (the pain) aspects of nerve function
   b. Electromyography (EMG) looks for significant motor dysfunction
2. Selective tissue conductance (STC):
   a. A direct measure of autonomic dysfunction that responds instantly to change
   b. Evaluates changes in sudomotor and vasomotor activity
3. Cold pressor:
   a. Another assessment of autonomic vasomotor function

Note that overlapping aberrancies in all three electrophysiologic studies direct the clinician to a more focused work-up. Objective data do reflect the presence or absence of nociception. The selective tissue conductance, cold pressor, and somatosensory evoked potential allow the physician to quantify physiologic change brought about through therapeutic intervention.

The work-up includes trial responses to the physical therapy, fitness conditioning, transcutaneous electrical nerve stimulation, smoke cessation, laboratory, and appropriate radiographic and electrophysiological capture of data prior to epidural injection. The radiographic data minimally consists of plain film. As the case becomes more complex and recalcitrant to conservative measures, CAT and MRI scans should be obtained.

Good outcomes go largely unnoticed except by the occasional grateful patient. A bad outcome due to poor preparation may result in alienation of colleagues and patients. The list of known complications and adverse events may appear to grow exponentially if preparation is not systematic and meticulous. The diagnosis must be specific and match the procedural plan.

The term "rule out" negates a diagnosis and leads to third-party rejection of the procedural claim. The cancellation of the work-up may be included in the denial as the impression was reduced to "rule out." The Healthcare Finance Administration (HCFA), the administrative and regulatory body for Medicare, requires that the documentation for epidural injection meet their criteria for diagnosis and treatment prior to issuing reimbursement. This is not innately evil; it is just difficult to find in the voluminous policy manual. The manual is available to all Medicare providers. It will be sent to the billing address, which may or may not be the mailing address. If your Medicare remittances are routed to a lockbox, so is your Medicare Policy Manual. The manual can also be found on the Internet at www.hcfa.gov. The manual can be printed from the Internet and contains over 350 pages. Familiarity with the manual will improve the economic and social relationship between the patient and practitioner. The coverage policies with HCFA are dynamic. By the time this chapter is published, the policies will have changed. The HCFA Web site will be the best source for current coverage information on epidural or any other injection.

Clinical impressions that may be appropriate for epidural injection include but are not limited to:

991.1 Frostbite of hand
991.2 Frostbite of foot
53.13 Post-therapeutic polyneuropathy
722.2 Displacement of intervertebral disc, site unspecified, without myelopathy
Discogenic syndrome NOS
Herniation of nucleus pulposus NOS
Intervertebral disc NOS:
Extrusion
Prolapse

Protrusion
Rupture

Neuritis or radiculitis due to displacement or rupture of intervertebral disc

337.21 Reflex sympathetic dystrophy of the upper limb
337.22 Reflex sympathetic dystrophy of the lower limb
724.3 Sciatica neuralgia, or neuritis of the sciatic nerve
353.6 Phantom limb (syndrome)
577.0 Acute pancreatitis

Giving a disease a name does not necessarily mea that is what the patient has; thus, objective criteria should be used when possible. The U.S. healthcare cu ture may contain numerous third-party administrative encumbrances. The administrative information reques for documentation can be overcome with proper radio- graphs, laboratory, and electrophysiology studies. Objective evidence of motor, sensory, or autonomic function allows the practitioner to practice evidence- based medicine. The known hazards of the procedur mandate the laboratory assessment.

Electrophysiologic studies were previously mentioned as instruments of objective measurement. Included in thi is an explanation to the third-party payer of why such instruments are medically necessary and are indicated for epidural injections. The detailed scientific answers follow.

Somatosensory evoked potentials. SSEP studies (or somatosensory evoked potentials) are the evaluation of the central nervous system via sensory tracts in the spinal cor connecting the extremities to the brain. This is the mech anism by which humans are able to perceive pain an temperature.

Selective tissue conductance. The operational defi- nition is the relative ability of biological tissue to conduct a weak (DC) electrical signal which is applied for a selected period of time to a selected limited and restricte surface area of that tissue.

Conductance is considered to include any or all of the methodological aspects of instrumentation, measuremen assessment procedures, applications, and analysis selective tissue conductance data.

One of the most important roles of the autonomic nervous system is to maintain a relative constancy of th internal milieu of the body. Because tissues and organ can function optimally only within a relatively small range of physical conditions, the neural and hormonal control of internal temperature, circulation, and fluid and electro- lyte contents must be maintained at all times. Otherwise, the results of even brief periods of autonomic subsystem failure can result in illness, tissue dysfunction, or death.

To provide adequate control of the internal environ- ment, the homeostatic mechanism must operate efficiently to compensate for rapid changes in the conditions outside the body. The responsive action, often exemplified by physiological change, which is caused by exposure to heat or cold, is mediated primarily through vasomotor and sudomotor divisions of the sympathetic systems.

Figures 29.5 and 29.6 demonstrate pre- and post-pro- cedural selective tissue conductance studies that corre- sponded to the patient's clinical subjective complaint. The key clinical pearl: to document objective parameters prior to interventions.

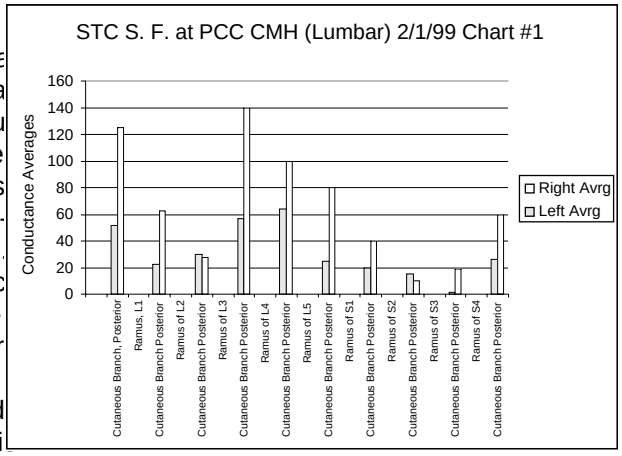

FIGURE 29.5 The asymmetry and increased activity of the nerve roots that correspond to the patient pattern of pain prior to an epidural injection and decompression of nerve roots.

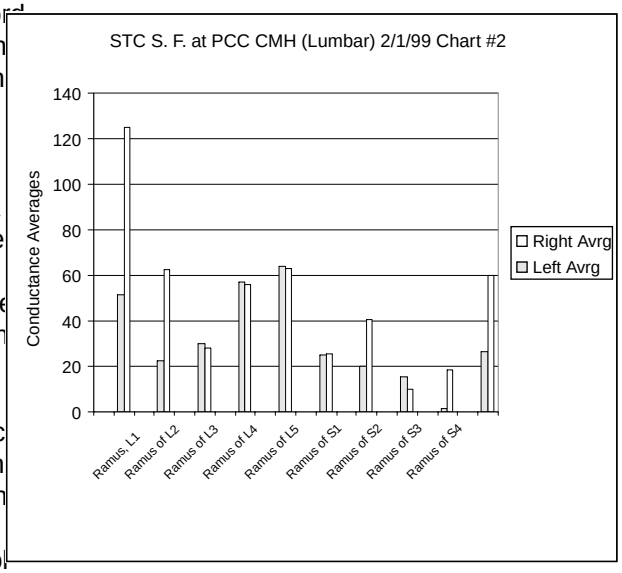

FIGURE 29.6 Substantial reduction of nerve activity of L-4, L-5, and S-1 24 hours after epidural decompression and adhesiolysis associated with elimination of the subjective complaint of pain.

PHARMACOLOGY

Numerous agents are used in the injection of the epidural space. Agents include but are not limited to:

1. Saline
2. Local anesthetics
3. Steroids
4. Alpha-2-adrenergic agonists
5. Antimicrobials
6. Neurolytics
7. N-Methyl-D-Aspartate Agonist

Below is a description of the two classes of agents most frequently injected into the epidural space — steroids and local anesthetics. The other agents are addressed elsewhere in the text. The information below is primarily from the Generex CD manufacturer's description of the drug with little modification. Note that although injection of steroids is one of the most popular applications, epidural injection is not one of the labeled uses.

Steroids

Methylprednisolone acetate is an "anti-inflammatory glucocorticoid, for intramuscular, intrasynovial, soft tissue, or intralesional injection. It is available in three strengths: 20 mg/ml; 40 mg/ml; 80 mg/ml. Glucocorticoids (e.g., hydrocortisone), which also have salt-retaining properties, are used in replacement therapy in adrenocortical deficiency states. Their synthetic analogs are used primarily for their potent anti-inflammatory effects in disorders of many organ systems. Glucocorticoids cause profound and varied metabolic effects. In addition, they modify the body's immune response to diverse stimuli. The product contains benzyl alcohol, which is potentially toxic when administered locally to neural tissue.

Prolonged use of corticosteroids may produce posterior subcapsular cataracts, glaucoma with possible damage to the optic nerves, and may enhance the establishment of secondary ocular infections due to fungi or viruses.

Avascular necrosis has been reported with a wide variety of doses and durations of recurrent exposures to steroids.

Average and large doses of cortisone or hydrocortisone can cause elevation of blood pressure, salt and water retention, and increased excretion of potassium. All corticosteroids increase calcium excretion. The list below is a partial compilation from numerous sources that lends some insight into the dangers of unmonitored steroid use. There will be no declaration that the maximum number of injections is three. One should follow electrolytes, cortisol, glucose, weight, complete blood counts, and manufacturer recommendations for diagnosing and management of toxicity when using these agents.

Prolonged or repeated exposure to steroids may result in:

- Fluid and electrolyte disturbances:
  - Sodium retention
  - Potassium loss
  - Fluid retention
  - Hypokalemic alkalosis
  - Congestive heart failure in susceptible patients
  - Hypertension
- Musculoskeletal disturbances:
  - Muscle weakness
  - Vertebral compression fractures
  - Steroid myopathy
  - Aseptic necrosis of femoral and humeral heads
  - Loss of muscle mass
  - Osteoporosis
  - Pathologic fracture of long bones
- Gastrointestinal disturbances:
  - Peptic ulcer with possible subsequent abdominal distention, perforation and, hemorrhage
  - Ulcerative esophagitis
  - Pancreatitis
- Dermatologic disturbances:
  - Impaired wound-healing
  - Facial erythema
  - Thin fragile skin
  - Hyperhidrosis sweating
  - Petechiae and ecchymosis
  - May suppress reactions to skin tests
- Neurological disturbances:
  - Convulsions
  - Vertigo
- Endocrine disturbances:
  - Menstrual irregularities
  - Decreased carbohydrate tolerance
  - Development of Cushinoid state
  - Manifestations of latent diabetes mellitus
  - Suppression of growth in children
  - Secondary adrenocortical and pituitary suppression
- Ophthalmic disturbances:
  - Posterior subcapsular cataracts
  - Glaucoma
  - Increased intraocular pressure
  - Exophthalmos
- Metabolic disturbance:
  - Negative nitrogen balance due to protein catabolism

Methylprednisolone is indicated for many inflammatory diseases. The specific indication for intraspinal disc disease is not specifically listed. The Food and Drug Administration Bulletin of April 12, 1982 provides information about off-label use of FDA-certified drugs.

Local Anesthetics

Local anesthetics block the generation and conduction of nerve impulses, presumably by increasing the threshold for electrical excitation in the nerve, by slowing the propagation of the nerve impulse, and by reducing the rate rise of the action potential. The progression of anesthesia is related to the diameter, myelination, and conduction velocity of affected nerve fibers. Clinically, the order of loss of nerve function is as follows: (1) pain, (2) temperature, (3) touch, (4) proprioception, and (5) motor function.

Systemic absorption of local anesthetics can produce effects on the cardiovascular and central nervous systems. At blood concentrations achieved with therapeutic doses, changes in cardiac conduction, excitability, refractoriness, contractility, and peripheral vascular resistance are minimal. Toxic blood concentrations depress cardiac conduction and excitability, which may lead to atrioventricular block, ventricular arrhythmias, and to cardiac arrest, sometimes resulting in mortalities. Myocardial contractility is depressed and peripheral vasodilation occurs, leading to decreased cardiac output and arterial blood pressure. Incremental dosing is necessary with blind injection. Fluoroscopy with contrast reduces the incidence of adverse reactions associated with injection of local anesthetics anywhere other than the target site.

Following systemic absorption, local anesthetics can produce central nervous system stimulation, depression, or both. Apparent central nervous system stimulation is usually manifested as restlessness, tremors, and shivering, progressing to convulsions, followed by depression and coma, and progressing ultimately to respiratory arrest. Local anesthetics have a primary depressant effect on the medulla and on higher centers. In some European countries, slow infusion of lidocaine has been used to treat seizures. The depressed stage may occur without a prior excited stage.

COMPLICATIONS

Informed consent is critical as complications do occur. Patients should be asked to make decisions that a reasonable person would make if placed in a similar circumstance as the patient. Guarantees and assurances should not be promised, but failure of expectation constitutes a perceived and real breach of contract. Do not say, “This will definitely take all your pain away, and there is no risk of anything bad happening to you.” The following components should be included in the informed consent and thought process for treating complications:

1. The patient should be aware of the nature (invasive vs. noninvasive) of the procedure.
2. The patient should be aware of the purpose (diagnostic, prognostic, or therapeutic) of the procedure.
3. The patient should be aware of the alternatives to the procedure (e.g., behavioral, pharmacological, physiotherapy, less-invasive procedures).
4. The patient should be aware of the course of the disease without the procedure (e.g., remain the same with unacceptable pain, get worse relative to pain and physiologic dysfunction).
5. The patient should be aware of the risk of the procedure. This is the predominant issue relative to informed consent in liability cases. The consent as a whole is important, but lack of disclosure of salient risks is often an important point of contention. The following is a brief list that should be disclosed when consenting for epidural procedures:.
   a. Bleeding (perioperative CBC and vital signs)
   b. Infection (perioperative CBC and vital signs)
   c. Adverse reactions to drugs (monitoring, perioperative CBC and vital signs)
   d. Allergic reactions to materials used (monitoring, perioperative cbc, and vital signs)
   e. Injury to any/all organs/organ systems (monitoring, perioperative CBC, and vital signs)
   f. Pain may be made worse (monitoring, pain rating scales, vital signs, SSEPs, and STCs)
   g. Pain may not be relieved (monitoring, pain rating scales, vital signs, SSEPs, and STCs)
   h. May need further procedures
   i. Paralysis (monitoring with emphasis on neurological, pain rating scales, vital signs, SSEPs, and STCs)
   j. Seizures (monitoring, pain rating scales, vital signs, CBC, electrolytes, drug levels, toxicology screen for additional agents such as cocaine, electroencephalogram, chest X-ray to follow potential seizure related aspiration, arterial blood gases)
   k. Collapsed lung (monitoring, vital signs, chest X-ray, arterial blood gas if vitals are unstable or patient is otherwise not healthy)
   l. Pulmonary embolism (monitoring, vital signs, chest X-ray, arterial blood gas if vitals are unstable or patient is otherwise not healthy)
   m. Headache (monitoring, vital signs, CBC, electrolytes, bedrest, fluid, caffeine, adrenocorticotropic hormone (ACTH), dural repair)
   n. Numbness (CBC, monitoring with emphasis on neurological, pain rating scales, vital signs, SSEPs, and STCs)

o. Weakness (CBC, monitoring with emphasis on neurological, pain rating scales, vital signs, SSEPs, and STCs)
p. Sexual dysfunction (monitoring with emphasis on neurological, pain rating scales, vital signs, SSEPs, and STCs)
q. Bowel dysfunction (monitoring with emphasis on gastrointestinal function, pain rating scales, vital signs, SSEPs, and STCs)
r. Bladder dysfunction (monitoring with emphasis on urological function, pain rating scales, vital signs, SSEPs, and STCs)
s. Death (advanced cardiopulmonary resuscitation)

SUMMARY

The clinical economic benefits of indicated epidural injection in properly selected patients are positive. Patients have experienced alleviation from the intractable side effects of painful diseases. This has facilitated completion of otherwise failed physical therapy. The agents commonly used are frequently applied in an off-label but widely published and acceptable manner.

Knowledge of radiographic anatomy, pharmacology, physiology, and medical management of perioperative comorbid disease is critical. Equal importance must be placed on early recognition of complications by constant monitoring (physical exam as well as electronic monitors).

The procedure can be performed safely by properly trained physicians, but must always be respected for its capacity to precipitate severe and deadly consequences.

The evolution of additional agents that may be effective in long-term pain relief make epidural injection one of the most valuable current and future skills in the physician's repertoire.

Myofascial Trigger Point Injection

Hal S. Blatman, M.D.

INTRODUCTION

This chapter discusses injection of trigger points as a technique for treating the increased muscle tension and pain that is caused by trigger points. As such, trigger point injection is one of several "body work" techniques that have been shown to be effective in treating myofascial pain. Other techniques include acupressure, vapo-coolant spray with stretching, myofascial release, reflexology, acupuncture, aromatherapy and chiropractic adjustment.

Myofascial pain is defined as pain that is generated by myofascial trigger points. Trigger points form in muscle, fascia, and tendon as a tissue response to injury. Fascia is the connective tissue that intertwines through muscle and ligamentous structures. Tendons attach muscle to bone at both ends. Examples of injuries that activate or cause formation of trigger points include repetitive strain, lifting something too heavy, and sudden high-velocity stretching.

LOCATIONS OF TRIGGER POINTS

Trigger points can be located and treated in three anatomic zones in muscle tissue. These include the ligamentous/tendinous origin, the insertion of the muscle, and the muscle belly. Trigger points at the origin and insertion of the muscle may not be discretely palpable. These areas will be tender, however, and may refer pain to distant sites with palpation and needling. A trigger point in the muscle belly will create a taut band of muscle fibers extending from the origin to the insertion of the muscle. Trigger points in the muscle belly will usually be palpable as nodular densities within the taut band.

TREATMENT OF MYOFASCIAL PAIN

The successful treatment of myofascial pain involves stretching the involved muscles to their normal (healthy) resting length. Trigger point injection is a tool that "unlocks," or releases a trigger point, thereby allowing this stretch to occur. Unlocking trigger points with injection techniques may be an essential component of a treatment plan. Additionally, treatment will be more effective when all the musculature and trigger points involved in a particular pain pattern are collectively treated at the same time. Some trigger points can be treated with non-injection techniques, while other trigger points are injected. After injection, the injected muscles should be stretched with hands-on myofascial release techniques.

ACTIVE VS. LATENT TRIGGER POINTS

Optimal treatment of a myofascial pain condition requires the physician to understand that latent trigger points are usually a very important component of the patient's pain pattern. Limiting trigger point injection therapy to active, very tender, and pain-referring trigger points will severely limit the success of this treatment modality. Palpable latent trigger points that can be expected to refer pain to the area of complaint should usually be treated with injection therapy, even if they are not tender.

TRIGGER POINT INJECTION

Trigger point injection means placing a needle into a trigger point, and then injecting a liquid solution or suspension into the area. The term "dry needling" refers to placing a needle into a trigger point without injection of

0-8493-0926-3/02/$0.00+$1.50

fluid, such as in acupuncture. Introducing a needle into a trigger point usually elicits a characteristic "twitch" response. With this twitch, the trigger point releases and the taut band relaxes. The twitch and subsequent relaxation are therapeutic, even without injection of fluid. Injection of fluid can have a synergistic effect by enhancing the relaxation response and/or decreasing post-needling discomfort.

Occasionally, needle insertion into a trigger point will not elicit a characteristic "twitch" response; however, the tissue may otherwise respond as expected, with concomitant relaxation and post-treatment soreness.

INDICATIONS FOR TRIGGER POINT INJECTION

Trigger point injections are indicated for the treatment of any patient with myofascial pain. Injection techniques will almost always facilitate relief of pain and restoration of function. Moreover, clinical improvement may not be possible without trigger point injection therapy. In general, the more chronic and more severe the condition, the more medically necessary injections become.

CONTRAINDICATIONS FOR TRIGGER POINT INJECTION

Contraindications for trigger point injection include infection at the injection site and allergy to injection medication. Relative contraindications for trigger point injection include patient use of anticoagulants and illness. In acutely ill patients, it may be best to limit treatment to one or two trigger point injections, administering these into the most active or important trigger point areas.

The duration of pain is not a contraindication for trigger point injection. Pain patterns of 20, 30, or more years will still respond to injection techniques.

PATIENT EVALUATION

An interim history should be obtained from every patient at the start of each office visit. It is important for the practitioner to understand how the patient's pain pattern is evolving in response to treatment. This helps determine which areas are more likely to require injection treatment at the time of the office visit.

A physical examination should also be performed on every patient prior to trigger point injection. During this examination, tenderness and activity of trigger points is evaluated. Treatment is best determined at the time of the office visit, based on the interim history, a thorough assessment of treatment results, and physical examination at the time of the office visit.

PATIENT INFORMED CONSENT

It is a good idea for patients to sign a document that represents informed consent prior to performing this invasive procedure. In addition, the American Academy of Pain Management Accreditation requires that the clinic documents informed consent for trigger point injections. The document should include the purpose of the procedure, alternative methods of treatment, common untoward effects, and risks of treatment.

CPT/BILLING CODE

The CPT/billing code for myofascial trigger point injections is 20550.

TECHNIQUE

The patient needs to be placed in a comfortable position, and the musculature to be injected should be totally relaxed. For most injections, the patient will be supine or prone. A patient will rarely be seated during injection. Some muscles are best injected with the patient lying on their side. With the muscles more relaxed, the technique is more easily performed and it is also less uncomfortable.

The muscle to be injected should be isolated as much as possible from major nerves, blood vessels, and visceral cavities. For example, when injecting the quadriceps, an effort should be made to isolate the femoral artery and nerve by palpation. When injecting the middle trapezius muscles, the needle should be kept mostly tangential to the chest wall, and the taut band should be isolated by palpation. Specific anatomical techniques are well illustrated elsewhere (Travell & Simons, 1983).

Most of the time, treatment will be effective if trigger points in the muscle belly are injected. For some conditions, it may be more important to also treat trigger points in the origin or insertion of the involved muscles. Optimal treatment of epicondylitis, for example, may require injection of both the origin and muscle belly trigger point zones.

It is usually not helpful to mark the skin over trigger points prior to injection. Palpating the taut band, eliciting a twitch response, and then marking the skin is likely to result in partial treatment of the trigger point. When a trigger point is even partially treated, the patient's pain pattern may shift to that of a more active trigger point. It is generally more time efficient if the area to be treated is identified by history and light palpation shortly before an injection is to be administered. With this in mind, however, it may be helpful for a partner to mark the painful areas they work on or find most tender.

The skin at the injection site should always be cleaned. Anything that is applied to the skin for cleaning can be absorbed— almost as if it were ingested. The best and

least toxic cleaning agent may be ethyl alcohol. In diluted form it is commonly ingested in small amounts. Isopropyl alcohol is more commonly used for skin cleaning; its use is discouraged here because it is too toxic to drink.

Sterile gloves are not necessary, although gloves may be worn by the practitioner for protection from blood-borne pathogens. For practitioners who insist on not using rubber gloves, barrier creams may offer some protection. Good hand-washing techniques are also important for protecting the patient.

Needle size should be determined by the procedure. It is best to use the smallest diameter needle that is long enough to reach through the trigger point and allow adequate control by the technician. Cervical and intra-oral trigger points may be reached with a 1-in., 30-gauge needle. In larger people, a 1.5-in., 27-gauge needle may be necessary. Injecting trigger points in the gluteal muscles may require 2-in., 25-gauge needles. Some larger people require 3-in. or even 6-in. long spinal needles for buttocks trigger point injections. It takes considerable skill and practice to be able to use a 3-in., 25-gauge needle; 22-gauge needles are easier to use and are most necessary when the needle is 6-in. long.

Syringe size should be chosen so that the syringe is easy to hold and use and there is control over how much fluid is injected. Three-milliliter (3-ml) syringes may be the best choice most of the time. One-milliliter syringes are too small, and 5- and 10-cc syringes hold much more fluid than is necessary for an area of trigger points.

SOLUTIONS FOR INJECTION

For the most part, success with trigger point injection is much more related to where the needle is inserted than to which fluid is injected. This is underscored by the success of "dry needling".

Short-Acting Local Anesthetic Agents

Trigger point injection area soreness is generally lessened by local anesthetics. Short-acting local anesthetic agents usually work very well. Lidocaine and procaine may be the most commonly used of the local anesthetics for trigger point injections. Procaine is well tolerated and may have physiologic benefit beyond its local anesthetic effect. Allergic reactions are usually due to preservatives in the solution. Procaine can be purchased preservative-free, making allergic reactions rare.

The procaine purchased from standard medical supply companies is acidic, and infusion is accompanied by burning discomfort at the injection site. Some of this burning can be lessened by buffering the solution prior to injection. One method is to inject 3 cc of sodium bicarbonate into the typical 30-cc bottle of 1% procaine prior to using the bottle. This will neutralize the pH and injections will be more comfortable. Preservative free procaine ordered from a compounding pharmacy can be buffered at the pharmacy with sodium hydroxide.

Long-Acting Local Anesthetic Agents

Trigger point injection soreness may be lessened for a longer period of time by long-acting local anesthetics. Etidocaine and bupivocaine are two examples of long-acting local anesthetics that have been used for trigger point injections. The use of bupivocaine has been associated with myotoxicity, and this should be considered.

Although long-acting local anesthetics may prolong some level of anesthesia and thereby ease stretching and rehabilitation, I have not found this to be a noticeable advantage over the use of procaine.

Homeopathic Agents

There are various homeopathic agents that are currently used for trigger point injections. These agents may be very helpful, and they have not been shown to be harmful.

Corticosteroid Agents

Corticosteroid agents should rarely be used for trigger point injections. There is little or no benefit in steroid injection compared with local anesthetic injection, provided the injection area is cleared of trigger points and the muscles are properly stretched afterward.

Botulinum Toxin

Trigger points that are resistant to injection with local anesthetic and vapo-coolant spray-and-stretch may relax for a longer period of time after injection with botulinum toxin. Use of this agent for routine trigger point injections is discouraged.

Epinephrine

Epinephrine decreases blood flow and should not be injected into a trigger point. Likewise, anesthetic agents that contain epinephrine should not be used for trigger point injection.

AMOUNT OF FLUID INJECTED

For the most part, success with trigger point injection is not related to how much fluid is injected. This is underscored by the success of "dry needling". To minimize the amount of fluid that is injected, first insert the needle through the skin and through the trigger point, eliciting a twitch response. Then withdraw the needle back through the trigger point, while maintaining gentle pressure on the

plunger of the syringe. This will place a few drops of fluid into the trigger point.

When several trigger points are injected and more fluid is used during a treatment session, it is important to consider the dose-related toxicity of the injected solution.

HOW MANY INJECTIONS SHOULD BE ADMINISTERED DURING AN OFFICE VISIT?

Optimal treatment for myofascial pain is for all of the trigger points in the pain pattern to be treated at the time of each office visit. This is not likely to be possible for a patient with a total body pain pattern. An effective and more limited treatment plan is to treat the more severe trigger points causing an area-wide pain pattern. Within any area, there may be several trigger point areas that can be injected. If the pain pattern involves both sides of the body, it is important to keep the body balanced by treating both sides. Treatment, however, does not need to be totally symmetric and can be focused on one side or the other.

TIMING OF INJECTIONS

The practitioner may find that the initial office visit should include history taking, physical examination, and instructions for stretching and dietary modification. Injections during the first visit are rarely of lasting benefit for chronic and diffuse pain patterns. Most patients are ready for injections by the time of their second visit. Their nutritional status has improved and they have been stretching as instructed. This stretching starts development of a healing routine and also prepares the body for more aggressive treatment.

It is usually best to limit the first trigger point injections to two areas, the same on each side of the body. For upper body pain, it may be best to inject bilateral shoulder trapezius or infraspinatus muscles, even if pain is mostly perceived on one side of the body. Myofascial pain is sympathetically mediated, and the sympathetic nervous system is not discrete with respect to one side or the other. Additionally, if treatment is discontinued after unilateral injection of shoulder trapezius musculature, it is possible for the patient to lose balance and fall when trying to walk.

During subsequent office visits, the patient will tolerate more aggressive therapy and more injections. For upper body pain, it may be possible to address muscles in the jaw, neck, upper shoulder, and upper back at the time of a single office visit. Some patients respond best to such a more diffuse and involved treatment session. In such a situation, it is not unreasonable to inject 7 to 14, or more, separate sites during a single office visit.

SYMPATHETIC NERVOUS SYSTEM CAUTIONS

Myofascial trigger point injection by this procedure can affect the body very deeply and very quickly. Each injection into a trigger point "touches" the sympathetic nervous system. If this system is stimulated too much, it may instigate a complex, uncomfortable reaction. The patient may become cold, light-headed, nauseous, and/or start to shiver. Sometimes this will occur after as few as two injection sites.

It is very important for the patient that the health care personnel remain calm and confident. Do not suggest that "you have never seen this before," without admitting that you have read about appropriate procedures for treating the reaction.

This reaction may resolve quickly and easily, or it may require an hour of direct attention and effort from a staff member. Keep the patient warm, hydrated, and resting. Do not perform additional injections. Craniosacral therapy, massage therapy, healing touch, aromatherapy, moist heat, and hydrotherapy may be particularly helpful, and generally have a profound effect on stopping the episode and restoring balance to the nervous system.

The patient will most likely be exhausted and perhaps a little disoriented when this is over. It may be prudent for the office to arrange transportation home for the patient.

LOCAL CAUTIONS

There may be bleeding at the injection site and deep into the muscle as a result of the needle puncturing a blood vessel. Hemostasis is best accomplished with direct pressure to the area of the injection, directly after removal of the needle. The most important time for application of pressure for this purpose is in the first 45 seconds after needle removal. This will minimize bleeding and bruising.

Extra precautions to prevent bleeding and bruising are especially important in the patient that has ingested aspirin-related products. Pressure may be applied during injection by using a firmer grip on the muscle. Pressure should be applied right after injection and may need to be maintained for a few additional minutes.

Vitamin C supplementation reduces bruising and bleeding at injection sites. This effect is generally optimized with ingestion of 1000 mg twice daily. Bleeding will often be noticed at the needle entrance after one or two missed doses from the previous 24 hours.

Additionally, trigger point injections seem to "use up" the patient's vitamin C stores. This will be manifested during a treatment session by bleeding at the needle sites of later injections. In these cases, increasing daily vitamin C supplementation should be considered. Illness may also

deplete vitamin C resources, and this should be taken into account when recommending a change in dose.

DISCOMFORT CAUTIONS

After trigger point injection, there is usually relaxation of the entire treated taut band of muscle. At 15 or 20 minutes after injection of trigger points with a short-acting local anesthetic, the muscle will usually begin to get sore. This soreness typically feels like the muscle had been exercised with weightlifting the day before after not having exercised for some time. This soreness typically subsides in 24 to 48 hours, just like what can be expected with most weightlifting. Occasionally, soreness will persist for a week or longer. With relaxation of a trigger point, the patient's pain pattern is likely to lessen in severity and shift its location. This apparent shift of location represents the quieting of some trigger points and the noticing of others that are now relatively more active.

Occasionally, a pain pattern will worsen after trigger point injection. This phenomenon represents muscle tightening and increased activity with respect to trigger points that may or may not have been treated during the particular treatment session. This is more likely to occur if the patient being injected is anxious or tense during the treatment session, or if the patient undergoes too much treatment during a particular treatment session.

Once in awhile, during post-injection stretching, an injected muscle may retighten. A taut band will be palpable, trigger points will be active, and the patient will be very uncomfortable. This is likely to occur if the patient was not relaxed during the injection treatment. When this happens, the best option is usually to re-inject the muscle and re-stretch it before the patient is discharged from the office. Other options include craniosacral therapy, aromatherapy, and deep tissue massage. This extra care and time from the physician and staff may disrupt a busy schedule, but it is extremely important and will usually prevent several days of misery and an emergency appointment during the next few days. Until the patient is more stable and can easily tolerate more bodywork, the physician should consider less aggressive treatment during future office visits.

COMPLICATIONS

More serious complications are related to the location of the needle. If the needle pierces the pleural cavity, pneumothorax may result. If the needle pierces a major blood vessel in the forearm or lower leg, a compartment syndrome may result. Treatment for pneumothorax may require intubation, and treatment of compartment syndrome may require surgical decompression.

Other serious complications are related to reactions to medications. Severe allergies to the injected solution may require treatment for rash and swelling, or resuscitation.

AFTERCARE

After trigger point injections, the injected muscles and other related muscles involved in the pain pattern should be gently, firmly, and fully stretched toward their normal resting length. It is important to remember that injection is the tool that makes this level of stretch possible, and that stretch is the treatment for myofascial pain.

The body is like a rubber band — it tends to tighten after stretching. It is important to keep the treated muscles from tightening back up, and the most concerted effort should be made during the first hours and then days after treatment. Patients should be advised to stretch slowly, gently, and even briefly anytime it feels like the muscle is tightening. Sometimes, this will be only 10 minutes after previous stretching. Usually, the treated muscles are more stable after a couple of hours and then should be stretched every hour or so until sleep.

The patient should be advised to drink a lot of water, usually at least one glass every hour for several hours. Trigger point injections relax muscle spasm and tension, improving circulation and bloodflow through the muscle. Toxins of metabolism will be released into the body and the water is important for detoxification. People who do not drink enough water may experience fever, nausea, and general malaise.

The Role of Cannabis and Cannabinoids in Pain Management

Ethan B. Russo, M.D.

INTRODUCTION

The herb cannabis is derived from the Old World species *Cannabis sativa* L. *Cannabis indica* and *C. ruderalis* may also merit species status. Cannabis has a history as an analgesic agent that spans at least 4000 years, including a century of usage in mainstream Western medicine. Quality control issues, and ultimately political fiat eliminated this agent from the modern pharmacopoeia, but it is now resurgent. The reasons lie in the remarkable pharmacological properties of the herb and new scientific research that reveals the inextricable link that cannabinoids possess with our own internal biochemistry. In essence, the cannabinoids form a system in parallel with that of the endogenous opioids in modulating pain. More important, cannabis and its endogenous and synthetic counterparts may be uniquely effective in pain syndromes in which opiates and other analgesics fail.

Despite hundreds of supportive journal articles over the past decade, the news about cannabis and cannabinoids has only slowly filtered into public and even professional acknowledgment. The attendant politics remain contentious, with certain states and countries acknowledging a role for cannabis in medicine, while other governmental bodies languish in inactivity or outright opposition.

No major medical text on pain has previously covered this topic to the author's knowledge. This chapter may then represent one point of departure in what I believe will be a major renaissance of interest in this plant, its healing attributes, and what it might tell us about our own internal mechanisms of analgesia. A unique set of clinical tools may be added to an armamentarium in pain management that never seems wholly adequate to the task at hand.

This chapter examines the use of cannabis and cannabinoids historically, scientifically, and anecdotally in relation to a variety of pain syndromes. The author has previously addressed this topic with respect to migraine — in short (Russo, in press) and at great length (Russo, 2001).

CANNABIS AND PAIN TREATMENT: A HISTORICAL SURVEY

China

Traditional knowledge of cannabis in China may span 5000 years, dating to the legendary emperor and "Divine Plowman", Shên-Nung. Julien (1849) wrote of the physician Hoa-tho in the early 2nd century and his use of a cannabis extract in surgical anesthesia:

> He gave to the sick person a preparation of hemp (Mayo), and, in a few moments, he became so insensible that it were as if he was plunged into rapture of loss of life. Then, following this instance, he practiced some overtures, incisions, amputations, and removed the cause of the malady; then he repaired the tissues with suture points, and applied liniments. (p. 197, translation EBR)

0-8493-0926-3/02/$0.00+$1.50

India

The Atharva Veda of India dates to between 1400 and 2000 BCE and mentions a sacred grass, bhanga, which remains a modern term of usage for cannabis. Medical references to cannabis date to Susruta in the 6th to 7th centuries BCE (Chopra & Chopra, 1957). Dwarakanath (1965), described a series of Ayurvedic and Arabic tradition preparations containing the herb indicated for migraine, neuralgic, and visceral pains.

Egypt

Previous scholars had thought cannabis to be absent from Ancient Egypt, but Nunn (1996) cited six supporting experts, indicating that it was utilized medicinally. These authors agree with the view of Dawson that the hieroglyphic shemshemet means cannabis. Physical proof includes discoveries of hemp remnants in the tomb of Akhenaten (Amenophis IV) around 1350 BCE, and cannabis pollen in the tomb of Rameses II, who died in 1224 BCE (Mannische, 1989). Cannabis has remained in the Egyptian pharmacopoeia since pharaonic times, administered orally, rectally, vaginally, on the skin, in the eyes, and by fumigation.

Mannische (1989) cites the following from Papyrus Ramesseum III, 1700 BCE: A "treatment for the eyes: celery; hemp; is ground and left in the dew overnight. Both eyes of the patient are to be washed with it early in the morning" (p. 82). This suggests a parallel to modern use of cannabis in glaucoma treatment.

Another passage (Ebers Papyrus 821) is reminiscent of the 19th-century use of cannabis as an aid to childbirth (Ghalioungui, 1987): "Another: smsm-t [shemshemet]; ground in honey; introduced into her vagina (inf). This is a contraction" (p. 209). Passage E618 refers to treatment of a toenail with a bandage containing hemp resin.

Sumer/Akkad/Assyria

Thompson (1924; 1949) documented 29 citations of the use of cannabis in Assyrian medical documents, and attested to its analgesic and psychogenic effects by various methods, including fumigation. The bulk of the references date to the second millennium BCE and pertain to A.ZAL.LA in Sumerian and azallû in Akkadian. Through philological arguments, Thompson (1924) concluded that:

> The evidence thus indicates a plant prescribed in AM [Assyrian manuscripts] in very small doses, used in spinning and rope-making, and at the same time a drug used to dispel depression of spirits. Obviously, it none other than hemp, Cannabis sativa L. (p. 101)

Specifically, according to Thompson (1949), hemp, or azallû, was employed to bind the temples (possibly for headache?). Furthermore, the Sumerian texts recommended internal use for depression and staying the menses, and "for 'poison' of all limbs, dry, pound, sift, and fumigate…" (p. 222).

Ancient Israel/Palestine/Judea

Physical evidence of medicinal cannabis use in Israel/Palestine was recently discovered (Zias, et al., 1993) in a burial tomb in Beit Shemesh where the skeleton of a 14-year-old girl was found along with 4th century bronze coins. Contained in her pelvic area was the skeleton of a term fetus, of sufficient size to disallow a successful vaginal delivery. In her abdominal area, gray carbonized material was noted and analyzed, yielding chromatographic and nuclear magnetic resonance spectroscopy evidence of delta-6-tetrahydrocannabinol, a stable metabolite of cannabis. The authors stated: "We assume that the ashes found in the tomb were cannabis, burned in a vessel and administered to the young girl as an inhalant to facilitate the birth process" (p. 363). They further remarked that cannabis retained an indication as an aid to parturition into the 19th century.

Greek and Roman Empires

In the 1st century of the Common Era, Dioscorides published his Materia Medica and described the analgesic role of cannabis (Dioscorides, 1968): "Cannabis is a plant of much use in this life for ye twistings of very strong ropes,… but being juiced when it is green is good for the pains of the ears" (p. 390).

Pliny (1951) described additional indications for hemp: "The root boiled in water eases cramped joints, gout too and similar violent pains. It is applied raw to burns,…" (Book XX, XCVII, p. 153).

The Islamic World

In the 9th century, Sabur ibn Sahl in Persia cited the use of cannabis several times in his dispensatorium, Aqrabadhin Al-Saghir (Kahl, 1994). According to the translation and interpretation of the text by Dr. Indalecio Lozano (personal communication, 2000), ibn Sahl prescribed a compound medicine containing cannabis juice that was used to treat a variety of aching pains and migraine that was instilled into the nostril of the afflicted patient.

Also in the 12th century, Al-Biruni (Biruni & Said, 1973) noted: "Galen says: 'The leaves of this plant [cannabis] cure flatus — Some people squeeze the fresh (seeds) for use in ear-aches. I believe that it is used in chronic pains'" (p. 346).

Umar ibn Yusuf ibn Rasul also suggested cannabis for ear and head pains at the end of the 13th century (Lewis, Menage, Pellat & Schacht, 1971).

Some time later, an electuary named bhang, or barsh, containing a variety of ingredients, sometimes including cannabis, became popular as an analgesic treatment in the Arab world. (Lozano Camara, 1990).

At the close of the 17th century in Indonesia, Rumphius studied cannabis use, including treatment of pleuritic chest pains and hernias (Rumpf & Beekman, 1981).

