By definition, chronic pain that is opioid insensitive does not respond to narcotic analgesics. Usually, this pain is either aberrant or organic, with nerve compression or nerve destruction (McQuay, 1989). Nerve destruction is common in accident-related trauma, tumor-related disease, post-herpetic neuralgia, and trigeminal neuralgia. Patients that provide the greatest clinical challenge present with both opioid-sensitive (e.g., nociceptive) and opioid-insensitive (e.g., neuropathic) pain at different sites. With nerve-related chronic pain that is opioid insensitive, unconventional drug therapy is indicated. Trials with tricyclic antidepressants and anticonvulsants, such as

carbamazepine (Tegretol®) and gabapentin (Neurontin®) have been shown to be effective in neuropathic and other opioid-insensitive pain syndromes.

Antidepressants

While tricyclic antidepressants remain the mainstay in pharmacotherapy for neuropathic and opioid-insensitive pain, consideration must be given to the newer serotonin- and norepinephrine reuptake inhibitors, of which venlafaxine (Effexor®) is the prime example. This category of antidepressant appears to mitigate neuropathic pain while presenting a minimum of side effects. It would appear that these drugs will receive significantly greater attention in pain care in the future.

Tricyclic antidepressants are rather curious analgesics. Clearly, antidepressant medications are effective in the treatment of endogenous depression. Because one of the symptoms of depression is chronic pain, usually vague in description, antidepressants exert an analgesic effect indirectly by combating the depressive illness. It has been postulated that tricyclics also have an intrinsic analgesic activity which assists in chronic pain management. This activity is secondary to the ability of tricyclics to effectively block the reuptake of serotonin. Additionally, tricyclics may also have a potentiating effect on narcotics, thereby facilitating chronic pain management. Also, tricyclics are effective for neuropathic pain. The analgesic activity of the tricyclics is most likely a combination of all three phenomena. Studies have demonstrated their effectiveness in the management of chronic pain in hundreds of patients (Tollison & Kriegel, 1988). The analgesic activity of tricyclics occurs within 5 to 7 days, rather than the 10 to 14 days required for their antidepressant effect. Usually, success is achieved at slightly lower than normal antidepressant doses.

Anticonvulsants

Carbamazepine (Tegretol®) is also often effective in painful conditions not responsive to narcotics. It is dosed at 200 mg three times daily to start and then increased to as much as 800 mg daily. It is very effective in trigeminal neuralgia at higher doses.

Gabapentin (Neurontin®), another anticonvulsant, is similarly effective when dosed from 300 to 500 mg, with reports of efficacy at 900 to 1200 mg daily in divided doses (Rosner, Rubin, & Kestenbaum, 1996). Responsive patients most often describe diminished levels of pain within 48 hours.

Other Drugs

For opioid-insensitive conditions not responsive to either tricyclics or these two anticonvulsants, mexiletine (Mexitil®) should be considered. It is dosed at 450 mg daily. It has been particularly helpful in neuropathic pain described as stabbing, burning, or warm sensations. Mexiletine should be given for a full week before pain management outcomes are evaluated.

Clonazepam (Klonopin®), dosed at 0.5 mg three times daily, is an alternative. It has been effective in combating phantom limb pain (Borg & Krijnen, 1996). It is also an agent that should be considered in combination with a tricyclic antidepressant in suspected neuropathies that are particularly nonresponsive to conventional treatments.

CHRONIC MALIGNANT PAIN

The World Health Organization (WHO) has developed a three-step approach to pain relief for the cancer patient. With malignancies that are customarily painful, the pain syndrome begins as mild pain, progresses to moderate pain, and further progresses to severe pain as the disease progresses. The three-step approach corresponds to the progressive nature of cancer. This approach is summarized in Figure 36.2 and described below.

Step 1: Aspirin, acetaminophen, or an NSAID is to be used in combination with an adjuvant for initial analgesia in malignant pain management. Analgesic adjuvants are not restricted to cases of malignant pain. These medications include tricyclic antidepressants, antihistamines, benzodiazepines, caffeine, dextroam-

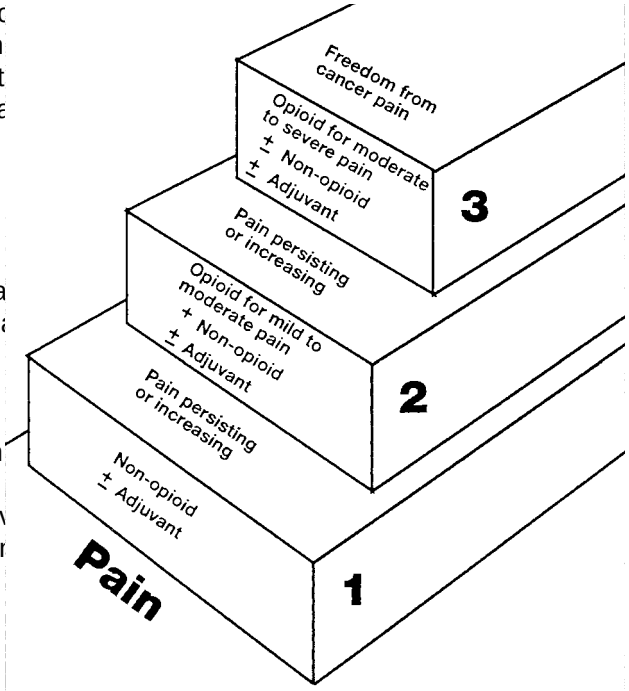

FIGURE 36.2 The WHO three-step analgesic ladder. (From World Heath Organization, 1996. Reproduced with permission.)

phetamine, steroids, laxatives, phenothiazines, and anticonvulsants. With the exception of tricyclic antidepressants and anticonvulsants (which provide direct and indirect pain relief), these analgesic adjuvants are given for their indirect benefits in pain management. The various reasons for using analgesic adjuvants include (1) direct analgesia (e.g., tricyclic antidepressants, anticonvulsants); (2) potentiation of narcotic analgesia (e.g., tricyclic antidepressants, caffeine, dextroamphetamine); (3) combating nausea (e.g., antihistamines, phenothiazines), alleviating anxiety related to pain syndromes (e.g., benzodiazepines, phenothiazines); (4) counteracting sedation (e.g., amphetamines); (5) alleviating nerve compression (e.g., steroids); (6) alleviating constipation (e.g., laxatives); and (7) alleviating itching (e.g., antihistamines).

Step 2 If the drugs used in the first step are ineffective, or become ineffective, in alleviating the pain, the initial drug should be continued in combination with an oral narcotic and adjuvant. In this step, codeine is the narcotic of choice in combination with aspirin, acetaminophen, or an NSAID. As for all persistent pain, the clinician must remember to recommend regular dosing on an around-the-clock basis. Of course, the patient need not be awakened for dosing during the night if sleeping. However, initial morning dosing should begin immediately upon awakening.

Step 3: When the patient fails to respond to second-step medications, these should be discontinued in favor of a more potent oral narcotic. Again, the preferred oral narcotic for cancer pain is morphine, in an oral dose sufficient to maintain patient comfort. This dose can be progressively increased without limit — all the while assessing the patient's respiration, mental status, and wakefulness. In cases of significant pain that requires very high morphine dosing, patients can be given stimulants (e.g., methylphenidate (Ritalin)) to allow them to attend to personal and family-related business in the latter stages of a terminal malignancy. There is simply no reason why terminal cancer patients should be allowed to spend their final days in pain. Physicians will surely balk at the prospect of huge doses of morphine, but the quality of life is far greater an issue than unfounded concern for the numeric value of the milligrams in a dose of analgesic medication.

MINOR CHRONIC MUSCLE PAIN

Muscle pain that is minor but bothersome can be treated topically if traditional oral analgesic and anti-inflammatory agents prove ineffective. These topical analgesic agents are classified as counterirritants, and they exhibit analgesic action by dilation of the vasculature and an increase in the blood flow to the affected muscle. The FDA advisory panel on nonprescription topical analgesics has labeled the following product ingredients as relatively more potent counterirritants, as well as safe and effective: allylisothiocyanate, ammonia water, methyl salicylate, and turpentine oil, capsaicin, capsicum, capsicum oleoresin. Many patients achieve substantial muscle pain relief with the appropriate use of these counterirritants, but patients should be warned to discontinue use of these products if excessive irritation develops.

SUMMARY

Many pain patients are undertreated because of unwarranted fears of adverse drug reactions on the part of clinicians, including respiratory depression, tolerance, and addiction. These effects would be extremely problematic; however, they do not seem to occur often enough to warrant timidity in the pain management approach. Pain is an excessively debilitating medical and psychologic problem that warrants aggressive initial treatment and diligent continued care.

The Role of Neural Blockade in the Management of Common Pain Syndromes

Steven D. Waldman, M.D., J.D.

INTRODUCTION

Pain is the most common medical complaint of civilized man. The Nuprin Pain Report estimates that there are over 70 million Americans with pain severe enough to require medical care (Saper, 1987). The cost of pain to society in terms of medical bills, lower productivity, and absenteeism is staggering. The purpose of this chapter is to provide the pain management specialist with an overview of the role of neural blockade in the management of common pain syndromes encountered in clinical practice. Practical suggestions to simplify the care of these sometimes-difficult patients are also included.

Neural blockade with local anesthetic can be used as a diagnostic procedure to identify specific pain pathways and to aid in the differential diagnosis as to the origin and site of pain. Neural blockade with local anesthetics can also be used in a prognostic manner to predict the effects of destruction of a given nerve. In addition to helping determine the efficacy of destruction of a given nerve, prognostic neural blockade can allow the patient an opportunity to experience the numbness, loss of function, and other side effects that may attend the destruction of a nerve. Therapeutic neural blockade with a local anesthetic, combined with steroids, or rarely a neurolytic agent, can be useful in relieving a variety of painful conditions. The addition of steroids to nerve blocks has extended the utility of this powerful pain-relieving modality. Steroids are thought to improve the efficacy of neural blockade via their ability to stabilize membranes and their salutory effect on the inflammatory process via both the prostaglandin and leukotriene cascades. Neural blockade should not be viewed as a stand-alone treatment for most pain syndromes, but should be intelligently integrated into a comprehensive treatment plan.

SYMPATHETIC NERVE BLOCKS

Sphenopalatine Ganglion Block

Indications

Blockade of the sphenopalatine ganglion with local anesthetic is useful in the management of acute migraine, acute cluster headache, and a variety of facial neuralgias, including Sluder's, Vail's, and Gardner's syndromes (Diamond & Dalessio, 1982; Kitrelle, Grouse, & Seybold, 1985; Phero & Robbins, 1985a; Waldman, 1996a, 1998a). This technique may also be useful in status migrainous and chronic cluster headaches.

Anatomy

The sphenopalatine ganglion (pterygopalatine, nasal, or Meckel's ganglion) is located in the pterygopalatine fossa, posterior to the middle turbinate (Katz, 1994a; Waldman, 1998a). It is covered by a 1- to 5-ml layer of connective tissue and mucous membrane. The ganglion is a 5-mm triangular structure comprising the largest group of neurons in the head, outside the brain. Major branches extend from the sphenopalatine ganglion to the trigeminal nerve, carotid plexus, facial nerve, and the superior cervical ganglion.

0-8493-0926-3/02/$0.00+$1.50

Technique

Sphenopalatine ganglion block is accomplished by the application of local anesthetic to the mucous membrane overlying the ganglion (Waldman, 1996a, 1998a) (see Figure 37.1). The patient is placed in the supine position. The cervical spine is then extended, and the anterior nares space is inspected for polyps, tumor, or foreign body. A small amount of 2% viscous lidocaine, 4% topical lidocaine, or 10% cocaine solution is then instilled into each nostril. The patient is asked to inhale briskly through the nose. This draws the local anesthetic into the posterior nasal pharynx, serving the double function of lubricating the nasal mucosa and providing topical anesthesia, allowing easier passage of 1/2 in. cotton-tipped applicators. These applicators are saturated with the chosen local anesthetic and then advanced along the superior border of the middle turbinate until the tip comes in contact with the mucosa overlying the ganglion. Then, 1.2 ml local anesthetic is placed along the cotton-tipped applicator in each nostril. The applicator acts as a tampon, allowing the local anesthetic to remain in contact with the mucosa overlying the ganglion and then diffuse through the mucosa to the ganglion. The applicators are removed after 20 minutes. The patient's pulse, blood pressure, and respirations are monitored for untoward effects secondary to sphenopalatine ganglion block.

Practical Considerations

Clinical experience has shown that this technique can be useful in aborting the acute attack of migraine or cluster headaches (Diamond & Dalessio, 1982; Kitrelle, Grouse, & Seybold, 1985; Waldman, 1996a, 1998a). Its simplicity lends itself to use at the bedside, in the emergency room, or in the headache or pain clinic. Although some experienced in this technique feel that cocaine represents a superior local anesthetic for this indication, the various political issues surrounding the use of this controlled substance make the use of other local anesthetics such as lidocaine a more practical option. For the acute headache sufferer, this technique can be combined with oxygen inhalation via mask through the mouth while the cotton-tipped applicators are in place. Experience indicates that this technique will abort approximately 80% of acute migraine or cluster headaches. This technique is utilized on a daily basis for chronic headache and facial pain conditions, with the end point being total pain relief. The author's clinical experience suggests that pain relief will generally occur within five to six daily sphenopalatine ganglion blocks.

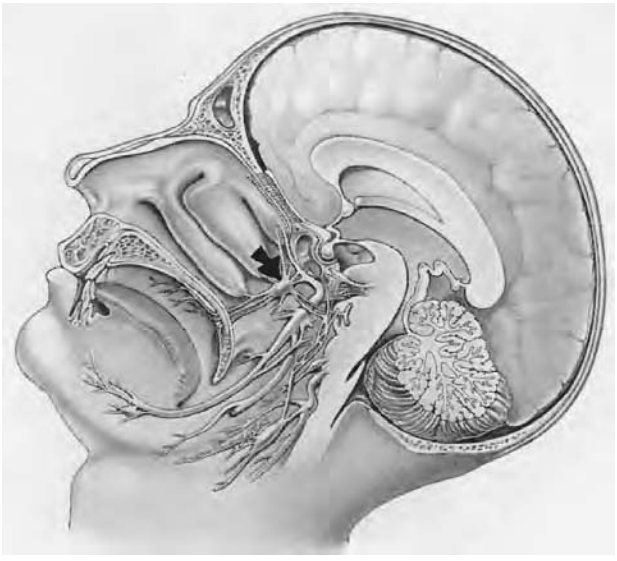

FIGURE 37.1 Sphenopalatine ganglion. (Courtesy of Astra Pharmaceutical Products, Inc. © Anazak Productions.)

Complications

The major complication with this technique is epistaxis. This complication occurs more frequently during the winter months when forced-air heating may cause drying of the nasal mucosa. Because of the highly vascular nature of the nasal mucosa, local anesthetic toxicity may occur if attention is not paid to the total maximum milligram dose of local anesthetic utilized to carry out sphenopalatine ganglion block. Occasionally, patients will experience significant orthostatic hypotension following sphenopalatine ganglion block. For this reason, the patient should be carefully monitored following the block, moved to a sitting position, and allowed to ambulate only with assistance.

Stellate Ganglion Block

Indications

Stellate ganglion block is indicated in the treatment of reflex sympathetic dystrophy of the face, neck, upper extremity, and upper thorax, as well as sympathetically mediated pain of malignant origin. Stellate ganglion block is also useful in the treatment of acute herpes zoster and postherpetic neuralgia (Waldman, 1998b, 2001a; Waldman & Waldman, 1987). This technique may help salvage fingers in patients suffering from vascular compromise of the upper extremity due to Raynaud disease, frostbite, or other forms of acute and chronic vascular insufficiency (Waldman, 1998b). Clinical reports suggest that stellate ganglion blocks may also be useful in the palliation of some atypical vascular headaches and facial pain syndromes. Patients suffering from upper extremity postmastectomy pain and edema may also benefit from stellate ganglion blocks with local anesthetic and steroid.

Anatomy

The stellate ganglion is located between the anterior lateral surface of the seventh cervical vertebral body and the neck of the first rib (Katz, 1994b). The ganglion lies central to the vertebral artery and the transverse process, and is separated by the longus coli muscle. The ganglion is medial to the common carotid artery and jugular vein, and lateral to the trachea and esophagus.

Technique

The medial edge of the sternocleidomastoid muscle is identified as the level of the cricothyroid notch (C6). The sternocleidomastoid muscle is then displaced laterally with two fingers. The pulsations of the carotid artery should then be identified. The skin medial to the carotid pulsation is prepped with alcohol, and a 1-1½-in., 22-gauge needle is advanced until contact is made with the transverse process of C6. The needle is then withdrawn approximately 2 mm and careful aspiration is carried out; 7 ml of 0.5% preservative-free bupivicaine or 1% preservative-free lidocaine is then injected. The addition of a depot steroid preparation such as methylprednisolone to the local anesthetic solution is useful in patients suffering from reflex sympathetic dystrophy or other pain syndromes that have a significant inflammatory component (e.g., acute herpes zoster). Careful monitoring of pulse, blood pressure, and respirations is indicated following stellate ganglion block.

Practical Considerations

Daily stellate ganglion block with local anesthetic either alone or in combination with steroid is beneficial for the previously mentioned pain syndromes. Careful explanation to the patient regarding the special side effect of Horner's syndrome from blockade of the stellate ganglion should be given prior to implementation of stellate ganglion block to avoid undue patient anxiety. Local anesthetic should never be injected if the transverse process of C6 cannot be identified with the needle, as doing so will lead to an unacceptable high rate of potentially life-threatening complications.

Complications

Hematoma, hoarseness due to blockade of the laryngeal nerves, difficulty in swallowing, and pneumothorax can occur. Due to the proximity of the great vessels of the neck, intravascular injection, with almost immediate local anesthetic drug toxicity, is a distinct possibility if careful aspiration and needle placement is not carried out. Epidural, subdural, and subarachnoid anesthesia can occur if the needle is allowed to pass between the transverse process of C5 and C6 and impinge upon the cervical root.

Celiac Plexus Block

Indications

Celiac plexus block with local anesthetic is indicated as a diagnostic maneuver to determine if flank, retroperitoneal, or upper abdominal pain is sympathetically mediated via the celiac plexus (Portenoy & Waldman, 1991). This technique is also used in a prognostic manner to determine if celiac plexus block with neurolytic solution, such as alcohol or phenol, will provide relief of the pain of chronic pancreatitis or, more commonly, pain of upper abdominal and retroperitoneal malignancy, such as carcinoma of the pancreas, adrenal gland, etc. Daily celiac plexus block with local anesthetic and depot steroid is also used in the palliation of pain secondary to acute pancreatitis. Clinical reports suggest that early implementation of celiac plexus block with local anesthetic and/or steroid may markedly reduce the morbidity and mortality associated with acute pancreatitis (Waldman, 2001).

Anatomy

The celiac plexus is situated in the prevertebral area at the level of T12-L1 vertebral body (Raj, 1985). It is composed of the ganglia of the right and left celiac, superior mesenteric, and aorticorenal ganglia and the dense network of sympathetic nerve fibers that connect them.

Technique

Diagnostic celiac plexus block with local anesthetic can be performed without radiographic guidance. However, it is the clinical impression of many pain management specialists that neurolytic celiac plexus block can be performed most safely utilizing computed tomography (CT) guidance or, if CT guidance is unavailable, fluoroscopy. The use of radiographic guidance should improve not only the safety but also the efficacy of the following technique.

The patient is well hydrated with intravenous fluids and is placed prone on the CT scanning table. A scout film is obtained to identify the T12-L1 interspace. A CT scan is then taken through this area. The scan is reviewed for position of the aorta relative to the vertebral body, the position of intra-abdominal and retroperitoneal organs, and the distortion of normal anatomy due to tumor, previous surgery, or adenopathy. The level at which the scan was taken is then identified on the patient's skin and marked with a gentian violet marker. The skin is prepped with antiseptic solution. The skin and subcutaneous tissues at a point approximately 1½-2 in. from the left of the midline are then anesthetized with 1% lidocaine utilizing a 22-gauge, 1½-in. needle. A 13-cm, 22-gauge styleted Chiba needle is then placed through the anesthetized area and is advanced until the posterior wall of the aorta is encountered. The needle is then advanced into the aorta

and the stylet is removed. A free flow of arterial blood should then be present. A well-lubricated, 5-cc glass syringe filled with preservative-free saline is then attached to the Hinck needle, and the needle and syringe are advanced through the anterior wall of the aorta (Feldstein, Waldman, & Allen, 1985). The glass syringe is removed, and a small amount of 0.5% lidocaine in solution with water-soluble contrast media is then injected through the needle. A CT scan at this same level is again taken. The scan is reviewed for the placement of the needle and, most importantly, for the spread of contrast. Contrast should be seen in the pre-aortic area surrounding the aorta. None of the contrast should be retrocrural. After satisfactory placement and spread of contrast is confirmed, 12 to 15 cc absolute alcohol or 6% aqueous phenol is then injected through the needle. The needle is flushed with a small amount of saline and then removed. The patient is observed carefully for hemodynamic changes, including hypotension and tachycardia secondary to the resulting profound sympathetic blockade.

Practical Considerations

CT-guided celiac plexus neurolysis utilizing the loss of resistance technique has been shown to be safe as well as efficacious for treatment of the above-mentioned pain syndromes (Liebarman & Waldman, 1990). This technique can be performed in the lateral position for patients who are unable to lie prone because of intractable abdominal pain or because of colostomy, ileostomy appliances, and the like. This technique avoids the possibility of spread of neurolytic substance onto the lumbar plexus. Posterior retrocrural spread of local anesthetic and contrast injected prior to injection of the neurolytic substance will alert the clinician to the possibility of this complication, and the needle can be repositioned. It is the author's clinical impression that the higher resolution and ease of identification of anatomic structures make the use of the CT scanner far superior to the use of fluoroscopy for this technique (Liebarman & Waldman, 1990). Celiac plexus block utilizing the anterior approach with either CT or ultrasound guidance may also be an option for patients who are unable to assume the prone position.

Complications

The most feared complication of celiac plexus neurolysis is the inadvertent injection of neurolytic substance onto the lumbar plexus, epidurally, subarachnoid, or intravascular. Inappropriate needle placement can result in damage to the kidneys. If the needle is placed too far anterior, injection into the pancreas or into the peritoneal cavity or liver can occur. As mentioned, the incidences of these complications can be markedly reduced by the use of CT guidance.

When properly performed, this technique results in profound sympathetic neural blockade. In the cancer patient who may have compromised cardiac reserve, this hypotension can be life-threatening. For this reason, the patient should be well hydrated prior to the procedure, and blood pressure should be monitored closely following the procedure. The patient should be cautioned that orthostatic hypotension may persist for a period of days, and the patient should get up only with assistance until the orthostatic hypotension has been resolved.

Lumbar Sympathetic Nerve Block

Indications

Lumbar sympathetic nerve block with local anesthetic is indicated as a diagnostic maneuver to determine if lower extremity pain is sympathetically mediated via the lumbar sympathetic chain and for sympathetic dystrophy of the lower extremity. Prognostically, the lumbar sympathetic chain can be blocked with local anesthetic to determine if destruction of the lumbar sympathetic chain with neurolytic substances such as phenol and alcohol, radio-frequency neurolysis, or surgical excision of a portion of the lumbar sympathetic chain will improve blood flow and/or relief of pain of the lower extremities. This technique is used therapeutically to treat acute and chronic peripheral vascular insufficiency, ischemia secondary to frostbite, acute herpes zoster of the lower extremities, and a variety of peripheral neuropathic pains of the lower extremities (Lobstrom & Cousins, 1988). Lumbar sympathetic block has also been utilized to palliate the pain of impacted renal or ureteral calculi.

Anatomy

The lumbar sympathetic ganglion lies along the anterolateral surface of the lumbar vertebral bodies and antromedial to the psoas muscle (Raj, 1985). The anterior vena cava lies just anterior to the right sympathetic chain, and the aorta lies anterior and slightly medial to the sympathetic chain on the left. The sympathetic innervation of the lower extremity arises from preganglionic fibers that take their origin from the cell bodies located in the T10-L2 levels of the spinal cord. Nearly all postganglionic fibers to the lower extremity leave the sympathetic chain interval below L2. Anterior to the chain is the visceral peritoneum and the great vessels.

Technique

The technique of lumbar sympathetic block and neurolysis is quite similar to that described in the section on celiac plexus neurolysis. The patient is placed in the prone position on the CT scanner table with a pillow underneath the abdomen to allow flexion of the thoraco-lumbar spine. This

opens up the space between adjacent transverse processes. A scout film is taken and the L2 vertebral body is identified. The skin overlying the transverse process of L2 is marked with a gentian violet marker and then prepped with antiseptic solution. Utilizing a 1½-in., 22-gauge needle, the skin and subcutaneous tissues are anesthetized with 1% lidocaine. A 22-gauge, 13-cm styleted needle is then advanced through the previously anesthetized area until the tip rests against the vertebral body. The needle is then redirected in a trajectory to pass just lateral to the vertebral body. A well-lubricated glass syringe filled with preservative-free saline is then attached, and loss of resistance technique is utilized while the needle is advanced through the body of the psoas muscle. As soon as the needle tip passes through the fascia of the muscle, a loss of resistance is encountered. This should place the needle adjacent to the sympathetic chain. A small amount of local anesthetic and water-soluble contrast media is then injected to ensure appropriate spread of contrast material in the prevertebral region. Then 12 cc of 0.5% preservative-free lidocaine or absolute alcohol is injected via the needle. The needle is flushed with preservative-free saline and removed. The patient is then observed carefully for hypotension and tachycardia secondary to sympathetic blockade.

Practical Considerations

The use of CT guidance when performing lumbar sympathetic neurolysis can markedly decrease the risk of complications. The patient should be warned that, in all likelihood, he or she will experience some backache following the procedure due to needle trauma to the muscles of posture. The patient should also be advised that following lumbar sympathetic block, the affected lower extremity may feel hot and somewhat swollen relative to the nonaffected extremity. This side effect is normal and will go away with time. Despite the use of radiographic guidance, a small percentage of patients will suffer persistent ilioinguinal or genitofemoral neuralgia due to either direct needle trauma or from spread of the neurolytic solution onto the nerve itself.

Complications

Complications (Lobstrom & Cousins, 1988) of lumbar sympathetic block are similar to those of celiac plexus neurolysis. Because the needle tip is more medial in its trajectory, damage to lumbar nerve roots and their branches as they exit the spinal column is a distinct possibility.

Hypogastric Plexus Block

Indications

Hypogastric plexus block with local anesthetic is indicated as a diagnostic maneuver to determine if pelvic pain is sympathetically medicated via the hypogastric plexus and for sympathetic dystrophy of the pelvis. Prognostically, the hypogastric plexus can be blocked with local anesthetic to determine if destruction of the plexus with neurolytic substances such as phenol and alcohol, radio-frequency neurolysis, or surgical excision of the plexus will provide relief of pain in the previously mentioned areas. This technique is used therapeutically to treat acute and chronic pelvic pain, acute herpes zoster of the sacral roots, cancer pain of the pelvic viscera, pelvic reflex sympathetic dystrophy, and a variety of peripheral neuropathic pains of the pelvis due to trauma, endometriosis, etc. Rectal pain, including proctalgia fugax, may also respond to therapeutic hypogastric plexus block with local anesthetic and steroid (Waldman, Wilson, & Kreps, 1991).

Anatomy

The hypogastric plexus represents the caudal continuation of the lumbar sympathetic chain. The plexus lies along the anterolateral surface of the sacrum just below the L5-S1 interspace. The iliac vessels lie just anterior to the psoas muscle and just lateral to the hypogastric plexus.

Technique

The technique of hypogastric plexus block is quite similar to that described in the section on celiac plexus neurolysis. The patient is placed in the prone position on the CT scanner table with a pillow underneath the lower abdomen to allow flexion of the lower lumbar spine. This opens up the space between L5 transverse processes and the sacral alae. A scout film is taken and the L4-L5 interspace is identified. The skin overlying the interspace is marked with a gentian violet marker and then prepped with antiseptic solution. Utilizing a 1½-in., 22-gauge needle, the skin and subcutaneous tissues are anesthetized with 1% lidocaine. A 22-gauge, 13-cm styleted needle is then advanced through the previously anesthetized area and directed approximately 30° caudad and 30° mediad toward the anterior lateral portion of the L5-S1 interspace. If the transverse process of the L5 vertebral body is encountered, the needle is withdrawn and directed slightly more caudad. If the needle impinges on the L5 vertebral body, the needle is redirected in a trajectory to pass just lateral to the vertebral body. A well-lubricated glass syringe filled with preservative-free saline is then attached, and loss of resistance technique is utilized while the needle is advanced through the body of the psoas muscle. As soon as the needle tip passes through the fascia of the muscle, a loss of resistance is encountered. This should place the needle adjacent to the hypogastric plexus. After careful aspiration, a small amount of local anesthetic and water-soluble contrast

media is then injected to ensure appropriate spread of contrast material in the presacral region in the retroperitoneal space. Then, 10 cc of 0.5% preservative-free lidocaine or absolute alcohol is injected via the needle in incremental doses after repeated careful aspiration. If alcohol is utilized, the needle is flushed with preservative-free saline and removed. The patient is then observed carefully for hypotension and tachycardia secondary to sympathetic blockade or bleeding into the presacral space from the iliac vessels. Unless there is significant scarring from previous surgery or tumor mass and/or adenopathy, there will be contralateral spread of the injectate, making placement of a second needle unnecessary (Waldman, et al., 1991).

Practical Considerations

The use of CT guidance when performing hypogastric plexus neurolysis can markedly decrease the risk of complications. The patient should be warned that, in all likelihood, he or she will experience some backache following the procedure due to needle trauma to the muscles of posture. Despite the use of radiographic guidance, a small percentage of patients will suffer persistent ilioinguinal or genitofemoral neuralgia due to either direct needle trauma or from spread of the neurolytic solution onto the nerve itself. Because of the proximity of the iliac vessels to the hypogastric plexus, the potential for intravascular injection is high. The presacral space can accommodate significant amounts of blood from traumatized vessels before tamponade should occur. The use of CT guidance should help decrease the incidence of this complication as well as needle trauma to the cauda equina. The potential for bowel and bladder difficulties and sexual dysfunction is always a possibility when performing hypogastric plexus neurolysis. Furthermore, it should be remembered that many patients suffering from pelvic pain syndromes of obscure etiology may have a significant behavioral component to their pain symptomatology.

Complications

Complications following hypogastric plexus block are similar to those of celiac plexus and lumbar sympathetic neurolysis. Because the needle tip is in close proximity to the iliac vessels and cauda equina, damage to these structures is a distinct possibility. The possibility of bowel and bladder difficulties and sexual dysfunction following hypogastric plexus neurolysis makes it advisable that this technique be reserved primarily for patients suffering from pelvic pain of malignant origin, although neurolysis of the hypogastric plexus can be used in carefully selected patients suffering from intractable benign pain syndromes.

SOMATIC NERVE BLOCKS

Occipital Nerve Block

Indications

Occipital nerve block with local anesthetic and steroid may be beneficial in the management of occipital neuralgia (Raj, 1989). Occipital neuralgia is characterized by suboccipital pain that is aching in nature. This pain radiates over the posterior lateral scalp. Superimposed electric-shock-like pain may also be present. With prolonged attacks of occipital neuralgia, the patient may also complain of deep retro-orbital ache. Pressure over the greater and lesser occipital nerve on the affected side may recreate the patient's pain symptomatology. In some patients, occipital neuralgia may trigger migraine headaches.

Anatomy

The greater occipital nerve perforates the semispinalis capitis and the trapezius muscles, approximately 3 cm lateral to the occipital protrubance, at the level of the linea nuchae. It is medial to the occipital artery, which can be palpated in some patients. The lesser occipital nerve is approximately $2\frac{1}{2}$ cm lateral to the greater occipital nerve and is found directly above and behind the mastoid process.

Technique

Deep palpation of the musculature overlying the greater occipital nerve will generally recreate the patient's pain symptomatology and help localize this nerve's exit from the bony skull. If the occipital artery can be palpated, this will serve as an additional guide. The skin and hair overlying the greater occipital nerve is then prepped with alcohol, and 10 ml of 0.5% bupivicaine and 80 mg methylprednisolone is injected around the greater and lesser occipital nerve. Nerve blocks are carried out on a daily or every-other-day basis.

Practical Considerations

Occipital neuralgia is greatly overdiagnosed. Many patients carrying this diagnosis actually suffer from tension-type headaches. This may explain the less than optimal long-term results that many patients who undergo occipital nerve block experience. If the patient who carries a working diagnosis of occipital neuralgia does not respond to daily blocks of long-acting local anesthetic and depot-steroid preparations, a trial of cervical epidural steroids is indicated. Because the pain of posterior fossa tumor or tumor compromising the upper cervical nerve roots may mimic the pain of occipital neuralgia, these potentially life-threatening conditions must be ruled out prior to implementation of occipital nerve block. Currently, magnetic resonance image scanning of the posterior

fossa and upper cervical spine is the best way to rule ou occult pathology in this anatomic region.

Complications

This block should be performed with care in patients who are anticoagulated. The needle should not be directe medially, or inadvertent subarachnoid injection with resultant total spinal anesthesia may occur.

Trigeminal Nerve Block

Indications

Use of trigeminal nerve block with local anesthetic and steroids serves as an excellent adjunct to drug treatme of trigeminal neuralgia (Waldman, 2000c, 2001d). The use of this technique allows rapid palliation of pain while oral medications are being titrated to effective levels (Phero & Robbins, 1985b). This technique may also be of value in patients suffering from atypical facial pain. Other indications for trigeminal nerve block include pain in maxillary neoplasm, cluster headaches uncontrolled by sphenopalatine ganglion block, and acute herpes zoster and postherpetic neuralgia in the area of trigeminal nerve not controlled by stellate ganglion block.

Anatomy

The trigeminal nerve is the largest of the cranial nerves, containing both sensory and motor fibers. The trigeminal nerve can be blocked utilizing an extra oral approach via the coronoid notch into the pterygopalatine fossa (Waldman, 1996a). The fossa is a triangular space between the pterygoid process of the sphenoid bone and maxilla of the upper part infratemporal fossa.

Technique

Palpation of the coronoid notch is facilitated by having the patient open and close the mouth. The notch should be encountered approximately 4 cm anterior to the acoustic auditory meatus (see Figure 37.2). The skin is anesthetized with antiseptic solution, and a 1½-in., 22-gauge needle is directed through the middle of the coronoid notch. The tip of the needle may encounter the lateral lamina of the pterygoid process. If blockade of the maxillary nerve is desired, the needle is withdrawn into the subcutaneous tissue and is redirected with the tip 1 cm further anteriorly and 1 cm further superiorly from the first bony contact. Paresthesia may be elicited in the area of the maxillary nerve. If blockade of the mandibular nerve is desired, the needle is withdrawn into the subcutaneous tissue and readjusted with the tip 0 cm posteriorly and 1 cm inferiorly. Paresthesia in the distribution of the mandibular nerve may be elicited. After careful aspiration, 5

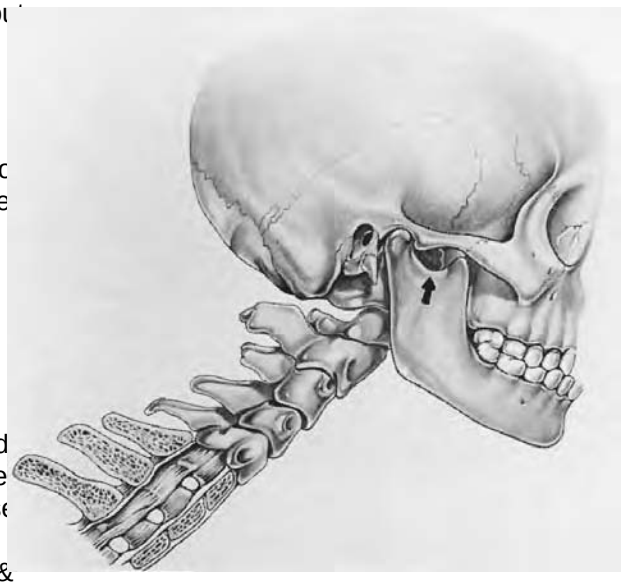

FIGURE 37.2 The coronoid notch. (Courtesy of Astra Pharmaceutical Products, Inc. © Anazak Productions.)

to 7 ml of 0.5% preservative-free bupivicaine in combination with 80 mg of methylprednisolone is injected. Subsequent daily nerve blocks are carried out in a similar manner, substituting 40 ml methylprednisolone for the initial 80-ml dose (Waldman, 2000a).

Practical Considerations

This technique represents an excellent emergency treatment for uncontrolled pain of trigeminal neuralgia. It can be utilized while carbamezepine (Tegretol), liorisal (Baclofen), phenytoin (Dilantin), or other medications are being titrated. With patients suffering from atypical facial pain secondary to temporomandibular joint dysfunction, this technique can be utilized to allow physical therapy and range of motion of the temporomandibular joint.

Complications

The major complication of trigeminal nerve block is inadvertent vascular injection. The pterygopalatine fossa is traversed with a large number of arteries and veins; and for this reason, careful and frequent aspiration should be carried out during injection of local anesthetic. Needle damage to this vasculature can result in significant hematoma formation. Although self-limited, it is recommended that patients be advised of this potential untoward effect so they will not be unduly alarmed should it occur.

Epidural Nerve Block

Indications

The use of epidural nerve blocks with local anesthetic and/or steroid is useful in the diagnosis and treatment of a variety

of pain syndromes. The efficacy of this technique has been demonstrated for the relief of pain secondary to acute and chronic cervical, thoracic, and lumbar strain and radiculopathy, spinal stenosis, bilateral sympathetically maintained pain such as reflex sympathetic dystrophy, peripheral vascular insufficiency, or ischemic pain secondary to frostbite. Epidural neural blockade with local anesthetic and/or steroid is also useful in the management of acute herpes zoster and postherpetic neuralgia of the extremities or trunk. Epidural nerve block with local anesthetic and steroid may also be useful in the palliation of pain secondary to diabetic polyneuropathy, pain of malignant origin, phantom limb pain, peripheral neuropathies, and demyelinating diseases. Pain secondary to acute vertebral compression fractures responds to epidural nerve block with local anesthetic and steroid and allows more rapid ambulation and return to activities of daily living (Waldman, 2000a, 2000b).

Cervical epidural nerve block with local anesthetic and steroid has also been shown to be efficacious in providing long-term relief in tension-type and chronic daily cervicogenic headache. Cronen and Waldman (1988) demonstrated this finding in a prospective study in a group of patients who had failed all treatment modalities, including the optimal use of simple analgesics, nonsteroidal antiinflammatory agents, antidepressant compounds, and biofeedback. Cervical epidural nerve blocks are also useful in the palliation of pain secondary to cervicalgia and whiplash-type injuries of the cervical spine. Clinical experience suggests that this technique is of value in patients with severe fibromyalgia of the cervical paraspinal musculature (Waldman, 2001b).

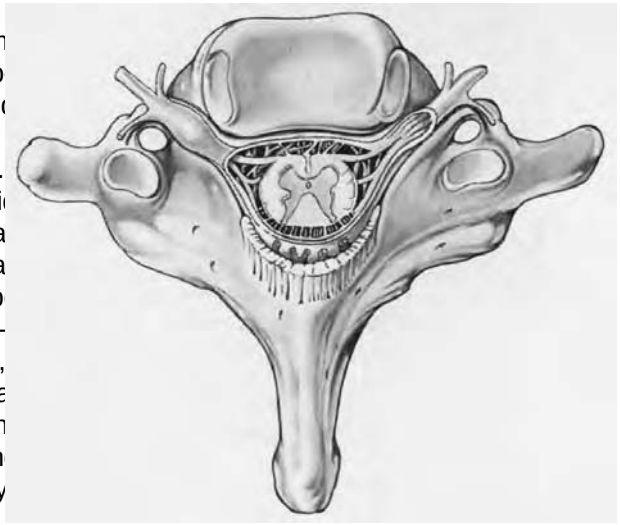

FIGURE 37.3 The epidural space. (Courtesy of Astra Pharmaceutical Products, Inc. © Anazak Productions.)

Anatomy

The epidural space extends from the foramen magnum where the periosteal and spinal layers of dura fuse together to the sacrococcygeal membrane (Bridenbaugh & Greene, 1989) (see Figure 37.3). The anterior portion of the epidural space is bound by the posterior longitudinal ligament, which covers the posterior aspect of the vertebral body and the intravertebral disc. Posteriorly, the epidural space is bound by the anterior lateral surface of the vertebral lamina and the ligamentum flavum. Laterally, the epidural space is bound by the pedicles of the vertebrae and the intravertebral foramen. From a technical viewpoint, the ligamentum flavum is the key landmark for identification of the epidural space. It is composed of dense fibroelastic tissue. It is thinnest in the cervical region. In the adult male, the epidural space is narrowest in the cervical region, with an anterior/posterior diameter of 2 to 3 mm in the cervical region when the neck is flexed.

Technique

Epidural nerve block is most easily carried out if the patient is in the sitting position with the cervical spine flexed and the forehead resting on a padded bedside table. The arms should rest comfortably in the patient's lap or at the patient's side. The skin overlying the appropriate vertebral interspace is prepped with antiseptic solution, and a sterile fenestrated drape is then placed. Careful palpation of the spinous process and intervertebral space is carried out. The exact midline position is then identified. The skin and subcutaneous tissues are anesthetized with 1% preservative-free lidocaine or 0.25% preservative-free bupivicaine. A 22- or 25-gauge 1.5 or 2 in. needle is then placed into the previously anesthetized area with a trajectory slightly cephalad and toward midline. A well-lubricated, 5-cc glass syringe filled with preservative-free saline or a syringe containing local anesthetic and steroid is attached to the epidural needle. With constant pressure on the plunger of the syringe, the epidural needle is carefully advanced. As the tip of the needle passes through ligamentum flavum into the epidural space, the operator will sense a sudden loss of resistance. After careful aspiration, 0.5% preservative-free lidocaine or 0.25% preservative-free bupivicaine combined with depot steroid preparations is then injected through the needle. The epidural needle is removed, a 4 × 4 gauze pad is placed on the injection site, and general pressure is applied. The patient is returned to the supine position, and careful monitoring of blood pressure, pulse, and respirations is carried out until the patient is fully recovered. Many experienced pain management specialists are utilizing these shorter and sharper 22- and 25-gauge needles for epidural blocks with a similar incidence of complications but with the advantage of less procedure-related pain (Waldman, 2000b).

Practical Considerations

Clinical experience suggests that the use of steroid epidural nerve block for the palliation of the above-mentioned

pain syndromes is most efficacious when carried out in the following manner (Waldman, 1994a). The initial epidural nerve block is performed with 80 mg methylprednisolone (Depo-Medrol, Upjohn) and 7 ml of preservative-free bupivicaine (Sensorcaine, Astra) in the cervical region, 10 ml in the lower thoracic region, and 12 ml in the lumbar region. Subsequent epidural nerve blocks are administered on an every-other-day basis with 40 mg methylprednisolone and an appropriate amount of preservative-free bupivicaine in each successive nerve block. The number of blocks that can be administered in this manner varies from patient to patient. For patients with relatively acute pain problems, four or five epidural blocks carried out on a daily or every-other-day basis will often result in complete palliation of the pain symptomatology. More chronic conditions, such as postherpetic neuralgia, cancer pain, or reflex sympathetic dystrophy, may require more aggressive use of neural blockade, with eight or nine epidural blocks being necessary to achieve the desired results. The amount of methylprednisolone should be decreased in diabetics or patients who have received prior treatment with systemic glucocorticoids, as well as patients who may require more than four or five epidural blocks. It is thought that the use of large doses of methylprednisolone (i.e., greater than 120 mg in a single nerve block) significantly increases the incidence of steroid-related side effects and should probably be avoided. Epidural nerve block can be utilized early in the course of treatment for the previously mentioned pain syndromes while waiting for other treatment modalities such as antidepressants or physical therapy to become effective. The addition of preservative-free morphine may be useful in patients suffering from cancer- or trauma-related pain.

It is the author's strong belief that increasing the frequency of epidural blocks to daily or every other day will result in increased efficacy block for block when compared with weekly, every other week, or monthly regimens. This increase in frequency will generally result in a lower number of epidural blocks being required to obtain the desired level of pain relief when compared to regimens of less frequent epidural blocks. Whatever regimen is chosen, the pain management specialist should avoid "cookbook" approaches to pain management and individualize treatment to optimize pain relief. This will often require providing epidural blocks to patients suffering from acute problems such as acute herpes zoster and peripheral vascular insufficiency on weekends and holidays (Waldman, 2000b).

Complications

Because an epidural block interrupts both somatic and sympathetic nerve conduction, cardiovascular changes, including hypotension and tachycardia, may occur (Waldman, 1989a). These cardiovascular changes can produce devastating complications if not promptly identified and treated. Respiratory compromise or failure can occur if blockade of the phrenic nerve or respiratory centers of the brain stem inadvertently occurs. For this reason, epidural nerve blocks should be performed only by those trained in airway management and resuscitation. Appropriate monitoring of vital signs is imperative, and resuscitation equipment must be readily available.

Minor untoward effects and complications of epidural nerve block include pain at the injection site, inadvertent dural puncture, and vasovagal syncope. Major complications include damage to neural structures, epidural hematoma, and epidural abscess. These major complications are rare but can be life-threatening when they occur.

Caudal Epidural Nerve Block

Indications

In addition to applications for surgical and obstetrical anesthesia, caudal epidural nerve block with local anesthetics can be utilized as a diagnostic tool when performing differential neural blockade on an anatomic basis in the evaluation of pelvic, bladder, perineal, genital, rectal, anal, and lower extremity pain. If destruction of the sacral nerves is being considered, this technique is useful as a prognostic indicator of the degree of motor and sensory impairment that the patient may experience.

Caudal epidural nerve block with local anesthetics and/or steroids can be utilized to palliate acute pain emergencies in adults and children, including postoperative pain, pain secondary to pelvic and lower extremity trauma, pain of acute herpes zoster, and cancer-related pain, while waiting for pharmacologic, surgical, and/or antiblastic methods to become effective. Additionally, this technique is valuable in patients suffering from acute vascular insufficiency of the lower extremities secondary to vasospastic and vaso-occulsive disease, including frostbite and ergotamine toxicity.

Caudal nerve block is also recommended to palliate the pain of hydrenadenitis suppurativia of the groin. The administration of local anesthetics and/or steroids via the caudal approach to the epidural space is useful in the treatment of a variety of chronic benign pain syndromes, including lumbar radiculopathy, low back syndrome, spinal stenosis, postlaminectomy syndrome, vertebral compression fractures, diabetic polyneuropathy, postherpetic neuralgia, reflex sympathetic dystrophy, phantom limb pain, orchalgia, proctalgia, and pelvic pain syndromes (Waldman, 2000c).

Because of the simplicity, safety, and lack of pain associated with the caudal approach to the epidural space, this technique is replacing the lumbar epidural approach for these indications in many pain centers. The caudal approach to the epidural space is especially useful

in patients who have previously undergone low-back surgery, which may make the lumbar approach to the epidural space less optimal. Because the caudal approach to the epidural space can be utilized in the presence of anticoagulation or coagulopathy, local anesthetics, opioids, and/or steroids can be administered via this route even when other regional anesthetic techniques, including the spinal and lumbar epidural approach, are contraindicated. This is advantageous in patients with vascular insufficiency who are fully anticoagulated and in cancer patients who have developed coagulopathy secondary to radiation and/or chemotherapy. The caudal epidural administration of local anesthetics, in combination with steroids and/or opioids, is useful in the palliation of cancer-related pelvic, perineal, and rectal pain. This technique has been especially successful in the relief of pain secondary to the bony metastases of prostate cancer and the palliation of chemotherapy-related peripheral neuropathy. As mentioned above, the caudal administration of local anesthetics, opioids, and/or steroids can be utilized in the presence of anticoagulation or coagulopathy.

Anatomy

The triangular-shaped sacrum consists of the five fused sacral vertebrae that are dorsally convex. The sacrum inserts in a wedge-like manner between the two iliac bones, articulating superiorly with the fifth lumbar vertebra and caudally with the coccyx. On the anterior concave surface, there are four pairs of unsealed anterior sacral foramina that allow passage of the anterior rami of the upper four sacral nerves. The posterior sacral foramina are smaller than their anterior counterparts. The vestigial remnants of the inferior articular processes project downward on each side of the sacral hiatus. These bony projections are called the sacral cornua and represent important clinical landmarks when performing caudal epidural nerve block. The triangular-shaped coccyx is made up of three to five rudimental vertebrae. Its superior surface articulates with the inferior articular surface of the sacrum. Two prominent coccygeal cornua adjoin their sacral counterparts. The tip of the coccyx is an important clinical landmark when performing caudal epidural nerve block. The sacral hiatus is formed by the incomplete midline fusion of the posterior elements of the lower portion of the S4 and the entire S5 vertebrae. This U-shaped space is covered posteriorly by the sacrococcygeal ligament, which is also an important clinical landmark when performing caudal epidural nerve block. Penetration of the sacrococcygeal ligament provides direct access to the epidural space of the sacral canal. A continuation of the lumbar spinal canal, the sacral canal continues inferiorly to terminate at the sacral hiatus (Waldman, 2000c).

Technique

The patient is placed in the prone position. The patient's head is placed on a pillow and turned away from the pain management physician. Another pillow is placed under the hips to tilt the pelvis and bring the sacral hiatus into greater prominence. The legs and heels are abducted to prevent tightening of the gluteal muscles, which can make identification of the sacral hiatus more difficult. If the lateral position is chosen because the patient is unable to lie prone, the dependent leg is slightly flexed at the hip and knee for patient comfort. The upper leg is flexed so that it lies over and above the lower leg and is also in contact with the bed. This modified Sims' position separates the buttocks, making identification of the sacral hiatus easier. Due to sagging of the buttocks in the lateral position, the gluteal fold is usually inferior to the level of the sacral hiatus and is a misleading landmark for needle placement (Waldman, 2000c).

A $1^1/_2$-in., 22-gauge needle is suitable for the vast majority of adult patients. A 1/2-in., 25-gauge needle is indicated for pediatric applications. A $1^1/_2$-in., 25-gauge needle is utilized when caudal epidural nerve block is performed in the presence of coagulopathy or anticoagulation. The use of longer needles, as advocated by some earlier investigators, will increase the incidence of complications, including intravascular injection and inadvertent dural puncture. Furthermore, the use of longer needles adds nothing to the overall success of this technique. Preparation of a wide area of skin with an antiseptic solution, such as povidone-iodine, is carried out so that all of the landmarks can be palpated aseptically. A fenestrated sterile drape is placed to avoid contamination of the palpating finger. The pain management physician's middle finger is placed over the sterile drape into the natal cleft, with the fingertip at the tip of the coccyx. This maneuver allows easy confirmation of the sacral midline and is especially important when utilizing the lateral position. After careful identification of the midline, the area under the pain management physician's proximal interphalangeal joint is located. The middle finger is moved cephalad to the area that was previously located under the proximal interphalangeal joint. This spot is palpated using a lateral rocking motion to identify the sacral cornua. The sacral hiatus will be found at this level if the pain management physician's glove size is $7^1/_2$ or 8. If the pain management physician's glove size is smaller, the location of the sacral hiatus will be just superior to the area located below the operator's proximal interphalangeal joint when the fingertip is at the tip of the coccyx. If the pain management physician's glove size is larger, the location of the sacral hiatus will be just inferior to the area located below the proximal interphalangeal joint when the fingertip is at the tip of the coccyx. Although there is normally significant anatomic variation of the sacrum and sacral hiatus, the spatial rela-

tionship between the tip of the coccyx and the location of the sacral hiatus remains amazingly constant. When the approximate position of the sacral hiatus is located by palpating the tip of the coccyx, identifying the midline, and locating the area under the proximal interphalangeal joint as described above, inability to identify and enter the sacral hiatus should occur less than 0.5% of the time.

After locating the sacral hiatus, a 22- or 25-gauge 1.5- or 2 in. needle is inserted through the anesthetized area at a 45° angle into the sacrococcygeal ligament. As the ligament is penetrated, a "pop" or "giving way" will be felt. If contact with the interior bony wall of the sacral canal occurs, the needle should be withdrawn slightly. This will disengage the needle tip from the periosteum. The needle is then advanced approximately 0.50 cm into the canal. This is to ensure that the entire needle bevel is beyond the sacrococcygeal ligament to avoid injection into the ligament. The force required for injection should not exceed that necessary to overcome the resistance of the needle. If there is initial resistance to injection, the needle should be rotated 180° in case it is incorrectly placed in the canal, but the needle bevel is occluded by the internal wall of the sacral canal. Any significant pain or sudden increase in resistance during injection suggests incorrect needle placement, and the pain management physician should stop injecting immediately and reassess the position of the needle (Waldman, 1998c).

When the needle is satisfactorily positioned, a syringe containing the drugs to be injected is attached to the needle. Gentle aspiration is carried out to identify cerebrospinal fluid or blood. Although rare, inadvertent dural puncture can occur, and careful observation for spinal fluid must be carried out. Aspiration of blood occurs more commonly. This can be due to either damage to veins during insertion of the needle into the caudal canal or, less commonly, intravenous placement of the needle. Should the aspiration test be positive for either spinal fluid or blood, the needle is repositioned and the aspiration test repeated. If negative, subsequent injections of 0.5-ml increments of local anesthetic are undertaken. Careful observation for signs of local anesthetic toxicity or subarachnoid spread of local anesthetic during the injection and following the procedure is indicated.

Local anesthetics capable of producing adequate sensory block of the sacral and lower lumbar nerve roots when administered via the caudal route include 1.0% lidocaine, 0.25% bupivicaine, 2% 2-chloroprocaine, and 1.0% mepivicaine. Current clinical practice suggests that smaller volumes of local anesthetics, i.e., 7.5 ml are as effusive as the larger volume of local anesthetics previously advocated with a decreased incidence of side effects. For diagnostic and prognostic blocks, 1.0% preservative-free lidocaine is a suitable local anesthetic. For therapeutic blocks, 0.25% preservative-free bupivicaine in combination with 80 mg depot methylprednisolone (Depo-Medrol, Upjohn) is injected. Subsequent nerve blocks are carried out in a similar manner, substituting 40 mg methylprednisolone for the initial 80-mg dose. Daily caudal epidural nerve blocks with local anesthetic and/or steroid may be required to treat the above-mentioned acute painful conditions and sympathetically maintained pain syndromes such as reflex sympathetic dystrophy and acute herpes zoster.. Chronic conditions such as lumbar radiculopathy and diabetic polyneuropathy are treated on an every-other-day to once-a-week basis, or as the clinical situation dictates. If selective neurolytic block of an individual sacral nerve is desired, incremental 0.1-ml injections of 6.5% phenol in glycerine or alcohol to a total volume of 1.0 ml can be utilized after first confirming the level of pain relief and potential side effects with local anesthetic blocks. If the caudal epidural route is chosen for administration of opioids, 4 to 5 mg morphine sulfate formulated for epidural use is a reasonable initial dose. More lipid-soluble opioids such as fentanyl must be delivered by continuous infusion via a caudal catheter.

Practical Considerations

As with the other approaches to epidural nerve block, increased efficacy will occur if caudal epidural blocks are performed on a daily or every-other-day basis rather than weekly, biweekly, or monthly. Again, a "cookbook" approach should be avoided and the care individualized to ensure optimal pain relief. Because of the simplicity, safety, and extremely low incidence of inadvertent dural puncture, caudal epidural nerve block is preferred over the lumbar approach to the epidural space for most patients and especially in those patients who have undergone prior back surgery. The ability to utilize the caudal approach to the epidural space in the presence of anticoagulants or coagulopathy is an added advantage (Waldman, 1998c).