Western Medicine

Medicinal uses persisted in England. In 1640, in The Theatrum Botanicum: The Theater of Plants (Parkinson & Cotes, 1640), John Parkinson indicated:

> Hempe is cold and dry … the Dutch as one saith doe make an Emulsion out of the seede, … for it openeth the obstructions of the gall, and causeth digestion of choller therein: … the Emulsion or decoction of the seede, stayeth laskes and fluxes that are continuall, easeth the paines of the collicke: and allayeth the troublesome humours in the bowels: … The decoction, of the roote is sayd to allay inflammations in the head or any other part, the herbe it selfe, or the distilled water thereof performeth the like effect; the same decoction of the rootes, easeth the paines of the goute, the hard tumours, or knots of the joynts, the paines and shrinking of the sinewes, and other the like paines of the hippes: it is good to be used, for any place that hath beene burnt by fire, if the fresh juyce be mixed with a little oyle or butter. (p. 598)

In 1758, Marcandier published his Traité du chanvre [Treatise on Hemp] which was translated into English several years later (1764):

> The grain and the leaves being squeezed, while they are green, and applied, by way of cataplasm, to painful tumours, are reckoned to have a great power of relaxing and stupefying. … The root of it boiled in water, and applied in the form of a cataplasm, softens and restores the joints of fingers or toes that are dried and shrunk. It is very good against the gout, and other humours that fall upon the nervous, muscular, and tendinous parts. It abates inflammations, dissolves tumours, and hard swellings upon the joints. Beat and pounded in a mortar, with butter, when it is still fresh, it is applied to burns, which it relieves greatly when it is often renewed. (pp. 24, 26)

Linnaeus acknowledged the pain-reducing properties of cannabis in his list of its medical applications in his Materia Medica (Linné, 1772): "narcotica, phantastica, dementans, anodyna, repellens" (p. 213).

In France, Chomel (1782) noted once more the benefits of hemp seed oil on burn treatment, promoting both pain and healing.

The medical use of cannabis, or what became known as "Indian hemp", was reintroduced to the West by O'Shaughnessy in 1839. His treatise on the subject dealt with the apparent utility of a plant extract administered to patients suffering from rabies, cholera, tetanus, infantile convulsions, but also a series of painful rheumatological conditions.

Shortly after Indian hemp came to England, Clendinning (1843) described his results of treatment of 18 patients: three with headaches, one with abdominal pain secondary to tumor, one with pain secondary to a laceration, two with rheumatic joint pain, and one with gout. In each case, the tincture of Indian hemp provided relief, even in cases of morphine withdrawal symptoms. He observed:

> I have no hesitation in affirming that in my hand its exhibition has usually, and with remarkably few substantial exceptions, been followed by manifest effects as a soporific or hypnotic in conciliating sleep; as an anodyne in lulling irritation; as an antispasmodic in checking cough and cramp; and as a nervine stimulant in removing languor and anxiety, and raising the pulse and spirits; and that these effect have been observed in both acute and chronic affections, in young and old, male and female. (p. 209)

In Ireland in 1845, Donovan (1845) extensively described his own extensive trials with small doses of cannabis resin, mainly in patients with various types of neuropathic and musculoskeletal pain. Effects were fairly uniformly impressive, with few side effects. He also described the benefits of local application of hemp leaf oil on hemorrhoids and neuralgic pains.

Christison (1851) endorsed benefits of cannabis in treating tetanus, augmenting labor, and treatment of neuralgic and musculoskeletal pain.

Grigor (1852) examined to role of cannabis in facilitating childbirth. In nine cases, little was noticeable; but in seven, including rive primiparous women, "the contractions acquire great increase of strength … it is capable of bringing the labour to a happy conclusion considerably within a half of the time that would other have been required" (p. 125). No untoward effects were observed on mother or child.

Over the next decades, numerous authorities recognized cannabis as helpful for painful conditions. Sir John Russell Reynolds was eventually to become Queen Victoria's personal physician. He successfully treated her dysmenorrhea with a cannabis extract throughout her adult life. Reynolds (1868) reported on various successes with Indian hemp, theorizing that:

> This medicine appears capable of reducing over-activity of the nervous centres without interfering with any one of the functions of organic, or vegetal life. The bane of

> many opiates and sedatives is this, that the relief of the moment, the hour, or the day, is purchased at the expense of tomorrow's misery. In no one case to which I have administered Indian hemp, have I witnessed any such results. (p. 160)

Silver (1870) reported five cases in detail of menorrhagia and dysmenorrhea, all relieved nicely with cannabis. He also referred to a colleague, who had never failed in over 100 cases to control pain and discomfort in these disorders within three doses.

In 1874, a popular textbook, *Practical Therapeutics* (Waring, 1874), stated of cannabis: "Of a good extract, gr. 1/4 to gr. 1/2, rarely gr. j, in the form of pill, is very effective in some forms of neuralgia" (p. 159).

In the French literature, Michel (1880) extensively reviewed and endorsed the success of cannabis in treating neuralgic afflictions.

In 1883, two letters to the *British Medical Journal* attested to the benefits of extract of *Cannabis indica* in menorrhagia, treating both pain and bleeding successfully with a few doses. (Batho, 1883; Brown, 1883)

Rennie (1886) reported from India on the therapeutic value of a cannabis tincture in curing acute and chronic dysentery and its attendant pain in some dozen patients.

Dr. Hobart Hare published an article that dealt with the indications of cannabis at length:

> CANNABIS INDICA has been before the profession for many years as a remedy to be used in combating almost all forms of pain, yet, owing to the variations found to exist as to its activity, it has not received the confidence which I think it now deserves. I have found the efficient dose of a pure extract of hemp to be as powerful in relieving pain as the corresponding dose of the same preparation of opium. During the time that this remarkable drug is relieving pain a very curious psychical condition sometimes manifests itself; namely, that the diminution of the pain seems to be due to its fading away in the distance, so that the pain becomes less and less, just as the pain in a delicate ear would grow less and less as a beaten drum was carried farther and farther out of the range of hearing. (pp. 225–226)

Soon thereafter, Farlow (1889) penned a treatise on the use of rectal preparations of cannabis: "Cannabis has few equals in its power over nervous headaches such as women with pelvic troubles are subject to" (p. 508).

Aulde (1890) lauded the drug as follows: "As a remedy for the relief of supraorbital neuralgia no article perhaps afford better prospects than cannabis …" (p. 118).

In the French literature, Séé (1890) submitted a detailed report on the use of cannabis in the treatment of various disorders producing gastric and intestinal pain. He found it preferable in efficacy and side effects to other agents of the day, including opiates and bismuth that remain on the modern scene.

In the article "On the Therapeutic Value of Indian Hemp," Suckling (1891) declared: I "have met with patients who have been incapacitated for work from the frequency of the attacks [of migraine], and who have been enabled by the use of Indian hemp to resume their employment" (p. 12). This echoes modern claims of clinical cannabis users who partake lightly of the drug and return to work or study.

Mattison was effusive in his praise in 1891:

> … Indian hemp is not here lauded as a specific. It will, at times, fail. So do other drugs. But the many cases in which it acts well, entitle it to a large and lasting confidence.
>
> My experience warrants this statement that cannabis indica is, often, a safe and successful anodyne and hypnotic. (pp. 270–271)

Mackenzie (1894) described the utility of cannabis in treating neuralgias, headache, including chronic daily headache, tabetic (syphilitic) pain, functional gastrointestinal pain (corresponding to modern idiopathic bowel syndrome, or "spastic colon"), and pruritic disorders.

That year in India, among many other indications, the encyclopedic Indian Hemp Drugs Commission (1894) reported that a small piece of charas (hashish) placed in a carious tooth would relieve aching pain.

An American 1898 drug handbook stated the following quaint prose under "Actions and Uses" for cannabis (Lilly, 1898): "Not poisonous according to best authorities, though formerly so regarded. Antispasmodic, analgesic, anesthetic, narcotic, aphrodisiac. Specially recommended in spasmodic and painful affections …" (p. 32).

Dixon (1899), a famed British pharmacologist, studied cannabis extensively and recognized its value "as a useful food accessory," supporting its current indications in the cachexia of cancer chemotherapy and HIV-positive patients. He also reintroduced the concept of smoking the drug to Western medicine:

> In cases where an immediate effect is desired the drug should be smoked, the fumes being drawn through water. In fits of depression, mental fatigue, nervous headache, and exhaustion a few inhalations produce an almost immediate effect, the sense of depression, headache, feeling of fatigue disappear and the subject is enabled to continue his work, feeling refreshed and soothed. I am further convinced that its results are marvellous in giving staying power and altering the feelings of muscular fatigue which follow hard physical labour. (p. 1356)

The same year, Shoemaker (1899) reported on a large series of patients with pain conditions, including migraine, dental neuralgia, gastralgia, enteralgia, cerebral tumor, and herpes zoster, all successfully treated with Cannabis indica.

As late as 1915, Sir William Osler (Osler & McCrae, 1915) the acknowledged father of modern medicine stated of migraine treatment: "Cannabis indica is probably the most satisfactory remedy. Seguin recommends a prolonged course of the drug" (p. 1089). This statement provided support of its use for both acute and prophylactic treatment of migraine.

In 1918, The Dispensatory of the United States of America (Remington, et al.) stated, "Cannabis is used in medicine to relieve pain, to encourage sleep, and to soothe restlessness... For its analgesic action it is used especially in pains of neuralgic origin, such as migraine, but is occasionally of service in other types" (p. 280).

In 1922, Hare still advocated the use of cannabis stating that: "For the relief of pain, particularly that depending on nerve disturbance, hemp is very valuable" (p. 181).

Hoechstetter, as late as 1930, noted the ability of cannabis to achieve a labor with pain burden substantially reduced or eliminated, followed by a tranquil sleep. He stated: "As far as is known, a baby born of a mother intoxicated with cannabis will not be abnormal in any way" (p. 1165).

In 1942, despite its political disenfranchisement, Morris Fishbein, the editor of the Journal of the American Medical Association, still advocated oral preparations of cannabis in the treatment of menstrual (catamenial) migraine (Fishbein, 1942).

Cannabis remained in the British armamentarium somewhat longer, and was extolled above opiates and barbiturates in the treatment of the pain of hospitalized patients with duodenal ulcers (Douthwaite, 1947).

Modern Ethnobotany of Cannibis in Analgesia

In Tashkent in the 1930s, cannabis, or nasha, was employed medicinally, despite Soviet prohibition (Benet, 1975): "A mixture of lamb's fat with nasha is recommended for brides to use on their wedding night to reduce the pain of defloration. The same mixture works well for headache when rubbed into the skin; it may also be eaten spread on bread" (pp. 46-47).

In Southeast Asia, cannabis remains useful (Martin, 1975):

> Everywhere it is considered to be of analgesic value, comparable to the opium derivatives. Moreover, it can be added to any relaxant to reinforce its action. Cooked leaves, which have been dried in the sun, are used in quantities of several grams per bowl of water. This decoction helps especially to combat migraines and stiffness... (p. 70).

A more recent study documents the ethnobotanical uses of cannabis by the Hmong minority in the China-Vietnam border region (Gu & Clarke, 1998): "Some older Hmong men may rarely smoke cannabis to 'relieve discomfort,' but they are not daily smokers" (p. 6).

In a book (Dastur, 1962) about medicinal plants of India, we see the following:

> Charas is the resinous exudation that collects on the leaves and flowering tops of plants [equivalent to the Arabic hashish]; it is the active principle of hemp; it is a valuable narcotic, especially in cases where opium cannot be administered; it is of great value in malarial and periodical headaches, migraine, acute mania, whooping cough, cough of phthisis, asthma, anaemia of brain, nervous vomiting, tetanus, convulsion, insanity, delirium, dysuria, and nervous exhaustion; it is also used as an anaesthetic in dysmenorrhea, as an appetizer and aphrodisiac, as an anodyne in itching of eczema, neuralgia, severe pains of various kinds of corns, etc. (p. 67)

In Colombia, the analgesic effects of a cannabis tincture was lauded (Partridge, 1975): "The knowledge that cannabis can be used for treatment of pain is widespread..." (p. 161).

Rubin (1976; Rubin & Comitas, 1975) documented extensive usage of cannabis in Jamaica for a variety of conditions, including headache. In Brazil, Hutchinson (1975) noted:

> Such an infusion [of marijuana leaves] is taken to relieve rheumatism, "female trouble," colic and other common complaints. For toothache, marijuana is frequently packed into and around the aching tooth and left for a period of time, during which it supposedly performs an analgesic function. (p. 180)

MODERN DATA ON CANNABIS AND ANALGESIA

Recent Theory and Clinical Data

A popular treatise (Margolis & Clorfene, 1969) on marijuana noted medicinal effects:

> You'll also discover that grass is an analgesic, and will reduce pain considerably. As a matter of fact, many women use it for dysmenorrhea or menorrhagia when they're out of Pamprin or Midol. So if you have an upset stomach, or suffer from pain of neuritis or neuralgia, smoke grass. If pains persist, smoke more grass. (p. 26)

Solomon Snyder (1971), the discoverer of opiate receptors, examined cannabis's pros and cons as an analgesic, commenting:

> For there are many conditions, such as migraine headaches or menstrual cramps, where something as mild as aspirin gives insufficient relief and opiates are too powerful, not to mention their potential for addiction. Cannabis might conceivably fulfill a useful role in such conditions. (p. 14)

Subsequent experimental studies by Noyes explored these reported analgesic effects of cannabis. One article examined pain tolerance thresholds (Milstein, MacCannell, Karr, & Clark, 1975). Both naïve (8% increase) and experienced human subjects (16% increase) noted statistically significant increases in pain threshold after smoking cannabis.

In humans, Noyes (Noyes & Baram, 1974) described case studies of five patients who voluntarily employed it to treat their painful conditions. Another study (Noyes, Brunk, Baram, & Canter, 1975) pertained to oral tetrahydro-cannabinol (THC) in cancer patients. Pain relief with escalating doses significant to the $P < 0.001$ level was observed. Peak effects occurred at 3 hours with doses of 10 and 15 mg, but were delayed until 5 hours after the 20-mg oral dose.

Noyes' research group compared the analgesic effect of THC to codeine (Noyes, Brunk, Avery, & Canter, 1975). In short, 10 mg of oral THC reduced subjective pain burdens by similar decrements to 60 mg codeine, as did 20 mg THC vs. 120 mg codeine. The 20-mg dose was sedative and not as well tolerated in some elderly, cannabis-naïve subjects.

Hollister (1986) addressed possible cannabis indications, including analgesia. He concluded that it seemed that no THC homologue would be an analgesic of choice, but that "It is too early to be sure, however" (p. 15). These were prophetic words in light of upcoming cannabinoid receptor research.

In 1991, a series of case studies on the utility of cannabis in treating chronic pain were published (Randall, 1991). One pertained to Lynn Hastings, an Idaho woman with severe juvenile rheumatoid arthritis, whose symptoms of pain, spasm, and depression were resistant to standard medicine, but were effectively treated with cannabis. A state Supreme Court finding of "medical necessity" followed her initial arrest for cultivation of cannabis. Eventually, the charges were dropped.

In 1993, the landmark book *Marihuana, The Forbidden Medicine*, was first published and has since been revised (Grinspoon & Bakalar, 1997). Although criticized in some quarters as anecdotal, the book contains numerous compelling testimonials from patients and their doctors attesting to the clinical efficacy of cannabis where conventional pharmacotherapy failed. Cases of painful conditions responding to cannabis are legion: osteoarthritis, ankylosing spondylitis, pruritus from allergic dermatitis, premenstrual syndrome (PMS), menstrual cramps, labor pains, gingival pain (with local application of cannabis tincture), migraine, phantom limb pain, Crohn's disease, and "functional" gastrointestinal pain. Often, these patients improved with cannabis, worsened without it, and were improved once more upon its resumption. These accounts fulfill criteria of "N-of-1 studies" and have been accepted by epidemiologists as proof of efficacy in rare conditions or ones in which blinded controlled trials are technically difficult (Guyatt, et al., 1990; Larson, 1990).

The American Journal of Public Health (1996) "Access", issued a particularly strong plea for liberalization of laws pertaining to medical cannabis in 1996, citing its activity in "decreasing the suffering from chronic pain..."

Hollister (2000) has recently reviewed indications for cannabis "for exploratory purposes, any patient with pain unrelieved by conventional analgesics should have access to smoked marijuana if they so desire" (p. 5).

Cannabinoid and Endocannabinoid Neurochemistry

In recent years, scientists (Barinaga, 1992; Devane, et al., 1992; Marx, 1990; Matsuda, Lolait, Brownstein, Young, & Bonner, 1990) have provided elucidation of the mechanisms of action of cannabis and THC (tetrahydrocannabinol, the primary psychoactive component) with the discovery of an endogenous cannabinoid (endocannabinoid) ligand, arachidonylethanolamide, nicknamed anandamide, from the Sanskrit word *ananda*, or "bliss." Anandamide inhibits cyclic AMP mediated through G-protein coupling in target cells, which cluster in nociceptive areas of the central nervous system (CNS) (Herkenham, 1993). Early testing of its pharmacological action and behavioral activity indicate similarity to THC (Fride & Mechoulam, 1993), although anandamide differs from THC in not causing dynorphin release (Strangman & Walker, 1999). Pertwee (1997) has examined the pharmacology of cannabinoid (CB) receptors in detail. CB_1 receptors are mainly confined to the CNS, while CB_2 receptors are found in the periphery, often in conjunction with immune mechanisms.

Further research has elucidated analgesic mechanisms of cannabinoids, which will be examined system by system.

Cannabinoids and Serotonergic Systems

Serotonergic mechanisms are implicated in many pain conditions, especially migraine and cluster headaches.

THC reduces serotonin release from the platelets of human migraineurs (Volfe, Dvilansky, & Nathan, 1985).

Cannabis has been observed to stimulate 5-HT synthesis, its brain content, decrease its synaptosomal uptake, while stimulating its release (Spadone, 1991).

Anandamide and other cannabinoid agonists inhibit rat serotonin type 3 (5-HT_3) receptors (Fan, 1995) that mediate emetic and pain responses. The recent advent of alosetron, a 5-HT_3 blocker employed in the treatment of irritable bowel syndrome ("Alosetron," 2000), would seem to support claims of the efficacy of cannabis in that disorder on the basis of this mechanism.

Recently, Boger and his group (1998) have demonstrated an 89% relative potentiation of the 5-HT_{1A} receptor response, and a 36% inhibition of the 5-HT_{2A} receptor response by anandamide. Similar effects by THC are likely, supporting efficacy for cannabinoids in acute symptomatic migraine treatment due to agonistic activity at 5-HT_{1A} or 5-HT_{1D}, and in prophylactic treatment of chronic headache due to antagonistic activity at 5-HT_{2A} (Peroutka, 1990a,b).

Kimura, Ohta, Watanabe, Yoshimura, and Yamamoto (1998) showed that high concentrations of anandamide decreased serotonin and ketanserin binding (a 5-HT_{2A} antagonist). 11-OH-delta 8-THC and 11-oxo-delta 8-THC metabolites of cannabis were also observed to modify serotonin receptor binding.

Ultimately, this author and colleagues (Russo, Macarah, Todd, Medora, & Parker, 2000) have shown that essential oil components of cannabis demonstrate potent serotonin receptor activity that supports putative synergism with THC in the modulation of analgesia.

Dopaminergic Systems

The importance of dopaminergic mechanisms in the treatment of migraine and other types of pain has received recent emphasis (Peroutka, 1997). However, existing neuroleptics are significantly sedating.

Ferri, Cavicchini, Romualdi, Speroni, and Murari (1986) were able to demonstrate that 6-hydroxydopamine, which causes degeneration of catecholamine terminals, was able to block THC antinociception.

In a more recent review article (Mechoulam, Fride, & diMarzo, 1998), a number of studies were reviewed as demonstrating that cannabimimetic drugs cause "inhibition of the dopaminergic nigrostriatal system" (p. 12).

Müller-Vahl and colleagues (Müller-Vahl, Kolbe, Schneider, & Enrich, 1998) cited Mailleux (Mailleux & Vanderhaeghen, 1992) in their discussion of cannabinoid interactions with the dopaminergic system stating that "cannabinoid receptors were found to be co-localized both with dopamine D_1 receptors on striatonigral dynorphin/substance-P-containing neurones and with dopamine D_2 receptors on striatopallidal enkephalinergic neurones" (p. 504).

Carta, Gessa, and Nava (1999) demonstrated that antinociceptive effects of THC are mediated by $_1$CB and dopamine D_2 receptors, and that combination of the agents improved analgesic effects in rats.

Inflammatory Mechanisms

Modern authors (Burstein, 1992; Evans, Formukong, & Evans, 1987; Formukong, Evans, & Evans, 1988, 1989) have examined the relationship between cannabinoids and inflammation. McPartland (2001) provides an excellent summary and analysis of the subject.

Burstein, Levin, & Varanelli (1973) demonstrated that THC and other cannabinoids inhibit prostaglandin E-2 synthesis. In 1979, experiments showed that smoked cannabis reduced platelet aggregation (Schaefer, Brackett, Gunn, & Dubowski, 1979).

In 1981, cannabichromene, often the second-most abundant cannabinoid in marijuana after THC, was demonstrated to be a more effective anti-inflammatory agent than phenylbutazone in carrageenan-induced rat paw edema and the erythrocyte membrane stabilization method (Turner & ElSohly, 1981). The authors stated: "The activity of cannabichromene through the oral route, its safety and its lack of behavioral-type (psychotomimetic) activity characteristic of THC(I) indicate its therapeutic potential for the treatment of inflammatory diseases" (pp. 288S–289S).

Evans (1991) has stated that: "Experiments involving oral administration of THC suggested that THC was 20 times more potent than aspirin and twice as potent as hydrocortisone" (p. 565). Cannabidiol (CBD) functioned as a dual cyclooxygenase and lipoxygenase inhibitor in various assays.

Klein (Klein, Friedman, & Specter, 1998) noted that THC had variable effects on tumor necrosis factor (TNF) production, depending on the cells and culture system selected.

In 1998, Jaggar and colleagues issued two reports addressing visceral and inflammatory pain in rats (Jagger, Hasnie, Sellaturay, & Rice, 1998; Jagger, Sellaturay, & Rice, 1998). The endocannabinoid anandamide, a $_1$CB ligand, prevented and reduced viscero-visceral hyperreflexia (VVH) in the inflamed bladder. In contrast, palmitoylethanolamide, a presumptive endogenous $_2$CB ligand that accumulates in inflamed tissues and reduces edema by down-modulating mast cells, only reversed VVH once previously established. The authors posited the possibility of development of non-sedating analgesic anti-inflammatory drugs based on $_2$CB receptor agonism.

In a 1999 review (Fimiani, et al., 1999), the authors noted: "Delta-9-THC blocks the conversion of arachidonic acid into all metabolites derived by cyclooxygenase activ-

ity, whereas it stimulates lipoxygenase, resulting in an increase in lipoxygenase products" (p. 27). The COX inhibition of THC may in fact be selective for the COX-2 isozyme, as more fully discussed by McPartland (2001). Clinically, no increased incidence of gastric ulceration was reported in chronic cannabis users (New York (City), 1973; Rubin & Comitas, 1975; Stefanis, Dornbush, & Fink, 1977), thus supporting its likely selectivity for COX-2. In 1978, cannabis was believed to reduce gastric acidity in humans (Nalin, et al., 1978), while another group demonstrated THC to have anti-ulcer effects in rats (Sofia, Nalepa, Harakal, & Vassar, 1973). In fact, one essential oil sesquiterpene component of cannabis, caryophyllene, has recently been demonstrated to have a gastric cytoprotective effect (Tambe, Tsujiuchi, Honda, Ikeshiro, & Tanaka, 1996).

Fimiani and co-workers (Fimiani, et al., 1999) also observed that the morphine-cannabinoid system modulates the eicosanoid cascade and its pro-inflammatory cytokine activity through induction of nitric oxide synthesis, averting damaging effects on tissues. They stated in summary (p. 30): "Thus, we can surmise cannabinoid-morphine systems are down-regulators of inflammatory processes in an attempt to restore homeostasis."

A recent report has demonstrated the efficacy of oral cannabidiol (CBD), a minimally psychoactive cannabis component, at a dose of 5 mg/kg/d in treating mice against collagen-induced arthritis, a model for human rheumatoid arthritis (Malfait, et al., 2000). Benefits were produced through a combination of immunosuppressive effects (diminished CII-specific proliferation and IFN-gamma production) and anti-inflammatory effects (decreased release of tumor necrosis factor by synovial cells).

Cannabis seed also has dietary benefits as an anti-inflammatory agent. It yields linolenic acid, which promotes formation of anti-inflammatory metabolites, and gamma-linolenic acid, which inhibits the formation of pro-inflammatory products from arachidonate (Conrad, 1997; Russo, 2000; Wirtshafter, 1997).

Flavonoid and terpenoid essential oil components of cannabis demonstrate anti-inflammatory effects at physiologically appropriate levels (McPartland & Mediavilla, in press). Cannflavin A and B inhibited prostaglandin E-2 production in human rheumatoid synovial cells 30 times more potently than aspirin (Barrett, Scutt, & Evans, 1986).

The cannabis flavonoid apigenin has anti-inflammatory actions on interleukin, TNF, carrageenan-induced edema, and by inhibition of up-regulation of cytokine-induced genes (Gerritsen, et al., 1995).

Quercetin, another flavonoid in cannabis, serves as an antioxidant and inhibits hydrogen peroxide-mediated NF-kappa B activity (Musonda & Chipman, 1998).

Burstein and co-workers have demonstrated eugenol to be a potent prostaglandin inhibitor (Burstein, Varanelli, & Slade, 1975).

Subsequently, both the alpha-pinene and caryophyllene components of cannabis have proven to demonstrate anti-inflammatory activity in the rat hindpaw edema model (Martin, et al., 1993).

Cannabinoid Interactions with Opiates and Endogenous Opioids

THC experimentally increases beta-endorphin levels Wiegant, Sweep, & Nir, 1987). Depletion of endorphins has been measured in the CSF of migraineurs during attacks (Fettes, Gawel, Kuzniak, & Edmead, 1985), and theoretically contributes to migraine effects such as hyperalgesia and photophobia.

Early exposure to THC in rat pups boosted adult levels of beta-endorphins in specific brain areas (Kumar, et al., 1990).

Mailleux and Vanderhaeghen (1994) have also demonstrated that THC regulates substance P and enkephalin mRNA levels in the basal ganglia. Manzanares and co-workers have shown that THC is able promote increases in beta-endorphin in rats (Manzanares, et al., 1998).

Meng and colleagues demonstrated that THC is involved in an analgesic brainstem circuit in the rostral ventromedial medulla that interacts with opiate pathways (Meng, Manning, Martin, & Fields, 1998).

Cichewicz, Martin, Smith, and Welch (1999) have suggested an opiate sparing effect of THC might be employed clinically in pain patients, echoing claims of the 19th century pioneers of Indian hemp. Similarly, Welch and Eads (1999) noted that cannabinoid-induced analgesia produced antinociception through spinal dynorphin release with synergistic effects with opiates. They stated, however: "THC, in comparison to the morphine derivatives, has a greater therapeutic range" (p. 188)

Many analgesic effects of cannabinoids cannot be reproduced by opiates, however, particularly in cases of neuropathic pain (Hamann & di Vadi, 1999). Nicolodi (1998) examined opiate aggravation of migraine.

Recently, Manzanares and colleagues cited that chronic cannabinoid administration could similarly promote hypothalamic production of beta-endorphin (Manzanares, Corchero, Romero, Fernandez-Ruiz, Ramos, & Fuentes, 1999).

Strangman and Walker (1999) demonstrated that a cannabinoid antagonist was able to decrease wind-up in spinal nociceptive neurons, producing hyperalgesia and allodynia in chronic pain states. The same group showed that cannabinoids selectively affect nociceptive neurons in the spinal cord and ventroposterolateral nucleus of the thalamus in a manner that promotes antinociception without anesthesia (Walker, Hohmann, et al., 1999). In all,

seven sites in the CNS involved in pain processing produced effects after microinjections of cannabinoids, effecting a circuit that mediates the descending pain suppressing effects of opiates.

Cannabinoids and the Periaqueductal Gray Area

In 1996, researchers demonstrated antinociceptive effects of delta-9-THC and other cannabinoids in the periaqueductal gray matter (PAG) in rats (Lichtman, Cook, & Martin, 1996). The PAG is a putative migraine generator area (Goadsby & Gundlach, 1991; Raskin, 1988). The PAG has received a lengthy analysis (Behbehani, 1995), citing its importance in the processes of ascending and descending pain pathways. A detailed review of effects of the PAG and cannabinoids in migraine is contained in Russo (2001).

Manzanares, Corchero, Romero, Fernandez-Ruiz, Ramos, and Fuentes suggested that cannabinoid-mediated antinociception in the PAG is produced by activation of endogenous opioids, supported by the fact that subchronic THC administration elevates proenkephalin gene expression in the area (Manzanares, et al., 1998).

Recently Walker and colleagues demonstrated that electrical stimulation of PAG in the rat stimulated anandamide release and CB_1 receptor-mediated analgesia (Walker, Hohmann, Martin, Strangman, Huang, & Tsou, 1999). The system seemed to be tonically active and cannabinoid antagonists produced hyperalgesia. The authors posited that this cannabinoid-modulated pain system would support the prospect of approaches with cannabinoids to opiate-resistant syndromes.

NMDA and Glutamate

A trigeminovascular system has long been implicated as subserving pain, inflammatory and vascular effects, again reviewed in Russo (2001).

In 1996, Shen and co-workers elucidated basic mechanism of cannabinoids in glutamatergic systems (Shen, Piser, Seybold, & Thayer, 1996). Through G-protein coupling, cannabinoid receptors inhibit voltage-gated calcium channels and activate potassium channels to produce presynaptic inhibition of glutamate release. Subsequently, it has been shown (Shen & Thayer, 1999) that THC is a partial agonist acting presynaptically via CB_1 to modulate glutamatergic transmission through a reduction without blockade.

Hampson and colleagues (Hampson, Bornheim, Scanziani, Yost, Gray, Hansen, Leonoudakis, & Bickler, 1998) demonstrated a 30 to 40% reduction in delta-calcium-NMDA responses by THC, which was eliminated by a cannabinoid antagonist. THC and CBD components of cannabis act as neuroprotective antioxidants against glutamate neurotoxicity and cell death mediated via NMDA, AMPA and kainate receptors (Hampson, Grimaldi, Axelrod, & Wink, 1998). Effects are independent of cannabinoid receptors. The natural cannabinoids were more potent in their anti-oxidant effects than either alpha-tocopherol or ascorbate.

Italian researchers Nicolodi, Sicuteri, and colleagues have recently elucidated the role of NMDA antagonists in eliminating hyperalgesia in migraine, chronic daily headache, fibromyalgia, and possibly other mechanisms of chronic pain (Nicolodi & Sicuteri, 1995, 1998; Nicolodi, Del Bianco, & Sicuteri, 1997; Nicolodi, Volpe, & Sicuteri, 1998). Gabapentin and ketamine were suggested as tools to block this system and provide amelioration. Given the above observations and relationships, it is logical that prolonged use of THC prophylactically may exert similar benefits, as was espoused in cures of chronic daily headache claimed in the 19th century with regular use of extract of Indian hemp (Mackenzie, 1887).

This concept is bolstered by examination of another series of articles by Richardson and co-workers. One study (Richardson, Kilo, & Hargreaves, 1998) examined peripheral mechanisms, wherein cannabinoids acted on CB_1 to reduce hyperalgesia and inflammation via inhibition of neurosecretion of calcitonin gene-related peptide (CGRP) in capsaicin-activated nerve terminals.

At the spinal level, they noted an antihyperalgesic effect of cannabinoids, mediated by the CB_1 receptor (Richardson, Aanonsen, & Hargreaves, 1998a). Additionally, experimental cannabinoid receptor blockade induced a glutamate-dependent hyperalgesia, suggesting a tonic activity of cannabinoids in averting such a development. The authors suggested the clinical utilization of cannabinoids in disorders "characterized by primary afferent barrage" (p. 152). Inasmuch as an increased potency of cannabinoids was observed in hyperalgesia this "may mean that there are dosages of cannabinoids that would be effective as antihyperalgesic agents but subthreshold for the untoward psychomimetic effects." This is akin to Dixon's (1899) observations of patients able to return to work after treating their headaches with a few inhalations of cannabis.

Elaborating on these themes, Richardson noted that a decrease in lumbar cannabinoid receptor numbers correlated with hyperalgesia, and could provide an etiology for certain chronic pain states, especially those unresponsive to opiates (Richardson, Aanonsen, & Hargreaves, 1998b).

In a more recent study (Li, Daughters, Bullis, Bengiamin, Stucky, Brennan, & Simone, 1999), the synthetic cannabinoid agonist WIN 55,212–2 was employed to block capsaicin-induced hyperalgesia in rat paws, much as has been observed for THC in formalin treatment.

Ko and Woods (1999) examined local THC administration and its activity on capsaicin-induced pain in rhesus monkeys. THC effectively reduced pain, which was blocked by a CB_1 antagonist and was effective at

a parenteral dose that produced no behavioral change or sedation.

Maneuf, Nash, Crossman, and Brotchie (1996) examined similar issues at higher CNS levels, and were able to show a tonic activation of the cannabinoid system serving to reduce GABA uptake in the globus pallidus.

Synergism and the Entourage Effect

Palmitylethanolamide (PEA) is another endogenous cannabinoid with analgesic effects, released with from a phospholipid in conjunction with anandamide (Calignano, La Rana, Giuffrida, & Piomelli, 1998). Ensemble, the two substances effect a 100-fold synergism on CB_1 and CB_2 peripheral receptors in cutaneous tissues.

Endocannabinoids and their inactive metabolites combine to boost physiological responses (the "entourage effect") (Mechoulam & Ben-Shabat, 1999). Given the likely contributions of cannabis flavonoids and essential oils to therapeutic effects on mood, inflammation, and pain reviewed in McPartland and Pruitt (1999), one may readily accept Mechoulam's quotation: "This type of synergism may play a role in the widely held (but not experimentally based) view that in some cases plants are better drugs than the natural products isolated from them" (Mechoulam & Ben-Shabat, 1999, p. 136)

PRACTICAL APPLICATION OF CANNABINOIDS TO ANALGESIA

Marinol® (Dronabinol): Pros and Cons

Marinol® is a synthetically derived THC dissolved in sesame oil, developed by Unimed Pharmaceuticals and marketed by Roxane Laboratories. It is available in capsules of 2.5, 5, and 10 mg and is marketed in the United States, Canada, Australia, and some areas in Europe (Grotenherman, in press a). Until 1999, Marinol® was a Schedule II drug in the U.S. with close scrutiny to its usage, which was restricted to indications of AIDS-associated anorexia and cancer chemotherapy. After safety studies revealed a low potential for abuse or diversion (Calhoun, Galloway, & Smith, 1998), dronabinol was "down-scheduled" to Schedule III, allowing refill prescriptions for up to 6 months, and its "off-label" administration for any indication.

Clinicians have utilized Marinol® to only a limited degree. Its bioavailability is only 25 to 30% of an equivalent smoked dose of THC (British Medical Asociation [BMA], 1997). Additional problems include the first pass effect of hepatic metabolism, which results in the production of a more psychoactive metabolite 11-hydroxy-THC, and its considerable cost, which may exceed U.S.$600 per month for the lowest dosage of 2.5 mg t.i.d. Considerable anecdotal data supports preference by patients of smoked cannabis over dronabinol (Grinspoon & Bakalar, 1997; Russo, in press).

Reports of dronabinol use in painful clinical conditions are few, but it has had some variable success in migraine prophylaxis (Mikuriya, 1997; Russo, 1998; 2000; in press).

Maurer, Henn, Dittrich, and Hoffman (1990) demonstrated efficacy of analgesia of 5 mg p.o. THC to 50 mg codeine in treatment of pain in a young paraplegic after removal of a spinal tumor. However, THC also limited spasticity, whereas codeine and placebo did not.

Holdcroft, et al. were able to demonstrate an analgesic benefit ($p < 0.001$) of THC 50 mg per day in five split doses in a patient with relapsing familial Mediterranean fever in a double-blind placebo-controlled trial (Holdcroft, et al., 1997).

Nabilone

Nabilone is a synthetic cannabinoid said to be pharmacologically similar to THC, but more potent, less apt to produce euphoria, and possessing lower "abuse potential" (BMA, 1997). It is produced by Eli Lilly Company as Cesamet® and is available in the United Kingdom, Canada, Australia, and certain countries in Europe (Grotenhermen, in press a) as an agent for nausea in chemotherapy. Some scattered reports have noted benefit in spasticity in multiple sclerosis, and effects on dyskinesias. Lethal toxicity in dogs has been noted with chronic use (Mechoulam & Feigenbaum, 1987).

A group in the U.K. recently assessed the analgesic effects of nabilone in patients, including some with neuropathic pain (Notcutt, Price, & Chapman, 1997). Side effects of drowsiness and dysphoria were troubling. Several patients claimed improved pain relief and fewer side effects with smoked cannabis and preferred it to this legal alternative. Nabilone's cost was also estimated to be 10 times higher than cannabis, even at "black market" rates.

Levonantradol

Levonantradol is a synthetic cannabinoid developed by Pfizer. Although analgesic responses of up to 6 hours were noted in postoperative pain patients (Jain, Ryan, McMahon, & Smith, 1981), no dose-response effects were observed and side effects were a significant issue. The latter included somnolence (50 to 100%) and dysphoria (30 to 50%), according to the British Medical Association (BMA, 1997), and were labeled "unacceptable" by that formal body.

Ajulemic Acid (CT3)

Ajulemic acid is synthetic derived from delta-8-THC that does not bind to cannabinoid receptors. CT3 is being developed by Atlantic Pharmaceuticals. It has shown anal-

gesic and anti-inflammatory properties in animal models without COX-1 inhibition side effects, and reportedly will be soon in Phase 1 human trials (Burstein, 2000, in press).

Cannabis Proper

Use of cannabis for pain conditions is extensive in the United States and some European countries. A survey of patients attending the Oakland Cannabis Buyers' Club revealed (Gieringer, in press):

> By far the largest category of patients interviewed by Mikuriya use cannabis for analgesia to treat conditions including: migraines and neuralgias; arthritis and rheumatism; spinal, skeletal and back disorders due to injury, deformity, or degenerative disease; and inflammatory gastrointestinal disorders, and a host of miscellaneous diseases.

Analysis of the totals revealed that at least 1133 of 2480 patients (or 46%) sought cannabis for analgesia in treatment of chronic pain conditions.

Cannabis is traditionally employed therapeutically by smoking or ingestion. Each has advantages and disadvantages. Grotenhermen (2001, in press b) has produced an excellent summary of "Practical Hints," as have Brazis and Mathre (1997).

Dosing of therapeutic cannabis must be titrated to the patient's need. In general, 5 mg represents a threshold dose for noticeable effects in the average adult. Whereas tolerance to cardiovascular effects (tachycardia) and psychoactive effects ("high") are achieved after some days to weeks of chronic usage, observed clinical and "anecdotal" reports support retention of analgesic efficacy over the long term. Occasionally, upward dose titration is necessary, as is true for any agent.

Allergies to cannabis are rare, although some may experience rhinitis symptoms, particularly when exposed to the smoke of the unrefined product.

More severe psychiatric conditions present a relative contraindication to the use of cannabis, while many milder emotional afflictions may benefit from the drug (Grinspoon & Bakalar, 1997; Russo, 2000). Although concerns have been raised about subtle neuropsychological sequelae in children born to mothers employing cannabis in pregnancy (Fried, in press), other studies have shown no significant abnormalities (Dreher, 1997). Certainly, no mutagenic or teratogenic potential has been demonstrated in humans.

Concerns about our youth employing cannabis are often well intentioned. However, there is some evidence that very young children may be relatively resistant to its psychoactive properties. A research group in Israel examined the anti-emetic effects of delta-8-tetrahydrocannabinol (a natural isomer) in a series of children undergoing chemotherapy (Abrahamov & Mechoulam, 1995). Excellent efficacy and tolerance were observed at doses that would be expected to produce significant psychoactivity in adults.

People employing cannabis therapeutically must be warned of the usual caveats assigned to any potentially sedative drug, especially due care with the operation of machinery and motor vehicles.

Acute overdosages of cannabis are self-limited and most frequently consist of panic reactions. These are uniquely sensitive to reassurance ("talking down") and are quite unusual once a patient becomes familiar with the drug. Cannabis has a unique distinction of safety over four millennia of analgesic usage: no deaths due to direct toxicity of cannabis have ever been documented in the medical literature.

Some cannabis-drug interactions are apparent, but are few in number or consequence. Additive sedative effects with other agents, including alcohol, may be observed. Similarly, however, additive or synergistic anti-emetic and analgesic benefits may accrue when combining dopamine agonist neuroleptics and cannabis (Carta, et al., 1999). Cannabis may accelerate metabolism of theophylline, while slowing that of barbiturates. Anticholinergic-induced tachycardia may be accentuated by cannabis, while this effect is countered by beta-blockers (Grotenhermen, in press b). Indomethacin appears to slightly reduce the psychoactive and tachycardic effects of cannabis (Perez-Reyes, Burstein, White, McDonald, & Hicks, 1991). As discussed, synergistic analgesic benefits may accrue with concomitant usage of cannabis and opioids (Cichewicz, et al., 1999; Hare, 1887).

Crude cannabis contains most of its THC in the form of delta-9-THC acids that must be decarboxylated by heating to be activated. This occurs automatically when cannabis is smoked, whereas cannabis that is employed orally should be heated to 200–210°C for 5 minutes prior to ingestion (Brenneisen, 1984).