It is possible to insert the needle incorrectly when performing caudal epidural nerve block. The needle may be placed outside the sacral canal, resulting in the injection of air and/or drugs into the subcutaneous tissues. Palpation of crepitus and bulging of tissues overlying the sacrum during injection is indicative of this needle malposition. An increased resistance to injection accompanied by pain is also noted. A second possible needle misplacement occurs when the needle tip is placed into the periosteum of the sacral canal. This needle misplacement is suggested by considerable pain on injection, a very high resistance to injection, and the inability to inject more than a few milliliters of drug. A third possibility of needle malposition is partial placement of the needle bevel in the sacrococcygeal ligament. Again, there is significant resistance to injection, as well as significant pain as the drugs are injected into the ligament. A fourth possible needle malposition is to force the point of the

needle into the marrow cavity of the sacral vertebra, resulting in very high blood levels of local anesthetic. This can occur in elderly patients with significant osteoporosis. This needle malposition is detected by the initial easy acceptance of a few milliliters of local anesthetic, followed by a rapid increase in resistance to injection as the noncompliant bony cavity is filled with local anesthetic. Significant local anesthetic toxicity can occur as a result of this complication. The fifth and most serious needle malposition occurs when the needle is inserted through the sacrum or lateral to the coccyx into the pelvic cavity beyond. This can result in the needle entering both the rectum and birth canal, resulting in contamination of the needle. The repositioning of the contaminated needle into the sacral canal carries the danger of infection.

Because of the potential for hematogenous spread via Batson's plexus, local infection and sepsis represent absolute contraindications to the caudal approach to the epidural space. Pilonidal cyst and congenital abnormalities of the dural sac and its contents also represent relative contraindications to the caudal approach to the epidural space.

Complications

With the exception of the decreased incidence of inadvertent dural puncture, the complications of the caudal approach to the epidural space mirror those of the lumbar approach. Because of the proximity of the rectum, scrupulous attention to sterile technique must be observed to avoid infection, which can easily spread via Batson's plexus to the epidural space. Because of the vascular nature of the caudal epidural space, the potential for local anesthetic toxicity remains ever present. Careful aspiration and incremental dosing of local anesthetics will help avoid this potentially lethal complication. As with all procedures performed in the prone position, careful attention to the airway must be observed.

Facet Nerve Block

Indications

The primary indication for injection of local anesthetic and steroid into or around the facet joint is palliation of the constellation of symptoms that has been given the rubric "facet syndrome." Facet syndrome is characterized by the following findings: (1) pain on palpation of the tissues overlying the facet joints, (2) reproduction of the patient's pain with hyperextension or rotation of extreme lateral bending of the affected spinal segments, (3) increased pain when remaining in one position for long periods of time, (4) pain localized to the affected spinal segments with no radicular symptoms or physical findings, and (5) radiographic findings of facet arthropathy. As clinicians have gained experience with facet block, it has become apparent that the efficacy of this technique is due in large part to blockade of the medial articular branch of the posterior primary ramus rather than injection of drug into the joint itself. This explains why the efficacy of nonradiographically guided approaches to facet nerve block may be greater than radiographically guided blocks where the needle is placed directly into the facet joint itself (Waldman, 1998d).

Facet nerve block is also indicated as a diagnostic maneuver to determine if spondylolysis is the cause of the patient's back pain. The technique can also help the pain specialist determine if the pseudarthrosis that occurs between the transitional vertebra in the lumbar spine is the source of the patient's pain prior to spinal stabilization surgery.

Technique

Facet nerve block can be done in the prone or sitting position. In the prone position, a pillow is placed below the patient to rotate the patient obliquely approximately 30 to 35°. This places the facet joints and nerves in a more vertical position. After the skin is prepped with antiseptic solution, the skin and subcutaneous tissues are anesthetized with 1% lidocaine. The needle is then advanced perpendicular to the table, with a trajectory 60° from the skin at an entry point approximately 7 cm lateral to the midline. The needle is advanced until bone is encountered. The pain specialist may then attempt to walk the needle into the facet joint or, in most cases, after careful aspiration for blood and cerebrospinal fluid, simply inject 1 to 2 ml of 0.25% preservative-free bupivicaine and 10 mg methylprednisolone at each joint to block the medial branch of the facet joint nerve. Most pain specialists recommend injecting at least two levels due to the variation and overlap of innervation of the facet joints and posterior elements of the spine. Bilateral injection is usually indicated unless the degenerative process and resultant pain are limited to one side. Radiographic guidance for needle placement is generally indicated only if one needs to ascertain if a specific facet joint represents the nidus of the patient's pain or if a facet rhizotomy with phenol or radio-frequency needle is being contemplated.

Practical Considerations

Facet nerve block is gaining increasing popularity among pain specialists in the treatment of nonradicular neck and back pain. A clear understanding of the anatomy will help the pain specialist perform the procedure with less discomfort for the patient. Blockade of the medial branch is generally sufficient to provide pain relief, and actual injection into the facet joint itself is rarely required. When used as a diagnostic maneuver, radiographic guidance is

useful to document needle placement, but the pain specialist should assess other behavioral factors that may impact the patient's response to facet nerve block, including chemical dependence on narcotic analgesics, and secondary gain issues.

Complications

Due to the proximity of the spinal nerve roots, direct trauma to the nerves is a distinct possibility. For this reason, intravenous sedation during facet nerve block should be avoided so the patient can warn the pain specialist of any paresthesias that occur during needle placement. Inadvertent injection of the local anesthetic into epidural, subdural, or subarachnoid space is also a possibility. Needle placement into the intervertebral disc can also occur if the initial needle placement is too far lateral and discitis has been reported.

Myofascial Trigger Point Injection

Indications

Injection of myofascial trigger points with local anesthetic and/or steroid is indicated in the treatment of myofascial pain syndromes of the head and neck (Raj, 1989). These myofascial trigger points are discrete, hypersensitive areas of muscle that in most instances will result from previous trauma. Palpation of these trigger points can initiate pain, autonomic disturbance in a nonsegmental and referred distribution. Trigger points can occur essentially in any muscle of the body. They are most frequently found in the trapezius, semispinalis capitis, splenius capitis, occipitofrontalis, and the muscles of mastication and facial expression, as well as the trapezius and rhomboids.

Technique

Localization of trigger points is accomplished by deep palpation and observation of the radiation of the patient's pain (Travell, 1976). The skin overlying the area is then prepped with alcohol, and 0.25 ml of 1% preservative-free lidocaine, or 0.5% preservative-free bupivicaine alone or in combination with methylprednisolone, is injected into the trigger points.

Practical Considerations

Most patients with muscle contraction headache and atypical head and facial pain syndrome will have multiple myofascial trigger points. A more central nerve block, such as cervical epidural nerve block or trigeminal nerve block, may be more effective in treating and decreasing the number of these trigger points than actual injection into the multiple trigger points that may be present. Discrete trigger points that remain after epidural or trigeminal nerve blocks can then be injected quite easily. With trigger point injection, patients should be informed that they may experience an exacerbation of pain symptomatology when the local anesthetic wears off. Recently, there has been interest in the use of botulinum toxin to inject trigger points that have failed to respond to more conservative methods (Waldman, 2001c).

Complications

Due to the highly vascular nature of the head and face, intravascular injection is a possibility. Care should be taken to avoid inadvertent subarachnoid injection with resultant total spinal anesthetic when injecting trigger points near the midline of the neck and occipital region.

Intercostal Nerve Blocks

Indications

Intercostal nerve block with local anesthetic and/or corticosteroid can be performed at the bedside or in the outpatient setting. This procedure may palliate pain secondary to acute traumatic or pathologic rib fractures, chest wall metastasis, postthoracotomy pain, or right upper quadrant pain secondary to hepatic metastasis (Waldman, 1998b, 1998e). Intercostal nerve blocks may also reduce pain due to percutaneous drainage devices such as chest tubes or nephrostomy tubes. Studies have demonstrated clinically significant improvement in pulmonary function in patients treated with this procedure (Waldman, 1998b).

Anatomy

The thoracic spinal nerves give off the white and gray rami communicantes of the sympathetic system which go to or come from the particular ganglion of the sympathetic chain. Distal to the rami communicantes, the nerve trunk divides into the dorsal and ventral branches. The dorsal branch innervates the skin and muscles of the back as well as the periosteum of the vertebra. The ventral branch follows the rib via the costal sulcus, into the dorsal thoracic region between the two lamina of the intercostal muscles into the lateral and ventral portion of the thorax. This intercostal nerve travels in tandem with the intercostal artery and vein (Raj, 1985).

Technique

Intercostal nerve block can be performed with the patient in the sitting, lateral decubitus, or prone position. The rib in the anatomic region to be blocked is identified by palpation, and the skin in the posterior axillary line is prepped with antiseptic solution. The intercostal nerve

can be blocked more anteriorly should the clinical situation dictate. A 22-gauge, 1½-in. needle attached to a 5-ml syringe is advanced vertically until bony contact with the rib is made. The needle is withdrawn back into the subcutaneous tissues, and the needle is then walked off the inferior margin of the rib, with care being taken not to advance the needle more than 0.5 cm. After careful aspiration, 3 to 5 ml of 0.5% or 0.75% preservative-free bupivicaine is injected. The needle is then removed. This technique can be repeated at each level subserving the pain, with care being taken to carefully monitor the total milligram dosage of local anesthetic injected (Waldman, 1998e).

Practical Considerations

Therapeutic intercostal nerve block is an excellent adjunct in the armamentarium of the pain management specialist to treat a variety of acute and chronic pain syndromes. Its simplicity lends itself to performance in the emergency room or at the bedside, provided appropriate resuscitation equipment and drugs are readily available. The highly vascular nature of the intercostal region makes careful monitoring of the total milligram dosage of local anesthetic, such as 0.75% bupivicaine, important. This technique can be performed on a daily basis to provide long-lasting pain relief for trauma and acute surgical incisions.

Complications

The major complication of intercostal nerve block is inadvertent and unrecognized pneumothorax. The incidence of this complication is approximately 0.5 to 1.0%. If the patient is being maintained on ventilatory support with positive pressure ventilation, tension pneumothorax can occur. As mentioned, vascular uptake of local anesthetic with systemic toxicity is also a problem if careful dosage guidelines are not observed.

Interpleural Catheter

Indications

Recent studies have demonstrated that local anesthetic installation via interpleural catheter is effective in the management of both acute and chronic pain (Reiestad & Stomstag, 1986). This simple technique can be performed on an outpatient basis or at the bedside. Indications are essentially the same as for intercostal nerve block. In addition to these indications, several clinical reports have suggested that the intrapleural catheter technique can be used to reduce pain below the diaphragm, including pain secondary to pancreatic malignancy (Waldman, 1998f).

Technique

The patient is placed in the lateral decubitus position with the painful side upward. The eighth and ninth ribs at the posterior axillary line are identified and then prepped with antiseptic solution. Sterile drapes are placed, and skin and subcutaneous tissues are anesthetized with 1% lidocaine. After adequate analgesia is obtained, a styleted Tuohy or Hustead needle is placed through the skin and into the subcutaneous tissue. A 5-ml syringe with 0.9% preservative-free saline is attached, and the needle and syringe are walked over the superior margin of the rib to avoid damage to the neurovascular bundle. The intrapleural space is then identified utilizing either the hanging drop technique or the negative intrapleural pressure technique as described by Reiestad, et al. (1986). A catheter is then introduced through the needle and advanced approximately 10 cm through the intrapleural space, the Tuohy needle is removed, and 12 to 15 ml of local anesthetic is then injected to ensure catheter integrity and to confirm adequate pain relief from the intrapleural catheter. If long-term use is anticipated, the catheter should be tunneled to avoid the risk of subcutaneous infection (Waldman, 1989b).

Practical Considerations

This technique has proven quite useful in the acute pain management arena. Recent clinical reports have demonstrated that this technique can also be used on a long-term basis. This is accomplished by tunneling the intrapleural catheter to reduce the incidence of infection. As the pleural space is highly vascular, careful attention to the total milligram dosage of local anesthetic used is indicated. In patients with significant pleural disease or pleural effusion, this technique should be used with caution, and the total dose of local anesthetic must be decreased to avoid toxic blood levels.

Complications

The complications of this technique are similar to intercostal nerve block. In addition, if infection occurs, empyema can result.

Epidural Blood Patch

Indications

Epidural blood patch is indicated for the treatment of post-dural puncture headache following lumbar puncture, myelographic procedures, or inadvertent dural puncture that may occur during attempted epidural anesthesia (Waldman, Feldstein, & Allen, 1987). This technique can also be utilized in the treatment of spontaneous

low-pressure headaches that may result from minor head or neck trauma.

Anatomy

The anatomy of the epidural space was described in the section on epidural nerve block. The epidural space is larger in the lumbar region relative to the cervical region, and clinical experience indicates that a larger volume of autologous blood will be required to relieve postdural puncture headaches in the lumbar region relative to the cervical region.

Technique

The patient is hydrated with intravenous fluids, and any co-existing nausea and vomiting is treated with antiemetics. After donning sterile surgical cap, gown, mask, and gloves, the antecubital fossa and skin overlying the area of dural puncture are prepped in a sterile manner with povidone-iodine solution. Identification of the epidural space is carried out, and autologous blood is obtained in a sterile manner from the previously prepped antecubital vein. Autologous blood (7 to 10 ml) is placed in the cervical region, with 12 to 15 ml of autologous blood required for the lumbar region.

Practical Considerations

Many patients with postdural puncture headache have severe nausea and vomiting that may lead to significant dehydration. This results in worsening of the headache and makes venous access to obtain autologous blood quite difficult. The use of preprocedure hydration is therefore indicated. The most common reason for failure of the epidural blood patch is the fact that the patient does not remain supine following the procedure. The patient and nursing staff must be instructed to closely adhere to the postepidural blood patch orders.

Complications

In addition to the complications attendant to identification of the epidural space, the most feared complication of epidural blood patch is infection. Although written about, the actual incidence of this potentially devastating complication (assuming that strict sterile technique is followed) is exceedingly rare. Occasionally, a second and rarely a third epidural blood patch may be required to palliate the above-mentioned pain syndrome.

SUMMARY

The use of neural blockade represents an excellent addition to the armamentarium of the physician caring for the patient in pain. Proper integration of these techniques into the comprehensive pharmacologic and behavioral treatment plan is essential if one is to maximize their efficacy. An understanding of the anatomic, technical, and practical considerations of each specific type of nerve block should lead to a high degree of success and minimal complications.

Myths and Misconceptions about Chronic Pain: The Problem of Mind–Body Dualism

Keith Nicholson, Ph.D., Michael F. Martelli, Ph.D., D.A.A.P.M., and Nathan D. Zasler, M.D., F.A.A.P.M.&R., F.A.A.D.E.P., C.I.M.E., D.A.A.P.M.

As with most other phenomena, there are many myths or misconceptions about chronic pain. At the risk of being mundane, pretentious, or even reinforcing existing misconceptions, this chapter explores what some of these may be. Simply, myths or misconceptions arise out of an incomplete understanding and reflect our ignorance of the material at hand. Myths or misconceptions can also arise out of apparent but possibly false dichotomies. A fundamental dichotomy permeating many domains of human activity, from at least the time of Descartes, is mind–body dualism. This can be especially problematic for the understanding of chronic pain. Much of the current chapter is devoted to one aspect or another of this dichotomy and the misconceptions or confusion that flow from a biased perspective. Although some may think that reviewing this issue is akin to "beating a dead horse," this may also represent an important misconception. Rather, it is argued that explication of what the interface between the two sides of this issue may be is a most important avenue of research. It should also be noted that many myths or misconceptions may be rooted in one's professional training or background. In this regard, it is acknowledged that the predominant perspective of the current chapter is from that of psychologists working in the field of chronic pain.

Perhaps the most elemental myth or misconception is that we know what pain is. We do not. Pain is but a four-letter word or, preferably, a construct that facilitates understanding and communication of a number of related phenomena. One touches a hot stove, experiences "pain," and pulls one's arm away or says "ouch." Certainly, there is a shared intersubjective experience of many acute pain phenomena and, in this sense, acute pain is similar to the experience of a yellow banana or red apple. There is some understanding of the underlying neurobiology of the acute pain experience traditionally associated with the specificity theory of pain and thought to involve peripheral nociception with transmission of information about pain via the lateral pain system to the brain where it is experienced (somehow) as pain. In such situations, the nociceptive stimulus is usually withdrawn or there is healing of damaged tissue and the experience of pain resolves. Although there is certainly much to be learned about this acute pain response (e.g., why one may not experience pain in the midst of battle, during hypnosis or other activity), the problem becomes more complex and mysterious when one considers the transition to chronic pain.

Unlike the situation with color perception (i.e., where specific wavelengths of light may reliably be associated with the perception of particular colors) or many other domains of experience, there is often a poor relationship between the "subjective" experience of pain and "objective" or external referents. This may be most evident in the case of chronic pain where apparently similar peripheral pathology, injury, or nociceptive input can result in markedly different presentations. Whereas patient self-report, using verbal analogue or other rating scales, is perhaps the most straightforward and appropriate means of determining pain severity (or other aspects of the pain experience), this is prone to response bias like all self-reports. In this regard, it has been suggested that less than 10% of the chronic pain

0-8493-0926-3/02/$0.00+$1.50

population may consume as much as 70 to 80% of the resources (Linton, 1999), possibly due to a response bias to report pain and related problems, dependency behavior or other factors associated with the distinction between impairment and disability (Martelli, Zasler, & MacMillan, 1998; Martelli, Zasler, Mancini, & MacMillan, 1999).

A response bias to report pain may be suspected when there are extremely high severity ratings and exuberant pain behavior with high affective distress and (possibly exaggerated) suffering in the context of few, if any, clinical findings. In such cases, one might conclude that underlying emotional problems rather than pain are really the primary problem. On the other hand, many patients present with an apparent "belle indifference" and, despite giving extremely high pain severity ratings (e.g., 9/10 or even 10/10 —"the worst that pain could ever be"), they may appear entirely comfortable, in no apparent distress whatsoever, and often in much better spirits than the examiner. When challenged, such patients will typically maintain that their pain is very severe (e.g., worse than childbirth). It becomes very difficult to ascertain what the meaning of pain is in such discrepant presentations. However, it is likely that the problem of response bias, which reflects the meaning of the experience of pain, is not restricted to the unusual or extreme cases and may often confound presentation in even more "legitimate" cases.

Most clinicians have encountered patients who complain that some doctors think their pain is "all in their heads", that is, it is just psychological, has no organic basis, or is not real. Many doctors may also sometimes hold such an opinion especially if there are no signs of any relevant pathological process, the presentation is otherwise inconsistent with expectation, or the patient appears somehow quirky and with obvious psychological problems. Of course, most would readily accept that lack of a discernible pathological process does not mean that there is not one. There is obviously much to learn about the underlying biological processes involved in chronic pain as well as in many other medical conditions. It is sometimes suggested (to patients or others) that pain is always experienced in the brain and thus is actually "all in the head". However, this begs the question about whether the pain is more "psychological" or "organic" as any psychological phenomena (e.g., reading this sentence or reading the next sentence) is presumed to have a neurobiological substrate. It should be remembered that the definition of pain accepted by the International Association for the Study of Pain (IASP) states that pain is always a psychological state (Merskey & Bogduk, 1994) but this should not be misinterpreted to mean that it is only a psychological state devoid of any physical basis in reality.

Another way of expressing the question of whether pain is in the mind or body is in terms of it being either functional or organic. Organic here implies structural damage or aberration generating "real" pain, whereas functional is commonly meant to imply that presentation is associated with (usually preexisting) psychological or psychiatric problems and that the corresponding perception or self-report of pain may be distorted or magnified. However, there is increasing realization that chronic pain problems may truly be functional but, in this sense, functional refers to the effects of distributed neural networks involved in the processing of pain in contrast with the view of pain as involving a static structural (peripheral or central) lesion generating some nociceptive or neuropathic process (Wall, 2000). This is perhaps especially true of chronic nonmalignant or idiopathic pain. Notably, distributed neural networks underlie many (or most) neuropsychological functions such as motor, vision, or language. In this regard, pain might be considered akin to vision where there is clearly a peripheral and central biological apparatus mediating function but where psychological factors are also clearly pertinent, and, therefore, we tend to see what we want to see or perception is otherwise colored by experience. Much of the brain has been shown to be involved in processing of painful information in one manner or another (Besson, Guilbaud, & Ollat, 1995; Bromm & Desmedt, 1995; Chundler & Dong, 1995). There is limited understanding of how several more dedicated areas actually operate. There is also very poor understanding of how the "pain system" interacts with other systems (e.g., endocrine, immune, motor, cognitive, etc).

With regard to the functional-structural distinction, Mailis, Amani, Umana, Basur, & Roe (1997) have documented a dissociation of separable components of pain in a sample of neuropathic pain patients, i.e., a deep pain component mediated by peripheral nociceptors plus a cutaneous component (allodynia) considered to be a product of central sensitization. Several further studies by this group utilizing sodium amytal or other techniques have purported to document structural-functional dissociations in several other patient samples and that functional aspects of presentation appear to be associated with specific psychosocial factors (Cohodarevic, Mailis, & Montanera, 2000; Mailis & Nicholson, 1997). Whereas the concept of central sensitization has certainly come into vogue, most study remains at the level of the spinal cord or periphery whereas the most important effects may well be supraspinal. Of course, it is much more difficult to conduct experiments at this level. It is also important to recognize that a focus upon how the brain is processing pain does not resolve the mind–body problem, although it may take it a step closer. Caution should also be exercised about neglecting peripheral factors in favor of how the brain is processing pain. It would be unfortunate if the pendulum were to swing and one misconception about chronic pain was displaced only to be replaced by another.

There is a widespread belief that functional neuroimaging will allow us to unlock the secrets of pain or at least provide for some better "objective" indices of pain. Unfortunately, most functional neuroimaging studies of pain

have involved acute pain challenges with normal controls. Results have revealed widespread patterns of activation and deactivation in multiple cortical and subcortical sites (Coghill, Sanf, Maisog, & Ladoralo, 1999; Hsieh et al., 1995; Treede, Kenshalo, Gracely, & Jones, 1999). Indeed, almost all of the brain has been shown to respond in one paradigm or another. There has been more consistent (albeit not always found) patterns of activation in the anterior cingulate, insula, somatosensory cortex (S1 and/or S2), and somatosensory thalamus, findings that might have been anticipated given what is known about the neuroanatomy of the pain system. Notably, however, the anterior cingulate is activated by almost any behavioral challenge (Cabeza & Nyberg, 1997) and the insula is activated by somatosensory stimulation whether noxious or not (Craig, Reinan, Evans, & Bushnell, 1996), although it may be that processing of pain takes place within discrete parts of these cortical areas (Davis, Taylor, Crawley, Wood, & Mikulis, 1997). Furthermore, activation may be seen in the same areas if the subject merely anticipates pain (Drevets et al., 1995; Porro, Francescato, Cettolo, & Baraldi, 1995), although one study has found that the sites of activation with actual vs. anticipated pain can be distinguished (Ploghaus et al., 1999). It remains unclear what the significance of most of these findings are, or whether this technique will fulfill the promise of providing an important inroad to the understanding of chronic pain. However, this technology by itself cannot be expected to resolve mind–body problems. Rather, such issues will only successfully be addressed with relevant psychological analysis of the phenomena of interest (e.g., fear avoidance, response bias to report pain, etc.) coupled with appropriate behavioral challenge during neuroimaging with groups of patients who have been well defined (psychologically and medically) prior to imaging.

There is a long tradition in distinguishing sensory-discriminative, motivational-affective, or cognitive-evaluative components of pain (Melzack & Casey, 1966). Such distinctions often resolve into the dichotomy between the sensory-discriminative vs. the motivational-affective, the latter subsuming the cognitive-evaluative. It seems to often be assumed, at least implicitly, that these are distinct or independent components of pain but that "real" pain necessarily involves the sensory-discriminative component, the motivational-affective or cognitive-evaluative components merely being the emotional or cognitive overlay. More recently it has been suggested that such distinctions are too simplistic or misleading, again leading into problems of Cartesian dualism (Treede et al., 1999; Wall, 2000). There has also been a tradition of distinguishing between the lateral and medial pain systems, generally corresponding to the distinction between the sensory-discriminative vs. motivational-affective and cognitive-evaluative components of pain (Vogt, Sikes, & Vogt, 1993). It remains unclear to what extent these systems are independent and processing information in parallel or how there is interdependence of function and modification of the experience of pain (Vogt, et al., 1993; Treede et al., 1999). Notably, this same issue, integration vs. independence or differentiation of function, has also been a subject of debate with regard to the function of basal ganglia-thalamocortical loops mediating motor, visual, cognitive, affective or other functions (Alexander, DeLong, & Strick, 1986; St-Cyr, Taylor, & Nicholson, 1995).

Many instances or types of central pain occur (e.g., post-stroke central pain) when central, often supraspinal, activation of the pain system produces the experience of pain independent from any peripheral pathology (Nicholson, 2000a). Such pain can be very severe and very real. As indicated previously, chronic pain can be expressed independent from any structural lesion (central or peripheral) as a consequence of central sensitization or functional neural networks. This might account for many puzzling presentations, perhaps especially in those cases of idiopathic pain or when there is no indication of any significant peripheral pathology, but mechanisms of effect remain largely unknown.

The gate control theory initially provided great promise of an integration of peripheral and central, ascending and descending, or neurobiological and psychological factors (Melzack & Wall, 1965). Unfortunately, this paradigm has failed to generate such integration, although there has been an immense amount of work devoted to understanding the microcircuitry of the spinal cord. In the recent past, several other models with a focus on supraspinal mechanisms have been suggested (Birbaumer, Flor, Lutenberger, & Elbert, 1995; Chapman, 1995, 1996; Flor et al., 1995; Flor, Braun, Elbert, & Birbaumer, 1997; Lenz, Gracely, Zirh, Romanowski, & Dougherty, 1997; Melzack, 1999; Wood, Alpers, & Andrews, 1999). These all accept, more or less explicitly, the importance of some neuropsychobiological interface. Some have provided good detail of possible neurobiological mechanisms but there has been very poor, if any, actual integration of psychological and neurobiological factors. Rather, there has been only general suggestion of how psychological processes (e.g., emotion, memory, conditioning, stress, personality) may be related to underlying neurobiological processes. Unfortunately, the neurobiological underpinning of personality is extremely rudimentary (Grigsby & Stevens, 1999).

Gabriel (1990, 1993, 1995) has developed a model system of discriminative avoidance learning that may prove useful in providing for future integration of psychological and biological components involved in chronic pain. Gabriel distinguishes between an anterior and posterior thalamocingulate circuit. The anterior thalamocingulate circuit, centered on the medial dorsal thalamus and the anterior cingulate (area 24b), is specialized for the rapid and flexible acquisition of conditioned avoidance responses. In contrast, the posterior thalamocingulate circuit, centered

upon the posterior cingulate with afferents from anterior thalamic nuclei, is specialized for the maintenance and retention of responses involved in discriminative avoidance learning. These circuits are heavily interdependent and also dependent upon inputs from several other structures (e.g., the amygdala). This model appears of interest, especially given that psychological dimensions associated with the development or expression of chronic pain problems (e.g., active-passive, motor-sensory, independent-dependent) might be mapped onto this neurobiological substrate (Nicholson, in preparation). The structure of such neuro-psychobiological circuits underlying chronic pain may also be seen to be associated with aspects of social behavior and psychosocial development (i.e., maternal behavior, separation cry, etc.) (MacLean, 1986, 1993; Nelson & Panksepp, 1998). Increasing understanding of the neurobiology of attachment or other aspects of social or interpersonal behavior can be expected to facilitate understanding of chronic pain problems. It is suspected that development of animal models that explore the psychobiological substrate may be especially useful but this would require raising laboratory animals in an environment that would produce psychological vulnerability.

Whereas there has been much investigation about the possible role of psychological factors in the presentation of chronic pain patients, there is very poor understanding and even poorer empirical documentation of what this might entail. One approach to this issue is that the psychology of chronic pain is merely a matter of how people react to or cope with the ("real" or "physical") pain they have. This appears to represent what has been the dominant cognitive-behavioral perspective prevalent in at least North America. Many who adopt this approach seem to think that psychological distress, as can be measured by various brief questionnaires, is the only pertinent psychological phenomenon to be assessed. On the other hand, others consider that psychosocial factors may contribute to a vulnerability for development or expression of chronic pain problems, or that there is some "psychogenicity" in the expression of a pain problem. In such cases, a more detailed psychological analysis is usually considered. It is likely that these two approaches are often two sides of the same coin. For example, fear avoidance is a prominent problem with many chronic pain patients who may be unwilling to try to be doing things because of a fear of increasing pain, whereas other patients who do not have such fear may be coping better with pain and related problems or engaging in activity that may help to reduce the pain. Although this phenomenon is usually interpreted as a coping mechanism, it can also be considered a disposition or premorbid vulnerability.

It is likely that there are many shades of meaning to the term "psychogenic pain," some involving a weaker or stronger sense of how psychosocial factors may be causal. It is unknown to what extent any pain problem may be primarily (or even exclusively) psychogenic or independent of peripheral factors. Even in such cases as sympathetic labor pain of a man whose wife is expecting, i.e., the couvade syndrome (Bardhan, 1965), there may be associated gastrointestinal effects related to the stress and anxiety of this event and focus upon gastrointestinal sensation that might generate some peripheral nociception. However, especially if such pain is severe, one might suspect there is central magnification of any actual peripheral nociception. Again, in general, it remains very poorly understood what pertinent psychosocial factors may be or what any specific mechanisms of effect might be. There is also very poor understanding of the interaction of psychosocial factors with the pain system or other systems (i.e., motor, immune, endocrine, autonomic, etc.). Nonetheless, there has recently been increasing attention devoted to these and related issues (Block, Kremer, & Fernandez, 1999; Gatchel & Turk, 1999; Grzesiak & Cicone, 1994; Nicholson, 2000b).

It is suspected that that there is typically an interaction of biomedical and psychological factors contributing to presentation in most cases of chronic pain. As is true for many traits, it might be expected that psychological predisposition or vulnerability is normally distributed with a minority (perhaps 5 to 15%) having marked disposition, another minority (again, perhaps 5 to 15%) being very resistant, and most of us somewhere in between. Thus, for someone with strong disposition, it may require little in the way of peripheral pathology/injury or peripherally generated nociception to activate central functional components associated with psychological factors. In others who are more resistant, it may require marked injury, perhaps under conditions of extreme stress, for a central sensitization effect associated with psychosocial factors or vulnerability to be activated. This is consistent with several recent vulnerability-diathesis-stress models of chronic pain (e.g., Dworkin & Banks, 1999). Returning to the example of fear avoidance, an individual with marked vulnerability may react with extreme fear avoidance to even little actual nociception (e.g., slight musculoskeletal strain). In an individual with little disposition, it may require much more severe injury and substantive nociception to limit activity due to fear avoidance. Notably, other vulnerability factors (e.g., genetic) should also be considered; but, again, an association or interaction with psychological factors can often be expected (e.g., gender, temperament, or other effects).

The nosological system of the American Psychiatric Association (APA, 1994) distinguishes between Pain Disorder Associated with Both Psychological Factors and a General Medical Condition versus Pain Disorder Associated with Psychological Factors. In the latter, psychological factors are considered to play the primary role in the onset, maintenance, severity, or exacerbation of chronic pain, whereas both psychological and medical factors are

considered to contribute to the former. Pain Disorder Associated with a General Medical Condition is not a psychiatric diagnosis and indicates that pain is associated with medical factors alone. Whereas these distinctions are certainly heuristic and useful, it should be noted that this nosological system provides no guidance about what psychosocial factors should be considered, how these might be measured, what any specific mechanisms of effect might be, or how any interaction effects between psychological and biomedical factors might operate. Again, just because psychological factors can be associated with onset, maintenance, exacerbation or severity of pain, and although they may well be primary, it does not mean that pain is not "real" or that there is not a neurobiological substrate to this disorder. This appears to be a common misconception (Teasell & Merskey, 1997). Again, psychological states or processes (e.g., pain, fear, responsibility, reading this sentence) are not merely figments of one's imagination but are presumed to have an underlying neurobiological substrate. "Functional" pain associated with psychological factors may be quite "real" and should perhaps be considered a variant of central pain as has previously been suggested (Nicholson, 2000b). Psychiatry has grappled with similar problems of what constitutes organic, functional, and psychologic factors in the understanding of several other disorders (e.g., depression) where both psychosocial and biomedical etiological factors can be identified and both biomedical or psychosocial treatments may be indicated.

There is a widespread misconception that what constitutes psychological factors contributing to presentation in chronic pain must be gross psychopathology, psychiatric disorder, or sexual/physical abuse during childhood. Whereas there is some evidence that physical or sexual abuse may play a part in the etiology of gastrointestinal or pelvic pain problems, there is otherwise little evidence that this is a relevant etiological factor in other pain problems (Drossman, 1994; Roy, 1998), although it may be that concurrent histories of abuse plus a significant nociceptive or neuropathic pain problem can result in increased affective distress and difficulty coping. There is mixed evidence on the causal relationship between pain and depression (more generally considered negative affect and certainly not always involving premorbid clinical depression), different studies suggesting that the relationship may be causal, reactive, or recursive (Robinson & Riley, 1999). On the other hand, it has also long been noted that many chronic pain patients appear to be model citizens and, although perhaps very active, with underlying dependence-independence conflicts or other identifiable characteristics, do not have gross premorbid psychosocial problems (Blumer & Heilbronn, 1982). In some cases, there are clear indications that psychological factors are playing a major role in presentation, such as when there is complete resolution of pain problems on administration of a placebo, when there is a marked exacerbation under stress or complete resolution in a calming environment, or when there is dramatic pain behavior when attention is focused on pain but no pain behavior when distracted. In many cases, however, the markers may be much more subtle.

Another important and often very contentious issue associated with many misconceptions about chronic pain is whether patients might be malingering (Martelli, Zasler, et al., 1999; Fishbain, et al., 1999a). Although it may be cruel to suggest that (actual) pain is just in the head, suggesting that it is not real or valid, it may be a greater insult to suggest that one's (actual) pain is the product of active dissimulation or malingering, that is, that the individual is just pretending to have pain (or greatly exaggerating pain) to obtain some financial or other benefits. On the other hand, some patients may be actively malingering and this can be very costly, diverting resources from those who need them. A recent review of the literature indicates that malingering might be present in from 1.25 to 10.4% of chronic pain patients but that estimates are not considered reliable and, furthermore, that there is no reliable method for detecting malingering with chronic pain patients (Fishbain, et al., 1999a).

Some signs, often considered to be "non-organic" (i.e., non-dermatomal sensory deficits) (Mailis et al., 2001; Waddell, McCulloch, Kummel, & Venner, 1980), have been found to be associated with actual abnormalities on functional neuroimaging, that is, lack of activation or deactivation of contralateral S1 cortex and other areas on stimulation of the affected side (Mailis et al., 2000). In addition, such nondermatomal somatosensory deficits are prevalent in several pain populations and are suspected as being associated with psychosocial factors (Fishbain, Goldberg, Rosomoff, & Rosomoff, 1991; Mailis & Nicholson, 1997).

Whereas symptom validity testing has been used in other domains (i.e., assessment of memory complaints) to quite unambiguously identify conscious dissimulation (e.g., when level of performance is statistically significantly below what would be expected on the basis of random responding), this is not possible with pain because there is no objective external criteria to evaluate the subjective report. Although there appears to be a trend to use certain cut-off scores on symptom validity testing with those pain patients who concurrently complain of cognitive problems, this is considered inappropriate because such techniques have not been normed on appropriate populations (i.e., chronic pain patients with affective or other problems). Furthermore, there is a large literature documenting cognitive deficits associated with either acute pain challenges in normal volunteers or chronic pain patients (Hart, Martelli, & Zasler, 2000; Martelli, Grayston, & Zasler, 1999; Nicholson, 2000c).

Although it may be very difficult to ascertain whether there is deliberate malingering, there is much stronger

evidence that compensation has the potential to influence presentation, for example, severity or duration of complaints (Cassidy et al., 2000; Loeser, Henderlite, & Conrad, 1995; Loeser & Sullivan, 1995; Nachemson, 1994; Rohling, Binder, & Langhinrichsen-Rohling, 1995). There is also consistent evidence that secondary gain, a concept that is crudely akin to social reinforcement of illness behavior, is an important factor affecting presentation (Fishbain, Rosomoff, Cutler, & Rosomoff, 1995). Again, it is often very difficult to disentangle the effect of these or other specific psychosocial factors from biomedical factors in individual cases.

Many myths and misconceptions about treatment for chronic pain also arise from our poor understanding of the phenomena or are specifically associated with a biased perspective of the mind–body problem. There appears to be a predominant misconception, on behalf of both patients and professionals, that medical science will solve the problem of pain and suffering. On the part of the patient, this may be associated with the idea that medical science is omniscient or omnipotent and can fix any and all problems. Some patients may relegate all responsibility for their pain problem(s) to their doctors. These or related attitudes can lead to persistent medical treatment seeking behavior. After repeated temporary successes (or failures) with numerous medical interventions, it might be questioned whether patients expect to be "cured" by medical science or if they really just want someone to take care of them, perhaps as their parents may once have done. Unfortunately, patients who present with much suffering and desire for treatment can usually find some physician who will provide treatment, whether or not there are good indications for any such intervention. Many interventions, especially surgical, can lead to very serious iatrogenic effects. Some patients may then end up with pain problems far worse than they previously had, wishing they had never had surgery. Iatrogenic effects are certainly not limited to medical interventions. Physiotherapy, chiropractic, or other physical therapies can also result in serious iatrogenic effects. Furthermore, psychological treatments, especially perhaps insofar as they enhance invalidism, can also greatly exacerbate problems. It should also be noted that many practitioners (whether they be plumbers, mechanics, physiotherapists, physicians, psychologists, lawyers, or others) will engage in their professional activity, applying the tools of their trade, often with little regard for the need or effectiveness of their interventions. It should not be forgotten that there are tremendous financial benefits on the part of practitioners. In this regard, it may be more pertinent to question the issue of compensation of practitioners than patients. It should also be recognized that there is a massive medical-industrial complex propagating biomedical research and treatments. Undue medicalization of a problem is not unique to the field of pain. For example, many people would rather have liposuction for weight control than maintain a proper regimen of diet and exercise or accept a less than ideal body weight. It may be easier to administer Ritalin or other stimulants to school children rather than provide appropriate structure or stimulation for problems of activity level. Patients or their doctors may prefer to take a pill for problems of depression rather than pursue cognitive-behavioral change that may be more effective.

Although it might be demonstrated that there is an organic or biomedical substrate for a pain problem, this does not necessarily mean that there should be medical treatment. For example, there may be some mild degenerative spinal changes demonstrated on CT, or functional neuroimaging might demonstrate that there are some patterns of brain activation (or deactivation) associated with low-back pain. However, it might be that pain in this case is primarily associated with inactivity, poor posture, or poor back hygiene. The treatment of choice may be to have the person engage in an appropriate exercise regimen or other activity rather than perform back (or brain) surgery. In this context, it should be noted that a recent meta-analysis indicates that opioids provide some good effect with nociceptive pain, are less effective with neuropathic pain, and are not effective with idiopathic pain (Graven, de Vet, van Kleef, & Weber, 1999). Although no attempt will be made to review the literature, it is apparent that there are many myths or misconceptions regarding opioid treatment, ranging from the extremes of believing opioids should never be prescribed because this will lead to drug addiction, to the other extreme where no consideration is given for this possible problem and opioids are heavily prescribed whether or not there is beneficial effect.

As previously suggested, whereas it might be demonstrated that psychosocial factors are involved in the etiology, maintenance, exacerbation, or severity of pain problems, this does not mean that such pain is "real." It also does not mean that such pain should be treated with psychological methods alone, nor that psychological interventions would necessarily be helpful at all. Indeed, pharmacological or other medical treatment might be the treatment of choice with these patients. It remains largely unknown to what extent any such pain problems would respond to psychosocial interventions or to what extent medical treatments may be required. In addition, whereas psychosocial factors may play an important or even primary role in the pain problem, with relatively little apparent peripheral pathology/nociception, it might be that alleviation of this minor peripheral component via medical intervention would be sufficient to completely resolve the problem.

Although psychosocial interventions have been shown to be effective for a wide variety of chronic pain problems, whether or not there is demonstrable peripheral pathology (Flor, Fydrich, & Turk, 1992; Holroyd & Lipchik, 1999; Morely, Eccleston, & Williams, 1999; Van Tulder, Koes, & Bouter, 1997), effect sizes are often limited and many

TABLE 38.1
Myths and Misconceptions about Chronic Pain

We know what pain is.
We know what the biological basis of pain is.
We know what the psychology of pain is.
Pain is either in the body or in the mind.
Pain has either sensory or affective and/or cognitive components.
Pain is psychogenic or pain is not psychogenic.
If there is no discernible organic basis, then pain must be "functional," that is, "only psychological."
Psychological means somehow not real or without any basis in physical reality.
If there is a psychological component, it is all in your head.
If there is a marked psychological component contributing to presentation, there is no organic substrate.
We have reliable tests that are specifically sensitive to "organic" vs. "non-organic" conditions, or we can accurately measure biomedical or psychological components contributing to presentation.
Patient self-report of pain severity or other problems is unbiased.
We know when a patient is malingering or to what extent compensation issues are affecting presentation.
Practitioners are not biased or are not influenced by compensation issues.
Medical science or biomedical treatments will solve all the problems of pain and suffering.
Psychological treatments are all that is necessary or you just need to be a better person or of better character.
If there is a major psychological component contributing to presentation, there should be psychological but not biomedical treatment.
Psychological presentation in chronic pain patients is either causal or reactive.
Psychological treatments are not helpful for real (organic) pain.
Because psychological factors may be associated with onset, maintenance, exacerbations, severity, etc., means that it is not a real.
Functional neuroimaging will allow us to unlock the secrets of pain and establish the organic vs. psychological basis of the pain.
Opioid use causes addiction or does not result in problems of addiction.
Pain does not cause cognitive problems.
All of a patient's problems are because of an accident/injury and pain.

patients do not find these helpful. It is largely unknown what specific techniques are effective for which patients. In addition, it has been suggested that any systematic treatment delivered with enthusiasm appears to be helpful, leading one to suspect placebo (or at least nonspecific) effects (Blanchard & Galovski, 1999). Indeed, placebo effects are common and prominent (Turner, Deyo, Loeser, Von Korff, & Fordyce, 1994). Again, the mechanism of effect is not well understood (Price & Fields, 1997), although it has been demonstrated that the placebo effect may be associated with a discrete neurobiological response (Benedetti, Arduino, & Aanzio, 1999; Harrington, 1997). There is clearly need for further study about how psychosocial or related interventions work.

Finally, there is a trend toward emphasizing the results of systematic reviews and meta-analyses (i.e., evidence-based medicine) to establish whether or not any specific treatment is effective. Although this is certainly laudatory and may help to weed out the "junk science" or inappropriate and possibly iatrogenic treatments, caution should be exercised about taking such reviews/analyses as "gospel." These may not always be of adequate quality, thus raising concern about conclusions (Fishbain, Cutler, Rosomoff, & Rosomoff, 1999b). Furthermore, just because a set of studies does not provide evidence for something, it does not mean that this is necessarily so. For example, although one could line up the studies indicating that there is no peripheral biological basis for fibromyalgia, this does not mean that some such process will not discovered. Following a strict set of guidelines based on the results of such reviews/analyses could prematurely limit the range of options for treatment or future research.

In conclusion, many myths or misconceptions about chronic pain exist today. These largely arise out of our poor understanding of the phenomena. This chapter focused on myths or misconceptions that are associated with the problem of mind–body dualism or the tendency to view pain problems from either an "organic" or a "psychological" perspective. In contrast, it has been repeatedly suggested that explication of the interface between these domains may be of critical importance in the understanding and treatment of chronic pain. Table 38.1 presents a summary of the primary myths and misconceptions that have been discussed in this chapter. It would be another misconception to think that many other myths and misconceptions do not exist.

Management of Procedural and Perioperative Pain in Children

John T. Algren, M.D., F.A.A.P. and Christine L. Algren, R.N., M.S.N., Ed.D.

INTRODUCTION

The relief of pain in children is a challenge to pediatric healthcare providers. Because the existence of pain in children has previously been denied and ignored (Eland & Anderson, 1977; Schechter, 1989), many children have undergone procedures and surgeries without adequate sedation, analgesia, or anesthesia. The recent interest in pediatric pain has resulted in major philosophical shifts and technical advances. Consequently, various innovative pediatric pain management strategies have evolved. This chapter addresses the care of children with acute pain associated with diagnostic and therapeutic procedures and surgery.

SEDATION AND ANALGESIA FOR PEDIATRIC PROCEDURES

Although pain is a universal experience for children, the type and intensity of pain are quite variable. Children experience brief, intermittent episodes of pain associated with cuts, bruises, and common childhood illnesses. Hospitalized children undergo painful procedures, ranging from venipunctures and intravenous catheter insertions to lumbar punctures and bone marrow aspirations. These diagnostic and therapeutic procedures can cause brief but intense pain. Children often describe these procedures as more distressing than any other aspect of their hospitalization or illness (Eland & Anderson, 1977). Unrelieved pain can have both negative physiological and emotional consequences. Effective pain prevention and treatment can prevent these adverse effects, yielding both short- and long-term benefits.

The goals of pain management for pediatric procedures include lessening patient and parent anxiety, minimizing pain, improving patient cooperation, and facilitating the successful completion of the procedure. Appropriate preparation and adequate analgesia and sedation for painful procedures are crucial not only for minimizing pain, but also for decreasing stress and anxiety. Optimal management should take into consideration the type of procedure being performed and individual factors such as the age and physical condition. Based on a thorough pain assessment, appropriate interventions may consist of pharmacologic agents and nonpharmacological interventions. (Acute Pain Management, 1992). With appropriate nonpharmacologic intervention and sufficient sedation, analgesia, and anxiolysis, children are able to undergo procedures with little physiological or emotional stress.

MONITORING AND MANAGEMENT GUIDELINES

Recent technological and therapeutic advances have led to an increase in diagnostic and minor surgical procedures. Although anesthesiologists provide sedation or general anesthesia for many of these procedures, practical issues of cost, logistics, and availability of personnel support the practice of sedation management by other healthcare providers as well. To promote safe sedation practices, the Committee on Drugs of the American

0-8493-0926-3/02/$0.00+$1.50

Academy of Pediatrics has promulgated guidelines for monitoring and managing pediatric patients undergoing conscious or deep sedation for diagnostic and therapeutic procedures (American Academy of Pediatrics, 1992). Other professional organizations have developed differing guidelines (American Academy of Pediatric Dentistry, 1993; American College of Emergency Physicians, 1993; American Society of Anesthesiologists, 1996), leading to considerable debate (Cote, 1994; Sacchetti, et al., 1994). All have the common goal of fostering safe yet efficient sedation practices. Regardless of perspective or bias, practitioners are urged to not allow expediency to compromise patient safety.

Effective sedation management should provide anxiolysis and analgesia and facilitate patient cooperation. Patient safety and welfare, however, must remain the primary concern of practitioners and assistants because depressed consciousness increases the risk of airway obstruction, respiratory depression, and aspiration, all of which can result in serious morbidity or mortality. When selecting sedatives and analgesics, practitioners must consider the risk of serious adverse events, as well as the incidence of minor problems such as vomiting and prolonged sedation.

Sedatives and analgesics cause depression of the sensorium, ranging from minimal sedation to general anesthesia. "Conscious sedation" is commonly preferred because patients maintain protective airway reflexes and airway patency. Patients remain responsive to verbal and physical stimuli and are able to follow commands. Conscious sedation may be insufficient, however, for some patients undergoing painful procedures. Young children are likely to move and become uncooperative if they experience any discomfort or pain.

"Deep sedation" produces greater depression of consciousness, resulting in diminished responsiveness to stimuli, including pain. Unfortunately, deep sedation may also obtund protective airway reflexes and compromise the patients' ability to independently maintain a patent airway. Such a state is associated with a greater risk of adverse events (e.g., respiratory depression, airway obstruction, and aspiration) and necessitates intravenous access and close and continuous monitoring of cardiorespiratory function. Due to the variability of individual response to depressant medications, administration of sedatives and analgesics for conscious sedation can result in deep sedation, increasing the risk of adverse events. Therefore, irrespective of the planned depth of sedation, practitioners should continuously monitor all patients and be fully prepared to manage potential problems and rescue patients who develop respiratory or cardiovascular depression.

Practitioners must be knowledgeable and competent to oversee all aspects of patient sedation, including drug administration, monitoring, and management of complications. Due to the small but real risk of serious adverse events such as respiratory depression, vomiting, seizures, anaphylaxis, and cardiorespiratory arrest, resuscitation equipment and emergency drugs must be readily available. Facilities should be suitable in size and configuration to accommodate emergency equipment and personnel. Practitioners and assisting personnel must, at a minimum, be trained in basic pediatric life support (American Academy of Pediatrics, 1992).

Serious complications can best be avoided or minimized by close observation and early detection of changes in patient status. All patients must be monitored throughout the period of sedation and recovery. After recording baseline vital signs, patient assessment should include continuous oxygen saturation and heart rate monitoring, intermittent blood pressure recording, and, depending on the depth of sedation, intermittent or continuous monitoring of ventilation.

Patients should not be discharged until they have sufficient recovery of vital system functions to assure safety. This should include recovery of protective airway reflexes, stable and satisfactory cardiovascular and respiratory function, recovery of presedation neurologic function (appropriate for age or developmental level), and adequate hydration. Patients may still be somewhat sedated at discharge but should be sufficiently recovered to be able to sit in a wheelchair and, if necessary, walk with assistance.

Suitable candidates for conscious or deep sedation are American Society of Anesthesiologists Physical Status Class I or II patients (see Table 39.1). Sedation of Class III or IV patients by non-anesthesiologists should be approached with caution due to the presence of severe systemic disease, which may increase the risk of complications. In preparation for a procedure, patients as well as parents should be thoroughly informed about the procedure and receive instructions concerning preparation for the procedure and care of the child after discharge.

To minimize the risk of aspiration of gastric contents, oral intake should be suspended prior to an elective procedure (see Table 39.2) (American Society of Anesthesi-

TABLE 39.1

ologists Task Force, 1999). Whenever possible, unscheduled procedures should be delayed until dietary precautions are met. Urgent or emergent situations may require that sedation be provided despite recent oral intake. Under such circumstances, practitioners should proceed cautiously with sedation to avoid depression of airway reflexes and minimize the risk of aspiration. Pharmacologic treatment with drugs such as ranitidine and metaclopramide, which increase gastric pH and decrease gastric volume, may be appropriate. Airway protection provided by tracheal intubation may be advisable if deep sedation is likely to be necessary.

NONPHARMACOLOGIC APPROACHES TO PROCEDURAL PAIN MANAGEMENT

Procedural pain is often associated with stress, fears, and anxiety. Strategies that reduce fear and stress and facilitate cooperation of the child comprise a variety of nonpharmacological interventions that may be helpful in the management of procedural pain. In addition, these interventions can be utilized in the management of chronic or recurrent pain problems, as well as postoperative pain. In addition to being noninvasive and inexpensive, these interventions can give children and parents a sense of control and involvement in the management of pain.

Preparation

Because stress and anxiety intensify the sensation of pain, any technique that reduces fear and anxiety can alter the child's perception of pain. Age-appropriate preparation is one of the most widely used interventions for reducing stress and anxiety in children undergoing an invasive procedure. Explanations about the procedure increase the understanding of both the child and parents and reduce fear of the unknown. If possible, the child should be encouraged to express fears, and time should be allowed for questions and answers. Information about why the procedure is necessary and what will be done during the procedure should be discussed. In addition, the explanation may include a description of how the procedure may feel. For example, a child might be told that he or she will feel a "small pinch" or prick when local anesthetic is administered. Various methods, such as tours, coloring books, dolls, puppets, and play therapy, can be used to prepare the child for the procedure.

Distraction

Distraction can be a powerful coping strategy during painful procedures. Although distraction does not actually reduce the intensity of the pain, it improves pain tolerance. Preschool and older children are more easily distracted than infants.

Healthcare personnel should first identify what is of interest to the child. Distraction can then be accomplished by focusing the child's attention on something other than the procedure. Listening to music with a headset, talking about pets or school, squeezing the nurse's hand, and singing or counting are effective distraction techniques. The perception of pain is only altered, however, during the distracting activity. When the child is no longer distracted, the pain may return.

Relaxation and Guided Imagery

In children who are capable of abstract thinking, relaxation and guided imagery are effective adjunctive therapies for pain management during painful procedures. These techniques do not have to be complex to be effective. Muscle tension, which intensifies pain, can be alleviated by methods such as deep breathing and progressive relaxation exercises (McDonnell & Bowdem 1989). Soothing music and talking in a soft, calm voice can also produce relaxation. Both "easy listening" music and personally preferred music have been reported to significantly decrease postoperative pain (Mullooly, Levin, & Feldman, 1988). These techniques also give the child a feeling of control instead of a sense of helplessness.

Guided imagery can also be used as a means of achieving relaxation during a painful procedure. Children can be guided into imagining pleasant images such as a favorite place, playing in the sand at the beach, or floating on a cloud. Children may also use fantasy to imagine medication traveling through the body to the pain site or heroes attacking the pain.

Hypnosis

Hypnosis has been an effective technique for managing procedural pain in children. Zeltzer and LeBaron (1982) reported on the use of hypnosis in children with cancer who were undergoing bone marrow aspirations and lumbar punctures. Hypnotic techniques were consistently more effective than nonhypnotic techniques such as dis-

traction and supportive counseling. Of course, the use of hypnosis requires specific training.

Positive Reinforcement

Positive reinforcement is a simple strategy for enhancing cooperation both during and after a procedure. For example, a child might be praised for holding still during a lumbar puncture or verbally encouraged during the procedure. After the procedure, the child might receive a tangible "reward" such as a badge of courage or sticker. A child should receive positive reinforcement for any positive behavior, even if the child cried and was distressed during the procedure. A child should not, however, be punished or ridiculed for uncooperative behavior.

Physical Modalities

Several physical modalities can be used to manage pain in children. Physical cutaneous stimulation as well as transcutaneous electrical nerve stimulation can be effective. These interventions are frequently used in combination with various pharmacological agents.

Cutaneous stimulation is a valuable noninvasive technique for reducing pain. Pleasant stimulation, such as stroking, patting, or massaging feet, hands, or the back, often produces muscle relaxation and reduces pain during injections, suturing, lumbar punctures, and venipunctures. Infants can frequently be soothed by allowing them to suck on a pacifier or by gently rubbing their heads. These techniques can often be performed by parents and, thus, have an emotional benefit as well.

The application of heat and cold is another cutaneous stimulation technique. Interventions such as handing an injured child an ice cube to rub above and below an injury, or rubbing ice on a site prior to an injection may reduce the pain and decrease the inflammatory response. Precautions must be taken, however, to avoid skin irritation. Applying heat for approximately 15 minutes before drawing blood promotes vasodilatation and relieves the intensity of the pain.

Transcutaneous electrical nerve stimulation (TENS) delivers small amounts of electrical energy to the skin via electrodes, modulating transmission of pain impulses at the level of the spinal cord (Eland, 1991). In addition, TENS may cause endorphin release. Although little research on the use of TENS in children has been cited in the literature, Eland (1993) and Lander and Fowler-Kerry (1991) have reported its effectiveness in decreasing procedural and chronic pain in pediatric patients. Thus, TENS may be a useful adjunct in the management of chronic and recurrent pain problems.

Restraints

Papoose boards and other types of restraints have been used to restrain children for procedures. These measures are frightening and usually inappropriate. In selected situations, however, physical restraint of a child may be necessary in conjunction with appropriate use of sedatives and analgesics (Selbst, 1993). When used as an adjunct to sedation, restraint may facilitate the injection of local anesthetic or the completion of a procedure and reduce the need for deep sedation.

TOPICAL AND LOCAL ANESTHETICS

Innovations in the formulation of local anesthetics have resulted in the availability of several new compounds that provide effective local cutaneous anesthesia for minor procedures (see Table 39.3). These compounds are designed to reduce or avoid the pain associated with injection of local anesthetics. Such improvements enhance the usefulness of topical anesthetics for minor procedures and, in many instances, reduce or eliminate the need for systemic sedation or analgesia.

The eutectic mixture of prilocaine and lidocaine (EMLA cream) promotes local anesthetic penetration of intact skin, producing effective cutaneous anesthesia for minor procedures such as intravenous cannulation and percutaneous accessing of subcutaneous intravenous injection ports (Hallen, Olsson, & Uppfeldt, 1984). EMLA cream is applied in a thick layer to the skin and covered with an occlusive plastic dressing. For effective analgesia, EMLA cream should be applied at least 1 hour prior to a procedure. Analgesia increases with longer application periods of up to 4 hours (Cooper, et al., 1987). EMLA is easy to apply and can

TABLE 39.3
Local Anesthetics

Drug	Dosage	Route	Comments
Lidocaine 0.5–1%, with or without epinephrine 1:200,000	Maximum dose: 5 mg/kg; 7 mg/kg if with epinephrine	Subcutaneous	Buffer with 1 mEq $NaHCO_3$ per 9 ml to reduce pain with injection
TAC	Usual: 1–3 ml; Maximum: 0.09 ml/kg	Topical	Avoid mucous membranes and digits
EMLA cream	Usual: 2.5–5 g applied 1–4 hr before procedure	Topical	Apply to intact skin only

be applied by parents at home so that waiting periods are minimized. Side effects are minor and include erythema, blanching, and rash. It should be applied only to intact skin. Prior application of EMLA cream can eliminate the pain associated with infiltration of local anesthetics and may be a useful adjunct for procedures such as lumbar puncture and bone marrow aspiration. EMLA cream has also been used for neonatal circumcision (Benini, et al., 1993).

Another effective method for numbing an area of skin is an intradermal delivery system called Numby Stuff®. Using iontophoresis, a technique that uses a mild electrical current to rapidly transport a solution of 2% lidocaine hydrochloride and 1:100,000 epinephrine through intact skin, Numby Stuff® provides dermal anesthesia to a depth of 10 mm within 8 to 10 minutes. It is effective for intravenous catheter insertion of various types and for pulsed dye laser therapy (Ashburn, et al., 1997). Although this system is approved for all age patients, some young children may be frightened by the tingling sensation produced by the electrical current.

A solution of tetracaine, adrenaline, and cocaine (TAC) provides effective topical anesthesia for repair of superficial lacerations in children (Bonadio & Wagner, 1988). The solution can be prepared by the local hospital pharmacy (tetracaine 0.5%, adrenaline 1:2000, and cocaine 11.8%). Alternative formulations that have been found to be effective and have a lower risk of toxicity are tetracaine 1%, adrenaline 1:4000, and cocaine 4% (Smith & Barry, 1990) and lidocaine 4%, tetracaine 0.5%, and adrenaline 1:2000 (Ernst, et al., 1995). To avoid systemic cocaine toxicity, TAC should not be applied to mucous membranes. Also, it must not be applied to areas supplied by terminal arteries, such as the nose, penis, or fingers. Hegenbarth, et al. (1990) found TAC anesthesia to be sufficient in 89% of patients with scalp and facial wounds; however, 57% of patients with extremity wounds required supplemental local anesthesia. The usual dose of TAC was 1 to 3 ml of solution (maximum dose 0.09 ml/kg), applied with a gauze pad held in place for 15 to 20 minutes. To avoid ischemia of the fingers, healthcare personnel should wear gloves when applying TAC.

The acid pH of local anesthetics enhances solubility and prolongs shelf life but substantially increases the pain associated with subcutaneous injection. Buffering of local anesthetic solutions reduces burning with injection and may increase efficacy. The addition of 1 mEq sodium bicarbonate to 10 ml of 1% lidocaine significantly reduces pain and stinging associated with injection, without causing precipitation of the local anesthetic (Christoph, et al., 1988).

SEDATIVE AND ANALGESICS

A variety of sedative-hypnotic drugs and opioids have been used to provide sedation and analgesia for minor procedures (see Table 39.4). Drug selection should be based on the anticipated level of sedation and analgesia required for the procedure, risk of potential side effects, and available routes of administration.

Chloral hydrate is a sedative-hypnotic agent devoid of analgesic properties. It is available for pediatric use in a liquid or suppository form and has been widely used in infants and children, primarily due to its low risk of adverse effects when administered in standard doses of 30 to 50 mg/kg. When administered in a dosage range of 35 to 75 mg/kg for computerized tomography (CT) scanning, onset ranged from 30 to 105 minutes, recovery ranged from 60 to 120 minutes, and sedation was inadequate in

TABLE 39.4
Sedatives and Analgesics for Procedures

Drug	Dosage	Comments
Chloral hydrate	50–100 mg/kg p.o., p.r.; maximum dose: 2 g	Higher dosage can cause respiratory depression
Pentobarbital	2–6 mg/kg i.v., i.m.	i.v. titration preferred
Midazolam	0.5–1.0 mg/kg p.o.	Onset: 10–20 min
	0.3 mg/kg intranasal	
	0.05-0.1 mg/kg i.v.; titrate to maximum of 0.2 mg/kg	Titrate to desired effect over 10-min. period
Morphine	0.1 mg/kg i.v., up to maximum of 0.2 mg/kg	Reduce dose when combining with sedatives
Meperidine	1 mg/kg i.v., up to 2 mg/kg	Reduce dose when combining with sedatives
Fentanyl	1 µg/kg i.v., titrate to maximum of 5 µg/kg	Reduce dose when combining with sedatives
Ketamine	6–10 mg/kg p.o.	
	0.5–1 mg/kg i.v.	Administer atropine or glycopyrolate
	4 mg/kg i.m.	

13% of patients (Strain, et al., 1986). Doses of 50 to 100 mg/kg (maximum of 2 g) can be used to accelerate onset and improve efficacy but may prolong recovery and increase the risk of respiratory depression (Anderson, Zeltzer, & Fanurik, 1993).

Recent concerns over possible carcinogenic effects of trichlorethanol, an active metabolite of chloral hydrate, are based on laboratory studies in rats and have no supporting clinical data. The primary disadvantages of this drug are slow onset, prolonged recovery, and a significant rate of inadequate sedation. The risk of respiratory as well as cardiac depression with higher dosages warrants continuous cardiorespiratory monitoring. Nevertheless, due to the relative ease of administration and overall safety, chloral hydrate remains a popular sedative for nonpainful procedures, such as CT scanning and magnetic resonance imaging (MRI) (Keeter, et al., 1990).

Barbiturates are also sedative-hypnotic agents devoid of analgesic properties. Short-acting barbiturates such as methohexital or thiopental have been used for induction of anesthesia and produce dose-dependent respiratory and cardiac depression. Both agents can be administered rectally to provide sedation in children. Rectal absorption, however, is somewhat variable and may result in either inadequate or deep sedation.

Pentobarbital is an intermediate-acting barbiturate that is a useful sedative for pediatric radiologic procedures. Strain, et al. (1986) studied the efficacy of intramuscular and intravenous administration of pentobarbital for CT scanning. A single intramuscular dose of 5 to 6 mg/kg produced effective sedation within 30 to 45 minutes in 86% of patients. Intravascular dosage was titrated to achieve satisfactory sedation, resulting in an average dose of 4.4 mg/kg (range, 2 to 6 mg/kg). Intravascular administration was found to be more efficacious due to more rapid onset (1 to 2 minutes), shorter recovery (55 minutes), and a low rate of failed sedation (0.5%).

Midazolam, a short-acting benzodiazepine, provides anxiolysis, sedation, and amnesia and is commonly used as a premedicant or sedative-hypnotic in children as well as adults. Due to limited oral bioavailability, doses of 0.5 to 0.75 mg/kg have been used for preoperative sedation (Feld, Negus, & White, 1990). Doses of 1 mg/kg may be required when midazolam is used as the sole sedative for procedures. Midazolam has also been administered to children by nasal and sublingual routes, which enable transmucosal absorption (Karl, et al., 1993). Transmucosal absorption increases bioavailability and shortens onset time, but children often find these routes of administration to be unpleasant.

Intravenous administration of midazolam produces rapid onset of anxiolysis and sedation and enables titration of dosage to produce the desired degree of sedation. Incremental doses of 0.05 mg/kg can be repeated every 5 to 10 minutes. Tolia, et al. (1991) found that a dose of 0.1 mg/kg is sufficient for gastrointestinal endoscopic procedures. Up to 0.2 mg/kg may be required for oncology patients undergoing lumbar puncture and bone marrow aspiration (Sandler, et al., 1992). Because midazolam has no analgesic properties, local anesthetics or analgesics should also be administered for painful procedures.

The risk of respiratory depression increases with higher doses of midazolam, as well as with the concomitant administration of opioid analgesics. Other side effects such as nausea and vomiting or hallucinations are uncommon. Recovery from midazolam sedation usually occurs within 1 hour. Persistent sedation may be reversed with the benzodiazepine antagonist flumazenil (see Table 39.5). In addition, flumazenil antagonizes, at least partially, the respiratory depressant effects of midazolam (Gross, Weller, & Conard, 1991).

Opioids such as morphine and fentanyl provide both sedation and analgesia for painful procedures. Fentanyl, a potent synthetic opioid, is most commonly used in perioperative anesthetic management. Due to its lipid solubility, it has a rapid onset, a large volume of distribution, and a relatively short duration of action, except when administered in high doses or by continuous infusion. The dosage of fentanyl and other opioids is limited by the risk of serious dose-related side effects, such as respiratory depression and chest wall rigidity. Sandler, et al. (1992) found fentanyl, administered in incremental doses up to 4 µg/kg, to be a satisfactory agent for oncology procedures. The majority of patients in the study preferred midazolam, however, presumably due to its amnestic effect. Continuous infusion of fentanyl provides effective sedation and analgesia for ventilated patients.

Oral transmucosal fentanyl citrate (OTFC) is an innovative formulation of fentanyl in a candy matrix lozenge attached to a stick. It provides effective pre-anesthetic sedation (Friesen, et al., 1995; Steisand, et al., 1989) and analgesia and sedation for painful procedures (Schechter, et al., 1995). Sucking the lozenge causes transmucosal absorption of approximately 25% of the dose, and the remainder is swallowed, ultimately resulting in a total bioavailability of approximately 50% of the administered dose. The recommended dose is 5 to 15 µg/kg, up to a maximum of 400 µg. Children may need a higher dose (10 to 15 µg/kg) than adults (5 to 8 µg/kg).

Side effects associated with OTFC include nausea and vomiting, pruritis, and respiratory depression. Nausea and vomiting can occur in over 30% of patients and may limit the acceptability of OTFC (Schechter, et al., 1995). Continuous monitoring, including pulse oximetry, is indicated for all patients receiving OTFC (Yaster, 1995). The commercial preparation of OTFC, Fentanyl Oralet®, is approved only for use in monitored anesthesia care or as an adjunct to anesthesia.

Opioids are commonly used in conjunction with other sedative-hypnotic agents, particularly benzodiazepines. In

TABLE 39.5
Antagonists

Drug	Dosage	Comments
Naloxone	1–100 μg/kg i.v.	1–2 μg/kg for mild opioid-induced respiratory depression; 10–100 μg/kg for severe depression or apnea
Flumazenil	0.01 mg/kg i.v. up to 0.2 mg; may repeat 2 to 3 times at 1-min intervals; usual maximum adult dose is 1 mg	May not reverse benzodiazepine-induced respiratory depression; resedation may occur; may increase risk of seizure in patients with seizure disorder

a study of pediatric oncology patients, midazolam combined with morphine or fentanyl provided safe and effective sedation (Sievers, et al., 1991). Despite conservative drug dosages, however, transient oxygen desaturation occurred in 12% of patients. The potential risk of respiratory depression resulting from the combination of fentanyl and midazolam has been previously reported (Bailey, et al., 1990; Yaster, et al., 1990). Sedation with this combination of drugs requires continuous monitoring, careful titration of dosages, and full capability to manage respiratory depression or apnea. Naloxone should be available for antagonism of respiratory depression unresponsive to verbal or physical stimulation. Opioid-induced respiratory depression can usually be reversed with incremental doses of 1 μg/kg of naloxone. Larger doses of 10 to 100 μg/kg should be reserved for respiratory arrest secondary to opioid overdose (see Table 39.5).

The "lytic cocktail" (demerol, phenergan, thorazine (DPT)) is a combination of meperidine, promethazine, and chlorpromazine for intramuscular injection. It has been extensively used in children to provide sedation and analgesia for minor procedures, such as laceration repair and closed reduction of fractures. However, sedation is sometimes inadequate, recovery is often prolonged, and respiratory depression may occur (Nahata, Clotz, & Krogg, 1985). Titration of intravenous sedatives and analgesics on an individual basis produces more rapid onset, predictable depth of sedation, and faster recovery. The Committee on Drugs of the American Academy of Pediatrics has criticized the use of this drug combination (American Academy of Pediatrics, 1995).

Ketamine, a dissociative anesthetic, has been recommended as a sedative and analgesic for minor pediatric procedures (Green, Nakamura, & Johnson, 1990; Tobias, et al., 1992). Ketamine is a unique drug that produces anesthesia, analgesia, and amnesia when administered in doses of 1 to 2 mg/kg intravenously or 3 to 5 mg/kg intramuscularly. Lower doses typically produce sedation and analgesia only. Due to stimulation of sympathoadrenergic activity, cardiovascular performance is maintained or even enhanced. Airway patency, reflexes, and respiratory function are also usually well maintained. However, anesthetic doses of ketamine may alter ventilatory drive and airway reflexes, increasing the risk of aspiration, laryngospasm, and hypoventilation. The risk of respiratory complications may be accentuated in young infants and in children with respiratory infections. Patients receiving anesthetic doses of ketamine should also receive an anticholinergic, either atropine or glycopyrolate, to prevent hypersalivation, which may complicate airway management. Ketamine increases cerebral blood flow and, consequently, may increase intracranial pressure. The prevalence of emergence delirium and hallucinations in teenagers and adults has limited the usefulness of ketamine. This problem is less severe and less frequent in children (Green, et al., 1990).

Green, et al. reported their experience with ketamine in emergency department patients. Patients received intramuscular injections of ketamine (4 mg/kg) plus atropine (0.01 mg/kg.) Only 3 of 108 were inadequately sedated. One patient developed transient laryngospasm, and another vomited during the procedure. Neither experienced any sequelae. The average time to discharge was 82 minutes. During recovery, agitation occurred in 21 patients but was considered "mild" in 18 patients. The authors concluded that intramuscular ketamine was a reliable and safe agent for minor emergency department procedures.

Oral ketamine has also been used for preoperative sedation as well as sedation for pediatric procedures. In a study of pediatric oncology patients, oral ketamine, in a dose of 10 mg/kg, produced effective sedation within 45 minutes in 87% of patients (Tobias, et al., 1992). Three of 35 patients experienced mild to moderate emergence problems, and the recovery period exceeded 2 hours.

Ketamine is a useful agent for painful procedures. However, practitioners should be mindful of the low but real risk of respiratory complications and of adverse effects such as emergence delirium and prolonged recovery. Ketamine is available only in parenteral solution.

Propofol is a sedative-hypnotic agent that is commonly used for induction as well as maintenance of general anesthesia. Its mechanism of action is unknown. Due to relatively rapid hepatic conjugation and renal excretion, propofol is useful when administered by continuous infusion for maintenance of general anesthesia or sedation. Similar to sodium thiopental, however, propofol causes dose-related loss of airway reflexes, hypoventilation, apnea, and cardiovascular depression. Although anesthe-

siologsits use propofol as a sedative agent, the safety of this practice by non-anesthesiologists has not been established (Litman, 1999).

MANAGEMENT OF PERIOPERATIVE PAIN IN CHILDREN

Often, children about to undergo surgery express fears regarding postoperative pain. For many of these children, their fears become a reality. Mather and Mackie (1983) studied 170 children postoperatively and found that 40% reported moderate to severe pain on the operative and first postoperative day. Using an integrated, multidisciplinary approach, however, postoperative pain can be minimized.

A comprehensive analgesia plan includes preoperative, intraoperative, and postoperative strategies for minimizing pain related to surgery (Acute Pain Management, 1992). The selection of analgesic strategies should be based on the planned surgical procedure and anesthetic techniques, the anticipated severity of postoperative pain, and the expected course of recovery (i.e., ambulation, physical therapy, dressing changes, etc.). The plan may include any or all of the following interventions for pain management: nonpharmacological approaches, regional anesthesia/analgesia, and systemic opioids and anti-inflammatory drugs. Once these interventions have been initiated, the child should be reassessed at frequent intervals. If the interventions have been ineffective, the plan should be reevaluated and modifications should be made to achieve optimal pain control.

Perioperative management begins with appropriate teaching and preparation for hospitalization and surgery. Surgery creates fear about both real and imagined events for most children and their parents. Without adequate preparation and accurate information, fantasies and fears can lead to distress and anxiety. Strategies that decrease stress and anxiety either reduce pain or enhance the patient's ability to tolerate it better. Explanations of what to expect should be simple and brief. Children should be warned that they will feel discomfort or pain following surgery, but that "medicine will help the pain go away."

PREMEDICANTS

Although preparation and teaching may allay the fears of older children, they may be less effective in toddlers and preschool children. Sedative premedications are useful in alleviating separation anxiety and facilitating induction of anesthesia. The decision to use a premedicant is based on the evaluation of the patient during preoperative assessment. Patients who are especially likely to benefit from a premedicant are young children prone to separation anxiety, uncooperative patients, children whose parents are very anxious, and children who have had unpleasant or painful healthcare experiences. Although a variety of sedatives and anxiolytics are available, oral midazolam (0.75 mg/kg) has become popular due to its safety, efficacy, quick onset, and short duration of effect (Feld, et al., 1990).

NONPHARMACOLOGICAL INTERVENTIONS

As noted previously in this chapter, nonpharmacological interventions such as relaxation, distraction, and imagery can be very helpful in reducing pain and anxiety. These strategies can be taught preoperatively and incorporated into the postoperative analgesia plan. When used effectively, these strategies can reduce the amount of analgesics needed for pain control.

HYPERSENSITIZATION AND PREEMPTIVE ANALGESIA

Acute pain serves as a warning, alerting us to potential or actual tissue injury. Persistent pain, however, contributes to pathophysiologic processes that compromise normal mobility and function. For example, following thoracic or abdominal surgery, pain may restrict breathing and coughing, resulting in impaired ventilation, atelectasis, and pneumonia (Duggan & Drummond, 1987; Ready, 2000).

Tissue injury and pain also activate the neuroendocrine stress response, increasing sympathoadrenergic activity and releasing "stress hormones" and inflammatory mediators, including catecholamines, cortisol, growth hormone, glucagon, vasopressin, interleukin-1, substance P, and tumor necrosis factor (Fitzgerald & Anand, 1993; Kehlet, 1989). The hypermetabolic and catabolic state that follows may be complicated by impaired immune function and increased postoperative morbidity and mortality (Kehlet, 1989).

Tissue injury and inflammation accentuate peripheral nociceptor sensitivity, resulting in hypersensitivity to mechanical and chemical stimuli (Woolf & Chong, 1993). In addition, dorsal horn neurons respond to sustained afferent stimulation with neurophysiologic and morphologic changes consistent with increased excitability to afferent stimulation (Woolf & Chong, 1993). The development of peripheral and central hypersensitization accentuates pain due to noxious stimuli (hyperalgesia) and produces pain with innocuous stimuli as well (allodynia).

Administration of local anesthetics and analgesics prior to tissue injury may inhibit stimulation of nociceptive pathways and thereby prevent activation of the neuroendocrine stress response and the development of peripheral and central hypersensitivity (Woolf & Chong, 1993). General anesthesia alone is ineffective, but local anesthetics, opioids, and nonsteroidal anti-inflammatory

drugs have been used with variable results. Preemptive analgesia appears to be a promising strategy for reducing postoperative pain and complications but remains a subject of some controversy and ongoing investigation (Dahl & Kehlet, 1993; Kissin, 2000).

REGIONAL ANESTHESIA/ANALGESIA

Regional blockade with local anesthetics can be used to provide postoperative analgesia as well as surgical anesthesia. Regional anesthesia techniques are commonly used in conjunction with general anesthesia in children (Dalens, 1989; Ross, Eck, & Tobias, 2000). When performed following induction of general anesthesia, regional blocks allow reduction of maintenance anesthetic requirements, enabling rapid emergence from general anesthesia. Regional analgesia usually persists for several hours, significantly reducing systemic analgesic requirements.

Peripheral and central nerve blocks are useful in infants and children. Commonly performed peripheral nerve blocks include the penile block for circumcision, ilioinguinal/iliohypogastric nerve block for inguinal hernia repair, and intercostal nerve blocks following thoracotomy. Other useful peripheral nerve blocks include brachial plexus blocks, femoral nerve blocks by various techniques, and popliteal blocks. Central blocks are useful for both intraoperative anesthesia and postoperative analgesia. They include single-shot and continuous caudal epidural blocks, and continuous lumbar and thoracic epidural blocks.

The single-shot caudal block is typically performed following induction of general anesthesia. This technique provides epidural anesthesia/analgesia for surgical procedures involving the lower abdomen, inguinal region, and lower extremities (Dalens & Hasnaoui, 1989). It is especially popular for genitourinary procedures, such as inguinal hernia repair, orchidopexy, and hypospadias repair. This block is relatively easy to perform and has a high success rate with a low risk of complications (Broadman, et al., 1987; Dalens & Hasnaoui, 1989). Injection of 0.5 to 1 ml/kg of 0.25% bupivacaine into the caudal epidural space produces effective analgesia for at least 4 to 6 hours. Caudal administration of morphine (0.03 to 0.07 mg/kg) provides analgesia for more than 12 hours but also introduces the risk of opioid-related side effects (Krane, Tyler, & Jacobson, 1989; Valley & Bailey, 1991).

Excellent postoperative analgesia can be provided by the administration of local anesthetics and/or opioids as intermittent boluses or continuous infusions through caudal, lumbar, or thoracic epidural catheters (Berde, et al., 1990; Desparmet, et al., 1987; Gunter & Eng, 1992). Epidural catheters are easily inserted via the caudal canal in infants and small children (Dalens & Hasnaoui, 1989). The tip of the catheter is commonly positioned in the lumbar region but can be advanced to the thoracic level, although this may be somewhat more difficult in children than in infants. Epidural catheters are most commonly inserted in the lumbar region in children. Insertion in the thoracic region is less common due to concern about the risk of neural injury in an uncooperative or anesthetized patient.

Epidural opioids, such as fentanyl, morphine, and hydromorphone, produce excellent analgesia but are associated with side effects that include pruritus, nausea and vomiting, urinary retention, and, rarely, respiratory depression (Taylor & Boswell, 1991). Opioid side effects can be treated with various antiemetics and antihistamines, as well as with opioid antagonists (see Tables 39.5 and 39.6). Concomitant administration of a low concentration of local anesthetic, such as 0.0625 to 0.1% bupivacaine, enables a reduction in opioid dosage, resulting in a lower incidence of opioid-related side effects and little or no motor blockade (McIlvaine, 1990). Selection of agents is usually based on the relative position of the epidural catheter tip to the surgical site. When in close proximity, a solution of fentanyl plus bupivacaine provides excellent analgesia. When the catheter tip is significantly inferior to the surgical site, an opioid that is less lipid soluble (e.g., morphine or hydromorphone) should be used to facilitate cephalad diffusion of the drug.

TABLE 39.6
Treatment of Opioid Side Effects

Side Effect	Drug	Dose	Comments
Pruritus	Diphenhydramine	0.5–1 mg/kg i.v., p.o. prn; maximum: 25 mg	Causes drowsiness
Pruritus	Naloxone	1–2μg/kg/hr continuous i.v. (e.g., add 0.1 mg/100 ml of maintenan .iv. fluids)	Epidural patients only; antagonizes systemic opioid effects
Pruritus	Nalbuphine	0.05 mg/kg i.v. q 4–6 hr prn	Epidural patients only; partially antagonizes systemic opioid effects
Nausea and vomiting	Metoclopramide	0.1–0.2 mg/kg i.v. q 6 hr prn	Extrapyramidal reactions
Nausea and vomiting	Promethazine	0.25–0.5 mg/kg i.v., p.o., p.r. prn	Causes drowsiness
Nausea and vomiting	Ondansetron	0.1 mg/kg i.v. q 6 hr prn	Expensive

TABLE 39.7
Analgesics

Drug	Dosage	Comments
Acetaminophen	10–15 mg/kg p.o. q 4 hr 20–40 mg/kg p.r.	Delayed rectal absorption
Codeine	0.5–1 mg/kg p.o. q 4 hr	
Fentanyl[a]	2–4 μg/kg/hr i.v.	Continuous infusion; ventilated patients only
Ibuprofen	4–10 mg/kg p.o. q 6 hr	
Ketorolac	0.5 mg/kg i.v. q 6 hr; maximum dose: 30 mg	Limit to 5 days; see text for side effects
Meperidine[a]	0.5–1 mg/kg i.v. q 2–3 hr	
Methadone[a]	0.1 mg/kg i.v. q 6–12 hr 0.1–0.2 mg/kg p.o. q 8–12 hr	
Morphine[a]	0.05–0.1 mg/kg i.v. q 2–3 hr 0.02–0.05 mg/kg/hr i.v. infusion	

[a] Continuous i.v. infusion or repeated i.v. administration of potent opioids may result in drug accumulation and respiratory depression. Periodic (usually hourly) patient assessment is advised. For infants < 3 to 6 months of age, initial dosage of potent opioids should be reduced to one third to one half of usual dose.

Routine patient assessment at many institutions includes continuous cardiorespiratory or oxygen saturation monitoring for patients receiving epidural opioids (McIlvaine, 1990). Other centers rely on close nursing observation, which includes frequent assessment of sensorium, respiratory rate, and ventilation. Continuous monitoring is reserved for patients at increased risk for respiratory depression (e.g., infants less than 6 months of age, patients with preexisting neurologic or pulmonary disorders, and patients receiving long-acting hydrophilic opioids such as morphine or hydromorphone) (Berde, et al., 1989). Complete patient assessment must also include periodic evaluation of pain status, sensorium, motor and sensory blockade, and side effects. Although somewhat complex and labor intensive, epidural delivery of anesthetics and analgesics provides excellent analgesia and is well suited for patients with severe pain problems or unique circumstances that limit the safety or efficacy of other analgesics.

OPIOID ANALGESICS

Parenteral opioids remain the mainstay of treatment for moderate to severe pain during the perioperative period. Analgesic requirements vary among individuals and over the course of a pain problem. Tolerance may develop with prolonged therapy. Therefore, dosage should be adjusted according to the severity and duration of pain. Treatment periods exceeding 7 to 10 days may result in physical dependence and require a period of weaning prior to discontinuation of opioid therapy (Shannon & Berde, 1989). Addiction rarely develops in pediatric patients receiving opioids for pain control and is not a valid reason for withholding opioid analgesics.

Common opioid side effects include nausea and vomiting, pruritus, urinary retention, and constipation. Respiratory depression can be avoided by adjusting dosage on an individual basis. For example, neonates are more sensitive to the depressant effects of morphine due to immaturity of the blood–brain barrier. Furthermore, clearance of morphine may be prolonged in infants less than 3 to 6 months of age (Shannon & Berde, 1989). Consequently, intravenous morphine should be titrated in young infants by incremental administration of lower doses (see Table 39.7). Young infants receiving intravenous opioids should receive close observation, usually supplemented by respiratory monitoring. Morphine is the gold standard for the management of severe pain. Equipotent doses of other opioids result in similar risks of side effects, (e.g., respiratory depression) (Yaster & Maxwell, 1993). Although popular, meperidine offers no significant advantage over morphine. Prolonged meperidine use, particularly in higher dosages, may result in seizures due to the accumulation of an active metabolite, normeperidine. Due to its lipid solubility, fentanyl has a relatively short duration of analgesia except when administered in high doses or by continuous infusion. Continuous infusion of fentanyl is an effective method for providing perioperative analgesia for ventilated patients. The fentanyl "patch" promotes sustained transdermal absorption of fentanyl over a 72-hour period. Onset is slow and absorption variable. Consequently, this transdermal delivery system is not suitable for management of acute pain (Gaukroger, 1993).

Patient-Controlled Analgesia (PCA)

For optimum pain control, analgesics should be administered on a scheduled rather than "as-needed" (PRN) basis.

The latter approach often delays treatment and compromises pain relief. Intramuscular injection of opioids is undesirable because it is painful and less effective than other alternatives (Berde, et al., 1991). Administration of opioids by continuous infusion or by patient-controlled analgesia (PCA) pumps maintains relatively constant drug levels and provides excellent analgesia (Wilder, et al., 1992). Morphine is the most common choice for PCA, but meperidine, fentanyl, or hydromorphone can also be administered by PCA if morphine is unsuitable. With age-appropriate instruction, most school-age children can safely and effectively control opioid delivery by PCA (Berde, et al., 1991; Gaukroger, Tomkins, and van der Walt, 1989).

A routine pediatric PCA regimen for morphine includes a loading dose of 0.05 to 0.1 mg/kg, followed by interval doses of 0.015 to 0.025 mg/kg every 8 to 15 minutes as needed, with a maximum of 0.25 to 0.35 mg/kg every 4 hours. A concomitant "background" infusion, which sustains drug levels during periods of sleep, has been advocated but has not been shown to significantly improve analgesia (McNeely, Pontus, & Trentadue, 1992). Considering the potential for drug accumulation and respiratory depression, it may be prudent to limit the use of background infusions to patients with severe pain that is not likely to be controlled by interval dosing alone.

Nurse or parent control of PCA interval dosing has also been reported for children incapable of independent control of PCA (Weldon, Connor, & White, 1991). Although convenient and efficient in some settings, this approach may compromise the inherent safety of PCA. Nevertheless, Lloyd-Thomas and Howard (1994) reported safe and effective analgesia in infants and children with nurse-controlled analgesia. Their regimen included a continuous infusion of 0.01 to 0.02 mg/kg per hour, supplemented by interval doses of 0.01 to 0.02 mg/kg every 30 to 60 minutes as needed.

The authors reported effective yet safe analgesia with nurse, parent, or patient control of PCA pumps (Algren, et al., 1998). The regimen used for nurse control was similar to that described by Lloyd-Thomas and Howard (1994). In contrast, the regimen for parent control provided an interval dose of 0.02 mg/kg of morphine every 12 to 15 minutes as needed, but did not routinely include a background infusion. No serious adverse effects were observed in 206 patients managed with nurse or parent control of PCA, as well as the 240 children who managed PCA independently.

Monitto, et al. (2000) described the use of combined "parent-/nurse-controlled" analgesia (PNCA), which allowed both nurses and parents to control PCA interval dosing for 218 patients. The routine PNCA regimen included a continuous background infusion plus interval dosing as needed to administer morphine, fentanyl, or hydromorphone. For example, the usual initial morphine dose was an infusion of 0.02 mg/kg/hr plus an interval dose of 0.02 mg/kg every 8 minutes as needed. This regimen provided effective analgesia; however, nine (4%) patients received naloxone for excessive sedation, oxygen desaturation, or apnea.

Thus, "surrogate" control of PCA interval dosing appears to be efficacious. However, the combination of a background infusion and frequent interval dosing may increase the risk of an opioid overdose. Somewhat conservative dosing regimens may be prudent, particularly with parent-controlled analgesia. Close monitoring and thorough instruction of nurses and parents regarding administration of interval doses and the risk of adverse effects are essential.

Oral Administration

When gastrointestinal function permits, oral administration of opioids offers the benefit of sustained pain relief and freedom from parenteral therapy. Onset is slow, however, so oral administration is usually unsuitable during the initial management of severe acute pain. Morphine, meperidine, and methadone are available in oral as well as parenteral forms and are useful for the management of ongoing pain of moderate to severe intensity. Methadone has a prolonged elimination half-life, enabling dosing intervals of 8 to 12 hours and relatively constant analgesia (Yaster & Maxwell, 1993). However, its prolonged half-life increases the potential for drug accumulation and toxicity and may necessitate dosage adjustment. Oral methadone is useful for patients requiring prolonged treatment with opioids or weaning from opioids (Tobias, Schleien, & Haun, 1990). Oral codeine, usually in combination with acetaminophen, is an effective analgesic for moderate pain. Oxycodone and hydrocodone, alone or in combination with acetaminophen, are effective alternatives for patients who may be intolerant to oral codeine.

NON-OPIOID ANALGESICS

Nonsteroidal anti-inflammatory drugs (NSAIDs) provide effective analgesia for mild to moderate pain. In addition, they may be useful in conjunction with opioids in the management of severe pain (Watcha, et al., 1991). By inhibiting prostaglandin synthesis, NSAIDs reduce inflammation and associated pain. These drugs are particularly effective in reducing musculoskeletal pain but are relatively ineffective in treating visceral pain. Due to a "ceiling effect", increasing dosage above the recommended maximum does not significantly improve analgesia (Maunuksela, 1993).

Ketorolac is the only parenteral NSAID approved for use in the United States. Although initially approved for intramuscular administration only, intravenous administration has been shown to be safe and effective (Reinhart,

et al., 1992). Intravenous ketorolac, in doses of 0.5 mg/kg (maximum dose, 30 mg) every 6 hours, is very effective in treating moderate orthopedic pain. In addition, for patients with severe pain or opioid-related side effects, ketorolac can be used to supplement intravenous or epidural opioids, thereby improving analgesia and reducing opioid requirements. Significant side effects may develop with prolonged administration of NSAIDs, particularly ketorolac. These disorders primarily result from inhibition of prostaglandin synthesis and include gastritis and gastrointestinal bleeding, platelet dysfunction, renal insufficiency, hepatocellular injury, and central nervous system stimulation. Serious side effects are uncommon for patients free of organ dysfunction. Intraoperative administration of ketorolac may increase blood loss by interfering with platelet function. Consequently, it should not be administered until hemostasis has been ensured. To avoid side effects, ketorolac administration should not exceed 5 days.

Acetaminophen, which primarily acts by interfering with prostaglandin synthesis in the central nervous system, remains popular for the management of mild pain as well as fever. Rectal administration of acetaminophen has been a common, but often inadequate, approach to the treatment of pediatric pain, such as postoperative pain following myringotomy tube insertion. Rectal administration results in slow, incomplete absorption, and dosages in excess of 35 mg/kg may be necessary to achieve therapeutic serum levels (Rusy, et al., 1995). Oral administration results in more predictable absorption. Acetaminophen can be combined with codeine, hydrocodone, or oxycodone for treatment of moderate pain.

Pediatric use of aspirin has dramatically declined since its use was linked to Reye's syndrome (Maunuksela, 1993). Ibuprofen has become very popular as both an antipyretic and analgesic in children and adults. Ibuprofen, in a dose of 6 to 10 mg/kg, is a very effective analgesic and anti-inflammatory agent. Other NSAIDs that have longer half-lives (e.g., naproxyn) are useful for chronic pain.

CONCLUSION

Contemporary pediatric management of procedural and perioperative pain strives to reduce anxiety and provide analgesia through the use of sedatives, analgesics, anesthetics, and numerous nonpharmacological strategies. Severe or recurrent pain is managed by synergistic combinations of opioids, NSAIDs, local anesthetics, and adjunctive approaches that inhibit nociceptive transmission at multiple sites along the nociceptive pathway. Such a comprehensive approach to pain management minimizes pain perception and reduces its adverse physiological and emotional consequences.

Pain Management in Geriatrics

Samuel K. Rosenberg, M.D. and Mark V. Boswell, M.D., Ph.D.

INTRODUCTION

Elderly patients are among the fastest growing segment of the world's population and often suffer multiple medical problems, of which pain is the most common complaint that motivates patients to visit the physician (Ferrell, 1991). In 1998, the U.S. census documented over 34 million people over the age of 65, of which at least 4 million were older than 85 years (U.S. Census Bureau, 1999). Moreover, in the next three decades, the elderly population in the U.S. is expected to increase by approximately 73%.

Pain is more common in the elderly than in the young (Brattberg, Mats, & Andrews, 1989), and population-based studies have shown that 25 to 50% of community-dwelling elderly suffer significant pain (Crook, Rideout, & Browne, 1984; Ferrell, 1991). It is estimated that 5% of elderly people reside in nursing homes, where the prevalence of pain is even higher, reaching 40 to 80%. Longitudinal studies suggest that 40% of people older than 65 years will spend some time in nursing homes in their lifetimes, and 20% of those older than 85 years reside in nursing homes (Ferrell, 1996).

Recent studies have shown a decrease in thermal and mechanical thresholds for pain with advancing age, while electrical thresholds for pain may not be affected by aging (Farrell, 2000). These may be due to a preferential contribution of C-fiber activation vs. $A\delta$-fiber activation in the elderly. Studies have shown a great degree of variability in pain sensitivity in those older than 80, and some evidence even suggests a decrease in pain tolerance with advanced aging (Farrell, 2000). Zheng, Gibson, Khalil, Helm, and McMeehen (2000) demonstrated that mechanical hyperlagesia was present despite aging, and that the duration of the secondary hyperalgesia was longer in the elderly. That may be explained by the theory that dorsal horn sensitization is dependent on a greater peripheral input, and once initiated is then less likely to resolve spontaneously. Therefore, after a stimuli exceeds a threshold, the aging nociceptive system may not respond adequately to inhibitory mechanisms, leading to more persistent levels of central sensitization, as can occur in postherpetic neuralgia.

The consequences of pain in the elderly include impaired activities of daily living and ambulation, depression, sleep disturbance, and increased healthcare costs (Ferrell, 1991). Pain may also be associated with deconditioning, gait abnormalities, falls, cognitive dysfunction, and polypharmacy.

Harkins, Kwentus, and Price (1984, 1990) described changing patterns of pain reported by the elderly visiting physicians' offices. Joint pain and fractures were more common, while back pain and headaches were relatively less frequent. In an epidemiologic study of osteoarthritis, more than 80% of elderly individuals were found to suffer some form of painful arthritis (Davis, 1988). The Nuprin pain survey (Sternbach, 1986) revealed similar findings, where headaches, back pain, dental pain and muscular pain were less frequent in those older than 65 years, but joint pain was much more prevalent. The National Health and Nutrition Survey (1987) documented an increased incidence of depression and impairment in activities of daily living in the elderly suffering pain. Cancer is more common in old age, and as many as 80% of cancer patients suffer substantial pain (Foley, 1994).

Many pain syndromes affect the elderly disproportionately, including herpes zoster and postherpetic neuralgia, temporal arteritis, polymyalgia rheumatica, and atherosclerotic peripheral vascular disease (Gordon, 1979).

0-8493-0926-3/02/$0.00+$1.50

Nonetheless, care must be taken to avoid mistakenly attributing new pain symptoms to preexisting conditions.

PAIN ASSESSMENT AND THE PHYSICAL EXAMINATION

Elderly people may underreport pain because they expect pain with aging, with their disease, and in the case of cancer pain, because of the fear of cancer progression. Family members as well as caregivers are often the best source of information (Ferrell, 1991). Although cognitive impairment may be a barrier to pain assessment, it is important to recognize that most cognitively impaired patients reliably report the presence of current pain at the moment they are asked (Ferrell, Ferrell, & Rivera, 1995).

Old age may be associated with an increase in threshold but not in dynamic response of higher-frequency mechanoreceptors in the skin. However, there is little evidence that perception of pain is diminished. Moreover, there is no evidence that age per se has an impact on the unpleasantness of pain. Indeed, pain in the elderly is a major source of unnecessary suffering and limitation of activities of daily living (Harkins & Price, 1992).

Pain assessment tools that work for the young are likely to work for the elderly (Harkins & Price, 1992).

The Visual Analogue Scale is an efficient and simple way to measure pain intensity (Melzac & Katz, 1994). It consists of a 10-cm horizontal line, with two endpoints labeled "no pain" and "worst pain ever." The patient is then asked to mark on the line that corresponds to pain intensity, the line is then measured, yielding a pain score. The advantages of this tool of pain assessment include its simplicity, ease of administration, minimal intrusiveness, and proven reliability in clinical and research settings.

The McGill Pain Questionnaire provides information about the quality of the pain experienced. Its descriptors fall into four categories: sensory, affective, evaluative, and miscellaneous. This tool is reliable and discriminative, and can help in the differential diagnosis of the pain (Melzac & Katz, 1994).

A crucial aspect of pain assessment is the physical examination, particularly in the elderly. The examination should include:

- Complete history and physical examination
- Review of pain location, intensity, factors that exacerbate or alleviate the pain, and pain impact on mood and sleep
- A screen for cognitive impairment (Folstein Mini-Mental Examination) (Folstein, Folstein, & McHugh, 1975)
- A screen for depression
- A review of the patient's activities of daily living (bathing, dressing, toileting, continence, feeding) and instrumental activities of daily living (using the telephone, shopping, food preparation, housekeeping, laundry, transportation, taking medicine, managing money), and the effect of pain upon functional status
- Gait and balance assessment
- Basic visual and auditory examination to screen for sensory deprivation

An important aspect of the pain assessment is the physical examination. The examination should include not only the organ systems relevant to the patient's complaint, but also a focused neurologic evaluation. For example, a patient with a history of lung cancer, coming with severe groin pain on external rotation of the lower extremity, might suggest a pathologic proximal femur fracture. On the other hand, pain upon percussion of the spine at T12-L1 might suggest tumor metastasis to the spine, producing concomitant referred pain to the groin in a T12-L1 dermatomal pattern. The clinician should examine for evidence of a neurologic deficit, which may herald epidural spread of tumor and possible cord compression. In such cases, further diagnostic studies, such as magnetic resonance imaging (MRI) of the thoracolumbar spine, may be necessary.

Neuropathic pain conditions are common in elderly patients and can pose diagnostic and treatment challenges. Herpes zoster infection is a classic example of acute neuropathic pain that affects 1 to 2% of the elderly each year (Harkins, et al., 1990). Subsequent postherpetic neuralgia is strongly dependent on age, affecting as many as 30 to 50% elderly, vs. 5 to 10% in all age groups. A neurologic examination, specifically looking for evidence of nerve injury (such as hypoesthesias) may help confirm the diagnosis. This may be useful in the unusual case when zoster presents without a cutaneous rash. Wu, Marsh, and Dworken (2000), in a recent review of sympathetic nerve blocks, confirm their role in acute herpes zoster infections. On the other hand, there have been no randomized, double-blind studies that prove the usefulness of sympathetic blocks in postherpetic neuralgia. However, newer techniques, such as the transforaminal approach to the epidural space, which ensures the delivery of steroids and local anesthetics near or at the dorsal root ganglia, may prove to be of great value. Also, the addition of fluoroscopically guided blocks may also translate into better and longer lasting pain relief.

Low-back pain is a frequent complaint in the elderly (Ciocon, Galindo-Ciocon, Amaranth, & Galindo, 1994). The examination of the back should be done in a systematic fashion (Borenstein & Burton, 1993). Initially, the spine should be evaluated with the patient in the erect position and kyphosis, lordosis, and scoliosis should be

noted. Palpation of the paravertebral muscles at each level should follow, and muscle spasms and trigger points should be noted. Palpation and percussion of the spinous processes may reveal localized tenderness, which suggests compression fracture, malignancy, or infection. Range of motion of the lumbosacral spine can reveal pain with flexion, which may suggest a herniated intervertebral disc or paraspinal muscle spasm. Pain on extension may suggest spinal stenosis, whereas pain with lateral rotation and extension can be seen with apophyseal disease, commonly known as lumbar facet pain.

Pain that radiates to the lower extremity may be due to an ipsilateral herniated intervertebral disc producing radiculopathy, particularly if the pain radiates below the knee in a dermatomal pattern. In the elderly, radiculopathy is more likely due to degenerative changes of the spine with facet and ligamentous hypertrophy and loss of disc height, than to a herniated disk (Deyo, Rainville, & Kent, 1992).

Deep tendon reflexes at the knee (L4) and ankle (S1) may be absent in the elderly, and reflexes may be significant only if asymmetric. On the other hand, hyperreflexia and a positive Babinski sign may reflect upper motor neuron disease. Motor function of the lower extremities can be tested in the supine or sitting position: knee extensors, L3-L4; knee flexors, foot evertors, hip extensors, L5-S1; dorsiflexion of the toes L4-L5; and plantarflexors, S1. The apophyseal joints (facet joints) as well as the sacroiliac joints should be palpated and tenderness ruled out, because they can be common sources of back pain (Schwarzer, April, & Bogduk, 1995). The prevalence of lumbar facet pain may be as high as 40% in the elderly (Schwarzer, Wang, McNaught, Laurent, & Bogduk, 1995).

Radiofrequency neurotomy of the lumbar median branches, an outpatient procedure, has been shown to provide at least 60 % pain relief at 1-year follow-up in 87% of those studied, and about 60% of those studied obtained at least 90% pain relief 12 months after the procedure (Dreyfuss, et al., 2000)

Patients with spinal stenosis typically have back and leg pain with standing and walking, which often resolves with sitting or lying with hips flexed. In such patients, abnormal physical findings include reproduction of the pain with back extension, wide-base gait and, in severe cases, motor weakness, particularly with ambulation. In such patients, coexisting peripheral vascular disease producing claudication must be excluded. In Amundsen, et al.'s (2000) recent, prospective 10-year follow-up in those with spinal stenosis, patients were randomized to either surgical or conservative treatment. A good result was found in 70% at 6 months, 64% at 1 year, and 57% at 4 years in those treated conservatively. The surgical group did better; that is, patients improved in 79% at 6 months, 89% at 1 year, and 84% after 4 years. The surgeries included one level (8%), two levels (52%), three levels (28%), and four levels (11%). Interestingly, patients with multilevel operations did not have a poorer outcome than those with single-level surgeries, and the delay of surgery did not translate into a worse outcome. Also, there was no association between the degree of narrowness of the spinal canal and the results after 4 years of follow-up. The study concluded that surgery for lumbar spinal stenosis was beneficial to at least 80% of individuals, but initial conservative treatment in those with milder symptoms appeared to be appropriate, especially since delaying surgery did not worsen the final outcome.

The differential diagnosis of back pain in the elderly should include other diseases that may also cause back pain. For example, an abdominal aortic aneurysm can present with back pain in addition to the presence of a pulsatile mass, abdominal bruit, decreased peripheral pulses, and signs of cutaneous ischemia. Pancreatic cancer and perforated duodenal ulcers also can present with pain referred to the upper lumbar and thoracic spine. Metastatic tumors that commonly invade the spine include prostate, breast, and lung cancers. Indeed, a history of cancer greatly increases the probability that new-onset back pain is tumor related (Deyo, et al., 1992)

EPIDURAL ANALGESIA FOR POSTOPERATIVE PAIN

Epidural anesthesia and/or analgesia in high-risk elderly surgical patients offers substantial benefits, as demonstrated in several prospective studies. Christopherson, et al., (1993) studied 100 patients with an average age of 64 years following revascularization of the lower extremities. Cardiovascular morbidity and mortality were similar in the control and epidural groups, but there was a much lower incidence of reoperation for graft thrombosis in the epidural group. In a prospective series by Tuman, et al. (1991), elderly patients with an average age of about 70 years undergoing lower extremity revascularization with general anesthesia and postoperative epidural analgesia were compared with patients having general anesthesia and postoperative patient-controlled analgesia with intravenous opioids. The patients in the epidural group received bupivacaine and fentanyl, and had a lower incidence of thrombotic events, such as graft occlusions and coronary artery and deep venous thromboses. In addition, cardiovascular morbidity, infectious complications, and ICU days were reduced in the epidural group. Yeager, Glass, Neff, and Brinck-Johnsen (1987) conducted a prospective trial in 53 high-risk surgical patients, comparing epidural anesthesia, light general anesthesia, and postoperative epidural analgesia to general anesthesia and postoperative parenteral opioids. Patients in the epidural group had significantly less car-

diovascular, respiratory, and infectious morbidity, and hospitalization costs were lower.

A review of epidural anesthesia and analgesia (Liu, Carpenter, & Neal, 1995) concluded that the benefits of epidural analgesia may transcend the immediate postoperative analgesia because perioperative coagulability is reduced, thereby decreasing the incidence of arterial and venous thromboses. In addition, there may be improved pulmonary function and gastrointestinal motility, particularly in those receiving thoracic epidural infusions with local anesthetics.

Transient postoperative reduction in cognitive function is frequently observed in the elderly and its pathogenesis is poorly understood (Berggren, et al., 1987). The nadir is seen on the second postoperative, with full recovery noted within a week (Riis, Lomholt, Haxholdt, & Kehlet, 1983). A study of postoperative patients between 50 and 80 years of age demonstrated that untreated pain — and not excessive analgesic intake — predicted decline in the first five postoperative days (Duggleby & Lander, 1994). Although prospective double-blind studies have not confirmed the beneficial effects of epidural analgesia on reducing transient cognitive dysfunction, epidural techniques may reduce the need for parenteral opioids and thereby minimize opioid-related side effects (Salomaki, Leppaluoto, Laitinen, Vuolteenaho, & Nutinen, 1993).

Epidural Steroids

Epidural steroid injections are common procedures done for patients with back pain with radiculopathy. If such injections are performed by properly trained physicians, the incidence of side effects is low (Spaccarelli, 1996).

Although there is a debate in the literature as to the efficacy of epidural steroids for back pain (Koes, Scholten, Mens, & Bouter, 1995), a recent prospective series of 30 patients with an average age of 76 years, along with radicular symptoms associated with spinal stenosis, noted significant pain relief following a course of epidural steroids. Pain relief lasted up to 10 months (Ciocon, et al., 1994). Another case report confirmed the effectiveness of epidural steroid injections for acute radiculopathy in the elderly (Ice, Dillingham, & Belandres, 1995).Lutz, Vad, and Wiseneski (1998), in an outcome prospective study of transforaminal lumbar epidural steroid injections under fluoroscopic guidance, confirmed their effectiveness in those patients with herniated discs and radiculopathy. Sixty-nine patients received one to four transforaminal epidural steroid injections under fluoroscopy, directed at the herniated disc. They were followed for an average of 80 weeks and ranged in age from 22 to 77 years. More than 75% of patients reported greater than 50% pain relief long-term, with an average of 1.8 injections.

The potential benefit of epidural steroid injections may include reduced pain, improved function, decreased analgesic medication intake, and possibly the avoidance of surgery. The use of fluoroscopic guidance may improve the accuracy of epidural injections, thus enhancing their efficacy.

PHARMACOLOGIC MANAGEMENT OF PAIN

It is important to recognize the physiologic changes that occur with aging in order to prescribe medications safely. With respect to renal function, there is a decline in creatinine clearance with aging. The decline is not linear, and clearance decreases more rapidly with advancing age. Also, renal plasma flow, tubular secretion, tubular reabsorption, hydrogen ion secretion, and water absorption and excretion are decreased with aging.

The gastrointestinal system shows less decrease in function with aging. Esophageal transit time is delayed and lower esophageal sphincter function is altered. The stomach retains relatively normal motility but there is a decrease in gastric acid production. Cytochrome P450 microsomal oxidase system efficiency declines with age. Demethylation, the process by which benzodiazepines are metabolized by the liver, is markedly decreased with aging. However, glucuronidation, a primary metabolic pathway for lorazepam, is not altered by aging. Drugs that undergo high hepatic first-pass metabolism, such as propranolol and lidocaine, may have a decreased clearance due to reduced hepatic blood flow.

From a treatment standpoint, it is clinically useful to determine whether pain is nociceptive, neuropathic, sympathetically mediated, or a combination of these types of pain. An example of this is cancer pain, which may be nociceptive due to tumor in the bone, and neuropathic pain from infiltration or compression of neural structures. Pharmacologic therapy should be directed at the specific mechanism of pain and based on a specific diagnosis. Neuropathic pain represents a challenge for clinicians because it is often poorly responsive to opioids and anti-inflammatory medications. Examples of neuropathic pain present in the elderly include trigeminal neuralgia, postherpetic neuralgia, diabetic neuropathy, phantom limb pain, and radiculopathy.

Neuropathic pain is commonly described as a lancinating, stabbing, at times burning pain. Allodynia, a painful reaction to a non-painful stimuli, and hyperalgesia, an exagerated pain reaction to a painful stimuli, are hallmarks of neuropathic pain. Nociceptive pain, on the other hand, can be described as an ache, sharp and, at times, burning as well. Visceral pain, a form of nociceptive pain, can be described as a diffuse or poorly localized, crampy discomfort, which sometimes is intermittent.

Neuropathic pain can be classified as stimulus evoked or stimulus independent pain. (Orza, Boswell, & Rosenberg, 2000) Inflammation and tissue injury may be the stimulus that activates the nervi nervorum in the affected nerves, and stimulus evoked neuropathic pain may be more responsive to opioids than the stimulus independent type of neuropathic pain. Stimulus independent pain may result from an ongoing disturbance in the afferent peripheral or central nervous system, associated with physiologic and morphologic changes in the dorsal root ganglia and dorsal horn of the spinal cord. Also, loss of the normal descending inhibitory mechanisms may also be implicated in the stimulus independent neuropathic pain, and inflammation is usually absent, and opioids are usually not beneficial (Arner & Meyerson, 1988; Portenoy, Foley, & Inturrisi, 1990).

Several days to months after nerve injury, persistent small-fiber activity may be evident at peripheral sites of injury, as well as in dorsal root ganglia. In the periphery, sprouting nerve terminals may display enhanced chemical and mechanical sensitivity to prostaglandins, cytokines, and catecholamines. In addition, there is evidence for up-regulation of sodium channels in injured axons that may be a source of ongoing ectopic discharge, maintaining the painful state. Dorsal root ganglia also show morphological changes ipsilateral to the injured nerve, often with an increased density of abnormal sympathetic nerve terminals, which may contribute to hypersensitization. Recently, changes in dorsal horn have also been documented following peripheral injury, with arborization of dendrites of large-diameter afferents (Aβ fibers) into superficial lamina, such as the substantia gelatinosa (Woolf, Shortland, & Coggeshall, 1992). Thus, neuropathic pain can result from a combination of peripheral and central nervous system changes.

Adjuvant "analgesic" medications such as tricyclic antidepressants and anticonvulsants are often useful for neuropathic pain. Proposed mechanisms of action of adjuvant drugs have been recently reviewed (Tanelian & Victory, 1995; Max, 1995). Anticonvulsants such as carbamazepine and phenytoin may inhibit ectopic neuronal activity by blocking sodium channels. Other anticonvulsants, such as clonazepam and gabapentin, may activate inhibitory gabaergic mechanisms in the dorsal horn. Tricyclic antidepressants appear to enhance endogenous descending inhibitory pathways involving serotonin and norepinephrine, although N-methyl-D-aspartate (NMDA) blockade may also play a role.

Anticonvulsants

Carbamazepine and phenytoin are useful for neuropathic pain, probably by action at sodium channels (Devor, 1995).Side effects can include sedation, confusion, ataxia, gastrointestinal disturbances, elevation of liver enzymes, and bone marrow depression. Although valproic acid may cause liver toxicity and thrombocytopenia in children, the drug is remarkably safe in adults. Mexiletine, a sodium channel-blocking agent, is structurally similar to lidocaine, and was originally developed as an anticonvulsant, although currently is approved as an antiarrhythmic drug. In doses of 450 mg/day, mexiletine may be effective in reducing lancinating and burning dysesthesias (Stracke, Meyer, Schumacher, & Federlin, 1992). Side effects include nausea, vomiting, and dizziness, which can be minimized by slow titration and administration with food. Mexiletine has the potential for inducing arrhythmias, although this is more of a concern in patients with ischemic heart disease, and an electrocardiogram (ECG) may be warranted in patients with cardiac disease or a history of arrhythmia.

Clonazepam is an alternative to carbamazepine for neuropathic pain (Swerdlow, 1984; Iacono, Linford, & Sandyk, 1987), and poses minimal risk from the standpoint of organ toxicity. However, side effects in elderly patients may include sedation and memory loss. The risk of habituation appears to be small, and the potential for serious abstinence syndrome on abrupt withdrawal of clonazepam is mitigated by the drug's long half-life (18 to 50 hours). Clonazepam is generally well tolerated in the elderly if started at a low dose (e.g., 0.25 to 0.5 mg at bedtime) and it should be titrated slowly. Typical daily doses at steady state are in the range of 1.0 to 2.0 mg. A single dose given at bedtime is usually sufficient, because of the drug's long half-life, which may minimize daytime sedation. Clonazepam may also be useful in improving sleep.