Contrary to disseminated propaganda in the United States, average cannabis potency has varied little over the last 3 decades (ElSohly, Ross, Mehmedic, Arafat, Yi, & Banahan, 2000; Mikuriya & Aldrich, 1988). It is true that the maximum potency has increased through applied genetics, cultivation, and harvesting techniques. This goal is achieved through production of clonal cultivation of the preferred female plants and maximization of the yield of unsterilized flowering tops known as sinsemilla (Spanish for "without seed"). In this manner, a concentration of stalked trichomes where THC and therapeutic terpenoids are produced is effected. Resultant yields of THC may exceed 20% by weight. This is potentially advantageous, particularly when smoked, because a therapeutic dosage of THC is obtained with fewer inhalations, thereby decreasing lung exposure to tars and carcinogens.

A considerable concentration of THC, and other cannabinoids and terpenoids as well, may also be achieved through some simple processing of crude, dried cannabis.

Techniques for sieving or washing of cannabis to isolate the trichomes to produce hashish are well described (Clarke, 1998; Rosenthal, Gieringer, & Mikuriya, 1997) and may produce potential yields of 40 to 60% THC. Clarke (1998) demonstrates a simple method of rolling the resultant powdery material into a joint of pure hashish, termed "smoking the snake," providing a relatively pure product for inhalation.

Cultivation techniques are beyond the scope of this review, but are freely available through a variety of guidebooks (Clarke, 1981; Rosenthal, Gieringer, & Mikuriya, 1997), magazines such as Cannabis Culture or High Times, or via the Internet to those who live in jurisdictions where this endeavor is legal. Outdoor, indoor, or hydroponic techniques are possible. Emphasis should focus on potent medicinal strains, scrupulous organic cultivation of female plants, clonal selection and augmentation, and appropriate processing.

Oral Use of Cannabis

A variety of issues attend this mode of cannabis administration. The most important concerns bioavailability. Oral absorption of cannabinoids is slow and erratic at best, often requiring 30 to 120 minutes. In HIV-positive or chemotherapy patients and in acute migraine with nausea and emesis, oral usage may be precluded altogether. Additionally, oral THC is subject to the "first pass effect" of hepatic metabolism yielding 11-hydroxy-THC, considerably more psychoactive than THC itself. Thus, some patients become "too high" even on low doses of medicine, such as 2.5 mg THC as dronabinol.

Advantages of oral usage are its avoidance of lung exposure in those who are immunosuppressed or have impaired pulmonary function, and its prolonged half-life. This may be of advantage for nocturnal complaints where sedation is less of an issue.

Grotenhermen (2001, in press b) suggests dose titration beginning with 2.5 mg oral THC b.i.d. with increases as needed and tolerated. For cannabis of 5% THC content, this would represent 50 mg herb per dose. For 10% THC cannabis, only 25 mg plant material would be required. Most painful clinical conditions require t.i.d. dosing of cannabis.

THC, CBD, and terpenoids are all highly lipophilic. Gastrointestinal absorption is markedly enhanced by inclusion of lipids in the cooked preparations. Traditional Indian cannabis cookery makes good use of ghee, or clarified butter. When cannabis tea is employed, added cream will enhance clinical benefits. Therapeutic tincture extraction in alcohol is also possible.

Smoked Cannabis

Techniques of smoking cannabis are legion and include marijuana cigarettes ("joint," "reefer," etc.), pipes, waterpipes ("hookahs"), and bongs. Pharmacodynamically, smoking would be an ideal method of application of clinical cannabis, except for the attendant pulmonary issues. Clinical effects are noted within seconds to minutes after smoking. Inhalation avoids the first pass effect that hampers oral use, and allows effective dosage titration. Doses as low as 5 mg may provide relief of clinical symptoms, while hundreds of testimonials indicate the ability to continue work or study with unimpaired effectiveness. When symptoms return, repeat dosage is achieved quickly and easily. Overdosage is effectively avoidable.

In chronic usage of smoked cannabis, it is true that isolated cases of head and neck carcinogenesis have been noted (Tashkin, in press). Precancerous cytological changes in the airways of heavy cannabis smokers have been observed via bronchoscopy, but do not seem to lead to emphysematous deterioration (Tashkin, Simmons, Sherrill, & Coulson, 1997).

The "amotivational syndrome" has been largely relegated to the dustbin of drug war propaganda (Zimmer & Morgan, 1997). In fact, the interested reader may wish to seek out three rare books of the past generation on chronic usage that are remarkable for their careful documentation of the few distinguishing features between chronic cannabis smokers and age-matched controls (Carter, Coggins, & Doughty, 1976; Rubin & Comitas, 1975; Stefanis, et al. 1977). These are rarely mentioned in current alarmist reviews of the dangers of cannabis.

Some old myths die hard. Traditional smoking techniques in the U.S. make prolonged holding of a marijuana "toke" de rigueur. From a dose-response standpoint, this is unnecessary. Inhaled THC is well absorbed after a very brief interval, and subjective high and serum THC levels do not increase beyond a maximum 10-second inhalation (Azorlosa, Greenwald, & Stitzer, 1995). Furthermore, prolonged breath-holding under pressure increases the potential for hypoxia or pneumothorax (Tashkin, in press).

Contamination of herbal cannabis by pesticides, herbicides, and bacterial or fungal agents is possible and may represent a threat to the smoker, especially immunosuppressed patients (McPartland & Pruitt, 1997; McPartland, in press; Tashkin, in press). Scrupulous cultivation techniques avoid some of these issues. McPartland (in press) recommends pasteurization of herbal cannabis by heating in an oven at 150°C for 5 minutes.

Waterpipes and bongs are popular techniques for cooling smoke. Although they may reduce particulate matter as well, THC content and pharmaceutical efficiency appear to be compromised (Gieringer, 1996a,b). Surprisingly, the unfiltered "joint" seems to represent the most efficient means for conventional smoking, although use of hashish in a pipe (without tobacco) was not examined.

Vaporizers for Cannabis Administration

Vaporization of herbal cannabis may allow THC and terpenoid components below the ash point of the leaf, thereby reducing exposure to smoke, tar, and carcinogens. The technology has been hampered in its development by paraphernalia laws. Initial investigations of available devices to date have had disappointing results (Gieringer, 1996a, b), but further studies are currently underway and appear very promising.

Rectal Administration

Suppository preparations of cannabis were employed in the 19th century and may be an acceptable alternative route of administration for some conditions. The first-pass effect is largely avoided, although the ability for close dose titration is lost. THC suppositories, particularly as a hemisuccinate, have proven to be twice as bioavailable as oral THC (Brenneisen, Egli, ElSohly, Henn, & Spiess 1996; ElSohly, Little, Hikal, Harland, Stanford, & Walker, 1991; Mattes, Engelman, Shaw, ElSohly, 1994). No studies have examined the use of this preparation with respect to analgesia, but one might expect comparison to dronabinol at least with regard to the spectrum of activity. Synergistic combinations of cannabis components may be more valuable.

Suppositories are not a popular method of drug delivery in the United States.

Sublingual Tincture of Cannabis

This method of administration is under investigation by GW Pharmaceuticals in the United Kingdom, employing combinations of specific strains of cannabis that are rich in THC or CBD. Terpenoids and other minor components that may be important to therapeutics effects of cannabis are retained in this fashion. Dose-metered sublingual sprays are currently in Phase 1 and Phase 2 clinical trials for a variety of indications. Initial results indicate good bioavailability, patient tolerance, and clinical effects.

Aerosol THC Preparations

Cannabis has a long history of use in asthma, even as a smoked preparation. A pure THC aerosol has been attempted numerous times in the past. Physical and delivery issues have been challenging, but more interestingly, pure THC seems to have an irritating and even bronchoconstrictive effect when employed in isolation (Tashkin, 1977). This author (Russo) believes that anti-inflammatory effects of concomitant terpenoid and flavonoid administration is necessary for full effects and tolerance in pursuit of the pulmonary route. Further research is underway by GW Pharmaceuticals, Inhale Therapeutic Systems, and possibly others.

Transdermal Administration

The American Cancer Society has received a large grant to examine the use of a THC skin patch. No pharmacokinetics data are currently available to ascertain whether transdermal THC administration is a viable option (Brenneisen, 2001, in press).

Nutrition for Pain Management

Hal S. Blatman, M.D.

The human body has built-in mechanisms for the purpose of healing. Some of these are more visible, such as callous formation after a bone fracture or scab formation after an injury to the skin. Other mechanisms of healing, such as the repair of oxidative damage, work at the level and size of molecules.

Nutrition affects pain and healing at three basic levels. One level is that food has to provide the basic raw materials for the body to build or manufacture parts for repair and development of body tissues. Another level of nutrition is that dietary supplements can enhance particular biochemical pathways, altering inflammation and affecting healing. A third level is that poisons can be ingested that negatively affect the body's ability to heal.

There is a mathematical formula that describes the basics of the relationship of nutrition to pain, healing, and wellness:

$$G - B + R \rightarrow P$$

In this equation, G represents the good things that can be done for or to the body, as well as good things that can be put into the body. B represents the bad things that can be done for or to the body, as well as bad things that can be put into the body. R represents the reserve that the body has left. This is an abstract measure of the life force that has been provided at birth and then partly used up with aging. These three categories (G, B, and R) imply the number P, which represents the degree of pain or problems (conversely, wellness) that a person experiences.

Patients seek medical attention because they are not happy with "P", the degree of pain and problems that they might be having. People pray to negotiate for how much "R" reserve their body has left. "G" and "B" are under more direct control by each person. By modifying the ratio of "G" good and "B" bad exposures to the body, the degree of "P" pain and problems will change. In other words, the body will create a level of function and healing that is directly related to nutrition.

To explain the impact of diet and nutrition on successful pain treatment and management, I have simplified the concepts into three rules.

RULE NO. 1: THOU SHALT NOT PUT "POISON" INTO THY BODY.

A poison is an ingested substance that adversely affects basic body functions. Two prevalent nutritional "poisons" should not be put into the body. These are aspartame and hydrogenated oil. Aspartame converts in the human body to methanol and formaldehyde. Formaldehyde is used in embalming fluid and has toxic effects on the body. Methanol is toxic to the nervous system and has been related to increased incidence of brain cancer. It is slowly excreted and accumulates in the body with frequent exposure. Additionally, aspartame outside the body is converted to methanol when it is heated to 85°F.

Sugar-free drinks and diet yogurt are examples of foods that contain aspartame. Recently, the food industry has been given permission by the FDA to add small amounts of aspartame to food without including it in the labeled list of ingredients.

Many people ingest aspartame without any noticeable adverse health effects. Other people will experience diffuse and body-wide pain symptoms. In some people, one diet soda every other day is enough exposure to cause this widespread pain. Pain symptoms will progressively lessen during the first 2 months after exposure is discontinued.

0-8493-0926-3/02/$0.00+$1.50

Hydrogenated oil is the other commonly ingested poison. Approximately 100 years ago, a scientist bubbled hydrogen gas into vegetable oil, forming margarine. In the United States, this discovery became important during World War II when there was a shortage of butter. Production of margarine quickly became an industry. Then it was discovered that bugs would not eat it, mold would not grow on it, and it would not sustain or support life.

At that time in the United States, the retail food industry needed product shelf-life to be extended. It was discovered that the shelf-life of food could be greatly increased if essential fatty acids were replaced by hydrogenated oil.

These processed oils have several effects on the human body. They increase cholesterol risk factors and contribute to atherosclerotic heart disease. In addition, they alter prostaglandin synthesis pathways, increasing inflammation. Most profoundly, however, they affect cell membrane synthesis and repair.

Every cell in the body has a cell membrane that separates the contents of the cell from the material outside. This membrane is composed primarily of two layers of fat. The basic functions of the cell membrane include bringing nutrients into the cell, sending waste products out of the cell, and maintaining flexibility. Cell membrane composition determines the quality of these processes.

Ingested fatty acids are raw materials that are incorporated into cell membranes in approximately the same ratio as what is in the food. The most important of these are the omega-3 and the omega-6 fatty acids. These raw materials are called "essential" fatty acids because the human body cannot synthesize them. Historically, fat in the unaltered or unprocessed human food supply was approximately four parts omega-6 fatty acids to one part omega-3 fatty acids. Indeed, cell membranes function best when their omega-6:omega-3 ratio approximates 4:1. For people who cannot get quality fatty acids from fruits, vegetables, fish, and nuts, the diet can be supplemented with oils such as borage oil, flax seed oil, evening primrose oil, and fish oil. Borage oil and evening primrose oil are primarily omega-6 oils; fish oil is composed of omega-3 oils; and flax seed oil is composed of mostly omega-3 and partly omega-6 oils.

Hydrogenation alters the shape and function of fatty acids and hydrogenated oils are foreign to the natural biology of life. When hydrogenated oils are eaten, they are incorporated into cell membranes throughout the body in the same ratio as the foods that supplied them. Cell membranes that contain hydrogenated fats do not function as well as cell membranes that are composed of omega-6 and omega-3 fatty acids in a 4:1 ratio. These cell membranes then do not transmit nutrients and waste as effectively, and they lose their flexibility. With these changes, the basic body parts become less able to respond and heal from injury. In other words, the body becomes "like a genuine GM truck that has been fixed with plastic parts."

In addition, when cells become injured, they release parts of their cell membranes into the general circulation. These cell membrane parts are integral components of biochemical inflammation processes. Some of these released cell membrane parts are pro-inflammatory and others are anti-inflammatory. Indeed, cellular membrane composition directly affects the biochemical process of inflammation and healing in this way also.

Many foods contain (partially) hydrogenated vegetable oil. These include margarine, peanut butter that does not require refrigeration after opening, donuts, cakes, crackers, potato chips, and pretzels. If a jar of peanut butter can be kept in the pantry for many months without growing mold, then it must have "poison" in it to keep the mold from growing. Restaurants are likely to cook egg dishes in margarine. Most important, virtually all foods cooked in a deep fat fryer have been bathed in this "poison" oil.

Patients should be advised to cook with olive oil, sesame oil, and butter. They should dispose of margarine and they should not eat foods that include hydrogenated or partially hydrogenated oil as an ingredient. Foods that have been cooked in deep fat should also not be eaten. These recommendations are not only very important for patients with pain, but also for patients with heart disease and high cholesterol.

RULE NO. 2: WHEN YOU ARE TRYING TO RUN A RACE CAR, USE 100-OCTANE FUEL.

The human body is a high-performance, biochemical "Ferrari." A brief look at children will show that they accelerate quickly, corner well, and wear out their tires. It makes sense that the energy level (octane) of food will affect the ability of the body to generate energy and heal. The lowest octane fuels that most people eat include sugar, wheat, and potatoes (white and red). Sugar drains the body of its energy, weakens the immune system, and affects personality. A typical serving of soda contains approximately 10 teaspoons of sugar. Moreover, to keep this much sugar in solution, phosphates are added to the mix. Processing these phosphates results in a loss of calcium. This loss of calcium has been associated with osteoporosis and childhood bone fractures. Soda should therefore be eliminated from the diet. Most store-bought fruit juices (including orange juice) also have very high sugar contents and are low-octane fuels. Food made from wheat (bread, pasta) is also of lower octane, and many people will do better if they avoid it. When there is a choice of bread to be made, wheat, multi-grain, and rye breads are higher on the octane list than white bread. Some breads, crackers, and pasta also do not contain wheat grain. Some patients are sensitive

enough to wheat food octane that eating a dinner roll will cause significant fatigue the following day. Finally, a medium-sized potato can be likened to half a cup of sugar. Patients with pain and fatigue should be especially counseled to avoid wheat and potatoes. Rice is generally a much better choice and can often be substituted for potatoes and pasta. Brown rice is higher up the octane scale than white rice (long grain and not instant). Sweet potatoes and yams are usually well tolerated.

RULE NO. 3: THE RULE OF CRITTERS.

Inside the human intestine are approximately seven or eight pounds of microorganisms. These organisms make up the intestinal flora, which can be loosely categorized as symbiotic or dysbiotic. A symbiotic relationship is mutually beneficial, helping both the microorganisms and the human body. Symbiotic organisms include acidophilus and lactobacillus. These bacteria are important for digestion of food, production of B vitamins, and regulation of the immune system. A dysbiotic relationship is not mutually beneficial, helping the microorganisms while harming the human body. Yeast is a dysbiotic organism. Dysbiotic organisms contribute to injury and destruction of intestinal endothelium, the cells that line the digestive tract.

The health of this endothelial lining is of major importance for the entire human organism, affecting the immune, nervous, and digestive systems. For the immune system, endothelial cells produce immunoglobulin A (IgA). IgA provides the front-line defense for the body. When the body is deficient with respect to production of IgA, white blood cells must work harder to "pick up the slack." When body energy is diverted to production of white blood cells, there is less energy left to "run the engines." The result of this decreased IgA is fatigue.

Intestinal endothelial cells also produce 95% of the seratonin in the human body. Seratonin is an important neurotransmitter for the brain and for the digestive system. If these cells do not produce enough seratonin, the person is likely to become constipated and depressed.

The endothelial lining also functions as a barrier to the toxins and waste that are always present in the large intestine. When endothelial injury causes this barrier to become incompetent, the colon leaks foreign proteins, pathogenic organisms, and other toxins into the body. This toxic exposure causes what is called leaky gut syndrome. It can be likened to the process of a toxic waste dump leaking "poison" into the body's water supply. This phenomenon occurs especially in patients with irritable bowel syndrome (IBS) and Crohn's disease.

To improve health, the endothelial lining needs to be restored and symbiotic flora need to flourish. L-glutamine is a safe nutritional supplement that can be prescribed for healing the endothelium. Nutrition is provided to symbiotic flora by eating green leafy vegetables. These organisms must be fed like pet fish in a fish tank. Dysbiotic flora eat sugar, wheat, and potatoes. To change the balance of flora and promote the health of the gut, diet must be adjusted accordingly. The cleaner a patient becomes with respect to these food choices, the more likely it is that healing will occur.

Finally, it is important to remember that the human body needs water. In addition to basic hydration needs, water helps the body to detoxify. Massage and body work increase this requirement for water, as the toxins released from muscle will cause flu-like symptoms if they are not flushed from the body. The estimated daily need for water is up to one quart for every 50 pounds of body weight.

Motivating patients to make better food choices can be extremely challenging. The healthcare professional must be confident that following these recommendations will lead to noticeable clinical improvement. Most chronic pain and fatigue patients will experience a dramatic change in their levels of pain and energy after following the guidelines and recommendations presented in this chapter. Many will notice improvement within the first 2 weeks. It is also important that the healthcare provider show a good example. Patients are much less likely to pay attention to these recommendations when they see their doctors drink a diet soda and eat french fries.

INTRODUCTION

The purpose of this chapter is to provide pain management clinicians with a review of the pertinent literature, and clinical and anatomic considerations in relation to an interventional regenerative treatment for chronic musculoskeletal pain.

There is an omnipresence of the connective tissue throughout the body. Structurally and biomechanically, they represent a heterogenous group with variations in collagen orientation, cross linking, shape, cell properties, and presence of synovial lining in various locations. Without connective tissue, the "musculoskeletal system" will cease to exist. A large variety of functions depend on the proper homeostasis of connective tissue. For example, without the storage and release of energy in connective tissue during locomotion, much higher energy requirements would be encountered (Dorman, 1992; Gray, 1995). On the other hand, many dysfunctional and painful syndromes may arise from pathologic conditions of the connective tissue.

The injury occurs when the internal or external forces exceed the threshold of failure for the specific connective tissue. This may be in the form of a ruptured or strained ligament, tendon, fascia, or bone fracture, or a prolapsed disc.

Pain arising from connective tissue pathology, such as degenerative and posttraumatic changes in the intervertebral disc, ligaments, tendons, aponeuroses, fasciae, and sacroiliac and facet joint capsular ligaments, is often difficult to differentiate based solely on clinical presentation. Individual variations in innervation further complicate the differential diagnosis. Left untreated, posttraumatic and overuse injuries of ligaments and tendons can linger indefinitely, leading to the progression of degenerative changes, loss of function, deconditioning, and perpetuation of disability and chronic pain (Bogduk, et al., 1991; Dreyfuss, 1997; Hackett, 1958; 1991; Merskey, et al., 1994; Shuman, 1958; Steindler, et al., 1938).

Interventional regenerative modalities for painful musculoskeletal pathologies have been described for more than two millenniums. For example, the technique of collagen thermomodulation, now known as thermocapsulography, was originally described by Hippocrates, who had created thermocoagulation of the anteroinferior capsule for treatment of recurrent shoulder dislocations "with red hot slender irons" (Dorman, et al., 1991; Shuman, 1958). It is currently recognized that sufficient thermomodulation of collagen can be achieved with lower temperatures to stimulate a proliferative and regenerative/reparative response. This concept has led to the development of intradiscal electrothermal (IDET) procedures, currently utilized with the intent to achieve nuclear shrinkage, seal annular fissures, and thermocoagulate nociceptors (Darby, et al., 1998; Saal, et al., 1998a, 1998b).

The coexistence of physical and chemical methods is well demonstrated in the contemporary practice of dermatology and plastic surgery, where chemical (carbolic acid/phenol) and laser-induced facial peels are utilized for regeneration and rejuvenation by chemo- and thermomodulation of the skin collagen.

0-8493-0926-3/02/$0.00+$1.50

A less-known but long-practiced method of interventional regenerative modalities is regenerative injection therapy (RIT), also known as prolotherapy or sclerotherapy (Linetsky, 1999a; Linetsky, et al., 2000). It was originally described by Celsus for treatment of hydroceles with injections of saltpeter (Hoch, 1939; Linetsky, 1999b). The current technique combines addressing the affected connective tissues with diagnostic local anesthetic blocks, followed by injection of solutions that, by virtue of their chemical properties, are able to stimulate a regenerative, reparative process in the injured tissues.

Application of RIT for low back pain has been described in numerous textbooks and articles; comparatively adequate applications for cervical and thoracic pain are lacking. We choose to emphasize cervicothoracic pain problems treated with RIT in this chapter (Cyriax, 1969; 1982; Dorman, et al., 1991, 1993; Hackett, 1991; Ombregt, et al., 1995).

ETYMOLOGY OF SOME TERMINOLOGY

Biegelesen (1984) first used the terms "sclerotherapy" in 1936. 'Sclero': derived from the word *skleros* (Greek, hard). Hackett (1958) felt that sclerotherapy implied scar formation; therefore, he coined the term "prolotherapy" and defined it as: "the rehabilitation of an incompetent structure by the generation of new cellular tissue" (derived from the word *proli* (Latin, offspring)). "Proliferate": to produce new cells in rapid succession. The former, however, is an integral attribute of a malignant, unsuppressed growth. Moreover, with advances in basic science and the contemporary understanding of the healing process, these authors prefer RIT because it is recognizes that regeneration extends beyond the proliferative stage. On a cellular level, RIT induces chemomodulation of collagen through repetitive stimulation of the inflammatory and proliferative phases in a sophisticated process of tissue regeneration and repair, mediated by numerous growth factors leading to the restoration of tensile strength, elasticity, increased mass, and load-bearing capacity of the affected connective tissue (Klein, et al., 1989; Liu, et al., 1983; Maynard, et al., 1985; Ongley, et al., 1987). These capabilities make RIT a specific treatment for degenerative, chronic, painful conditions such as enthesopathy, tendinosis, and ligament laxity, versus commonly utilized steroid injections and denervation procedures (Klein, et al., 1997; Reeves, 1995).

LOCAL ANESTHETICS IN DIAGNOSIS OF MUSCULOSKELETAL PATHOLOGY: BRIEF HISTORY

In 1930, Leriche introduced the application of procaine for differential diagnosis and treatment of ligament and tendon injuries of the ankle and other joints at their fibroosseous insertions. In 1934, Soto-Hall and Haldeman reported on the benefits of procaine injections in the diagnosis and treatment of painful shoulders. Subsequently in 1938, they published a study on diagnosis and treatment of painful sacroiliac dysfunctions with procaine injections. After infiltration of posterior sacroiliac ligaments, interspinous ligaments at L4–5 and L5-S1 levels, and zygapophyseal joint capsules with procaine, they observed a marked relaxation of spastic musculature and added the routine use of sacroiliac joint manipulations, establishing manipulation of axial joints under local anesthesia (Haldeman, et al., 1938).

In 1938, Steindler and Luck made a significant contribution to currently validated approaches in the diagnosis and treatment of low-back pain based on procaine injections. The authors pointed out that posterior divisions of the spinal nerves provide the sensory supply to the musculature; tendons; supraspinous, interspinous, iliolumbar, sacroiliac, sacrotuberous, and sacrospinous ligaments; and origins and insertions of aponeurosis of tensor fascia lata, gluteal muscles, and thoracolumbar fascia. They emphasized that, based on clinical presentation alone, no definite diagnosis could be made and postulated that five criteria must be met to prove that a causal relationship exists between the structure and pain symptoms (see Table 33.1).

Subsequently, in 1948, Hirsch demonstrated relief from sciatica following intradiscal injection of procaine (Hirsch, 1948).

Local anesthetic diagnostic blocks are currently the most reliable and objective confirmation of the precise tissue source of pain and clinical diagnosis (Bonica, et al., 1990; Cousins, et al., 1988; Merskey, et al., 1994; Wilkinson, 1992).

HISTORY AND EVOLUTION OF RIT

The scientific rationale for implementing RIT regenerative injection therapy in chronic painful pathology of ligaments and tendons evolved from clinical and histologic research performed for injection treatment of hernias, hydroceles and varicose veins. The therapeutic action of the newly formed connective tissue was different in each

TABLE 33.1
Radiating/Referral Pain Postulates

1. Contact with the needle must aggravate the local pain.
2. Contact with the needle must aggravate or elicit the radiation of pain.
3. Procaine infiltration must suppress local tenderness.
4. Procaine infiltration must suppress radiation of pain.
5. Positive leg signs must disappear.

From Steindler, et al., 1938, Journal of the American Medical Association, 110, 106–113. With permission.

condition. In hernias, the proliferation and subsequent regenerative/reparative response led to fibrotic closure of the defect (Riddle, 1940; Warren, 1881; Watson, 1938). In hydroceles, hypertrophied subserous connective tissue reinforced the capillary walls of serous membrane and prevented further exudate formation (Hoch, 1939; Linetsky, 1999b). The latter mode of action was employed in the treatment of chronic olecranon and pre-patellar bursitis by Poritt in 1931. He drained the fluid from the sac and injected 5% sodium morrhuate. In cases of persistence, he injected a 5% phenol solution into the bursae (Poritt, 1931).

In 1935, Schultz, while searching for a better way to treat painful subluxations of TMJs, conceived the idea that strengthening of the joint capsule by induced ligament fibrosis would lead to capsular contraction and prevent subluxations. Animal experiments were conducted with several solutions, among those, Sylnasol provided the best outcomes and therefore was chosen for the clinical trials. (Note: Sylnasol-sodium psyllate was an extract of psyllium seed oil produced by Searle Pharmaceutical and discontinued in the 1960s.) A clinical study of 30 human subjects after biweekly injections of 0.25 to 0.5 ml Sylnasol demonstrated "entire patient satisfaction." Schultz (1937) concluded that the principle of induced hypertrophy of the articular capsule by injecting a fibrosing agent might be applied to other joints capable of subluxations or recurrent dislocations. He also concluded that Sylnasol was a dependable agent. Injections restored normal joint function and the method was within the scope of treatment of a general practitioner. Twenty years later, Schultz presented the positive results of Sylnasol injections on several hundred patients, successfully cured of painful hypermobility of TMJs (Schultz, 1956).

Also in 1937, Gedney reported some details of collateral ligament injections for painful unstable hypermobile knees and posterior sacroiliac ligaments of unstable painful sacroiliac articulations. Small amounts of sclerosant solutions were injected along the entire affected structures. Six months later, he extended this treatment to recurrent shoulder dislocations, acromioclavicular separations and sternoclavicular subluxations (Gedney, 1937; 1938).

In 1939, Kellgren injected volunteers with hypertonic saline and implicated interspinous ligaments as a significant source of local and referred pain. He published maps of referred pain from deep somatic structures, including interspinous ligaments (Kellgren, 1939).

In 1940, Riddle included a chapter on "The Injection Treatment of Joints" in his text and described the injection treatment of TMJs and shoulders in great detail, giving Schultz the appropriate credit for initiation of this treatment.

Shuman described injection treatment of recurrent shoulder dislocations via strengthening of the inferior capsular ligaments with Sylnasol in 1941. Subsequently, in 1949, he adopted the term "sclerotherapy" for this injection modality, modifying it later that year to "joint sclerotherapy" (Shuman, 1949a, 1949b).

In 1945, Bahme published the first retrospective study of 100 patients who improved after injection of Sylnasol to the sacroiliac ligaments. Patients were under his care for an average of 4 months. The average number of injection treatments was five; 80% reported complete resolution of symptoms. He also found these injections to be very helpful in the treatment of unstable ribs, and reported improvement in 12 patients. He described a significant coexistence of painful hypermobile ribs with hypermobile sacroiliac joints, explaining the phenomenon by concomitant functional scoliosis.

By 1944, Lindblom demonstrated radial annular fissures during cadaveric disc injections and later described nucleographic patterns of 15 discs in 13 patients. Thereafter, in 1948, Hirsch relieved sciatic pain with intradiscal injection of procaine. These two articles prompted Gedney, and subsequently Shuman, to explore therapeutic applications of sclerosants for pain related to intervertebral disc (IVD) pathology.

By 1951, Gedney had extended treatment with sclerosant injections to painful degenerative lumbar disc syndromes and described the detailed technique of Sylnasol injections into the lateral annulus of the lumbar disc without fluoroscopic guidance. He reported L4 disc involvement in 95% of cases and a 50% clinical improvement after treatment of this disc alone (Gedney, 1952a). In the treatment of hypermobile sacroiliac joints, he emphasized that the amount of solution and quantity of treatments were highly individual and depended on the patient's response (Gedney, 1952b). In a retrospective study, Gedney (1954a) emphasized the significant statistical coexistence of sacroiliac pathology with disc pathology at L3, L4, and L5 levels. By 1954, he had completed a prospective study of 100 patients; 65 were initially treated with the injections into the disc, and 35 were initially treated with injections into the posterior sacroiliac ligaments. The latter group required fewer intradiscal injections. Thus he concluded that, in the presence of sacroiliac pain and hypermobility, adequate stabilization of the sacroiliac joint should be achieved in all cases prior to addressing discogenic pain (Gedney, 1954a). He emphasized the importance of interspinous and iliolumbar ligament injections in the treatment of lumbar spondylolisthesis (Gedney, 1954b).

In 1954, Shuman evaluated the effectiveness of sclerosant injections to the sacroiliac joints, intervertebral discs, spondylolisthesis, zygapophyseal joint capsules, knees, and shoulders in 93 respondents in a retrospective survey. Improvements ranged from 75 to 98%. Only those patients who were able to perform their usual occupations were considered to have positive results. Subsequently, he detailed many aspects of treatment with integration of manipulative techniques, including manipulation under local anesthesia (introduced 20 years earlier by Haldeman

and Soto-Hall). Shuman stated that zygapophyseal joint pathology (emphasized by Hackett in 1956) and disc pathology were the more common causes of lower back pain than sacroiliac joint pathology (Shuman, 1958).

Hackett, the inventor of prolotherapy, postulated in 1939 that ligaments were responsible for the majority of back pain (Hackett, 1953). By 1958, he came to the conclusion that tendons at the fibroosseous junctions were another significant source of chronic pain syndromes (Hackett, 1958). In a retrospective study, he reported on 84 patients with sacroiliac pain treated by sclerosant injections of Sylnasol, five to seven times to each affected area. In this study, 82% reported themselves entirely symptom-free for a duration of 6 to 14 years (Hackett & Henderson, 1955). In the initial animal experiments, he demonstrated a 30 to 40% increase in tendon size after injections of Sylnasol (Hackett, 1956) (Figures 33.1 and 33.2). Not satisfied with the term "sclerotherapy" because it implied hardening of the tissue and scar formation, Hackett introduced the term "prolotherapy" in 1956. He did this because the results of his experimental study did not support scarring but rather hypertrophy induced by proliferation of connective tissue in a linear fashion (Hackett, 1956). Hackett employed and emphasized the importance of the earlier referenced postulates of Steindler. He confirmed ligament or tendon involvement as pain generators reproducing local and referred pain by "needling" and abolishing the pain by infiltration of local anesthetic prior to injecting the proliferants (Hackett, 1956). He published maps of referred pain from ligaments and tendons, initially of the lumbopelvic region. These were derived from 7000 injections in over 1000 patients treated over 17 years. He subsequently developed maps of the cervicothoracic region (Hackett, 1958) (Figure 33.3). Later, he pointed out that loose-jointed individuals had a lesser ability to recuperate from sprains, because of the congenital laxity of their ligaments, and have a predisposition to chronic lingering pain for decades. He emphasized their positive response to prolotherapy (Hackett, 1959).

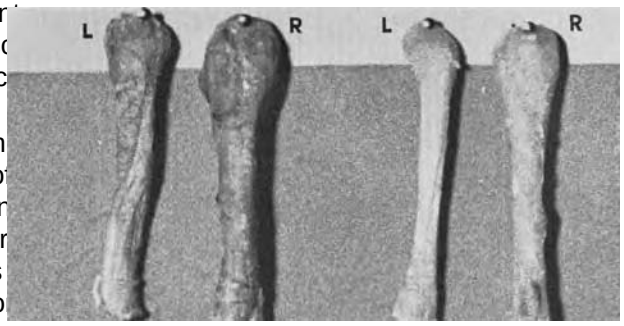

FIGURE 33.1 Hypertophied rabbit tendons 9 and 12 months after injection with proliferant; controls (L), treated (R). (From Hackett, G. (1958) Ligament and tendon relaxation (skeletal disability)-treated by prolotherapy (fibro-osseous proliferation), 3rd ed., Springfield, IL: Charles C Thomas. With permission.)

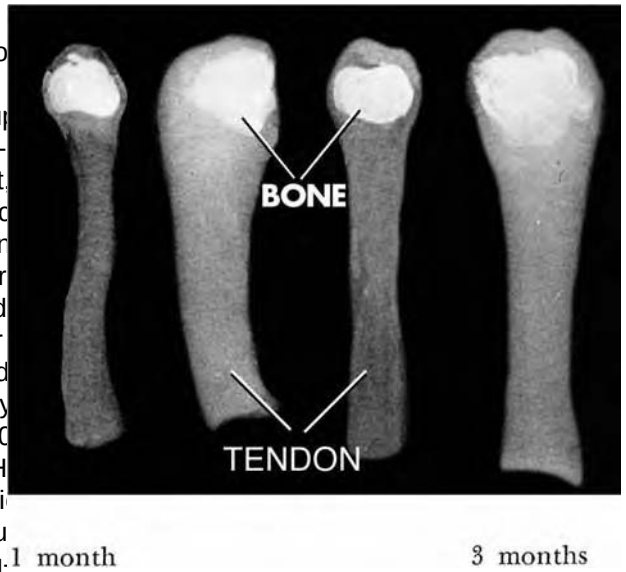

FIGURE 33.2 Paired radiograph of hypertrophied rabbit tendons, fibro-osseous attachment 1 and 3 months after injection of proliferant. Treated tendons are on the right side of each pair, controls on the left. (From Hackett, G. (1958) Ligament and tendon relaxation (skeletal disability)-treated by prolotherapy (fibro-osseous proliferation), 3rd ed., Springfield, IL: Charles C Thomas. With permission.)

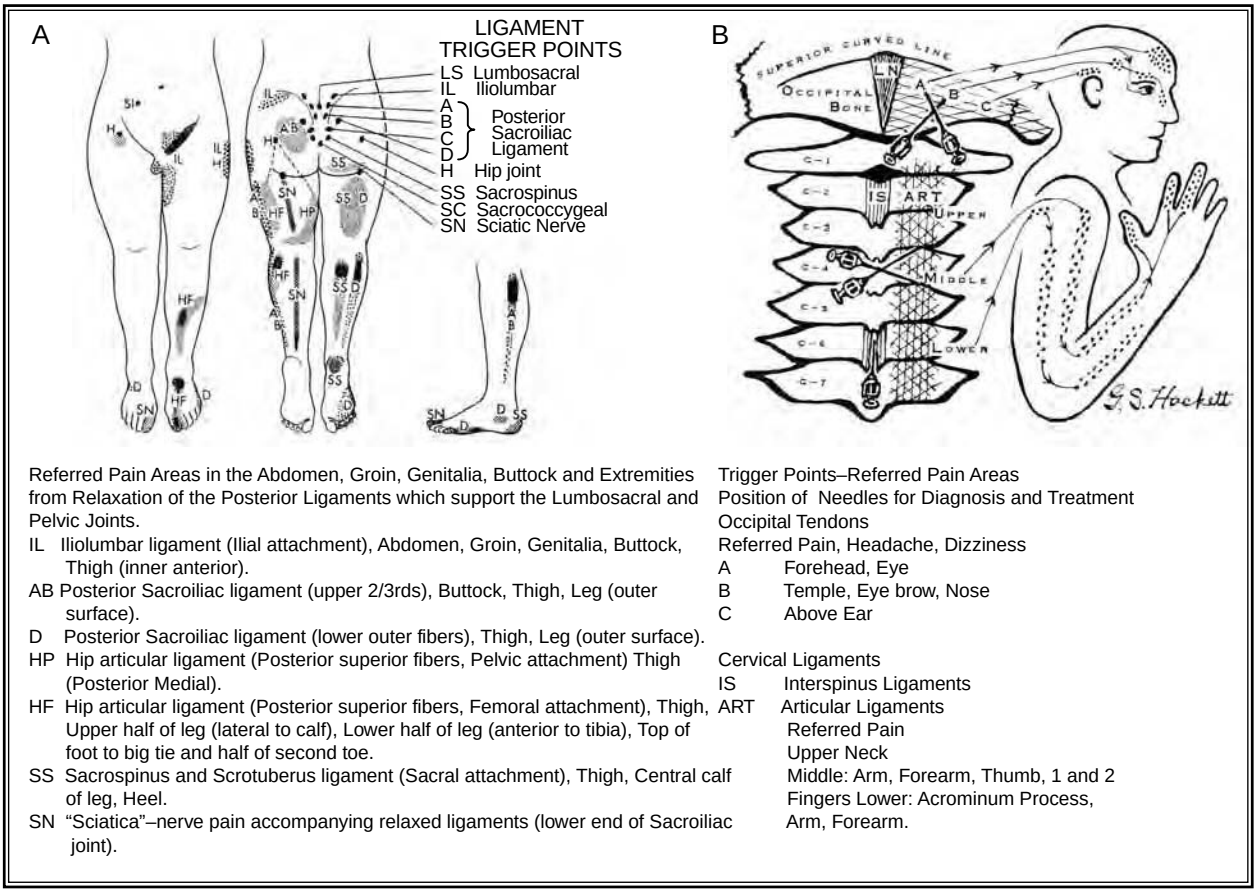
In several subsequent publications, Hackett emphasized the common pathogenesis of impaired local circulation in chronic conditions such as neuritis, headaches, whiplash, osteoporosis, bone dystrophy, bronchospasm, and arteriosclerosis. Excess antidromic, sympathetic, and axon reflex stimulation caused local vasodilatation and edema, with a perpetuating vicious cycle, "tendon relaxation", the condition now understood as degenerative changes, enthesopathy, tendinosis, and laxity (Hackett, 1959a, 1959b, 1960a, 1960b, 1961, 1966a, 1966b, 1966c, 1966d, 1967; Hackett et al., 1961, 1962).

Extended subsequent animal experiments with multiple solutions conducted by Hackett revealed that the strongest fibroosseous proliferations were achieved with Sylnasol, zinc sulfate solutions, and silica oxide suspensions. The strongest acute inflammatory reaction was obtained with Sylnasol and zinc sulfate, followed by silica oxide the whole blood moderately stimulated fibroosseous proliferation. Hydrocortisone used alone or in combination with proliferants inhibited proliferation for 3 to 4 weeks. At the fracture sites, proliferants increased callus formation in 3 weeks; whereas, used in combination with steroids the callus formation was markedly inhibited (Hackett, et al., 1961).

Hackett's positive results were initially corroborated by others (Compere, et al., 1958; Green, 1956, 1958; Myers, 1961; Neff, 1959). In fact, Myers reported improvement in 82% of patients.



Referred Pain Areas in the Abdomen, Groin, Genitalia, Buttock and Extremities from Relaxation of the Posterior Ligaments which support the Lumbosacral and Pelvic Joints.

IL Iliolumbar ligament (Ilial attachment), Abdomen, Groin, Genitalia, Buttock, Thigh (inner anterior).

AB Posterior Sacroiliac ligament (upper 2/3rds), Buttock, Thigh, Leg (outer surface).

D Posterior Sacroiliac ligament (lower outer fibers), Thigh, Leg (outer surface).

HP Hip articular ligament (Posterior superior fibers, Pelvic attachment) Thigh (Posterior Medial).

HF Hip articular ligament (Posterior superior fibers, Femoral attachment), Thigh, Upper half of leg (lateral to calf), Lower half of leg (anterior to tibia), Top of foot to big tie and half of second toe.

SS Sacrospinus and Scrotuberus ligament (Sacral attachment), Thigh, Central calf of leg, Heel.