Gabapentin, an analog of gamma-aminobutyric acid, is approved for partial seizures with and without generalization in adults. Gabapentin has been shown in two randomized controlled clinical trials to be effective in diabetic neuropathy and in postherpetic neuralgia (Backonja, et al., 1998; Rowbotham, Harden, Stacey, Bernstesin, & Magnus-Miller, 1998). It was shown to be as effective as tricyclic antidepressants, and may also be considered a first choice in those neuropathic pain syndromes. Gabapentin may be effective for lancinating pain and is an alternative to carbamazepine and clonazepam. The anticonvulsant mechanism of action of gabapentin is not clear (Beydoun, Uthman, & Sackellares, 1995). Although gabapentin is presumed to enhance GABAergic activity (Honmou, Kocsis, Richerson, 1995), it does not bind to GABA receptors (Beydoun, et al., 1995), and neither GABA antagonists A or B reverse the analgesia from gabapentin (Gillin & Sorkin, 1998). Gabapentin has a high affinity for the alpha2-delta subunit of the calcium channel, but its significance remains unknown. Gabapentin has also been shown to improve pain in multiple sclerosis and cancer-related pain. It is mostly helpful in reducing spontaneous, paroxysmal pain with burning and lancinating quality, as well as allodynia to cold and tactile stimuli. It is less likely to be

beneficial for the dull, aching pain, as well as for hyperalgesia. (Mao & Chen, 2000).

Gabapentin is not metabolized by the liver, nor is it an enzyme inducer, but is largely excreted unchanged by the kidneys. Therefore, the dose should be reduced in the presence of renal insufficiency. Overall, gabapentin is well tolerated, and no adverse drug interactions have been reported. Side effects, which are usually mild, include somnolence, fatigue, headache, nausea, weight gain and dizziness. In the elderly, starting doses range from 100 mg at nighttime to three times a day.

Tricyclic Antidepressants

Antidepressants have a proven role in the treatment of neuropathic conditions such as postherpetic neuralgia and diabetic neuropathy (Max, 1995). Side effects include constipation, dry mouth, and urinary retention, attributable to the anticholinergic actions of the drugs. Cognitive side effects, including sedation, may also occur, possibly due to anticholinergic or antihistiminic effects. Adrenergic side effects include postural hypotension and tachycardia due to peripheral receptor blockade. Tricyclic antidepressants may have cardiac effects that are similar to type 1 antiarrhythmic agents. Electrocardiographic changes may include QRS widening, PR and QT prolongation, and T-wave flattening. Therefore, it is advisable that elderly patients with underlying ischemic cardiac disease have a baseline ECG prior to starting tricyclic antidepressants. The use of tricyclic antidepresants and paroxetine has resulted in very high doses of the former, which may result in adverse side effects. If paroxetine is to be used along with tricyclic antidepresant agents, careful monitoring of blood levels should be followed (Aranow, et al., 1989)

In the elderly, tricyclics with the least anticholinergic side effects, such as desipramine or nortryptiline, should be tried first, starting with a low dose and titrating slowly to effect. Reasonable starting doses are in the range of 10 to 25 mg at bedtime. Target doses of around 100 mg/day may be necessary to maximize analgesic effects, although such doses are often not tolerated, decreasing the clinical usefulness of antidepressants for pain management. Selective serotonin reuptake inhibitors such as fluoxetine generally do not appear to be as effective for neuropathic pain, although they are better tolerated than tricyclic antidepressants (Max, et al., 1992). However, paroxetine has been shown to be effective for diabetic neuropathy, but at doses higher than usually required for depression (Sindrup, Gram, Brosen, Eshoj, & Mogensen, 1990).

Nonsteroidal Anti-inflamatory Drugs (NSAIDs)

NSAIDs are highly protein-bound organic acids that undergo extensive hepatic metabolism. Their analgesic action is mediated by inhibition of prostaglandin synthesis at sites of inflammation. In addition, NSAIDs may decrease neutrophil migration into injured tissue and inhibit the release of free radicals such as nitric oxide. Analgesic effects may also result from inhibition of prostaglandin synthesis in the dorsal horn of the spinal cord (Brooks & Day, 1991; Souter, Fredman & White, 1994).

Inhibition of prostaglandin synthesis by NSAIDs is due to a reversible inactivation of cyclooxygenase (COX), which converts arachidonic acid to prostaglandin intermediates. Two types of cyclooxygenase have been identified: COX-1 is the constitutive isoform present in blood vessels, stomach, and kidney, whereas COX-2 is inducible at sites of inflammation by cytokines and other mediators of the inflammatory process. Most NSAIDs nonselectively inhibit both forms of the enzyme, which accounts for the wide range of side effects experienced by patients, especially the elderly. Side effects include gastrointestinal bleeding, renal injury, fluid retention, platelet inhibition, constipation, and central nervous system effects such as confusion and dizziness. However, nabumetone, a selective COX-2 inhibitor, is associated with a lower incidence of ulceragenic side effects (Insel, 1996). A recent celecoxib long-term arthritis safety study (CLASS) on the gastrointestinal side effects of celecoxib at doses of 400 mg twice a day, vs. ibuprofen 800 mg three times a day or diclofenac 75 mg twice a day, demonstrated less gastrointestinal side effects, including ulcers, especially in patients not taking concomitant aspirin (Silverstein, et al., 2000). Elderly patients are at increased risk for complications from NSAIDs, having a higher incidence of gastrointestinal bleeding, renal injury, confusion, tinnitus, and hearing loss. Approximately 2 to 4% of patients taking NSAIDs on a chronic basis will develop upper intestinal bleeding, a symptomatic ulcer, or intestinal perforation per year (Fries, et al., 1989). These complications may also occur after acute administration of NSAIDs. It should be noted that abdominal pain and dyspepsia are not predictive of gastrointestinal bleeding, and up to two thirds of NSAID users have no symptoms before bleeding or perforation (Popp & Portenoy, 1996).

A randomized controlled trial of celecoxib, naproxen, or placebo in 1003 osteoarthritis patients, has confirmed the eficacy of celecoxib, especially at 100 and 200 mg twice a day doses, as well as a comparable tolerability in comparison with naproxen, but with fewer gastrointestinal side effects (Bensen, et al., 1999).

In the elderly, NSAID-related nephrotoxicity can result in acute renal failure due to renal ischemia, interstitial nephritis with nephrotic syndrome, and rarely papillary necrosis (Henrich, Agodoa, & Barrett, 1996). Patients at risk for acute renal failure have underlying volume depletion from any cause or preexisting kidney disease. There is an added risk of nephrotoxicity when NSAIDs are combined with aspirin as well as with ace-

taminophen (Henrich, Agodoa, & Barrett, 1996). Interestingly, misoprostol, a prostaglandin (PGE) analog used for prophylaxis against NSAIDs-induced gastrointestinal injury, has also been shown to have a protective effect against indomethacin-induced renal dysfunction in the elderly (Nesher, Sonnenblick, & Dwolatzky, 1995).

NSAIDs may also have deleterious effects to articular cartilage and bone resorption, and may be worsen osteoarthritis (Davies & Wallace, 1996).

NSAIDs can be given with food to decrease abdominal discomfort because the bioavailability of these drugs is not altered. The dose-response relationship for NSAIDs is characterized by a minimal effective dose and a ceiling dose for analgesia; therefore, doses higher than 1.5 to 2.0 times the starting dose may not offer significant added analgesia and can only increase the risk of side effects.

Opioids

Morphine and other pure-agonist opioids are used with increasing frequency for moderate to severe pain, particularly cancer-related pain. Although pharmacokinetic data for opioids are derived mainly from young adults, several studies have demonstrated age-related differences in potency and clearance of morphine. A retrospective analysis of postoperative analgesia with morphine administered intramuscularly to cancer patients demonstrated a two-fold difference in pain relief between the extremes of adult age (Kaiko, 1980; Kaiko, Wallenstesin, Rogers, Gabrinski, & Houde, 1982). Plasma morphine levels in older patients (mean age of 71 years) were approximately twice those of the younger group (average age of 29 years), consistent with decreased morphine clearance in the elderly patients. Although older patients experienced greater maximum pain relief, the predominant effect was a longer duration of analgesia after a given dose. Therefore, age-related increases in pain relief with parenteral morphine appear to be primarily related to increased duration of analgesia rather than peak analgesic effect.

The pharmacokinetics of intravenous and oral immediate and controlled-release morphine have been evaluated in healthy young and elderly volunteers (Baillie, Bateman, Coates, & Woodhouse, 1989). Morphine pharmacokinetic profiles were determined over a 24-hour period after administration of 10 mg morphine to young (average age, 27 years) and older subjects (mean age, 74 years). Although maximum plasma concentrations (Cmax) after intravenous administration were not significantly different between younger and older subjects, Cmax was larger in elderly subjects after both oral preparations (see Figures 40.1 and 40.2). Moreover, areas under the plasma concentration-time curves were greater in older than younger subjects for all three modes of administration, suggesting decreased systemic clearance and possibly reduced first-pass hepatic metabolism of morphine in the elderly.

When administered epidurally, morphine also appears to be more potent in elderly patients (Moore, Vilderman, Lubenskyi, McCans, & Fox, 1990). In a study comparing young (mean, 36 years) and elderly patients (mean, 77 years) following elective major abdominal surgery, the quality of analgesia after a single dose of epidural morphine (0.07 mg/kg) was consistently better in the elderly group and the duration of analgesia was longer. Plasma

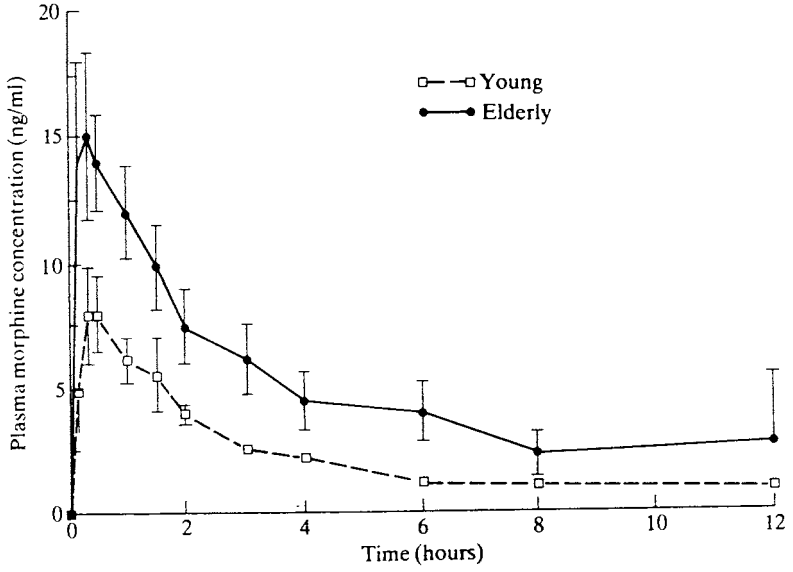

FIGURE 40.1 Plasma morphine concentrations for 12 hours after a 10-mg oral dose of immediate-release morphine solution in young and elderly healthy subjects (mean ± SEM). (From Baille, et al., Age and Ageing, 18, 258, 1989. With permission.).

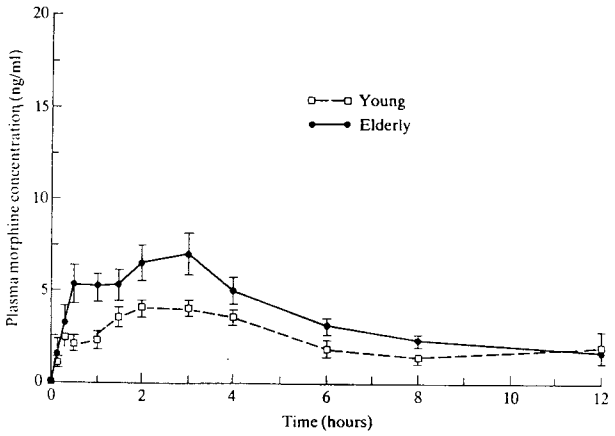

FIGURE 40.2 Plasma morphine concentrations for 12 hours after a 10-mg, oral controlled-release morphine tablet (MST Continus™) in young and elderly healthy subjects (mean + SEM). (From Baille, et al., Age and Ageing, 18:258, 1989. With permission.)

morphine concentrations in both groups were not significantly different, suggesting a centrally mediated increase in sensitivity to morphine in elderly patients.

Patient-controlled analgesia (PCA) allows patients to self-administer small doses of analgesic on demand. The technology has been available for close to three decades and is safe and effective (White, 1988). In elderly patients, the use of intramuscular medications may be hazardous, particularly in frail patients. A prospective controlled trial with 83 high-risk, postoperative elderly patients compared PCA morphine to intramuscular morphine (Egbert, Parks, Short, & Burnett, 1990). Significant improvement in analgesia, without sedation, was noted in patients who received morphine by PCA. In addition, confusion and respiratory depression were less common and serum morphine concentrations showed less variability on the first postoperative day, demonstrating the advantages of PCA drug delivery for elderly patients.

Oral opioids are cost-effective, particularly for patients out of the hospital. Controlled-release preparations of opioids are convenient, minimize the number of daily doses required, and optimize patient comfort and compliance. Oxycodone, an opioid analgesic with a potency similar to morphine, has recently been recognized as an alternative to oral morphine for the management of postoperative and cancer pain (Poyhia, Vainio, & Kalso, 1993). However, in contrast to morphine, oxycodone's pharmacokinetic and pharmacodynamic parameters are not significantly different between healthy young adults and elderly subjects (Figure 40.3), and dosage reductions for healthy elderly patients in moderate to severe pain do not appear necessary (Kaiko, et al., 1996). This makes OxyContin™, a controlled-release preparation of oxycodone, an attractive alternative to controlled-release morphine for elderly patients.

Opioids are remarkably effective for nociceptive pain and remain the gold standard against which all other analgesics are measured. However, concerns about addiction and side effects, which are often overstated, may interfere with appropriate prescribing for both acute and chronic pain syndromes. The risk of addiction with opioids is probably very small, as shown in the Boston collaborative drug surveillance program, which identified only four cases of drug addiction in a follow-up of close to 40,000 patients (Porter & Jick, 1980). Opioid analgesics are the cornerstone of postoperative pain management and the incidence of addiction in this setting is virtually zero (Pasero & McCaffery, 1996). Based on a favorable experience with opioids for cancer pain, there is increasing belief that opioids may also be appropriate for some forms of chronic nonmalignant pain. For patients who have well-defined pain syndromes and no history of drug abuse, opioids may have a better therapeutic index than currently available NSAIDs. Indeed, opioids do not appear to produce organ toxicity, as shown in longitudinal studies with patients on methadone maintenance (Kreek, 1973). Issues related to opioids for chronic nonmalignant pain have been discussed in detail by Portenoy (1994). In a survey conducted by Turk, Brody, and Okifuji (1994), long-term prescribing of opioids is widespread and the legal requirements of some states for triplicate prescriptions appear to have had little impact on opioid-prescribing practices.

Recently, tramadol was released for use in the U.S., although the drug has been available in Canada and Europe since the early 1970s. Initial enthusiasm for the drug in the U.S. was probably based on the impression that tramadol was a nonopioid analgesic with a potency similar to codeine, but without the stigma of being a controlled substance. More recently, the manufacturer has addressed this issue in direct mailings to physicians, noting that the drug is a centrally acting analgesic with μ-agonist activity and therefore has the potential for abuse. In addition, a recent notification that tramadol may cause seizures at usual therapeutic doses, particularly in patients taking tricyclic antidepressants, has dampened enthusiasm for the drug. As an analgesic, tramadol may have some value for neuropathic pain because it appears to inhibit reuptake of serotonin and norepinephrine, in a manner similar to tricyclic antidepressants, which may partially account for the analgesic action of the drug. Tramadol is generally well tolerated by elderly patients, and a double-blind study evaluating 390 elderly patients with chronic pain found tramadol comparable to acetaminophen with codeine (Rauck, Ruoff, & McMillen, 1994). Side effects are similar to codeine and include nausea, constipation, dizziness, and somnolence.

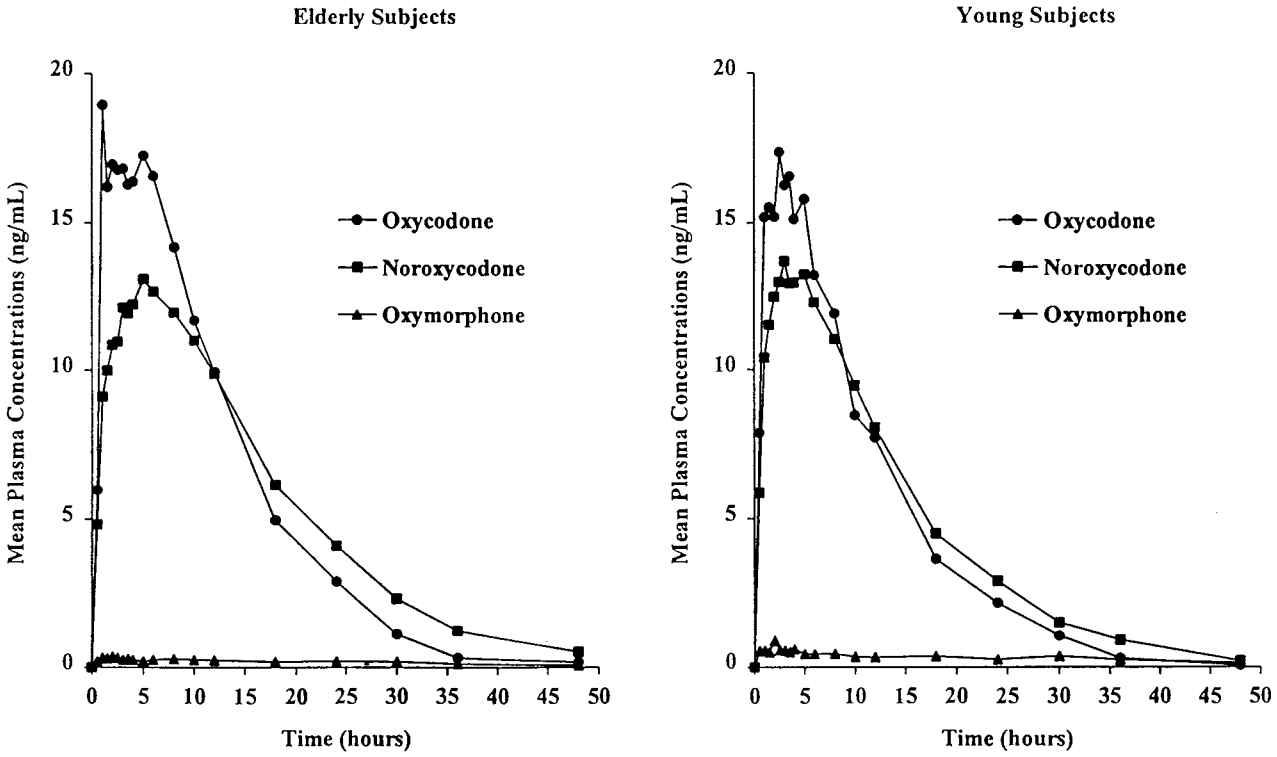

FIGURE 40.3 Mean plasma concentrations of oxycodone, noroxycodone, and oxymorphone in elderly and young healthy subjects for 48 hours after administration of a single, 20-mg, controlled-release oxycodone tablet (OxyContin). Noroxycodone is the major metabolite in plasma and does not appear to contribute to analgesia. Although oxymorphone is more potent than oxycodone, plasma levels are not clinically significant. No differences in plasma concentrations of oxycodone or metabolites were evident between elderly and young subjects. (From The Perdue Frederick Company, Norwalk, CT, 1996. With permission.)

SUMMARY

It appears that pain perception is not altered by age. Indeed, pain is more common in the elderly. Pain assessment tools used in young adults are also useful for elderly patients. As with younger patients, other dimensions of pain should be evaluated, including cognitive, functional, and psychological status, to ensure optimum treatment and appropriate utilization of healthcare resources. The pain assessment and physical examination must be thorough, and the clinician should look for possible coexisting disease.

It is useful to determine whether pain is nociceptive or neuropathic in nature, which may help direct therapy. Although opioid analgesics are effective for nociceptive pain, adjuvant analgesics such as tricyclic antidepressants and gabapentin will be more effective for pain associated with nerve injury. Pharmacologic management should be based on a specific diagnosis if possible, and therapy directed at the mechanisms of pain. Because pharmacokinetic and pharmacodynamic parameters can vary between young adults and elderly patients, analgesic dosing regimens may need to be adjusted for older patients. To improve pain relief and minimize side effects in elderly patients, analgesics should be started at lower doses than with younger patients and titrated more slowly to effect. Although perhaps more labor intensive than with younger patients, this approach should improve compliance and optimize patient care.

Finally, newer techniques such as radiofrequency denervation and transforaminal epidural steroid injections under fluoroscopy may help reduce the discomfort and medication use in appropriate cases.

Sleep and Weight Problems Associated with Pain

Arnold Fox, M.D. and Barry Fox, Ph.D.

> So neither ought you attempt to cure the body without the Soul, and this … is the reason why the cure of so many diseases is unknown to the physicians of Hellas, because they are ignorant of the whole which ought to be studied, also, for part can never be well unless the whole is well.
>
> Plato

INTRODUCTION

Sleep and weight generally affect all chronic pain patients. In addressing this topic, the authors recognize that many complex factors enter into health and disease, including stress. Pain, suffering, and disability are described as a cycle dependent, in part, on our expectations.

Problems associated with weight gain and sleep disturbance exacerbate treatment for pain and must be regarded as perpetuating factors needing resolution concomitant with pain management.

SINGLE CAUSES AND SIMPLE EQUATIONS

As a young medical student, I (Arnold Fox) was taught to look for the single cause of disease, for the specific germ, perhaps the *Mycobacterium tuberculosis*. This single cause, said the medical sages and literature, would define the disease, explain the cause, and point to the cure.

Streptococcus "explained" strep sore throat, as well as the rheumatic fever and rheumatic heart disease that struck many children and young adults. The polio virus "explained" why we had hospital floors filled with patients lying helpless in their iron lungs. Look for the germ, they told us … find the vitamin deficiency, the endocrine imbalance … the single factor that elucidates the disease process.

It was all so simple. Germ X = disease X, germ Y = disease Y. The equation was simple. Yes, the single-cause theory was exciting and enticing; it made everything so easy — cause and cure, effect and response. Unfortunately, the single-cause theory failed to consider the fact that people who are exposed to various germs and other disease-causing factors remain perfectly healthy. I spent many months in the tuberculosis ward at the Los Angeles County Hospital. I saw entire families that had been exposed to tuberculosis, who had been coughed on countless times by the patient they cared for, yet they never came down with the disease.

Clearly, disease was more than the result of being exposed to a germ. The response of the invaded body had to be considered, as well as the person's immune system, nutritional, physiologic, and psychological state, and more. Sometimes, the body's misreading of the situation leads to disease. This happens with allergies; the body labels relatively harmless pollen as a potential poison, triggering a violent reaction. The body is hit by "friendly fire," producing allergies or worse.

Obviously, the equation was more complex than we thought. And clearly, the physical factors (such as germs and vitamins) do not stand alone in the health equation. Every formula must include the psychological and spiri-

0-8493-0926-3/02/$0.00+$1.50

tual factors as well as the physical factors. Indeed, we have learned that the effect of the psychological factors (stress) on the immune system are among the most powerful of all, especially those of a chronic nature (Cassel, 1986; Friedman & Glascow, 1974; Mason, et al., 1979; Syme, 1975).

IS STRESS THE SINGLE CAUSE?

"Well, just a minute", some have said. Can we consider stress to be the single cause of disease — or of many diseases? No, because we all react differently to stress. For years, those who suffered from migraine headache were characterized as suffering the effects of ongoing and severe stress. Yet it has been shown that migraine headache sufferers and individuals who do not have migraine headaches have just about the same type of life otherwise (Henry, Gutt, & Rees, 1973). Other equally interesting studies include one that measured the response to stress among women awaiting breast biopsies for presumed cancer of the breast. All the women faced the same serious, possibly deadly, disease, yet there was wide variety in their measures of cortisol (in the form of 17-hydroxycorticosteroid, which is known to be elevated with stressful situations) (Katz, et al., 1970). This and thousands of other studies have convinced most physicians and others in the health care field that there is no single cause of disease — not even stress.

A COMPLEX EQUATION

Many factors enter into the health and disease equation. The entire interaction between the person and his or her environment must be considered. This is especially true with chronic pain. All the factors must be considered, especially the psychological, for what we think influences how we feel.

Reciprocal interactions between persons/patients and their environments help determine what they think about their problems, thus influencing how they feel. One person with a history of chronic low back pain who wakes up with back pain may consider it a minor annoyance, a cost of growing older. So this person takes a hot shower, a simple analgesic (e.g., aspirin), does a few stretching exercises, then goes to work, fully expecting to be able to get through the day. Another person with similar pain may look upon the pain as a punishment, or be angry at the driver of the car that rear-ended him or her. This person expects to feel miserable and believes that he or she cannot possibly get through the day. This person may lie in bed, become angry, fight with a spouse, resent the boss for being so uncaring, go to a physician, or seek an attorney. Increasing resentment, anger, and irritability result, along with sleep disturbances. Inactivity and increased food intake (to assuage the stress) lead to weight gain — which often increase the pain and disability. Such cycles can go forever, or so it seems.

What we think, what we believe, and what we expect (cognitive factors) may have more influence on our pain than other factors. The pain equation is long and complex.

OBESITY

To complicate matters, obesity, a major problem here in the U.S., is often associated with chronic pain. All of us who care for patients have noted that those with chronic pain problems tend to gain weight. Away from work, sitting at home, not exercising, eating more to alleviate the psychic and physical pain, eating the wrong foods, and/or suffering a drop in self-esteem, pain patients tend to pack on the pounds. Gaining weight exacerbates their disability, increases joint problems, and deleteriously affects the entire pain-control process. Studies (e.g., Jamison, et al., 1990) have shown that there is a significant relationship between a chronic pain patient's weight gain and decreased physical activity, an increased tendency to have accidents, heightened emotional stress with all the associated physiologic and psychological problems, and even increased sensitivity to pain.

Such studies support the observation that obese subjects may be more sensitive to pain than non-obese subjects (McKendall & Haier, 1983). (This was felt to be related to the endogenous opiate systems, although the mechanism is far from clear.) Electrophysiologic studies measured nociceptive threshold in 30 obese women (30% or more above ideal weight) and 20 controls. The nociceptive threshold was significantly lower in the obese individuals than in the controls (Pradatier, et al., 1981). The authors' experience in raising the endogenous endorphin levels using dl-phenylalanine (DLPA) (Fox & Fox, 1985), plus dietary and related methods, have shown that the pain threshold can be lifted and pain decreased. This often speeds the patient's recovery.

(Authors' Note: In 1972, Dr. Candace Pert and Dr. Solomon Snyder showed that morphine [a powerful pain-killing drug] fits into certain nerve cell structures in the brain like a key fits its lock [i.e., morphine can unlock previously unknown powers of the brain]. But this was a puzzling discovery. Why do human brain cells have specific structures that interact with morphine? These two scientists, along with others, proposed a simple, yet radical, explanation: The human brain must produce its own form of morphine. Studies at major universities around the world have shown that the brain does, in fact, produce many hormone-like chemicals that bear a close functional resemblance to morphine. These morphine-like chemicals are called endorphins because they are produced by the body [they are endogenous] and are similar to morphine. Pain researchers began testing the endorphins, finding that

the endorphins are more powerful than morphine, the strongest painkiller we have. Unfortunately, the body that produces endorphins also degrades them. In fact, it was theorized that, in some pain patients, the body was keeping natural endorphin levels too low, resulting in pain. Dr. Seymour Ehrenpreis of the Chicago Medical School found that a nutritional amino acid called phenylalanine [PA] blocked the degradation of endorphins. DLPA [the dl-form of phenylalanine] protects our naturally produced endorphins, effectively extending their life in the nervous system. I (Arnold Fox) have had a great deal of success treating pain patients with DLPA. As part of the full treatment, DLPA helps in raising their threshold to pain, lifting their depression, and losing excess weight.)

PAIN, SELF-PERCEPTION, AND OBESITY

The weight gain that often accompanies chronic pain can damage the patient's self-esteem. This can lead to, among other problems, dysfunctional responses to the stress of pain and disharmony within the network of family and friends, and the medical team — the very people who should all be working together to support the patient. As patients become increasingly immobilized by their pain, weight gain, stress, and increased sensitivity to pain, they may develop feelings of helplessness and hopelessness. Convinced that they have lost control, patients wonder why they should even bother trying to get well. Manageable pains may become intolerable burdens. The pain equation is complex indeed.

OBESITY AND PAIN

I (Arnold Fox) have seen many patients whose pain was worsened by their obesity. For example, I have treated a number of obese patients with carpal tunnel syndrome who were obese and had no other predisposing factors (e.g., repetitive occupational use of wrists or hands, pregnancy myxedema, rheumatoid arthritis, acromegaly, and gout) (Swick & McQuillen, 1976). In many of these patients, significant weight loss was enough to abolish symptoms and normalize nerve velocity studies.

Osteoarthritis is characterized by a gradual loss of the joint cartilage, leading to deformities of the joints involved, plus progressive pain and loss or limitation of motion in the affected joint. Obesity may contribute to or worsen this process, especially in weight-bearing joints. Pseudogout is a form of arthritis caused by the release of calcium pyrophosphate crystals into the joint space, which, in turn, causes an inflammation of various joints. Acute exercise may trigger attacks involving one or several joints in some areas. We doctors aspirate the fluid from the joint and find the crystals in the joint fluid. We treat pseudogout with medications and rest. We help prevent further attacks by reducing aggravating factors, including obesity.

Back pain is a major problem, the incidence of which is staggering. Approximately 80% of the population will, at some time, have back pain sufficient to interfere with their regular activities, or send them to see a doctor (Nachemson, 1976). Obesity can cause or aggravate low back (lumbar spine) pain, especially fat in the abdominal area. "Beer bellies" may cause the muscles of the abdomen to become distended, producing increased lordosis. (Picture the pregnant female in the last part of pregnancy.) The muscles of the anterior abdominal wall have a very important function: stabilizing the lumbar spine and pelvis. Obesity reduces the tonus (strength) of these muscles, increasing lordosis (curve of the lumbar spine). This produces strain of the anterior lumbar spinal ligaments, and possibly impingement of the posterior joint facets and spinous processes on occasion, adding to more back pain. There may also be disturbances of the weight-bearing duties of the feet, knees, and hips with obesity. The abnormal posture caused by obesity can lead to pain in the lower extremities and hips. In addition, with obesity there may be weakness of the pelvic floor, especially in females, that may cause referred pain to the sacrum and coccyx.

There are various pains caused by trapping of a nerve. For example, pain on the anterior (front) side of a thigh may be caused by the lateral femoral cutaneous nerve becoming entrapped beneath the inguinal ligament, producing a syndrome called neuralgia paresthestica (Kitchen & Simpson, 1972), which may often be a complication of obesity. The symptoms can include a burning, tingling pain and numbness over the anterior thigh area made worse by walking or standing. Weight loss is very effective. (This can also occur with pregnancy, or be caused by a tight girdle.)

PAIN AND SLEEP DISORDERS

Pain patients often complain about their sleep disorders, especially an inability to fall asleep. So many patients report that they are more aware of their pain in the evening and nighttime hours, and that the pain is more intense at that time. I (Arnold Fox) learned back in the 1950s that pain seems greater during the dark hours. As an intern, I was called to see patients all night long (and wound up with my own sleep problems). Patients whose chronic pain appeared to be stabilized in the daytime became unstable during the sleep hours. Why? For one thing, there was less activity at night. Various external stimuli (e.g., lights, TV, visitors) are absent. The focus of the patient's attention moves inward, settling on the pain. Patients may fear another sleepless, painful night, and their fears worsen their pain. Focus and fear are great inducers of pain.

Depression is another enemy of sleep. The link between depression and chronic pain is well-established. Many depressed chronic pain patients have difficulty in falling asleep and staying asleep. They have early-morning awakenings, fitful sleep patterns, and they wake up feeling very tired. (Some depressed people may sleep more than usual.) Antidepressants can be used to raise the person's (subjective) pain threshold, which may help restore the sleep cycle.

Patients may resist antidepressants, saying that they are not depressed, or not depressed enough to require medications. It is important to convey to these patients that the antidepressant is being used to raise their pain threshold. We must stress that we understand that their pain is real, and not imagined.

CASE HISTORY

Mr. Jones, a 35-year-old factory worker, is one of the multitude of chronic pain patients I (Arnold Fox) have seen through the years. Many of the pain factors discussed previously have played a role in his disability and recovery. He injured his low back while lifting boxes at work. The company doctor examined him, took X-rays, and prescribed medications and 4 weeks of physical therapy. The doctor's attitude, according to Mr. Jones, was negative: "He didn't believe that I was hurt."

The patient was sent back to work. His back still hurt, but he had to work to support his family, and he figured his back would improve. It did not, despite copious quantities of over-the-counter and prescribed pain medications. When I interviewed Mr. Jones, he vehemently denied depression, but did acknowledge that since the injury he had difficulty falling asleep and staying asleep, had early-morning awakenings, and felt tired upon awakening. He also admitted to some other biological associates of depression, such as poor appetite, fatigue, difficulty in concentrating and focusing his thoughts, a decreased sexual interest, plus a decreased interest in formerly pleasurable activities (e.g., movies, theater, reading, family outings). His MMPI (Minnesota Multiphasic Personality Index) showed a rather significant rise in the depression scale; and although he denied depression, his voice, expression, and body language supported the impression of depression.

He stated that his sleep disturbances became noticeable when, 7 to 8 weeks after the injury, he realized that his pain was not going to go away as quickly as he thought it would. Eight months passed and he was still unable to work. His disability checks stopped when the company disputed the work injury. His small savings account was quickly exhausted. His wife went to work while he sat at home feeling guilty and useless. He feared that his three children would view him in a negative light. He was careful not to complain, preferring to bear his pain and disability "like a man".

He "didn't feel like" eating. In fact, he avoided sitting down to a meal. Instead, he snacked all day. Over 18 months, 5′ 10″ and 170 pounds, he grew to 225 pounds. His feet and knees hurt. His back pain grew worse. His blood pressure was high (for the first time). He attributed the weight gain to his lack of exercise. He saw many specialists, practicing many modalities, all of whom were helpful for a while. He took various medications, ranging from nonsteroidal anti-inflammatory drugs (NSAIDs, some of which increase weight) to narcotics. He took up smoking again, puffing his way through two packs a day, along with a six-pack of beer, to assuage his symptoms.

With each treatment failure, Mr. Jones's pain and other problems grew worse. He only slept a few hours a night, waking up tired and irritable. His morale plummeted. His physicians and other healthcare providers became more negative as his problems continued. As they became more negative, they attempted to distance themselves from him and "shuffled him over" to other specialists. (This is called the "dumping syndrome"—dump the patient on someone else.)

Skewing the Equation

Why was Mr. Jones so long in recovering? Every treatment we physicians, and others, offer to our patients carries a message. That message is there, whether or not we label it as a message, or even understand that it exists. In what we do and say, we convey to the patient an impression. It may be positive: "Yes, I am a professional. Yes, I am optimistic. Yes, we are going to lick this thing together." The message may also be negative: "There is no hope. You will have to learn to live with it. Stop complaining. If you are not getting better, it is your fault. How can I get rid of you?"

I believe that Mr. Jones received the latter message and it was reflected in continuing and even worsening symptoms, not only of his back pain but, more importantly, of his deterioration as a person — as a father, husband, son, worker, and citizen.

It is important that everyone who meets with and deals with patients — from the receptionist to all the healthcare professionals and associates — presents the most optimistic picture that can be honestly given. I was taught that there is always something that we can do to help the patient. Something. Perhaps we cannot alter the pathology, but we can offer what we know, understanding, empathy, a kind hand, and not withdraw from the patient. (The doctor for whom Barry Fox is named always offered a kind hand, and never in defeat. He sat quietly with my grandmother, holding her hand at home, as she died. He taught me that there is always something we can do.)

SOLVING THE EQUATION

In Mr. Jones's case, the interdisciplinary team was assembled. Therapy suggestions were made and considered. He was weaned from his analgesics and soporifics (sleeping pills). Antidepressants were used for a time to raise his threshold to pain, and then gradually reduced. To help him sleep, he was taught the Meditation-Relaxation Response, a technique we have used for years (Fox & Fox, 1989). The response helped him relax, setting up the mechanisms for sleep.

We also used biofeedback, demonstrating to this demoralized patient that he could control certain physiologic functions and that he had some control over his body. We also started him on the DLPA program (Fox & Fox, 1985). The DLPA program includes the use of DLPA, specific dietary instructions and nutrients, plus exercises and affirmations.

Involvement: The Often-Missing Factor

One of our main goals was to get Mr. Jones actively involved in his own treatment and recovery. We emphasized to him, and he accepted, the fact that the benefits of the various treatments were largely a result of what he did himself. The team members worked together with Mr. Jones, emphasizing that we looked upon him as a human being operating in his environment and not a low-back patient.

His family was also involved because the entire family is affected by his pain and plays a role in his recovery (or lack of). We can assume that even a well-functioning family group can become dysfunctional with time, as the chronic pain patient loses his/her family and occupational role, gradually assuming the role of "the sick one" (Roy, 1982, 1984; Maruta, 1981). One must ask the question: What purpose does the pain serve for the patient or the family? It has been shown that in many family settings there may be a definite role prolonging and perpetuating the chronic pain (Swenson & Maruta, 1980).

Some 30 years ago, when I was a young, newly graduated consultant, a woman patient with severe pain was referred to me by a general practitioner. Finding nothing I could deal with or understand, I sent her to a psychiatrist. The psychiatrist promptly called me and asked, "What do you want me to do?" I replied, "Take away her pain." He said, "Arnold, don't you see that the way the family is constituted, both she and they 'need' the pain? Until this family dysfunction is resolved, there will be no resolution of the pain." I learned a valuable lesson.

We must also remember that spouses and other close family members of the chronic pain patient suffer a higher degree of depression than do members of families without chronic pain members. Furthermore, it is well-known that spouses of chronic pain patients may be even more depressed than the patients themselves. It is important to involve the entire family.

With a multidisciplinary healthcare team, with the family involved, with the patient convinced that he could recover, with the Meditation–Relaxation Response, the exercises, diet, and DLPA program, Mr. Jones began to recover. He was able to sleep at night. His self-esteem returned. He lost his excess weight, went through a special exercise program, and was eventually able to return to a full family and occupational life.

The pain equation is complex, often too difficult for one professional to solve. The factors are many: the patient; the patient's feelings and fears; the doctor's attitude; the germs; the medicines and treatments; the family; and more. There is rarely a single cause with a simple solution. It often takes a team of experts to solve the complex pain equation.

MEDITATIVE RELAXATION

The following is a "script," which may be tape-recorded, for the meditative-relaxation technique that I and others have used successfully to help chronic pain patients (and other patients) relax, sleep better, and overcome pain. Meditative relaxation may not be as glamorous or high-tech as drugs and surgery, but it worked well in many cases.

Part 1: Every Muscle Needs a Total Loosening

I have found that this three-tiered program of meditative relaxation helps many chronic pain patients reduce their stress and pain, and sleep better. I suggest to patients the following:

Go into a quiet room twice a day for 10 to 15 minutes, turn off the lights, close the shades, unplug the phone, loosen all belts and ties, and tell everyone not to bother you.

Push a comfortable chair up against a wall and take a seat. Rest your feet on the floor, a little bit in front of you. Place your hands on your knees.

Tensing for Relaxation

Begin by tensing and relaxing your eyes, mouth, neck, arms, trunk, and legs. To help my patients remember the order, I tell them that Every Muscle Needs A Total Loosening (that is, Every = eyes, Muscle = mouth, Needs = neck, A = arms, Total = trunk, and Loosening = legs).

Every = Eyes

Begin by closing your eyes. Hold them clenched shut, as tightly as you can. Clench them still

tighter. Hold those muscles taut while you count slowly: one thousand … two thousand … three thousand… four thousand ..five thousand … six thousand … seven thousand … eight thousand… nine thousand … ten thousand.

Relax your eye muscles.

Now take a slow, deep breath in through your nose. Hold it. Then let it slowly out through your mouth, very slowly, taking at least 5 seconds to let it all out.

Take another slow breath. Fill your lungs. Feel your diaphragm pulling down to open the lungs wide. With your mind's eye, see your diaphragm dropping down as your lungs fill.

Now repeat. Squeeze your eyes tightly shut. Hold your eyes closed tightly while you count slowly: one thousand … two thousand … three thousand… four thousand ..five thousand … six thousand … seven thousand … eight thousand… nine thousand … ten thousand.

Slowly relax your muscles, and then slowly open your eyes.

Take a deep breath in through your nose … a nice, deep breath. Feel your diaphragm pulling down to open your lungs wide. With your mind's eye, see your diaphragm dropping down as your lungs fill.

Hold your breath for a moment. Now let it out through your mouth, very slowly, taking at least five seconds to empty your lungs.

Take another big breath; fill your lungs.

Hold it for a moment. Now let it out very slowly. Take 5 seconds or more to blow it all out.

The muscles around your eyes do not feel tired anymore. They feel good.

Muscle = Mouth

Now tighten up the muscles of your mouth. Grimace. Show your teeth, and tighten up the muscles around your mouth and the front of your neck. Tilt your chin up. Now, with your teeth still bared, open your lips as wide as you can. Hold them open, teeth clenched, as you also tighten your cheek and neck muscles. Teeth clenched, cheeks and neck tight, lips pulled open. Hold these muscles tight while you count slowly: one thousand … two thousand … three thousand… four thousand ..five thousand … six thousand … seven thousand … eight thousand… nine thousand … ten thousand.

Slowly relax your lips, jaw, cheek, and neck muscles.

Now take a slow, deep breath in through your nose. Hold it. Then let it slowly out through your mouth, very slowly, taking at least 5 seconds to let it all out.

Take another slow breath. Fill your lungs. Feel your diaphragm pulling down to open the lungs wide. With your mind's eye, see your diaphragm dropping down as your lungs fill.

Now repeat. Tighten the muscles of your mouth, clench your teeth, and grimace. Tilt your chin up and tighten the muscles around your mouth and in the front of your neck. Hold that for a moment, then open your lips wide as you tighten your cheek and neck muscles. Hold these muscles tight while you count slowly: one thousand… two thousand … three thousand … four thousand ..five thousand-six thousand … seven thousand … eight thousand … nine thousand… ten thousand.

Slowly relax your jaw, lips, cheek, and neck muscles.

Take a deep breath in through your nose … a nice, deep breath. Feel your diaphragm pulling down to open your lungs wide. With your mind's eye, see your diaphragm dropping down as your lungs fill.

Hold the breath for a moment. Now let it out through your mouth very slowly, taking at least 5 seconds to empty your lungs.

Take another big breath; fill your lungs.

Hold it for a moment. Now let it out very slowly. Take 5 seconds or more to blow it all out.

The muscles of your mouth and the front of your neck now feel light and relaxed.

Needs = Neck

Next comes the neck: gently, but firmly, push your head against the wall behind you. This puts the muscles in the back of your neck into contraction. Hold that position while you count slowly: one thousand … two thousand … three thousand… four thousand ..five thousand … six thousand… seven thousand … eight thousand … nine thousand … ten thousand.

Slowly relax, letting your head slump forward just a little.

Now take a slow, deep breath in through your nose. Hold it. Then let it slowly out through your mouth, very slowly, taking at least 5 seconds to let it all out.

Take another slow breath. Fill your lungs. Feel your diaphragm pulling down to open the lungs wide. With your mind's eye, see your diaphragm dropping down as your lungs fill.

Again. Gently, but firmly, push your head against the wall behind you. Hold that position while you count slowly: one thousand … two thou-

sand … three thousand … four thousand … five thousand … six thousand … seven thousand … eight thousand … nine thousand … ten thousand.

Slowly relax your jaw, lips, cheek, and neck muscles.

Take a deep breath in through your nose … a nice, deep breath. Feel your diaphragm pulling down to open your lungs wide. With your mind's eye, see your diaphragm dropping down as your lungs fill. Hold the breath for a moment. Now let it out through your mouth, very slowly, taking at least 5 seconds to empty your lungs.

Take another big breath, fill your lungs.

Hold it for a moment. Now let it out very slowly. Take 5 seconds or more to blow it all out.

Now push up your shoulders so that they almost touch your ears. Tilt your chin up and your head back, so that the back of your head almost touches your raised shoulders. Push your neck down and back, into your shoulders, feeling the muscles at the base of your neck, where your neck meets your shoulders, contracting. Lift your shoulders up into your neck as high as you can. Feel the tension in the back of your neck and upper shoulders as you count slowly: one thousand … two thousand … three thousand … four thousand … five thousand … six thousand … seven thousand … eight thousand … nine thousand … ten thousand.

Slowly relax your neck and lower your shoulders.

Now take a slow, deep breath in through your nose. Hold it. Then let it slowly out through your mouth, very slowly, taking at least 5 seconds to let it all out.

Take another slow breath. Fill your lungs. Feel your diaphragm pulling down to open the lungs wide. With your mind's eye, see your diaphragm dropping down as your lungs fill.

Once more, tilt your neck back and lift your shoulders up into your neck. Hold your neck and shoulders tense as you count slowly: one thousand … two thousand … three thousand … four thousand … five thousand … six thousand … seven thousand … eight thousand-nine thousand … ten thousand.

Slowly relax your jaw, lips, cheek, and neck muscles.

Take a deep breath in through your nose … a nice, deep breath. Feel your diaphragm pulling down to open your lungs wide. With your mind's eye, see your diaphragm dropping down as your lungs fill.

Hold the breath for a moment. Now let it out through your mouth, very slowly, taking at 5 five seconds to empty your lungs.

Take another big breath, fill your lungs.

Hold it for a moment. Now let it out very slowly. Take 5 seconds or more to blow it all out.

The muscles of your shoulders and the back of your neck now feel light and tingly.

A = Arms

Put both arms straight out in front of you at about shoulder level, palms facing down. Make two very tight fists, as tight as you can make them. Bending at the wrist, push yourstfis down toward the floor as hard as you can. Feel the muscles in your wrists and forearms tighten, and feel the tension, especially in your forearms, up to your elbows. Hold that position while you count slowly: one thousand … two thousand… three thousand … four thousand … five thousand … six thousand … seven thousand… eight thousand … nine thousand … ten thousand.

Slowly relax. Open your stfis. Rest your hands, palms down, on your knees. Feel how relaxed, refreshed, and tingly your hands, wrists, and arms feel.

Now take a slow, deep breath in through your nose. Hold it. Then let it slowly out through your mouth, very slowly, taking at least 5 seconds to let it all out.

Take another slow breath. Fill your lungs. Feel your diaphragm, pulling down to open the lungs wide. With your mind's eye, see your diaphragm dropping down as your lungs fill.

Again, put both arms straight out in front of you at about shoulder height, palms facing down. Make two very tight fists, as tight as you can make them. Bending at the wrists, push your fists down toward the floor as hard as you can. Feel the muscles in your wrists and forearms tighten, and feel the tension, especially in your forearms, up to your elbows. Hold that position and count slowly: one thousand … two thousand… three thousand … four thousandfive thousand… six thousand-seven thousand … eight thousand … nine thousand … ten thousand.

Now slowly relax your jaw, lips, cheek, and neck muscles.

Take a deep breath in through your nose … a nice, deep breath. Feel your diaphragm pulling down to open your lungs wide. With your mind's eye, see your diaphragm dropping down as your lungs fill.

Hold that breath for a moment. Now let it out through your mouth, very slowly, taking at least 5 seconds to empty your lungs.

Take another big breath; fill your lungs.

Hold it for a moment. Now let it out very slowly. Take 5 seconds or more to blow it all out.

Now hold your arms out to the sides of your body at shoulder level, palms up. Close your hands into tightly clenched fists. Bend your arms at the elbow, bringing your fists to your ears. Clench your arm and shoulder muscles, especially the biceps muscles in your upper arms. Hold tight and count slowly: one thousand … two thousand … three thousand … four thousand… five thousand … six thousand … seven thousand… eight thousand … nine thousand … ten thousand.

Slowly relax, dropping your arms to your lap as you take in a deep breath through your nose.

Take in another deep breath through your nose. Hold it for a moment. Now let it out slowly, very slowly, through your mouth, taking at least 5 seconds to empty your lungs.

Take another big breath, filling up your lungs. Hold it for a moment. Now let it out slowly, very slowly.

Again, hold your arms out to the sides of your body at shoulder level, palms up. Close your hands into tightly clenched fists. Bend your arms at the elbow, bringing your fists to your ears. Clench your arm and shoulder muscles, especially the biceps muscles in your upper arms. Hold tight and count slowly: one thousand … two thousand … three thousand … four thousand… five thousand-six thousand … seven thousand… eight thousand … nine thousand … ten thousand.

Slowly relax, dropping your arms to your lap as you take in a deep breath through your nose.

Take in another deep breath through your nose. Hold it for a moment. Now let it out slowly, very slowly, through your mouth, taking at least 5 seconds to empty your lungs.

Take another big breath, filling up your lungs. Hold it for a moment. Now let it out slowly, very slowly.

Concentrate on your arms for just a moment. Feel how light and tingly they are.

Total = Trunk

Fill your lungs with as much air as you can. Holding the air in your lungs, bear down as if you were going to have a bowel movement. While holding the air and bearing down, place your fists up by your chin. Squeeze your arms tightly against your chest. Feel the tension in your chest muscles as you count slowly: one thousand… two thousand … three thousand … four thousand… five thousand … six thousand … seven thousand … eight thousand … nine thousand… ten thousand.

Slowly relax, letting the air out of your lungs.

Now take a slow, deep breath in through your nose. Hold it. Then let it out slowly through your mouth, very slowly, taking at least 5 seconds to let it all out.

Take another slow breath. Fill your lungs. Feel your diaphragm pulling down to open the lungs wide. With your mind's eye, see your diaphragm dropping down as your lungs fill.

Fill your lungs once again, bear down, hold your fists by your chin and squeeze your arms against your chest. Hold that position, chest muscles clenched tightly, as you slowly count: one thousand… two thousand-three thousand … four thousand… five thousand … six thousand … seven thousand … eight thousand-nine thousand… ten thousand.

Slowly relax and exhale.

Take a deep breath in through your nose … a nice, deep breath. Feel your diaphragm pulling down to open your lungs wide. With your mind's eye, see your diaphragm dropping down as your lungs fill.

Hold that breath for a moment. Now let it out through your mouth, very slowly, taking at least 5 seconds to empty your lungs.

Take another big breath, fill your lungs. Hold it for a moment. Now let it out very slowly. Take 5 seconds or more to blow it all out.

Your trunk now feels relaxed.

Loosening = Legs

Straighten out your legs in front of you, lock your knees, and raise your feet off the floor. Hold them at about the level of your chair seat, toes pointing forward. Feel the tension in your calves, ankles, and in the front and outside of your thighs. Hold that position. Keep your toes pointed forward as you slowly count: one thousand… two thousand … three thousand … four thousand… five thousand … six thousand … seven thousand … eight thousand-nine thousand… ten thousand.

New slowly relax, lowering your feet to the floor. Take a slow, deep breath in through your nose. Hold it. Then let it out slowly through your mouth, very slowly, taking at least 5 seconds to let it all out.

Take another slow breath. Fill your lungs. Feel your diaphragm pulling down to open the lungs wide. With your mind's eye, see your diaphragm dropping down as your lungs fill.

Again, lift your feet off the floor, knees locked, toes pointing forward. Hold tight and count slowly: one thousand … two thousand … three thousand… four thousand ..five thousand … six thousand … seven thousand … eight thousand-nine thousand … ten thousand.

Slowly relax and exhale.

Take a deep breath in through your nose … a nice, deep breath. Feel your diaphragm pulling down to open your lungs wide. With your mind's eye, see your diaphragm dropping down as your lungs fill.

Hold that breath for a moment. Now let it out through your mouth, very slowly, taking at least 5 seconds to empty your lungs.

Take another big breath; fill your lungs. Hold it for a moment. Now let it out very slowly. Take 5 seconds or more to blow it all out.

Your leg muscles feel relaxed. It feels good. **You have relaxed your whole body.**

Now go back to the neck and shoulders one more time: Push your neck down and slightly back. Raise your shoulders up into your neck. Hold them tight as you count slowly: one thousand … two thousand … three thousand four thousand… five thousand … six thousand … seven thousand … eight thousand … nine thousand… ten thousand.

Relax and take a deep breath. Hold it, and then exhale slowly, taking at least 5 seconds to let it all out.

Another breath … hold it … let it out slowly.

Push your neck back down and your shoulders up one more time. Clench those muscles and count slowly: one thousand … two thousand … three thousand… four thousand ..five thousand … six thousand … seven thousand … eight thousand… nine thousand … ten thousand.

The muscles in your neck feel relaxed.

Part 2: Concentration on Relaxation

Now your entire body is nice and relaxed. Get comfortable in your chair, keeping your feet on the floor. Close your eyes. You are going to become aware of various parts of your body. You are going to actually "feel" them. Breathe in and out slowly through your nose, concentrating on your feet. Relax and focus on your feet. See your feet with your mind's eye … both of your feet … toes … along your soles from your toes to your heels … along the top from toes to the ankles. Feel your feet relaxing. Feel all of your toes relaxing … your right and left soles..right and left heels … the tops of both your feet relaxing. Silently tell yourself that both feet are totally relaxed … your toes, soles, heels, tops and bottoms of both your feet are totally relaxed.

Now feel your ankles relaxing. Concentrate on both your left and right ankle as you continue breathing through your nose, in and out, slowly. Feel both ankles. See them, in your mind's eye, relaxing. Silently tell yourself that your ankles are relaxed.

Continue breathing in and out through your nose, slowly, as you feel relaxation spreading to your calves, on the back sides of your lower legs. See them with your mind's eye. Concentrate on the feeling as both of your calves relax. Silently tell yourself that your calves are now relaxed.

With your calves relaxed, the feeling spreads around the front of your legs to your shins. Feel your right and left shins relaxing. See your shins with your mind's eye; feel them relaxing. Silently tell yourself that your shins are relaxed.

Continue breathing slowly through your nose, eyes closed, as you feel your knees relaxing. Concentrate on your left and right knees as you tell yourself that they are relaxed. See your knees with your mind's eye. Silently tell yourself that both of your knees are now relaxed.

Eyes closed, continue to breathe slowly, in and out through your nose, as you concentrate on your upper legs. See your upper legs, left and right, in your mind's eye. Feel the front of your upper legs relaxing. Now the relaxed feeling begins to spread to the outsides of your thighs … to the bottoms of both your thighs. Concentrate on your upper legs as the relaxation moves back up the insides … around to the tops. Silently tell yourself that both of your legs, from toes to thighs, are totally relaxed. And so they are.

As you continue breathing slowly through your nose … slowly … eyes closed … feel your buttocks and genital area relaxing. Concentrate on the feeling of relaxing. Silently tell yourself that these areas are relaxed.

Continue concentrating as the relaxed feeling spreads to your lower abdomen, below your navel. Concentrate as the feeling of relaxation spreads through your lower abdomen. Eyes closed, breathing slowly through your nose, feel the relaxation. Silently tell yourself that your lower abdomen is relaxed.

Now feel your lower back relaxing, loosening up. Concentrate on the feeling of relaxation in your lower back. See your lower back in your mind' eye. Silently tell yourself that your lower back

is relaxed. Feel the tension gathered in your lower back fading away.

Move your mind's eye up a little to focus on your belly, from your navel to your chest. Feel the relaxation moving up past your navel to your lower chest. Concentrate on the feeling of relaxation. Silently tell yourself that you are relaxed from your navel to your chest.

Now the relaxed feeling continues up your chest to the base of your neck. See your chest with your mind's eye. Focus on the pleasant feeling of relaxation as it covers your entire chest. Silently tell yourself that your chest is now relaxed.

Eyes still closed, breathing slowly … in and out through your nose … concentrate on the relaxation as it spreads over your upper back. See your upper back with your mind's eye. Concentrate on the relaxation as it covers your entire upper back. Silently tell yourself that your back, belly, and chest are now totally relaxed.

Concentrate as the great feeling of relaxation continues up into your shoulders. See your shoulders … right and left … in your mind's eye. Feel the tension and tightness drain from both shoulders. Eyes closed, breathing slowly in and out through your nose, concentrate as your shoulders totally relax. Silently tell yourself that your shoulders are now relaxed.