FIGURE 33.3 (From Hackett, G. (1958). Ligament and tendon relaxation (skeletal disability)-treated by prolotherapy (fibro-osseous proliferation), 3rd ed., Springfield, IL: Charles C Thomas. With permission.)

In 1961, Blaschke reported the first prospective study of 42 patients treated with prolotherapy for lower back pain. Thirty-two were workers' compensation cases, notoriously the most difficult cases to treat, and ten were private insurance cases. Complete recovery was achieved in 20 patients observed for 3 years. Thirteen patients reported no change in their condition and nine underwent surgery. Four patients with clinical presentation of acute herniated disc, in whom prolotherapy was utilized without hope of success, had better results than any other patients in this study. In three instances of surgical intervention, specimens were obtained from the sites of injections and were reported as "normal fibrous tissue".

A multicenter study conducted by Kayfetz, et al. was published in 1963. Of 264 patients treated by prolotherapy for headaches, 78% had headaches of traumatic origin, 58% had non-traumatic headaches, and 56% had symptoms of Barre–Lieou syndrome. In addition, 86% had symptoms longer than 1 month and 46% had symptoms longer than 1 year. The traumatic group reported satisfactory results in 79%, with excellent results in 60%. The non-traumatic group reported satisfactory results in 47% and excellent results in 29%. Of 264 cases, 60% of patients were followed for over 1 year and 27% were followed for 3 to 5 years. There were no infections or other complications following prolotherapy.

Also in 1963, Kayfetz reported a 5-year follow-up study of 189 cases with whiplash injuries treated by prolotherapy. Of these, 149 cases (79%) were due to automobile accidents; 153 (81%) had associated injuries to the thoracic and lumbar areas; 98 (52%) had an associated Barre–Lieou syndrome; and 55% had symptoms longer than 1 month's duration and 21% longer than 1-year duration. The majority of patients received 6 to 30 injections in one setting and were treated on one to ten occasions. Duration of treatment was from 1 to 6 months. Excellent results, in terms of pain, were obtained by 113 (60%), good results by 15 (8%) and fair results by 34 (18%). Some 75% of patients considered themselves cured of pain.

In response to adverse effects published after alleged incidental intrathecal injections of zinc sulfate, experiments were conducted with intrathecal injections of this solution in rabbits (Schneider, 1959; Keplinger, 1960; Hunt, 1961). Clinical doses (4 to 5 drops) did not produce any noticeable effect. Those animals receiving increased doses that produced spinal anesthesia, completely recovered after the

anesthetic wore off. It was necessary to use much greater than clinical dosage to induce paraplegia for a few weeks' duration, which also cleared up" (Hackett, et al., 1961).

In 1967, Coleman brought medicolegal aspects of prolotherapy to the attention of the medical community. He pointed out that Hackett's technique was accepted as a standard of care. It was declared by a California court that a physician treating a patient had deviated from the method as described by Hackett. Conclusion was made that one did not have to follow the method of treatment followed by the majority of the physicians in the community. A physician is permitted to follow a method or a form of treatment followed by a minority of physicians if they are reputable and in good standing. But if he or she varies from the minority method of treatment he or she does so in violation, just as if he or she deviated from the generally accepted method of treatment.

The court concluded: "... as a matter of law that prolotherapy as a method of treatment cannot be said to be inappropriate or to be malpractice even though it has not been accepted as a common method of treatment by the medical profession generally" (Coleman, 1968).

Abroad, positive results with Hackett's method were obtained by Ongley, Cyriax (1969, 1982), Barbor (1964) and Coplans (1972). Barbor presented a study of 153 patients with back pain for up to 20 years duration. Of 153, 111 (74%) of them reported relief to their satisfaction; 17 (11%) failed to improve; 25 (16%) were lost for follow-up; and 31 (23%) required periodic booster injection for relief. The solution utilized was dextrose phenol-glycerine (DPG) mixed in proportions of 2 cc DPG to 3 cc local anesthetic.

Cyriax (1969, 1982, 1993) included detailed descriptions of "sclerosant injections" to interspinous and facet joint capsular ligaments of the cervical, thoracic, and lumbar regions in his texts. Further, he described a clinical blind study of "sclerosant therapy" presented by Sanford in 1972. Of 100 patients, only 3 were lost for follow-up. The following three solutions were compared: (1) 2 ml DPG sclerosant mixed with 8 ml saline; (2) 10 ml of 0.5% procaine; and (3) 10 ml normal saline. The diluted sclerosant and procaine solutions were almost equally effective, by relieving pain in more than 50% of cases. Procaine and normal saline were equally ineffective by not helping in 50% of cases. Saline solution helped less than a third of patients. The dilution of DPG sclerosant down to 20% of the original strength significantly impaired its proliferant action.

In 1974, Blumenthal reported two cases of migraine headache and one case of cluster headache successfully cured by prolotherapy and a minor modification of Hackett's technique in the treatment of cervicodorsal pain.

By 1976, Leedy had reported a 70% improvement in the condition of 50 low-back pain patients treated with sclerosant injections and followed for 6 years. He also published several descriptive articles of the method (Leedy, 1977; Leedy, et al., 1976).

Also in 1976, Vanderschot compared prolotherapy with acupuncture in the treatment of chronic musculoskeletal pain and concluded that prolotherapy has a faster onset of action and longer-lasting pain relief (Vanderschot, 1976a,b).

In 1978, Chase reported up to 70% or better improvement in long-standing cases of painful head, neck/shoulder, and low-back syndromes.

Also in 1978, Koudele reported findings of Haws and Willman on histologic changes in human tissue treated up to five times with sclerosant injections for low-back pain. The following changes were observed and documented on slides. DPG solution produced early coagulation necrosis, followed by early collagen formation. By 6 months, a small zone of residual inflammatory cells were documented in an area of very dense collagen. In two other specimens treated with DPG, a dense collagen with fibrosis, occluded blood vessels, and a dense whirl of scar were observed.

After injection of a pumice suspension, an area of dense collagen and fibrosis surrounding a "lake" of pumice was documented, without foreign body reaction but with a capsule formation (Koudele, 1978).

In 1982, Hirschberg, et al. reported a prospective study of 16 patients with the iliolumbar syndrome. Nine were treated with infiltration of lidocaine at the insertion of the posterior iliolumbar ligament to the iliac crest, and seven were injected with a mixture containing equal amounts of 50% dextrose and 2% xylocaine (a total of 5 cc). Significant recovery was reported by ten patients. Six out of the seven treated with dextrose/xylocaine recovered, whereas only four out of the nine treated with xylocaine recovered.

Liu, et al., in a 1983 double-blind study, injected rabbit medial collateral ligaments (MCLs) and demonstrated that repeated injections of 5% sodium morrhuate at the fibroosseous attachments (enthesis) significantly increased its bone–ligament–bone junction strength by 28%, ligament mass by 44%, and thickness by 27%, when compared with saline controls. Morphometric analysis of electron micrographs demonstrated a highly significant increase in the diameter of collagen fibrils in the experimental ligaments vs. controls. These findings confirmed that sodium morrhuate had a significant regenerative influence on dense connective tissue at the insertion sites.

Maynard and co-workers reported a decrease in collagen fibrils and hydroxyproline content and an overall increase in the mass of tendons in experimental animals injected with sodium morrhuate. The average tendon circumference increased up to 25%.

Ongley, et al. (1987) in a double-blind, randomized study of chronic low-back pain in 81 subjects, statistically demonstrated a significant improvement greater than 50% in patients injected with a DPG solution vs. saline. In

terms of disability scores, the experimental groups demonstrated a greater improvement than the control group ($p < 0.001$), ($p < 0.004$), and ($p < 0.001$), respectively (Ongley, 1987). Subsequently, Ongley demonstrated a significant statistical improvement in five patients treated for painful instability of the knees with prolotherapy. Ligament stability data was obtained via three-dimensional computerized goniometry, integrated with force measurements (Ongley, et al., 1988).

Bourdeau (1988) published a 5-year retrospective survey of patients with low back pain treated with prolotherapy. Seventeen patients (70%) reported excellent to very good results.

Klein, et al. (1989) histologically documented proliferation and regeneration of ligaments in human subjects in response to injections of DPG solution, accompanied by decreased pain and increased range of motion, as documented by computerized inclinometry.

Roosth (1991) described gluteal tendinosis as a distinct clinical entity and Klein (1991) described the treatment of gluteus medius tendinosis with proliferant injections.

Also in 1991, Schwartz et al. reported a retrospective study of 43 patients with chronic sacroiliac strain who received three series of proliferant injections at biweekly intervals. Improvement was reported by all but three patients, and ranged from 95% reported by 20 patients to 66% reported by four patients; ten patients reported recurrence. Schwartz concluded that induced proliferation of collagen and dense connective tissue of the ligament is associated with a reduction of painful subluxations.

Hirschberg, et al. (1992) reported positive results in treating iliocostal friction syndrome in the elderly with proliferant injections and a soft brace.

Klein, et al. (1993) reported a double-blind clinical trial of 79 patients with chronic low-back pain who had failed to respond to previous conservative therapy. Subjects were randomly assigned to receive a series of six injections in a double-blind fashion at weekly intervals of either lidocaine/saline or lidocaine/DPG solution into the posterior sacroiliac and interspinous ligaments, fascia, and facet capsules of the low back from L-4 to the sacrum. All patients underwent pretreatment MRI or CT scans. Patients were evaluated with a visual analog, disability, and pain grid scores, and with objective computerized triaxial tests of lumbar function 6 months following the conclusion of injections. Thirty of the 39 patients randomly assigned to the proliferant group achieved a 50% or greater decrease in pain or disability scores at 6 months compared to 21 of 40 in the group that received lidocaine ($p = 0.042$). Improvements in visual analog ($p = 0.056$), disability ($p = 0.068$), and pain grid scores ($p = 0.025$) were greater in the proliferant group.

Massie, et al. (1993) reported that it was possible to stimulate fibroplasia in the intervertebral discs with proliferant injections. Also in 1993, Mooney advocated proliferant injections for chronic painful recurrent sacroiliac sprains if the clinician was skilled (Mooney, 1993a, b).

Grayson (1994) reported a case of sterile meningitis after injection of lumbosacral ligaments with proliferating solutions. Matthews (1995) found significant improvement in painful osteoarthritic knees after injection of the ipsilateral sacroiliac ligaments with proliferant solutions. Also in 1995, Reeves pointed out that degenerative changes of enthesopathy may be painful, and prolotherapy with a less aggressive solution such as 12% dextrose with xylocaine is the only type of specific treatment for these pathologic changes of ligaments and tendons.

Eek (1996) reported on the benefit of proliferating injections for intradiscal pain. Klein and Eek have described proliferant injections for low-back pain in detail (Klein, 1997).

The clinical anatomy in relation to RIT/prolotherapy for low-back pain was reviewed by Linetsky & Willard (1999). The presence of the connective tissue stocking surrounding various lumbar structures, dictating their function as a single unit in a normal state and the necessity to include multiple segmental and extrasegmental structures in differential diagnosis of low-back pain, was emphasized (Linetsky, 1999).

Subsequently, in March of 2000, Reeves demonstrated in a randomized, double-blind, placebo-controlled study the beneficial effects of 10% dextrose with lidocaine in knee osteoarthritis with anterior cruciate ligament laxity. Goniometric measurements of knee flexion improved by 12.8% ($p = 0.005$) and anterior displacement difference improved by 57% ($p = 0.025$). By 12 months (six injections), the dextrose-treated knees improved in pain (44% decrease), swelling complaints (63% decrease), knee buckling frequency (85% decrease), and flexion range (14° increase). He concluded that proliferant injection with 10% dextrose stimulated growth factors and regeneration, and resulted in a statistically significant clinical improvements in knee osteoarthritis (Reeves, et al., 2000). The history of RIT/prolotherapy from the 1930s through the 1980s was recently reviewed (Linetsky, et al., 2000, 2001).

To understand the essence of RIT/prolotherapy, it is important to review the basic science related to the healing process, as well as some anatomical and biomechanical properties of connective tissue and clinical anatomy.

INFLAMMATORY-REGENERATIVE/ REPARATIVE RESPONSE AND DEGENERATIVE PATHWAYS

The inflammatory response is intertwined with the regenerative, reparative process. A complex inflammatory reac-

tion induced in vascularized connective tissue by endogenous or exogenous stimuli may lead to two distinct repair pathways. The first is regeneration, which replaces injured cells by the same type of cells; and the second is fibrosis, or the replacement of injured cells by fibrous connective tissue. Often, a combination of both processes contributes to the repair. Initially in both processes a similar pathway takes place with migration of fibroblasts, proliferation, differentiation, and cell-matrix interaction. The latter, together with the basement membrane provides a scaffold for regeneration of pre-existing structures (Cotran, et al., 1999). " … modulation of these cell matrix responses, regardless of the method, provides an intriguing challenge" (Leadbetter, 1992). Cell replication is controlled by chemical and growth factors. Chemical factors may inhibit or stimulate proliferation, whereas growth factors such as cytokines/chemokines, TGF-β1 (transforming growth factor β1), PDGF (platelet derived growth factor), FGF (fibroblast growth factor), VEGF (vascular endothelial growth factor), IGF (insulin-like growth factor), CTF (connective tissue growth factor), and NGF (nerve growth factor) stimulate proliferation. The regenerative potential depends on cell type, genetic information, and the size of the defect. In the presence of a large connective tissue defect, fibrotic healing takes place (Cotran, et al., 1999; Reeves, 2000).

Under the best circumstances, natural healing restores connective tissue to its pre-injury length but only 50 to 75% of its pre-injury tensile strength (Leadbetter, 1992; Reeves, 1995). Connective tissues are bradytropic (their reparative capability is slower than that of muscle or bone). In the presence of repetitive microtrauma, unjudicious use of nonsteroidal anti-inflammatory drugs (NSAIDs) and steroid medications, tissue hypoxia, metabolic abnormalities, and other less-defined causes, connective tissue may divert toward a degenerative pathway (Leadbetter, 1992, 1994, 1995; Reeves, 1995, 2000). " judicious utilization of anti-inflammatory therapy remains useful, albeit adjunctive therapy …" (Leadbetter, 1995). Biopsies of these tissues demonstrate disorganized collagen, excessive matrix, insufficient elastin, disorganized mesenchymal cells, vascular buds with incomplete lumen, few or absent white blood cells, neovasculogenesis, and neoneurogenesis (Jozsa, 1997; Leadbetter, 1994). Degenerative changes in tendons may be hypoxic, mucoid, mixoid, hyaline, calcific,fibrinoid, fatty, fibrocartilaginous and osseous metaplasia, and any combination of the above (Jozsa, 1997).

Similar degenerative changes were found in fibromyalgia syndrome with dense foci of rough, frequently hyalinized fibrillar connective tissue. Vascularization occurred at the periphery of these foci, only where thin nervous fibrils and sometimes small paraganglions were seen with severe degenerative changes of the collagen fibers, and marked decrease of fibroblasts. Inflammatory markers were absent (Tuzlukov, et al., 1993).

Repeated eccentric contractions diminish muscle function and increase intramuscular pressure. For example, the intramuscular pressure in the supraspinatus and infraspinatus is four to five times higher than that in the deltoid or trapezius at the same relative load (Ranney, 1997). Edema arising in one muscle compartment secondary to overuse does not spread to adjacent compartments. Prolonged static muscular efforts predispose to edema, which leads to a decrease in perfusion pressure and a subsequent reduction of blood flow with granulocyte plugging of the capillaries and further metabolite accumulation and vasodilatation (Jozsa, 1997; Leadbetter, 1994; Ranney, 1997).

Further repeated eccentric contractions are notorious for microtraumas with microruptures either at the fibrooosseous junctions, in the mid substance of the ligaments and tendons, or at the myotendinous interface. Repetitive microtrauma with insufficient time for recovery leads to an inadequate regenerative process that turns to a degenerative pathway in tendons, muscles, discs, joint ligaments, and cartilage. Improper posture, in combination with eccentric contractions (such as driving with both hands on a steering wheel or typing on a computer with improperly positioned keyboard and monitor), are the most common examples of eccentric contraction (Jozsa, 1997; Leadbetter, 1992, 1994, 1995; Ranney, 1997; Reeves, 2000).

Impaired circulation at the fibromuscular and fibrooosseous interface eventually leads to impaired intraosseous circulation with diminished venous flow out and increased intraosseous pressure. This, in turn, stimulates intraosseous baroreceptors and contributes to nociception transmitted through fine myelinated and nonmyelinated fibers that accompany nutrient vessels into bone and located in perivascular spaces of Haversian canals. Decreased circulation leads to hypoxia, affects calcium metabolism, and contributes to the progression of osteoarthritis (Gray, 1995; Hackett, 1959, 1960a, 1960b, 1961, 1966a, 1966c, 1966d, 1967; Hackett, et al., 1961, 1962; Shevelev, et al., 2000; Sokov, et al., 2000; Zoppi, et al., 2000).

SOME ANATOMICAL AND BIOMECHANICAL PROPERTIES OF LIGAMENTS AND TENDONS

Ligaments are dull white, dense connective tissue structures that connect adjacent bones. They may be intraarticular, extraarticular, or capsular. Collagen fibers in ligaments may be parallel, oblique, or spiral. These orientations represent adaptation to specific directions in restriction of joint displacements.

Tendons are glistening white collagenous bands interposed between muscle and bone that transmit tensile forces during muscle contraction. There are considerable variations in shape of fibrooosseous attachments from

cylindrical, fan shaped to wide, flat, and ribbon shaped. The myotendinous junctions have significant structural variations from end to end, to oblique and singular intermuscular fibers. The collagen content of tendons is approximately 30% wet weight, or 70% dry weight (Butler, et al., 1978; Gray, 1995).

Under the light microscope, ligaments and tendons have a crimped, wave-form appearance. This crimp is a planar zigzag pattern that unfolds during initial loading of collagen (Butler, et al., 1978; Gray, 1995). Elongated below 4% of original length, ligaments and tendons return to their original crimped wave appearance; beyond 4% elongation, they lose the elasticity and become permanently laxed. However, in degenerative ligaments, subfailure was reported as early as 1.5% elongation. Laxity of ligaments obviously leads to joint hypermobility. Experimental studies have confirmed that the medial collateral ligament (MCL) failed more abruptly than either the capsular ligaments or the anterior cruciate ligament (ACL). This happens because the MCL has more parallel fibers with uniformity in length and, therefore, they fail together. The capsular fibers are less organized than the MCL or ACL, and their lengths and orientations vary. Because these fibers are loaded and fail at different times a large joint displacement is needed before capsular failure is complete.

Three principal failure modes exist. The first and most common is ligament failure. The second is a bone avulsion fracture; and the third, the least common, is a shear or cleavage failure at the fibroosseous interface.

Collagenous tissues are deleteriously affected by inactivity and are favorably influenced by physical activity of an endurance nature. They are also deleteriously affected by NSAIDs and steroid administrations.

In fact, "Administration of even a single dose of corticosteroids directly into ligaments or tendons can have debilitating effects upon their strength. Intraarticular injections of methyl-prednisolone acetate given either once or at intervals of several months may be less detrimental to ligament or tendon mechanical properties" (Butler, et al., 1978).

Tendons are strongly attached to the bones by decussating and perforating Sharpey fibers. Current understanding of OTJ (osseo tendinous junction, a.k.a. enthesis fibroosseous junction) is such that the fibers insert to the bone via four zones: tendon zone, fibrocartilage zone, mineralized fibrocartilage zone, and lamellar bone. However, it does not shed much light on the mechanism of tendon avulsion and overuse-induced pathology, as was emphasized by Hackett, et al. (1991) and Jozsa (1997). The tensile strength of tendons is similar to that of bone and is about half that of steel. A tendon with a cross section of 10 mm in diameter can support a load of 600 to 1000 kg (Butler, et al., 1978; Gray, 1995; Jozsa, 1997).

Three types of nerve endings in posterior ligamentous structures of the spine were confirmed microscopically. They are free nerve endings, and Pacini and Ruffini corpuscles. The free nerve endings were found in superficial layers of all ligaments, including supraspinous and interspinous, with a sharp increase in their quantity at the spinous processes attachments (enthesis). Paciniform corpuscles are located in adipose tissue between supraspinous ligaments and lumbosacral fascia and in the deep layers of supraspinous and interspinous ligaments acting as nociceptors in all locations and as mechanoceceptors with a low threshold, and are stimulated by stretch of the ligaments and muscle actions. Ruffini receptors are located in the interspinous and flaval ligaments; they respond to stretch; and they control the reflex inhibitory mechanism (Yahia, et al., 1989).

Neoneurogenesis and neovasculogenesis have been documented in chronic connective tissue pathology. The nerve and vascular tissue ingrowth into diseased intervertebral discs, posterior spinal ligaments, hard niduses of fibromyalgia, together with neuropeptides in the facet joint capsules, have been observed (Ashton, et al., 1992; El-Bohy, et al., 1988; Freemont, et al., 1997; Tuzlukov, et al., 1993).

During postnatal development, tendons enlarge by interstitial growth, particularly at the myotendinous junction (a.k.a. fibromuscular interface) where there is a high concentration of fibroblasts. The nerve supplies are largely sensory (Best, 1994; Butler, et al., 1978; Gray, 1995; Jozsa, 1997).

Insertion pathology of the trunk muscles (enthesopathy at the fibroosseous junctions) most commonly affects the following sites: occipital and scapular insertions; the spinous processes, especially at the cervicodorsal and thoracolumbar regions; iliac crest; sternum; and symphysis pubis (Figures 33.4 and 33.5). Histopathologically, the following findings were observed: calcium deposits and mineralization of the fibrocartilaginous zone (Jozsa, 1977). A large study examined traumatically ruptured tendons from 891 patients in comparison with 445 tendon specimens obtained from similar local sites in similar age and gender groups of "healthy" individuals who died accidentally. Degenerative changes were well-documented in 865 ruptured tendons (97%) and only in 149 control tendons (27%). Similar statistical differences were observed comparing tendons of individuals who died 3 years after quadriplegia and those who died accidentally. Irreversible lipoid degenerations at the muscle tendon junctions were documented as early as 3 months after onset of quadriplegia (Jozsa, 1977).

The cervical zygapophyseal joint (z-joint) is responsible for 54% of chronic neck pain after "whiplash" injury. The prevalence may be as high as 65% (Barnsley, et al., 1994). In populations presenting with headaches after whiplash, over 50% of the headaches stem from the C2–3

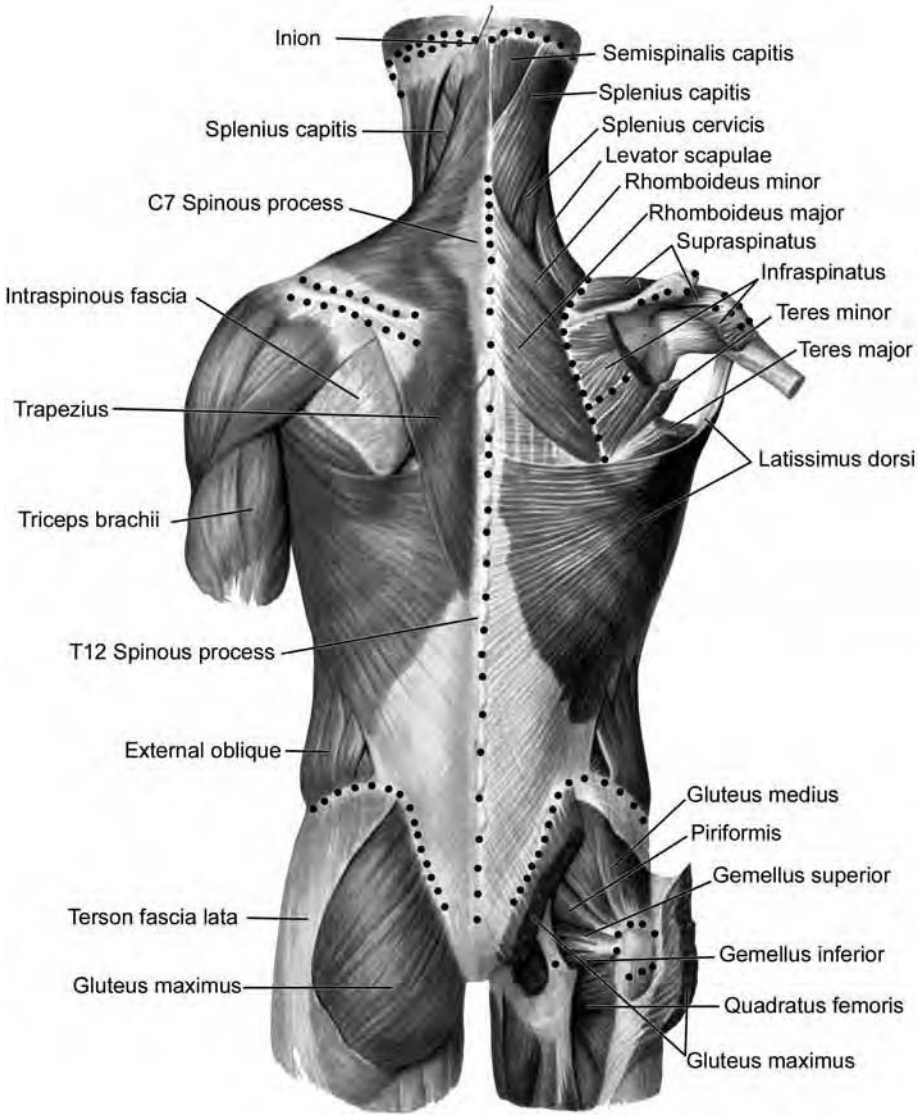

FIGURE 33.4 Dots represent some of the common enthesopathy areas in the trunk muscles at bony fibrous insertions (enthesis), at the occipital, scapular, humeral, trochanteric, iliac crests, and spinous processes. Dots also represent the most common locations of needle tips during RIT droplet infiltrations. (Please note: not all of the locations must be treated in each patient.) (From Sinelnikov Atlas of Anatomy (1972) Vol. I, Moscow: Meditsina. Modified by Tracey Slaughter.)

z-joint (Bogduk, 1986, 1996; Bogduk, et al., 1996; Lord, 1986). Intraarticular corticosteroid injections are ineffective in relieving chronic cervical z-joint pain (Barnsley, et al., 1994). These data strongly suggest that there is a presence of nociceptors other than z-joints and intervertebral discs. Pain patterns from synovial joints at the cranio-cervical junction overlap with the pain patterns from the lower z-joints and suboccipital soft tissues (Aprill, et al., 1990; Dreyfuss, et al., 1994a; Hackett, 1958, 1960a; Hackett, et al., 1962, 1991; Travell, et al., 1983). Their contribution to nociception requires confirmation with intraarticular blocks under fluoroscopic guidance by a practitioner with a significant amount of experience (Bogduk, 1988; Dreyfuss, et al., 1994a).

CLINICAL ANATOMY OF CERVICOCRANIAL, CERVICAL, AND CERVICODORSAL REGIONS IN RELATION TO RIT

It is important to realize that various ligaments, tendons, and fasciae of the cervical, thoracic, and lumbar regions form a continuous connective tissue stocking which incorporates and interconnects various soft tissue, muscular, vascular, and osseous structures. Although each of the connective tissues has a slightly different biochemical content, they blend at their boundaries and function as a single unit. The innervation is generally segmental and posteriorly provided by

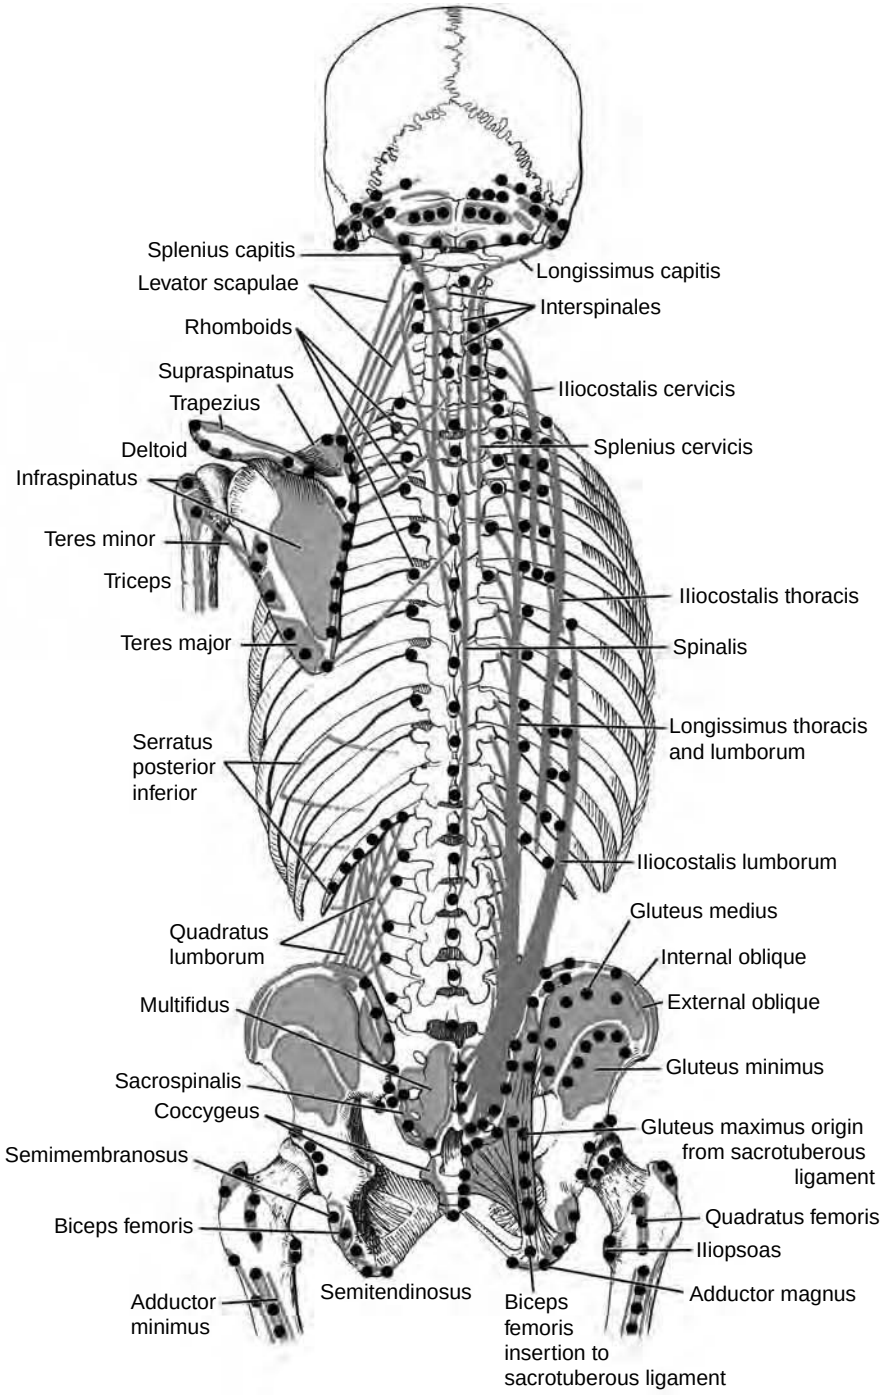

FIGURE 33.5 Schematic drawing demonstrating sites of origins and tendon insertions (enthesis) of the vertebral, paravertebral and peripheral musculature in the cervical, thoracic, and lumbar regions and partly upper and lower extremities. Clinically significant painful enthesopathies are common at these locations defined by dots. Dots also represent most common locations of needle insertions and infiltration during RIT (Please note: not all of the locations must be treated in each patient.) (Feneis, Sinelnikov Atlas of Anatomy (1972) Vol. I, Moscow: Meditsina. Modified by Tracey Slaughter.)

the respective medial and lateral branches of the dorsal rami (Agur, et al., 1991; Gray, 1995; Linetsky, 1999; Willard, 1995).

Differential diagnosis is based on a thorough understanding of the regional and segmental anatomy and pathology. Currently prevailing trends in diagnostic efforts are addressing discogenic, facetogenic, and neurocompressive components of spinal pain. Consequently, therapy is directed toward neuromodulation or neuro-ablation with radiofrequency generators. Also, surgical ablations and

fusions correct the mass effects in neurocompressive mod els, or discogenic pain.

In the mid-cervical area, blocking the putative medial branches of the dorsal rami at the waist of the articular pillars, as the initial step in differential diagnosis, is considered diagnostic and prognostic for z-joint pain (Bogduk, 1988; Lord, 1996). However, such an approach as an initial step in differential diagnosis may be misleading for two reasons. First, it interrupts orthodromic and antidromic transmission at the proximal segment of the medial branch of the dorsal rami (MBDR), excluding other putative nociceptors located distally on its course from the differential diagnosis. Second, there is significant individual variation in the location of the dorsal rami bifurcations into the medial and lateral branches (Willard, personal communication, October 9, 2000).

All cervical spinal nerves divide into ventral and dorsal rami. The dorsal rami in turn divide into the medial and lateral branches, except for the first dorsal ramus, which is also called the suboccipital nerve. The first dorsal ramus supplies the muscles of the suboccipital region — rectus capitis posterior minor and major, inferior and superior oblique, and semispinalis capitis — and has an ascending cutaneous branch that connects with the greater and lesser occipital nerves and may contribute to the occipital and suboccipital headaches (Bogduk, 1986, 1988; Gray, 1995). The second cervical dorsal ramus also supplies the inferior oblique, connects with the first one, and divides into lateral and medial branches (MBDR). Its medial branch (the greater occipital nerve) pierces the semispinalis capitis and trapezius at their insertion to the occipital bone on its ascending course. Thereafter, it connects with the branches from the third occipital nerve along the course of the occipital artery supplying the skin of the skull up to the vertex (Bogduk, 1986, 1988; Gray, 1995).

Anatomical texts (Agur, et al., Gray, 1995) indicate that the dorsal ramus proper of the lower cervical nerves is located laterally at the waist of the articular pillars (Figures 33.6 and 33.7). On the other hand, current trends in therapeutic and diagnostic blocks are based on the assumption that the anatomy and course of the MBDR is constant, and that it arises from the intertransverse space and wraps around the waist of the respective articular pillars (Aprill, et al., 1990; Bodguk, 1988). However, the clinical observations supported by ongoing research and microdissections of Willard (personal communication, October 9, 2000) indicate that bifurcations into medial and lateral branches are not consistent in their location and may originate in the intertransverse space or in the projections of the lateral and posterior aspects of articular pillars (Figures 33.6 and 33.7). Quite often, the course of the medial (MB) and lateral branches (LB) is parallel at the waists of the

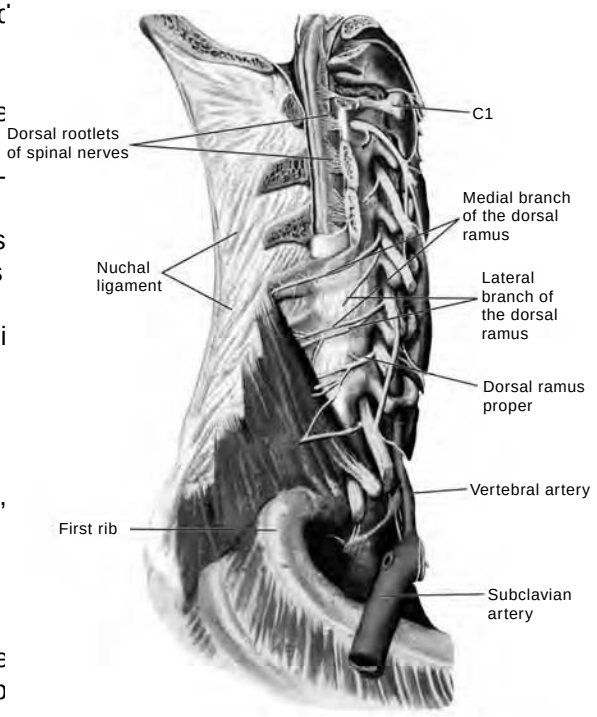

FIGURE 33.6 The course of the medial, lateral branches and the dorsal ramus proper, represented semi-schematically. (From Sinelnikov Atlas of Anatomy, Vol. I, Meditsina Moskow, 1972. Modified by Tracey Slaughter.)

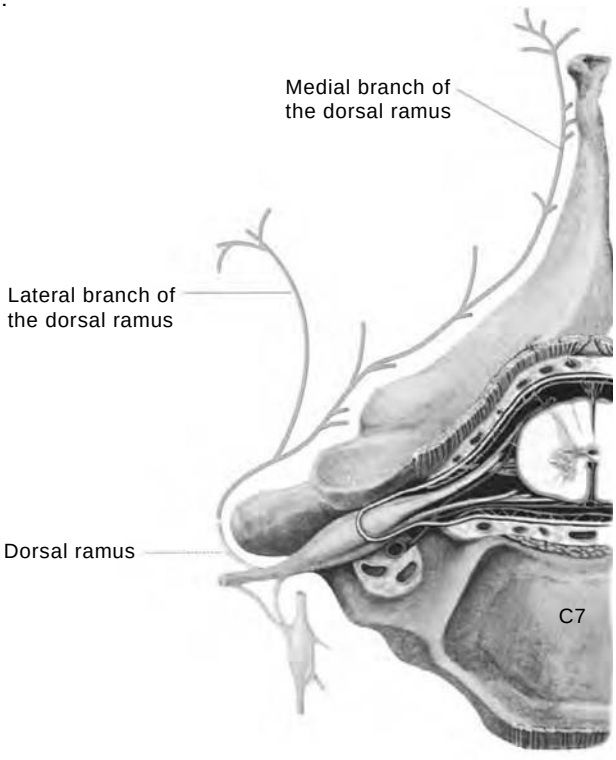

FIGURE 33.7 The course of the dorsal ramus proper and its medial and lateral branches, represented semi-schematically. (From Sinelnikov Atlas of Anatomy, Vol. I, Meditsina Moskow, 1972. Modified by Tracey Slaughter.)

articular pillars with the MB being proximal to the osseous structure. Thereafter, the MB of the dorsal ramus (MBDR) furnishes twigs to zygapophyseal joint capsules and continues along the lamina and spinous process toward its apex, innervating structures inserting or originating at the lamina and the spinous process on its course (Agur, et al., 1991; Gray, 1995; Willard, personal communication, October 9, 2000). For example, the fourth and fifth cervical MBDRs supply the semispinalis cervices and capitis, multifidi, interspinalis, splenius and trapezius, supraspinous ligaments, and end in the skin. The lowest three MBDRs have a similar course (Figures 33.6 and 33.7).

Lateral branches supply the iliocostalis, longissimus cervices, and longissimus capitis. Similar anatomic relationships are observed in the thoracic region where medial branches of the upper six thoracic dorsal rami supply the zygapophyseal joints, semispinalis thoracis, multifidi, piercing trapezius, and rhomboid, and reach the skin most proximal and lateral to the spinous processes (Agur, et al., 1991; Gray, 1995).

RIT/PROLOTHERAPY MECHANISM OF ACTION

The RIT mechanism of action is complex and multifaceted.

1. The first is the mechanical transection of cells and matrix by the needle, causing cellular damage and stimulating inflammatory cascade.
2. The second is compression of cells by the extracellular volume of the injected solution, stimulating intracellular growth factors (Reeves, 2000).
3. The third step is chemomodulation of collagen through inflammatory proliferative, regenerative/reparative response induced by the chemical properties of the proliferants and mediated by cytokines and multiple growth factors (Cook, 2000; DesRosiers, et al., 1996; Kang, et al., 1999; Lee, et al., 1998; Harui, et al., 1997; Nakamura, et al., 1998; Reeves, 1995, 2000; Rudkin, et al., 1996; Spindler, et al., 1996).
4. The fourth is chemoneuromodulation of peripheral nociceptors and antidromic, orthodromic, sympathetic, and axon reflex transmissions (Hackett, 1958, 1960b, 1961, 1966a, 1966b, 1966c, 1966d; Hackett, et al., 1961, 1962).
5. The fifth is modulation of local hemodynamics with changes in intraosseous pressure leading to a reduction of in pain. Empirical observations suggest that a dextrose/lidocaine combination has a much more prolonged action than lidocaine alone (Hackett, 19598, 1960b, 1961, 1966a, 1966b, 1966c, 1966d; Hackett, et al., 1961, 1962; Shevelev, et al., 2000; Sokov, et al., 2000; Zoppi, et al., 2000).
6. The sixth is a temporary repetitive stabilization of the painful hypermobile joints induced by inflammatory response to the proliferants, providing a better environment for regeneration and repair of the affected ligaments and tendons (Bahme, 1945; Gedney, 1952a, 1952b, 1954a, 1954b; Hackett, 1958; Hackett, et al., 1991; Shuman, 1958).