Now the feeling of relaxation spreads up through your neck, from the bottom to the top. See your neck with your mind's eye. Feel the front of your neck relax. Concentrate on the feeling as it spreads around the right side of your neck … the back … the left side. Silently tell yourself that your whole neck is now completely relaxed.

Eyes closed, slowly breathing in and out through your nose, concentrate on the feeling of relaxation as it moves from your shoulders down both your arms. Picture your arms in your mind's eye. From your shoulders, the feeling of relaxation moves into the left and right upper arms … front and back … to both elbows … front and back … to your forearms … front and back. Concentrate on the relaxation as it envelops both of your arms. Now your wrists are relaxing … both wrists are relaxing. Concentrate as your fingers relax … the fingers on both hands … your thumbs … index fingers … middle fingers … ring fingers … little fingers. Silently tell yourself that both of your arms … from your shoulders to the tip of each finger … are relaxed.

Eyes closed, breathing slowly through your nose, see your head in your mind's eye. Concentrate on your head as the relaxation spreads up from your neck to your chin … from the sides of your neck to the sides of your head … from the back of your neck up the back of your head. Feel the relaxation spreading over your head … your cheeks … mouth … nose … eyes … temples … ears … forehead. Concentrate carefully as the relaxation spreads up your head to the very top. Silently tell yourself that your head is now relaxed.

With your whole body totally relaxed, focus on your left arm. Eyes closed, breathing slowly through your nose, silently tell yourself that your left arm is heavy, very heavy. Feel your left arm becoming heavy. See it in your mind's eye … heavy. Concentrate on the feeling of heaviness.

Now see your right arm in your mind's eye. Concentrate on your right arm … silently tell yourself that your right arm is heavy, very heavy. Feel your right arm becoming heavy. Concentrate on the feeling of heaviness in your right arm.

Now let the heaviness totally drain out of both arms. Your breathing is slow and easy. Your whole body is relaxed.

Part 3: "One"

As soon as you've completed your relaxation exercise, move right into meditation.

You are totally relaxed. Keep your eyes closed. Silently, to yourself, begin saying "one" over and over. Say it slowly. If you can sense your heart beat, say "one" in time with your heart. If not, say it slowly, over and over again.

Now see the numeral "1" with your mind's eye. See it and say it silently, slowly, over and over. Do not count the numbers of times you say "one." Just keep seeing and saying it. If you get tired of the number "1" switch over to the word "one." See the three letters "o," "n," and "e" with your mind's eye.

If your mind begins to wander, if you start thinking about work or supper, gently bring your attention back to "one."

If you can, see the "one" in color. See it in soft blue with your mind's eye. See it in green, the green of trees in the woods. When you can see it in color, or against a background, you know you are doing something powerful with your mind.

Keep seeing and saying "one" until you feel it is time to stop. Do not set an alarm to go off at a certain time. You will know when the session should end. Ten or 15 minutes for the entire

relaxation-meditation session should be enough, but go for no more than 20 minutes.

When you are finished, slowly open your eyes. Sit quietly for a few moments, then rise and go about your business.

LOW-FAT EATING

Weight loss is a vital part of the equation for many overweight pain patients. Dieting, difficult enough, is made more confusing by the proliferation of "light," "lean," "natural," and "heart healthy" labels. Hundreds of diet books fill the bookstore shelves, but few are effective and safe. The basic principles of the Beverly Hills Medical Diet (Fox, 1982), which was awarded four stars by Consumer Guide in Rating the Diets, are still the best: a low-fat, low-cholesterol eating regimen based on the complex carbohydrates found in fresh vegetables, fruits, and whole grains.

Watch out for the hidden fats in foods, especially in processed foods. The average American takes in some 40 to 50% of his or her calories in the form of fat — way too much. Only 20% of our calories, or fewer, should come from fat. Complex carbohydrates (especially from vegetables and whole grains) should comprise the greater part of our calories.

What should you eat? The following foods are low in fat: apples, apricots, artichokes, asparagus, bananas, barley, beets, berries, black beans, broccoli, brown rice, buckwheat, buttermilk, cabbage, carrots, cauliflower, celery, cherries, chestnuts, chicken (white, no skin), cilantro, cod, corn, cranberries, cress (water and garden), cucumbers, dandelion greens, eggplant, endive, flounder, garbanzo beans, garlic, grapefruit, haddock, halibut, hoop cheese, Jerusalem artichokes, jicama, kale, kidney beans, kohlrabi, lentils, lettuce (dark green), lychee nuts, mangoes, melons, milk (skim or 1% fat), millet, mushrooms, mustard greens, nectarines, oats, okra, onions, oranges, papayas, parsley, parsnips, peaches, pears, peas, peppers, perch, pike, pineapple, pink beans, plantains, plums, pompano, potatoes, pumpkin, radish, red beans, red snapper, rutabagas, whole grain rye, sand dabs, scallops (steamed), sea bass, sole, spinach, split peas, sprouts, sweet potatoes, tangerines, tomatoes, tuna (packed in water), turkey (white, no skin), turnips, whole grain wheat, white beans, and wild rice.

Some tips for vegetables: Vegetables are sources for many vitamins, minerals, and enzymes, as well as dietary fiber. A diet including many vegetables lowers blood fats. Cook vegetables for as short a time as possible — just until they are tender and crisp. Use more raw than cooked vegetables, as cooking destroys many vitamins and minerals.

Some tips for fruit: Fruits are packed with vitamins, minerals, and sweetness. Eat whole, fresh fruit, not cooked, canned, or frozen fruit. Eat fresh, not dried fruits. Eat two to four fruits a day, according to your weight and sugar sensitivity.

Some tips for whole grains: Whole grains are rich sources of B vitamins, minerals, fiber, low-fat protein, and complex carbohydrates. Use whole grains as cereal and for casseroles. Use breads made of all whole grains.

Some tips for legumes: Legumes are dried beans and peas, such as black beans, garbanzo beans, Great Northern beans, kidney beans, lentils, lima beans, red beans, small white beans, and split peas. Legumes are high in vitamins B1, B6, and others. They are high in minerals, such as calcium and iron, high in fiber, low in fat, and contain up to 20% protein.

Some tips for dairy products: Drink skim or buttermilk, if desired. If you like yogurt, eat plain, low-fat yogurt. Use low-fat yogurt instead of sour cream and mayonnaise. Cheese is high in fat and salt. Use hoop cheese, up to 4 ounces a day, instead.

Nuts and seeds are high in fat. Use them sparingly, just to add flavor and crunch to your foods. Avoid processed nuts and seeds.

Finally, a note on water: Water is a terrific weight-loss helper. Not only that, we need lots of water for good health. Drink at least 6–8 8-ounce glasses of water each day.

EATING FOR GOOD SLEEPING

The drop in blood sugar called hypoglycemia can make it difficult to fall asleep — or it may wake you up once you have fallen asleep. When your blood sugar falls, the body pumps out a slew of hormones to bring the sugar back to normal. These include epinephrine from the adrenal glands, glucagon from the pancreas, cortisol from the adrenal cortex, and growth hormone. For example, when your blood sugar drops, the adrenal medulla causes epinephrine to be secreted in order to liberate sugar from the glycogen stored in the liver. This is just one of the mechanisms by which the body maintains homeostasis — and thereby keeps the blood sugar within acceptable levels. Unfortunately, there is a "side effect." The epinephrine quickly stabilizes blood sugar, but it also raises your heart rate, causes anxiety, and wakes up your brain. How can you sleep when that is going on?

That is why it is not a bad idea to snack on a small amount of whole-grain muffin or crackers, or other complex carbohydrates before going to bed. This will help keep your blood sugar within comfortable limits. And the complex carbohydrates in the food will also help increase brain levels of serotonin, which should lead to sounder sleep.

Perhaps some people can get away with drinking caffeine-containing beverages late at night, but this is not the case for most people. The ability of the body to "deactivate" caffeine varies from person to person, but

to be safe, do not drink coffee, tea, or soft drinks with caffeine, chocolate and cocoa, or even coffee-flavored candy or ice cream.

A quick note on alcohol: Many people drink alcohol late at night in order to get to sleep. The problem is that, in most people, alcohol causes the adrenal glands to secrete epinephrine, which impairs the ability to sleep. Furthermore, an essential amino acid called tryptophan, which the body can convert into the "sleep-helping" serotonin, is adversely affected by alcohol.

SUPPLEMENTS FOR SLEEP

Serotonin, which the body makes from the amino acid tryptophan, is important for getting to sleep. In the late 1980s, the Food and Drug Administration reclassified tryptophan: it was no longer available over-the-counter in health food stores, etc. Instead, it was a prescription medication. Inside the body, tryptophan is converted into 5-HTP (5-hydroxytryptophan) and then to serotonin. Because it is difficult to obtain tryptophan, we have been using 5-HTP, which is actually better, and closer than tryptophan to serotonin, the natural "sleep"aid.

A number of double-blind medical studies have shown that 5-HTP decreases the number of nighttime awakenings from sleep, as well as the latent period (from the time you try to go to sleep, until you actually do). We have found that 5-HTP works even better when taken with a small amount of fruit. Additionally, 5-HTP works best when there are good body levels of magnesium and vitamins B6 and B3 because these three substances are important in the conversion of 5-HTP to serotonin in the body.

Another helpful sleep substance is melatonin, a hormone made by the pineal gland in the brain. When we close our eyes to go to sleep, the lack of light on the retina causes the pineal gland to secrete melatonin. Unfortunately, in some people melatonin levels fall low and they have trouble sleeping. We have been using melatonin for such patients for many years, and it works well in most cases. (In addition to its sleep-promoting effects, melatonin also helps stimulate the immune system.) We prefer patients to take from 0.5 mg up to 3.0 mg, sublingually, about 30 minutes before going to sleep.

Several herbs are helpful in inducting relaxation and sleep, including valerian. Clinical studies have shown that this herb has a good ability to not only help people get to sleep and stay asleep, but also to improve the quality of their sleep. (Balderer & Borbely, 1985; Lindahl & Lindwall, 1989). The standardized preparation of valerian is preferable: 300 mg at bedtime. Note: When you open a bottle of valerian, if it does not smell like dirty sneakers or socks, it is not valerian.

Passionflower, also called passiflora incarnata, has been used by civilizations as far back as the Aztecs. The active ingredient, harmine, appears to have the ability to slow the breakdown of serotonin; 300 mg passion flower at bedtime is a commonly recommended starting dose.

Kava, also known as Piper methysticum, comes from the Polynesian Islands and has been used for its calming effect. Although kava is not primarily used for sleep, it can be helpful for those who cannot sleep because they are anxious or nervous. Taking a capsule with 75 mg of kavalactones at bedtime will be effective for most people, although some may require more.

Many other substances are used to induce sleep; these are the ones we have found to be most useful.

Hospice, Cancer Pain Management, and Symptom Control

Samira Kanaan Beckwith, A.C.S.W., L.C.S.W. and B. Eliot Cole, M.D., M.P.A., F.A.P.A.

INTRODUCTION

Death has not been conquered; we are all terminally ill to some degree. In 1900, the average life expectancy was only 50 years and infant mortality was very high. Because of sanitation efforts and immunization programs, antibiotics, better management of acute illnesses and trauma, and improved chemotherapy, Americans now live well into their late 70s or 80s (Emanuel, von Gunten, & Ferris, 1999). Due to these advances, patients now expect to have prolonged experiences of living with chronic illnesses and ultimately dying.

Some 69% of patients said they would opt for suicide if they felt their pain could not be relieved (Levin, Cleeland, & Dar, 1985). Fear of unacceptable pain was a major component of requests to physicians for assisted suicide (Helig, 1988; Emanuel, et al., 1999). The increased awareness of the public in assisted suicide, due to the activities of Dr. Jack Kevorkian during the 1990s, and the popularity of the "how to commit suicide" book *Final Exit* (Humphry, 1991) give evidence to this well-founded concern. Undertreatment of acute and chronic cancer pain persists despite decades of efforts to provide clinicians with information about analgesics (American Pain Society [APS], 1995).

When finding a cure for the patient's disease is no longer possible, the emphasis shifts to palliation (Kaye, 1989). Palliative management, the focus of hospice care, affords relief and reduces the severity of bothersome symptoms, but does not produce toxicity or hasten the death of the patient (Johanson, 1988). Palliative care becomes necessary when the patient's disease is beyond cure, when the tumor process is the cause of symptoms, when realistic treatment goals have been established, and when clear communication exists among the professional team, the patient, and the family regarding the treatment plan (Brescia, 1987). No specific therapy is excluded from consideration. The test of palliative treatment lies in the agreement by the patient, the physician, the primary caregiver, and the hospice team that the expected outcome is relief from distressing symptoms, easing of pain, and enhancement of quality of life (National Hospice Organization [NHO], 1996). The absolute goal for palliative care is to improve the quality of the patient's life while avoiding side effects worse than the symptoms being treated (Emanuel, et al., 1999). Good palliative care focuses on pain control and symptom management to help the patient avoid a lingering and suffering death. To realize this goal, it is essential for the clinicians involved to believe and to assess the severity of each pain complaint.

Total pain management cannot be undertaken by an individual alone, but only by individuals working together as a team (Lack, 1984). This underlying principle of working together in hospice care manifests through the use of a multidisciplinary approach and a creative process of individualized patient management. This results in an empowered patient who is able to experience comfort and dignity. Hospice care integrates the best of psychological support, physical care, and spirituality for the patient directly and provides long-term bereavement assistance for the surviving loved ones.

0-8493-0926-3/02/$0.00+$1.50

Hospice is based on a philosophy of caring for the terminally ill embracing a number of concepts. Death is viewed as a natural part of the life cycle. When death is inevitable, hospice will neither seek to hasten nor postpone it. Hospice exists in the hope and belief that through appropriate care and the promotion of a caring community sensitive to their needs, patients and their families may be free to attain a degree of mental and spiritual preparation for death that is optimal for them (NHO, 1996). Despite the successful growth of the hospice movement in the U.S. during the past 30 years, nearly 85% of Americans die in hospitals and long-term care facilities, making palliative care interventions relatively unused in the settings in which most of them die (Rummans, Bostwick, & Clark, 2000).

Pain relief and symptom control are appropriate clinical goals, with psychological and spiritual pain considered to be as significant as physical pain. Addressing all three simultaneously requires the skills and experience of an interdisciplinary treatment team. Such hospice teams include physicians, nurses, social workers, pharmacists, aides, chaplains, homemakers, volunteers, bereavement counselors, and other therapists as needed. Patients with their families and loved ones are the functional units of care, and this care is generally provided to them regardless of their ability to pay.

Hospice was viewed by many as unconventional at its beginning. Many thought that hospice programs actually shortened the lives of the people served through covert euthanasia practices. Nothing was farther from the truth. Hospice medicine became quite scientific and developed, with a large body of knowledge about providing care for people at the end of life (Appleton, 1996). Hospice medicine established new standards for medication dosing, medication selection, home care limitations, and the ability to provide "whole patient" care.

Hospice is now recognized as one of the standards for clinical practice. Based on these concepts of "whole patient" care, hospice is now a specialized healthcare program focusing on the provision of pain management, symptom control, emotional support, personal care, and bereavement counseling. More economical than hospital, home health, or nursing home (long-term) care, hospice provides a cost-effective choice for providing wonderful care at the end of life. Because hospice care combines the best quality and value for most terminally ill patients, it is now covered by Medicare, many insurance companies, and in most states by Medicaid programs for the medically indigent. A majority of hospice programs also look to members of their communities for additional support to assist them in providing indigent care and other unmet needs.

The primary focus of hospice care is to maintain patients in their homes for as long as possible. This is the experience of the authors; additionally, care is also provided in inpatient hospice units, long-term care nursing facilities, and contract hospitals. Electing hospice care allows patients to make choices, control their destinies, and maintain their dignity while avoiding the sense of abandonment and solitude often associated with a hospital death.

WHOLE-PATIENT ASSESSMENT AND HOSPICE CARE

Whole-patient assessment is an important skill for practitioners caring for the terminally ill. Whole-patient assessment clarifies the diagnosis and prognosis; coordinates the activities of the hospice team members; improves trust between patients, their families, and their professional caregivers; and leads to the best therapeutic effects (Emanuel, et al., 1999). Thorough assessment allows establishment of a comprehensive plan of care with the task of the multidisciplinary hospice team being to provide care that is interdisciplinary in scope.

Certain diseases can be expected to follow predictable courses. However, hospice is not about providing routine care, but instead focuses on providing an individualized hospice plan of care that is prepared uniquely for every new admission and then updated continuously. This plan of care begins the moment the patient is referred to the hospice program and evolves as the needs of the patient change. Although the initial plan of care is the collaboration of the intake nurse, attending physician, hospice medical director, and social worker, the other members of the interdisciplinary team, including chaplains, aides, volunteers, and other therapists, participate in the frequent revisions.

The whole-patient view of end-of-life care encompasses many domains simultaneously. These domains include the patient's complete illness and treatment summary, ongoing physical and psychological care requirements, decision-making capacity, communication needs, social and spiritual issues, practical day-to-day assistance, and anticipatory planning for death (Emanuel, et al., 1999). The goal of this assessment is control of bothersome symptoms, improvement in function, reduction of suffering, minimization of further laboratory testing, and bettering the overall quality of life remaining.

The referring source often has certain expectations about services for the patient, and the hospice team must consider these wishes along with the overall hospice philosophy. The orderly transition of the patient from a hospital setting to hospice necessitates a close relationship between the attending physician, discharge planners, and the hospice staff. Problems identified in the earliest stages of hospice involvement tend to reflect uncontrolled symptoms, specific equipment needs, and accessibility to the attending physician. Once the patient has settled into the

program, a number of the hospice team members visit the patient to develop an appropriate plan of care.

Relocation issues are important considerations for hospice care provided in the home when either the patient or the primary caregiver has to relocate to accommodate the care demands. These changes in living arrangements often result in disruption for everyone as new routines are established. Not only must the medical aspects of care be undertaken, but in addition, the more mundane aspects of daily living must also be addressed. Who will pay the bills? Who will feed the pets? Who will do the grocery shopping? Who will get the prescription medications filled? Who will do the chore work around the house? These issues must be resolved to successfully care for any patient at home.

In a home environment there are important concerns related to the physical safety of the debilitated patient; thus, specialized adaptive equipment is often provided to improve the care of the challenged patient. Emotional support coupled with extensive and practical education provides the new caregiver with the requisite confidence to assume the challenge of providing care for the terminally ill patient. Despite all this wonderful support, it remains very difficult to prepare the new caregiver for the personal sacrifices that must be made to provide care for the very ill patient. The simplest errand often takes on monumental qualities when care for the terminally ill patient must be provided continuously. The caregiver does not have a day off unless alternate caregivers are available. This "24/7" routine often results in the exhaustion of the caregiver, physically and emotionally, and necessitates the need for respite care.

Trust issues manifest early in the care of the hospice patient. Loyalties to the attending physician and past healthcare providers must be expanded to include the hospice team members. Many attending physicians are not able to follow their patients at home and thus rely on the skills of the hospice team members to provide the day-to-day aspects of care. The reality that most hospice patients are older and seriously medically ill, yet are frequently cared for by younger family members, produces interesting reversals in generational hierarchies. The daughter, or daughter-in-law, who typically becomes the caregiver for her, or her husband's, parent, and the actual patient, must adjust to the new patterns. Long-standing, unresolved conflicts may reappear due to the stressful conditions that exist and can lead to power struggles and other dysfunctional expressions.

Hospice care embraces the idea that psychosocial, emotional, and spiritual factors all impact physical symptoms. Plato once said, "As you ought not to attempt to cure the eyes without the head or the head without the body, so neither are you to attempt to cure the body without the soul; for the part can never be well unless the whole is well; therefore, if the head and body are to be well, you must begin by curing the soul." Later, in the 6th century, Galen wrote that melancholic women were more prone to cancer than those of sanguine temperament. In the 15th century, Lorenzo Sassoli, a physician, wrote to a patient: "To get angry and shout at times pleases me for this will keep you your natural heat; what displeases me is your being grieved and taking all matters to heart; for this is as the whole of physics teaches which destroys our body more than any other cause."

The connections between the mind and body have continued to be the focus of attention for many researchers. Outcomes attributable to psychosocial factors range on a continuum from the readily explicable to the most controversial. These outcomes include enhanced physical comfort, increased responsiveness to medical treatment, relief from emotional anguish, extension of survival time after disease onset, and outright "psychogenic" cure. For these reasons, we believe that the psychosocial, emotional, and spiritual components of a patient's pain experience must be thoroughly addressed to understand the totality of the pain. The experience of pain, and the resulting suffering, may be greater when the pain is accompanied by anger, anxiety, depression, fear, and the meaning given to the pain by the sufferer. Because many patients report less pain when they are rested, distracted, and have other symptoms under good control, many questions are raised about what specific factors influence how an individual patient may experience pain. Factors considered involve the duration of the pain experience, the course the pain has taken during that time, the anticipation that the pain will be controlled, the expected interval before improvement will be realized, and the time anticipated until meaningful comfort will be attained. Patients must be given hope that their pain will be managed.

A comprehensive psychosocial assessment is important and must include an appropriate analysis of gender, present financial situation, family history, relationship patterns, previous coping strategies, previous losses, history of alcohol and substance abuse, past mental health problems, occupational history, and ethnic and cultural issues, as well as an exploration of religious and spiritual beliefs. The specific information regarding finances, environment, and care costs is necessary to develop a plan of care that is realistic and achievable. Many patients and their caregivers express concern about the cost of their analgesic medications and other needed services.

Fear is a major factor that adversely influences the experience of cancer pain. It is natural to be afraid of death, as death is the ultimate unknown (Ryder, 1993). Fear of pain takes at least two forms: fear of the pain itself and fear of the inability to control pain (Hill & Shirley, 1992). Most patients expect the pain from cancer to be very severe, perhaps to the point of interfering with life-prolonging treatment and causing them to die a painful death. The popular knowledge that most cancer pain is

poorly controlled does not offer newly diagnosed cancer patients much reason to be hopeful about their personal pain management.

Unnecessary concerns and myths about the consequences of opioid analgesic usage, including addiction, confusion, constipation, disorientation, tolerance, and withdrawal problems, continue to prevent many patients from receiving the medications they legitimately deserve. Patients should never need to wish for death because of their physicians' reluctance to use adequate amounts of effective opioids (Reisine & Pasternak, 1996).

Fear also arises from concerns about loss of control and dignity, loss of relationships, being abandoned, becoming a burden to care for, and having bothersome symptoms poorly controlled (Emanuel, et al., 1999). Professional caregivers must explore patient fears and ultimately affirm their commitment to care for the patient. Failure to do this may lead to the patient contemplating suicide and requesting the assistance of the caregiver if unable to perform the act alone.

Untreated anxiety and depression also worsen the pain experience, resulting in interference with restful sleep, impaired cognitive processes, and altered social patterns. Depression associated with uncontrolled pain plays a significant role in suicidal ideation; and when coupled with a sense of helplessness and hopelessness, it becomes a deadly predictor of actual suicide. Pain relief clearly enhances the sense of hope and well-being for the patient. Failure to appreciate the psychological needs of the patient will render even aggressive treatment of pain with analgesics or procedures ineffective (Patt & Isaacson, 1996).

Healthcare professionals must make their treatment decisions with a focus on the whole person rather than just the specific disease state. People must be the focus of care. Caregivers need to understand that having a serious, potentially terminal condition can by itself be a reason for demoralization and loss of hope. Patients need to be reassured by their professional caregivers that care, compassion, and concern will always be available to them and that they will not be abandoned. Information about the disease, expected outcomes, and treatment options, including their effects on the quality of life, must be communicated in common terms that the patient and family can understand.

Helping the family caregiver with practical day-to-day tasks can reduce the caregiver fatigue and potential for overload and burnout. Using the psychosocial assessment process, resources needed can be identified and provided. Giving the patient and caregiver a wall chart with the names and duties of the professional team members can clarify the roles and relationships. Done properly, the patient and caregiver can view their appropriate place in the care continuum and feel that they are valuable team participants.

Many caregivers report that much of their day is centered on the dying patient, attending to positioning, feeding, bathing, and medicating. The care needs of the patient direct the life of the caregiver. Although appropriate and encouraged during the patient's hospice care, upon the death of the patient, the routine is radically altered for the caregiver. This loss of activity and fulfillment of nurturing needs should be acknowledged as part of the emptiness experienced after death. Hospice programs provide bereavement support, maintaining continued involvement with the caregiver through the professional staff and volunteers, utilizing a variety of techniques including support groups, classes, and individual counseling. The bereavement plan of care must be based on an assessment of risk indicators (Beckwith, et al., 1990). Bereavement care demonstrates the hospice philosophy and communicates, "We still care for you, and we will help you get through this."

Bereavement, a separation or loss through death, is derived from the Old English *bereafian*, meaning "to rob", "to plunder", or "to dispossess" (Burnell & Burnell, 1989). Bereavement is the general state of being that results from having experienced a significant loss (Cook & Dworkin, 1992). It is the price paid in emotional pain for having meaningful relationships. All caregivers have loss experiences that color how they handle subsequent losses, and these losses need acknowledgment in preparation for healthy grieving after the loved one's death. Soon after the death, or often through the dying process, caregivers must look for ways to adjust their identities. Caregivers may experience an initial sense of relief and simultaneous feelings of emptiness when new coping patterns have not been developed. Confusion over identity arises with a shift in focus from the care needs of the patient to the personal needs of the caregiver.

Ultimately, the search for meaning and the exploration of spiritual issues can contribute to the alleviation of emotional distress for patients and their families. A review of things enjoyed and loved, such as people, places, events, and experiences, can bring genuine comfort and relief from suffering. Although formal psychiatric involvement may be needed for those with histories of prior psychiatric illness, supportive techniques of psychotherapy can often be helpful for most who elect to use them. This spiritual search for meaning can also impact the perception of the pain experience.

Spirituality needs require thorough exploration from the outset of hospice care. We must acknowledge that pain is not just a response to a physical problem; all facets must be addressed if we are to treat the whole person (Cosh, 1995). Almost all who connect their pain with impending death review the events of their lives and seek to determine the significance of their lives. Some return to religious values of earlier days, and others make intense demands on their faith (Lack, 1984). Rectifying previous religious traditions with present affiliations can prove problematic. When spouses are of different faith traditions or one spouse is a relative nonbeliever, the provision of spiritual

care can be more complex. It is not the responisiblity of the hospice team to resolve religious matters or to "save" people, but rather to assess and attempt to provide spiritual support as desired by the patient and family. Symptom control has to precede spiritual or psychosocial support; a person cannot think about the meaning of his or her life while in pain (Kaye, 1989).

The nursing assessment focuses on the safety of the patient in the environment, the patient's chief complaint, use of medications, care needs over time, and developing the initial plan of care. In the assessment process, the nurse gathers information from the patient that allows for understanding the pain experience and its effect on the quality of life (McCaffery & Beebe, 1989; McCaffery & Pasero, 1999). It is important to avoid making assumptions about the patient's wishes. Asking the patient for ideas and opinions makes his or her wishes known (Kaye, 1989). Inquiring "How are you right now?" lets the person know that human needs will be addressed. This helps to establish trust and build the relationship that allows screening for care requirements, such as diet, appetite, bowel function, managing unpleasant side effects, sexual and intimacy issues, and successful pain management. The interdisciplinary approach to care in conjunction with trained volunteers ensures that no person has to travel the final days alone.

The hospice physician primarily attends to the management of unpleasant symptoms, serves as a supervisor for the interdisciplinary team, and acts as a liaison with the attending physician. Education of the team, support for the team members as they deal with terminal patients, and representing the hospice program are key duties for this physician. A willingness to be available, often 24 hours a day, and to work collaboratively with the interdisciplinary treatment team adds to the services provided by the traditional medical staff in the community. The house call, with care provided in the home of the patient rather than the office or the hospital, is the preferred method of management for the hospice patient. The hospice physician must be flexible, able to handle routine medical problems, and practice medicine with a minimum of complicated technology often associated with institution-based care.

CANCER PAIN MANAGEMENT

Approximately 70% of advanced cancer patients report pain as a major symptom (Bonica, 1987). For half of them, the pain is moderate to severe in intensity; while for a third, the pain is severe to excruciating (World Health Organization [WHO], 1986). It is tragic that although pain in one in ten cancer patients is difficult to control, pain in 50 to 80% of cancer patients is not satisfactorily relieved because their physicians do not aggressively treat the pain problem (Bonica, 1985). With six million newly diagnosed cancer cases in the world each year, every physician who cares for cancer patients or others at the end of life must be able to elicit a detailed pain history and be able to bring relief to these sufferers (WHO, 1986). Cancer pain may be due to direct tumor progression and related pathology, operations and other invasive diagnostic or therapeutic procedures, toxicities of chemotherapy and radiation, infection, or from muscle aches when patients have limited physical activity (Foley, 1985).

The basic pain evaluation must begin with believing the pain complaint expressed by the patient (Foley, 1988). Pain is whatever the person experiencing it says it is, and it exists whenever the person experiencing it says it does (McCaffery & Beebe, 1989; McCaffery & Pasero, 1999). Because all pain is very real and distressing to the patient, trying to assign relative proportions to organic or functional causes is of little value. It is more useful to determine if the pain limits the activity of the patient and disturbs sleep, appetite, or the ability to engage in productive or pleasurable endeavors. Knowing what the patient can or cannot do, how medications have or have not worked, and what side effects the patient will or will not tolerate are key initial questions to be answered. It is vital that a language about the pain be developed among the patient, the caregiver, and the hospice team to allow skillful management. Descriptive words such as mild, moderate, and severe indicate the intensity of acute pain fairly well. Words such as excruciating, incapacitating, overwhelming, and soul stealing better define the pain of cancer. A number of pain scales have been developed to quantify and track the pain experience, such as the descriptive (uses words), numerical (uses numbers), visual (uses anchors of "no pain" and "worse pain") analogs.

To most thoroughly treat the pain, it is best to obtain the richest detail about the pain complaint that the patient and family can provide. A careful, comprehensive physical examination that is global in scope should be performed, because many cancer pain patients have been recently cared for by specialists who might not have provided total care for them. If necessary, the physician should order and personally review needed diagnostic studies to better elaborate the overall problems of the cancer patient (Portenoy, 1988). All of the possible methods of controlling the pain — not just pharmacological means — must be considered and blended to individualize the plan of care for the patient. Finally, the level of pain control and patient satisfaction after each intervention must be assessed. There is no point in frequently changing methods until compliance with what was previously ordered has occurred. Establishing clear and reasonable goals with the patient and the family is necessary to enssure a successful outcome. Everyone must understand that analgesics are not anesthetics; although absolute pain elimination may not be a realistic goal, improved comfort can be provided. With a clear understanding of the pain problem, treatment can be staged from least to most complicated.

Through hospice, medical equipment and supplies that are needed to facilitate even complex care of the patient can be provided either in the home or in the hospice inpatient unit. The capacity and emotional status of non-professional caregivers should be assessed to be certain that they are not overwhelmed or at risk for burnout. A balance must be struck among the capabilities of medical science, the wishes of the patient, and the realistic abilities of the caregiver. The loss of the caregiver at home is a frequent reason for a patient needing to enter a long-term care nursing facility or an inpatient setting.

Pharmacotherapy

The correct route of administration for medication is the one best tolerated by the patient. As long as the patient is able to swallow, pain can be routinely managed with oral medications. Transmucosal, transdermal, rectal, and parenteral routes may be utilized when swallowing is compromised. The important premise that oral medication is the preferred route of administration for a patient able to eat and take fluids orally, leads to the recommendation that practitioners follow the guidelines of the WHO guidelines, as well as the Agency for Health Care Policy and Research (AHCPR), reorganized as the Agency for Healthcare Research and Quality (AHRQ) in 1999, and systematically progress (1) from an oral non-steroidal anti-inflammatory medication or acetaminophen, (2) to a weak, or lower potency, oral opioid analgesic and then, if necessary, (3) to a strong, or higher potency, oral opioid analgesic (WHO, 1986; AHCPR, 1994). These three steps best describe the management of mild, moderate, and severe intensities of pain. At each of these steps, adjunctive, or additional, medications may be added, but similar analgesic products of the same step are unnecessary for the majority of patients. Ultimately, instead of trying to titrate patients to the medications, the medications are adjusted to the patients. The right dose of any medication becomes the dose that produces comfort and minimal toxicity.

Acetaminophen, often part of combination medications, has no anti-inflammatory effects and thus affords little benefit beyond mild pain relief and a real risk of hepatotoxicity when daily doses exceed 3 to 4 grams. Patients with chronic alcoholism and liver disease, or those who are fasting can develop hepatotoxicity at standard doses (APS, 1999).

Starting with the nonsteroidal anti-inflammatory drugs makes good sense for most pain problems, as these medications work to relieve pain in the periphery, where the nociceptive experience originates (Kanner, 1987). Nonsteroidal anti-inflammatory agents interfere with the manufacture of local pain-sensitizing and inflammation-mediating components (prostaglandins) and thereby limit pain transmission from the periphery to the central nervous system and eventual consciousness (Insel, 1996). While aspirin significantly interferes with platelet aggregation irreversibly, most of the other nonsteroidal anti-inflammatory medications decrease platelet aggregation only while therapeutic levels are maintained (APS, 1989). Notable exceptions are the COX-2 selective inhibiting agents celecoxib and rofecoxib, nabumetone, and choline magnesium trisalicylate. Choline magnesium trisalicylate is a non-acetylated aspirin derivative that does not appear to have effects on the aggregation of platelets (APS, 1989; Kanner, 1987). Choline magnesium trisalicylate is a generic medication that can be used orally, as tablets or a liquid suspension (helpful for those with swallowing difficulties), with the same general side-effects profile as aspirin and the ability to follow salicylate levels. Celecoxib is available in capsules and rofecoxib is available in tablet and suspension (helpful for those with swallowing difficulties) forms.

The nonsteroidal anti-inflammatory medications in general may produce gastric upset and the potential gastrointestinal bleeding; however, nabumetone, celecoxib, and rofecoxib have lower event rates for these problems (Insel, 1996; Medical Economics Company, 2000) but they do have the potential for renal problems. It is a common occurrence in the hospice setting to encounter patients with pain that is controlled quite poorly despite high-dose opioid analgesics at the time of their admission. These patients benefit significantly from the late addition of nonsteroidal anti-inflammatory agents (if they are not already taking such medications) without further increases in the opioid analgesics when pain is due to bone metastases (Foley, 1985; Walsh, 1985).

Case Example

Mr. H was a 75-year-old gentleman with advanced prostate cancer with extensive bone metastases. He was initially able to control his pain with 2 mg hydromorphone orally every 4 hours. He later experienced high levels of localized pain in his lower back and pelvis. Rather than increase his opioid analgesic, he was additionally given 750 mg of the nonsteroidal anti-inflammatory agent choline magnesium trisalicylate four times daily, with significant improvement. As his disease progressed, he eventually required more hydromorphone to remain comfortable. His dose was adjusted to 4 mg orally every 4 hours, and he died comfortably.

If the pain is not controlled with nonsteroidal anti-inflammatory medications, the next step is the addition of an opioid analgesic. Routinely, Drug Enforcement Agency (DEA) schedule three (Ciii) combination medications are prescribed after nonsteroidal agents and before pure opioids. This is not a legal requirement, but one of custom. It is important to remember that all of the combination opioid medications, like the pure opioid medications, are effective analgesics if used at equianalgesic dosages (the amount of one medication that produces the same relief as another medication; see Table 42.1). The limiting factor

TABLE 42.1
Equianalgesic Dosages:

Medication	Equianalgesic Dosage (in mg)			Duration of Action (hours)
	i.m.	p.o.	p.r.	
Opioid agonists:				
Codeine	130	200	N/A	3–4
Fentanyl[a]	0.1–0.2	N/A[b]	N/A	1–2
Hydrocodone	N/A	30	N/A	3–4
Hydromorphone	1.5	7.5	3	3–4
Levorphanol[c]	2 (single dose)	4	N/A	4–5
	1 (repeated doses)	1		
Meperidine[d]	75	300	N/A	3–5
Methadone[e]	10 (single dose)	20	N/A	4–6
	2–4 (repeated doses)	2–4		
Morphine[f]	10	60 (single dose)	10–20	4–5
		30 (repeated doses)		
Oxycodone[g]	10–15[h]	15–20	N/A	4–6
Oxymorphone	1–1.5	N/A	10	4–6
Propoxyphene[i]	N/A	300–400	N/A	4–6
Opioid partial agonist:				
Buprenorphine	0.4	N/A	N/A	4–5
Opioid agonist-antagonists:				
Butorphanol[j]	2[k]	N/A	N/A	4–6
Nalbuphine[j]	10	N/A	N/A	4–6
Pentazocine[j]	60	180	N/A	4–6

[a] Transdermal fentanyl dosage is not calculated as equianalgesic to a single morphine dose. In the steady-state condition, a 25-μg/hour patch is approximately equivalent to 10 mg of oral morphine sulfate every 4 hours.

[b] Oral transmucosal fentanyl citrate absorption is variable due to both immediate transmucosal absorption and slower gastrointestinal absorption.

[c] Levorphanol has a long half-life and accumulates over time.

[d] Meperidine is not appropriate for cancer patients due to the half-life of its metabolite, normeperidine, being 8 to 21 hours. Meperidine should never be administered beyond 400 mg/day as the accumulation of normeperidine leads to agitation, myoclonic twitching, and seizures.

[e] Methadone has a long half-life and accumulates over time.

[f] Morphine-6-glucuronide has a longer half-life than morphine and leads to greater morphine effectiveness over time.

[g] Many equianalgesic tables have oxycodone as either equianalgesic to morphine or 1.5 times more potent than morphine. The product insert for OxyContin indicates that oxycodone is two times more potent than morphine.

[h] Oxycodone is only commercially available as an oral preparation in the U.S. It is used parenterally outside the U.S.

[i] Propoxyphene is so weak that it is rarely effective for cancer pain of any significance.

[j] Mixed agonist-antagonist medications must never be given to patients concomitantly receiving pure opioid agonist medications. Butorphanol and pentazocine produce psychotomimetic effects at higher doses.

[k] Nasal butorphanol is equianalgesic to the intravenous form.

for the schedule three agents used in the U.S. is the presence of the co-analgesic (acetaminophen, aspirin, or ibuprofen). Because of the toxicity associated with the co-analgesic agents (gastrointestinal upset and/or bleeding, hepatotoxicity, platelet aggregation interference, and nephrotoxicity), there is a finite limit for the number of schedule three combination products that may be taken daily. This barrier due to the co-analgesic may result in inadequate pain relief for those experiencing more than moderate pain intensity.

Contributing to some of the confusion about effectively prescribing pure opioid analgesics is the continuing observation that most standard textbooks of pharmacology describe opioid analgesic dosages with respect to acute pain, but few references mention the complexities of chronic pain management. Under-dosing the cancer patient is more commonly the rule than the exception (Hill, 1988), and fear about possible respiratory depression due to opioids is best countered by remembering that the most potent antagonist to opioid-analgesic-induced respiratory depression is pain itself (Johanson, 1988). Respiratory depression is not a problem until the pain is well controlled; no one has died from opioid-induced respiratory depression while awake (APS, 1999).

In general, the relative potency of oral to parenteral opioid analgesics is about three to one, due to the first-pass effect of hepatic metabolism. One must take approximately three times more oral medication to obtain the same level of comfort produced by intramuscular or intravenous medication (Pasero, Portenoy, & McCaffery, 1999). Oxycodone is an exception, with 60 to 87% or more of oral doses being bio-available and escaping the first-pass hepatic metabolism (Kaiko, et al., 1996; Leow, Smith, Williams, & Cramond, 1993; Poyhia, Vainio, & Kalso, 1993).

The most frequent error in working with opioid analgesics is to assume that dosages are constant despite the route of administration (not accounting for first-pass liver effects). It is still common to find opioid orders written for 50 to 75 mg meperidine orally or intramuscularly every 4 to 6 hours as needed for pain. This situation shows pharmacological ignorance in two areas: the equianalgesic difference between oral and parenteral routes of administration (300 mg orally is equivalent to 75 mg parenterally) and the 2- to 3-hour duration of analgesic action (Pasero, et al., 1999).

Most important for properly prescribing opioids is their administration on a time-contingent, by-the-clock (or around-the-clock) basis, rather than a pain-contingent, as-needed basis, so that comfort is constantly maintained instead of being continually sought. The development of sophisticated medication release technology has allowed several opioids (fentanyl, morphine, and oxycodone) to provide sustained analgesic action for 8 to 72 hours with stable blood levels, increasing overall comfort and lessening potential toxicity.

By maintaining control of the pain around the clock, most patients experience a better quality of life (lower pain intensity, less medication toxicity, improved sleep, and satisfaction) and use less medication (Reuben, Connelly, & Maciolek, 1999). From a learning theory perspective, the use of as-needed medication may cause the patient to use more medication over time because of the linkage made between having pain, taking medication, and experiencing pain relief, resulting in the development of psychological craving. The time-contingent dosing pattern dissociates pill-taking from pain relief (because medication is taken on a fixed time schedule) and thus may prevent the most feared but least likely complication of opioid analgesic use — addiction.

In reality, very little abuse of opioid medication actually occurs among hospice patients or medical patients with legitimate use of these agents. It is inconceivable that cancer patients would ever be removed from their medications as they died, but studies of nonterminal chronic pain patients show little justification for concern when the probability of iatrogenic addiction is 1/800 to less than 1/10,000 (Medina & Diamond, 1977; Perry & Heidrich, 1982; Porter & Jick, 1980). Although 6 to 15% of the U.S. population may have a substance abuse disorder of some type, only 3% of inpatient and outpatient consultations performed by the Psychiatry Service at Memorial Sloan-Kettering Cancer Center were requested for the management of drug-related issues (Passik & Portenoy, 1998).

Physical dependence does occur over time, but the need to increase analgesic medication doses in cancer patients more often relates to the progression of the underlying disease than the rapid development of pharmacological tolerance. Physical dependence is not addiction (a primarily psychological disorder with eventual physiological and sociological manifestations), and patients should not be identified as addicts just because they manifest tolerance of or physical dependence on opioids. Addiction, or psychological dependence, signifies that the medication is compulsively sought and utilized for effects other than pain relief (APS, 1999). Physical dependence simply means that a person needs the medication to prevent distressing symptoms secondary to the absence of the agent, the so-called “withdrawal” or “abstinence” reaction (Hill, 1988). The cancer patient has a constant supply of medication that is used time contingently if administered correctly, and little if any drug-seeking behavior is seen (Passik & Portenoy, 1998). In fact, one of the greatest barriers to compliance with the time-contingent administration of these medications when patients are relatively comfortable is the mistaken belief by patients that they will develop an addictive disorder (Breitbart, et al., 1998; Foley & Inturrisi, 1987; Ward, et al., 1993).

The data related to the risk of addiction have been traditionally obtained by surveying known addicts rather than prospectively following patients receiving legitimately prescribed opioid analgesics. In the past 20 years, it has been observed that the true incidence of opioid

TABLE 42.2
Commonly Used Opioid Analgesics in the United States:

Generic name:	Proprietary name:	Dose Forms:	Manufacturers:
Buprenorphine	Buprenex	i.v./i.m. Epidural	Reckitt & Colman
Butorphanol	Stadol	i.v./i.m. Nasal	Bristol-Myers Squibb

Sufentanil	Sufenta	i.v./i.m.	Taylor
Tramadol	Ultram	p.o.	Ortho-McNeil

analgesic abuse is insignificant among patients with medically justified opioid use, only 1 in 800 for headache sufferers to less than 1 in 10,000 burn patients (Medina & Diamond, 1977; Passik & Portenoy, 1998; Perry & Heidrich, 1982; Portenoy, 1990; Porter & Jick, 1980). Even the U.S. Government has declared the risk of addiction in cancer patients to be "an exceedingly rare event" (AHCPR, 1994).

Once the decision to use opioid analgesics is made, the issue becomes which one of them to use (Table 42.2). For mild to moderate pain, it is customary to start with the lower potency opioid analgesics, such as codeine, hydrocodone, or propoxyphene. Using codeine for pain management poses an interesting problem for some patients because codeine is a prodrug that must be converted to an active analgesic, morphine, via the CPY2D6 component of the hepatic P450 microsomal enzyme system and that system is lacking in 7% of Caucasians, 3% of Blacks, and 1% of Asians (Lurcott, 1999), and generally suppressed in all patients receiving the SSRI medications fluoxetine and paroxetine (Stahl, 2000). In the U.S. these medications are commonly given as combination tablets containing aspirin, acetaminophen, or ibuprofen that often is more effective than the amount of the opioid analgesic involved. Codeine and propoxyphene tend to be quite toxic for some patients (the elderly, those with renal insufficiency or opioid allergies), with hydrocodone products tending to be better tolerated and more effective as analgesics.

Some clinicians erroneously view oxycodone as a weak opioid analgesic, much like codeine, hydrocodone, and propoxyphene; but in reality, the co-administration of acetaminophen and aspirin limits the amount of oxycodone patients can take in the form of a fixed combination medication. This leads to the mistaken belief that oxycodone is not strong enough for cancer patients. Pure immediate-release and sustained-release oxycodone preparations are free of acetaminophen or aspirin and permit further titration of the medication to analgesia without the toxicity associated with the co-analgesics. Uniquely, immediate-release and sustained-release oxy-

codone, used either alone or after converting from a combination oxycodone-containing product, allow for the continued use of the same initial opioid analgesic from mild through moderate to severe pain. In the American Medical Association's Project to Educate Physicians on End-of-Life Care, only oxycodone is listed as both a step 2 (moderate pain) and 3 (severe pain) appropriate agent (Emanuel, et al., 1999).

When the pain is consistently more severe, or when the lower-potency opioid analgesics do not produce adequate relief, high-potency opioid analgesics are recommended. The reference gold standard for these opioid medications is traditionally morphine, because it has the distinct advantage of being available in the widest variety of routes of administration (immediate-release and sustained-release tablets, elixirs of varied strengths, concentrate, suppositories, preservative-containing solutions for intramuscular and intravenous use, and preservative-free solutions for epidural and intraspinal techniques) on a worldwide basis.

Morphine is the historic analgesic "gold standard" because it is an effective, relatively inexpensive opioid analgesic with a reasonable 4-hour duration of action (Twycross & Lack, 1984), a short half-life, and is generally available throughout the world. Unlike opioid analgesics with a long half-life (methadone and levorphanol), morphine-caused complications and toxicity are resolved within a matter of hours. The ability to convert from one route of administration to another is quite simple with an equianalgesic table (Table 42.1). Sustained-release morphine allows the patient to have uninterrupted comfort and allows intact sleep for the patient and the caregiver. Sublingual morphine concentrate, although variable in efficacy, allows those patients for whom it is effective to obtain pain relief without the unpleasantness of parenteral or rectal administration. The metabolite of morphine, morphine-6-glucuronide, is an active analgesic with a longer duration of action and half-life than morphine (Osborne, Joel, & Slevin, 1986). The accumulation of morphine-6-glucuronide probably accounts for the observation that repetitively administered oral morphine is one-third as effective as intramuscular, while single-dose-administered morphine is only one sixth as effective (Reisine & Pasternak, 1996). Opioid equianalgesic tables in pharmacology textbooks are generally based on acute pain models rather than pain patients receiving chronic opioids and report the oral to parenteral efficacy of morphine as six to one. Hospice patients are not opioid naïve and should be dosed using the three-to-one conversion factor when estimating the oral-to-parenteral conversion of morphine.

All of the other opioid analgesics are equally effective in controlling pain and are typically used as alternatives when patients are allergic to morphine, experience morphine-related toxicity, or express concern about taking morphine (the drug addicts use). The only opioid analgesic that is best avoided in cancer patients is meperidine, due to the accumulation of the metabolite normeperidine, which is associated with the development of irritability, myoclonic jerking, and generalized tonic-clonic seizures (AHCPR, 1994; APS, 1999; Foley & Inturrisi, 1989). Because most cancer patients require relatively high doses of opioid agonist medication, the additional use of a mixed agonist-antagonist (butorphanol, nalbuphine, and pentazocine) is also strongly discouraged, because of the possible precipitation of opioid withdrawal and severe pain for these patients (APS, 1999; Foley & Inturrisi, 1987). Tramadol hydrochloride (a weak opioid-agonist that also inhibits the reuptake of norepinephrine and serotonin) is generally not used for cancer patients and must not be given in doses greater than 400 mg per day for the relatively "healthy" younger patient, 300 mg per day for the greater than 75-year-old patient, 200 mg per day for the patient with creatinine clearance less than 30 ml/min, and only 100 mg per day for patients with cirrhosis (APS, 1999; Medical Economics, 2000).

Opioid-related myoclonus has been reported for heroin, hydromorphone, meperidine, methadone, and morphine (Mercadante, 1998). Metabolites of these opioids may accumulate with renal insufficiency, leading to irritation of the cortex and brain stem reticular formation. High levels of morphine-3-glucuronide, morphine-6-glucuronide, and normorphine accumulate with renal failure and result in generalized myoclonus when patients receive morphine (Reisine & Pasternak, 1996). The neuroexcitatory metabolites of morphine and hydromorphone may be responsible for the hyperalgesic state seen in cancer patients treated with high doses of these medications (Mercadante, 1998).

Whether or not patients experience significant toxicity with morphine therapy, it is often prudent to change to a semisynthetic opioid analgesic. Many of these are currently available (or soon to become available) as controlled-release preparations. Hydromorphone is frequently selected, as the duration of analgesic action and plasma half-life are the same as morphine (Pasero, et al., 1999). Perhaps relatively less nauseating and (central nervous system (CNS) "toxic" than morphine, hydromorphone is available in immediate-release oral tablets (controlled-release tablets are available in Canada and are in clinical trials in the U.S.), suppositories, and injectable solutions (including a 10 mg/ml solution that is quite useful for end-stage cancer pain management, when high-dose parenteral infusions are common).

Case Example

Mr. C, a 70-year-old gentleman, had advanced lung cancer complicated by sacroiliac and fifth lumbar vertebral metastases. He experienced severe pain in his left

thigh with muscular wasting. He had previously tried oral morphine with an unclear "reaction." Although he was able to tolerate oral fluids and solids without any overt difficulty, he was quite anxious about taking any oral analgesics and requested that his medication be provided by intravenous route, a dosing format in which he had great confidence. Because he was cared for by his daughter, who was able to learn the needed skills, it was possible to consider the use of parenteral analgesics. He had been started on intravenous hydromorphone in the hospital before coming home to the hospice program. The hospice nursing staff maintained a patent intravenous access with a saline peripheral port, and his daughter gave him doses of 5 or 6 mg hydromorphone every 3 hours, with good relief of his pain for the first week on the program. He was able to sleep well and developed a good appetite. By the second week, his pain was beginning to bother him much more, and a home pain management evaluation was completed. It was decided to add the anti-inflammatory choline magnesium trisalicylate, at 750 mg orally four times daily with food, and to maintain the intravenous hydromorphone at 6 mg every 3 hours. Through the next week, he felt much better, but he developed the need for increasing doses given at decreasing intervals by the fourth week. When his intravenous hydromorphone reached 11 mg every 2.5 hours, he developed considerable nausea and vomiting, associated with anxiety about the ability to ever control his side effects and pain simultaneously. He was given 1 to 2 mg of sublingual haloperidol every 4 hours as needed, relieving his nausea and vomiting. In the final and fifth week on the program, he continued to increase the use of the hydromorphone, eventually reaching 20 mg every 3 hours, yet remained alert, active, and involved with his family and care needs. His family was grateful that they could maintain meaningful dialog with him and complete much of the anticipatory bereavement work. On the day before he died, he met with the funeral director to plan the details of his own funeral and met with a close friend to help prepare the eulogy that would be delivered. Later that day, he went to sleep and died during the night. Although he had miotic pupils, suggesting an opiate effect, throughout his participation in the hospice program, he never developed any respiratory depression except as an agonal event.

Oxycodone and fentanyl are also commonly used medications and allow for very good pain relief with relatively little toxicity. Both of these medications are available in oral formulations in the U.S. Fentanyl transdermal patches (used as the base analgesic and supplemented with oral transmucosal fentanyl citrate for breakthrough pain) can provide analgesia for 2 to 3 days with each patch. In the chronic steady-state condition, a 25 mg/hr transdermal fentanyl patch is approximately equianalgesic to 10 mg oral morphine sulfate every 4 hours or 30 mg every 12 hours when given as sustained-release tablets (Emanuel, et al., 1999). Fentanyl patches may improve medication compliance because patients only have to change them every 3 days; but patients and staff caring for cancer patients often report that patches are difficult to titrate, require the use of a second medication for breakthrough pain, may cause skin irritation, do not stick very well in hot and humid environments, have erratic blood levels due to nonstandard thermal conditions or body weight less than 110 pounds, and have significant cost. During episodes of fever (temperature >104°F), exertion combined with sunny and warm environments, and exposure to high external temperature sources (heating pad, heated water beds, electric blankets, and car seats in the summer), the actual dose of fentanyl delivered may exceed the dose printed on the patch and lead to potential increases in serum fentanyl levels (Newshan, 1998). Dosing tables for fentanyl transdermal patches (suggesting that 45 to 134 mg per day of morphine is equivalent to 25 mg per hour of transdermal fentanyl) have been based on the 6:1 oral to parenteral morphine ratio, resulting in undershooting the dose when going from oral morphine to the fentanyl patch and overshooting when going from the patch to oral morphine and other opioids (Enck, 1995; Johanson, 1993).

Controlled-release oxycodone has been designed to provide sustained delivery of oxycodone over 12 hours, with an oral bioavailability of 60 to 87% (Medical Economics, 2000). With repeated dosing, steady-state levels are achieved in 24 to 36 hours; however, controlled-release oxycodone exhibits a unique biphasic absorption pattern with two apparent absorption half-times of 0.6 and 6.9 hours (describing the initial release of oxycodone from the outer layer of the tablet, followed by prolonged release from the core of the tablet through the use of a patented technology). This unusual release system allows for prompt establishment of stable blood levels of oxycodone with the first dose and little need to overlap parenteral medications with controlled-release oxycodone. Oxycodone is metabolized primarily to noroxycodone (a considerably weaker opioid than oxycodone) and minimally to oxymorphone (a potent analgesic mediated by the CYP2D6 P450 system). Similar to other controlled-release medications, controlled-release oxycodone must be swallowed whole and never broken, chewed, or crushed, which could lead to rapid release and absorption of a potentially toxic dose of medication. With renal or hepatic failure, initial doses are one third to one half of the usual doses; however, oxycodone is not associated with myoclonus or significant CNS toxicity due to its metabolites (Medical Economics, 2000).

The practice of combining opioid analgesics to provide better patient comfort is confusing for patients, their caregivers, and even the prescribing physicians. It is not justified under most circumstances, and there is often misuse of multiple opioid medications because few appreciate that pill size has little to do with relative potency or that sustained-release tablets do not adequately control pain

until proper titration has occurred over 2 to 3 days. When two different molecules are given simultaneously, it is usually because the base medication is not available in more than one or two routes of administration, the base medication has not been titrated to full effect, or there is some toxicity being experienced.

It is routinely necessary to provide additional immediate-release opioid medication for breakthrough pain occurring at certain times (incident pain, movement-related pain), especially when the base opioid analgesic is a sustained-release preparation. Unanticipated changes in pain can thus be effectively managed on an immediate basis, with day-to-day tailoring of the overall opioid analgesic medication by observing the use of these additional doses. Monitoring the 24-hour total usage of medication, and readjusting the daily dosage, are essential for keeping up with the oral opioid analgesic medication needs of the patient. The approximate dose of additional medication providing good control of breakthrough pain is 5 to 15% of the total daily amount of base medication (Emanuel, et al., 1999). Using 10% is an easier method, allowing the prescriber to simply move the decimal point one digit to the left (avoiding the need for calculators) to determine the breakthrough dosage. This 10% method of calculating the breakthrough dose assumes that the same route of administration is used for the immediate-release medication as for the base controlled-release medication. After receiving three back-to-back doses of breakthrough medication (every 30 to 60 minutes for oral liquid concentrates, or every 1 to 2 hours for solid tablets and capsules), the patient still having considerable pain must be reassessed.

Oral transmucosal fentanyl citrate (often used for breakthrough pain control when using transdermal fentanyl), a solid form of fentanyl incorporated into a sweetened lozenge on a handle, is partially absorbed rapidly through the oral mucosal and subsequently more slowly absorbed in the gastrointestinal tract (APS, 1999). The blood levels achieved will vary, depending on the fraction of the dose that is absorbed through the oral mucosal and the fraction swallowed and absorbed from the gastrointestinal tract (Medical Economics, 2000). Normally, about 25% of the total dose of oral transmucosal fentanyl citrate is rapidly absorbed from the buccal mucosa, and the remaining 75% is swallowed with the saliva and slowly absorbed; the generally observed 50% bioavailability is divided equally between rapid transmucosal and slower gastrointestinal absorption (Medical Economics, 2000). Because only about one third of the swallowed medication escapes first-pass liver metabolism to become systemically available, patients with impaired swallowing (or those incapable of swallowing) receive only half of the potential analgesic efficacy of oral transmucosal fentanyl citrate.

The major complication of all opioid analgesic therapy is constipation, regardless of the route of administration. Constipation must be vigorously managed from the initiation of treatment (prevention). Constipation not relieved adversely impacts the quality of life and must not be ignored. Failure to correct opioid-induced constipation leads to intractable nausea, vomiting, abdominal discomfort, and bowel perforation, as well as emotional distress. Options for treating constipation include: stimulant laxatives, combination stimulant/stool softeners, prokinetic agents, osmotic agents, lubricants, and enemas. Dietary interventions alone or the use of bulk-forming agents are often inadequate and not recommended for those with advanced disease and poor mobility (Emanuel, et al., 1999). Recalling that dirt and water alone produce mud, a viscous material, but the combination of dirt, water, and fiber (straw, grass) produces brick (as in adobe), should make the admonition to avoid bulk-forming agents more clear.

Case Example

Mr. F was sent home from the hospital with advanced prostate cancer and widely spread bone metastases, with no bowel movement for 1 week prior to entering the hospice program. He was fairly comfortable from a pain perspective, although he experienced increasing abdominal fullness and discomfort thought to be due to opioid-analgesic-induced constipation. Digital examination of the rectum found significant hard, impacted stool that was manually decompressed. Once free of the impaction, he was started on an oral laxative and stool softener combination, and he developed bowel regularity within 2 days. There were no further episodes of impaction, and his bowel integrity was maintained with the same daily laxative/softener combination.

Although nausea and vomiting are initially common with opioids, once acclimated to these medications (in a matter of days for most patients), nausea and vomiting developing later more often result from unrecognized and ineffectively treated constipation. Early in the use of opioids, nausea and vomiting are usually controlled with dopamine-blocking agents (droperidol, haloperidol, metoclopramide, perphenazine, prochlorperazine, promethazine, or trimethobenzamide), antihistamines (diphenhydramine, hydroxyzine, or meclazine), anticholinergics (scopolamine), and serotonin antagonist (dolasetron, granisetron, or ondansetron) agents (Emanuel, et al., 1999). Respiratory depression, significant central nervous system dysfunction, allergic reactions, and the risk of chemical dependency are insignificant in comparison to constipation or nausea and vomiting.

When opioid analgesics fail to provide relief of significant pain despite clear toxicity (respiratory or central nervous system depression), it is necessary to remember

that these agents are not always effective for deafferentation (neuropathic) pain due to nerve involvement, viscus or muscle spasm, or extreme psychological distress. It is the use of the adjunctive medications — with or without further opioid analgesics — that is warranted.

Adjunctive medications include antidepressants, antipsychotics, anticonvulsants, anxiolytics, and psychostimulants. These useful materials can be added at any step in the continuum of cancer pain management and often save patients from unnecessary progression to high-potency opioid analgesics or complex analgesic technologies. The adjunctive medications manipulate the neurochemistry of the nervous system and augment the overall effectiveness of both nonsteroidal anti-inflammatory and opioid analgesic combinations.

The antidepressants are remarkable agents, with the ability to block the presynaptic reuptake of norepinephrine and serotonin, resulting in elevated levels of these important neurotransmitters in the brain (Botney & Fields, 1982; Hendler, 1982). The benefit of enhanced serotonin centrally is the consequent periaquaductal release of endogenous opioid peptides with a dampening effect on pain perception (Frier, 1985). These agents correct the depression (which is so common with persistent pain); stabilize sleep; and improve appetite, energy level, concentration, and the ability to experience pleasure. The ability of antidepressants to relieve pain is independent of the antidepressant effect (Feinmann, 1985). Tricyclic antidepressants are recommended as one of the first-choice medications for painful polyneuropathy (Sindrup & Jensen, 2000) and especially for patients experiencing burning and tingling neuropathic pain (Emanuel, et al., 1999). Although the antidepressants most traditionally used for neuropathic pain management are generally the serotonin-enhancing tricyclic agents (amitriptyline and imipramine), the more norepinephrine-enhancing tricyclic agents (desipramine and nortriptyline) are often particularly useful when patients are intolerant to the serotonin-enhancing products or when psychomotor-retarded depression is present. Antidepressants are not habit forming and have little effect on respiration when used in therapeutic doses. Serotonin-enhancing tricyclic antidepressants are associated with a number of annoying anticholinergic side effects that limit their usefulness unless patients can tolerate them. The newer selective serotonin reuptake inhibitors (SSRIs such as citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline) are generally free of the anticholinergic adverse effects (having unique side effects of their own), but are disappointing as co-analgesics (Emanuel, et al., 1999). Atypical antidepressants (bupropion, mirtazapine, nefazodone, trazadone, and venlafaxine) are being evaluated for their analgesic usefulness and may provide benefit with less potential toxicity (Emanuel, et al., 1999).

Case Example

Mr. D, a 75-year-old gentleman, had severe lability of affect, impaired sleep, and advanced pulmonary cancer, leaving him short of breath and in need of continuous oxygen therapy. He had used diazepam for many years as a bedtime hypnotic, but the hospice staff was concerned about the cumulative respiratory depression of diazepam and sustained-release morphine. Rather than administer diazepam with the sustained-release morphine at 60 mg twice daily, he was started on 10 mg of doxepin hydrochloride at bedtime, which was eventually adjusted upward to 20 mg the next week with improvement in sleep, stabilization of his mood, loss of affective lability, and better management of his chest wall pain.

Antipsychotic medications still commonly referred to as neuroleptics or major tranquilizers, block the postsynaptic dopamine receptors and prevent the transmission of neuronal information. The consequence of these agents is the functional disconnection of the limbic system (the modern-day equivalent of a noninvasive frontal lobotomy), with the patient relatively unconcerned about the pain problem. This effect often permits the rapid tapering of high-dose opioid analgesic medication, especially intravenous, when a patient is trying to leave the hospital to return to the home setting. With antipsychotic medications, it is possible to significantly decrease the opioid dosage and maintain the patient in a relaxed state. Antipsychotic agents are also powerful antiemetics and control nausea and vomiting (Hanks, 1984; Johanson, 1988). The high-potency medications droperidol and haloperidol are particularly noteworthy because they work with minimal effect on the cardiovascular system. Droperidol is only available as a parenteral agent, but haloperidol is available as oral tablets and an oral concentrate (2 mg/ml)that can be used sublingually (Johanson, 1988). The low-potency medications chlorpromazine and thioridazine are relatively toxic for the cardiovascular system and are best avoided in the seriously ill patient. Extrapyramidal reactions do occur with the high-potency medications, but they can be easily managed with the anticholinergic agents benztropine and diphenhydramine.

Case Example

Ms. M was a 45-year-old woman with end-stage human immunodeficiency virus infection. She did not experience significant pain, but she suffered from intractable nausea and vomiting that were not relieved with standard antiemetics used orally or rectally. She was given 1 mg of sublingual haloperidol every 4 hours, with good control of her symptoms.

In general, the anticonvulsants are frequently the only effective oral medications for deafferentation (neuro-

pathic) pain, nerve injuries, and pain characterized by burning, tingling, or paroxysms (Swerdlow, 1986). Anticonvulsants stabilize nerve cell membranes and inhibit spontaneous discharge by blocking sodium channels unspecifically, resulting in the control of seizures centrally or neuropathic pain peripherally (Sindrup & Jensen, 2000; WHO, 1986). The most commonly used agents (carbamazepine, clonazepam, gabapentin, phenytoin, and valproic acid) have been employed in the management of lancinating or stabbing dysesthetic pain (Emanuel, et al., 1999; Lack, 1984; Sindrup & Jensen, 2000). Recently, Bruera, et al. (1999) reported that most patients with neuropathic pain do improve on opioid analgesics. Based on a prospective open label study in which more than two thirds of patients with neuropathic pain achieved good analgesia with opioids alone, coupled to the expected effectiveness of adjuvants rarely exceeding 30%, Bruera, Walker, and Lawlor (1999) recommended opioids as the first-line treatment for these patients. They advised using the adjuvants when patients reached dose-limiting toxicity.

Clonazepam is a potent benzodiazepine with a relatively greater anticonvulsant effect than its congeners (Hanks, 1984). Clonazepam is one of the least difficult anticonvulsants to use in the home hospice setting due to the ability to use it without the need for blood level monitoring. Because it does tend to accumulate and may cause a moderate degree of sedation, clonezapam is often avoided in severely ill patients. However, the long half-life of clonazepam does allow for effective once-daily dosing for many patients.

Gabapentin has become the more typically utilized oral anticonvulsant for neuropathic pain management (Emanuel, et al., 1999). Gabapentin is generally started in low doses (100 mg, one to three times daily) and titrated upward to clinical effect (the reduction of pain) or the manifestation of dose-limiting toxicity (sedation and ataxia). There are no specific blood levels correlating to pain relief, and patients may require 3600 mg per day or more to obtain pain relief. Based on numbers needed to treat (to obtain more than 50% pain relief) studies, gabapentin is considered to be one of the medications of first choice for the treatment of painful polyneuropathy (Sindrup & Jensen, 2000).

Carbamazepine (with the relative risk of bone marrow suppression) and valproic acid (with the relative risk of gastric upset), coupled to the need for blood level monitoring, are generally unattractive as anticonvulsants for the home hospice patient. Carbamazepine is one of the medications of first choice for the treatment of painful polyneuropathy (Sindrup & Jensen, 2000). Carbamazepine is traditionally a preferred medication for trigeminal neuralgia and for other supraclavicular pain problems (phenytoin having the historical reputation for being the anticonvulsant to treat infraclavicular pain), but carbamezapine and valproic acid have the distinct disadvantage of requiring several days of oral titration before therapeutic improvement is noted. Both blood level monitoring and complete blood counts are recommended for the use of carbamazepine.

Anxiety, depression, fear, sleeplessness, and restlessness may all lower a patient's pain tolerance (Emanuel, et al., 1999; Hanks, 1984). Benzodiazepines, although not thought of as analgesics, have a limited role in the management of cancer pain. Most hospice patients sleep fairly well; but as some of them near the end of their lives, they may have disturbing dreams and recurrent nightmares interfering with the restful quality of their sleep for which benzodiazepines may prove helpful. Additionally, when pain interferes with the normal sleep pattern such that little or no stage four delta-wave sleep occurs, the addition of a short-acting sedative hypnotic agent (estazolam, triazolam, or zolpidem) is beneficial. It appears that without the deepest stage of sleep, muscles do not completely relax, and muscular pain may spontaneously develop, causing the patient widespread discomfort. By improving deep stage four sleep, this diffuse muscular ache that many cancer patients experience, which is also a consequence of their debilitation and malnutrition, can be lessened. When patients are morbidly anxious about their condition, the addition of a benzodiazepine medication may significantly improve their anxiety. The long half-life benzodiazepine medications, with maintained blood levels by time-contingent dosing, are preferable to the short half-life medications, which are more likely to produce wide swings in blood levels and consequent rebound anxiety.

Psychostimulants, such as dextroamphetamine and methylphenidate, are useful for the relief of depression, diminishing excessive sedation due to opioids, potentiating the analgesic effect of opioids in patients with postoperative and cancer pain, improving appetite, promoting a sense of well-being, and lessening feelings of weakness and fatigue (Breitbart, Passik, & Payne, 1998). Doses commonly used are 5 to 10 mg once or twice daily (breakfast and lunch), with few patients requiring more than 30 mg per day (Emanuel, et al., 1999). Although pemoline, a unique alternative to the amphetamine-like medications, lacks abuse potential, has mild sympathomimetic effects, has low DEA scheduling permitting telephone orders, and comes in a chewable tablet form that can be absorbed through the buccal mucosal, it is not established that it potentiates opioids although it counters the sedation of opioids and relieves depression (Breitbart, Passik, & Payne, 1998). Pemoline should be used with caution in patients having underlying liver disease.

Anesthetic Techniques

Certain anesthetic techniques are occasionally needed for the hospice patient. Some of the more useful procedures include the celiac plexus block for abdominal pain, the

stellate ganglion block for upper quarter pain, the lumbar sympathetic block for lower extremity pain, the intraspinal neurolytic block for bilateral lower body pain, and the epidural use of opioid analgesics (Cousins & Mather, 1984; Foley, 1985).

Case Example

Ms. N was a 50-year-old woman with ovarian and abdominal carcinomatosis, colectomy, and colostomy. She suffered from extreme abdominal, upper and lower back, and pelvic pain. Despite 10 to 20 mg of intravenous morphine per hour, she was never able to achieve effective control of her pain. She was not convinced that further chemotherapy would help her condition and elected hospice care. After consultation with an anesthesiologist, she received an epidural catheter. After it was placed, she had reasonable control of her abdominal and pelvic pain components using 5 to 10 mg hydromorphone every 5 hours. This was supplemented with 10 mg of oral methadone every 5 hours to control the upper back pain, which was not well managed by the epidural catheter. Later, as her disease spread, she experienced more abdominal pain, and a celiac plexus block was done, giving her very good relief. Her methadone was reduced to just 5 mg every 6 hours, with epidural hydromorphone at 10 mg every 6 hours. Although she was finally comfortable with this complex management, her course was punctuated over the last 2 months of her life by good and bad days, impaired appetite, poor sleep, and then pervasive depression. With the addition of 25 mg amitriptyline at bedtime, these symptoms quickly improved. Although she became more emaciated over time, she tolerated both invasive procedures without significant adverse outcome. As she was actively dying, she spent her final hours in the arms of her husband and communicated her wishes for the music to be played at her funeral.

The celiac plexus block provides good abdominal analgesia for several months and is perhaps the ideal management approach for pancreatic (Parris, 1985), hepatic, and intestinal cancer and abdominal carcinomatosis from ovarian malignancy. A significant reduction in pain after this block is reported by 60 to 90% of patients (Foley, 1985; Verrill, 1989). If survival extends beyond several months, the block can be repeated, although frequently with a less successful outcome.

The stellate ganglion block is useful for sympathetically mediated pain involving the scalp, face, neck, arm, and upper chest (Campbell, 1989). This technique is frequently used in the management of upper quarter pain related to brachial plexus involvement by lung cancer or highly invasive breast cancer. Often, a single block is useful; but commonly, a series of these blocks is performed to modify the discomfort. When effective, the results of this block can be quite impressive and startling.

Case Example

Ms. W, a tragic 37-year-old woman, had suffered from widely metastatic breast cancer for 3 years when she was first seen for pain control. Over many months, she had been tried on several different analgesic medications. A series of hypnotic sessions proved to be useful and allowed her to rest for a short time, but only while she was profoundly relaxed during the sessions. When her right arm began to swell quite rapidly, it was decided to try a stellate ganglion block to see if her pain might be sympathetic in origin. The block was performed late in the afternoon, and upon return to her room, she was smiling and reporting very little overall discomfort. She drifted off to sleep, for the first time in days, and died peacefully a few hours later without awakening. The first reaction of the anesthesiologist upon learning of the sudden demise of Ms. W was to assume that there had been an adverse outcome from the technically well-done stellate ganglion block. However, it was clear that she was finally able to experience comfort for the first time in years and was able to let go and die in her sleep.

Intraspinal neurolysis is a highly destructive technique used for intractable pain when lower-body motor function, along with bowel and bladder control, is lost, usually due to a spinal cord tumor or invasion of the spine by metastatic lesions. It involves the deliberate chemical coagulation of the remaining cord structures by placing alcohol or phenol in the subdural space (Ferrer-Brechner, 1989). The end result is absolute anesthesia below the level of the completed cord destruction.

Case Example

Mr. A, a 65-year-old gentleman, had a widely metastatic prostate cancer that had invaded his lumbar spine anteriorly and left him paralyzed below the level of the lesion, without bowel or bladder control, but in constant excruciating pain in his lower body. Despite adequate trials of nonsteroidal anti-inflammatory medication, low- and high-potency opioid analgesics, and transcutaneous electrical nerve stimulation, nothing seemed to relieve his suffering. After consultation with an anesthesiologist, it was decided to complete his cord lesion with intraspinal alcohol. This was done with the patient's informed consent and quickly produced complete resolution of his lower body pain. He still required some anti-inflammatory and opioid analgesic medication for his upper body pain, but was much improved and relatively comfortable after the spinal neurolysis.

Epidural and spinal administration of opioid analgesics is quite effective when the pain is fairly localized, especially if it is entirely below the level of the nipples. Long-term use of intraspinal opioids is recommended for cancer patients with regionalized pain below T1 failing to

achieve pain control after adequate trials of several different systemic opioids (APS, 1999). By placing the opioid analgesic into the epidural space or intraspinal, the patient experiences relatively little cognitive impairment, and while the pain is significantly relieved, normal sensation is preserved. Once the catheter is in place, the opioid (usually fentanyl, hydromorphone, or morphine) is administered by continuous infusion or by bolus injections. The availability of small, lightweight, battery-powered portable infusion pumps allows the hospice nursing staff to provide a 24- to 48-hour supply of medication to the patient without the risk of catheter infection due to poor injection technique by the nonprofessional caregiver. Contraindications (absolute and relative) for epidural and spinal opioids with or without anesthetic agents include: bleeding diathesis, septicemia, local cutaneous infection at the site of catheter insertion, known immune suppression, insulin-dependent diabetics, and lack of appropriate support for the ongoing management of the catheter (Swarm & Cousins, 1998).

Special Considerations for Parenteral Therapies

Parenteral opioid infusions are used much more frequently than anesthetic procedures, but less frequently than oral medications. They can be extremely beneficial for those patients who have patent intravenous access, swallowing difficulties that prevent the use of oral medications, the need for large dosages of medication, and the lack of other routes of administration of opioids. The common technique for the administration of parenteral opioids is via a portable infusion pump delivering high-potency opioid analgesics through a small needle inserted into the subcutaneous tissue.

Case Example

> Ms. T was a 60-year-old woman with advanced hepatic cancer with pelvic metastases. She had delayed chemotherapy to allow for a long-hoped-for trip to Europe. When she first presented to the hospice program, she was experiencing severe bilateral hip pain with radiation into her thighs. Bothersome muscle spasms complicated her pain problem. She was a suspicious, guarded woman who did not have much faith in her physicians. She did not want to take any medication and desperately wanted to avoid being hospitalized. She was initially treated for her pain with intravenous morphine at 12 mg/hr, but was successfully converted to oral morphine in sustained-release form at 400 mg every 12 hours. Once she went home, she began to need more morphine and was quickly using 150 to 180 mg of immediate-release morphine every day in addition to the sustained-release morphine. The hospice staff observed that she used more morphine when her family members were present. Due to the wide fluctuations in her comfort level, and her increasing belief that the oral medications would never entirely control her discomfort, she was started on a subcutaneous hydromorphone infusion at 2 mg/hr, with satisfactory pain control within 1 day.

For cancer pain that becomes "out of control," Berger, et al. (2000) have described a technique using intravenous ketamine (2 mg/ml), fentanyl (50 µg/ml), and midazolam (0.1 mg/ml) to control pain after traditional analgesics were unsuccessful. They felt that ketamine, an N-methyl-D-aspartate (NMDA) receptor antagonist, and midazolam, a benzodiazepine useful for myoclonus, nausea, and cognitive disturbances associated with opioid therapy, would enhance the overall opioid therapy with fentanyl. As all nine patient studies exhibited some degree of qualitative improvement in cognitive compromise and agitation associated with previous therapy, as well as in overall pain control, Berger, et al. suggested that subcutaneous infusion or dermoclysis of ketamine/fentanyl/midazolam solution be used if intravenous access is lost.

Non-Pharmacologic Approaches

Cancer pain is also managed by a number of nonpharmacologic methods, including cognitive therapy, hypnosis, relaxation and imagery, distraction, reframing, patient education, peer support groups, transcutaneous electrical nerve stimulation (TENS), radiation therapy, and physical and occupational therapy services (AHCPR, 1994; Emanuel, et al., 1999). For prominent muscle spasm, predictably painful procedures, depression, and anxiety, the cognitive techniques are useful (Cleeland, 1987). Hypnosis can augment pain control but rarely relieves the pain completely. Providing orthotics or prosthetics, assistive devices, range-of-motion exercises, and bedside stretching can keep the remaining activities of daily living accessible for the patient. Radiation therapy and TENS are often effective management for bone metastases and pathologic fractures (Bosch, 1984; Howard-Ruben, McGuire, & Groenwald, 1987). TENS requires the participation of the patient. While a meta-analysis of studies of TENS therapy in postoperative patients found that both TENS and sham TENS significantly reduced pain intensity, with no significant differences found between the two for either analgesic use or pain intensity, suggesting that part of the efficacy of TENS could be attributed to placebo effect, patients with mild pain may benefit from a trial of TENS (AHCPR, 1994).

Radiotherapy

Radiation therapy is perhaps the most effective form of treatment for local metastatic bone pain, spinal cord and cauda equina compression, brain metastasis, mediastinal compression and superior vena cava obstruction, lung col-

lapse due to bronchial obstruction, urinary tract obstruction, and limb edema (Hoskin, 1998). The strategy for palliative radiation therapy differs from the techniques used for active cancer treatment. Protracted regimens of more than ten treatments may be more appropriate for patients with life expectancy longer than 6 months to reduce potential late radiation effects or acute effects such as nausea if critical structures such as the stomach have to be included in the radiation field. However, for patients with a more limited life expectancy, radiation can be administered in fewer fractions (Lawton & Maher, 1991; Maher, Coia, Duncan, & Lawton, 1992). In the hospice setting, a single high dose of radiation is generally as effective as multiple smaller doses for the control of pain from bone metastases. Serious late radiation damage (unlikely when life expectancy is short) is related to both high total doses and the delivery of radiation in large fractions over a relatively short period (Hoskin, 1998). Most retrospective and prospective studies report that 75% or more of patients obtain relief from pain and about half of those who achieve relief become pain-free (Nielsen, Munro, & Tannock, 1991).

Radiopharmaceuticals are used therapeutically for the relief of pain in cancer patients (AHCPR, 1994). Iodine-131 results in bone scan evidence of response in 53% of patients with bone metastases from thyroid cancer (Maxon & Smith, 1990). Strontium-89 is the most extensively evaluated as a treatment for bone pain and compares favorably with hemibody irradition in randomized trials, but is only potentially effective in the treatment of pain due to osteoblastic bone lesions or lesions with an osteoblastic component (Hoskin, 1998). Strontium-89 is reported to provide partial pain relief in 65 to 80% of patients and complete pain relief for 10% of patients (AHCPR, 1994; Hoskin, 1998). Rhenium-186 and samarium-153 phosphonate chelates have demonstrated 65 to 80% efficacy in international trials (Maxon, et al., 1990; Turner, Claringbold, Hetherington, Sorby, & Martindale, 1989). These beta-emitting radiopharmaceuticals, requiring only a single intravenous injection, are used to relieve pain from widespread osteoblastic skeletal metastases visualized with bone scintigraphy; 50% of patients will respond to a second administration if pain recurs (AHCPR, 1994).

Bisphosphonates (previously called diphosphonates) inhibit osteoclast activity and reduce bone resorption. Pamidronate and clodronate produce pain relief and reduce other skeletal morbidity (Hoskin, 1998). Placebo-controlled studies with oral clodronate in women with metastatic breast cancer demonstrated lower numbers of hypercalcemic events, vertebral fractures, rates of vertebral deformity, and combined rates of all morbid skeletal events. Because analgesia often begins weeks after treatment is initiated, the late use of bisphosphonates in hospice patients may not produce significant pain improvement if they are only for agonal pain control (Hoskin, 1998).

Final Comments about Cancer Pain Control

To successfully manage the terminal cancer pain patient, all of the underlying issues must be globally addressed. The etiology of the pain must be accurately identified to direct the appropriate therapy. The analgesics may progress from nonsteroidal anti-inflammatory agents to opioids and adjuvants, but with the clear understanding that the medications are titrated and used for sufficient time to adequately assess their efficacy. Realistic goals about pain and its management must be set and clear communication maintained with all of the parties involved. Education of the patient and the family regarding the use of resources and decision making for choices of therapy are part of the process (Ferrer-Brechner, 1984). Education about the ability to control pain effectively and correction of myths about the use of opioids must be included as part of the treatment plan (AHCPR, 1994; Emanuel, et al., 1999). The emotional and spiritual needs of the patient are as important, and as aggressively managed, as the somatic needs (Emanuel, et al., 1999). Psychosocial interventions should be introduced early in the course of illness so that patients can learn and practice these strategies while they have sufficient strength and energy (AHCPR, 1994).

PROBLEM SYMPTOMS

In addition to pain, hospice patients — especially those with cancer — are bothered by constipation, nausea and vomiting, poor appetite and weight loss, seizures, difficulties with oral care, hydration, skin integrity, and itching. These symptoms are bothersome and steal quality and comfort from the patient and must be as aggressively managed as pain.

Constipation

As noted earlier, constipation is the expected consequence of opioid analgesic management and must be anticipated and preventively controlled from the moment pain is treated. Most patients can be given a high-fiber diet or a bulk laxative early on in their illness to prevent constipation. If ineffective, or if the patients are taking opioid analgesics, additional laxative strategies are needed (Emanuel, et al., 1999; Portenoy, 1987). Bowel care products are available in a variety of groups, including stool softeners, which prevent excessive drying; stimulants, which increase mucosal secretion and peristalsis, causing movement of fecal material; and combination products. Osmotic wetting agents, lubricants, and prokinetic medications are also available. The goal of therapy for the prevention of constipation is to maintain bowel regularity and keep the stool texture similar to that of toothpaste. In that way, even the weakest patient remains able to expel stool with little straining or effort.

Nausea and Vomiting

Nausea and resulting vomiting may initially be due to the opioid analgesics, but over time may result from metastases, unrelieved constipation, meningeal irritation, metabolic abnormalities, medications, mucosal irritation, infections, or bowel obstruction (Emanuel, et al., 1999). If a correctable process is the culprit, it is best to manage the symptom by focusing on the pathology. When this is not possible, then the routine use of antiemetics is justified. Metoclopramide improves gastric emptying and affects the central nervous system vomiting center at higher doses (Ventafridda & Caraceni, 1994). The high-potency antipsychotic medications droperidol and haloperidol, either oral, sublingual, or parenteral, are effective for nausea and vomiting (Johanson, 1988). The lower-potency antipsychotic medications, such as the typical antiemetics, are generally more sedating than the high-potency agents and are more likely to produce unpleasant side effects such as dry mouth, constipation, urinary hesitancy, and hypotension. Intractable nausea may respond to serotonin antagonists that are able to suppress the serious chemotherapy-induced nausea associated with even Cisplatin (Johanson, 1993). Until vomiting is well controlled, most patients and their family members experience high levels of discomfort.

Loss of Appetite and Cachexia

Appetite loss and declining weight leave most hospice patients weak, listless, and susceptible to skin breakdown. As a result of chemotherapy, radiation therapy, surgery, and the overall debilitation of chronic illness, many patients experience a reduced level of pleasure associated with eating. Some patients may even become anxious about eating due to swallowing difficulties, the risk of choking, or aspiration. The involvement of a dietitian to assist with food preferences or a communication therapist to improve swallowing may be quite useful. Small, frequent portions of favorite foods are better tolerated than large, traditional meals (Lang & Patt, 1994). If chemotherapy has left the patient with little sense of taste, altering the diet to include highly seasoned or spicy foods or serving meals as colorfully as possible may help to stimulate the appetite (Kaye, 1989). Education for caregivers about loss of appetite as part of the dying process is critical because these caregivers may view the patient's loss of interest in food, and resulting cachexia, as therapeutic failure on their part, as food is tied so closely to nurturing in many cultures (Emanuel, et al., 1999). Ultimately, hospice patients should be permitted to eat whatever might give them enjoyment, not what the caregivers think is best for them to eat.

Case Example

Ms. A was a severely emaciated woman with advanced ovarian and abdominal carcinomatosis. She had undergone extensive surgical resection of her tumor, radiation therapy, and several courses of chemotherapy. She had lost most of her appreciation for taste and consequently found all food to have the taste and texture of oatmeal. It was hard for her to maintain her weight without motivation to eat. She began to experiment with different foods and found that spicy Mexican and Chinese meals were satisfying and helped her remain motivated to eat, whereas the more traditional oral nutrition supplements were refused. She enjoyed the cold and creamy quality of vanilla ice cream over any other dessert-type food.

Pharmacologic strategies for stimulating appetite include the use of alcohol, corticosteroids, megestrol, androgens, and the marijuana derivative dronabinol (Emanuel, et al., 1999). Preliminary research suggests that treatment with medications stimulates appetite with relatively low risk of serious side effects (Lang & Patt, 1994).

Seizures

Seizures are a significant concern for patients with metastatic brain lesions and cause a great deal of distress for their family members who must witness seemingly unrelenting convulsions. Although fairly easy to control with oral anticonvulsant and steroidal medication, seizures occurring near the end of life are problematic because the patients often are no longer able to swallow effectively. An alternative to the use of crushed tablets or liquid suspensions via a feeding tube is the injectable form of the benzodiazepine lorazepam. Lorazepam provides seizure control for 3 to 4 hours (Leppik, 1983), does not significantly accumulate because it has no active metabolites, and is rapidly absorbed from intramuscular injection sites, unlike the other benzodiazepines. As seizures are often an agonal event, giving a few intramuscular injections is rarely a problem for caregivers once they understand that patients are not going to experience significant pain. Other possible seizure management alternatives include valproate sodium injection (if intravenous access is present), given at less than 20 mg per minute and over 60 minutes per dose; diazepam, 20 mg per rectum once or twice daily; midazolam, 30 to 60 mg per day by continuous infusion; and phenobarbital, 200 to 600 mg per day by continuous infusion (Twycross & Lichter, 1998).

Case Example

Ms. H was a 65-year-old woman with ovarian cancer that had metastasized to her right brain, producing a left hemiplegia and motor seizures. Her pain involved

her right hip. She was a remarkably angry woman who, while mildly dysphasic in her speech, was actually electively mute at times. Initially, 300 mg phenytoin at bedtime controlled her seizures, and 250 mg oral naproxen three times daily managed her hip discomfort. Later, 1 mg clonazepam was added at bedtime to control sleep and reported spasm, along with 30 mg sustained-release morphine twice daily. This produced marked daytime agitation, which was felt to be due to the benzodiazepine, and it was replaced by 2 mg oral haloperidol every 2 hours as needed. She lost control of swallowing and stopped taking any oral medications, fluids, or foods in the last week of her life. This resulted in more frequent and severe motor seizures that resulted in secondary generalization. As her daughter was able to administer intramuscular injections, she was managed for the last 2 days of her life with 1 to 2 mg of intramuscular lorazepam every 4 hours, with good control of her seizures. Although she steadily deteriorated, she did not appear to experience significant pain and was able to remain seizure-free with the lorazepam.

Skin Care

Skin care is vitally important for hospice patients, especially those who are bed bound. Minor and usually reversible skin disorders may become a major problem in the chronically sick patient, where healing powers are limited (Mortimer, 1993). Changes in body position, with frequent turning, proper padding with heel and ankle protectors, and a thick foam mattress cover should be utilized to prevent decubitus ulceration. There must always be 1 inch of foam between the lowest point of the patient and the surface of the bed (Emanuel, et al., 1999). Once ulcers are established, they are difficult to treat due to the poor wound healing of malnourished and debilitated patients. Bowel and bladder incontinence will produce skin breakdown if the patient is not kept relatively clean and dry. While powders and absorbent surfaces are helpful in keeping the patient dry, the use of urinary catheters and rectal tubes may be of assistance if soiling is constant and/or the patient is highly debilitated. The application of a "barrier" ointment can be quite effective once the skin is irritated.

Case Example

Ms. K, an 80-year-old woman with pancreatic cancer and secondary liver failure, had developed skin breakdown of her buttocks due to frequent diarrhea. Cleansing of her buttocks and perineum was associated with burning pain due to extensive irritation. She became progressively more fearful of any type of bowel activity and would allow herself to remain in a fecal- and urine-soaked bed rather than request appropriate care. To relieve her condition, and her resulting anxiety about hygiene, she was given a topical material made from equal parts of zinc oxide ointment, vitamin A and D ointment, and 1% dibucaine, to be applied to the involved area every 4 to 6 hours. Within the first few applications, immediate comfort was obtained, and significant healing occurred over the next week.

Itching

Itching can be quite serious for patients with extremely dry skin and is often a complication of hepatic failure. Applying topical moisturizers may be helpful for skin dryness, but for protracted distressing itch, use of the antihistamines diphenhydramine and hydroxyzine or low-dose antidepressants may provide relief (Johanson, 1988; Kaye, 1989). One particularly useful agent for itching is the antidepressant doxepin hydrochloride, a potent antihistamine (about 800 times more antihistaminic than diphenhydramine) that produces moderate sedation (Richelson, 1979).

Mouth Care

Oral care is routinely performed by healthy individuals and sadly forgotten in some terminal patients. With dehydration due to decreased oral intake, coupled with mouth-breathing as death approaches, it is common for the oral membranes to become dry and caked with debris. Cleansing the mouth with small quantities of water, giving ice chips, wiping the mouth with a lemon-flavored glycerine swab, and applying a lip balm are soothing for the dying patient (Kaye, 1989).

CONCLUSION

Hospice care should be a choice for every person coping with the end of life. It requires a special commitment on the part of the caregiver and the support of a skilled hospice team. Personal illustrations from actual cases effectively managed by the hospice program were presented in this chapter. The stories are human experiences, and they serve as the best teachers. Hospice work with pain and symptom management is enriched by the patients who believe in the hospice philosophy and provide the opportunity to participate in their living and in their deaths. There is no single or best way to control any particular symptom, but the coordinated efforts of the interdisciplinary team bring effective relief for physical, emotional, and spiritual discomfort. Although the team members are important for a successful outcome, the patients remind us that hospice management is not finite. It is evolving, and individualized care must be absolute. Only the patients and their families are able to judge the effectiveness of the hospice team.

Work Disability and Return to Work

43

Postinjury: The Return-to-Work Challenge

Stephen A. Lawson, M.S., C.R.C., C.I.R.S.

CASE STUDY

"I don't give a damn about you people … and I especially don't give a damn about my insurance company. When they took my arm, they took my ability to work … they took everything. Everything!"

When I first met Gary, I found a man who had incurred a very serious work injury. Gary had suffered two levels of ruptured discs and damage to the nerves of the dominant hand/arm. In addition, the C-spine laminectomy surgical procedure caused more damage to his dominant side and left Gary with severe pain. Unfortunately, Gary developed degenerative disc disease with scarring and spondylolisthesis at the injury site. In essence, he lost practically all function, his ability to lift, his fine finger dexterity, and his ability to perform anything but extremely limited range of motion with his dominant arm/hand. As a result of the loss of function, Gary also developed a partially frozen shoulder, adding to the pain and frustration with which he was already trying to cope.

Perhaps more disabling, though, was Gary's response, emotionally and psychologically, to his injury. Gary had been a plumber for 15 years and took tremendous pride in his work. He also established his work identity as a plumber, and this was the only thing that he desired to do in life, or, for that matter, saw himself doing throughout the course of his life. Gary once informed me in a counseling session, "I've always shown my family that I love them by working so hard. Before my injury, I worked 12 to 15 hours a day, 6 days a week, and that's how I told my family that I loved them."

Gary is a strapping six-footer whose well-muscled arms come from a lifetime of hard, physical labor. He possesses a high school diploma with no further education. His work has been strictly in the areas of residential, commercial, and industrial plumbing, and he worked his way up at certain jobs performing supervision and job estimating. Therefore, when his dominant arm became affected because of the cervical injury, Gary was left totally unable to perform his usual and customary work as a plumber. It should also be mentioned that Gary was in constant moderate to severe pain at rest, and he was having an extremely difficult time coping with all the losses he had incurred.

Another complication is that Gary did not look injured whatsoever (unseen disability), yet Gary was very seriously impaired. His friends and acquaintances oftentimes would say, "You look pretty good, Gary," but, in fact, Gary was not well at all. Had he experienced a disability others could see, perhaps a different social phenomenon would have occurred. That is usually the case.

This contributed to Gary's denial and "as-if" behavior. The latter refers to when individuals act "as if" they are able-bodied with no limitations and generally wind up hurting themselves all the more. This is a form of denial and results in working or playing outside their physical limitations. This is generally a fairly common phenomenon in the early stages of disablement and is especially pervasive in men who are gainfully employed and derive much of their masculinity from work.

Upon background examination, I learned that Gary was of Native American descent and had lived in a number of foster homes until he ran away at age 14 to live on his own. His home life had consisted of an alcoholic mother and a father who abandoned him. Gary was the oldest of several children, and from an early age, he took it upon himself to be responsible for the entire family. To him, working was the way he expressed his self-worth and

0-8493-0926-3/02/$0.00+$1.50

validated his existence and manhood. Gary's full range of psychological and emotional expression was dependent upon his ability to perform work and gain the proper recognition from significant others.

Throughout my years of experience as a vocational rehabilitation counselor, Gary stands out as an individual to whom I feel particularly close. By the same token, Gary was certainly one of the most challenging clients I have ever had.

Postinjury, Gary began to isolate himself from his "work friends" and began an emotional landslide that culminated in extreme marital problems and a fragmented relationship with his children. As he says in his soft Georgia drawl, "I felt as bad as a sore-tailed cat in a room full of rocking chairs".

Eventually, Gary's emotional and physical pain led him to the point where he did not care about anyone, including himself, and this led to suicidal and homicidal ideations and actions. In fact, Gary informed me in a counseling session that each day he would put an unloaded rifle barrel in his mouth and pull the trigger to "practice". One day, he actually loaded the rifle and was preparing to kill himself when he had an adverse reaction to the heavy medications he was taking and blacked out. The following day, he woke up in jail, after an apparent scrape with the law. Later, Gary was hospitalized for major depression and substance abuse and was referred to a pain clinic.

These events precipitated the referral to a multidisciplinary program, and Gary was provided with the help that he desperately needed.

OPERATIONAL DIAGNOSIS

Even though Gary's physical condition had stabilized, for the most part, his emotional and psychological life was deteriorating rapidly.

Clinically speaking, Gary became depressed, anxious, suicidal, and even homicidal. Gary basically became a man who lost contact with the world he valued so much and lost touch with himself in the process.

Gary was in constant pain, and this affected his moods, and, as he put it, he found that sleeping was a luxury." But even more significant was Gary's adverse reaction to his inability to work. As a result, he took his hostility out on everyone, including himself. He literally gave up on life. He was living a nightmare with a life crisis on his hands.

Clinically, I saw Gary as being stuck in the early phases of adjustment to his disability. Yet, there was more going on. Upon closer examination, I began to find a number of complexities in Gary's case that needed sorting out. Fortunately, Gary responded well to the counseling I provided and to the other treatment modalities that made up the multidisciplinary approach.

As an aside, Gary underwent a full course of medical treatment before being referred to a pain management center for approximately 2 years; he was treated at the pain center for another year thereafter. During this time, his vocational rehabilitation case was interrupted on several occasions for prolonged periods. I also testified at a Social Security hearing as an expert witness on his behalf and he was awarded benefits.

Later, he asked to return to me for further vocational rehabilitation evaluation efforts, and because of the very fine efforts provided by the multidisciplinary team, we were able to bring Gary to a physical and mental work-ready status.

Gary's case ultimately became a success; he is now self-employed as a plumber, a rehabilitation plan I recently developed on his behalf. However, in Gary's case, there was no possible way I could have handled all of the complexities involved in his situation, and I desperately needed a multidisciplinary approach. Because of the multidisciplinary approach, his life was saved, and he returned to a productive work effort. (A multidisciplinary team is not needed for every injured person, but can be very beneficial in certain cases.)

There are millions of individuals like Gary who, after the course of injury, have experienced emotional traumatization, accompanied by injury/illness, resulting in low self-esteem, confusion, frustration, depression, loss of meaning and masculinity or femininity, feelings of withdrawal and isolation, and fear. Generally, if an individual is injured to the point that he or she is unable to work because of increased symptomatology, most people will begin an "emotional landslide" unless they are able to find a support group, a professional helper, or they locate someone other than themselves who can assist them in any number of ways to adjust to their disablement and particular life situations.

As practitioners, we should keep in mind that emotional trauma after injury is a very real phenomenon, and if ignored, it can increase pain symptomatology (pain magnification) and also weaken an individual's coping mechanisms. Psychological and physical destruction can occur, such as in Gary's case, but bear in mind that there is hope for salvaging the injured person's remaining assets and maximizing potential through proper case management.

SERVICES RENDERED

- After Gary had completed a full course of medical evaluation and treatment through the normal channels, he was still left with numerous problems and was referred to a pain management center that utilized a multidisciplinary approach. Because all other studies and treatment procedures had failed, a pain center became his last hope. He had new studies performed, such as an

MRI, myelography, and EEG. The studies revealed a second ruptured disc above the prior cervical surgical site, spinal stenosis, cervical spondylolisthesis, and an increase in degenerative disc disease.

- Gary was also referred for psychiatric help. He entered a self-help group with individuals experiencing similar problems with work-related injuries. A Minnesota Multiphasic Inventory revealed major depression and an adjustment disorder. Gary was prescribed tranquilizers and began a program of psychotherapy.
- Gary began a pain management program, which included biofeedback, relaxation, visualization, and transcutaneous electrical nerve stimulation.
- Gary was also referred to an anesthesiologist, and he was evaluated for an implant, although this was not actually performed. He was provided with a program of epidural blocks.
- He began a marriage and family counseling program.
- After completing the pain program, Gary was better able to attempt a return-to-work effort through vocational rehabilitation services. This was ultimately accomplished and he is now a self-employed plumber, is able to control the hours he works and the type of jobs he can physically handle. He farms out work that he cannot perform.

Gary had the courage to press on in a return-to-work effort because of the importance he ascribes to being productive and gainfully employed. What he needed the most was help from people who cared about him, who were proficient in their specialties, and who were truthful with him. After proper treatment and therapy, he took it from there, and now is in control of his life again.

FACTORS OF VOCATIONAL REHABILITATION

Let's examine some factors of vocational rehabilitation that are within the scope and service delivery of the profession. An overview of the profession follows.

History of Vocational Rehabilitation

Vocational rehabilitation had its birth following the Industrial Revolution and World War I (1908 Workman's Comp and 1916 National Defense Act), after society began to realize that injured workers can be productive again when given a chance.

A number of programs on the federal, state, and private levels were developed to assist injured workers in their plight to adjust to their disablements, reach within themselves and identify potential, and then make use of that potential to become productive once again in a work setting.

As such, vocational rehabilitation counselors came on the scene, and vocational rehabilitation became a professional entity within its own specialty.

Over the years, millions of individuals have received help from vocational rehabilitation counselors, and the cost/benefit ratio has certainly proved worthwhile from a monetary view, but more than that, individuals who otherwise probably would have been unable to return to work have experienced and realized their intrinsic right to work with the help of vocational rehabilitation programs.

The basis for vocational rehabilitation programs is twofold:

1. Individuals have an inherent right to work.
2. Individuals have worth, and work opportunities should be extended to them.

Vocational rehabilitation offers professional services to assist injured workers to readapt and restore themselves to a new occupation postinjury that is within their physical and mental limitations. A target goal is to help individuals adjust to their disablement through proper counseling and guidance and to help them adjust to their new self-image and limitations.

Counselors must take on the roles of:

- Counselor
- Teacher
- Medical interpreter
- Legal interpreter
- Friend
- Guide
- Evaluator
- Job specialist
- Negotiator
- Service coordinator
- Case manager

Counseling Relationship

A trusting relationship between counselor and client generally must occur for maximum benefit to be realized. The counselor will provide insight and help for the injured to struggle, survive, and succeed with the many complexities that stem from disablement. Vocational rehabilitation is a specialty of its own and blends with the medical, psychological, legal, occupational, educational, training, counseling, psychometric, and work-hardening specialties.

The most critical factor in vocational rehabilitation affecting change in the injured worker is the counselor–client rapport. Other strong factors include the skill and expertise of the counselor and the motivation and aptitudes/abilities of the client to work together to develop new opportunities.

Effectiveness

Vocational rehabilitation has been found to be an extremely valuable benefit for injured individuals. Studies of various vocational rehabilitation programs vary, but all show that the benefit is worthwhile in returning the injured to suitable, gainful employment.

Perhaps not as well publicized or noted is the emotional stabilization provided by the rehabilitation counselor in helping a person to became work ready and self-actualized to maximum potential. This author personally feels that greater appreciation should be focused on this aspect of vocational rehabilitation as a service component. In some cases, rehabilitation success can only be achieved by individuals "working through" their emotional deficits and emotional/psychological adjustment phases before they can reach a work-ready state. One would not expect to construct a building without first laying a foundation, and in many cases, counseling to help the individual adjust to his or her disablement becomes the foundation to the remaining steps of service delivery.

There are cases in which individuals are totally unable to attempt a return-to-work effort because of the severity of their problems. However, these same people may benefit from participating in vocational rehabilitation because of the counseling they receive. Therefore, vocational rehabilitation can still be partially successful without the injured worker returning to work if, in fact, he or she learns to readapt and cope with the imposed limitations of the disablement. Unfortunately, there is a segment of disabled individuals who will never be able to return to either a part-time or full-time occupation because of their limitations, but the same persons may, in fact, benefit from counseling to better cope with their life situation and limitations.

Because of the unpredictable nature of disablement, there are cases in which an individual can adjust to disablement, become work ready via his or her skill level, and yet not enter the work world at that time. However, it is also this author's opinion that in these cases, rehabilitation can still be considered successful as long as the individual is competitive for work even though it comes at a later time.

WORK IS IMPORTANT — THAT'S WHY WE DO IT

Work Motivations

Work can provide healthy therapy in a number of ways. It provides us with a sense of meaning and identity (work identity). When we meet a new person, most often the second question asked after learning the person's name is, "What do you do for a living?" Therefore, we ascribe much of our personal meaning and self-worth to what we do for work.

Societal Expectations

A number of societal expectations and rewards accompany work as well. More often than not, people who do not work or cannot work do not find the same favor as those who do. It also seems that in society as a whole we place a strata of significance and importance on different jobs. For example, an individual who is a professional athlete is generally viewed differently than someone who is a typist. Value has been ascribed by members of society not only to those who do work, but also to those who can work and to the various occupations within the given populace.

Cultural Expectations

Work also has a number of cultural expectations and meanings. Some cultures place tremendous pressure on the individual to perform, either in an educational or work setting or both. Consider the Japanese work ethic. In this culture, failure to achieve could result in ostracization and other levels of rejection.

Conversely, other cultures do not place the same pressure and expectations on the individual to work. Living within this type of culture has a totally different meaning than the former. For example, while on vacation in Mexico, I had to adjust to the slower pace and lesser work demand while there. The point is that our culture can affect how we grow in the work world as we develop over the years.

There are also various types of subcultures that exist within the work world. This means that in order for the individual to be successful and accepted in certain jobs, he or she must conform to the expectations within the subculture pertinent to that occupation.

As an example, the mental picture one draws of an iron worker is certainly different from the mental picture one draws of a florist, and the expectations of each of these individuals to be accepted by their peers within their subcultures of work are different.

Personal Values

As individuals, we place value and meaning on our ability to work and also on the occupation in which we participate.

Work has a way of helping us feel worthwhile, productive, and useful. Work also provides us with the chance to make friends, pass time, face challenges, and assert our opportunity to remain in control. The workplace also provides us with the ability to concentrate on something other than ourselves by way of on-task situations, and gives us a sense of purpose, duty, belonging, and obligation. These factors allow us to benefit from accomplishing job tasks and, hopefully, reap intrinsic

and extrinsic reward as a result. Our work personality develops from the above factors.

Work as Therapy

Physical and mental pain can be unusual and confusing phenomena. A fact often overlooked is that physical pain can expose emotional deficits that can overshadow the original physical problem. In essence, a work-related illness/injury known as a disability can evolve into an entire life problem in certain instances.

It has been my experience that doctors typically are not equipped, trained, or otherwise have time to deal with many of the emotional aspects of disablement because their primary focus tends to be on diagnoses, treatment, and seeking a cure within the organic and physical realm. This does not, however, diminish the injured person's need to talk about his or her feelings about the injury, residual limitations, his or her present situation and resulting losses, and hope for the future.

Pain behaviors also can be expressed in a variety of ways, have a number of social and cultural and even moral implications (some see injury as a result of sin) and, at the very least, if severe enough, can wear down even the most stoic person over time.

Pain can magnify as well. It can spread and cause debilitating problems in the most sensitive and precious areas of an individual's life. Over time, mood changes can occur, bitterness and anger can set in, and confusion and frustration with outbursts of anger can become commonplace and wreak havoc on the injured person's family and friends. Injured persons may isolate themselves from relationships, and this will only create more problems.

An individual experiencing unmanaged pain syndromes may find himself or herself feeling as though the pain is "all in their mind". This phenomenon may be perpetuated by treating physicians, family members, friends, and insurance companies to the extent that they feel the problem is in the person's mind. Unfortunately, this may leave the individual feeling as if he or she is "mentally ill," which may not be the case at all. I have seen a number of cases over the years where this phenomenon has occurred and later medical studies revealed a legitimate injury that would validate symptomatology expressed by the person. These individuals may feel ugly, useless, worthless, depressed, unwanted, punished, victimized, withdrawn, angry, fearful, discouraged, unable to sleep restfully, and suicidal or even homicidal. Their behaviors may appear to others as argumentative, unsociable, irresponsible, irrational, hostile, unusually quiet, timid, tired, short-tempered, and with an inability to concentrate.

There is often a significant loss of income, loss of body capabilities to participate in preinjury activities, loss of esteem, loss of personal power, loss of friends, loss of possessions, loss of resources, and perhaps loss of spouse and family. In essence, these individuals begin to collapse, both in their inside world (psyche) and in their outside world, which may have been supportive of them but no longer is.

It is unfortunate, but oftentimes when individuals drop to the bottom of themselves, they push the outside world away with an ulterior thought that says, "I'm no good. I'm not adequate. You'd be better off without me, and I have no control over myself or over my world any longer."

Indeed, injuries/illnesses can become tragic and devastating, and a disability problem can spread to become a life problem. Therefore, if an injury, mental or physical, occurs, more dynamics within the person's life come into play, and this is where a good rehabilitation counselor can step in and help the person to sort out problems, deal with them emotionally and intellectually, and look for hope to face the challenges. The experienced counselor knows that work can become therapy, as we attach many of our emotions, perceptions of self-worth, and attitudes to how we are at work, and this can help us become better within ourselves.

Work Personality

We all know that everyone wears a variety of masks as we have a number of roles we must play, both at home and in the workplace. As such, we develop two different types of personalities. The first type involves our personhood and provides us with our own set of characteristics, traits, identity, and value systems. By the same token, we develop a work personality over our life span with many of the same features, only associated with work.

From a clinical standpoint, whereas the psychiatrist is concerned with rebuilding and restructuring the personality, the vocational rehabilitation counselor is concerned with rebuilding and restructuring the work personality of the client.

Some of the foundational blocks the rehabilitation counselor may wish to explore are worker personality, identity, values, traits, characteristics, and ethics.

In addition, the counselor will consider both the verbal and tested interests of the client to ascertain information of occupational value. Medical information and residual limitations, as well as the individual's work personality type, the labor market, and tested aptitudes and abilities, along with other factors, will be considered in helping the individual and counselor make an intelligent and informed occupational choice.

The vocational exploration phase of developing a plan is critical and instrumental in helping individuals not only to test their own limits, but also to provide them with a vehicle to come to grips with their potential, assuming responsibility, undergoing a new vocational choice, and working their way toward maximizing their potential and earning strength.

A great deal of resource material is available from various publications, computer software, labor market surveys, tests, and the like to help the client and counselor in vocational exploration. Job trials, job analyses, on-site informational interviews, and work tolerance evaluations are also helpful in assessing vocational choices. Many techniques and resources exist to help individuals in their exposure and study of the many jobs in the competitive work world. The counselor will act as a teacher, guide, and advisor to the injured in their job and career planning. Factors considered are the client's limitations, aptitudes and abilities, skill level and general learning ability, the labor market, occupational trends, and the client's interest and work personality type.

Work Adjustment

Work adjustment is a training process designed to help individuals and groups understand the meaning, value, and demands of work and to modify and develop their attitudes, personal characteristics, work behaviors, and functional capacities as required for achieving their optimal level of vocational development. A number of techniques and modalities will work as an adjunct. These consist of job trials or simulated work to help the injured worker make the adjustments necessary to become work ready. Work adjustment takes place not by chance, but rather by careful and professional planning and execution by the counselor and client.

Psychological Adjustment

Considering the many negative effects of disability, it is only natural that the onset of a major disability will often be accompanied by significant emotional reactions (Shontz, 1965). A useful way of describing reactions would be as follows.

Shock

During the first few hours or days after onset of disability, the individual is usually feeling and reacting minimally and may have little awareness of what has happened. This initial phase is called shock and usually involves only muted emotional reactions of the individual.

Realization

Realization is the phase in which some recognition of the reality and seriousness of disability begins to develop. Anxiety, possibly even panic, may be the predominant emotional reaction. This fear is based on anticipation of possible death, critical losses, or unpredictable change. Its extent may or may not be consistent with the seriousness of the disability, but it is important for the counselor to recognize that the client typically feels great fear. Depression and anger also may occasionally appear during this phase.

Defensive Retreat

The anxiety that normally follows onset of disability could easily overwhelm the individual if there were no defense mechanisms available to help him or her cope with the situation. Predominant among these defenses is denial. Such denial may persist or reappear occasionally, long after onset of disability, usually in the form of the individual refusing to make reasonable or realistic allowances for the disability or to accept the limitations imposed.

Acknowledgment

Acknowledgment refers to the phase in which the individual achieves an accurate understanding of the nature of the disability and the imposed limitations. Some persons may demonstrate a very thorough intellectual understanding of the disability prior to the disability, but still not display full appreciation of its implications. Acknowledgment is usually marked by the onset of some degree of depression. The depression that often accompanies recognition of the reality and seriousness of a disability is a very natural grief reaction to the losses that result.

Adaptation

Adaptation is the final phase of adjustment to disability. The term simply means the individual has worked through any major emotional reaction to the disability, is realistic about his or her limitation, and is psychologically ready to make use of his or her potential. This is sometimes referred to as the acceptance phase, but it should be noted that accepting a disability does not imply a willingness to accept a diminished life or to be happy about being disabled. Rather, acceptance or adaptation means learning to live with certain limitations and to make the best use of the remaining assets.

Facilitation of Adjustment to Disability

The emotional reactions and efforts to cope with disability shown by an individual will be determined by a combination of personal characteristics, learning history, and current circumstances. Helping individuals to establish new hope, new goals, and self-actualize to restore their work personality becomes an important factor for readjustment to occur. Helping individuals to resocialize and gain knowledge of how to compete for new employment opportunities, develop new skills, deal with their problems and pain thresholds, and gain insight into their remaining

assets allows the injured to develop the confidence and courage they need for restoration to occur.

Qualifications of Counselors

Counseling practitioners within vocational rehabilitation programs generally have a minimum of a bachelor's degree, ranging up to a Ph.D. In most programs, however, this author believes education alone is not enough. A sincere desire to help individuals, the ability to work within a multidisciplinary (or interdisciplinary) approach, to provide guidance and counseling, to politic on behalf of another, to coordinate and synthesize a number of factors, and to develop vocational plans all become pertinent considerations regarding a practitioner's ability and skills.