PUTATIVE PAIN-GENERATING STRUCTURES ADDRESSED BY RIT/PROLOTHERAPY

1. Ligaments: Intraarticular, periarticular, capsular
2. Tendons
3. Fascia
4. Enthesis: The zone of insertion of ligament, tendon, or articular capsule to bone (Dorland, 1985; Jozsa, 1997; Klein, et al., 1997; Mirman, 1989) (a.k.a. fibroosseous junctions of ligaments and tendons). In the orthopedic literature, this is referred to as OTJ (osseo/tendinous junction) (Jozsa, 1997; Leadbetter, 1992, 1994, 1995; Reeves, 2000). For the purpose of this chapter, enthesis and fibroosseous junction are interchangeable.
5. Intervertebral discs

TISSUE PATHOLOGY TREATED WITH RIT/PROLOTHERAPY

1. Sprain: Ligamentous injury at the fibroosseous junction or intersubstance disruption. A sudden or severe twisting of a joint with stretching or tearing of ligaments; also, a sprained condition (Leadbetter, 1994; Merriam-Webster, 1995; Reeves, 1995; Simon, et al., 1987).
2. Strain: Muscle/tendon injury at the myotendinous or fibroosseous interface. When concerned with the peripheral muscles and tendons sprains and strains are identified as separate injuries and in three-stage gradations: first-, second-, and third-degree sprain, and similarly for strain. With regard to vertebral and paravertebral ligaments and tendons, no consensus exists among authors and the definitions are quite vague (Dorland, 1985; Leadbetter, 1994; Mirman, 1989).

3. Enthesopathy: A painful degenerative pathological process that results in the deposition of poorly organized tissue, degeneration and tendinosis at the fibroosseous interface and transition toward loss of function (Jozsa, 1997; Klein, et al., 1997; Leadbetter, 1994; Linetsky, 1999a; Reeves, 1995).
4. Tendinosis/ligamentosis: A focal area of degenerative changes due to failure of cell matrix adaptation to excessive load and tissue hypoxia, with a strong tendency toward chronic recurrent pain and dysfunction (Best, 1994; Jozsa, 1997; Klein, et al., 1997; Leadbetter, 1994; Reeves, 1995; Roosth, 1991).
5. Pathologic ligament laxity: A post-traumatic or congenital condition leading to painful hypermobility of the axial and peripheral joints (Dorland, 1985; Dorman, et al., 1991; Hackett, 1958; Leedy, 1977; Reeves, 1995, 2000; Reeves, et al., 2000; Simon, et al., 1987).

INDICATIONS FOR RIT/PROLOTHERAPY

1. Chronic pain from ligaments or tendons secondary to sprains or strains
2. Pain from overuse or occupational conditions known as repetitive motion disorders (i.e., neck and wrist pain in typists and computer operators, "tennis" and "golfer's" elbows, chronic supraspinatus tendinosis).
3. Painful chronic postural neck and cervicodorsal junction problems
4. Painful recurrent somatic dysfunctions secondary to ligament laxity that improve temporarily with manipulation. Hypermobility and subluxation at a given peripheral or spinal articulation or mobile segment(s), accompanied by a restricted range of motion at reciprocal segment(s).
5. Thoracic vertebral compression fractures with a wedge deformity that exerts additional stress on the posterior ligamento-tendinous complex.
6. Recurrent painful subluxations of ribs at the costotransverse, costovertebral, and/or costosternal articulations.
7. Spondylolysis and spondylolisthesis
8. Intolerance to NSAIDs, steroids, or opiates. RIT may be the treatment of choice if the following modalities are contraindicated. Or failure to improve after physical therapy, chiropractic, or osteopathic manipulations, steroid injections or radiofrequency denervation, or surgical interventions in aforementioned conditions.

SYNDROMES AND DIAGNOSTIC ENTITIES CAUSED BY LIGAMENT AND TENDON PATHOLOGY THAT HAVE BEEN SUCCESSFULLY TREATED WITH RIT/PROLOTHERAPY

1. Cervicocranial syndrome (cervicogenic headaches, alar ligaments sprain, atlanto-axial and atlanto-occipital joint sprains)
2. Temporomandibular pain and dysfunction syndrome
3. Barre–Lieou syndrome
4. Spasmodic torticollis
5. Cervical segmental dysfunctions
6. Cervical and cervicothoracic spinal pain of "unknown" origin
7. Cervicobrachial syndrome (shoulder/neck pain)
8. Hyperextension/hyperflexion injury syndromes
9. Cervical, thoracic, and lumbar facet syndromes
10. Cervical, thoracic, and lumbar sprain/strain syndromes
11. Costo-transverse joint pain
12. Costovertebral arthrosis/dysfunction
13. Slipping rib syndrome
14. Sternoclavicular arthrosis and repetitive sprain
15. Thoracic segmental dysfunction
16. Tietze's syndrome/costochondritis/chondrosis
17. Costosternal arthrosis
18. Intercostal arthrosis
19. Xiphoidalgia syndrome
20. Acromioclavicular sprain/arthrosis
21. Shoulder–hand syndrome
22. Recurrent shoulder dislocations
23. Scapulothoracic crepitus
24. Myofacial pain syndromes
25. Ehlers–Danlos syndrome
26. Osgood-Schlatter disease
27. Marie–Strumpell disease
28. Failed back syndrome

CONTRAINDICATIONS TO RIT/PROLOTHERAPY

1. Allergy to anesthetic or proliferant solutions or their ingredients, such as dextrose, sodium morrhuate, or phenol
2. Acute nonreduced subluxations or dislocations.
3. Acute sprains or strains of axial and peripheral joints
4. Acute arthritis (septic or posttraumatic with hemarthrosis)
5. Acute bursitis or tendinitis

6. Capsular pattern shoulder and hip designating acute arthritis accompanied by tendinitis
7. Acute gout or rheumatoid arthritis
8. Recent onset of a progressive neurologic deficit, including but not limited to severe intractable cephalgia, unilaterally dilated pupil, bladder dysfunction, and bowel incontinence
9. Requests for a large quantity of sedation and/or narcotics before and after treatment
10. Paraspinal neoplastic lesions involving the musculature and osseous structures
11. Severe exacerbation of pain or lack of improvement after local anesthetic blocks
12. Relative contraindications: central spinal canal, lateral recess and neural foraminal stenosis

CLINICAL PRESENTATIONS

Patients may present with a variety of complaints ranging from one area of localized pain and tenderness to any combination of referred pain patterns known with cervical disc, cervicocranial, and cervicobrachial or cervical and thoracic facet syndromes. Headaches accompanied by cervical muscle spasms are a common complaint. Other compaints include: (1) exacerbation of pain while standing or sitting in the same position for a given period of time, and increased pain after exertion or physical activity are typical; (2) a feeling of weakness in the neck, back, or extremities and extreme fatigability; (3) pseudoradicular patterns of change in sensation, such as burning, numbness, and tingling; (4) difficulties in maintaining balance, ringing in the ears, and blurred vision; (5) feeling the need for repetitive self-manipulations, or chiropractic or osteopathic manipulations; (6) painful clicking, popping, or locking of axial or peripheral joints; (7) dropping of objects, weakness of the hands, and "heaviness of the head" (Dorma et al., 1991; Hackett, et al., 1991; Kayfetz, 1963; Kayfetz et al., 1963; Reeves, 1995, 2000).

PHYSICAL EXAMINATION

Tenderness is the most common finding over the chroni cally strained or sprained ligaments or tendons. Provoke tenderness rarely reproduces radiating or referral pain; is a local phenomenon. However, intensity of such tender ness may be changed or abolished completely after mani ulation. Patients are able to point out such pain with thei finger in the posterior cervicodorsal region.

Such local tenderness, as well as referred and rad ating pain, can often be abolished by infiltration of nociceptors in the involved tissue with local anesthetic. Tenderness is an objective finding, especially when elicited at posterior structures (Borenstein, et al., 1996; Broadhurst, et al., 1996; Hackett, 1958; Hackett, et al., 1991; Linetsky, 1999).

RADIOLOGIC EVALUATION PRIOR TO RIT/PROLOTHERAPY

1. Plain radiographs are of limited diagnostic value in painful pathology of the connective tissue; however, they may detect:
   a. Structural or positional osseous abnormalities
   b. Anterior or posterior listhesis on lateral views (flexion, extension)
   c. Degenerative changes in general and deformity of zygapophyseal articulation (Browner, et al., 1998; Harris, et al., 1981; Resnick, 1995; Watkins, 1996).
2. Videofluoroscopy or digital motion radiography is currently a valuable diagnostic method in evaluating painful hypermobility and instability due to posttraumatic and degenerative pathology of capsular and axial ligaments. Evaluation of certain axial and peripheral joints in motion affords a noninvasive opportunity to identify specific segments responsible for nociception. At the upper cervical levels, this technology is capable of identifying excessive motions at atlanto occipital, lateral and median atlanto axial joints, and, indirectly, pathology of their respective fibrous articular capsules and periarticular ligaments (Figures 33.8, 33.9, and 33.10). Capsule-related pathology with hypo- and hypermobility can be identified and documented in caudally situated cervical zygapophyseal articulations. The integrity of the posterior ligamentous complex con-

FIGURE 33.8 Posterior listhesis of C3 on C4 during extension identified with digital motion radiography. This was not identified with plain flexion, extension radiography. (Images acquired utilizing Visualizer 2000 from VF-Works, Inc. Modified by Tracey Slaughter.)

FIGURE 33.9 Listhesis of C1 on C2 during lateral flexion. Identified by digital motion radiography. This was not identified by plain film radiography. (Images acquired utilizing Visualizer 2000 from VF-Works, Inc. Modified by Tracey Slaughter.)

FIGURE 33.10 Flexion oblique view demonstrating widening of the facet joint suggestive of capsular ligament tear identified by digital motion radiography. This was not well visualized by plain film radiography. (Images acquired utilizing Visualizer 2000 from VF-Works, Inc. Modified by Tracey Slaughter.)

tributing to listhesis-related pathology can be documented. Small avulsion fractures of articular pillars as well as vertebral bodies or spinous processes can be identified. The pathology of TMJs is visualized and correlated with audio/video captioning. Painful instability of peripheral joints such as shoulder, elbows, wrists, knees, and ankles has also been identified and documented (Antos, et al., 1990; Buonocore, et al., 1996; Fielding, 1957, 1963; Jones, 1967; Tacharski, et al., 1981). Such studies must be performed with high-quality digitized equipment by well-trained technologists to produce high-quality contrast resolution and to be of diagnostic value, as currently available from VF Works, Inc. Combined with computerized range of motion studies, this technology may afford the opportunity to objectively document progress after RIT/prolotherapy, or other procedures directed toward the stabilization of axial and peripheral articulations such as facets, shoulders, knees and TMJs.

3. MRI may detect intervertebral disc pathology, enthesopathy, ligamentous injury, interspinous bursitis, zygapophyseal joint disease and sacroiliac joint pathology, evaluation of the neural foraminal pathology, bone contusion, neoplasia infection or fracture, as well as exclude or confirm spinal cord disease and pathology related to intradural, extramedullary, and epidural space (Resnick, 1995; Stark, et al., 1999).
4. CT scan may detect small avulsion fractures of the facets, laminar fracture, fracture of vertebral bodies and pedicles, or degenerative changes (Resnick, 1995).
5. Bone scan is useful in the assessment of the entire skeleton, ruling out metabolically active disease processes (Resnick, 1995).

SAFE INJECTION SITES

Common sites for injections are the enthesis of the structures that insert or originate at the spinous processes and are innervated by the medial branches of the dorsal rami. At the cervicodorsal junction, from superficial to deep, these include the supraspinous ligament, superficial layers of the cervicodorsal fascia, and multiple tendons. The apex of the spinous process may be considered a "spinous rotator cuff" (Figures 33.11 and 33.12). At the cervicocranial junction, these are bifibroosseous insertions at the superior and inferior nuchal lines, lateral aspects of the apex at the C2 spinous process and C2-3 posterior z-joint capsule.

The following step-by-step approach to a differential diagnosis is based on knowledge of anatomy and pathology, to investigate all potential nociceptors in the distribution of the medial and lateral branches extending it beyond z-joints, as is currently accepted (Aprill, et al., 1990; Barnsley, et al., 1994; Bogduk, 1986, 1988, 1996; Bogduk, et al., 1996; Dreyfuss, et al., 1994b, 1995; Dussault, et al., 1994; Dwyer, et al., 1990; Lord, 1996).

Accordingly, in the presence of significant midline tenderness, the most painful medial structures innervated by terminal filaments of the MBDRs are blocked initially. If after local anesthetic block, the paramedian pain persists, laminar enthesis of structures are blocked. If pain still persists, the posterior cervical or thoracic facet joint capsules are blocked, because the facet joints are the most proximal structures innervated by MBDRs on their emerging course from the dorsal ramus. Pathology of the

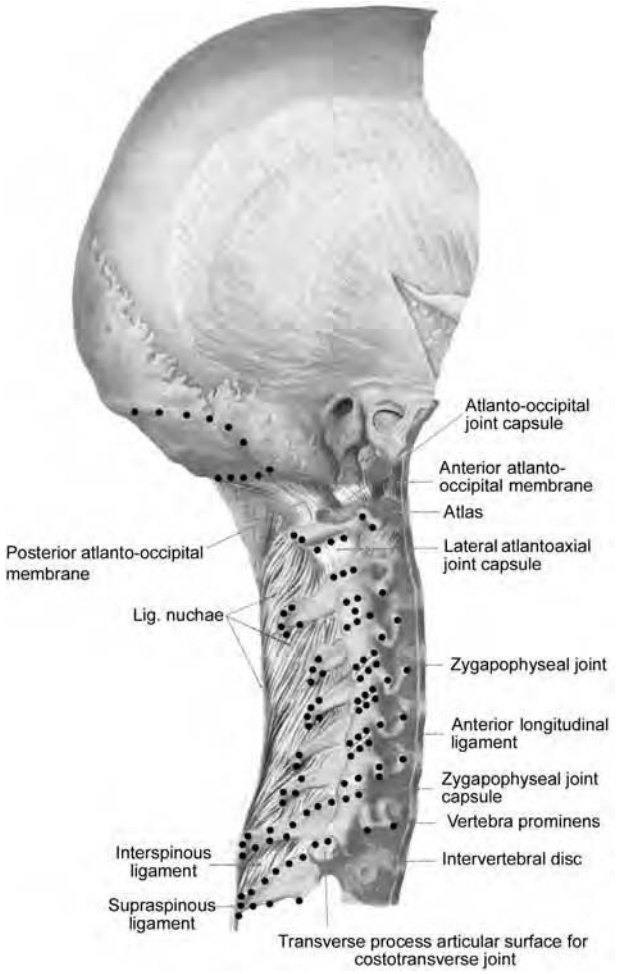

FIGURE 33.11 Cervical ligaments and joint capsules at their enthesis. Clinically significant painful enthesopathies are common at the locations defined by dots. Dots also represent most common locations of needletips during RIT droplet infiltrations. (Please note: not all of the locations must be treated in each patient.) (From Sinelnikov Atlas of Anatomy, Vol. I, Meditsina Moskow, 1972. Modified by Tracey Slaughter.)

capsular ligaments and periarticular tendons is an integral part of the facet joint syndrome.

Laterally positioned structures are innervated by the lateral branches of the dorsal rami. If laterally arising pain persists, enthesis at posterior tubercles of the cervical transverse processes and in the thoracic area capsules of costotransverse articulations are injected. If the pain persists, the iliocostalis cervices and thoracis tendons, at their respective fibroosseous rib insertions, are blocked.

Regarding z-joints, the intention is to inject the joint capsule posteriorly, initially with lidocaine utilizing the posterior approach, and thereafter with a mixture of bupivacaine and proliferating solution. Patients usually experience slight unsteadiness after injection of the C2-3 or C3-4 z-joint capsules, indicating a disturbance of postural tonic reflexes and indirectly successful blocks of the medial branches.

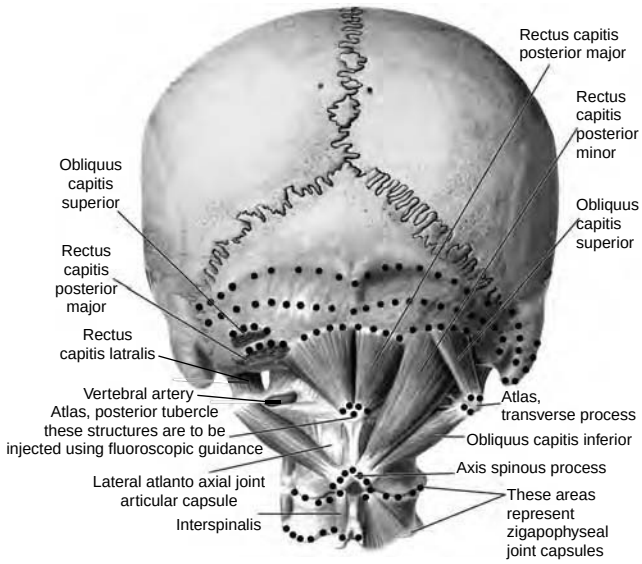

FIGURE 33.12 Sites of tendon origins and insertions (enthesis) of the vertebral and paravertebral musculaturein the upper cervical and occipital region. Clinically significant painful enthesopathies are common at these locations defined by dots. Dots also represent the most common locations of needle tips during RIT droplet infiltrations. (Please note: not all of the locations must be treated in each patient.) (From Sinelnikov Atlas of Anatomy, Vol. I, Meditsina Moskow, 1972. Modified by Tracey Slaughter.)

SOLUTIONS UTILIZED

The most common solution is 12.5% dextrose. Dilution is made with local anesthetic in 1:3 proportion, (i.e., 1 ml of 50% dextrose mixed with 3 ml of 1% lidocaine (Hackett, et al., 1991; Reeves, 1995, 2000).

For intra-articular injection of the knee, Hemwall has recommended a 25% dextrose solution (Hackett, et al., 1991). Reeves, et al. (2000) have pointed out that a 10% dextrose solution may be equally effective. If this proves ineffective, gradual progression to sodium morrhuate full strength has been described (Dorman, et al., 1991; Hackett, et al., 1991).

Sodium morrhuate (5%) is a mixture of sodium salts of saturated and unsaturated fatty acids of cod liver oil and 2% benzyl alcohol, which acts as a local anesthetic and a preservative. Note that benzyl alcohol is chemically very similar to phenol.

Dextrose/phenol/glycerine solution, originally produced in England by Boots Company Ltd. of Nottingham for treatment of varicose veins, was introduced to pain management by Ongley, et al. (1988). The solution consists of 25% dextrose, 2.5% phenol, and 25% glycerine and is referred to as DPG (a.k.a. P2G). Prior to injection it is diluted in concentrations of 1:2; 1:1, or 2:3 with a local anesthetic of the practitioner's choice. Some authors exclusively use this solution in 1:1 dilution (Dorman, et al., 1991). Others modify it, reducing the percentage of glycerine to 12.5%

The 6% phenol in glycerine solution was utilized by Poritt in 1931 and reintroduced in the late 1950s by Maher (1957) of England for intrathecal injections in the treatment of spasticity. Subsequently, after gaining sufficient experience with intrathecal use of this solution, Wilkinson (1992), a neurosurgeon trained at Massachusetts General Hospital, began injecting it at the donor harvest sites of the iliac crests for neurolytic and proliferative responses.

CONCLUSIONS

1. RIT/prolotherapy is a valuable method of treatment for correctly diagnosed, chronic painful conditions of the locomotive systems.
2. Thorough familiarity of the physician with normal, pathologic, cross-sectional, and clinical anatomy, as well as anatomical variations and function is necessary.
3. Current literature supports manipulation under local joint anesthesia.
4. The use of RIT in an ambulatory setting is an acceptable standard of care in the community.
5. The current literature suggests that NSAIDs and steroid preparations have limited utility in chronic painful overuse conditions and in degenerative painful conditions of ligaments and tendons. Microinterventional regenerative techniques and proper rehabilitation up to 6 months or a year, supported with mild opioid analgesics, are more appropriate.

The future is such that, instead of indirect stimulation of growth factors through inflammatory cascade, specific growth factors will become available. The challenge will remain as to what specific growth factors to utilize. Most probably, a combination of several growth factors will be utilized, together with specific genes responsible for production of these growth factors. It appears that the delivery mode will be injections for deep structures; however, superficial structures will probably be addressed through transdermal delivery systems (Cook, 2000; DesRosiers, et al., 1996; Kang, et al., 1999; Lee, et al., 1998; Marui, et al., 1997; Nakamura, et al., 1998; Reeves, 1995, 2000; Rudkin, et al., 1996; Spindler, et al., 1996).

A physician who is versatile in manipulation as well as diagnostic and therapeutic injection techniques as described previously may have ample opportunity for RIT use in the practice of pain management.

BIBLIOGRAPHY

Readers interested in incorporating RIT/prolotherapy in their pain management practice are referred to the following textbooks containing the bulk of information about this subject. These books were published in the 1980s and 1990s but remain reliable sources of basic principles and information.

The Illustrated Manual of Orthopaedic Medicine by Cyriax (1993) is available from Butterworth & Heinemann.

Diagnosis and Injection Techniques in Orthopedic Medicine and Prolotherapy in the Lumbar Spine and Pelvis (Dorman, 1995) is available from T. Dorman, M.D. at 2505 South 320th St., #100, Federal Way, WA 98003.

Hackett, et al's (1991) text is available from the Institute in Basic Life Principles (IBLP), Box 1, Oak Brook, IL 60522–3001.

Lennard's text, Pain Procedures in Clinical Practice (see Reeves, 2000) is available from Hanley & Belfus.

A System of Orthopaedic Medicine (see Ombregt, et al., 1995) by Ombregt, is available from W.B. Saunders.

Movement, Stability and Low Back Pain: The Essential Role of the Pelvis by Vlemming, et al. (1997) is available from Churchill Livingstone.

The Failed Back Syndrome Etiology and Therapy by Wilkinson (1992) is available from Springer-Verlag.

ACKNOWLEDGMENTS

The authors would like to extend special thanks to Pamela Ward and Dianne Zalewski for their invaluable help in the preparation of this manuscript, and to Tracey Slaughter for preparing the illustrations for publication.

Prescription NSAIDs: Choices in Therapy

Linda L. Norton, Pharm.D.

GOALS

The goal of this chapter is to help clinicians select appropriate nonsteroidal anti-inflammatory drugs (NSAIDs) for patients with specific risk factors by:

- Providing an overview of these agents
- Increasing the understanding of NSAID pharmacology
- Increasing the awareness of characteristics of NSAIDs that make individual NSAIDs better or worse choices in specific patients

This information is presented in the hope and belief that selection of the most appropriate pharmacologic agent will improve patient outcomes by decreasing side effects and improving compliance and tolerability.

INTRODUCTION

Nonsteroidal anti-inflammatory drugs (NSAIDs) have been in use since the 1900s. They have been developed from a variety of sources, including natural products and as the result of developments and advances in our understanding of medicinal chemistry and pharmacology. Not all NSAIDs that have been developed, used medicinally, and marketed in the United States. have stood the test of time and prospective and retrospective investigation. For example, an NSAID approved by the Food and Drug Administration (FDA) in July 1997 for short-term use in acute pain (i.e., less than or equal to 10 days) was released to the U.S. market and then voluntarily withdrawn in June 1998 following reports of liver failure when the drug was used for extended periods of time (FDA, 1998). However, several products discovered early in the NSAID timeline have stood the test of time and extensive use, and are still available and in use today. For example, willow bark, a natural product with an active ingredient called salicin, was first isolated in 1829 and still appears in some natural products listings and texts (Insel, 1996). Similarly, the use of sodium salicylate to treat rheumatic fever was reported in 1875, and products containing sodium salicylate are still marketed today. Interestingly, one of the most commonly used NSAIDs, aspirin, was developed and later marketed by Dresser in 1899, based on work from the 1850s by the chemist Gerhardt. Later Hoffman, a chemist at Bayer, prepared acetylsalicylic acid (ASA); and, as mentioned, ASA was marketed in 1899 as aspirin. Numerous other NSAIDs have been developed and marketed, mostly in the latter half of the 20th century, with most being marketed in the past 20 to 30 years. Cyclooxygenase (COX)-2 inhibitors are the latest class of NSAID to be marketed in the U.S., with the first of the class approved by the FDA in December 1998 and actually reaching the market in 1999 (Kaplan-Machlis & Klostermeyer, 1999). Peer-reviewed publications on the long-term safety and efficacy of COX-2 inhibitors are currently in progress with one containing the results of the CLASS study published in September of 2000 (Silverstein, et al., 2000).

NSAIDs and related products are used to reduce pain, stiffness, inflammation, platelet aggregation, and temperature, and are among the most frequent products prescribed by physicians or selected for self-care. ASA is the most commonly used household analgesic and one of the most widely prescribed analgesic, antipyretic, and anti-inflammatory agents in the United States. (APhA, 1999; Insel, 1996). Some estimates place the number of NSAID prescriptions in the U.St. at 50 to 100 million annually (APhA, 1999; Fung & Kirschenbaum, 1999). Furthermore, each

0-8493-0926-3/02/$0.00+$1.50

day, more than 13 million Americans use NSAIDs (Kaplan-Machlis & Klostermeyer, 1999). In the U.S., the cost of these products is greater than $1 billion annually, with some estimates ranging as high as $2.2 billion per year (Boyce & Takiya, 2000; Kaplan-Machlis & Klostermeyer, 1999). The range in costs is based, in part, on the large number of factors that affect cost, including which cost is being discussed (i.e., consumer cost, medical center acquisition cost, or third-party payer cost), and it is largely artificial. These numbers are presented only to demonstrate the magnitude of use of these medications. The 1995 estimates of worldwide sales listed sales at greater than $5.7 billion (Kaplan-Machlis & Klostermeyer, 1999). And, as much as 10,000 to 20,000 tons of ASA may be used in the U.S. annually (Insel, 1996). It is difficult to visualize 20,000 tons of aspirin; but picture a line of pick-up trucks, each with a half-ton of ASA in the back. If the trucks were parked end to end, the line would stretch from New York City to Hartford, Connecticut. By any estimate, ASA and other NSAIDs are widely used and widely prescribed.

PRIMARY ACTIONS/MECHANISMS OF ACTIONS

When considered in its simplest form, inflammation is a series of physiologic reactions that result in erythema, edema, tenderness, or pain (Insel, 1996). Inflammation can be caused by a variety of factors that may be as easily identified as an injury, infection, or ischemia, or as difficult to trace as a previously unidentified antigen-antibody reaction. Inflammation occurs in three phases. The first phase is what patients often report. In this phase, the events are usually easily noticed and are usually reported as swelling and redness. The swelling and redness result from local vasodilation that leads to increased capillary permeability. Next, a delayed phase results in the migration of leukocytes and phagocytic cells. Finally, a chronic phase can occur in which tissue degeneration and fibrosis are seen. These are the events that anti-inflammatory medications are intended to block. In most cases, the anti-inflammatory agent of choice is an NSAID. A large part of this choice is due to the fact that although NSAIDs can have significant, even lethal adverse effects, they are associated with fewer problems than the other large category of anti-inflammatory drugs, the steroids.

Acetaminophen (APAP) is often not considered a nonsteroidal anti-inflammatory drug because it has no anti-inflammatory activity at recommended doses, and unlike many NSAIDS, APAP has no anti-platelet effect (Insel, 1996). It is included in this chapter, however, because of the tight connection between APAP and NSAIDs in clinical use and because APAP is often the drug of choice in noninflammatory pain in patients for whom NSAIDs should not be used or in patients who cannot tolerate NSAIDs (Kastrup, 2000; McEvoy, 1999). Additionally, it is included because clinicians may not provide adequate information to patients/consumers on the differences between APAP and NSAIDs, and although APAP is generally well tolerated, it, too, is associated with significant risk, especially risk of hepatoxicity. APAP is effective in decreasing mild to moderate pain and for decreasing temperature, but it may not be the best choice of agents to treat pain associated with inflammation and should not be used to decrease platelet aggregation. The importance of this general lack of efficacy as an anti-inflammatory agent and also as an anti-platelet agent should be explained to patients, because many patients have used recommended doses of APAP successfully to relieve aches and pains with very few, if any, side effects. Due, in part, to its low side-effect profile and low cost, APAP appears to patients/consumers to be an attractive alternative to NSAIDs. Unfortunately, in the absence of adequate information, patients may substitute APAP for an NSAID when an anti-inflammatory or anti-platelet effect is needed. Patient/consumer education by clinicians may be the key to avoiding this confusion.

APAP's antipyretic activity is at the hypothalamic heat-regulating center (Kastrup, 2000; McEvoy, 1999). This action increases vasodilation and sweating and allows heat loss. Additionally, the action of endogenous pyrogens on the heat-regulating centers is inhibited, and central, but not peripheral, inhibition of prostaglandin synthetsis occurs. APAP's mechanism for reducing pain is not fully known. The question of APAP and anti-inflammatory action is complex. Although under some circumstances weak anti-inflammatory effects may be seen, these actions are rarely seen at doses safe for clinical use. This may be because APAP is only a weak inhibitor of cyclooxygenase (COX), and this weak inhibition appears to be seen only in low concentrations of peroxide. Interestingly, areas of inflammation tend to have increased levels of peroxides produced by leukocytes (Insel, 1996).

Salicylates are organic acids that are hydrolyzed to salicylic acid (Insel, 1996; Kastrup, 2000; McEvoy, 1999). Salicylamide and diflunisal are products that are structurally similar to salicylates, but are not hydrolyzed to salicylic acid (Kastrup, 2000; McEvoy, 1999). The salicylates and related products are effective in decreasing pain, temperature, and inflammation, but have a variable impact on platelet aggregation. Aspirin, but not other salicylates, inhibits platelet aggregation for 4 to 11 days, which is the life of the platelet (Insel, 1996; Kastrup, 2000; McEvoy, 1999). In addition to aspirin, salicylamide, and diflunisal, other products considered in this category include choline salicylate, magnesium salicylate, combinations of choline and magnesium salicylate, sodium salicylate, sodium thiosalicylate, and salsalate (salicylsalicyclic acid).

Salicylates tend to accumulate at sites where inflammation is present, and can be particularly effective when it is

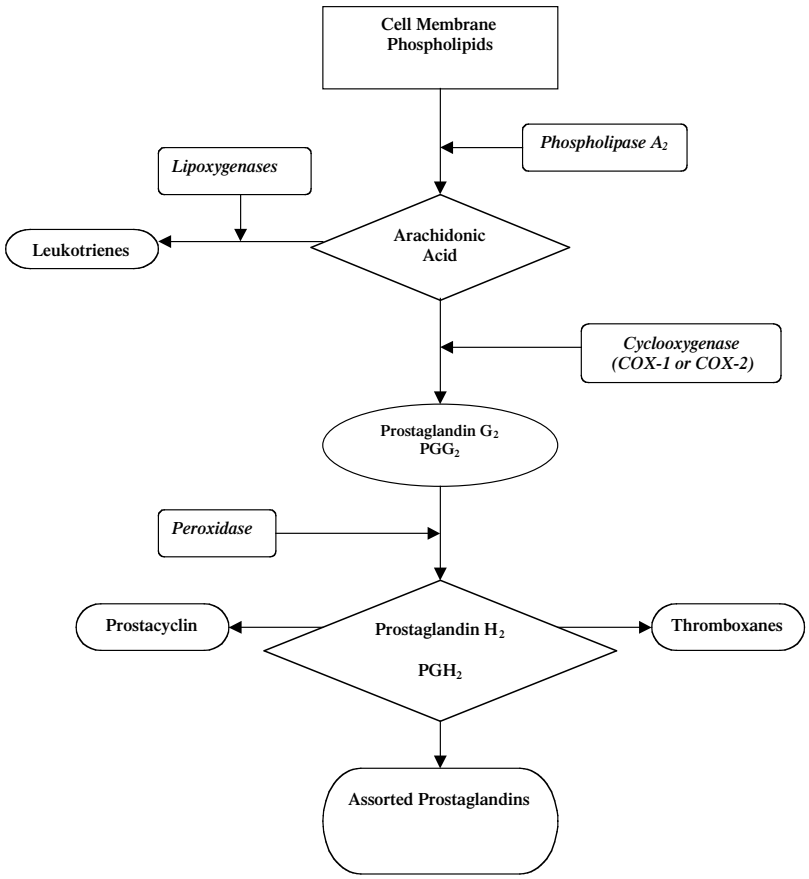

FIGURE 34.1 Arachidonic acid, prostaglandins, and COX: The role of COX-1 and COX-2. (Adapted from Campbell & Halushka, 1996; Kaplan-Machlis & Klostermeyer, 1999; McEvoy, 1999; Simon, 1999.)

their anti-inflammatory action that is needed (Insel, 1996). Reduction of pain and the anti-inflammatory action of salicylates are primarily due to inhibition of prostaglandin synthesis (Kastrup, 2000; McEvoy, 1999) (see Figure 34.1). The irreversible anti-platelet action of ASA has been attributed to the irreversible acetylation of COX, especially COX-1, resulting in decreased thromboxane A_2 synthesis and eventually decreased platelet aggregation. The duration of the effects of ASA are related to the turnover rate of COX in cells (Insel, 1996). Because platelets have little or no ability to synthesize COX or other proteins, the effect of ASA in platelets is for the life of the platelet (Insel, 1996; Kastrup, 2000; McEvoy, 1999). The antipyretic actions of the salicylates are due to inhibition of prostaglandins that have an effect in the hypothalmus and by peripheral vasodilation that increases heat loss.

Many combination products are marketed as pain relievers. Some of these include combinations of acetaminophen and salicylates or salicylate-like products, and barbiturates, caffeine, phenyltoloxamine citrate, pyrilamine maleate, pamabrom, antacids, and meprobamate. These combination products are not specifically discussed in this chapter.

NSAIDs are organic acids that also tend to accumulate at sites of inflammation (Insel, 1996). One exception to the organic acid classification is the non-organic nabumetone. However, nabumetone is converted to a form of acetic acid in vivo. NSAIDs are also effective in decreasing pain, temperature, and inflammation and have variable impact on platelet aggregation. They are generally considered to be effective analgesics for mild to moderate pain; but for some pain, such as certain types of postoperative pain, they may be more effective than opioid analgesics. The NSAIDs are classified chemically as acetic acids, fenamates, anthranilic acids, naphthylalkanones, pyrazolidinediones, oxicams, propionic acids, pyranocarboxylic acids, pyrrolizine carboxylic acids, or COX-2 inhibitors (Kastrup, 2000; McEvoy, 1999).

Listings of these classifications are not constant, with some listings including the naphthylalkanones in the acetic acid category along with other similarly minor changes (Boyce & Takiya, 2000; Insel, 1996; Kastrup, 2000; McEvoy, 1999). And, these differences are quite accurate. Nabumetone, mentioned above, is an inactive pro-drug that is metabolized to an active acetic acid form. It is the one product marketed in the U.S. that is listed in the naphthylalkanone class. Other single-agent classes of NSAIDs, the pyranocarboxylic acids (i.e., etodolac) and the pyrrolizine carboxylic acids (i.e., ketorolac), are some-

times also listed as subcategories of acetic acid NSAIDs. Additionally, pyrazolidinediones (phenylbutazone) have the only one NSAID in the class. Other classes such as the acetic acids, fenamates, oxicams, propionic acids, and the COX-2 inhibitors have more than one product per class. Members of the acetic class are diclofenac, indomethacin, sulindac, and tolmetin. Two products, meclofenamate and mefenamic acid, are classified as fenamates; and two products are classified as oxicams (i.e., piroxicam and meloxicam). The propionic acids include fenoprofen, flurbiprofen, ibuprofen, ketoprofen, naproxen, and oxaprozin; the COX-2 inhibitors are celecoxib, a sulfonamide-like agent, and rofecoxib, a furanone.

For some of the NSAID chemical classes, such as the propionic acids, there is considerable similarity in efficacy and safety although, between products in this class, there is large variability in half-lives and duration of action (Boyce & Takiya, 2000). For many others of the NSAID chemical classes, the only consistency within the class appears to be in the chemical structure. However, for some chemical classes, these chemical and structural similarities allow clinicians to predict side-effect profiles and potentially which patients may have allergic reactions. For example, knowing that celecoxib is a COX-2 inhibitor should suggest that this product might have fewer GI side effects than products from another class. In addition, knowing that celecoxib is a sulfonamide-like COX-2 agent will help a clinician predict that patients who are allergic to sulfonamide antibiotics should avoid this product because they may also be allergic to this sulfonamide-like agent. Interestingly, this same type of logic may not hold true for ASA. In general, patients who are allergic to ASA should be instructed to avoid all NSAIDs. However, the likelihood of an ASA allergic patient having an allergic reaction is actually greater with non-salicylate NSAIDs that with nonaspirin salicylates (Insel, 1996; Lipman, 1996).

The anti-platelet activity of the NSAIDs, as well as their effects in reducing pain and inflammation, are primarily a result of inhibition of prostaglandin synthesis (Insel, 1996; Kastrup, 2000; McEvoy, 1999). The inhibition of prostaglandin synthesis occurs when the enzymatic action of cyclooxygenase (COX) is blocked, thereby preventing the conversion of arachidonic acid to prostaglandin G2 and H2 and eventually to a more diverse series of prostaglandins (see Figure 34.1). Additionally, NSAIDs may inhibit the movement of leukocytes and contribute to a reduction in superoxide radicals as well as induction of apoptosis (Kastrup, 2000; McEvoy, 1999). Decreases in nitric oxide synthetase, tumor necrosis factor-alpha, and interleukin-1, and changes in lymphocyte activity and cellular membrane function are believed to play a role in decreasing inflammatory action. Diclofenac, ibuprofen, indomethacin, and ketoprofen have been shown, in animal models, to have central analgesic activity. Antipyretic activity is due to the inhibition of prostaglandin-E2 synthesis in the central nervous system in and/or near the hypothalamic area (Kastrup, 2000; McEvoy, 1999).

As mentioned, NSAIDs inhibit COX. Depending on the NSAID used, the inhibition may be of both COX-1 and COX-2, primarily COX-1, or primarily COX-2. As shown in Figure 34.1 and described previously, inhibiting COX-1 and/or COX-2 inhibits the conversion of arachidonic acid to prostaglandins. With less prostaglandin production, there is less pain and inflammation; however, nonenzymatic pathways produce products that contribute to inflammation and are not affected by NSAIDs.

Currently, most NSAIDs used in the U.S. are nonselective inhibitors of COX-1 and COX-2 (Insel, 1996). However, some—including aspirin, ketoprofen, ibuprofen, indomethacin, piroxicam, and sulindac—have modest selectivity for inhibiting COX-1, while ibuprofen, naproxen, and diclofenac may have less selectivity for COX-1 (Fung & Kirschenbaum, 1999; Kaplan-Machlis & Klostermeyer, 1999; Kastrup, 2000). Nabumetone and possibly etodolac are slightly selective for COX-2 inhibition (APhA, 1999; Kastrup, 2000). Meloxicam has intermediate COX-2 inhibition selectivity. Celecoxib and rofecoxib are selective for COX-2 inhibition. Thus, inhibition of COX, whether it is selective or nonselective, is the primary mechanism for NSAIDs and appears to provide the majority of the effect in decreasing pain and inflammation. Inhibition of COX also contributes to other activities of the NSAIDs and to their side-effect profiles. However, when COX selectivity of the NSAIDs is discussed, some differences are listed. For example, some sources state that at low doses, aspirin is almost exclusively COX-1 selective (APhA, 1999). In addition, there is some disagreement as to the selectivity of etodolac, with some sources listing nabumetone as the only agent with some, but less than intermediate, COX-2 selectivity (Insel, 1996).

Structurally, NSAIDs that primarily inhibit the actions of the enzyme COX-2 differ from nonselective NSAIDs (i.e., inhibitors of COX-1 and/or COX-2 enzymes) by the presence of a rigid side extension on the COX-2 inhibitor molecule. The COX-2 inhibitor's side extension fits into a "pocket" on the COX-2 enzyme, preventing the activity of the COX-2 enzyme (APhA, 1999; Simon, 1999). Think of the COX-2 selective products as a hand with the fingers closed but the thumb extended. The COX nonselective products would then look like a hand with the fingers and thumbs closed. The hand with the fingers and thumb closed (nonselective NSAID) would fit easily into a mitten (COX-2 receptor) or a tube sock (COX-1 receptor). The hand with the fingers closed and the thumb extended (COX-2 selective NSAID) would fit into the mitten, but would be difficult to fit in the tube sock.

The activities of COX are many and varied. COX-1 is considered a constitutive enzyme that has a "housekeeping role" (APhA, 1999; Kaplan-Machlis & Klostermeyer, 1999; Simon, 1999). It is present in all tissues and cell types. Its major impact is on prostaglandin production and the production of thromboxane A2. Remember, thromboxane A2 has effects on increasing platelet aggregation and may affect vasoconstriction. COX-1 is also responsible for normal renal function, hemostasis, and most notably, GI mucosal integrity. Prostaglandins produced under the influence of COX-1 decrease gastric acid secretion, increase mucous secretion, increase mucosal blood flow, and aid in the maintenance of the stomach lining. Renal function is also affected by prostaglandins produced under the influence of COX-1. These prostaglandins contribute to dilation of the renal vasculature, especially under circumstances where there is reduced renal blow flow due to such problems as decreased systemic blood flow, blood volume depletion, and low cardiac output. There is also some compensation for the effects of the renin-angiotnesin-aldosterone and sympathetic activity.

COX-2 is an inducible enzyme known for its role in the inflammatory process (APhA, 1999; Kaplan-Machlis & Klostermeyer, 1999; Simon, 1999). Under normal circumstances, it is usually undetectable in most tissues. The tissues that are exceptions, where it appears to have a fairly constant role, include parts of the brain, in bones, in normal kidneys, and in the female reproductive system, especially the ovaries and uterus (Simon, 1999; Wallace, 1999). Effects in these areas that appear to be mediated by COX-2 are those involved in mitogenesis and growth, regulation of the reproductive process in females, bone formation, and renal function where it is involved in the regulation of sodium, circulatory volume, and blood pressure. However, in most tissue, pro-inflammatory products such as interleukin-1, lipopolysaccharide, tumor necrosis factor, mitogens, and others induce COX-2 activity (Kaplan-Machlis & Klostermeyer, 1999). Once COX-2 activity is induced in damaged tissue, there is an increase in the production of prostaglandins that contributes to the inflammatory process. Thus, blocking COX-2 is an effective way to decrease inflammation and pain. The problem is that COX-2 affects more than just the pain. For example, while COX-2 is almost undetectable in the GI tract in normal circumstances, when the GI tract is injured, the effects of COX-2 contribute to the healing process (Wallace, 1999). Despite this contribution, the information to date (October 2000) supports the use of selective inhibition of the COX-2 enzyme to decrease the adverse effects of NSAIDs on the GI tract. This means that, overall, the effects that occur when the COX-1 enzyme is blocked must contribute more to GI problems than the effect that COX-2 contributes to healing an injury of the GI tract.

FACTORS AFFECTING PRODUCT SELECTION

For most types of medications, product selection is based on patient symptoms, and other patient factors and product factors. For NSAIDs, this is also the product selection process. If all these factors are equal, the choice of NSAIDs is largely empirical (Boyce & Takiya, 2000; Insel, 1996; Kastrup, 2000). When the product is selected, it should be given for 1 week or more, depending on the agent's half-life, to assess efficacy. Agents with a long half-life (e.g., piroxicam) should be given for 2 weeks or more to allow time for the effects of the drug to be seen. If an adequate therapeutic response is seen, the product should be continued for the duration of the need at the lowest effective dose, unless toxicities occur or the product is only approved for short-term use. Of note, there are large variations in the responses of individuals to individual NSAIDs, even if the NSAIDs are from the same chemical class (Insel, 1996). For example, in studies that compared the activity of some propionic acids, patients preferred naproxen for relief of pain and morning stiffness. When considering side effects, naproxen was preferred, followed by ibuprofen and fenoprofen. However, there were large interpatient variations in preference and no effective way to predict, before starting therapy, which product would work best with the fewest side effects in any given patient.

When all factors are not equal, selecting a medication becomes even more difficult. However, the factors mentioned previously can help to narrow the selection process (APhA, 1999). Patient characteristics that should be considered include the patient's age, concurrent disease states, organ function, medication allergies, and what products have worked or not worked well in the past. In addition, the patient's reproductive status and any physical limitations are important. The reproductive status of women of child-bearing age should always be considered, in part because about 50% of the pregnancies in the U.S. today are unplanned pregnancies, but also because of the potential of medications to contribute to difficulties in conception and harm to a developing fetus. The patient's vision and physical limitations, such as difficulties with opening vials and bottles, identifying tablets and capsules, measuring liquids, and even swallowing, should be considered. This is especially true when these difficulties are related to specific dosage forms (e.g., syrups, suspensions, tablets, or capsules) because many of these issues can be avoided with thoughtful prescribing. Factors to consider that are related to patient symptoms include the patient's description of the problem, along with details of the onset of

symptoms and factors that increase or decrease the symptoms, and the frequency, nature, and severity of symptoms. Finally, product characteristics to consider are the safety of the ingredient for the particular symptom, COX selectivity, availability (i.e., from local sources as well as formulary restrictions), cost, dosage form and regimen, and the inactive ingredients in the product such as dyes and lactose content (APhA, 1999).

As mentioned, a general recommendation is to begin with the lowest dose that is expected to produce an adequate response and evaluate response and toxicities. However, as also mentioned, it is difficult to predict which medication will be the most effective in any given patient; even in clinical trials, the doses given were often too low to be effective. However, there is some good news. Recently, physicians in Australia have reported success in general practice with single-patient trials (Nikles, et al., 2000). The objective of the trials was to improve decision-making in the use of long-term medications for chronic medical conditions by piloting a single-patient trials design. Investigators in academic general practice designed the single-patient trials as a 12-week within-patient, randomized, double-blind, placebo-controlled, crossover comparison of two medications. In the design, which included 2-week treatment periods grouped into three pairs, patients with osteoarthritis were tested on ibuprofen and acetaminophen. To be included in the trials, patients must have had pain of at least 1 month's duration with the expectation that ongoing, long-term use of pain medication would probably be needed. Outcome measures were pain and stiffness, comparative measures of arthritis, preference for each product at the end of the product's 12-week period of use, use of escape medication, side effects, and changes in therapy as a result of participation in the trial. A survey of the results showed that 8 of 14 participants completed the trials with useful information that improved the decision-making process for each of the eight. Medications were changed for six of the eight completing the trial. The authors concluded that this type of trial can be used in a general-practice setting and may help identify patients who will respond to medications as well as which medication may be a better choice.

INDICATIONS AND UNLABELED USES

Acetaminophen is approved for a variety of nonvisceral analgesic and antipyretic uses such as muculoskeletal pain, headache, earache and the aches, pains, and fever of colds, flu, and other infections. In contrast, the salicylates, including aspirin, are approved for relief of various inflammatory conditions as well as the treatment of mild to moderate pain and fever (Kastrup, 2000; McEvoy, 1999). In addition to these uses, ASA has also been used to decrease the risk of stroke and heart attacks. Unlabeled uses of aspirin abound. It has been considered as a possible prevention for cataract formation and even for possible prevention of toxemia of pregnancy. Similar to the salicylates, the NSAIDs are approved for a variety of pain and inflammatory indications. These include rheumatoid and osteoarthritis, treatment of mild to moderate pain, primary dysmenorrhea, tendintis and bursitis, as well as for gout and fever (Kastrup, 2000). Each NSAID has been used successfully for its FDA-approved (i.e., labeled) indications; but in most cases, APAP and the NSAIDs are also used for an assortment of pain-related uses that are not FDA approved (i.e., unlabeled) uses (see Table 34.1).

When the indications are viewed, reports of the trials are read, and clinicians are questioned, several interesting points emerge as being worthy of discussion. First, for many types of pain, any of the NSAIDs appear to be as effective as any other NSAID in reducing pain when given at equal analgesic dose — which is, more or less, the definition of equal analgesic doses. However, APAP is not included in this group, and an exception to this general rule of efficacy is that the salicylate NSAIDs do not seem to be as effective as the non-salicylate NSAIDs for relieving pain associated with dysmenorrhea (APhA, 1999; McEvoy, 1999). Of note, although only one of the currently available COX-2 inhibitors (rofecoxib) is indicated for primary dysmenorrhea, the COX-2 selective agents would be expected to be particularly effective for this use. This is due to the expected efficacy of the COX-2 inhibitors in preventing the increase in prostaglandins seen following ovulation when an increase in leutenizing hormone induces the COX-2 enzyme (APhA, 1999; Simon, 1999). Increased amounts of COX-2, in the presence of adequate substrate (arachidonic acid) result in increased production of prostaglandin, as is seen during the luteal and menstrual phases of the cycle and especially when dysmenorrhea is present. Blocking COX-2 should result in less prostaglandin production and a decrease in dysmenorrhea. However, NSAIDs, including COX-2 inhibitors, should be used with caution in women of childbearing age because their full effects on conception and the developing fetus are still not completely understood.

Another point suggested from trials and clinician experience is that the dosing of NSAIDs for pain is different than the dosing NSAIDs for anti-inflammatory use (Kastrup, 2000; McEvoy, 1999; Vlessides, 2000). In general, for pain, dosing of NSAIDs should be toward the lower end of the dosing range at the lowest dose that is expected to be adequate for relief of pain. This has been referred to as an osteoarthritis dose. Again, in general, for treatment of inflammation, dosing of many NSAIDs should be from about mid-range to the higher end of the dosing range. This has been referred to as a rheumatoid or anti-inflammatory dose. For NSAIDs with shorter half-lives, a significant degree of pain relief should be noticed within a day to up to a week (Insel, 1996). For longer half-life drugs, significant pain relief can take longer. The

TABLE 34.1
Selected Indications and Unlabeled Use of NSAIDs

Generic	Trade/Brand Name	Select Indications	Select Unlabeled Uses
Aspirin	Many (e.g., Bayer®, Ecotrin®, Empirin®)	Mild to moderate pain, fever, inflammation, others (see text)	(see text)
Acetaminophen	Many (e.g., Tylenol®, Feverall®, Aspirin Free Pain Relief®, Panadol®)	Analgesic, antipyretic (especially in patients who should not take aspirin), musculoskeletal pain, headache, earache, toothache, and relief of discomfort of conditions that cause fever and chills	Prophylaxis in children receiving DPT injections
Etodolac	Lodine®	Rheumatoid arthritis, osteoarthritis, pain	Tendinitis, bursitis, fever, ankylosing spondylitis
Ibuprofen	Many (e.g., Motrin®, Advil®, Nuprin®)	Rheumatoid arthritis, osteoarthritis, juvenile rheumatoid arthritis, mild to moderate pain, primary dysmenorrhea, fever in children	Migraine (abortive and prophylactic), resistant acne vulgaris, psoriatic arthritis, ankylosing spondylitis, gout, juvenile rheumatoid arthritis
Ketoprofen	Orudis®	Rheumatoid arthritis, osteoarthritis, mild to moderate pain, primary dysmenorrhea, OTC for minor aches and pains and reduction of fever	Juvenile rheumatoid arthritis, migraine (prophylactic and menstrual), ankylosing spondylitis, Reiter's syndrome, gouty arthritis
Ketorolac	Toradol®	Moderately severe acute pain	Long-term use for chronic pain
Nabumetone	Relafen®	Rheumatoid arthritis, osteoarthritis	None located
Naproxen	Many (e.g., Aleve®, Anaprox®, Naprosyn®)	Rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, mild to moderate pain, primary dysmenorrhea, juvenile rheumatoid arthritis (not naproxen sodium), tendinitis, bursitis, acute gout	Migraine (abortive, prophylactic, menstrual), premenstrual syndrome, Paget's disease of bone, Bartter's syndrome, OTC as an antipyretic
Sulindac	Clinoril®	Rheumatoid arthritis, osteoarthritis, acute gouty arthritis, inflammatory conditions (ankylosing spondylitis, tendinitis, bursitis, acute painful shoulder)	Juvenile rheumatoid arthritis
Rofecoxib	Vioxx®	Osteoarthritis, mild to moderate pain, primary dysmenorrhea	None located
Celecoxib	Celebrex®	Rheumatoid arthritis, osteoarthritis, familial adenomatous polyposis (FAP)	None located

full anti-inflammatory effects of the NSAIDs may take from 1 to 4 weeks to occur.

DOSING ADJUSTMENTS

Dosing adjustment is most frequently considered in children, the elderly, and in patients with organ system dysfunction. Children have very specialized dosing considerations, and these are not discussed here. For the elderly, some products, such as ketoprofen and ketorolac, have specific recommendations (Kastrup, 2000; Lipman, 1996; McEvoy, 1999). In the elderly, use caution and evaluate need but, for use of most NSAIDS, start low and monitor for toxicities including renal, hepatic, central nervous system (CNS), and gastrointestinal (GI) effects that are all of greater concern with these products in this population. Medication clearance in the elderly has not really been thoroughly studied for many NSAIDs. However, we do know that clearance is reduced for etodolac, ketoprofen, nabumetone, rofecoxib, and sulindac; and thus these NSAIDs, as well as some salicylates, may need dosing adjustments (Boyce & Takiya, 2000; Kastrup, 2000; McEvoy, 1999). Dosing adjustment may be also necessary in naproxen products. Diclofenac, however, does not appear to show reduced clearance in the elderly.

Adjusting the doses of NSAIDs in the elderly is important because the adjustment can help compensate for the potential to have increased serum levels and decreased clearance of medication. Increased monitoring for adverse events is equally important. Unfortunately, even with decreased doses and increased monitoring, many elderly users of NSAIDs are still at greater risk of adverse drug reactions (ADRs), especially those associated with renal and GI effects (Boyce & Takiya, 2000). The elderly and individuals taking large numbers of medications are also at increased risk for drug–drug interactions.

Caution should be used in recommending or prescribing NSAIDs to any patient with suspected organ damage. This is especially true because many NSAIDs have been shown to contribute directly or indirectly to damage or dysfunction of many major organ and tissue systems, including the renal, hepatic, cardiac, and endocrine systems as well as vascular, endothelial, mucous membranes, and skin tissue. Studies support adjusting the dose of selected NSAIDs in liver or kidney disease.

When liver disease is present or suspected, use caution in the use and dosing of NSAIDs due to the risk of higher than anticipated serum levels of non-plasma-protein-bound NSAID, which can contribute to an increased incidence of ADRs. This effect can be attributed to several mechanisms. Hepatic disease can contribute to decreased plasma protein production and decreased protein binding of medications. These medications include NSAIDs as well as other medications a patient may be taking.Patients with severe hepatic disease may encounter decreased drug metabolism and decreased elimination and excretion of medications. Fortunately, for many NSAIDs, dosing adjustment is usually only required in very severe disease or failure (Boyce & Takiya, 2000; Kastrup, 2000; McEvoy, 1999). For others, such as fenoprofen, naproxen products, nabumetone, sulindac, and the COX-2 inhibitors, a dosing adjustment should be considered when liver disease/failure is present. It has been recommended that ASA and potentially diclofenac should be avoided in patients with liver disease/failure because both of these medications may be more likely to contribute to hepatic changes (Boyce & Takiya, 2000). Use of NSAIDs and decreased plasma protein is not always a critical problem as far as drug-drug interactions are concerned. For example, a patient with a history of long-term use of two medications that are known to cause problems due to drug-drug interactions and changes in plasma-protein-binding can be stable and not experiencing any problems. As long as the medications and the patient's status do not change, the potential for the drugs to create problems is reasonably low. However, problems do arise when patients are taking highly protein-bound medications with narrow therapeutic indices and have a change of status or when medications are started or stopped.

In patients with renal disease, again, use caution due to the potential for decreased clearance of NSAIDs, decreased protein binding, and increased risk of GI and renal toxicities. Dosing adjustment is recommended for many of the NSAIDs, including definite recommendations for ketoprofen, oxaprozin, ketorolac, and possibly diflunisal, fenoprofen, ibuprofen, naproxen products, nabumetone, sulindac, tolmetin, and piroxicam. Patients with renal disease should avoid mefenamic acid (Boyce & Takiya, 2000; Kastrup, 2000; McEvoy, 1999).

SELECTED SIDE EFFECTS, ADVERSE DRUG REACTIONS, AND TOXICITIES

NSAIDs and related products are associated with a large number of side effects, adverse reactions, and toxicities. Select problems are discussed here. Some of the most commonly seen problems with the NSAIDs are GI in nature and range from mild dyspepsia to life-threatening GI bleeds. The GI irritation and ulceration can be attributed to two mechanisms: local irritation and a systemic effect that includes a change in gastric acid secretion, decreased mucosal blood flow, and decreased mucous production. None of the NSAIDs marketed to date that have anti-inflammatory action have completely overcome the problem of an increased risk of GI ulceration and bleeding. Notably, APAP, which at clinical effective doses does not have anti-inflammatory actions, is not usually associated with GI complaints. And, the nonacetylated salicylates are associated with fewer GI problems (Insel, 1996). The newly marketed, moderately COX-2 selective meloxicam and the selective COX-2 inhibitors rofecoxib and celecoxib are believed to have fewer GI-related problems than the nonselective NSAIDs (Kastrup, 2000; Silverstein, et al., 2000). In contrast, indomethacin, aspirin, tolmetin, ketorolac, and piroxicam are associated with significant GI problems (Kastrup, 2000; McEvoy, 1999; Redford, 2000).

Aspirin and diclofenac have been associated with an increased risk of hepatoxicity, and probably should not be used in the presence of existing liver disease (Boyce & Takiya, 2000; Redford, 2000). However, a number of the NSAIDs have been implicated in reports of hepatic problems, and have precautions listed in their package inserts. For example, the insert from a selective COX-2 inhibiting agent suggests that patients at risk should be monitored, and if clinical signs and symptoms that indicate liver problems occur, the drug should be discontinued (Celebrex™, 1999).

Indomethacin, tolmetin, piroxicam, and ketorolac have been associated with renal problems (Redford, 2000). Clinicians should use caution when prescribing any NSAIDs in patients with renal problems or insufficiency because, in general, NSAIDs are not recommended for use in patients with advanced kidney disease. The use of NSAIDs in patients reliant on prostaglandins may contribute to renal and systemic problems because inhibition of prostaglandins can decrease renal vasculature dilation. This is of particular concern in patients at increased risk, such as those with cardiac compromise due to increased age, hypertension, congestive heart failure, renal or hepatic disease, or alterations in systemic volume. Additionally, NSAIDs may contribute to fluid retention, hypertension, and congestive heart failure. Even COX-2 selective inhibitors have been associated in at least one report with complicating therapy in two patients with chronic renal insufficiency (Perazella & Eras, 2000).

TABLE 34.2
Selected Drug–Drug Interactions

Drug	Interaction	Drug	Interaction
Aspirin	Omeprazole can increase the rate of absorption of enteric coated aspirin, leading to toxic levels.	Digoxin	Ibuprofen and indomethacin can both lead to increased digoxin levels.
Celecoxib	Fluconazole can inhibit the metabolism of celecoxib that may require reduced doses.	Phenytoin	NSAIDs may lead to increased phenytoin levels, leading to toxicity.
Midazolam	Rofecoxib can induce the enzyme CYP3A4, which can increase the dose of midazolam needed.	NSAIDs	Diuretics may increase the risk of renal failure when taken with ketoprofen and possibly other NSAIDs.
Rofecoxib	Rifampin can decrease rofecoxib concentrations, increasing the dose of rofecoxib needed.	NSAIDs	Alcohol (especially heavy use) may increase the risk of GI bleeds when taken with NSAIDs.
Salicylates	Alcohol may increase the risk of GI ulceration when taken with ASA.	NSAIDs	Cyclosporine use with NSAIDs may increase the renal toxicity of both products.
Acetaminophen	Alcohol use with APAP may increase the hepatoxicity.	NSAIDs	Probenicid may lead to increased NSAID concentrations and toxicity; probenicid should not be taken with ketorolac.
Piroxicam	Ritonivir may inhibit the metabolism of piroxicam and lead to toxicity.		

CNS effects such as dizziness, drowsiness, headache, nightmares, and/or confusion have been reported with many of the NSAIDs. Tinnitis is a well-known problem associated with excessive aspirin use (Kastrup, 2000). At least one account of celecoxib-induced auditory hallucinations has been reported (Lantz & Giambanco, 2000). Aspirin has been shown to cause hypersensitivity reactions, especially in patients with asthma and nasal polyps, or chronic urticaria. As well, ASA and the salicylates have been associated with Reyes syndrome and should be cautiously used ~~if~~ at all — in children (Kastrup, 2000).

SELECTED DRUG–DRUG INTERACTIONS

Drug interactions with the NSAIDs are numerous and, although similar among many of the NSAIDs, striking differences are apparent among the NSAIDs when warfarin, methotrexate, ACE inhibitors, beta-blockers, loop and thiazide diuretics, and several other medications are considered. Many of the especially problematic interactions involve medications that are metabolized by cytochrome enzymes (Boyce & Takiya, 2000; Insel, 1996; Kastrup, 2000; Nikles, et al., 2000) (see Table 34.2). Of special note are interactions between NSAIDs and warfarin. NSAIDs that inhibit platelet aggregation, most notably aspirin, when taken with warfarin can increase the risk of bleeding. The COX-2 inhibitors should have a less impact on platelets and result in a lower risk of bleeding. Although limited information is available on interactions between warfarin and the COX-2 inhibitors celecoxib and rofecoxib, reports of bleeding, especially in the elderly, have been noted with at least one of these products (Celebrex, 1999). Additionally, both of these products inhibit enzyme systems that are required for warfarin metabolism. There have been reports on this interaction with rofecoxib; none were located for celecoxib (Boyce & Takiya, 2000; Fung, et al., 1999). Prothrombin times should be closely monitored, and patients should be counseled to monitor for signs of bleeding while taking any NSAID.

Aspirin also figures prominently with regard to concomitant use of NSAID therapy and methotrexate. It has been reported to increase low-dose, methotrexate-induced liver toxicity. Diclofenac, sulindac, and rofecoxib have also been associated with alterations is methotrexate kinetics, with rofecoxib reported to cause up to a 23% decrease in methotrexate clearance. Celecoxib has not been associated with changes in methotrexate kinetics (Boyce & Takiya, 2000; Kastrup, 2000; Celebrex, 1999). NSAIDS are reported to interact with beta-blockers and thiazide and loop diuretics to generally decrease the effectiveness of these medications. Many NSAIDs have the potential to affect blood flow through the renal arteries, decreasing renal function and increasing sodium and fluid retention, but sulindac appears to be a better choice for therapy, at least where interactions with beta-blockers are concerned (Kastrup, 2000). Decreases in renal function caused by NSAIDs is also a concern when patients on NSAIDs are also taking lithium. In this scenario, serum concentrations of lithium can reach toxic levels. Again, sulindac may be a better choice for patients who must take an NSAID and lithium (McEvoy, 1999).

COST

Prices for NSAIDs vary tremendously, with major differences existing between products, between brand and generic, and between the exact same product acquired from different sources. On the low end, acquisition costs for a 5-day supply of NSAIDs dosed for acute pain range from $1.88 for indomethacin (25 mg b.i.d.) and $2.70 for ASA (650 mg q.i.d.), to $21.82 for mefenamic acid (250 mg q.i.d.). In contrast, initial anti-inflammatory dosing costs of NSAIDs range from $20.70 for a 30-day supply of generic ibuprofen (800 mg t.i.d.) to $134.01 for a 30-day supply of diclofenac potassium (50 mg t.i.d.) (Boyce & Takiya, 2000). The cost of the medication dispensed to patients can be much higher.

Overall, acquisition costs for the NSAIDs are only one component of the full cost of drug therapy for pain patients taking NSAIDs. In select cases, providing a more expensive drug can result in decreased overall costs. This may be especially true of therapy for patients at increased risk for adverse events or drug interactions from certain NSAIDs. For example, the use of a computer program to predict costs of therapy at McDonald Army Community Hospital in Newport News, Virginia, showed that the selective use of COX-2 inhibitors could save over $12,000 annually at that facility (Vlessides, 2000). The predicted cost savings would occur if all patients (n = 112) at that facility receiving NSAIDs and a proton pump inhibitor (omeprazole) were switched to the COX-2 inhibitor celecoxib. Information in the same report showed that switching patients receiving nabumetone at that institution to celecoxib would not result in a savings and, in fact, would cost the institution several thousand dollars more per year.

As discussed in the introduction, costs of medications are relative. However, when discussing medication acquisition costs for consumers (i.e., fee for service), there is tremendous variability — not only among products, but also among pharmacies. Patients should be cautioned to select a pharmacy and pharmacist much as they would select a physician. Ask friends, family, co-workers, and others about their experiences; and ask the pharmacy staff about the services they provide. Finally, patients should compare prices between pharmacies that provide the services and convenience they need. However, comparing prices for products received through a no-service mail order, an e-mail system, or a limited service facility to those at a full-service, patient-oriented pharmacy that offers clinical services may not be productive. Whatever types of healthcare services patients select, they should be counseled to communicate with all their healthcare providers to be sure that providers know what medications the patients are taking. This communication can help to reduce adverse drug reactions, medication misadventures, and costs both to patients and the healthcare system. One way to increase this communication is for patients to have a primary physician prescribe all their medications and a single pharmacy or pharmacist provide all their medications and counseling with the medication.

CONCLUSION

All medications have the potential to improve a patient's condition or to cause adverse events. NSAIDs are no different from other medications in this regard. The goal of this chapter has been to present information on NSAIDs that will help clinicians select appropriate the NSAIDs for patients with specific risk factors and thereby improve patient outcomes by decreasing medication side effects and improving patient compliance and adherence and product tolerability.

Chronic Pain Management with a Focus on the Role of Newer Antidepressants and Centrally Acting Agents

Robert L. Barkin, M.B.A., Pharm.D., F.A.C., N.H.A., D.A.A.P.M., Jan Fawcett, M.D., and Stacy J. Barkin, M.A., M.Ed., Psy.D., D.A.A.F.C.

INTRODUCTION

Of the range of recalled negative experiences that beset human existence, pain is among the most debilitating and the most fear and anxiety provoking. Pain, defined both as an unpleasant sensory and emotional experience associated with actual or potential tissue damage (Merskey & Bogduk, 1994), or described in terms of such damage, has the capacity to subjectively affect every aspect of life. The physiological effects of pain include diminished functional capacity, endurance, autonomic and peripheral events and, in some individuals, disorders of initiating and maintaining sleep. The psychosocial effects of pain include somatic preoccupation and perceived loss of control, coupled with increased anxiety, anger, fear, agitation and depression. The societal impact of pain includes feelings of guilt and altered relationships (e.g., social, vocational, avocational, personal, financial, familial, and marital). Anti-depressant treatment for chronic pain has been fully described elsewhere (Barkin & Fawcett, 2000) and utilized in the preparation of this chapter.

CLASSIFICATION OF PAIN

An entirely subjective experience, pain involves a highly complex array of emotional, affective, and sensory phenomena. Pain can be categorized according to whether its etiology is organic or nonorganic (psychogenic) (Table 35.1). In addition, pain can be classified as (1) acute; (2) disease-related (e.g., pain caused by cancer, sickle cell disease, fibromyalgia syndrome, or complex regional pain [CRP] syndrome); or (3) chronic nonmalignant (Chapman, 1993). In the true sense of the word, all pain is "malignant". Discrimination among these three pain classifications is a function of the following characteristics: duration, physical pathology association, psychological challenges, autonomic and peripheral indices of prominence, nerve conduction, prognosis for resolution, treatment focus appropriateness, and biologic purpose or value associated with the pain (Barkin, et al., 1996). See Table 35.1 for current terms used in the literature.

ACUTE PAIN

Acute pain is typically precipitated by a known noxious insult such as injury or trauma. Acute pain's physiologic purpose is protective in nature; it occurs when tissues are being or have been damaged, and causes the individual to react and remove or avoid the pain stimulus. The severity of acute pain is a function of objective autonomic and peripheral events associated secondary to tissue injury, and it generally resolves following tissue regeneration and/or repair over time and may be augmented by subjective pain indices (behaviors, i.e., suffering, guardian, grimacing, etc.) Acute pain is brief by definition—generally less than 1 to 3 months (Barkin, et al., 1996).

TABLE 35.1
Pathophysiologic Pain Classification

Organic Etiology
- Neuropathic (deafferentation):
  - Nonnociceptive
  - May be associated with involvement of peripheral nerves
  - May benefit from treatment with antidepressants, anticonvulsants, sodium channel blockers, excitatory amino acid receptor blockers
- Nociceptive (acute: somatic, visceral):
  - From peripheral tissue injury/trauma by nerve ending damage, inflammation, hyperalgesia (i.e., mechanical, thermal, chemical, ischemic stimuli)
  - Peripheral stimulation of nociception at somatic and visceral sites
  - Benefits from opioids and nonsteroidal anti-inflammatory agents
- Mixed or undetermined, unspecified, unknown:
  - Chronic cephalalgia
  - Vascular pain
  - Benefits from multidisciplinary approach of cognitive or behavioral therapy, physical therapy, pharmacotherapy

Psychogenic Etiology
- Psychologic/psychiatric conditions with significant features of pain following complete exclusion of somatic pathology

The assessment of acute pain should include pain intensity and quality, distribution, onset, duration, circumstantial variability, and functional status, coupled with patient-specific collateral issues (anxiety, insomnia, anger, frustration, depression, etc.).

The body's autonomic reaction to acute pain is consistent with sympathetic fight and/or flight responses. Such responses are approximately proportional to the intensity of the initial noxious event or stimulus. Objective responses to acute pain stimuli involve a range of autonomic and peripheral indices, including elevation in heart rate, stroke volume, and blood pressure; pupillary dilatation; muscle tension; and a decrease in gut motility and salivary flow (xerostomia). Anxiety, which is almost universally present in acute pain, represents the subjective psychological response (Barkin, et al., 1996). Pain is therefore a subjective experience lacking the objectivity of vital signs. The disorders of initiating or maintaining sleep secondary to acute pain is a predictable consequence and additionally deserves specific treatment and management.

Disease-Related Pain

Although the progress of disease-related pain is unpredictable, the prognosis and pathophysiology are predictable and defined. Collateral pain conditions (e.g., depression, anxiety, insomnia, frustration, and anger) are generally predictable, thus precipitating multimodal interventions (Craig, 1994). Disease states associated with painful episodes include the following (Barkin, 1997b; Barkin & Richtsmeier, 1995; Barsky, et al., 1990; Bayer, Chadha, Farag, & Pathy, 1986; Bowsher, 1995; Casadevall, et al., 1996; DeWester, 1996; Galer, 1995; Kauver, 1993; Larue, Fontaine, & Colleau, 1997):

1. Rheumatologic (articular, osteoarthritis, rheumatoid arthritis, soft tissue: fibromyalgia syndrome [FMS])
2. Orthopedic (failed low-back surgery syndrome)
3. Cardiac (myocardial infarction, angina)
4. Neurologic (migraine, multiple sclerosis, neuropathies)
5. Sympathetically mediated pain (complex regional pain syndrome [CRPS])
6. Endocrine (endometriosis)
7. Chronic pelvic pain
8. HIV pain syndromes
9. Neoplastic
10. Sickle cell vaso-occlusive crisis pain
11. Gastrointestinal (GI) tract (pancreatitis, adhesions, biliary colic, intestinal ischemia)
12. Genitourinary (renal stones, ureteral obstruction)

Chronic Nonmalignant Pain

Chronic nonmalignant pain may, on occasion, be associated with past injury. Again, all pain is malignant in nature. It is, however, devoid of biologic purpose or value and persists far beyond the tissue damage caused by the initial etiologic insult. It is generally considered to have a duration of 1, or 3 to 6, months or more; and, except in the case of an acute exacerbation of a chronic pain complaint, autonomic responses may develop some habituation, but may resume during acute painful exacerbations of the chronic pain. Moreover, the etiology of chronic nonmalignant pain is often difficult to determine because the pain behavior and the patient's subjective sense of the pain are perceived from an objective perspective as disproportionate to the initial insult or injury (Barkin, et al., 1996). Medical management of chronic nonmalignant pain is often particularly challenging. This category of pain, hereinafter referred to as chronic pain, is the focus of this chapter (Addison, 1984; Barkin, et al., 1996; Godfrey, 1996; Lister, 1996; Pappagallo & Heinberg, 1997).

CLINICAL PRESENTATION OF CHRONIC PAIN

Chronic pain may have its source in a physical disease state (e.g., arthritis, CRPS, FMS) or it may be secondary to

learned behaviors from a resolved physical insult. It may also be related to somatization disorder, conversion disorder, depression, anxiety or other pain-related psychiatric diagnoses (Barkin, Leikin, & Barkin, 1994; Dworkin, Von Korff, & LeResche, 1990; Parmalee, Katz, & Lawton, 1991). The onset of chronic pain is usually gradual and its character may be either continuous or intermittent. Chronic pain has numerous psychosocial components, including irritability, depression, somatic preoccupation, anhedonia, withdrawal from outside interests, and diminished strength of vocational, avocational, familial, and social relationships. In addition, changes in appetite, decreased sleep, and libido are frequently noted (Barkin, et al., 1996).

Regardless of the particular anatomical site of chronic pain, other organ systems are frequently involved as well. Somatic complaints, which occur in "masked depression" presenting as chronic pain, often account for the somatization of depression and further somatic complaint may present for anxiety (Barkin, et al., 1996; Gruber, Hudson, & Pope, 1996). These masked depression complaints frequently involve the GI tract and include abdominal pain, constipation, flatulence, altered appetite, and an unpleasant taste in the mouth. Such patients complain of physical symptoms and have a paucity of overt manifested depressive symptoms, and are thus atypical in their clinical presentation. Common musculoskeletal complaints include generalized muscle aches, arthritic-type pain, backaches, and fatigue (Bigos, et al., 1994; Grube,r et al., 1996). Patients with chronic pain may also have cardiac complaints, including palpitations, weakness, diminished activity due to alleged heart disease, fatigue, noncardiac chest pain, and other expenditures (Barkin, et al., 1996; Gruber, et al., 1996; Rost, Zhang, Fortney, Smith, & Smith, 1998). Table 35.2 describes pain associated with physical pathology and psychopathology.

In addition to somatic complaints, the patient with chronic pain typically presents with a number of psychological and socioeconomic issues related to diminished capacity to function (American Psychiatric Association [APA], 1994, pp. 458–461, 317–392). Characteristic features include catastrophizing affective components of pain, which are often invoked as suffering, coupled with depression, frustration, agitation, and anxiety. Loss of gainful employment and significant inactivity exacerbate these affective components (Barkin, et al., 1996; Huff & Barkin, 1994).

Further complicating the clinical picture is the fact that previous attempts at pain relief may have led to misuse of prescription and nonprescription medications (over-the-counter, phytopharmaceuticals) and/or the use of alcohol and recreational drugs. Table 35.3 lists the chronic pain syndromes, often antidepressant responsive, that are frequently encountered in the primary care setting. Effective chronic pain management requires precise therapeutic judgment in all patients, but particularly in the elderly patient, due to pharmacotherapeutic challenges including polypharmacy, psychosocial factors, cognitive impairment, drug interactions, multi-organ dysfunction, noncompliance, and side effects (Barkin & Barkin, 1998; Barkin, et al., 1996).

TABLE 35.2
Pain Described by Physical Pathology and Psychopathology

- Peripheral and central:
  - Inflammatory pain
  - Neuropathic pain
  - Cutaneous, somatic visceral pain
- Psychologic pain aspects:
  - Emotional and cognitive pain (see DSM-IV)
- Soft tissue, joints, bone:
  - Acute and postoperative pain
  - Osteoarthritis
  - Rheumatoid arthritis
  - Orthopedic pain from trauma
  - Skeletal muscle pain
  - Low back pain (psychological origin with spinal referral also)
  - Upper extremity pain
  - Fibromyalgia and myofacial pain syndrome (chronic)
  - Cephalalgia
  - Back pain, temporomandibular disorders
  - Spinal and radicular pain syndromes of cervical, lumbar, sacral, and coccygeal origins
- Visceral and deep pain:
  - Chest and vascular pain
  - Eye pain
  - Orofacial pain
  - Abdominal pain, GI distress
  - Chronic gynecologic pain
  - Labor pain
  - Genitourinary pain (bladder, uterus, ovaries, adnexa uteri)
  - Rectal, perineum, external genitalia
- Nerve root damage:
  - Post-amputation and phantom limb pain
  - Peripheral neuropathies
  - Complex regional pain (CRP) syndrome (Type I — reflex sympathetic dystrophy; Type II — causalgia)
  - Trigeminal neuralgia and atypical facial pain
  - Nerve root damage and arachnoiditis
- Carcinoma/malignancy
- Central pain (neuropathic)
- Lesions:
  - Failed back
  - Orthopedic surgery pain
- Parkinson's pain
- Multiple sclerosis pain

TABLE 35.3
Chronic Pain Syndromes Frequently Encountered in Primary Care

- Low-back pain and failed low-back surgery syndrome[a]
- Cancer pain[a]
- Neuropathic pain[a]
- Complex regional pain syndrome (CRPS)[a]
- Sickle cell pain
- Primary dysmenorrhea[a]
- Chronic pelvic pain[a]
- Herpes simplex/zoster[a]
- Postherpetic neuralgia[a]
- Trigeminal neuralgia
- Atypical facial pain[a]
- Phantom limb pain (postamputation)[a]
- Fibromyalgia syndrome (FMS)[a]
- Burn pain
- Multiple sclerosis pain[a]

[a] Responds to antidepressants.

PATHOPHYSIOLOGY OF PAIN AND PAIN SIGNAL TRANSMISSION

Pathophysiologically, pain involves at least three transmission circuits: (1) a spinal cord-thalamic frontal cortex–anterior cingulate pathway, which has a role in the subjective psychological and physiological response secondary to pain; (2) a spinal cord-thalamic somatosensory cortex pathway, which plays a role in the sensation of pain; and (3) a descending pathway involving the periaqueductal gray (PAG) region, which modulates pain signals. This system can inhibit or induce pain transmission at the level of the dorsal spinal cord, modulating the lamina on the dorsal horn where endogenous opioids are concentrated (Barkin, et al., 1996; Bonica 1990; Bonica, et al., 1990; Braverman, O'Connor, & Barkin, 1993; Guilbaud, Bernard, & Besson, 1994; LaMotte, 1986; Larue, et al., 1997; Meyer, Campbell, & Raja, 1994; Ruda, 1986; Seybold, 1986; Siddall & Cousins, 1995; Tarster, 1990; Yaksh, 1996; Yaksh & Malmberg, 1994).

Pain is transmitted from peripheral pain receptors by A-delta (δ) nerve fibers (small myelinated fibers with conduction velocities of 12 to 30 ms^{-1}) and C-fibers (small unmyelinated fibers with conduction velocities of 0.5 to 2 ms^{-1}), passing the dorsal root ganglion to lamina II on the dorsal horn of the spinal cord and synapse within the substantia gelatinosa. The primary ascending somatosensory pathway for cephalad pain impulse transmission is the spinothalamic tract. Nerve impulses proceed from the thalamus to the cortical somatosensory areas. Nociceptive input perception is multilevel, modulated in the afferent sensory pathway extending from peripheral nerves to the cerebral cortex (Bennett, 1994; Bonica, 1990; Bonica, et al., 1990; Braverman, et al., 1993; Chakour, Gibson, Bradheer, & Helme, 1996; LaMotte, 1986; Meyer, et al., 1994; Ruda, 1986; Seybold, 1986; Siddall & Cousins, 1995; Tarster, 1990; Yaksh, 1996). Repeated C-fiber stimulation at the peripheral level progressively builds up the central nervous system (CNS) response, a temporalis with increased persistent pain and increased receptive field and hyperalgesia which is known as CNS neuroplasticity.

A conceptual model of pain transmission involves ascending afferent excitatory somatosensory pathways and descending inhibitory pain pathways (utilizing NE and 5-HT), as well as various neurotransmitters and neuromodulators, including monoamines, amino acids, and neuropeptides. Pain impulse transmission can be modulated by descending inhibitory pain pathway activation, passing from the brain down the spinal cord. This results in the release of inhibitory pain neurotransmitters, which limit pain impulse transmission from pain receptors by ascending afferent fibers. The source of pain migrates up the CNS from peripheral sites. Therefore, the peripheral noxious stimulus causes nociception, pain becomes a thalamic cessation, suffering is a cortex event, and pain behaviors are learned prefrontal cortical experiences.

The gate control theory of nociceptive mechanisms implicates the spinal cord dorsal horn in the function of a gate that controls the synaptic pain impulse transmission by the spinothalamic tract. Large afferent fiber activation (as seen with transcutaneous electrical nerve stimulator [TENS] therapy) may provide a counterirritant effect by small pain fiber inhibition (Bonica, 1990; Bonica, et al., 1990; Braverman, et al., 1993; LaMotte, 1986; Melzack, 1996; Ruda, 1986; Seybold, 1986; Tarster, 1990).

Serotonergic and noradrenergic pathways in the spinal cord modulate the lamina on the dorsal horn of the spinal cord. Tramadol, for example, exerts its binary mechanism of action in part at this spinal level, with re-uptake blockade of NE and 5-HT; additionally, it provides μ_1 opiate agonist effects supraspinally (Barkin, 1995a, 1995b; Barkin, et al., 1996; Braverman, et al., 1993; Gibson, 1996; Ruoff, 1996).

MANAGEMENT OF CHRONIC PAIN

In the majority of cases, the first step in the management of chronic pain is an attempt to document a neurologic lesion. More often than not, however, an etiologic source is either elusive or nonexistent. Therefore, the optimal treatment approach is multidisciplinary, including not only efforts at pain relief but also aggressive intervention aimed at psychosocial factors. The overall treatment goal is to improve the patient's functional status and the ability to perform necessary activities of daily living without significant pain-related interruption or dysfunction (Barkin, et al., 1996; Dworkin & Gitlin, 1991).

Treatment modalities for chronic pain include therapies provided by physical medicine and rehabilitation services; surgical interventions; cognitive and behavioral therapies; vocational, physical, and occupational therapies; anesthesiology augmentation (i.e., nerve blocks) within a multidisciplinary comprehensive pain center; and pharmacotherapy (McQuay & Moore, 1997; Philipp & Fickinger, 1993). Antidepressant pharmacotherapy is the primary focus of the remainder of this chapter, although some information is provided on opiates. An optimal treatment plan amalgamates all or most of the available therapeutic options in a coordinated, multidisciplinary manner. In general, the longer the interval between the onset of chronic pain and the commencement of appropriate treatment, the poorer the prognosis for restoration of optimal functioning (Barkin, et al., 1996).