It is also the author's opinion that counselors should be able to provide counseling to help empower the injured by way of encouragement and hope, to redevelop meaning; recreate simulated work environments and expectations; reactivate such qualities as work ethics, worker values, worker traits, and characteristics; and create a desire to seek out meaningful work effort, as well as to work through crises.

In addition, practitioners should have a strong handle on the medical aspects of disability, a working knowledge of the various stages of adjustment to disability within the injured/ill client, a strong background in and knowledge of psychometric measurement and interest testing, a full range of knowledge about work tolerance evaluation and work-hardening programs, an understanding of the work personality and how to develop and help people make commitments for vocational rehabilitation plans, and a working knowledge of the psychological implications of primary and secondary illness/injury.

Vocational rehabilitation has an interest in many disciplines. It is generally one of the last services offered to an injured person and is best begun after the medical treatment is concluded.

Like other disciplines, vocational rehabilitation is becoming more sophisticated and technological. The human element of interaction and restoration developed between client and counselor is not to be overlooked.

TABLE 43.1
Steps of Service

Referral	
Initial Evaluation	**Generally Includes**
Benefits review	Vocational counseling
Examination of relevant socioeconomic factors	Vocational exploration
Examination of medical work restrictions	Adjustment to disability
Work history/transferable skills analysis	Counseling recommendations
Testing	**Generally Includes**
Intelligence and aptitude/ability testing	Reading development
Examination of vocational interests	Vocabulary development
Spatial relations assessment	Arithmetic skills inventory
Numerical reasoning assessment	Test review assessment
Job-Seeking Skills Training/Work Readiness/ Skills Assessment/Job Analysis	
Return to work via	
Vocational training	(Same employer)
	Self-employment
Academic training	Modified work
On-the-job training	Alternate work
Postemployment Monitoring (30–60 Days)	
Case Closure	

CONCLUSION

In the case study discussed earlier, Gary was successful. He has been able to psychologically and emotionally adjust to his injury and has learned to work within his physical limitations. The price tag for this success was very high and required a number of professional helpers to assist him in the return-to-work process.

Gary still lives with his pain and is fully aware of all of the losses that he has incurred, but as he puts it, "It hurts more when I work, but I feel great."

It is a very pleasant sight to see Gary when he talks about his work. As he speaks, a slow smile crosses his face: "I have trophies of the work I do everywhere around me. When I drive down a street and see a house or an apartment complex or a laundromat that I worked on — those are my trophies." Gary calls these buildings his trophies because he says that no one can take them away from him. In fact, he signs his plumbing somewhere on every project he finishes.

The change in Gary has been dramatic. This man has gone from an "all or nothing" personality, as his psychiatrist calls it, to a man who is, each day, able to "thank God for the tender mercies," as Gary states softly.

It was a very special moment for me when in one of my last counseling sessions with Gary he reached into his wallet and pulled out a small card with the following scripture, "All as God wills, who wisely heeds to give or to withhold: and knoweth more of all my needs than all my prayers have told."

Gary told me that he had carried this scripture in his wallet for many years, and now he wanted me to have it.

I now carry the scripture in my wallet.

Neuro-Orthopedic Impairment Rating

Gabriel E. Sella, M.D., M.P.H., M.Sc., Ph.D. (Hon. C.), F.A.A.D.E.P., S.D.A.B.D.A., F.A.C.F.E., F.A.C.F.M., D.A.A.P.M.

DEFINITIONS: IMPAIRMENT VS. DISABILITY IN THE NEURO-ORTHOPEDIC EVALUATION DOMAIN

The independent medical examiner (IME) deals frequently with injuries or pathologies of the neuro-orthopedic systems. These systems comprise nerves, muscles, tendons, ligaments, fascia, capsules, and bones. These tissues are of primary concern in impairment evaluation. However, the evaluation of these tissues should not exclude the evaluation of other systems within the realm of a comprehensive physical exam and objective investigations.

The AMA Guideshave established by consensus a number of impairment values that could be granted for permanent injuries under specific sets of conditions. The present chapter is written within the framework of the AMA Guidessystem of granting percentages. In addition to the general description, there is a section on the strengths and limitations of the granting modality according to the authors' 10-year experience in the realm of impairment evaluation.

TABLE 44.1
The Neuro-Orthopedic Systems: Structural and Functional Pathology Considered in Impairment Evaluation

Tissue	Structural Dysfunction	Functional Disruption
Nerves: Motor	Hypotonus	Loss of agility, strength, and endurance
Sensory	Loss of sensory fibers (A, δ, C)	Paraesthesia
Muscles	Atrophy	Loss of strength
Tendons	Rupture	Loss of agility
Ligaments	Inflammation	Loss of joint ROM
Fascia	Myofascial scar	Myofascial pain syndrome
Capsules	Capsulitis	Loss of joint ROM
Bursae	Bursitis	Pain, loss of joint ROM
Bones	Fracture	Loss of ROM

Within the framework of neuro-orthopedic impairment, it should be clear to the reader that this is a medical issue. By definition, impairment is "any loss or abnormality of psychological, or anatomical structure or function". Within the neuro-orthopedic field, this may refer to one or a combination of the following factors described in Table 44.1.

By definition, disability is a legal conclusion related to a permanent impairment. It is a resulting reduction or loss of an ability to perform an activity. Within the neuro-orthopedic framework it refers to a permanent impairment related to one or more tissue components described in Table 44.1. Whereas the IME can grant a given percentage for a permanent loss of a neuro-orthopedic structure/function, the actual final consideration of the relevance of that number in economic, legal, administrative, and other matters is beyond the evaluative aim and lies purely within the realm of the administration and law authorities involved in the case.

0-8493-0926-3/02/$0.00+$1.50

In concrete terms, the loss of the right index finger because of amputation could be granted a permanent percentage value, i.e., 11% WPP (whole person partial impairment). However, the meaning of the loss to a person whose vocation does not rely to a great extent on the right index finger is not the same as that of a surgeon, pianist, or other professional who would have to renounce his or her given profession and no longer be able to practice it. Therefore, whereas the 11% WPP granted by the IME is the same for any person who suffered the amputation of the right index finger, the disability factor granted by the other authorities will depend on a number of factors, not the least of which is the relevance to one's vocation and livelihood.

It is relevant, therefore, for the reader to understand from the beginning the differences between granting an impairment percentage for a permanent injury/body damage and that of disability evaluation and granting of monies or other social and economic benefits to the sufferer.

BASIC PRINCIPLES OF IMPAIRMENT EVALUATION OF THE NEURO-ORTHOPEDIC SYSTEMS

Causation

The definition of causation within this realm is the factor(s) that are known to have caused the structural or functional impairment. Causation may need to be proven in many cases where there may have been pre-existing or post-existing conditions.

Within this framework, the IME needs to investigate whether the claimant has any history of a pre-existing neuro-orthopedic condition, which should not be confused with that possibly or plausibly created by the accident/injury under claim. The post-existing condition also may be possible/plausible. In other words, the claimant may have had some other injury of a neuro-orthopedic nature after the date of the injury under claim. Therefore, the IME needs to carefully investigate these two possibilities in order to rule out the "purity" of the probable permanent injury as related to the claimed injury factor. At times, the IME has to deal with a multiple causation and is asked to apportion the final impairment(s) to each one of the injury dates.

Therefore, the causation factor is very relevant in the impairment granting process of the neuro-orthopedic systems.

Maximum Medical Improvement (MMI)

By definition, this is the factor that allows or rules out the granting of permanent percentage of impairment. There are two types of MMI. The first type refers to an irreversible situation, such as an amputation. The second one refers to a medically or surgically rehabilitative state that was rather constant within the 6 months prior to the evaluation and may be considered rather constant and unchanging within the foreseeable 24 months without major medical/ surgical discoveries. For instance, rehabilitation may improve muscle strength, which can be measured objectively with dynamometry. If it can be demonstrated that the structural damage and the subsequent physical rehabilitation rendered a muscle strength only at 50% of the original or normal for that individual for at least 6 months prior to the evaluation, barring unforeseen medical discoveries, the IME may decide that there is no foreseeable change in the forthcoming 24 months and the loss of muscle strength is permanent at 50% of the original. In this case, the MMI can be granted under those conditions.

Permanency of Injury/Pathology

As described in the paragraph above on MMI, no impairment percentage can be granted if the injury or pathology is not of a permanent nature and has not attained MMI. In other words, an injury, no matter how severe, may not be granted the status of permanency if it is considered to be temporary. For instance, an acute brain concussion, no matter how severe, cannot be granted the status of permanency. The injured party needs to be evaluated in terms of permanency after at least 6 months of treatment. The stability of the post-concussion symptoms, if present, needs to be assessed. Only when those symptoms have been present in a stable form for at least 6 months and foreseeably the forthcoming 24 months could a permanent percentage of impairment be granted.

Granting of Permanent Percentage of Impairment

The granting of the whole person permanent percentage of impairment (%WPP) is a process of clinical evaluation and diagnostic objective investigation that can be done by an experienced IME. The granting takes into consideration the presence of MMI and permanency of impairment.

A number of considerations apply:

In the case of an injury to a limb, if the %WPP is only one, i.e., dependent on only one injury to one tissue or system, the value will have to be transformed from a partial limb value to a whole person value. In the case of injury to the axial skeleton, the percentage values given in the *AMA Guides* or similar texts are already in the whole person format.

When granting a %WPP to a person who already had another permanent injury and percentage of impairment, the new impairment percentage

has to be calculated from the vantage point of (100% – previous percentage value). In other words, the primary assumption behind granting percentages of impairment is that the whole person without any permanent injury is considered 100%. Once a permanent percentage of injury is granted, the whole person is no longer 100% but less than that. If the amputation of the right index finger discussed above pre-exists a new amputation, the original value is 11% WPP. The new WPP% has to be calculated from the equation (100 –11 = 89%). Therefore, should the new amputation have an equal value of 11% from the original 100%, it would only be validated at 10% because it is calculated now as 11/89%. Of course, a new %WPP would have to be calculated from (100 – 11 –10 = 79%) because the whole-person concept prevails only within 79% that is not permanently damaged in this condition.

The granting of several partial percentages of permanent impairment may be needed in many medical evaluations. If the IME uses the *AMA Guides*, the percentages are to be found in the appropriate sections and the final granting value has to be done in accordance with the mathematical results of the combined values chart.

A further complication occurs in areas that are stipulated as "may be added" or "need to be combined." Herein lies the experience and ongoing education of the IME.

Issues of Symptom Magnification and/or Malingering

Symptom magnification and/ or malingering are prevailing questions in the minds of defense attorneys or defense insurance. They prevail in any system but especially in the neuro-orthopedic systems because of the prevalence of permanent injuries within their realm.

By definition, malingering is a rather unique situation whereby the claimant presents with a number of symptoms stated to be the result of a given injury. When one investigates the causation, one finds there was no such injury event or the claimant was not physically present at the location of an injury. The IME needs to be very careful to rule out somatoform disorders from malingering. In the first case, the claimant may have psychiatric symptoms and, within that realm, truly believes that he/she was injured. An example of this may be a person who watches the news on TV and sees a train accident with several hundred people injured. Believing that he/she was present at the site of the accident and was injured, the person may present to the emergency section of a hospital and give details of symptoms compatible with concussion, etc. The accident may have occurred in Seattle and the somatoform patient may be in New York.

The somatoform condition of actual belief of being injured at the site of the accident may become reality until medical and other investigations determine that there is no causation to the symptoms but they are the offspring of a psychiatric disorder.

True malingering is the situation whereby a person with a clear secondary agenda, most usually monetary or other gain, invents an accident and presents with very well-defined symptoms, asking eventually for a permanent percentage of impairment and disability rights. A good investigation finds out there was no causation. Furthermore, photographic or other documentation prove that the claimant does not have the symptoms/signs of neuro-orthopedic suffering that would allow any believability. For instance, one may see pictures of the sufferer using a walker in the physician's office and playing baseball in a park with friends. In a number of instances, the IME may request a psychiatric evaluation. However, barring the findings of somatoform disorders, the IME may discover true malingering. Within the evaluative process, the IME is alerted to any degree of symptom magnification/malingering/somatoform presentation because the performance of a number of objective tests of neuro-orthopedic evaluation is done in an inconsistent manner. Furthermore, the inconsistency is the trademark of any one or all of these tests.

RATINGS OF PERMANENT PERCENTAGE OF IMPAIRMENT

Temporary vs. Permanent Impairment/Disability

The definition of temporary vs. permanent neuro-orthopedic impairment has been given above. In terms of the disability concept, it may be relevant to note that the disability grantors need a wider basis of information in their calculation, above and beyond that given by the IME-derived % WPP. That calculation presumes the attainment MMI status of and permanency of structural or functional impairment as defined above. Pain is usually a relevant factor, associated with suffering and described only fractionally in the *AMA Guides*. The disability grantor has to consider pain and suffering, most usually in addition to the % WPP. The monetary award considered by the disability grantors has to take into account not only the parameters described above, but also future costs related to the the neuro-orthopedic impairments. Vocational retraining may be one consideration of disability granting. A retrained individual would by definition be far less dependent on society, family, or employer.

Permanency of Anatomic (Neuro-Ostheopathic) Pathology

The permanency of pathology beyond the foreseeable 24 months past the evaluation period is the *sine qua non* of

impairment granting. The IME needs to be careful to report that if medical progress is made within 24 months and what appears to be a permanent impairment reduced or annulled related to new medical discoveries/treatments, the percentage granted may not apply under such new circumstances.

Permanency of Functional Neuro-Orthopedic Pathology

The principle of application of new medical treatment with regard to functional neuro-orthopedic pathology applies as above. However, the functional pathology of these two systems is usually of such amplitude that it is relevant to consider increasing the overall percentage value conservatively described in the *AMA Guides*. Part of this consideration is related to the subject of chronic pain as discussed in the *Guides*. The main premise is that of dysfunctional, depression-related chronic pain. In reality, the *Guides* need to consider more the corollary relationship between pain of neuro-orthopedic origin and difficulty with accomplishing activities of daily living (ADLs) as well as vocation-related activities.

Permanency of Effects on the Ability to Perform ADLs

Impairment of the neuro-orthopedic systems may affect most ADLs as described in any text. This holds true for the neurologic system including CNS activities involved in mentation, sensory and motor function, as well as ANS activities involved in emotion and autonomic functions. The osteopathic system is, of course, involved directly in any motion activity. This includes standing, sitting, walking, squating, reaching, bending, twisting, leaning, and hand functions. The functional pathologies of both systems affect self-care, communication, travel, sexual functions, sleep, and social and recreational activities. Again, chronic pain related to either system pathology may be an underlying reality in the overall ADL accomplishment dysfunction.

Neuro-Orthopedic-Related Vocational Considerations

1. Ability to perform the main task of a given vocation
2. The concept of reasonable accommodations
3. The concept of undue hardship

The neuro-orthopedic systems contribute to all vocational tasks. The Americans with Disabilities Act stipulates the definitions of "the main task" of a given vocation as compared to secondary tasks. It also defines the concepts of "reasonable accommodations" and "undue hardship".

Within the context of the neuro-orthopedic systems, the individual needs to be rehabilitated in order to perform mentally or physically demanding acts required at a professional level within the work environment. Thus, a person with sequalae of motor dysfunction may be able to return to work to do tasks of a sedentary nature or light duty activities. It also is possible to enact reasonable accommodations, such as new equipment that does the actual heavy task while the injured person works on it by controlling buttons, etc. The actual heavy task is still accomplished by the person with permanent neurologic disability; however, it is done so with the help of additional equipment.

Permanent orthopedic impairment may result in the need for prosthetic equipment. Many times, the working environment can be modified to allow for the use of prostheses enabling walking at a slower speed, etc. Thus, the possibility of reasonable accommodations for orthopedic disability may return many people injured in the course of their vocation to work, even if a modified environment is necessary.

Work reality may be such that it is not possible to accommodate for disability. When that is demonstrated by the principle of undue hardship, the ADA parameter of reasonable accommodations may not apply. An example is a work environment where a worker may need to walk up and down one to two flights of stairs several times every hour every day. If the structure of the building and the stairs is such that electric stairways or an elevator cannot be installed or that the cost of such installation could not be a reasonably supported or affordable business expense, it would be considered an undue hardship.

In that case, the neuro-orthopedic pathology would be considered as incompatible with the working environment. New vocational training may be offered to the disabled individual for other types of vocation or opportunity.

The Neuro-Orthopedic Systems and Insurance Issues

There are several work-related insurance categories. A partial list includes the social security system, workers compensation systems, federal or state insurances, and finally, private insurance companies with policies related to disability.

Each of the entities mentioned above is regulated by a variety of rules and regulations.

In general, though, they consider remuneration for disability either under an all or none or as a partial system. Furthermore, what may be the rule for one level of insurance, may be the exception or exclusion for another.

In terms of the neuro-orthopedic systems, it is very important for the IME to consider the final impairment

conclusions within the legal and regulations framework of the claim.

A careful consideration may help both the needs of the injured claimant and those of the insurance entity, which only considers the claim in light of contractual obligations and the legal requirements.

STEPS OF THE NEURO-ORTHOPEDIC SYSTEMS EVALUATION

Medical History

1. The medical history needs to be focused on the injury under claim. However, the IME must inquire about and report any other relevant histories. These include prior work-related neuro-orthopedic or other injuries, prior non-work conditions, as well as any other current injuries or diseases.
2. General medical history with special relevance to pre-existing conditions and especially conditions related to the neuro-orthopedic systems must be taken. The general medical history allows the IME to place any neuro-orthopedic system injury/ pathology within the framework of the overall body function. It is very relevant to take an accurate medical history, which can be done effectively and reliably with the use of a comprehensive general health questionnaire. Of special relevance is any prior or concurrent history of pathology affecting the neuro-orthopedic systems. Pre-existing conditions are a relevant factor in terms of the intensity and/or frequency of the symptoms and/or signs presented within the context of the neuro-orthopedic systems pathology under claim.
3. Focus on the causation vs. association with symptoms. The topic of causation has been described above. The IME needs to take a good history of the injury- or disease-causing event in order to rule out any association or lack of association of such event with the neuro-orthopedic presentation under claim. It is more likely than not that a severe fracture of the back, witnessed and well documented, may produce chronic low back pain. It is not likely that the advent of a pneumonia within 2 months of the actual injury would contribute such pain. Just because pathology occurs it does not mean that it is causal or associated with a presentation for permanent impairment evaluation in front of the IME.
4. There should be compatibility and consistency of the medical history with the course of treatment and current symptomatic presentation. Whereas the causation is the primary event in the course of a neuro-orthopedic pathology, the diagnostic follow-up and rehabilitation treatment are the most relevant subsequent events. One should not wonder why a neuro-orthopedic dysfunction does not heal in time if not treated. This currently is affecting the diagnosing of myofascial pain syndrome months or years after the injurious event. The claimant may suffer from classic trigger-point related pains and dysfunctions and yet the insurance authorities question why the person is not healed. Can one heal necessarily without adequate diagnostic recognition and treatment?

Therefore, the IME needs to follow closely the chronologic course of the diagnostic work-up and treatment. If there was failure in either of them, the claimant may suffer from pathology related to that failure to a relative extent. At times, because of this, the IME may not be able to grant MMI or permanent percentage at the time of the evaluation and may need to suggest appropriate diagnostic and treatment follow-up for a period of 6 to 12 months before a new and final evaluation.

Examinee's Perception of the Neuro-Orthopedic Condition under Claim

It is relevant for the IME to investigate the examinee's perception of the condition and, related to this, the motivation for further improvement. At times, people may be influenced by the medical authorities in an iatrogenic sense and believe that their overall condition is far worse than it actually is. This perception needs to be investigated or ruled out by the IME.

Self-Perceived Functional Limitations

The IME needs to provide a questionnaire including all regular ADLs. Of special relevance are the ADLs related to the neuro-orthopedic systems, such as described above. The ability to fulfill such ADLs on a regular basis is highly relevant in determining the %WPP by the IME and especially the extent of disability by the administrative/legal bodies that grant such disability and monetary and other awards.

Perceived Pain/Discomfort

Pain is possibly the single most relevant factor in determining the ability and will to fulfil ADLs as well as vocational activities. The intensity and frequency of the neuro-orthopedic-related pain must be investigated by the IME. A more complete discussion of this subject is

found in Chapter 84 of this text. Suffice it to say that the IME needs to use a "pain grid" which compares and correlates the neuro-orthopedic pain with the ability to function in terms of accomplishment of ADLs.

Perceived Effect on Ability to Achieve/Accomplish the Normal ADLs

The IME may ask about this subject as described above. It may be of relevance to utilize/ask for a functional capacities examination, usually performed by specialized physical therapists. It is not possible most of the time to assess in a consistent manner the perceived and actual abilities of a claimant to perform ADLs in the office. Therefore, the claimant's history, examiner's observations and, when necessary, the functional capacity exam may confirm the extent of the perceived vs. actual ability to perform ADLs.

Self-Perceived Emotional Status and Stress Level

A number of neuro-psychological tests may fit a variety of neuro-orthopedic systems pathologies. The tests may work in terms of ruling out perception of stress and negative emotions (anxiety/depression) vs. actual test scores. More often than not, the IME may need to rely on a neuropsychologist or psychiatrist to assess the emotional component related to post-traumatic conditions of the neuro-orthopedic systems. It is important to note that this may grant further permanent percentage of impairment in cases documented to warrant such additional percentage by psychiatrists or neuropsychologists.

Review of Systems

A comprehensive review of systems allows the IME to place the neuro-orthopedic pathology within the overall systematic review. In addition to the general review, one may utilize more specialized questionnaires to rule out the extent of the neuro-orthopedic dysfunction in terms of the claimant's overall pathology.

Assessment of Current Neuro-Orthopedic Clinical Pathology and Status

The IME needs to perform a comprehensive physical examination. If the IME is a specialist who no longer performs such a comprehensive examination, one should state that and refer the claimant to an IME who can do it.

Above and beyond the comprehensive examination, the IME needs to perform a very detailed neurologic and/or orthopedic evaluation such as required by the pathology under claim. In addition to the physical examination, one usually must perform a number of appropriate objective tests.

More often than not, the IME would have available at the time of the examination previous evaluations or investigations done by the treating physicians and/or by prior IMEs. It is very important for the IME to note if there are chronologic symptomatic/signs changes in the claimant's presentation and especially if such changes became stable within the 6-month period prior to the evaluation. This allows for the granting of MMI to all or part of the presentation.

There are times, however, when the IME notices significant discrepancies between the symptomatic presentation, including chronology between one or more previous examinations. The same may apply to the results obtained at different times on objective tests, which creates questions of further pathology unrelated to the event under claim or symptom magnification, malingering, or functional overlay. These issues need to be resolved in terms of clear notification in the examination report.

One of the most relevant factors for the IME to present in the report is consistency of presentation of neuro-orthopedic symptoms/signs within the chronological framework. The question of consistency is the "most consistent question" asked by the opposing counsel or insurance authorities. It is fraudulent for a person to fake symptoms and gain monetarily and otherwise from it. Therefore, the IME needs to rule out this factor not only in the previous exams but also through the objective testing done from the day of injury to the day of the present evaluation.

The neuro-orthopedic physical examination should include the following.

- A number of body expressions related to pain or other emotions needed to be observed during the examination. Was any body expression found frequently?
- Did the examinee exhibit any behavioral signs of pain or other suffering?
- Testing for behavioral consistency vs. symptoms magnification. The Waddell signs were not originally meant to define symptom magnification but can be used within this context when necessary. Did the eight Waddell signs show any overt inconsistency, compatible with the definition of symptom magnification?
- Hoover test. Was the normal response of straight leg raising in the supine position observed?
- Trochanter pressure test. Was there any low back pain while pressing inward on both greater trochanters?
- Were the reflexes normal or abnormal? Name the abnormal reflexes. (See Table 44.2.)
- The Babinski reflex is an abnormal reflex. Was the Babinski negative bilaterally?
- Posture and gait are assessed with the Romberg and Tandem walk (eyes opened and closed) tests.
- Were the Romberg and Tandem walks positive and nondirectional, positive, or negative?

TABLE 44.2
Deep Tendon Reflexes (DTR)

DTR ×3	Brachialis	Radialis	Tricipital	Patellar	Achilles
Right					
Left					

Toe walking, heel walking, everted and inverted foot walking, and squatting represent the testing for L4-L5 roots. Were toe walking, heel walking, everted and inverted foot walking on either foot, squatting, standing from a squatting position, and hopping normal and not antalgic?

Cranial nerves. Nerves I through XII have to be tested bilaterally for the motor and sensory (where applicable) components.

CN I: Olfactory. Does the examinee present with an intact sense of smell for coffee, vinegar, musk, and lemon juice?

CN II: Optic. Does the examinee present with intact vision in both eyes (20/20) without correction? Does the examinee need correction on either eye? What are the Snellen testing results with/without correction? Does the examinee present with intact color vision for green and red, yellow and blue? Does the examinee present with photophobia or blurriness of vision during the examination?

CN III, IV, and VI: Oculomotor (Motor and Parasympathetic), Trochlear, Abducens. Does the examinee present with normal extra-ocular muscle motion with no lateralization, normal ciliary and iris sphincter muscles?

CN V: Trigeminal Motor. Does the examinee present with normal masticatory ability? Sensory. Does the examinee present with normal tactile sensation to the facial skin and trigeminal mucosa of the nose and mouth?

CN VII: Facial, Motor/Parasympathetic. Does the examinee present with normal facial expression, with no asymmetry or lateralization, normal lacrimation and mucous membranes of the mouth and nose, and normal sublingual and submandibular salivation? Sensory. Does the examinee present with normal tactile sensation to the external ear and auditory canal? Does the examinee present with normal taste sensation to the anterior two thirds of the tongue?

CN VIII: Vestibulo-Cochlear, Vestibular N. Does the examinee present with normal equilibrium on Rhomberg and Tandem walks with the eyes opened and closed? Cochlear N. Does the examinee present with normal hearing ability regarding the spoken voice? Does the examinee present with hypoacusia with regard to the spoken voice?

CN IX: Glossopharyngeal Motor. Does the examinee present with normal pharyngeal function, with no asymmetry or lateralization? Parasympathetic. Does the examinee present with normal parotid gland salivation, with no asymmetry or lateralization? Sensory. Does the examinee present with normal tactile and taste sensation to the posterior one third of the tongue?

CN X: Vagus Motor. Does the examinee present with normal pharyngeal and laryngeal function, with no asymmetry or lateralization? Sensory. Does the examinee present with normal tactile sensation to the auditory canal?

CN XI: Accessory. Does the examinee present with normal laryngeal function, with no asymmetry or lateralization? Does the examinee present with normal sternocleidomastoid and trapezius functions, with no asymmetry or lateralization of shoulder shrugging?

CN XII: Hypoglossal. Does the examinee present with normal tongue movements, with no asymmetry or lateralization?

Testing of the brachial plexus and the lumbosacral plexus. The testing needs to be done for each salient nerve which represents more than one particular root while being aware that there is no nerve that comes from only one root.

Was there any brachial plexus root or trunk abnormality?

Was there any brachial plexus nerve motor or sensory abnormality?

Was there any lumbosacral plexus abnormality?

Was there any lumbosacral nerve motor or sensory abnormality?

Cerebellar Function. The finger-to-nose-to-hammer test denotes normal or abnormal cerebellar function. What was the examinee "finger-to-nose-to-hammer" response? Does the examinee

present with normal sensation to light touch, pinwheel, heat, cold, vibration, proprioception, topognosis, and stereognosis as well as pain with no asymmetry or lateralization on head and neck, trunk and limbs? Is there any evidence of focused anesthesia, hypoesthesia, hyperesthesia, or dysesthesia?

Normal range of two-point discrimination on different parts of the body. Does the examinee show any two-point discrimination loss?

Joint position and vibratory loss denote probable compression of peripheral nerves or nerve roots. Was there any joint position or vibratory loss found?

Vibration. Vibratory sense to a tuning fork #256 should be normal bilaterally on the forehead, elbows, wrists, knees, ankles, and first toe. Was the vibratory sense normal?

Positional sense. A normal position sense is tested on the ability to perceive passive extension and flexion on the big toe bilaterally. Did the examinee present with normal, equivocal, or abnormal extension and flexion recognition on the big toe bilaterally?

Speech. Did the examinee present with expressive aphasia or speech impairment? Could the speech be understood and sustained within normal limits? Did the examinee have a good vocabulary and command of language?

Autonomic Nervous System. Vasomotor changes. Did the examinee present with any vasomotor changes such as abnormal skin temperature and edema?

Sweat changes. Did the examinee present with any area of hypohydrosis, anhydrosis, or hyperhydrosis?

Trophic changes. Did the examinee present with abnormality of the skin such as indentations, lack of elasticity, unusual smoothness or shine? Did the finger nails present clubbing, transverse stripes, brittleness, or increased thickness? Did the skin present alopecia or hypertrichosis?

This chapter does not discuss traumatic brain injury affecting any component of the brain.

Mentation. The mental status examination may be simple or complex according to the physical needs and symptomatic presentation of any changes of mentation. A summary of the commonly utilized parameters of the mental status exam is given below.

a. Orientation. Did the examinee present with any orientation problems with regard to time, space, and person?
b. Memory. Did the examinee present with any recent or remote memory loss events?
c. Ability to concentrate. Did the examinee present with any inability to concentrate and maintain attention?
d. Ability to communicate. Did the examinee present with any problems of communication with the examiner and assistant?
e. Appearance. Did the examinee appear anxious or distressed about the evaluation?
f. Restriction of activities of daily living. The examinee needs to be questioned on the subject with relation to the ADLs described below. There may be need to investigate further with regard to other ADLs as necessary.
   i. Self-care and personal hygiene. Is there any deficiency in the ability to fulfill the ADLs related to self-care, dressing/undressing, and personal hygiene?
   ii. Communication. Is there any deficiency in the ability to fulfill the ADLs related to verbal or written communication? Is there any deficiency in the ability to fulfill the ADLs related to the ability to use a telephone or a computer for communication?
   iii. Normal living postures. Is there any deficiency in the ability to fulfill the ADLs related to normal living postures including recumbency, sitting, reclining, standing, bending, twisting, pushing, pulling, lifting, and carrying?
   iv. Ambulation. Is there any deficiency in the ability to fulfill the ADLs related to walking including climbing and descending stairs?
   v. Travel. Is there any deficiency in the ability to fulfill the ADLs related to travel including driving or getting into and out a public transportation vehicle?
   vi. Sexual functions. Is there any deficiency in the ability to fulfill the ADLs related to sexual functions?
   vii. Sleep. Is there any deficiency in the ability to fulfill the ADLs related to falling asleep, staying asleep, or waking up? Is there any history of sleep apnea or narcolepsy?
   viii. Social and recreational activities. Is there any deficiency in the ability to fulfill the ADLs related to social and recreational activities on an individual or family basis?

Is intellectual functioning at the estimated level compatible with the examinee's education level and age?

Personalfinancial affairs. Are there grounds to believe that the examinee cannot manage personalfinancial affairs?

Zung testing for anxiety is a useful test. If done, does it reveal a normal score or one that indicates minimal to moderate anxiety/moderate to high anxiety?

Musculo-skeletal testing (Table 44.3).

a. Body type. Is the examinee of ectomorphic, mesomorphic, endomorphic, or mixed body type? Is the body well proportioned?

b. Gait. Does the examinee present with an abnormal gait for body size, age, and sex? Are there any complaints of lower back and limb antalgia?

c. Two scales, double weighing. Double scale weighing is a methodology for identifying and ruling out unilateral postural defects. It is especially useful in lower limb pain/dysfunction as well as in low back and hip pain/dysfunction. The method can also be used to rule out symptom magnification in presentations of these body sections. The examinee is weighed four times on identical scales in order to determine any significant inequality of weight placement. The results are indicated in Table 44.4. The results indicate that the examinee places % of his weight on the left foot and % of his weight on the right foot. Is there a significant trend in unilateral weight placement, i.e., > 10% placement on one foot vs. the other?

TABLE 44.4
Double Weighing Method for Static Gait

Scale (lbs)	Weight Trial I	Weight Trial II	Weight Trial III	Weight Trial IV	Average
Right Foot					
Left Foot					

i. Antalgia. Does the examinee exhibit an antalgic gait characterized by a short stance phase on the painful side? If the gait is not antalgic, does it exhibit a stance phase approx. 60% of the time and a swing phase approx. 40% of the time?

ii. Lower extremities size. Are the lower limbs equal and proportional to the body size? (See Table 44.5.)

iii. Short leg gait. Is one lower limb shorter than the other by > 2 cm? Does the gait

TABLE 44.5

show signs of oblique pelvic and flexion deformity on either knee?

iv. Coxalgia. Does the examinee complain of, or exhibit, any pain or abnormal stance related to the coccyx?

v. Coxalgic gait. Does the examinee exhibit an antalgic gait with a lurch toward the painful hip?

vi. Metatarsalgia. Does the examinee complain of, or exhibit, any pain or abnormal stance related to the forefeet?

vii. Metatarsalgic gait. Does the examinee attempt to avoid bearing weight on the painful forefoot?

Standing position

a. Posture. Does postural examination show that the examinee presents with cervical lordosis, scoliosis, dorsal kyphosis, or lumbar lordosis? Are the posterior superior iliac spines proportional? Is the back excursion normal with mild laxity of the sacrum?

b. Alignment of the lower extremities. Does the examinee present with any alignment deformities of the lower limbs? Which alignment deformities are observed for flexion deformity of knees, genu varum, genu valgum?

c. Ankles and feet position. Does the examinee present with any alignment deformities of the feet? Does the position of ankles and feet show varus/valgus, heels, atfl feet, inversion/eversion of the feet?

d. Back motion. Does the examinee present with normal back motion for body size, age, and sex? Is there any complaint of pain or ankylosis on the motions of flexion, extension, and lateral rotation? (See Table 44.6.)

TABLE 44.6
Back Length Standing and Flexed

Back (cm)	Level	Normal	Examinee
Straight			
Flexed	C7–S5		
Maximal	C7–T12	2.5	
Flexion	T12–S5	7.5	

Note: Normal extension is approx. 10 cm with spine flexion.

e. Range of motion of back. Does the examinee present with a normal range of motion of the back for body size, age, and sex? The lumbosacral column ROM examination needs to be done with inclinometry, as per protocol.

Seated position

a. Head and neck motion. Does the examinee present with a normal range of motion of the neck for body size, age, and sex? Are the head and neck motions restricted in flexion, extension, lateral bend to the right, left, rotation to the right or left, or restricted by ankylosis? The cervical column examination done with inclinometry is presented below.

b. Motion of the thoracolumbar spine. Is the thoraco-lumbar spine motion with the pelvis fixed observed to be within normal limits? Does the motion of the thoraco-lumbar spine in the seated position with the pelvis fixed show rounding, straightening of the back, lateral flexion or rotation abnormalities?

c. Temporomandibular joints. Does palpation and examination of the lower jaw motion show a normal aperture with the mouth fully open? Is there any crepitus or asymmetry of mouth aperture?

Upper extremities

a. Shoulders. Does the examinee present with a normal contour and range of motion of the shoulders for the body size, age, and sex?

b. Contour. Does the examinee present with a normal contour of both shoulders and no asymmetry? Is there any deltoid atrophy on either side? Is there any tissue swelling? (See Table 44.5.)

c. Range of motion. The shoulder ROM examination needs to be done with inclinometry, as per protocol.

d. Glenohumeral joint motion. Is there restriction of the glenohumeral joint motion on either shoulder? Is there ankylosis of either glenohumeral joint?

e. Elbows. Does the examinee present with a normal contour and range of motion of the elbows for the body size, age, and sex?
f. Inspection. Do the elbows appear equal and normal on inspection? Does either elbow appear swollen or ankylosed?
g. Palpation. Is there any olecranon bursitis or synovitis noted on palpation of either elbow? Are there any subcutaneous nodules and tophi noted in the olecranon bursa or over the extensor surfaces of the elbows?
h. Range of motion. The elbow ROM examination needs to be done with inclinometry, as per protocol.

Wrists and hands. Does the examinee present with a normal contour and range of motion of the wrists and hands for the body size, age, and sex? (See Table 44.5.)

a. Inspection. Does inspection of the wrists and handsfind any deformities or edema? Does inspection and palpation of the wrist find any deformities of the metacarpal phalangeal (MCP), proximal interphalangeal (PIP), and the distal interphalangeal (DIP) joints of the fingers and carpometacarpal (CMC), MCP and interphalangeal (IP) joints of thumbs? Were there any deformities such as boutonniere, swan neck, or radial or ulnar deviation noted on either wrist?
b. Soft tissue swelling. Did the dorsum of either wrist distal to the ulna and over the radiocarpal joint show any soft tissue swelling? Was any soft tissue swelling (volar synovitis) noted on the palmar surface? Was thenar atrophy noted on either palmar area?
c. Finger joints. Did inspection and palpation of the finger joints reveal soft tissue swelling, capsular thickening, or bony enlargement?
d. Fists. By definition a fist is described as 100% when all fingers reach the palm and the thumb reaches and closes over the fingers. Was the examinee able to form both fists at 100%?
e. Range of motion. The range of motion of the wrist, hand and fingers has to be done with goniometry, as per protocol.
f. Grip. Gripometer testing. Is the examinee left/right hand dominant? Was the ability to grasp and manipulate with each hand within normal limits? The strengths of the grip and pinch are assessed in Table 44.7 using the highest of three readings.
g. Pronation and supination. Both are considered as combined functions of the elbow and wrists. Did the examinee show normal pronation and supination?
h. Neck and chest inspection. Does the examinee present with a normal contour of the neck and chest for body size, age, and sex? Were the sternoclavicular joints noted to be equal and symmetrical? The measurements of the chest expansion are described in Table 44.8. By definition, normal expansion at the nipple line is above 4 cm in deep inspiration.

Prone and supine positions

a. Knees alignment. Was the alignment compared to that noted on weight bearing different or abnormal?
b. Back. Did inspection and palpation of the back reveal normal paraspinal musculature with the dorsal spines not visible from the cervical to the sacral area? Was kyphosis, scoliosis, or abnormal lumbar lordosis noted? Were there any sudomotor changes in the affected area?
c. Traction maneuvers. Does any straight leg raising maneuver show any symptoms? (See Table 44.9.)

d. The Gaenslen maneuver. This maneuver detects sacroiliac (SI) joint inflammation. Did the examinee have any pain in the SI joint ipsilateral to the extended hip? Was SI joint inflammation diagnosed with this maneuver?

Hips. Does the examinee present with a normal contour and range of motion of the hips for body size, age, and sex? Does internal and external rotation of the hip joint in extension have a normal range of motion? Do abduction and adduction of the hips in extension have a normal range of motion? Does flexion of the hips have a normal range of motion when the knees are flexed and the hips are carried toward the chest? Is extension of the hips normal (–30°) with the examinee in prone position? The hip ROM examination needs to be done with inclinometry, as per protocol.

Leg lengths measurements. Are the leg lengths as measured from the umbilicus to the medial malleolus found to be equal? Are any joint contractures are present?

Knees. Does the examinee present with a normal contour and range of motion of the knees for body size, age, and sex? Are the patellar position and mobility found to be normal on inspection and palpation bilaterally? Could soft tissue swelling be observed on bimanual evaluation? Was a patellar click sign indicative of intra-articular fluid demonstrated on either knee? Was a bulge sign indicative of a small amount of effusion demonstrated on either knee? Is the popliteal area normal? Is a synovial cyst present on sitting or standing? Is the knee stability demonstrated to be normal bilaterally on stressing the medial and lateral collateral ligament? Is the anteroposterior stability of both knees assessed to be intact by the maneuver of the drawer sign? The knee ROM examination needs to be done with inclinometry, as per protocol.

a. Maneuvers for medial and lateral meniscus testing. Did the testing show negative findings bilaterally of the medial/lateral meniscus tear clinically on either knee?

Ankles and feet. Does the examinee present with a normal contour and range of motion of the ankles and feet for body size, age, and sex? Is there any synovial soft tissue swelling noted on either ankle? Was subtalar motion, which assesses inversion and eversion of the foot, found to be 100% normal? The ankle ROM examination needs to be done with inclinometry, as per protocol.

Toes. Did inspection and palpation of the toes note any deformities of alignment or soft tissue swelling? Were any of the following toe deformities noted: hammer toes, claw toes, hallux valgus?

Joints. Did inspection and palpation of all joints demonstrate any abnormality at rest or in motion? Did inspection and palpation of all joints at rest or in motion show any swelling, tenderness, temperature and color changes over any joint with or without crepitation and deformity? Was any joint tenderness noted? Are warmth and erythema over any joint noted? Is stress pain produced on any joint at any degree of motion from extension? Is crepitation of any joint palpable and audible at rest and in motion? Is any deformity of any joint noted? Is it assessed to be caused by bony enlargement/subluxation/and ankylosis in a normal or abnormal position? Extra-articular, fibromyalgia, and myofascial testing are not discussed in this chapter.

Manual muscle testing. Neck, back, and limbs muscle testing is done actively. It is suggested that passive movements testing should be done only with the expressed permission of the evaluee. The testing is classically scored on a 0-to-5 scale with 5 showing good strength and 0 showing no ability whatsoever to resist any motion.

OBJECTIVE TESTING

Objective testing of the neuro-orthopedic systems may be done with a variety of equipment either during the evaluation and/or referred outside the office. Whatever methodology is utilized, it has to follow statistical protocol rules whereby the test in question is repeated at least five times with resting intervals in order to allow the computation of appropriate averages, standard deviations, and coefficients of variation.

Any methodology needs to be done in a standardized manner so that the IME can compare the results done in previous testing proceed with the same protocol if any testing is done during the evaluation. Many times IMEs are asked to compare apples and oranges. This may be the case especially with range of motion measurements.

In terms of disability evaluations, the usual neurologic system objective tests are the following (but are not exclusive): MRI; CT scan; X-rays; ultrasound; and electrophysiological tests such as nerve conduction, current perception threshold, needle EMG, surface EMG, somato-sensory evoked potentials, EEG, PET scanning, SPECT scanning, vibration testing, and autonomic nervous modalities testing (electrodermal response, CPT, PTM, and TCM).

In terms of disability evaluations, the usual orthopedic system objective tests are MRI, CT scan, X-rays, ultrasound, goniometry (inclinometry), and dynamometry.

Considerations of Treatment from the Time of Injury

The IME needs to study carefully the chronology of investigation and treatment of the injuries of the neuro-orthopedic systems under claim from the time of injury to the time of the evaluation, including giving advice for further appropriateness of treatment.

The IME needs to summarize the positive and negative aspects of the treatment in the terms of chronology appropriateness, fitness to the symptoms, frequency, intensity.

The aim of neuro-orthopedic rehabilitation treatment is to reduce and, if possible, get rid of any symptoms/signs of pathology related to the injury under claim. The evaluee must make a statement regarding the overall reduction of symptoms as perceived by him or herself. The IME needs to take that statement into consideration and compare it with the notes of the various treatments. A conclusion regarding the fit between the clinical file and the evaluee's perception should be part of the report.

Whether the evaluee has achieved the status of MMI and a %WPP is granted, the question of the need for future treatment remains. If there is such a need, the IME is usually asked to provide a plan for short- and long-term neuro-orthopedic rehabilitation.

Diagnosis(ses)

The IME needs to report on the diagnosis(ses) pertinent to the injury/pathology under claim found at the time of the examination. Should the diagnosis not fit the previous one(s), the IME has to give an explanation. The explanation may allow the disability grantors to understand if the original diagnosis may have changed over time because of the treatment or lack of it.

The IME must describe any concurrent pathologies unrelated to the claim there are and explain if any structural or functional associations with the neuro-orthopedic diagnoses under claim.

Prognosis

The IME needs to describe the clinical prognosis pertinent to the injury/pathology under claim for the foreseeable 24 months in terms such as good, conservative, poor, or very poor. This needs to be done in relation to the granting of the MMI and the %WPP.

The IME may need to write a statement if a concurrent unrelated pathology may change or affect the prognosis of the condition under claim.

Conclusions and Recommendations

The IME may be asked to provide advice on future treatment or consultation. Unless clearly stated, it should not be assumed that the IME is the treating physician for the condition under claim.

Vocational rehabilitation is the desired goal in most neuro-orthopedic injuries. The IME may suggest a future need for physical or vocational rehabilitation with the goal of returning the injured party back to work with the original vocation or a new one.

Ergonomics for the Pain Practitioner

Hal S. Blatman, M.D.

INTRODUCTION

Ergonomics comes from the Greek ergos, meaning work, and nomos, meaning laws. It has become a "buzzword" that describes a variety of conditions and objects from specific tasks in the work environment to tool design and seating. The term ergonomics and the term human factors are sometimes used interchangeably. Most people probably recognize use of the term ergonomics in relation to seating and task analysis. The term also is used in relation to lighting and the psychology of shift work. Practically speaking, ergonomics relates to the interface between people and their environment. In the academic setting, the ergonomist may be found in the biomechanics, engineering, medicine, and psychology departments.

The medical professional treating pain patients often hears about physical activities that cause exacerbation of pain symptoms. These activities may be job related, involving materials handling (lifting and placing objects), awkward or sustained postures, repetitive motion, and keyboard data entry. Sometimes, it is the activities at home or away from the workplace that cause significant problems.

When treating pain patients, an awareness of basic ergonomic principles will serve the practitioner well. With an understanding of these principles, the caregiver can be more effective in helping impaired people function in their environment more effectively and with less discomfort.

SUPPLY AND DEMAND

One important concept to understand is nutrient supply and demand with respect to muscle tissue. When a muscle is resting, the cells require less nutritional support than when it is contracting. A resting muscle is softer and blood flow through the muscle is relatively unobstructed. When muscles contract to perform work, the cells of the muscle require nutrients at a level in proportion to the work that is being performed.

A muscle that is contracting requires more nutrients. When a muscle is alternately contracting and relaxing, blood flow through the muscle is enhanced by a pumping action of the muscle. This pumping helps keep the muscle cells supplied with nutrients at the increased level required for the work being performed.

When a muscle is contracting to maintain a posture or position, this sustained contraction requires even more nutrients than does a muscle alternately contracting and relaxing. With this sustained contraction, blood flow is hampered by increased pressure within the contracting muscle tissue. In this case, the nutrient requirements of the muscle are increased and the blood supply is relatively decreased. This leads to a significant imbalance with respect to nutrient supply and demand. It therefore costs the body more to stay in one position (sustained posture) than it costs to move.

This concept can be simply illustrated by trying to hold one arm straight out in front of the body, keeping it perfectly still. Before long, a feeling of fatigue is noticed, and the arm seems to get very heavy. Later, after a few minutes of rest, hold the arm straight out in front of the body again. This time move the hand and arm in small circles. This slight movement of the arm and shoulder results in some degree of alternate relaxing and contracting of the deltoid and trapezius muscles. Even small motions will facilitate blood flow and nutrient supply. Usually with the arm making small motions, the feeling of fatigue is noticed more slowly, and the length of time this posture/motion can be maintained is significantly

0-8493-0926-3/02/$0.00+$1.50

longer. If nutrient supply and metabolic by-product removal are facilitated by muscular contraction and relaxation, the physical activity can be maintained for a longer period of time and with less fatigue.

The concept of muscle tissue nutrient supply and demand has clinical relevance with pain patients. Many pain patients relate that they do better when they are moving, and that they have problems sitting or standing in one position for any length of time. Sometimes maintaining one position causes stiffness, and sometimes it causes an increase in pain. For many people, even 15 minutes of a sustained posture is considered to be a prolonged period of time. It should be realized that even sitting in a relaxed position might require significant static contraction of supportive and balancing musculature. This relaxation may translate to increased stiffness and pain. Instructing patients with low back pain to slightly wiggle or otherwise move their hips every few minutes while sitting can greatly increase the length of time that seated posture can be maintained. This is likely to be important when sitting at the office as well as when riding in a car.

REPETITIVE MOTION INJURY

Repetitive motion injury (RMI) was previously termed both repetitive strain injury (RSI) and cumulative trauma disorder (CTD). Nationally, the Bureau of Labor Statistics calls these conditions illnesses and not injuries. The Occupational Safety and Health Administration (OSHA), the National Institute of Occupational Safety and Health (NIOSH), and the National Academy of Science have replaced these terms with the more neutral Work-Related Musculo-Skeletal Disorders.

Tissue pathology with respect to repetitive motion injuries is generally believed to primarily involve inflammation. Typical diagnoses that fall into this definition include tennis elbow, shoulder bursitis, tendonitis, and carpal tunnel syndrome. Treatment protocols for these conditions may include splinting, physical therapy modalities, anti-inflammatory medication, cortisone injections, and surgery.

For many people, these treatments are not effective. One reason is that pathology of repetitive strain injury (RSI) is not simply inflammation. Indeed, the primary pathology may be trigger points and myofascial pain. Tennis elbow, for example, is always associated with myofascial trigger points in the muscles that do wrist extension and supination the wrist. Shoulder bursitis is always associated with myofascial trigger points in various shoulder girdle muscles.

Myofascial Trigger Points with Repetitive Strain Injury

It is important to examine pain patients for myofascial trigger points in muscle groups that cause and/or refer pain to the area of complaint. Repetitive motion activities will cause formation of new trigger points, as well as activation of latent trigger points. As myofascial trigger points become more active, they generate more pain.

Sustained posture activities will cause tightening of the active muscles, as well as generalized tightening of the fascia through the muscle tissue. In addition, myofascial trigger points within the muscle will become more active. This increase in trigger point activity will cause an increase in pain, both localized and referred.

Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) is usually suspected when there is numbness and/or tingling in the thumb, index, long finger, and the thumb-side half (radial aspect) of the ring finger. People may also be awakened at night by pain in the wrist and forearm. When symptoms progress, people experience forearm and hand weakness, and even light objects such as coffee cups may be dropped.

The condition is often job or activity related, and people who use their hands a lot may be at risk for developing the problem. CTS has been associated with wrist and hand positioning, repetitive wrist use, use of heavy or vibrating tools, trauma, as well as light work such as typing.

In order to better understand what happens in the body in developing symptoms of CTS, it is helpful to understand the anatomy of the wrist. The carpal tunnel is bordered on the top of the wrist by the wrist bones and on the palm side by thick connective tissue. This thick connective tissue is called the transverse carpal ligament. These bone and ligament borders are thought to be relatively fixed and unchanging. Inside the tunnel created by the ligament and bones are the flexor tendons that curl the fingers, and the nerve (median nerve) that enables one to feel the thumb, index finger, long finger, and half of the ring finger.

Carpal tunnel syndrome has traditionally and mistakenly been thought of as a condition resulting from flexor tendon inflammation or swelling that is caused by repetitive motion of the forearm, wrist, and hand. It is thought that when people use their fingers and bend their wrists a lot, the tendons in the tunnel become inflamed, thereby causing them to swell. Because the borders of the tunnel are fixed and there is no extra room in the tunnel for this swelling, the median nerve gets squished, and some of the fingers go numb.

Moreover, the size of the carpal canal is not constant. The canal is largest when the wrist is in neutral (dorsiflexed 15°) position. It gets smaller when the wrist is bent in any direction. When bent positioning compromises canal size, an already marginal situation can be made worse, and this may induce symptoms of numbness and tingling. To evaluate this, a Phalens test can be performed. To perform a Phalens test, compromise the size of the

carpal tunnel by palmar flexing the wrist approximately 90°. The test is considered to be positive if the radial fingers start to tingle. Usually the positive result is recorded as well as the time (in seconds) required for the numbness to be appreciated. Some examiners prefer the test to be positive within 10 to 20 seconds, while others wait until 60 seconds before calling the test negative.

In accordance with this inflammation model, the treatment for CTS traditionally involves keeping the wrist in a neutral posture and taking anti-inflammatory medication. Wrist braces are often recommended to ensure that the wrist remains straight, especially during work and sleep. To further aid in reducing the theorized inflammation, cortisone may be injected into the canal. When these treatments do not work well enough, surgeons will cut the transverse carpal ligament so the tunnel can expand to make room for the swollen tendons.

Unfortunately, the results from these treatments may be less than satisfactory. When this is the case, people take their medications and struggle in their braces to continue their jobs. Many experience continued weakness, numbness, and pain. When surgery is helpful, the condition will usually worsen or recur when people go back to their same jobs. Work modification is often an important part of returning these people to gainful employment.

Fortunately, there is a very different way to think about CTS. Recent research has demonstrated that the theorized inflammation of the wrist tendons may not occur. Other research has indicated that there are exercises that can be done to treat and prevent CTS and that this treatment may be more successful than the traditionally prescribed medication and surgery.

New Theory

A more modern idea to explain the pathophysiology of carpal tunnel syndrome is that it actually starts in the biceps muscle of the arm, and not in the wrist. People who use their wrists and fingers a lot, steady and support their forearms and hands with a sustained contraction of the biceps muscle. This continuous contraction of the biceps muscle eventually causes tightening of the connective tissue in the arm, called fascia. The biceps muscle crosses the elbow joint and attaches to the radius bone in the forearm. Because the biceps muscle is a part of the forearm, it also pulls on the fascia of the forearm. With time and continued sustained biceps contractions, the fascia in both the arm and forearm tightens. As this process continues, the transverse carpal ligament (fascia) also tightens. When this ligament tightens, the carpal tunnel gets smaller. In other words, CTS is not caused as much by the tendons of the wrist swelling and becoming larger, but rather by the canal itself getting smaller.

This theory provides a mechanism by which to understand why cortisone injections and anti-inflammatory medicines may not be helpful. It also sheds light on why surgery may initially provide relief and upon resumption of activity the symptoms may return. This theory also provides a mechanism to help understand why various stretching techniques have been effective in the treatment of carpal tunnel syndrome.

TOOLS

Tool design is an important consideration when a job or task needs to be made more "body friendly." There are catalogs of ergonomic tools for many different jobs and functions. In examining the use of tools and considering their modification, basic ergonomic principles provide important guidance.

One very important rule is that, wherever possible, the tool should be bent, and not the wrist. The wrist should be kept in a neutral position as much as possible. As a general rule, the less the wrist deviates from neutral posture, the better. Bent-handled pliers, hammers, and power tools are examples of commercially available alternatives to standard gripped models. These tool modifications allow the worker leverage and mechanical strength while keeping the wrist in a neutral position.

Another consideration in evaluating tools is to investigate the quality of the surface that comes in contact with the body. Bare metal is cold. In tools run by compressed air, the surface gets even cooler with use. In addition, sharp edges can put significant pressure on the skin and body part of contact. An example of poor tool handle design is a pair of metal-handled pliers where the handle has sharp square edges. Design improvements would include rounding the handles and covering them with a thin, tacky, cushioned and insulated material. In checking for factors that contribute to CTS, notice whether the tool handle presses directly upon the carpal canal. A cold hard surface that pounds or vibrates against the wrist can be problematic.

Headsets and Phone Use

Telephone use can be a significant factor in perpetuation of myofascial pain of the head and neck. There are three major muscular forces that are applied during ordinary phone use. First, the handpiece is held up to the level of the ear and mouth. This requires sustained postural contraction of the upper trapezius muscle. Second, most people push the earpiece into the ear in an effort to hear better and drown out external noise. This activity demands an even more forceful contraction of muscles that raise the arm. Finally, the lateral neck muscles must contract to push back against the force of the earpiece pushing against the ear. In summary, the upper trapezius and lateral neck

muscles contract more forcefully and remain contracted in order to keep this posture.

An even worse scenario occurs when a patient attempts to hold the phone receiver by pinching it between the shoulder and ear. This activity requires the upper shoulder and lateral neck muscles to contract and maintain a posture with the muscles shortened. The ingredients of postural contraction and shortened muscles are very strong perpetuators for activation of myofascial trigger points and myofascial pain. Sometimes even 30 seconds of holding the phone in this manner can cause a stiff neck the next day.

A headset can significantly minimize the effect of phone use as a perpetuating factor in cases of myofascial head and neck pain. The set should be comfortable, have variable amplification, and perhaps block out some outside noise. The treating physician should be sensitive to this, and not hesitate to prescribe a headset for job modification when phone use is a suspected cause of a patient's head and neck pain.

POSTURE FOR KEYBOARD WORK

It used to be thought that typists should be seated in an upright position with the typewriter at desk level and the copy flat on the desk. For some people, this posture may require significant energy expenditure, and a partial relaxed slouch may be more comfortable. Efficient posture depends upon the particular typing task being performed. Most computer typists prefer the copy to be propped up on a stand next to the monitor.