OPIOID/OPIATE ANALGESICS

Opioid analgesics are a mainstay of pain treatment. Opiates used in the management of chronic pain have been described in a variety of chronic pain states, such as Parkinson's disease, depression, and chronic low-back pain. Opiates are agonists at stereospecific endogenous opioid receptors, which are found at both presynaptic and postsynaptic central and peripheral nervous system sites (Table 35.4) (Stein & Read, 1997). Opiate receptors are guanine protein-coupled receptors, which include muscarinic (M), adrenergic (NE), and gamma-aminobutyric acid (GABA). Naloxone-sensitive opiate-binding sites in man are classified as μ_1, μ_2, Δ, and κ receptors (Table 35.4) (Barkin, et al., 1996; Chapman, 1993; Merskey & Bogduk, 1994).

Opioid receptor activation inhibits presynaptic release of excitatory neurotransmitters from peripheral nociceptive nerve terminals. This results in neuron hyperpolarization caused by increased potassium conduction and/or calcium channel activation. Opioid receptors and endogenous ligands function as an endogenous pain suppression system. Opioid receptors are located supraspinally in the brain-stem PAG matter and spinal cord substantia gelatinosa. These areas are involved with pain perception, impulse integration, and pain response (LaMotte, 1986; Ruda, 1986; Seybold, 1986). The proposed mechanism of action of opiates/opioids involves the activation of opiate receptors (Table 35.4), leading to an efflux of potassium and the resultant hyperpolarization, which limits calcium intracellular entry. Furthermore, coupling of the opiate receptors to G_i proteins results in a decreased formation of intracellular cyclic adenosine monophosphate (CAMP), which leads to a decrease in calcium channel phosphorylation and consequent diminished calcium entry. The opioids' action upon G proteins, which are independent of CAMP formation, directly diminishes calcium channel opening and enhances the opening of potassium channels. This blocks substance P release, an 11-amino-acid neurokinin neuropeptide with vast CNS distribution belonging to the tachykinins group of neuropeptides, resulting in blockade of nociceptive transmission (Barkin, 1996, 1997; Barkin, et al., 1996; Bonica, 1990; Bonica, et al., 1990; Braverman, et al., 1993; Popp & Portenoy, 1996; Tarster, 1990).

The opiate/opioid sites of action are the primary afferent sensory presynaptic neurons, which inhibit the release of nociceptive peptide substance P. In the brain, the initial binding of opiates in the PAG signals release of inhibitory 5-HT from the raphe nucleus. This 5-HT release inhibits dorsal horn neurons. Morphine affects the descending NE pathway; and NE release in response to opiates results in spinal analgesic effects (Barkin, Barkin, & Barkin, 1997–1998; Barkin, et al., 1996; Bonica, 1990; Bonica, et al., 1990; LaMotte, 1986; Popp & Portenoy, 1996; Ruda, 1986; Seybold, 1986; Tarster, 1990; Yaksh, 1996).

TABLE 35.4
Opiate Receptor Classification

Receptor	Effect
μ_1	Supraspinal analgesia, miosis, nausea, vomiting, pruritus, urinary retention, endorphins endogenous agonist
μ_2	Spinal analgesia, physical dependence, sedation, euphoria, hypoventilation, bradycardia, ileus, endorphins endogenous agonist
Δ $\delta_{1,2}$	μ Receptor modulation; enkephalin endogenous agonist $\delta_{1\&2}$ – Spinal and to a lesser extent supraspinal (δ_2) analgesia
$\kappa_{1,2,3}$	Analgesia, sedation, miosis, dysphoria, endogenous agonist, dynorphin coupled with calcium channels (N channels) κ_3 supraspinal κ_1 spinal

The Role of Substance P as a Focus in Antidepressant Activity and Pain

Distribution of substance P is found in cell bodies and terminals of small-diameter (Aδ and C-fibers) primary afferent neurons. Substance P, found in the afferent sensory neurons, in the spinal cord dorsal horn and in dorsal root ganglia, is a peptide neurotransmitter facilitating nociceptive stimuli passage from peripheral sites to the spinal cord and supraspinal structures (Yaksh, 1996).

The substantia gelatinosa has enkephalins in interneurons of the dorsal spinal cord that have antinociceptive effects. Antinociceptive effects may be initiated by pre- and post-synaptic actions, inhibiting substance P release and decreasing the cellular activity, which projects from the spinal cord to supraspinal CNS areas (Yaksh, 1996). This dorsal horn neuropeptide neurochemical, substance P, is restricted within the laminar distribution and can act as a primary afferent transmitter. Depletion from the cord provides analgesia for thermal nociception, and possibly by chemoreception and baroreception.

A possible antidepressant mechanism of action is substance P antagonism. Substance P antagonists produce analgesia following intrathecal administration, and plasma substance P is then lower in chronic-pain (neuropathic pain,fibromyalgia, low-back pain) patients than in healthy volunteers (Yaksh, 1996).

Both 5-HT and NE are involved in the descending inhibitory mechanisms and alterations in spinal cord neurochemical (monoamines, amino acids, neuropeptides) transmission. Furthermore, the interaction with endorphin/enkephalin modulating systems occurs with spinal application of 5-HT/NE and morphine-producing analgesia (Reisine & Pasternak, 1996; Yaksh, 1996).

Studies of antidepressant effectiveness in pain management include anecdotal reports, open studies, case reports, reviews, and double-blind, controlled studies. Overall, the antidepressants have had a role in the management of pain. The use of antidepressants in the comprehensive multidisciplinary treatment plan of pain should be strongly considered despite some flaws inherent in the methodology of studies evaluating antidepressants for this indication.

The mechanisms of action of antidepressants for pain relief have been described as (1) relief of underlying depression that intensifies the suffering of the patient (suffering is the affective component of pain); (2) a common underlying biochemical substrate integral to experience of pain and depression; and (3) neuromodulatory effects of antidepressants on the endogenous opioid system (Feinmann, 1985). Antidepressants have usefulness as an integral part of comprehensive multidisciplinary treatment plans for chronic pain and alone possess analgesic activity (Raj, 1992).

A distinct mechanism for antidepressant activity by blockade of central substance P receptors has been described. Substance P preferring neurokinin-1 (NK_1) is highly expressed in brain regions critical to regulation of affective behavior and neurochemical response to stress. Additionally, this provides interactions between substance P and convergent NE/5-HT pathways through which antidepressants act, suggesting substance P antagonists might also be used in the treatment of psychiatric disorders. Some NE/5-HT containing cell bodies co-express substance P. Chronic in vivo antidepressant administration down-regulates substance P biosynthesis, speculating that alterations in the neurokinin system contribute to antidepressant effects.

Antidepressants block behavioral effects of central substance P receptor stimulation. There is clinical evidence that substance P antagonism represents a distinct marker for antidepressant activity. This raises the question of whether substance P antagonism and antidepressants act by distinct molecular targets (i.e., monoamine transporters or the NK_1 receptors). The amygdala, in particular, is a potential site for antidepressant activity. An output projection from the amygdala is directed to the hypothalamus and substance P provides the monosynaptic input from medial amygdala to the hypothalamus. Furthermore, another projection from the amygdala is directed to the periaquaductal gray (PAG) matter with dense substance P activity. Additionally, stress causes release of substance P (Kramer, et al., 1998).

Antidepressants: A Therapeutic Option in Pain Management

The use of antidepressant agents in the management of chronic pain has been reported in the literature for the past 40 years (Barkin, et al., 1996; Braverman, et al., 1993; Bryson & Wilde, 1996; De Angelis, 1992; Eija, Tiina, & Pertti, 1996; Galer, 1995; Magni, 1991; Sindrup, 1993; Watson, 1994). Nevertheless, these agents are probably not prescribed for this application as frequently, nor as optimally, as they should be for their beneficial therapeutic possibilities to be realized. Ample evidence exists to support the efficacy and safety of the use of antidepressant agents as part of a comprehensive treatment program for patients with chronic pain (Barkin, et al., 1996, 1997–1998; Braverman, et al., 1993).

The literature describes a broad variety of chronic pain syndromes in which antidepressants have been used (Table 35.5). The categories of chronic pain that appear to be most responsive to antidepressant pharmacotherapy include neuropathic pain, such as nerve compression or nerve destruction; deafferentation pain; dermatome distribution of pain if peripheral; and nondermatome pain if central, including diabetic neuropathy (Eija, et al., 1996; Onghena & Van Houdenhove, 1992). HIV-related neuropathy (Lister, 1996), herpetic pain, and pain of malignancy (nerve tumor involvement, [brachial, cervical, lumbosacral, plexic] peripheral neuropathy due to tumor infiltration, radiation fibrosis, chemotherapy). Patient descriptors of neuropathic pain include burning, numbness, pins/needles, shooting, electric shock, radiating, stabbing, and searing (Atkinson & Grant, 1994; Borestein, 1995; Galer, 1994; Hunter, 1994; Rowbotham, 1994). Antidepressants have also been reported to be effective in the treatment of failed back surgery syndrome, a challenging condition to manage (Taylor & Rowbotham, 1996).

TABLE 35.5
Pain Syndromes Described in the Literature with Antidepressant Nociception

Low-back pain	Coccygeal pain
Nerve damage pain	Acute diabetic neuropathy
Rheumatic pain conditions	Somatoform pain disorders
Chronic paranasal sinus pain	Somatization of pain
Abdominal migraine	Traumatic neuralgia
Fibromyalgia syndrome (FMS)	Postoperative pain
Neuropathic pain	Nocturnal ulcer pain
Pain in HIV disease	Thalamic pain syndromes
Oral facial neuralgia	Psychogenic pain
Painful diabetic peripheral neuropathy	Atypical odontalgia
Postherpetic neuralgia	Cranial mandibular pain
Neuropathic pain	Acute sickle-cell crisis pain
Head and neck cancer pain	Rheumatoid arthritis
Neuropathic pain of peripheral pain origin	Pericardial pain
Chest pain	Phantom limb pain
Noncardiac chest pain	Chronic nonmalignant pain
Chronic pelvic pain	Fibrocystic syndrome
Breast cancer pain	Lower extremity post amputation pain
Terminal cancer pain	Polyneuropathy
Atypical facial pain	Arthralgia
Chronic fatigue syndrome	Cervical disk degeneration
Cephalalgia	Central post-stroke pain
Irritable bowel syndrome	Opiate postoperative analgesia
Premenstrual dysphoric disorder pain	Idiopathic pelvic pain
Polyneuropathy	Vulvodynia
Central pain	Thalamic pain syndrome
Chronic facial pain	Sickle cell disease or occlusive pain crisis
Herpes zoster	Chronic benign pain
Fibrositis	Acute back pain with spasm
Pudendal neuralgia	Cortical origin pain
Dysesthetic pain	Brachial plexus injury pain
Deafferentation pain	Idiopathic genital pain
Psychogenic oral facial pain	Acute low-back pain and muscle spasms
Cutaneous disorders associated with psychiatric disorders	Chronic abdominal pain

It is evident that antidepressants provide analgesia independent of their antidepressant effects (Braverman, et al., 1993; Godfrey, 1996). However, there is evidence (Loeser, 1986; McQuay, et al., 1996; Sindrup, Brosen, & Gram, 1992a, 1992b; Tacey, 1996) to suggest that the mechanism of action of antidepressants in the relief of pain may be different from their action in the relief of depression. The effectiveness of antidepressants in treating chronic pain has been described. The extent of the analgesic effect is not significantly different in the following situations: pain of organic or psychologic origins; in the presence or absence of a (masked or manifested) depression; in the presence or absence of an antidepressant effect; in doses less than those effective in depression, or in therapeutic doses; and finally, in sedating or nonsedating pharmacotherapy (Onghena & Van Houdenhove, 1992). For example, the observation that antidepressants are helpful even when no depression is present suggests that these drugs have intrinsic analgesic activity (Magni, 1991).

A central (supraspinal) mechanism of action involving the monoamine and opioid systems has been postulated by several investigators. Alterations in the CNS pain modulatory system at the spinal cord level have also been hypothesized (Gonzales, 1995). Further, CNS plasticity (neuroplasticity) results in a reorganization/alteration in receptive fields and probably changes in the modulation of sensory perceptions (Braverman, et al., 1993; Coderre, Katz, Vaccarino, & Melzack, 1993). Experimental evidence has shown cellular and gene expression changes within the CNS following peripheral nerve system injury (Yaksh & Malmberg, 1994). Pain may result directly from dysfunctional peripheral nerves or from alterations in the CNS function, which may then enhance and maintain pain perception (Braverman, et al., 1993).

Some evidence suggests an interaction between antidepressant agents and opioid receptors, and this may be the mechanism by which antidepressants provide antinociception. Specifically, opioid-dependent neurons may be

secondarily activated by nonopioid neurons, and this, coupled with inhibition of the re-uptake of biogenic monoamines, may lead to antinociception (Gonzales, 1995). This latter mechanism, as noted earlier, has been demonstrated in the case of the centrally acting analgesic tramadol, which has a binary mechanism of action, with both an enantiomer leading to μ_1 opioid receptor agonism and an enantiomer that blocks the spinal reuptake of 5-HT and NE. Also, antinociception with tramadol occurs when the agent is co-administered with an opioid antagonist (Barkin, 1995a, 1995b; Barkin, et al., 1996; Braverman, et al., 1993; Gibson, 1996; Ruoff, 1996). An implication of antinociceptive influence of antidepressants over substance P has also been described (Braverman, et al., 1993).

Antidepressant Options for the Management of Chronic Pain

Several classes of antidepressants are currently available, and many of them have been employed in the management of chronic pain (Table 35.6) (Barkin, et al., 1996; Braverman, et al., 1993). Substantial differences exist with respect to their antinociceptive usefulness as discussed earlier (Richardson, 1993). The tricyclic antidepressants (TCAs) have the longest history of use in general, and consequently the most extensive record in the treatment of chronic pain. The mechanism of action of TCAs in chronic pain is incompletely understood but implicates substance P (as discussed previously). However, activity within the CNS brainstem-dorsal horn nociceptive modulating systems has been described, with both 5-HT and noradrenergic projections between brainstem and spinal dorsal horn nuclei with implication in nociceptive modulation (Braverman, et al., 1993; Parmelee, et al., 1991).

The impact of the TCAs on both NE and 5-HT, the two monoamines believed to be key in the etiology of depression, is also important to their effects on chronic pain. The TCAs also block other neuroreceptors, which mediates physiologic effects unrelated to the treatment of depression and to that of chronic pain. It is the antagonism of these unrelated neuroreceptors that produces the well-known adverse nontherapeutic effects associated with the TCAs. These side effects may jeopardize compliance, thereby negating their potential therapeutic benefit as co-analgesics in a patient's treatment plan. For example, blockade of the muscarinic receptors produces amblyopia, xerostomia, sinus tachycardia, constipation, urinary tension, and memory dysfunction; while blockade of histaminergic (H_1) receptors produces sedation, drowsiness, weight gain, and potentiation of CNS depressants. Alpha (α_1)-adrenergic blockade (also with nefazodone, trazodone) is associated with dizziness and postural hypotension, while α_2-adrenergic blockade is associated with, but not limited to, priapism and decreased antihypertensive efficacy when co-administered with such agents as clonidine, methyldopa, guanabenz, and guanadrel. A direct membrane stabilization effect is produced. Finally, dopamine receptor blockade (as seen with amoxapine) has been associated with extrapyramidal symptoms (EPS) and movement disorders, including dystonia, akathisia, rigidity, tremor, akinesia, and tardive dyskinesia, and with neuroleptic malignant syndrome and increased prolactin secretion (Barkin, et al., 1996; Braverman, et al., 1993; Cookson, 1993; Eschalier, Ardid, & Coudore, 1992).

As a group, the selective serotonin reuptake inhibitors (SSRIs) have a plasma protein binding percentage in the range of 30% (citalopram) to 99% (sertraline); the $t_{1/2\beta}$ of the SSRI parent drug is in the range of 15 to 20 hours (fluvoxamine/paroxetine), up to 48 to 72 hours (fluvoxamine); and the half-life of active metabolites is 60 hours (sertraline), up to 168 to 340 hours (fluvoxamine). All SSRIs except sertraline have linear pharmacokinetics.

Anecdotal evidence exists to support the use of the newer antidepressants as antinociceptive agents; however, no double-blind, placebo-controlled studies have been published to date. Because they exert an effect on only one monoamine, the newer SSRIs have a far more favorable 5-HT-specific adverse effect profile than the TCAs (Sindrup, Gram, Brøsen, Eshøj, & Morgensen, 1990; Zitman, Linssen, Edelbroek, & Van Kempen, 1992). For the same reason, however, they may be less effective than the TCAs in the management of chronic pain. Nevertheless, these agents may be useful in cases in which heterocyclic antidepressants are poorly tolerated or contraindicated (Barkin, et al., 1996; Braverman, et al., 1993). SSRIs may initially create gastrointestinal symptoms, anxiety, insomnia, agitation (e.g., fluoxetine, sertraline), overstimulation (sertraline), panic (sertraline), sexual dysfunction, and sedation (paroxetine) in treatment. Pharmacokinetic drug interactions are produced by SSRIs by CYP450 inhibition (1A2, 2D6, 2Cs, 3A4). This CYP450-inhibition (e.g., with codeine and hydrocodone) will decrease both of the pro drug analgesic

TABLE 35.6
Antidepressants Used in the Management of Various Pain States

Amitriptyline	Maprotiline
Bupropion	Mianserin
Carbamazepine (TCA-like structure)	Mirtazapine
Citalopram	Nefazodone
Clomipramine	Paroxetine
Desipramine	Phenelzine (MAOI)
Dibenzapine	Sertraline
Dothiepin	Trimipramine
Doxepin	Trazodone
Femoxetine	Venlafaxine
Fluoxetine	Zimelidine
Imipramine	

effects to their active therapeutic metabolites morphine and hydromorphone, respectively. (See Table 35.7, CYP IID6.)

Monoamine oxidase (MAO) inhibitors act by inhibiting the MAO enzyme system and causing an increase in the concentration of endogenous epinephrine, norepinephrine, and serotonin in storage sites throughout the CNS. Because they have a wide range of clinical effects and the potential for serious drug–food and drug–drug interactions, MAO inhibitors have been reserved for patients who are resistant to other antidepressants. Use in treating chronic pain is limited. As mentioned, administration to patients receiving meperidine (a reuptake blocker of 5HT and NE) can lead to potentially fatal side effects (i.e., hypertensive crisis and serotonin syndrome).

An ideal antidepressant agent for the management of chronic pain would be characterized by modulation of both NE and 5-HT, but would lack the nontherapeutic acute synaptic effects associated with the TCAs or heterocyclic antidepressants, have a robust onset of effect, once-daily dosing for compliance enhancement, mild to minimal side/adverse effects, a paucity of drug interactions and minimal overdose consequences. Among the newer antidepressants, venlafaxine and mirtazapine are unique in providing the therapeutic advantages of both serotonin and noradrenergic effects, non-SSRIs, but without the acute synaptic insults of α_1- or α_2-adrenergic, histaminergic (H_1, H_2), or anticholinergic events. These two agents offer the therapeutic benefits of the TCAs and SSRIs, but without these groups of iatrogenic insults associated with the TCAs and SSRIs (Augustin, Cold, & Jann, 1997; Barkin, et al., 1996; Braverman, et al., 1993).

Venlafaxine: Serotonin Noradrenergic Reuptake Inhibitor

Venlafaxine has been studied in several chronic pain states, including fibromyalgia, chronic pain (primarily of cephalalgia), and neuropathic pain (Barkin, et al., 1996; Godfrey, 1996; Gonzales, 1995; Rowbotham, 1995; Tamler & Meerschaert, 1996). In addition, reports in the literature suggest the usefulness of venlafaxine in other pain states, including reflex sympathetic dystrophy, sympathetically mediated pain, intercostal neuralgia, atypical facial pain, multiple sclerosis, peripheral neuropathy, post-stroke pain, post-Zoster pain, and may improve restorative rehabilitation (Davis & Glassman, 1989; Taylor & Rowbotham, 1996). Venlafaxine appears to provide an antinociceptive effect independent of its antidepressant efficacy (Songer & Schulte, 1996; Taylor & Rowbotham, 1996). Effective doses have ranged between 37.5 mg and ≥300 mg per day, with varying degrees of patient-described pain relief (Barkin, et al., 1996; Holliday & Benfield, 1995; Taylor & Rowbotham, 1996).

In our clinical experience, venlafaxine has provided pain relief equal to or greater than that achieved with TCAs or SSRIs. We have noted particular efficacy in patients suffering from neuropathic pain, post-herpetic neuralgia, polyneuropathies, cephalalgia, failed low back surgery syndrome, fibromyalgia, and HIV-related pain syndromes (Barkin, 1997b; Barkin, et al., 1996; Dwight, Arnold, O'Brien, Metzger, & Morris-Park, 1996; Gonzales, 1995; Ruoff, 1996; Yunus, 1996). In addition, patients have found venlafaxine significantly more tolerable than the TCAs and some of the SSRIs (Barkin, 1995a, 1998; Barkin, et al., 1996; Cerruto, 1996; Rani, Naidu, Prasad, Rao, & Shobha, 1996; Songer & Schulte, 1996).

Unlike the SSRIs, venlafaxine and mirtazapine have not shown a loss in efficacy with maintenance therapy (Yunus, 1996). Venlafaxine is a phenylethylamine bicyclic antidepressant, which blocks the transporter reuptake of, in order of decreasing potency, 5-HT (low dose), NE (medium dose), and dopamine (high dose). The weak inhibition of dopamine reuptake occurs primarily at doses ≥225 mg (Augustin, et al., 1997; Barkin, et al., 1996; Holliday & Benfield, 1995). Venlafaxine's effect on CNS β-adrenergic receptors is of interest because it demonstrates an acute subsensitivity of β-adrenergic cAMP-generating systems (Barkin, et al., 1996, 2000; Cohen, 1997). There may be other mechanisms by which venlafaxine produces an antidepressant or antinociceptive outcome.

It is theorized that antidepressants are associated with the down-regulation of this system, most likely in the pineal gland (murine model), and it has been suggested that venlafaxine has a more robust effect on this system, with resulting early onset of therapeutic response (Davis & Glassman, 1989; Barkin, et al., 2000; Cohen, 1997; Huff & Barkin, 1994). Two racemates, the R and S enantiomers, are present within the parent compound, each with individual pharmacologic profiles. Binding of either enantiomer to cholinergic, histaminergic, α_1-, α_2-, or β-adrenergic receptors appears to be minimal, if it occurs at all. The major metabolite is O-desmethylvenlafaxine (ODV).

The pharmacokinetics of venlafaxine have been described (Augustin, et al., 1997; Barkin, et al., 1996; Feighner, 1994; Holliday & Benfield, 1995; Montgomery, 1993). The T_{max} is approximately 1.4 to 3.0 hours; the clearance (Cl) is approximately 0.58 to 1.85 l/hr/kg; the $T_{1/2}$-β is 2.2 to 11.3 hours and is prolonged in both liver and renal dysfunction. The volume of distribution (Vd) is 2 to 22.7 l/kg and protein binding is 25 to 30%. The ODV metabolite T_{max} is 3.1 to 6 hours; the Cl is 0.2 to 0.5 l/hr/kg; the $T_{1/2}$β is 6.5 to 16 hours; the Vd is 3 to 7.5 l/kg; and plasma protein binding is 30%. Further, extensive tissue distribution is seen and metabolism is probably first pass and saturable. Dosages greater than 75 mg every 8 hours display nonlinear (zero order) distribution kinetics seen with the conversion from the parent drug to the ODV metabolite (Barkin, 1998; Holliday & Benfield, 1995).

TABLE 35.7
Pharmacotherapeutic Inhibitors, Inducers, and Substrates of Cytochrome P450 Enzymes Used in the Management of Pain

Xenobiotic CYP Enzyme	Inhibitor	Inducer	Substrate
1A2	Anastrozole	Bupropion (possible)	Acetaminophen (APAP)
Polymorphism: Yes	Bupropion	Carbamazepine	Beta-adrenergic blocking agents
≈13% or a deficit in	Cimetidine	Charcoal-broiled foods	Bupropion (possible)
activity or poor	Ciprofloxacin	Cigarette smoke	Caffeine
metabolizers	Citalopram	Cruciferous vegetable	Chlorzoxazone
(Caucasians, Asians,	Clarithromycin	Dihydralazine	Clozapine
Blacks)	Diethyldithiocarbamate	Omeprazole	Cyclobenzaprine
	Diltiazem	Phenobarbital	(demethylation)

TABLE 35.7 (CONTINUED)
Pharmacotherapeutic Inhibitors, Inducers, and Substrates of Cytochrome P450 Enzymes Used in the Management of Pain

Xenobiotic CYP Enzyme	Inhibitor	Inducer	Substrate
	Norfloxacin		Nefazodone
	Norfluoxetine		Nifedipine
	Omeprazole		Phenytoin
	Paroxetine		Prednisone
	Propranolol		Protease inhibitors
	Propoxyphene		Quetiapine
	Protease inhibitors		Quinidine
	Quinidine		Ropivacaine
	Quinine		Sertraline
	Ranitidine		Sex hormone
	Ritonavir		Sufentanil
	Saquinavir		Tiagabine
	Sertraline		Tamoxifen
	Trazodone		Tramadol
	Troglitazone		Trazodone
	Troleandomycin		Triazolam
	Verapamil		TCAs (demethylation)
	Venlafaxine (very weak)		Amitriptyline (minor)
	Zafirlukast		Clomipramine
	Ziprasidone		Imipramine
			Venlafaxine (n-demethylation)
			Verapamil
			Zolpidem
IIIA5–7	Clotrimazole	Phenobarbital	Midazolam (3A5)
	Ketoconazole	Phenytoin (PHT)	Triazolam
	Metronidazole	Primidone	
	Miconazole	Rifampin	
	Troleandomycin		

Note: From a primary care clinician's and consultant's guide to medicating for pain and anxiety, J. Huff and R. L. Barkin, 1994, American Journal of Therapeutics, 1, 186–190; Loss of antidepressant efficacy during maintence therapy: Possible mechanisms and treatments, S.E. Byrne and A. J. Rothschild, 1998, Journal of Clinical Psychiatry, 59, 279–288; Pharmacokinetics of the newer antidepressants: Clinical relevance, C.L. DeVane, 1994, American Journal of Medicine, 97 (Suppl. 6A), 6A-13S–6A-23S; Opiate, opioids, and centrally acting analgesics and drug interactions: The emerging role of the psychiatrist, R.L. Barkin, D.S. Barkin, S.J. Barkin, and S.A. Barkin, 1998, Medical Update for Psychiatrists, 3(6),172–175.

Venlafaxine substrate metabolism appears to occur via the cytochrome hepatic isoenzyme (CYP-4502D6) (DeVane, 1994).

Venlafaxine's inhibition of this isoenzyme is significantly less and weaker than that reported with SSRIs and produces negligible hepatic isoenzyme inhibition. Consequently, venlafaxine has a significantly lower potential for clinically relevant pharmacokinetic interactions, including those agents used in chronic pain management (Table 35.7) (Barkin, et al., 1998, 2000; Bazine & Benefield, 1997–1998; Cohen & DeVane, 1996; Huff & Barkin, 1994). In addition, because of its low plasma protein binding (25 to 30%), interaction with agents that are highly protein bound is unlikely. Cytochrome P-4503A4 is the isoenzyme used for the N-demethylated metabolite (Table 35.7). Approximately 1 to 10% of the drug is excreted unchanged, 30% is excreted as the ODV metabolite, 6 to 19% as the N,O-di-desmethyl metabolite, and 1% as the N-desmethyl metabolite. The $t_{1/2}$-beta of the parent compound ranges between 3 and 4 hours, while that of the ODV metabolite is about 10 hours (Barkin, 1998; Barkin, et al., 1996, 2000; Feighner, 1994; Montgomery, 1993).

Although serotonin syndrome has not been reported with venlafaxine as of this publication, the agent should not be administered with MAOIs or within a 14-day period

following MAOI discontinuation (Sternbach, 1991). A 7-day pharmacokinetic-based washout period should precede initiation of an MAOI following a gradual discontinuation of venlafaxine. Prescription and nonprescription forms of cimetidine decrease the clearance of venlafaxine and increase the area under the curve (AUC) and peak plasma concentration (Barkin & Fawcett, 2000; Byrne & Rothschild, 1998). Refer to Table 35.7 for CYP450 isoenzyme induction and inhibition of agents utilized in the management of pain.

Side effects associated with venlafaxine include 5-HT-mediated nausea and vomiting, which is self-limited and dose-related and may respond to mirtazapine. Anorexia, somnolence or sedation, dizziness, and xerostomia have also been reported, and their frequency appears to be less with the extended-release dosage form (Barkin & Fawcett, 2000).

Infrequently reported side effects include NE- and 5-HT-receptor-mediated palpitations, fatigue, headache, constipation, self-limiting insomnia/anxiety (which may be treated with zolpidem, mirtazapine, or trazodone), sexual dysfunction (erectile failure, delayed orgasm, anorgasmia, impotence, abnormal ejaculations [which may be diminished by addition of mirtazapine]), blurred vision, asthenia, and diaphoresis. Slight increases in blood pressure (≤5 to 8 mmHg) and heart rate may be noted at doses exceeding 200 mg per day. A slight increase in serum lipid levels (2 to 3 mg/dl) may occur. The incidence of side effects such as dyspepsia, diarrhea, and headache is comparable to that associated with placebo. Overall, venlafaxine is well tolerated. A slow decremental titration is appropriate to prevent withdrawal symptoms such as GI distress, diaphoresis, or dizziness (Barkin & Fawcett, 2000).

Notably, venlafaxine is one of the few antidepressants (in addition to bupropion) associated with loss of appetite or anorexia, with an incidence of 11%. One of the authors found that, in a limited number of patients, venlafaxine may be cautiously prescribed with bupropion when necessary for concomitant or adjunctive purposes in the nicotine-dependent and/or obese patient, without iatrogenic side effects. It may be possible to exploit this therapeutic side effect to the patient's advantage, because weight reduction (in obesity) and nicotine-dependency management are critical for patients with chronic pain involving the musculoskeletal system, particularly given the severe negative impact of excessive body mass on weight-bearing joints and in patients attempting to abate habituation of smoking (Barkin, 1995a, 1998; Barkin & Fawcett, 2000; Barkin, et al., 1999, 2000; Braverman, et al., 1993; Fawcett & Barkin, 1997).

Mirtazapine (NASSA)

Mirtazapine is an atypical antidepressant described as a noradrenergic serotonin-specific antagonist. NASSA has been reviewed elsewhere. This agent produces unique therapeutic antagonism at presynaptic α_2-auto and heteroreceptors, thus facilitating rapid, robust, enhanced noradrenergic and serotonin release, respectively. There is no transporter reuptake inhibition mechanics No sexual dysfunction, a decrease in migraine headaches, and decreased anxiety, agitation, and depression are associated with 5-HT_2-, H_1-, α_2-hetero-, and α_2-autoreceptor blockade, as with mirtazapine. Further antagonism occurs at 5-HT_2-receptors (decreasing anxiety and cephalalgia, agitation) and at 5-HT_3 receptors (decreasing nausea and GI distress, augmenting antidepressant effects).

Mirtazapine is rapidly and completely absorbed following oral administration and has a mean half-life ($t_{1/2\beta}$) of about 20 to 40 hours. The mean elimination half life of mirtazapine after oral administration ranges from approximately 20 to 40 hours across age and gender subgroups, with females of all ages exhibiting significantly longer elimination half lives than males (mean half life of 37 hours for females vs. 26 hours for males).

The disposition of mirtazapine was studied in patients with varying degrees of renal function. Elimination for mirtazapine is correlated with creatinine clearance. Total body clearance of mirtazapine was reduced approximately 30% in patients with moderate (Clcr = 11 – 39 ml/min/1.73 m^2) renal impairment when compared to normal subjects.

The oral clearance of mirtazapine was decreased by approximately 30% in hepatically impaired patients. Peak plasma concentrations are reached within about 2 hours following an oral dose. Mirtazapine is extensively metabolized. Major pathways of biotransformation are demethylation and hydroxylation, followed by glucuronide conjugation. Human liver microsomes indicate that cytochrome 2D6 and 1A2 are involved in the formation of the 8-hydroxy metabolite of mirtazapine, whereas cytochrome 3A is considered to be responsible for the formation of the N-desmethyl and N-oxide metabolite. Mirtazapine has an absolute bioavailability of about 50% It is eliminated predominantly via urine (75%) with 15% in feces. Several unconjugated metabolites possess pharmacological activity but are present in the plasma at very low levels. The (–) enantiomer has an elimination half-life that is approximately twice as long as the (+) enantiomer and therefore achieves plasma levels that are about three times as high as that of the (+) enantiomer.

Plasma levels are linearly related to dose over a dose range of 15 to 80 mg. The mean elimination half-life of mirtazapine after oral administration ranges from approximately 20 to 40 hours across age and gender subgroups, with females of all ages exhibiting significantly longer elimination half-lives than males (mean half-life of 37 hours for females vs. 26 hours for males). Steady-state plasma levels of mirtazapine are attained within 5 days, with about 50% accumulation (accumulation ratio = 1.5). Mirtazapine is approximately 85% bound to plasma proteins over a concentration range of 0.01 to 1.0 µg/ml.

H_1 receptor antagonism at low doses (< 30 mg) produces drowsiness, facilitating sleep and improving appetite. No clinically significant interactions are revealed on the CYP450 system. Mirtazapine is a useful adjuvant agent with a robust onset of action in the management of chronic pain, FMS, migraine headache, failed low-back surgery syndrome, neuropathic pain, etc. Mirtazapine $5HT_3$ antagonism decreases the nausea and of some pharmacological tramadol and venlafaxine. Beneficial effects for the initial combination of venlafaxine and mirtazapine are for many pain patients needing restful sleep. At doses of 7.5 to 22.5 mg, the benefits decreased in insomnia and agitating anxiety, and enhanced appetite, especially beneficial in cachectic patients. This agents pharmacology decreases the need for benzodiazepines. Mirtazapine will provide dose-related effects, which include xerostomia, enhanced appetite, constipation, drowsiness, and of clinical importance is the low-dose-mediated appetite. Drowsiness events are much less at 45-mg than at 22.5-mg doses and below due to less prominence of the H_1 receptor pki at higher doses (Barkin, Chor, Braun, & Schwer, 1999; Barkin & Fawcett, 2000; Barkin, Oetgen, & Barkin, 1999; Barkin, et al., 2000; Bhatia, Bhatia, & Barkin, 1997; Davis & Barkin, 1999; Fawcett & Barkin, 1998a, 1998b; Kao, Barkin, and Leikin, 1997). A soluble oral tablet dosage form is available.

Tramadol: Centrally Acting Analgesic

Tramadol is centrally acting due to an analgesic binary mechanism of action. It combines centrally acting (the enantiomer binds to μ receptor), mild opioid activity with an additional spinal mechanism of monamine transporter reuptake inhibition as seen with TCAs. With its weak affinity for μ-opioid receptors, in consort with a synergistic action with serotonin ([+] enantiomer provides 5HT transporter reuptake) and norepinephrine ([–] enantiomer NE transporter reuptake blockade, tramadol interferes with central pathways that mediate pain. The spinal analgesia is modulated by descending nonadrenergic and serotonergic pathways affecting laminae I) (A-delta and C fiber project and synapse) on the dorsal horn of the spinal cord. Tramadol has a lower degree of respiratory depression than opioids. A very low potential for tolerance or abuse is seen with tramadol. Indications include management of moderate or moderately severe pain. The concomitant use of tramadol and nonsteroidal anti-inflammatory drugs (NSAIDs) (i.e., rofecoxib and others) may offer the therapeutic benefits of both central and peripheral analgesia, although the requisite studies have not yet been conducted. This combination is frequently initiated in clinical practice. Tramadol is a good choice for patients who are at risk for the side effects of NSAIDs but are reluctant to use opioid analgesics. The action of tramadol is without prostaglandin-mediated effects and therefore does not exhibit the GI and renal side effects associated with traditional NSAIDs. Dose-related side effects include dizziness, nausea, headache, and constipation.

Tramadol appears in plasma within 15 to 45 minutes of oral administration, with almost complete absorption (75% bioavailable). It achieves a peak plasma concentration in about 2 hours. Onset of action following oral routes is within 25 to 35 minutes, and analgesia duration is 3 to 11 hours. Mean elimination half-life is 6 hours after single doses and 7 hours after multiple doses. About 30% of an oral dose is excreted by the kidneys, with 60% excreted as metabolites. Both CYP-450 3A4 (M1 metabolite desmethyl tramadol) and 2D6 isoenzymes (parent) are involved as a substrate in the hepatic metabolism (see Table 35.7). Renal impairment produces both a decreased extent and rate of excretion of the parent drug and active metabolites. The low plasma proteins binding (20%) provides a benefit in hypoalbuminic patients. Tramadol exhibits linear pharmacokinetics. Dialysis removes less than 7% of a given dose, which may be a benefit in patients undergoing hemodialysis (HD). Hepatic cirrhosis results in decreased metabolism of both the parent drug and its active metabolites. Tramadol has not, in clinical experience, been shown to modulate sphincteric muscles (no urinary retention, biliary tract spasms, or ampulla of Vater in the pancreas).

Tramadol has been studied in elderly populations and for a variety of conditions. It has been well tolerated overall and has proven to be effective in fibromyalgia, osteoarthritis, back pain, and neuropathic pain. Side-effect minimization can be accomplished by titrating the dose in increments of 25 to 50 mg/day every 3 days until an effective analgesic is reached, to a maximum of 400 mg/day in the non-elderly patient with normal hepatic and renal function. Any nausea may further be diminished by co-prescribing mirtazapine. The analgesic effects of tramadol will not be totally reversed with naloxone administration. In patients with a decreased seizure threshold or in patients taking antidepressants, neuroleptics, or other drugs that decrease that threshold, a risk-benefit analysis should be made. In other countries, tramadol at 1 to 2 mg/kg every 6 hours has been used in children. Children predictably have more rapid clearance of tramadol. A combination with acetaminophen (APAP) and sustained action dosage form are to be available in the near future. These dosage forms have been effectively utilized with co-pharmacotherapy (NSAIDs, membrane stabilizers, antidepressants, anxiolytics, [e.g., venlafaxine mirtazapine] anticonvulsants [e.g., topiramate, etc.] opiates, and skeletal muscle relaxants. (Barkin, 1995a, 1995b, 1996; Barkin, Lubenow, et al., 1996; Barkin, Oetgen, & Barkin, 1999; Gaynes & Barkin, 1999). A combination dose form with acetaminophen is available, with a long-acting and liquid dosage form available in the near future.

CONCLUSION

Antidepressants have a clear role in the treatment of chronic pain, whether or not depression is involved. The best choice of a particular antidepressant class for use in this application is somewhat less clear, however. The TCAs have been shown to be effective in the management of chronic pain. However, the associated adverse effects may compromise compliance. The SSRIs have a more favorable adverse-effect profile than TCAs, but they have not been well studied in patients with chronic pain. The pharmacokinetic and pharmacodynamic profiles of both venlafaxine and mirtazapine are superior to those of the TCAs, and the agent offers significant patient-specific advantages over some of the SSRIs, including a paucity of pharmacokinetic interactions. Venlafaxine and mirtazapine are certainly worthy of pharmacotherapeutic consideration in the patient with chronic pain.

Drug Management of Pain

Robert B. Supernaw, Pharm.D.

INTRODUCTION

As is the case with almost any medical problem, the best pharmacotherapeutic approach to acute and chronic pain management is no drug therapy at all. However, the option of not using drugs in managing many pain syndromes is not realistic. When the clinician has determined that the pain condition is significant and beyond the scope of being treated solely with physical medicine (e.g., ice packs, massage, physical therapy), drug therapy is indicated. To determine the best pharmacotherapeutic response to pain, the nature and severity of the pain must be assessed and considered. Whether the pain is acute or chronic must be taken into account, as well as whether the pain is malignant, benign, organic, psychogenic, vascular, or depression related. Neuropathic pain is addressed in a completely different manner than nociceptive pain. Additionally, the pain should be graded as mild, moderate, severe, or excruciating before an appropriate drug regimen and drug delivery system are formulated.

Treatment plans are formulated on the basis of the categorization of the pain syndrome. For example, mild acute respondent pain is treated differently than chronic severe aberrant pain. Because the nature or categorization of the pain is important, the interdisciplinary pain treatment model is considered state-of-the-art. Unlike the basic therapeutic approach to other commonly encountered problems (e.g., hypertension, hyperlipidemia), where drug therapy is initiated in relatively small doses and built until the therapeutic threshold or desired outcome is achieved, the therapeutic approach to pain is predicated on the basis of matching the pain category to the appropriate agent.

That is, there is no need to begin drug therapy for any pain complaint with the less potent, over-the-counter analgesics before attempting more potent drug therapy. A severe, chronic, benign cluster headache will not respond to aspirin or acetaminophen therapy; thus, there is simply no justification in trying. This treatment principle underscores the need for an accurate categorization of the pain complaint. Therefore, the clinician's familiarity with the pain scales, such as those described above, is essential. The International Association for the Study of Pain deems the role of pharmacotherapy in pain management to be of such vital importance that it established a focus group for the design of a pain curriculum for all pharmacy students.

ACUTE PAIN

When a patient presents in acute distress, often the clinician's attention is first drawn to the comfort of the patient, and alleviating the pain is attempted even before the cause of the distress is considered. For this reason, the clinician must make a quick and accurate assessment of the relative degree of the pain. In acute pain, the same classification system is used as for chronic pain (i.e., mild, moderate, severe, and excruciating).

CHRONIC PAIN

Chronic pain can be thought of as a completely different medical problem than its acute phase. Chronic pain has elements of acute pain, but it is generally more psychologically innervated, debilitating the personhood as well as the physical nature of the body being treated. For this reason, the patient suffering chronic pain should be treated just as aggressively as the patient suffering acute

0-8493-0926-3/02/$0.00+$1.50

distress. Quality-of-life issues are important considerations in chronic pain, whereas simply diminishing the intensity of the pain is the primary focus in the treatment approach to acute pain. Chronic pain serves no useful purpose; acute pain can be helpful in deducing the underlying cause.

MILD PAIN

First-Line Pharmacotherapy

Because, by definition, acute mild pain is limited in its duration, it need not be aggressively treated. Often, it need not be treated at all. In that chronic pain is, by definition, long-term pain, often nonpharmacologic pain-mitigating therapy is indicated. However, if a decision is made to treat the mild acute or chronic pain, first consideration should be given to aspirin. For the aspirin-allergic patient, acetaminophen is an excellent alternative, although it has insignificant anti-inflammatory activity. Internal, over-the-counter (OTC) analgesics are the mainstay for mild pain, and sales of these agents (i.e., aspirin, acetaminophen, ibuprofen, naproxen sodium, and ketoprofen) totaled $2,660,831,000 in 1995 (Information Resources, 1996).

Aspirin

Aspirin, given as a 650-mg dose (two tablets) every 4 hours, is the mainstay of first-line drug therapy in various mild pain-related problems such as minor arthritis flare-ups, mild tension-type headaches, and chronic minor low-back pain. Aspirin is absorbed very rapidly in the duodenum; there are insignificant differences in absorption between buffered and nonbuffered varieties. As with all salicylates, aspirin is metabolized in the liver and is highly albumin-bound. Therefore, caution is warranted when aspirin is given to a patient taking an oral anticoagulant (OAC) in that the OAC is approximately 97% albumin-bound. The concomitant use of aspirin will displace a significant amount of the OAC from its inactive binding sites, causing an increase in the active dose (drug level) of the OAC.

Aspirin was first introduced to the U.S. market in 1899. It has analgesic, anti-inflammatory, antiplatelet, and antipyretic activity. Its mechanism of action is by inhibition of prostaglandin synthesis, and it is effective in mild and mild-to-moderate pain. The benefits of aspirin therapy are well known. It is cheap, readily available, has a very long track record, is very effective in the relief of mild or mild-to-moderate pain, and reduces inflammation, especially at higher doses. Additional benefits include its ability to reduce fever and its antiplatelet adhesion properties.

However, the use of aspirin is not without risk. The gastrointestinal (GI)-related risks include everything from mild stomach irritation to ulceration and GI bleeding. Hearing loss has been associated with very high doses of aspirin. Generally, tinnitus will forewarn the clinician of too high an aspirin dose before problems arise. Aspirin has also been implicated in blood-related problems, including decreased white blood cell and platelet counts and hemolytic anemia.

Aspirin should not be taken if the patient is allergic to salicylates, has a bleeding disorder, has peptic ulcer disease, or during the last 3 months of pregnancy (see pregnancy category note below). Clinicians should also warn patients to throw out aspirin that has an odor of vinegar, which indicates that the aspirin has chemically degraded. Extra caution is indicated if the patient (1) is taking an anticoagulant, (2) is taking an oral antidiabetic agent, (3) has a history of peptic ulcer disease, (4) has systemic lupus erythematosus, (5) is pregnant or contemplating pregnancy, (6) is scheduled for surgery, (7) is receiving a new prescription, or (8) any time the patient is experiencing a new significant adverse effect.

Aspirin has a tentative Food and Drug Administration (FDA) Pregnancy Category of D, which means that studies in pregnant women demonstrate positive evidence of human fetal risk. Aspirin is present in breast milk. For infants and children into their teens, aspirin is contraindicated in viral infections, including flu and chicken pox, as it has been implicated in Reye's syndrome, It is suggested that complete blood cell counts be monitored in patients taking daily doses of aspirin, as well as monitoring kidney function/urine analyses along with liver function.

Dosing guidelines are very specific and are formulated on the basis of weight or age:

- Children age 2–11, 64 mg/kg/day in four to six doses or
- Children age 11, 480 mg/day
- Children age 9–10, 400 mg/day
- Children age 6–8, 325 mg/day
- Children age 4–5, 240 mg/day
- Children age 2–3, 160 mg/day
- Children younger than 2, by weight
- For adults, and children over 11, 325–650 mg every 4 hours, not to exceed 4 g/day

Acetaminophen

For patients who cannot tolerate aspirin, acetaminophen is indicated. It is given in doses similar to aspirin; however, some caution is warranted in higher dosing schedules. Acetaminophen (Tylenol®) first appeared on the OTC market in 1954. It is an analgesic and has antipyretic properties. It tends to be better tolerated than aspirin in individuals who experience GI-related complications with analgesics. Its mechanism of action is similar to the salicy-

lates; however, it possesses only very weak anti-inflammatory activity.

Acetaminophen has been widely used largely because of its reputation for safety. Although its reputation is deserved, it is not without risks. Hepatotoxicity is a significant adverse drug reaction associated with the use of acetaminophen. Because many patients with pain tend to take medications on a routine basis, it is the clinician's responsibility to warn of possible liver damage with as little as 2.6 g acetaminophen daily, over extended periods of time. Patients should not take acetaminophen if they have experienced an allergy to it, if they have diminished liver function, if they are alcoholics, if they are fasting, or if they have significant kidney damage or loss of kidney function.

Extra caution is indicated any time a patient who is contemplating taking acetaminophen (1) requires higher chronic doses, (2) is alcoholic, (3) has compromised liver or kidney function, or (4) experiences a significant adverse drug reaction.

The specific adverse drug reactions to watch for include GI bleeding, anemias, rash, and signs and symptoms of hepato- and nephrotoxicity. Acetaminophen is classified by the FDA as Pregnancy Category B, which means that animal studies are negative for fetal abnormalities, or animal studies are positive while human studies are negative. Although acetaminophen is present in breast milk, studies have shown that only an insignificant 0.88 mg is passed on with each feeding. Laboratory monitoring should include periodic liver function tests if chronic relatively high doses are being taken.

Dosing guidelines are as follows:

- Adults, 325–650 mg every 4–6 hours, not to exceed 4 g/day for acute pain
- Children age 11, 480 mg
- Children age 9–10, 400 mg
- Children age 6–8, 320 mg
- Children age 4–5, 240 mg
- Children age 2–3, 160 mg
- Children age 1–2, 120 mg
- Children age 4–11 months, 80 mg
- Children younger than 4 months, 40 mg

Second-Line Pharmacotherapy

If the mild pain does not respond to aspirin or acetaminophen and the doses have been pushed to the extent deemed appropriate, consideration should be given to second-line therapy. There are now three OTC nonsteroidal anti-inflammatory drugs (NSAIDs) that are readily available– ibuprofen, naproxen sodium, and ketoprofen– and they are excellent second choices for mild pain complaints. The NSAIDs exert their pharmacologic effects by virtue of their ability to inhibit the synthesis and/or release of prostaglandins.

Ibuprofen

Ibuprofen was first introduced onto the prescription market in the United States in 1969; and in 1984, the 200-mg dosage form became an OTC item (Advil®, Nuprin®). Ibuprofen is in the class of NSAIDs, and it has analgesic, anti-inflammatory, some antipyretic, and some antiplatelet activity. It is thought to work by decreasing tissue concentrations of prostaglandins and related compounds. It is approximately 80% absorbed. Perhaps the most important concept for clinicians to remember about OTC ibuprofen is that in the OTC dose (i.e., 200 mg), the drug has little anti-inflammatory effect. At this dose, its primary effects are analgesic and antiplatelet adhesion.

Ibuprofen has been shown to be an effective OTC analgesic. However, it should be monitored for its potential adverse drug reactions. Perhaps the most common side effect is GI pain or even ulceration. GI complications are thought to be dose related; thus, the OTC dose would have the least possibility of provoking GI-related complications. Nevertheless, the practitioner would be wise to warn patients of this potential problem. Patients who are particularly sensitive to NSAID-related GI distress should be counseled to take their medication with a full glass of water and not to lie down for 30 minutes. Ibuprofen is safe to crush for patients in skilled nursing facilities. Also, ibuprofen may be taken with food to limit GI irritation.

Patients should not take ibuprofen if they are subject to asthma or nasal polyps caused by aspirin, if they have active peptic ulcer disease, if they have a bleeding disorder or blood cell disorder, or if they have significant kidney damage.

The physician should be consulted any time a patient is considering using ibuprofen on an OTC basis if the patient (1) is allergic to aspirin, (2) has a history of peptic ulcer disease, (3) has a history of a bleeding disorder, (4) has diminished liver or kidney function, (5) has high blood pressure or heart failure, (6) is taking acetaminophen chronically, or (7) experiences a significant adverse drug reaction.

In addition to GI irritation, other adverse drug reactions include altered pattern and timing of the menstrual cycle (30% of women are affected). It may also give false-positives for fecal occult blood, and it may cause drowsiness in sensitive individuals.

One study has shown an increased analgesic activity when taken with caffeine; however, the drawbacks seen with caffeine intake must be weighed against its advantages.

Ibuprofen, as well as naproxen sodium, appear to be especially helpful in menstrual cramps. It has been tentatively assigned by the FDA to Pregnancy Category B, which means that animal studies are negative for fetal

abnormalities, or animal studies are positive while human studies are negative. It is not recommended for use during the last 3 months of pregnancy. It is present in very small amounts in breast milk. If a patient is taking ibuprofen for extended periods of time, monitoring of CBC as well as liver and kidney function may be warranted.

The OTC dose of ibuprofen is 200 mg every 4 to 6 hours. Ibuprofen was not recommended for children on an OTC basis until 1996. Children's Motrin® and Children's Advil® are approved for OTC use. If given by prescription, the children's dosing schedule is as follows:

- Children 11–15.9 kg (24–35 lb.), 100 mg
- Children 16–21.9 kg (36–47 lb.), 150 mg
- Children 22–26.9 kg (48–59 lb.), 200 mg
- Children 27–31.9 kg (60–71 lb.), 250 mg
- Children 32–43.9 kg (72–95 lb.), 300 mg

Naproxen Sodium

Naproxen sodium was first introduced in 1974 as a prescription NSAID and was approved for OTC use in 1994 (Aleve®). It has analgesic, anti-inflammatory, some antipyretic, and some antiplatelet activity.

Naproxen sodium is thought to work by decreasing the tissue concentrations of prostaglandins and related compounds. It is virtually 100% absorbed. Naproxen sodium has been shown to be an effective OTC analgesic; however, it, too, should be monitored for potential risks. An advantage of naproxen sodium over other NSAIDs is that it has a lower incidence of adverse effects, including less GI irritation and a lower incidence of liver and kidney complications. Nevertheless, because it is an NSAID, patients should be warned to monitor GI irritation; and for those who are particularly sensitive to NSAID-related GI distress, taking their medication with a full glass of water and not lying down for 30 minutes will be helpful. Naproxen sodium is safe to crush for patients in skilled nursing facilities. Also, it may be taken with food to limit GI irritation.

Patients should not take naproxen sodium if they are subject to asthma or nasal polyps caused by aspirin, if they have active peptic ulcer disease, if they have a bleeding disorder or blood cell disorder, or if they have significant kidney damage.

The physician should be consulted any time a patient is considering using naproxen sodium on an OTC basis if the patient (1) is allergic to aspirin, (2) has a history of peptic ulcer disease, (3) has a history of a bleeding disorder, (4) has diminished liver or kidney function, (5) has high blood pressure or heart failure, or (6) experiences a significant adverse drug reaction.

As discussed earlier, naproxen sodium has less GI-related irritation potential than other NSAIDs. Adverse drug reactions include altered pattern and timing of the menstrual cycle. It may also give false-positives for fecal occult blood and may cause drowsiness in sensitive individuals. It may also cause fluid retention.

Naproxen sodium, as well as ibuprofen, appears to be especially helpful in menstrual cramps. It has been tentatively assigned by the FDA to Pregnancy Category B, which means that animal studies are negative for fetal abnormalities, or animal studies are positive while human studies are negative. It is not recommended for use during the last 3 months of pregnancy. It is present in very small amounts in breast milk. If a patient is taking naproxen sodium for extended periods of time, monitoring of CBC as well as liver and kidney function may be warranted.

The OTC dose of naproxen sodium is 220 mg every 8 to 12 hours. It is recommended that the drug be initiated as two tablets (440 mg) immediately, then one tablet every 8 to 12 hours, not to exceed 660 mg in a 24-hour period. For patients over 65, the recommended dose is one tablet every 8 to 12 hours, not to exceed 440 mg in 24 hours. It is not recommended for children under 12 on an OTC basis; however, if absolutely necessary, the recommended prescription doses of naporxen for children are as follows:

- Children 12.5 kg (29.5 lb.), 125 mg (1 tsp. of a 125-mg/5-ml suspension in two divided doses)
- Children 25 kg (55 lb.), 250 mg (2 tsp. of a 125-mg/5-ml suspension in two divided doses)

Ketoprofen

Similar to ibuprofen and naproxen sodium, ketoprofen was first approved for use as a prescription drug. In 1995, it was approved for OTC sales by the FDA as Orudis®-KT and Actron®. Ketoprofen is a phenylpropionic acid, in the same chemical family as ibuprofen and naproxen sodium. As with ibuprofen and naproxen sodium, it possesses minimal anti-inflammatory activity at the OTC dose.

Ketoprofen is available OTC as a 12.5-mg tablet and is dosed as a second-line analgesic at 12.5 mg every 4 to 6 hours for adults. If pain is not relieved within 1 hour, a second tablet may be taken. Doses above two tablets (i.e., 25 mg) are not considered appropriate for OTC use. Additionally, without prescription, doses should not exceed six tablets (75 mg) in a 24-hour period. It is not recommended for children under 16.

At the OTC dose, ketoprofen is effective in managing pain associated with colds, minor back discomfort, toothache, menstrual cramps, muscle aches, and minor pain associated with arthritis.

Peak serum concentrations of ketoprofen are reached in 30 minutes to 2 hours, and almost 100% of the drug is absorbed. Although it has a rapid onset, its relatively short duration of action necessitates dosing three to four times daily. As with other NSAIDs, the chief adverse effects are associated with GI irritation; however, these problems can

be minimized by following the procedures described below. Additionally, concomitant use with antacids does not appear to affect the absorption of ketoprofen.

Ketoprofen has been assigned by the FDA to Pregnancy Category B, which means that animal studies are negative for fetal abnormalities, or animal studies are positive while human studies are negative. Its appearance in breast milk is insignificant. It is not recommended for children under 12 on an OTC basis; however, if absolutely necessary, the recommended prescription doses for children are as follows:

- Children 3 months to 14 years of age, 0.5–1.0 mg per kilogram of weight for fever
- Children with juvenile chronic arthritis, 25–50 mg

MODERATE PAIN

Third-Line Pharmacotherapy

As the pain complaint reaches the moderate level, the dose of aspirin, acetaminophen, ibuprofen, naproxen sodium, or ketoprofen is increased as third-line therapy. Seldom does a tension-type headache respond to the equivalent of 650 mg aspirin. The dose will need to be increased to the equivalent of 1000 mg aspirin to expect success. Lower doses will simply diminish the level of appreciation the patient has for OTC pharmacotherapy; thus, the prudent clinician best not be too timid to begin therapy at the equivalent of 1000 mg aspirin. No specific NSAID has been shown to be more effective or less toxic than others (Brooks & Day, 1991).

With increased dosing levels of NSAIDs, the procedure moves from an OTC recommendation to a prescription drug. NSAIDs account for 3.8% of all prescriptions written ("Antiarthritic," 1992), and the clinician must be ever-mindful that these prescriptions are responsible for some 20 to 25% of all adverse drug reactions reported. The chief complaint is GI irritation. With increased dosing levels, there will be an associated increase in the likelihood of an adverse effect, particularly GI irritation. Patients should be instructed to take their NSAIDs with a full glass of water and not to lie down for 30 minutes after dosing. A small amount of food may be taken with the drug. This simple procedure will significantly decrease the incidence of GI-related distress.

Recently, a new category of NSAIDs has become available. These drugs are termed COX-2 inhibitors. This term derives from their ability to selectively inhibit just the COX-2 enzyme in preference to both the COX-1 and COX-2 enzymes. This difference inhibits the cascade that converts substrates to the prostaglandins that enhance pain transmission and provoke inflammation, while not blocking the production of the prostaglandins that cause platelets to aggregate (clump) and not blocking the production of the prostaglandins that protect the gastrointestinal mucosa. Therefore, these new drugs are superior in their adverse effect profiles in that they do not significantly provoke gastrointestinal irritation. However, they do not contribute to platelet antiadhesion, so they do not possess the cardiovascular effects of aspirin and traditional NSAIDs.

The three COX-2 inhibiting drugs most widely available in the United States are celecoxib (Celebrex®), rofecoxib (Vioxx®), and meloxicam (Mobic®). Celecoxib and rofecoxib are excellent choices for the patient who is experiencing GI irritation with other NSAIDs. These are also excellent choices for the patient for whom the NSAID dose must be pushed upward, often provoking GI irritation with traditional NSAIDs. These drugs are indicated for osteoarthritis, and rofecoxib is indicated for pain, although both should be considered for pain. Meloxicam is significantly less COX-2 selective; therefore, it should be considered a third choice.

Fourth-Line Pharmacotherapy

If the increased doses of the first- and second-line therapies (i.e., third-line therapy) are not successful, an alternate NSAID may be substituted, and COX-2 inhibitors are suggested. It is recommended that the second NSAID be selected from a different chemical family. Chemical families are described in Table 36.1. Prescription-strength ibuprofen, ketoprofen, naproxen sodium, and naproxen are the most commonly employed selections. The drug-specific information related to effective use of the NSAIDs is summarized in Table 36.2.

As previously mentioned, when NSAIDs are used, GI irritation is a concern. Studies have shown that up to 4% of patients treated with NSAIDs on a long-term basis will develop GI complications, including ulcers, bleeding, or perforation. The elderly and patients with a history of peptic ulcer disease are at highest risk.

Hepatotoxicity and nephrotoxicity are the only major adverse drug reactions with NSAIDs (GI distress is considered a minor adverse effect). Therefore, kidney and liver function should be monitored, especially in patients taking long-term doses, very large short-term doses of NSAIDs, or concomitant doses of acetaminophen. Also, significant GI irritation is widely reported in some patients taking even small amounts of NSAIDs. In this case, it appears that an individual sensitive to one NSAID will be sensitive to all NSAIDs. It is the responsibility of the clinician to recommend discontinuation of NSAID therapy before GI-related problems lead to significant GI bleeding. Even the non-oral form of these drugs can cause significant GI irritation; therefore, GI effects appear to be not just a local effect of the drug on the GI mucosa.

Injectable NSAIDs (only two are currently available) are not indicated for moderate pain, even if the pain is acute and would appear to demand a treatment that is more

TABLE 36.1
Family and Chemical Classes of Commonly Used NSAIDs

Chemical Class	NSAID
Acetylated carboxylic acid	Aspirin
Nonacetylated carboxylic acids	Choline salicylate
	Diflunisal
	Magnesium salicylate
	Salicylamide
	Salsalate
	Sodium salicyiate
Acetic acids	Carprofen
	Fenbufen
	Fenprofen
	Flubiprofen
	Ibuprofen
	Ketoprofen
	Ketorolac
	Pirofen
	Indoprofen
	Naproxen
	Naproxen sodium
	Oxaprozin
	Suprofen
	Tiaprofenic acid
Fenamic acids	Flufenamic acid
	Mefenamic acid
	Meclofenamic acid
	Meclofenamate (fenamate)
	Niflumic acid
Enolic acids	Isoxicam
	Oxyphenbutazone
	Phenylbutazone
	Piroxicam
	Sudoxicam
	Tenoxicam
Nonacidic compounds	Bufexamac
	Nabumetone
	Proquazone
COX-2 inhibitors	Celecoxib
	Rofecoxib
	Meloxicam
Pyrole acetic acid	Indomethacin

immediate in action than the oral medications. It is important to remember that the drug is to be matched to the category, and moderate pain is not matched with the injectable NSAIDs. These dosage forms are addressed later in another pain intensity category.

Fifth-Line Pharmacotherapy

If the clinician believes that an oral medication is appropriate and also believes that a narcotic is indicated for moderate pain, the combination of aspirin or acetaminophen with codeine is an appropriate first choice. In a study of 100 patients, codeine sulfate (65 mg) and aspirin (650 mg) was judged by the patients to be superior in its pain-alleviating activity when compared with (1) oxycodone (9.75 mg) and aspirin (650 mg); (2) pentazocine hydrochloride (25 mg) and aspirin (650 mg); (3) propoxyphene napsylate (100 mg) and aspirin (650 mg); (4) promazine hydrochloride (25 mg) and aspirin (650 mg); (5) pentobarbital sodium (32 mg) and aspirin (650 mg); (6) caffeine (65 mg) and aspirin (650 mg); (7) ethoheptazine citrate (75 mg) and aspirin (650 mg); (8) aspirin (650 mg) alone; and (9) placebo (Moertel, et al., 1974). When codeine is added to aspirin or acetaminophen, the side effects of the opiates present themselves.

Mechanism of Action of the Opioids

Drugs in the opiate family exert their analgesic and nonanalgesic effects secondary to their binding and activation of stereospecific receptors, predominantly in the central nervous system, but also in the periphery. The three most important opiate receptors are mu, kappa, and delta (Collin, et al., 1993). The sigma (PCP receptor) should not be considered an opiate receptor in that its activation is not reversible by employment of an opiate antagonist.

Opioid drugs have a high affinity for the mu receptors, which are located principally at supraspinal sites. Mu activation produces analgesia, respiratory depression, euphoria, and physical dependence. It has been determined that the relative potency of an opiate is a function of its affinity (strength of binding) to the mu receptor (Chen, Irvine, Somogyi, & Bochner, 1991).

The opioid receptors of the kappa variety are located principally within the spinal cord. Kappa activation mediates spinal analgesia, miosis, and sedation (Sabbe & Yaksh, 1995). Delta binding sites promote analgesia, yet their ultimate utility in pain management has yet to be fully determined.

Opioid agonist drugs fully occupy and activate the opioid receptors, mimicking the natural effects of endogenous endorphins and enkephalins. Thus, the greater the quantity of agonists administered, the more significant the analgesia and the more pronounced the adverse effects. Agonists are not limited by a ceiling effect.

The most bothersome of these side effects are the GI effects. It is common for patients taking these combinations to complain of constipation and gastric distress, as well as nausea. Because constipation occurs secondary to the stimulation of the opioid receptors, bulk-forming laxatives are of little benefit. Stimulant or irritant laxatives will be necessary to promote GI motility. Patients should be warned of the possibility of constipation, and it is prudent to suggest an appropriate laxative. In the category of stimulant/irritant laxatives,

TABLE 36.2
Commonly Used NSAIDs and Their Prescription Doses

Generic Name	Trade Name	Usual Prescription Dose (mg)	Dosing Schedule (h)
Aspirin	Various	325–1000	4–6
Celecoxib	Celebrex®	100–200	12
Choline magnesium trisalicylate	Trilisate®	750–1000	12–24
Diclofenac potassium	Cataflam®	50–200	8
Diclofenac sodium	Voltaren®	50	8
Diflunisal	Dolobid®	250–500	8–12
Etodolac	Lodine®	200–400	6–8
Fenoprofen	Nalfon®	400	4–6
Flubiprofen	Ansaid®	50–100	8
Ibuprofen	Motrin®, Advil®, Nuprin®	200–800	4–8
Indomethacin	Indocin®	25–50	8–12
Ketoprofen	Orudis®	25–75	6–12
Ketorolac	Toradol®	30–60 i.m. stat, then 15–30 mg every 6 hours, not to exceed 150 mg 1st day or 200 mg/day thereafter	As described
Meclofenamate	Meclomen®	50–100	4–6
Mefanamic acid	Ponstel®	250	6
Nabumetone	Relafen®	500–1000	4–6
Naproxen	Naprosyn®	250–500	12
Naproxen sodium	Anaprox®	275–550	12
Oxaprozin	Daypro®	1200–1800	24
Phenylbutazone	Butazolidin®	100	6–8
Piroxicam	Feldene®	10–20	12–24
Rofecoxib	Vioxx®	12.5–25	24
		50 (acute pain)	24
Salsalate	Disalcid®	1000–1500	8–12
Sulinac	Clinoril®	150–200	6–8
Tolmetin	Tolectin®	200–800	6–8

the most frequently recommended choices are, in order, Dulcolax®, Correctol®, Ex-Lax®, and Senokot® ("Pharmacists' Top Choices," 1996). The popular bulk-forming laxative Metamucil® would be of little or no value in opioid-induced constipation.

Sedation can also occur; therefore, patients should be warned to take precautions in driving or operating machinery. Patients should also be cautioned about the additive central nervous system (CNS) depressant activity when alcohol is consumed.

Although codeine is an effective agonist, it has a significant limitation in its unique activity. It appears to act as an agonist/antagonist or partial agonist (see explanation underseventh-line pharmacotherapy) in that it yields added analgesia up to approximately 65 mg. Doses exceeding 65 mg appear to produce no adsded benefit yet significantly increase the complications of adverse effects, especially constipation.

Sixth-Line Pharmacotherapy

If the outcomes of moderate pain management with codeine and codeine-like combinations are not satisfactory, consideration should be given to the use of tramadol (Ultram®). Tramadol has the unique ability to activate the mu-opioid receptor as well as inhibiting norepinephrine reuptake, much like the newer antidepressants. In doses of 50 to 100 mg every 4 to 6 hours, not to exceed 400 mg/day, this drug has been quite effective in some patients. However, because it has far less affinity for opioid receptors when compared with the classic opioids, it should not be given in combination with other narcotics.

Tramadol is also given intravenously (i.v.), intramuscularly (i.m.), subcutaneously (s.c.), and rectally in 100-mg doses. It can be administered to children over the age of 1 year at a dose calculated on the basis of weight (1–2 mg/ kg).

Because of tramadol's unique pharmacologic activity, it may prove to be effective in patients who have a combination of nociceptive and neuropathic pain syndromes. As with other antineuropathic pain management regimens, the effects of tramadol may be delayed, requiring a 10-day trial before final management decisions are made.

SEVERE PAIN

Seventh-Line Pharmacotherapy

For pain conditions that are considered severe, more potent pharmacotherapy is necessary. Three rather obvious criteria should be considered an indication for aggressive treatment of pain with a narcotic agent such as morphine: (1) if the clinician has previously tried non-narcotics in reasonable doses and has achieved less than effective results, (2) if the pain is considered significantly more debilitating than moderate pain, and (3) if the patient has a history of pain relief when narcotics are used. If any of these criteria are met and rapid relief is required, then a narcotic is appropriate.

Of the parenteral narcotics available, morphine sulfate is clearly the standard. Although it should be remembered that oral dosage forms are preferred unless the patient is in acute distress, the clinician should not hesitate to administer morphine sulfate injection in severe acute pain situations.

Morphine is an excellent narcotic analgesic because it is a pure agonist. That is, it attaches to the narcotic receptors and activates them fully. Therefore, the greater the amount of morphine administered, the greater the number of narcotic receptors occupied, and the greater the analgesia. Agonists have no therapeutic ceiling (except for codeine) and thus are effective for long periods of time as the dose is steadily increased to achieve greater pain relief. Therefore, they are very effective in progressive diseases such as cancer (malignant pain).

Mixed agonist-antagonists fully occupy both principal receptors but activate just the kappa receptors, blocking activation of the mu component of the receptor complex. Therefore, these drugs (e.g., pentazocine, nalbuphine, butorphanol) exhibit a ceiling effect, and increased doses do not provide increased analgesia above the ceiling level. This is because no matter how much of the mixed-action drug is given, the blocked component of the occupied receptor complex cannot be activated to provoke increased analgesia.

Partial agonist narcotics (e.g., buprenorphine) act similarly to mixed agonist-antagonists in that they activate only part of the receptor complex (the mu site). They do not occupy the kappa sites; however, by partially occupying the complex, they effectively block the occupation and activation of the kappa narcotic receptor component of the receptor complex.

Because of the nature of receptor occupation, there is no justification for the use of more than one type of narcotic (i.e., agonist, agonist/antagonist, partial agonist). If an agonist were to be used in conjunction with a mixed-action or partial agonist, the results would not be favorable for (enhanced) analgesia. In fact, a diminished clinical response to the agonist could be anticipated because fewer receptor sites would be available for binding and activation. Narcotic characteristics and equivalencies are summarized in Table 36.3.

Acute Severe Pain Management

For acute severe pain, unlike other drug regimens in which the practitioner starts off at a relatively low dose and gradually ascends to higher doses or adds other drugs until the

TABLE 36.3
Commonly Used Opioids and Their Prescription Doses

Opioid	Trade Name	Opioid Type	p.o./i.m. Potency	Usual Oral Dose
Morphine		Agonist	3–6	10–100 mg every 4 h
Morphine extended release	MSContin® RoxanolSR® Kadian®	Agonist	NA	15–100 mg every 12 h
Codeine		Agonist	NA	30–65 mg every 3–4 h
Methadone	Dolophine®	Agonist	2	5–20 mg daily
Hydromorphone	Dilaudid®	Agonist	5	4–8 mg every 4–6 h
Hydrocodone	Lorcet® Lortab® Vicodin®	Agonist	NA	30 mg every 3–4 h
Oxycodone	Roxicodone® Percocet®, Percodan® Tylox®	Agonist	NA	30 mg every 3–4 h
Oxymorphone	Numorphan®	Agonist	NA	NA (i.m. 1 mg every 3–4 h)
Pentazocine	Talwin®	Agonist/antagonist	3	50–150 mg every 3–4 h
Nalbuphine	Nubain®	Agonist/antagonist	NA	(i.m. 10 mg every 3–4 h)
Butorphanol	Stadol®	Agonist/antagonist	NA	NA (i.m. 2 mg every 3–4 h)
Buprenorphine	Buprenex	Partial agonist	NA	NA (i.m. 0.3–0.4 mg every 6–8 h)

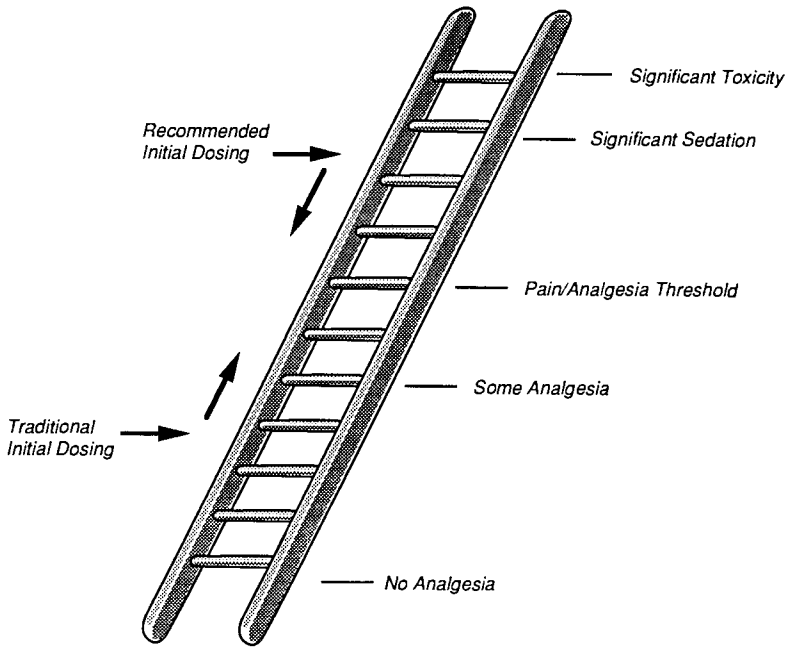

FIGURE 36.1 Analgesic dosing ladder.

condition is managed (e.g., hypertension, hyperlipidemia), the drug regimen should be equal to the task of alleviating the pain immediately. This philosophy of aggressive dosing, termed "descending the ladder," is graphically illustrated in Figure 36.1. It has gained acceptance, at least partially, because too often fears of addiction and respiratory depression have led to too timid dosing of narcotics (Marks & Sachar, 1973). Simply stated, a dose that is felt to be adequate should be administered, and the subsequent doses are slightly tapered down until the pain threshold is discovered. Then, the dose is adjusted just slightly upward to alleviate the pain on an around-the-clock basis without overdosing. This system should lead to lower maintenance doses because the patient is rapidly rather than gradually brought into the realm of comfort. Care must be taken for the opioid-naïve patient.

A usual initial dose of parenteral morphine sulfate (i.e., i.m. or s.c.) for an adult is 10 to 20 mg. If an effective oral dose of morphine is already established, then one sixth to one third of that dose should be administered parenterally. If the pain is excruciating, then a larger dose is appropriate before beginning to descend the ladder. After the initial dose, the patient will need repeated doses every 4 to 6 hours. With parenteral morphine, the patient should begin to feel relief within a few minutes. If morphine is going to be continued, it should be changed to an oral dosage form, as there is no real advantage to continuation of the parenteral form (Twycross, 1974). For long-term maintenance, consideration should be given to long-acting morphine sulfate (MSContin®, RoxanolSR®). The long-acting dosage form appears to provide 12-hour relief at a dosage level of approximately 75% of the immediate-release oral dosage forms (Cundiff, et al., 1988).

As with all aggressive treatment regimens, the clinician should be most diligent in monitoring side effects, especially because the opiates have CNS depressant activity. Sedation should be carefully evaluated. Significant sedation will present itself at narcotic levels above the pain threshold. The ideal dose will be achieved if sedation is not significant and pain control is maintained. Sedation later in therapy may be an indication of an accumulation toxicity effect. If this is the case, it may be difficult to cut back the dose late in therapy without causing the pain to recur. Short of reinitiating the dosing regimen, the use of amphetamines or methylphenidate (Ritalin®) may be contemplated, especially in terminal care. While the use of one drug to cover up the adverse effects of another is considered irrational polypharmacy, for patients in acute distress, intractable pain, or for the terminally ill, the use of these CNS stimulants may be indicated as long as the sedation is simple sedation and not mental confusion, symptomatic of a more serious toxicity.

Respiratory depression is also a fear of many clinicians who administer potent doses of narcotics. The fear of respiratory depression appears to be misplaced. Although respiratory depression is fairly easy to demonstrate in non-pain patients, significant respiratory depression is not common in pain patients receiving narcotics (Walsh, et al., 1981). The adverse drug effects commonly associated with chronic narcotic use, including addiction and tolerance, will be addressed in the next section on chronic severe pain management.

Epidural injection of narcotics is another method of both rapid and longer-acting narcotic administration. Epidural (or extradural) injection of morphine will result in almost immediate pain relief, and that relief will continue for approximately four times the duration expected with oral or i.m. administration (Leavans, et al., 1982). The narcotic injection must be preservative-free. The logic associated with this form of drug delivery is that the narcotic, usually morphine, can be given nearer to the CNS to work directly on the receptors. As with other parenteral routes, epidural injection of morphine eliminates the first-pass effect of hepatic degradation, thereby allowing for lower doses to be equally effective as higher oral doses. Additionally, epidural injection may allow for even slightly lower doses than required for other parenteral narcotics because of the greater general systemic absorption of i.m.- or s.c.-administered doses. Therefore, the epidural/extradural route has been shown to have significant advantages for the obstetric pain patient. However, to date, few additional benefits have been achieved with this route for other pain patients, and adverse effect profiles for these administrations appear to be no better than those for conventional injections (McQuay, 1989). Significant itching has also accompanied epidural injections of narcotics. This seems to be alleviated with the combined use of hydroxyzine (Vistaril®, Atarax®) with the narcotic.

Chronic Severe Pain Management

When a narcotic is indicated in chronic pain care, morphine sulfate is the narcotic of choice. There are no advantages to parenteral administration of morphine in chronic pain care, except in the few cases where the patient cannot take or cannot tolerate oral medications. The initial oral dose of morphine sulfate is variable, based upon the clinician's assessment of the severity and nature of the chronic pain. Doses of from 10 to 100 mg may be required. Tablet strengths customarily available are 10, 15, 30, and 100 mg. There are no established upper limits of the dose to be given to a patient suffering from severe chronic pain. Many clinicians feel that any dose that helps the patient in maintaining a relatively comfortable state, without causing mental confusion or significant respiratory depression, is justified. Because of the nature of the opioid receptors and pure agonist narcotics (e.g., morphine), raising the dose will always increase the analgesia (i.e., no therapeutic ceiling). Oral morphine will have to be redosed every 4 hours to achieve continued pain relief. Sustained-release, 12-hour oral morphine formulations (MSContin®, RoxanolSR®) have proven to be very effective, and they have been shown to actually diminish the 24-hour total dose of morphine required. Recently, Kadian®, a sustained-release, single-daily-dose (24-hour) formulation, has been approved by the FDA.

Dosing Schedule

Some clinicians believe that when chronic pain is not manifesting itself, the patient should not be taking medication. Therefore, these practitioners feel that chronic pain medication should be administered on an as-needed (prn) basis. It has now been demonstrated that around-the-clock administration of pain medication provides superior analgesia. Not allowing the pain symptoms to recur causes less mental and physical trauma and can actually lead to less medication used with better pain control. Pain memory (when the patient begins to feel pain and anticipate continued pain distress) can be eliminated when the pain control pharmacotherapy is regularly scheduled.

Toxicity

The extended use of opioids in chronic pain management has not led to widespread toxicity in cancer patients (Kreek, 1973, 1978).

Respiratory Depression

Activation of the mu-opioid receptor will decrease the responsiveness of the respiratory centers (Mueller, et al., 1982; Martin, 1967), along with increasing analgesia. However, in chronic dosing, the clinical consequences of this are limited (Walsh, et al., 1981). It appears that if the opioid is not causing clouded thought processes, respiratory risk is minimal (Lipman, 1988).

Tolerance and Addiction

With chronic narcotic use, there persists a fear of tolerance and addiction. Clearly, these fears are overemphasized. In studies, addiction has been shown to be of minor concern in the patient with chronic pain. In one study, nearly 12,000 pain patients receiving narcotics were followed, and of these, only four patients became addicted (Porter, et al., 1980). Tolerance does not appear to be a common characteristic among pain sufferers in acute distress. Increasing doses of narcotics is likely attributable to the normal progression of the disease process rather than tolerance in acute pain cases. However, in chronic conditions, tolerance is significant. Patients on long-term narcotic therapy will require increased doses, unless therapeutic and receptor-stimulation substitution is attempted.

Drug dependence is not a significant problem in the pain patient population. In the large study of over 12,000 pain care cases, only 0.03% were inadvertently addicted to their narcotic drugs. Of course, overdependence on narcotics without a real need for them is indefensible; however, a summary of several studies indicates that toxicity and addiction are not significant problems, and efficacy is achievable in chronic nonmalignant narcotic pharmacotherapy (Portenoy, 1996).

Patient-Controlled Analgesia

Another system that has gained popularity is patient-controlled analgesia (PCA). A PCA device, about the size of a deck of playing cards, is programmed to deliver regular doses of a narcotic directly into the patient (usually i.m.), and the microprocessor is adjusted to a set dose for drug delivery around the clock. Additionally, the PCA device allows the patient to administer bolus injections of medication when the pain level increases. The device will not allow the patient to overdose, as limits are programmed into the portable device. The more sophisticated models can give the practitioner a printout of doses administered, including bolus doses administered by the patient. Studies have shown that PCA devices are very effective in controlling pain, with minimal side effects (White, 1988). A list of several commercially available PCA devices is given in Table 36.4. Most of these devices are simple microprocessors with small battery-driven motors that activate screw-driven plungers that inject predetermined amounts of medication into the muscle. Some clinicians prefer to add a steroid, such as dexamethasone (0.02 mg/ml), to the narcotic to limit needle trauma and inflammation. Also, the implant site should be rotated about every 4 days. With PCA devices, the patient has a renewed sense of being in control of his or her pain, which can be an exhilarating and liberating feeling for most chronic pain sufferers.

Pain Cocktails

The original pain cocktail is Brompton's mixture, dating back to the 1800s. It was formulated using morphine, cocaine, alcohol, and chloroform. It is now thought that the cocaine was used to numb the throat, and the chloroform was used to give the mixture a bitter taste, which was a requirement for all British medicines in those times. Because these two ingredients are not appropriate (and chloroform is not permitted in medications in the United States), contemporary pain cocktails, usually labeled as "hospice mixture," contain just morphine sulfate in solution. Some pain clinics allow their pain cocktails to include any other patient-specific medications that are physically compatible with the hydroalcoholic mixture. Frequently, antidepressant medications will be added but these are not required to justify the label "pain cocktail." The addition of other agents has been shown to have no demonstrable advantage over morphine sulfate solution alone.

OPIOID-INSENSITIVE PAIN