Most importantly, the body should be well supported and, for the most part, in a position of rest. When using a computer, the eyes should be able to look slightly downward at the monitor. Tearing is important for nutrition and lubrication of the cornea, and it is increased with downward gaze angle. In addition, the neck should be comfortable, and not in a forward leaning posture.

Other more recent introductions into office furniture concepts place the monitor inside the desk under a glass surface. If desk or counter space constraints are of primary importance, this may be optimal for the particular situation. However, this hardware positioning may be aggravating to the musculoskeletal system of the operator.

Sometimes the most comfortable and best-supported posture will be slouching. This posture may be optimal when typing from copy that is propped up so that the typist can look out with only a slight downward angle. While perhaps more comfortable, this posture may restrict the operator's reach envelope, making it more difficult to answer the phone, refer to other materials, and open a drawer. When typing without copy, it may be most comfortable to lie back, as in a dentist's chair, keyboard in the lap, with the monitor suspended above at a comfortable distance. This posture may be limited to young hackers who can tolerate decreased tearing.

Upright posture seems to be more appropriate when typing from copy that is flat on the desk. Ergonomic seating should be adjustable so that the body can be well supported in the best position of function for the task.

APPLICATION OF ERGONOMIC PRINCIPLES IN MEDICAL PAIN PRACTICE

During initial interviews and as patients progress in treatment, it will become evident that certain activities seem to be associated with an increase in pain symptoms. The activities may vary from specific job tasks to the use of tools and even posture, such as riding in a car or standing at a counter.

One of the most important considerations for the practitioner is the need to accurately understand the particular task or job environment involved. Obviously, the most direct way is to perform a site visit and see the activity in question on a firsthand basis. This, however, may be logistically difficult.

A much less expensive and often suitably effective method for performing a "site" visit is to ask the patient to bring pictures or a video of his or her work site and activities. Two sets of pictures, each with two or three different perspectives, should be obtained. One set should include the chair and furniture layout without the patient in the pictures. Other sets of pictures should also be obtained, with the patient posed in each of the positions/postures in which he or she spends significant time. It is important to see the patient lift, stoop, answer the phone, type on the keyboard, go into file, lean on the counter, etc. The patient should be instructed not to pose, just to act naturally. It is important to capture on film bad posture, poor lifting techniques, and true phone habits.

The task of taking pictures involves people in their own medical care and makes them start to think about the possibility of changing their environment. It also demonstrates that the medical practitioner is willing to go the extra mile in an effort to help them.

These pictures are usually reviewed during the context of an office visit. The practitioner can see where basic ergonomic principles can be applied to support the body and minimize sustained posture, repetitive strain, and poor lifting habits.

When giving professional advice regarding changing aspects of the work environment, it is important to make suggestions that are not costly and can easily be tried. These suggestions should be based upon basic ergonomic principles and common sense. Follow-up is also very important, as the success or failure of these suggestions cannot be accurately predicted. Review of corrective

actions and results of these efforts provides an environment for continued modification and refinement that is important in any ergonomic safety program. If the situation becomes too complicated and modifications do not work out as hoped, it may be time to consult with a professional ergonomist.

Axiologic Disorders — The Missing Outcome Dimension: Innovations in Pain Management

Richard S. Materson, M.D. and C. Stephen Byrum, Ph.D.

> We must look at the value orientation of individuals. Treatment must be of the person, not just the disease.
>
> C. Stephen Byrum, Ph.D.

In the new world of interdisciplinary pain management, many advances have been made to assure the correct holistic approach to evaluation and treatment. Medical holism requires attention to the four main pillars of wellness: physical, social, psychological, and spiritual. Other chapters in this book direct the reader to innovations in physical, social, and psychological domains. More controversial and unfortunately quite rare is adequate attention devoted to spiritual domains. Even with the pioneering work of Dossey (1991, 1993) and others who have explored the crossroads of medicine and spirituality, attention to this element of care evokes spirited discussion among care givers. Patients and their families, and an increasing number of healthcare workers, however, have evidenced their interest by attending mind–body medicine courses and spirituality and healing presentations such as those offered under the direction of Harvard's Herbert Benson, M.D. (1975, 1984; Benson & Stark, 1996), and his colleagues. The Center for Complementary and Alternative Medicine at the National Institutes of Health is now supporting investigations into the biologic substrate of the effects of a number of complementary and alternative modalities (CAM). In fact, evidence suggests a strong role for the hypothalamic-pituitary-adrenal axis in this effect, likening the process to the relaxation response. The relaxation response is the opposite of the fight–flight response coined earlier at Harvard. The field of psychoneuro-immunology was born of these findings.

AXIOLOGY

The entire discussion of innovations in pain management can be advanced by the introduction of the term *axiology*, a word that undoubtedly is new to most people involved in these discussions. However, the term is extremely old, reaching back into Greek philosophy and Plato's attention to better understanding of the idea of goodness, stretching into the modern age in the thought of the English philosopher G. E. Moore, and finding its epitome in the work of Robert S. Hartman (1967). The term derives from the Greek *axio*, which means "value," so axiology becomes the study of the significance of the valuing process to human existence.

Basically, we human beings are, indeed, rational and emotional, but this often stereotyped dichotomy (right brain/left brain—men from Mars/women from Venus, etc.) may be a less-than-adequate mechanism for understanding human interactions with self, world, and others. A higher-order activity unique to human beings, an activity that stands at the peak of consciousness and beyond and at the same time encompasses the rational and emotional, is the capacity to value, to make value judgments, to evaluate, to weigh, assess, and discern. There is, for example, a distinct difference in the range of consciousness involved when one speaks of wisdom as compared, for example, to speaking of thinking. Wisdom, in this context, is an axiological phenomenon, a value reality.

0-8493-0926-3/02/$0.00+$1.50

Exploring the axiological/value dimension may be the avenue to begin to open the complexities and subtleties of the spiritual arena that is commanding legitimate attention in the healing arts.

Axiological phenomena find many diverse expressions. For example, a pain patient presents to the medical practitioner presumably because of sickness and suffering and pain associated with that sickness. A detailed history and directed physical examination, imaging, and laboratory investigation lead to a diagnostic hypothesis and a treatment regiment is suggested to cure the sickness and its associated pain or at least control it. Pain patients, especially those with chronic pain, along with other chronically ill patients, are rightly described as suffering.

Moving toward an axiological expression, in the ancient world, at least, suffering represented one level of the human response to pain. Beyond this there was—for want of a better word—the acknowledgment of a deeper level of pain that, to use more modern expressions, developed from within the self (the soul, the spirit, the heart, etc) more than from the body. This deeper pain, which could be brought on by bodily suffering, accompany bodily suffering, or cause bodily suffering (sickness, pain, depression, or even death), was acknowledged with such terms as (in our English translation) ailing. The ancient Hebrews, for example, frequently used the word *dowleka* to describe this ailing, and felt it could only be responded to—and here the language is dealing with a phenomenon of such depth that the very language itself is defied—by something that would "lift people up", give people a "lift", or even "lift spirits". Therefore, the term ailing points to the spiritual or axiological dimensions of pain, suffering, and sickness; there is great distinctiveness in describing axiological disorders or value disorders.

The Symptoms of Axiologic Disorders: Ailing

How does one recognize the symptoms of ailing? The overriding issue is that something valued by the person is lost or threatened. This produces the second symptom of ailing. The third is a diminished capacity to be touched by the beautiful, to be loved, and to experience goodness. And, the final symptom is a value malaise (general weakness, lack of direction, disorientation, the inability to experience, or the loss of a sense of worth). This loss of a sense of worth can be experienced in numerous dimensions of human loss. As only a limited example, the loss could be internal—a loss of the sense of my worth as a individual. There is also external loss of worth and value—a loved one who dies, the loss of a job including the losses that occur at normal retirement, the loss of important possessions, or financial reversal. The possibilities are endless, and there are often combinations of axiological/value loss that exponentially compound themselves. Yet, seldom are practitioners attune to developing conversations that will specifically involve an exploration of valuables lost that have been become causative factors in lack of health and well-being or valuables present that can be capitalized upon to advance the healing processes. We may not have to know about unique, individual value packages possessed by our patients — which are our patients on a fundamental level — in order to move in the direction of cures, but the axiological dimension is perhaps a cornerstone to any practice that promotes and sustains healing.

To explore the deeper meaning of loss or the threat of losing something of personal value, one must understand various levels of cognition, i.e., the way we think about things. The reader is invited to follow this exercise.

Consider that most humans are aware about thinking about things in a rational vs. an emotional manner. The rational mind follows the laws of science, physics, mathematics, and logical reasoning. The emotional mind follows a more psychosocial model and feeling tones, moods, and the like. An example might be the birth of a child. Rationally, the birth is the final result of an impregnation, usually a 9-month gestation, and can be described with precise anatomic and physiologic terms. Observed from an emotional perspective, love, pride, elation, beauty, fulfilment, trepidation, and anxiety are potential terms. But there is still a higher level of thinking, the value judgment or spiritual level. This level is often laden with more universal intonations that are frequently "religious like" (Figure 46.1). (To say "spiritual like" would be more consistent with the force of our discussion; religion relates to more institutional and parochial expressions.)

The late Abraham Maslow (1962, 1963) described these phenomena as peak experiences. Maslow would invite a group of learners to "think of the most wonderful experiences of your life; happiest moments, ecstatic moments, moments of rapture, perhaps from being in love, or from listening to music, or suddenly being 'hit' by a book or a painting or from some other great creative moment". He then invited his group to "first list these and then try to tell me how you feel in such acute moments; how you feel differently from the way you feel at other times; how you are at the moment a different person in some ways". The reader is encouraged to create such a memory in your own mind now. What is being recalled are value experiences, experiences that add value to life.

Dr. Maslow discovered an initial resistance among those he challenged, even among those who later admitted to having such experiences. The subjects feared being stigmatized as unsophisticated squares or being exposed as possessing abnormal personalities if, in this climate of scientific rationalism, they shared their true thoughts. Once the resistance was overcome, however, a large number reported what in Maslow's terms were basically religious experiences — for our purposes, axiologic experiences.

Maslow described these peak experiences associated with great moments of love (a mother fondling a newborn infant), moments of asthetic appreciation (observing the spray of the sea on rocks at dawn or dusk), moments of peak creativity (some meaningful and difficult task adequately performed), or great moments of insight and discovery.

Adjectives used to describe the associated feelings were wonder, awe, reverence, humility, surrender, and worship. Subjects recalled feeling that they were recipients of gifts, owe for what they have been given, and are under obligation to repay acts of goodness. The whole universe is perceived as a meaningful and integrated whole. "One feels that he has a place in it, that he belongs in it." Connected is another frequently used term.

Answering the question about how different the world looked at such times, participants replied that love and justice and all the values we commonly call religious or spiritual appear to be part of the very structure of the world. The world is not just there; it is essentially good. Such experiences are "valu-able;" that is, value-enabling/axiologically en-abling, with *able* constituting the polar opposite of ailing.

Ordinary cognition, in contrast to peak experiences, is highly volitional, demanding, prearranged, and preconceived. In peak experiences, the will does not interfere, it is held in abeyance. It receives and does not demand. We cannot command the peak experience. It happens to us (that is, unless we are suffering an axiologic disorder). One is reminded of philosopher Martin Buber's (1970) two attitudes by which man can and does relate to the world: "I–It" and I–Thou." "I–Thou" relations are characterized by immediacy, present-ness, subjectivity, spontaneity, unpredictability, and uniqueness. The person confronted by such a relation is not a passive object but an active subject to be confirmed in other-ness. By contrast, "I–It" relations are characterized by detachment, impersonalism, analysis, objectivity, and the search for an ordered, predictable structure of experience.

Leland Kaiser (1999), a well-recognized futurist, advises us, when looking at the unlimited parallel possibilities of future, to engage in precognition. We are advised to give up the bounds of worldly order, such as the rules of physics and mathematics, and to envision the future as it would be at its very best. We temporarily get out of our left-brain mode and into our right-brain function, thus expanding our consciousness. Then, he suggests, we can grasp the future as it should be and as we wish it to occur in a perfect world, then come back to cognition in a real world and get about making the future happen by aligning with like-minded thinkers and doers. Kaiser's precognition is probably reflective of a transient shift from "I–It" to "I–Thou" and back again having enjoyed a peak experience.

Armed with an appreciation of "Things We Value," one can observe the great loss if we are deprived by this high order of experiencing reality. In fact, this loss leads to ailing, the failure to be able to tune in to this higher level of cognition when we wish to, and later the loss of desire to experience these peak experiences.

There are various degrees of this diminished capacity to be touched by the valuable, the beautiful, love, or goodness: from less frequent and more difficulty attaining this level of cognition to complete absence of the capacity.

Values malaise is the way this is commonly expressed to others. "I don't care any more." "No one cares." There is a loss of focus, a loss of what to care about. "It doesn't matter." "Nothing matters!" "It is not worth it!" There is a surrender to this negative mode of existence, a willingness to give up. Self-value and self-worth are depleted or gone. There seems to be no worth or value in anything. The sufferer is observed to have a loss of motivation. There seems to be little tenacity or stamina. Hope is lost. The mindset is so negative it seems "catchable." Others wish to avoid persons with values malaise, compounding the problem with isolation and loneliness, a self-fulfilling prophecy of the cognitive state. Finally, the sufferer experiences little evidence of joy or fun in life.

Therefore, it is not surprising that a patient whose illness is cured but who remains unrelieved of ailing or suffering associated with being sick has had incomplete treatment outcome (and, therefore, does not feel well or able to function efficiently or meaningfully). Adding to proper medical treatments, the relief of axiologic disorders brings a nearly immediate feeling of positive well-being, uplifting, and enormous gratitude; a patient is *en-abled*

Treatment of Axiologic Disorders: Exposure to Beautiful Things

The axiologically disordered patient is deprived of the ability to appreciate the good and beautiful things of this universe, the good and beautiful in others, and the good and beautiful with the aspects of the self. Treatment is by concerted effort of exposure to those realities. Ultimately, the loss of appreciation makes the sufferer detached from others and lonely. As studies of marasmus demonstrated in orphaned infants, love, affection, touching, and being touched are absolutely necessary for normal human growth and development. Just as the affected infants who were malnourished, maladapted, and slightly unresponsive, the sufferer has to one degree or another the same sparse repertoire of healthy engagement. After cuddling, rocking, touching, and communication response in an atmosphere of loving returns, those infants experience healthy growth and development and response patterns. Similarly, the sufferer ends the isolation and gains happy and productive engagement, thus fo

some added base of potential for movement to health and a sense of well-being.

Meaningful Attachment

The first step necessary is that the suffer be cajoled, led, or otherwise influenced to form at least one deep meaningful attachment to another human being. This will require that the sufferer engage in doing kind, loving, and caring things needed by the person to whom he attaches. This can be a giant step for a sufferer whose every impulse is to maintain the isolated world, but it is the key event in returning to a healthy lifestyle and cannot be put off or neglected. There is always someone who can become that object of attachment. Someone on the clinical team must assume responsibility for assisting the identification of the right person and facilitating the introduction or contact. There is a sufficient supply of children, elderly, handicapped, impoverished, or simply unlucky who can be found. Social organizations, family members, and religious service groups have a great abundance of need so the sufferer always will be able to find a rich potential list of beneficiaries.

Acts of Compassion

Conscious acts of compassion is the second sufferer penicillin. This is different from the attachment discussed above and more than a warm fuzzy feeling. In the recipient, it fulfills the desire not to hurt but to be happy. The natural right to pursue happiness is reinforced for both the giver and the receiver. This forces affinity with persons who lack the opportunity not to be hurt and not to be happy. This concept goes far beyond feeling sorry for someone, but rather requires the performance of specific actions as a duty and obligation to create an environment for diminished hurt and increased happiness. While some sufferers possess the innate skills to produce conscious acts of compassion toward others, some will require significant coaching of the deeds and the necessary attitudes. Charles Dickens certainly caught the flavor of this in his inspiring story *A Christmas Carol*, when the reformed Ebenezer Scrooge accumulates profound and extraordinary personal benefits exceeding even those given to the Cratchit family and Tiny Tim by his conscious acts of compassion. In order for me to feel good, someone else will have to feel good because of my conscious actions first!

Diminishing the Comparing Mind

Diminishing of the Comparing Mind is the next hurdle on the road to end ailing. The mind in its left-brain cognitive function is exclusive, comparing, and competitive. More right-brained spiritual thinking is inclusive, noncomparing, and noncompetitive. In a connected universe there are ample good things for all of us and each of our portions is equally meaningful. A person is more than his or her job title, rank, salary, or social class. We must not value persons based on their economic achievements but rather value each person for who they are and how they uniquely contribute. This causes us to be more open and accepting of others and to value them. In this fashion we abandon living our life between the "I wish I were" and "I'm glad I'm not" sort of thinking.

Calming the Mind

Conscious Disciplines That Lead to Calming of the Mind is the next therapy required. This concept derives from Thales' "Know yourself" and from Qualb, Muslim for "mind within the mind". Methods vary, but they require conscious exposure to the beautiful, peaceful, relaxing, rhythmic, and calming. The sufferer must seek out his best space to achieve this renewal. Often nature provides the environment, a walk in the woods, a garden, the beach, a sunset over mountains or waves crashing on rocks, a stream trickling through a mossy ravine. One can go to his/her place through meditation, by blocking out the external, turning consciousness inward. This can be assisted by attention to breathing, contract–relax types of progressive relaxation, listening to music with relaxation-inducing harmonics, or paying attention to a work of art. One need not actually go to the woods or the sea, because having identified a safe place, one can envision it during meditation and transform oneself virtually. Guided imagery assists persons to find a theme or environment most conducive to achieving the desired result.

Bensen and others have identified effective means of evoking the "relaxation response" which not only lead to the calming of the mind but also engage the psycho-neuro-immune system in a positive direction mediated in part by the hypothalamic-pituitary-adrenal axis. These techniques can be successfully achieved by nearly everyone. They require practice and repetition to become automatic and, therefore, easy to engage, much like learning to drive a stick-shift car. In the beginning, the task appears so formidable, and in the end, so ridiculously easy. Persistence pays and is rewarded by recharged batteries and renewed appreciation for those beautiful things of our universe, a profound sense of gratitude for the gifts we have been given. In other words, the renewed ability to enjoy peak experiences.

Conscious Depersonalization

Conscious Depersonalization becomes the next step on the path to healing. Grief and loss are universal conditions. The sufferer feels alone but is not. The suffering is not personal or a punishment for a misdeed or failure.

Bad things happen to good people all of the time; this is the nature of life. We must get over the inclination to believe that we are the ones selected for whatever bad happenstance. All others have experienced grief and loss, and will again. This is part of the life cycle and part of the human condition. However, it is unfortunately easy to slip back into the "it's just me" mindset, and so conscious depersonalization repetition is required.

Rejection of Regret

Conscious Rejection of Regret is the final pill in the bottle of recovery but is as important as each of its predecessors. Regret leads to guilt, which is a major cause of axiologic disorders; guilt and blame becoming automatic powers of devaluation. One needs to put material satisfaction into perspective. Who you are is not what you have! This method of viewing life must be changed consciously to an uplifting approach. Therefore, one must view a partly completed work as a celebration of the effort to date rather than regret or guilt that it is incomplete. The glass must be viewed as half filled rather than half empty. Obviously, both statements are true, but the former carries with it optimism and hope, and the latter, regret — "What have I achieved so far?" rather than "How far am I behind?" What are the positive qualities we possess rather than enumerating the negatives? Perhaps most importantly, "What significant actions have I taken to help others?" rather than "What have I failed to do?"

Who Does What?

Each pain practitioner must decide the mechanism by which the treatment team will assess the axiologic information and assure provision of therapeutic interventions. The reasons for the inquiries and the goals of the interventions must be shared with the patient and his family or support group. Insistence on addressing these issues is probably one of the few forgivable paternalistic actions left in medicine. Obviously, the best methodology requires patient agreement, yet the value of success is so great that the representation of data should be persistent even for the most reluctant. Remember that you are not imposing your own belief system on the patient. No proselytizing for any religion is permitted here. Rather, universal spiritual issues are involved which are backed by bio-psycho-social literature. Each treatment team will of necessity decide who does what. Certainly, if a chaplain well versed in the material is available, that person should be invited to contribute. But the tasks can be accomplished by physician, nurse, social worker, psychologist, and/or some therapists sensitive to and trained in the techniques. One always finds outcome measures helpful when applying a treatment. The Medical Outcome Study short form-36 (MOS-SF-36), the Sickness Impact Profile (SIP), and others may be useful. Less formal measures include clinical observations that document the patient's emergence from his or her isolated shell, their celebrations of doing meaningful things for others, brighter colors and happier subjects in their art work, success in their meditation and visualization, and their developed capacity to describe peak experiences.

The Spiritual Tendencies Inventory© published by Byrum is available in the Appendix at the end of this chapter. This instrument, which is directly related to axiologic assessment, is a very useful self-help device for those persons wishing to better understand themselves on a spiritual matrix. It is designed to be private (not included in a medical record), nor should it be used as a measurement instrument to document a clinical outcome. Rather, it assists the taker inventory his status vs. a control group for feedback which can be used or ignored as desired in the search for added information about the self. In the inventory's ten "domains", there are indications of both spiritual strengths and obstacles which can impact the axiological dimensions of health, well-being, and the associated phenomena of ailing, suffering, and pain. There is no correct score. There is, however, a perceptive mirror which reflects an individual's attitudes and self-judgments and values, with some helpful generalized feedback supplied to advance conversation and consideration. If a patient desires professional advice regarding the data acquired via this route, the treatment team should be prepared to supply it.

In summary, the relief of "ailing," a fundamental component and contributing cause of "suffering," has been one of the most neglected areas in pain medicine, yet one of near universal need. Familiarity with the very simple and pragmatic diagnostic criteria, and implementation of the treatment protocols will provide both the patient and the treatment team with a warm glow of mutually celebratory success.

SPIRITUAL TENDENCIES INVENTORY©

The insights gained from this unique instrument can provide important information about the level of spiritual strength available to a person, which can be of significant help in situations of illness, stress, trauma, or high-demand challenges of daily life. The instrument will also provide a comprehensive picture of obstacles that inhibit and diminish spiritual strength.*

INTRODUCTION

During the past decade, numerous studies have addressed the relationship of spiritual tendencies to health and well-being. A fairly large body of anecdotal data and several controlled studies have concluded, somewhat persuasively, that such tendencies can make a positive contribution to a person's sense of well-being and impact physical health in a positive manner. Most of the anecdotal data have been compiled in situations in which persons are facing substantial challenges to personal health, and the conclusion has been advanced that spiritual tendencies have helped people cope and sustained them through difficult times. The sole purpose and intent of this Inventory is to gain insight into and establish some conversation about your spiritual tendencies in this regard.

DISCLAIMER

The above-noted studies and collections of anecdotal evidence have not succeeded in two areas. First, they have not defined in a scientific manner the word spiritual. It should be assumed that the word is not a synonym for religious, that religious refers to conventional, institutional, traditional expressions that arise in specific cultures, and that being religious does not necessarily mean that a person is spiritual. The term spiritual refers to a deeper core experience that is highly personal, ultimately incapable of being defined, and part of the unique essence of an individual's character and personality.

Second, there is no scientifically validated profiling instrument that relates to spirituality. In the most widely used profiling instruments, the issue of scientific validity is vague and open to debate. Simply realize that the instrument you are using here, which is an evolved form of the best instruments available, is seen as a mechanism for insight, conversation, and contemplation; it does not present itself as a scientific instrument, although its practical usefulness is strongly and confidently asserted.

In conclusion, the following questions are highly personal, are not intended as invasive, will result in absolutely no value judgment about an individual person, and are designed to be of personal benefit. The great benefit will be establishing a conversation from which individuals can gain important insights that will impact their own self-understanding, health, and well-being.

DIRECTIONS

Please contemplate the following questions and give your own personal answers in the spaces provided with each question. Keep in mind that there are no right or wrong answers, no answers that are better than others. To the extent that you are totally honest, the findings will be of more meaning and benefit to you.

PART I INVENTORY OF POTENTIAL STRENGTHS

1. To what extent do you feel that you have a sense of purpose in life?

   __Never __Seldom __Randomly __Regularly __Often

2. To what extent is it important to you to have what you would call meaningful life experiences?

   __Never __Seldom __Randomly __Regularly __Often

3. To what extent do you feel a sense of connectedness to others?

   __Never __Seldom __Randomly __Regularly __Often

* ©C. Stephen Byrum, Ph.D., The Byrum Consulting Group, LLC, 17 Grayswood Hill Road, Signal Mountain, Tennessee 37377. Phone/Fax (423) 886-5587.

4. To what extent do you feel a sense of connectedness to nature?

__Never __Seldom __Randomly __Regularly __Often

5. To what extent do you feel a sense of connectedness to your own personal self?

__Never __Seldom __Randomly __Regularly __Often

6. To what extent do you feel a sense of connectedness to that which you personally identify as God/The Divine/The Creator/The Source/or whatever name/idea/concept is meaningful to you personally?

__Never __Seldom __Randomly __Regularly __Often

7. To what extent is wholeness a meaningful concept to you or a word you use in regard to your life or the lives of others?

__Never __Seldom __Randomly __Regularly __Often

8. To what extent do you use the terms higher or deeper to describe levels or dimensions of life you believe you can or do experience?

__Never __Seldom __Randomly __Regularly __Often

9. To what extent do compassion, empathy, sympathy, and caring describe experiences/feelings that are part of your life and are directed at others?

__Never __Seldom __Randomly __Regularly __Often

10. To what extent do you feel that something you are doing is what you are supposed to do, something about which you have a sense of calling?

__Never __Seldom __Randomly __Regularly __Often

11. To what extent do you feel attracted to, captivated by, even startled by some reality which is beautiful to you?

__Never __Seldom __Randomly __Regularly __Often

12. To what extent do you feel part of a larger community, if that community is defined by the word family?

__Never __Seldom __Randomly __Regularly __Often

13. To what extent do you feel part of a larger community, if that community is defined by the word humankind?

__Never __Seldom __Randomly __Regularly __Often

14. To what extent do you feel part of a larger community, if that community is defined by the words cosmic universe?

__Never __Seldom __Randomly __Regularly __Often

15. To what extent do you feel that there are "Truths" that can be conveyed by inspiration, revelation, or messengers such as prophets, wise teachers, or holy scriptures?

__Never __Seldom __Randomly __Regularly __Often

16. To what extent do you experience what you might call a deep sense of personal satisfaction in regard to some action, decision, involvement, or activity you have participated in?

__Never __Seldom __Randomly __Regularly __Often

17. To what extent is the phenomenon of hope a personal lens through which you relate to life?

__Never __Seldom __Randomly __Regularly __Often

18. To what extent is the word transcendent a part of your vocabulary?

__Never __Seldom __Randomly __Regularly __Often

19. To what extent, in spite of the negative realities that are invariably a part of life, are you able to sustain an attitude of optimism?

__Never __Seldom __Randomly __Regularly __Often

20. To what extent are you able to live/act on what you personally would refer to as faith when there is no scientific evidence that is available?

__Never __Seldom __Randomly __Regularly __Often

21. To what extent are you engaged in attendance at religious services conducted in a formal setting (church, synagogue, mosque, etc.)?

__Never __Seldom __Randomly __Regularly __Often

22. To what extent do you participate in what you would personally define as prayer?

__Never __Seldom __Randomly __Regularly __Often

23. To what extent do you spend time in what you would personally define as devotional time /meditation/contemplation/reflection?

__Never __Seldom __Randomly __Regularly __Often

24. To what extent do you spend time reading spiritual/religious writings?

__Never __Seldom __Randomly __Regularly __Often

25. To what extent to you become engaged in religious activities designed to help others in situations of need?

__Never __Seldom __Randomly __Regularly __Often

PART II INVENTORY OF POTENTIAL OBSTACLES

1. To what extent do you experience a sense of anger as a primary response to people and circumstances that come into your life in a negative way?

__Never __Seldom __Randomly __Regularly __Often

2. To what extent do you experience a sense of hate as a primary response to people and circumstances that come into your life in a negative way?

__Never __Seldom __Randomly __Regularly __Often

3. To what extent do you have to deal with problems of financial debt in your life that make you feel vulnerable or jeopardized in some way?

__Never __Seldom __Randomly __Regularly __Often

4. To what extent do you have what you would identify as problems with sleep or a lack of adequate rest?

__Never __Seldom __Randomly __Regularly __Often

5. To what extent do you experience what you would identify as impatience as a primary response to people and circumstances that come into your life in a negative way?

__Never __Seldom __Randomly __Regularly __Often

6. To what extent do you experience what you would identify as a desire to win as a primary motivation in your life?

__Never __Seldom __Randomly __Regularly __Often

7. To what extent do you find yourself dwelling on negative events that have occurred in your past?

__Never __Seldom __Randomly __Regularly __Often

8. To what extent do you experience a sense of blame that you direct toward other people or circumstances in your life?

__Never __Seldom __Randomly __Regularly __Often

9. To what extent do you feel that you have spent significant parts of your life in circumstances of criticism and complaint directed at you personally?

__Never __Seldom __Randomly __Regularly __Often

10. To what extent do you feel that you have a tendency to hold grudges or to think about retribution or revenge in regard to what you perceive as negative events that have been directed toward you by others?

__Never __Seldom __Randomly __Regularly __Often

11. To follow an old saying, to what extent do you feel that you have a tendency to forgive but not forget?

__Never __Seldom __Randomly __Regularly __Often

12. How often do you lose your temper?

__Never __Seldom __Randomly __Regularly __Often

13. To what extent do you experience what you would identify as a sense of worry (foreboding, impending harm) about people and circumstances in your life?

__Never __Seldom __Randomly __Regularly __Often

14. To what extent are meaningful events in intimacy and affection a part of your life that is absent or insufficient to the needs you feel?

__Never __Seldom __Randomly __Regularly __Often

15. To what extent do you experience what you would describe as blown, depression, lethargy, a bad case of the don't cares?

__Never __Seldom __Randomly __Regularly __Often

16. To what extent do you feel that you are the victim of bad luck or the fates being against you?

__Never __Seldom __Randomly __Regularly __Often

17. To what extent do you feel that you need to be in control?

__Never __Seldom __Randomly __Regularly __Often

18. To what extent are there times in your life that you feel that the use of alcohol or drugs has become excessive?

__Never __Seldom __Randomly __Regularly __Often

19. To what extent do you feel that you have to be right?

__Never __Seldom __Randomly __Regularly __Often

20. To what extent do you have times in your life during which you feel that you cannot get caught up, that you are always behind?

__Never __Seldom __Randomly __Regularly __Often

21. To what extent do you believe that there is a personal power of evil in the world that desires to do you harm?

__Never __Seldom __Randomly __Regularly __Often

22. To what extent do you feel that you are unable to successfully meet the expectations of others?

__Never __Seldom __Randomly __Regularly __Often

23. To what extent do you feel that your life is complicated and diminished by the amount of clutter that surrounds you?

__Never __Seldom __Randomly __Regularly __Often

24. To what extent do you experience what you would define as fear?

__Never __Seldom __Randomly __Regularly __Often

25. To what extent are you dissatisfied and fail to find contentment with the role of these sexual experiences in your life?

__Never __Seldom __Randomly __Regularly __Often

Scoring

While there are no right or wrong answers for this inventory and the scoring is not designed to be any kind of contest with stronger or weaker scores, the following scoring system can establish beneficial implications. Please assign the following points:

Never = 1
Seldom = 2
Randomly = 3
Regularly = 4
Often = 5

Totaling your overall score will create a number between 25 and 125 on Parts I and II.

Your total score on the inventory for Part I is _____ .
Your total score on the inventory for Part II is ____ .

Possible General Implications Part I

1. For a score of 25–59
   The spiritual arena is not of high importance to you in terms of your present tendencies and activities. Why this is the case is unique to your own personal background, but it may be important for you to reflect on the causative influences that have produced this score.
   The arena of the spiritual may be of little benefit as a positive influence on situations of personal health and well-being. The spiritual may not be an active part of your personal coping mechanisms.
   It may be that exploratory inquiries or study in the spiritual area might be of interest and benefit. If such exposures in the past have been blatantly negative to you for whatever reason, exposures of some new variety might be more helpful. Try not to let any negative experiences from the past close doors of possible insight and discovery for you.
2. For a score of 60–94
   The arena of the spiritual is of moderate importance to you in terms of your present tendencies and activities. Why this is the case is unique to your own personal background, but it may be important for you to reflect on the causative influences that have produced these scores.
   The spiritual arena may be of more than passing adequate benefit as a positive influence on situations of personal health and well-being. The spiritual may be of reasonable importance as an active part of your personal coping mechanisms.
   Because you already have some taste for spiritual inquiry, further explorations in this area may deepen the strengths you are finding. Perhaps exposures to new areas of inquiry would enhance the experiences you are already having. Try to hold open a sense of discovery and enlightenment as new dimensions of spirituality are experienced.
3. For a score of 95–125
   The arena of the spiritual is of high importance to you in terms of your present tendencies and activities. Why this is the case is unique to your own personal background, but it may be important for you to reflect on the causative influences that have produced these scores.
   The spiritual arena will be of highly important benefit as a positive influence on situations of personal health and well-being. The spiritual will be an active part of your personal coping mechanisms.
   The present strength of your involvement in spiritual inquiry is likely to be a platform upon which a good deal of your overall-life is built. Continued experiences of growth may be of further benefit. Try not to feel that

you have arrived and have no additional dimensions of growth to explore.

Possible General Implications Part II

1. For a score of 25–59
   While you should pay attention to any individual question(s) that you marked often, in general you do not have great obstacles that stand in the way of what can be defined as spiritual.
   Often we are challenged to give attention to correcting negative indicators or solving problems, but we are also challenged by strong, positive indicators. Your challenge may be to understand what you are doing well with regard to these obstacles to the spiritual and keep following and building on those patterns. It also will be important to understand why you have done well in these areas, what personal history has contributed to this, and who may have helped you in making this level of scoring possible.
2. For a score of 60–94
   These scores give evidence of a substantial number of obstacles to the strengths which can be derived from the spiritual. In all likelihood, these obstacles will be having a general impact on quality of life and general happiness. No matter how strong your spiritual strengths might be, they will be compromised to some extent by these obstacles.
   Begin by looking at the areas you have marked "often" and "regularly." Then, give consideration to the various domains, and see if you have a concentration of obstacles in any one or two domains.
   Try to establish personal strategies designed to create conversations; seek input from trusted colleagues and friends, and actions that might reduce the impact of these obstacles.
3. For a score of 95–125
   These scores give evidence of an unusually high number of obstacles to the strengths that can be derived from the spiritual. In all likelihood, the obstacles are having a profound impact on quality of life and general happiness. No matter how strong your spiritual strengths might be, they will be substantially compromised and eroded by these obstacles.
   Calculate your domain scores, and then take note of these scores from the most negative to the most positive. Clearly, the domains with the most negative scores indicate the area where most work is needed. Think about past influences in your personal history, the impact of people who presently populate your life. Can these negative, causative factors find any resolution? Think about the powerful role that your perception of events and people can also play. What is the relationship of your perceptions and responses to reality? These negative obstacles should be approached with great seriousness as they constitute a real threat to personal happiness, success in relationships, general health, and a sense of emotional well-being.

PART I/DOMAIN 1 THE ROLE OF COMPASSION, EMPATHY, AND CARING

YOUR SCORE FOR QUESTIONS 9 AND 25

Scoring Range: 2----------10

weaker---------- stronger

Our ability to get outside of ourselves is enhanced and accelerated by direct actions of compassion and a spirit of empathy and caring that is directed at other people, particularly when other people are in situations of need, pain, or hurt.

Most people report a genuinely positive feeling of meaning and happiness that rises within them when they extend help and care to others. This feeling, while incapable of being logically defined, is a powerful indication of our own humanity at its best, our almost innate connection to others, and a catalyst for positive self-esteem.

Individuals who deal with depression, both as persons afflicted by the malady and professionals involved in treatment, have found that direct involvement with actions of compassion and empathy tend to diminish the intensity of all but the most severe forms of chemical depression. Without question, the positive feelings gained from actions of care can contribute remarkably to human health and well-being. If nothing else, when we are exposed to deep needs of others, we may gain a better perspective on the way that our own lives — in spite of very real challenges— are indeed blessed.

Unfortunately, the positive, spiritual feelings that are the result of actions of compassion and empathy too often occur by accident and coincidence. Is it possible to construct positive strategies of spiritual health and well-being by consciously incorporating into our daily lives actions of care and compassion? Is it possible to create personal spiritual projects designed to help others that may, in the end, have more of a positive impact on us as helpers than on anyone we reach out to help?

PART I/DOMAIN 2 A SENSE OF CONNECTEDNESS

YOUR SCORE FOR QUESTIONS 3–5, 12–14

Scoring Range: 6----------30

weaker----------stronger

When those first astronauts who walked on the moon sent back those amazing pictures of Earth, most human beings were stilled, if not stunned, by the images. No one who has ever lived on this planet has been afforded exactly that particular perspective. How beautiful our blue and white globe was hanging there almost like a cosmic ornament in outer space. How small we seemed, certainly not the egotistical center of the universe assumed by some past generations. But, more than anything else, how much we who inhabit this planet are interconnected, mutually dependent, in this together. We are not alone!

Loneliness is emotionally and then physically destructive. While we all need moments of personal privacy — "Calgon take me away!" — isolation will destroy us. We need connectivity of any and all varieties; so much so that healthy human beings consciously seek ways to promote and pursue healthy relationships.

Connectivity can be experienced in many dimensions, and the dimensions enhance one another and are mutually reinforcing. The experience of connection in one dimension will exponentially add to the experience in other dimensions; a lack of, antipathy for, or cynicism about connection in any dimension will have a limiting impact on the entire field of potential.

The experience of connectivity can find expression most simply with other people, and then potentially with nature, with what some identify as the Divine/the Holy, perhaps with animals, and even with inanimate objects of personal worth and value.

Although it is not given sufficient attention, the experience of connectivity with self/one's best self/one's ideal self/one's essence is also of deep meaning. The experience, not the intellectual concept, of wholeness is the experience of connection with self, and usually is buoyant, with personal meaning and positive consequences for health and well-being.

PART I/DOMAIN 3 THE ROLE OF TRADITIONAL RELIGIOUS ACTIVITIES

YOUR SCORE FOR QUESTIONS 6, 15, 20–24

Scoring Range: 7----------35

weaker----------stronger

It has been difficult for people to be nonjudgmental about many traditional religious activities. For some, due to the negative excesses in the history of traditional religion and negative personal experiences, there is a deep cynicism about anything that smacks of traditional religion. For others dealing with their own comfort zones and sometimes defensive exclusivism, if some religious practice is not exactly like their religious practice, it is suspect and illegitimate.

If it is possible to get beyond these two invalidating predispositions, there remains a distinct and expansive field of evidence that convincingly suggests that traditional, religious-like activities can be of real positive consequence for health and a sense of well-being.

Whether a person prays or meditates is not the issue; the value of prayer-like or meditation-like states of consciousness for health is almost beyond question. Whether a person recites a Hindu mantra, works rosary beads through his or her fingers, or enjoys joining in the rhythmic singing of congregational hymns is simply a matter of upbringing and personal taste, not an occasion for some competitive debate set on determining who is closer to God or whose practices are right or wrong. The calming rhythms established in activities is the key to health, not the traditions that give rise to the different expressions. It is the quietness and beauty of the holy place that promotes a sense of rest and personal revitalization; that the place is a synagogue, mosque, or church is of very secondary importance.

There is an amazingly diverse world of religious activities in the world today and across centuries of human culture. Within these complex and often curious expressions, legions of human beings have gained deep and lasting meaning for their lives. If we could set aside some of our stereotypes and caricatures and open some of the limiting boxes we live in, there is no telling what we might find that would benefit our lives and contribute in a positive manner to our health and well-being. Who knows, it might be worth a serious look!

PART I/DOMAIN 4 A SENSE OF PURPOSE, CALLING, AND MEANING

YOUR SCORES FOR QUESTIONS 1, 2, 10, 16

Scoring Range: 4----------20

weaker----------stronger

The survival instinct has often made the vital difference between life and death. This instinct has guided human lives through a maze of dangers, difficulties, and threats. Now, as times have changed and, following Maslow, basic survival needs have become more easily met, the survival instinct has evolved into a more sophisticated form.

The sense of purpose and calling, the core of our search for meaning, is an advanced, evolved form of the old survival instinct. On levels of basic living, there must be survival; on levels of self-actualization and self-realization, there must be purpose and calling. Purpose and calling promote survival on a more essential, more intrinsic level. Purpose and calling contribute to authentic living today as profoundly as basic survival.

Too often we have added our own dimensions of competition and judgment to purpose and calling. One purpose or calling is seen as being somehow better than another. Suddenly, there are artificial hierarchies that end up prescribing who is of value and what work has worth. People make choices on the basis of culturally defined roles that may not be fulfilling at all without honoring the clues of their own uniqueness.

Purpose and calling need to be defined in concert with cultural precedents and suggestions, but the motivation of experiencing personal happiness must become a high indication of where personal meaning is to be found. Under no circumstances should economics or social status be the only determinative factor in narrowing the range of life choices which may produce purpose and calling.

Finally, be sure to keep in mind that any sense has an intuitive dimension that cannot be reduced to pure logic or rationality. Just as a survival instinct must be trusted and acted on to some extent daily, so a sense of purpose and calling must intuitively and instinctively be responded to with a substantial degree of self-trust, trust in others, and perhaps even a trust in a power of beneficence at the core of existence.

PART I/DOMAIN 5 A SENSE OF THAT WHICH IS BEYOND

YOUR SCORE FOR QUESTIONS 7, 8, 11, 17–19

Scoring Range: 6----------30

weaker----------stronger

The brilliance of Albert Einstein is usually associated with relativity theory and the famous axiom $E = MC^2$. However, for Einstein, before there was math or physics — or any thinking pursuit — there was something more fundamental. The great genius put it this way:

> At the core of all of the sciences and humanities there is a common experience—a sense of mystery. That person who is unable to stand in wonder, rapt in a sense of awe, is as good as dead. His mind and his eyes are blind (Byrum, 1991).

So, the critical component to life in many respect is wonder. For Einstein, everyone has the capacity for this experience, but for one reason or another, does not exercise this capacity. They may be too busy to take long walks in a beautiful place. The aesthetic experience of beautiful objects or the appreciation of something of goodness/quality may escape their notice. So, there is little of the wonderful, and what does occur in this domain is more by accident than intentional design.

Without experiences of wonder and awe, life becomes sterile and one-dimensional. When the capacity for wonder is not exercised, we get caught up within ourselves and lose perspective. As children, we have a gift of wonder, and it is exercised constantly; unfortunately, too many of us become all-business, serious adults, put away our childish things, and think that our grown-up status is somehow superior. In fact, we have lost our best selves.

An ancient holy text says, "He who does not believe is condemned already." The text is not claiming some absolute that unaccepted and unrated brings damnation. Rather, it is saying that without the exercised capacity of an advanced dimension of consciousness, here called believing, an entire level of potential for life is closed off. When this self-limiting occurs, sickness, depression, loss of emotional well-being cannot be far behind. We must watch children caught up in play and filled with an awesome enthusiasm of just living. As adults, we must reclaim this wonder and joyfulness. To do so is to create a context for getting better.

PART II/DOMAIN 1 PERSONAL LIFESTYLE ISSUES

YOUR SCORE FOR QUESTIONS 3, 4, 14, 18, 25

Scoring Range: 5----------25

more positive----------more negative

This domain involves a kind of catchall of personal lifestyle issues that may be obvious. However, because so many people have their potentials for good health and balanced well-being lessened because of these issues, perhaps reassertion and reaffirmation are important.

Rest is nature's way of recharging the batteries of our lives. There is no substitute for rest, no potion we can take that does for us what rest does. Health, well-being, clarity of judgment, and facility of performance are all impaired by lack of rest. Part of knowing who we are in our uniqueness is knowing how much rest we require. Intimacy and affection are survival needs, pure and simple.

Intimacy and affection are survival needs, pure and simple. Intimacy needs are a part of the unique core of our humanity. Deprivation or abuse in these areas will

eventually become destructive, even to the point of impairing our immune systems and brain chemistry. Healthy sexuality is a divine gift.

Alcohol and drugs can be part of a nexus of unresolved personal and interpersonal problems. While not intrinsically wrong, they often challenge an individual's ability to be in control of his or her own life and destiny. Too harsh a judgmental condemnation of alcohol and drugs may actually encourage abuse. A laid-back, it-doesn't-matter tolerance defies the fact that powerful chemicals will create powerful, often unpredictable interactions with complex body chemistry. A middle ground of absolute control and honest temperance may be the key, all the time knowing that self-honesty in these areas can be very difficult. (Similar assessments of diet and exercise issues can easily be made and have parallel relevance.)

Debt must become part of this set of lifestyle issues. The burden of the debt being assumed by many Americans is a direct, causative factor in health problems. A careful line must be drawn between needs and wants, what we might like, and what we can afford. We must resist allowing who we are to be defined in terms of what we have.

The person who juggles these issues is like a skilled, highwire artist. Balance and good judgment in these areas give a spiritual gracefulness to life.

PART II/DOMAIN 2 THE POWER OF STRONG, NEGATIVE EMOTIONS

YOUR SCORES FOR QUESTIONS 1, 2, 12, 13, 15, 24

Scoring Range: 6----------30

more positive ---------- more negative

When the ancient religious texts called upon people not to worry, they were not simply trying to give us another rule that we can feel badly about when we fall short. Nor is there an empty-headed, Alfred E. Newman *Mad* Magazine "What, Me Worry" attitude or a Pollyanna-ish "Don't Worry, Be Happy" platitude being advanced. Real, practical advice is being offered.

The ancient texts advise that the problem with worry about the future (or other realities over which we have little control) is that the realities we will face today will require all of the personal energy we can assemble.

Worry, fear, anger, hate—all of our strong, negative emotions—are powerful realities of personal evaluation that drain us of personal energy at a profound speed. To become obsessively and compulsively consumed with "what ifs," with fits of temper, with fear of worst-case scenarios diminishes our ability to energetically, creatively, and productively deal with what demands our focus today.

If worry and fear or other negative emotions are painful, and if pain is naturally avoided, is it possible that on some level we choose to embrace these negative emotions? Do their manifestation give us attention, gain us some kind of emotional leverage with others, or create some kind of self-punishment that we feel we deserve? If any of this is true, we certainly need to work on why we allow the negative emotions to be taken to such dangerous extremes.

On the other hand, involvement with negative emotions may simply be the result of unexamined habits that have come to dominate in our lives. Maybe there are actions of the will that can help us break habits of worry or temper that are just as real, and work with similar tactics, as actions of the will that allow us to break bad habits of eating, drinking, smoking, etc. Habits can take on a life of their own, be in charge of our lives, and destroy us. So, it becomes time for us to take control of ourselves, even in regard to the expression of emotions.

PART II/DOMAIN 3 WHAT HAVE WE DONE WITH TIME?

YOUR SCORE FOR QUESTIONS 5, 9, 20, 22, 23

Scoring Range: 5----------25

more positive----------more negative

With all of the expectations that assault our lives, we have no option — or so it seems — but to whittle away, a little more and a little more, at the time we have for rest, our free time, or the time we have to really carefully fashion something into a finished, complete project in which we can take real pride. We are continually frustrated by there not being enough time and feeling tired and worn out during much of the time that we do have.

All of our wiggle room is used up. We leave for meetings at the very last moment possible, depending on traffic to cooperate with our need to be somewhere across town by a certain time. We schedule last possible flights or close connections, depending on airlines to run on announced schedules so that we can make the pieces of our lives work. And, when the traffic slows toward gridlock or the planes are late, we find ourselves in fits of emotion that move from nervous anxiety to full-fledged rage. A significant fear that has asserted itself in modern life is the vulnerability we feel in the face of travel rage; road rage has become a penetrating symbol of our modern lives.

What we do to our health and well-being because of the stress of time, expectation, and general accumulating clutter is altogether frightening. Feeling like we will never get caught up can kill us. Thinking that we can perfectly

meet the expectations of everyone else and, therefore, becoming "Super-worker" or "Super-parent" can kill us.

The old axiom about the person who cannot manage time well cannot manage anything well, the ultimate test of our ability to cope becoming how we manage time, is exactly right. Managing time begins by making an absolutely uncompromising commitment to downtime that is built into every day, every week of our lives. Mark out downtime on schedules in the same way that you would schedule the most important appointment. Build in wiggle room. There are no compromises here. The compromises will be in personal health and relational health.

PART II/DOMAIN 4 HAVING TO BE IN CONTROL

YOUR SCORE FOR QUESTIONS 6, 16, 17, 19, 21

Scoring Range: 5----------25

more positive ---------- more negative

Believing that we have control is like sending a new, teenage driver out the door with the injunction, "Be careful," and thinking that simply because we have said the words the reality will happen. Perhaps the greatest myth of human life is the myth of control. Yet, we crave control, we convince ourselves that we must have it, and even become obsessive and compulsive in our drive to make sure that we possess it. The old phrase from the Beatles, "Let it be, let it be, let it be," is so far from the way we actually approach life that it is amazing; in our push for control, we can't leave anything alone, allowing it to find its own way—we micromanage everything and create situations of amazing stress and self-destruction in the process.

One of the most powerful ways that we try to exert control is in our unending pursuit of winning. We have created a culture in which winning is everything and coming in second conveys a personal weakness or lack of virtue. Everything becomes a contest, and someone who would attempt to kill a child's parent to distract that child from a cheerleader competition ceases to seem all that strange or outlandish. We become so caught up in being the best we can be that we distort reality and create a world of expectations that no one could accomplish.

Finally, we raise the ante on this whole issue of control by complicating life with over-personalizations that make no sense. We bring into play the phenomenon of bad luck; we feel like the fates are against us, or even that some metaphysical power has it in for us and has picked us out of the masses for some cruel temptation or test. Do our egos really believe that we are so much the focal point of creation?

The Janice Joplin/Kris Kristofferson song, "Me and Bobby McGee", has the line "Freedom's just another word for nothing left to lose" (Kristofferson, 1971). Maybe that is the key. Maybe it's okay to lose sometimes, to come in second, not to be in control. Maybe there is real freedom in consciously setting aside our need to be in control, to be right, to be No. 1.

PART II/DOMAIN 5 THE POWER OF THE PAST

YOUR SCORE FOR QUESTIONS 7, 8, 10, 11

Scoring Range: 4----------20

more positive----------more negative

We have all kinds of clichés: "Nothing is as old as yesterday's newspaper;" "It's over and done;" "What's done is done." Yet, few of these old sayings, as true as they are, really work for us. Instead, what took place yesterday, or years of yesterdays ago, can hold power in the present tense of our lives in astounding ways. Perhaps, it is we human beings and not elephants who are incapable of forgetting. The past can create a reign of terror in our lives.

We hold onto past events with a destructive passion. We clearly remember past mistakes and rehearse over and over again how we might have done something different or better. We place blame, hold grudges, say we can forgive but not forget, and simply add to our already overburdened lives realities that cannot be changed or altered no matter how much emotional energy we give to them.

A major part of authentic human maturity is the ability to write off those negative issues from the past. Sure, we can learn from them, but how often do they have to be in the forefront of our minds for the lesson to really take hold. Everyone has bad things that have happened to them. No one has perfect parents. No one's track record is without blemish. Okay. So, what else is new? Let's move on!

Some psychologists believe that people hold onto the past as a way of exerting additional punishment for some old mistake or lapse in judgment. We have not whipped ourselves enough, so we keeping bringing up the past painfulness. Or, we believe that someone else has not been punished enough, so we keep bringing up negatives from their lives. Do we not have anything better or more constructive to do with our time?

It is the present that is the only real possession of life that we have. To the extent that we find ways to focus

attention on the past or become obsessed with the future, we diminish and undermine the real time we do actually have. One of the greatest blessings of life is to forget, but we have to want to forget, to practice forgetting, and let the past go away.

Surface Electromyography in the Assessment and Treatment of Muscle Impairment Syndromes in Pain Management

Jeffrey R. Cram, Ph.D.

INTRODUCTION

Despite an extensive armamentarium of electrophysiological tools available practitioners in the field of pain management, many limitations exist. Without doubt, it is extremely difficult to evaluate patients suffering from pain using traditional electrophysiological technology. While surface electromyography is not a new technique, recent developments have shown it to be a valuable diagnostic tool and one that allows for the development of precise neuromuscular treatment protocols. The purpose of this chapter is to briefly review the limitations of traditional electrodiagnostic tools in pain management, while providing an overview of the role which surface electromyography (sEMG) can play in the assessment and treatment for muscle impairment syndromes. Specifically, seven muscle impairment syndromes will be reviewed, along with 15 sEMG retraining strategies that attempt to address neuromuscular contributions to chronic pain.

Despite major advances in the field of medicine, knowledge of the causes and mechanisms of pain continues to be limited. Because of the seemingly apparent subjectivity of the clinical evaluation, pain disorders are extremely difficult to document. In order to develop appropriate treatment methods, assessment protocols are necessary which can provide objectivity and reproducibility. Practitioners today are faced with many individuals suffering from a variety of ongoing refractory painful conditions. Utilizing traditional electrophysiological techniques, it can be impossible to quantify or to substantiate a patient's claim. Throughout this chapter, examples are provided that focus on specific applications of sEMG, thus giving considerable insights into the nature of a chronic pain disorder that entails muscle impairment as a component.

With the recent evolution of the understanding of pain, most clinicians believe that a person can truly suffer from a specific painful disorder without traditional objective correlation. In the past, it was believed that an individual was not truly experiencing pain if certain clinical criteria were not fulfilled. For the most part, this contention may have merit for acute pain syndromes. However, the experienced pain practitioner knows well that often one cannot depend purely on clinical acumen to establish an accurate diagnosis or to document or record the basis for a patient's complaint of chronic pain.

The medical practitioner, psychologist, physical and occupational therapist, or chiropractor who provides ongoing therapy is expected to substantiate the degree of patient improvement. Unfortunately, with many of the present-day technologies available, this can be impossible. The third-party payer or insurance carrier may discontinue or refuse to pay for further treatment based upon lack of substantiation of progress. In accordance with the rising costs of healthcare in the present economic climate, it is essential for third-party payers to limit unnecessary ongoing medical care. Without doubt,

0-8493-0926-3/02/$0.00+$1.50

this is a reasonable approach. Unfortunately, many honest patients continue to suffer from pain throughout their lives, because they had not received proper care for an unsubstantiated disorder that was thought to be a certain expression of malingering.

From a medical perspective, physicians have become dependent on neuroimaging studies, such as MRI scans, CT scans, or bone scans, as well as needle EMG (electromyography) or nerve conduction studies and EPs, evoked potentials. (See Table 47.1.) The clinical practitioner may not be aware of the precise applications and limitations of these studies in the context of attempting to establish the basis for a chronic pain disorder. The correlation between symptoms and neuroimaging findings is limited. It is sometimes believed that a normal needle electromyogram (EMG) may rule out the existence of a pain disorder. Based upon negative findings from these tests, the patient's complaints may be disregarded or assumed to be a product of deception. The pain sufferer, thereafter, is labeled a malingerer and is deprived of appropriate medical care. Of utmost concern is the fact that failure to establish a correct diagnosis at onset may lead not only to ongoing suffering but may also augment the overall cost of medical care. Often, the longer a pain syndrome is left untreated, the more refractory and difficult is the solution.

In the early years of medicine, medical practitioners depended on their primary senses to evaluate an individual and to provide an accurate diagnosis. As technology evolved, instrumentation was developed to enhance those senses. The stethoscope, although still used today as a diagnostic instrument, is known to have certain limitations that have been surpassed in an extraordinary manner by the use of echocardiography. Rather than simply auscultating the chest with a simple diaphragm and bell, computer technology utilizing an advanced electronic interface has provided exceptional insights into cardiac physiology. In a similar manner, physicians in many specialty fields have learned that their abilities to recognize disorders by pure physical examination are most certainly limited.

Surface electromyography can provide the information necessary to evaluate and follow pain sufferers with muscle impairments, as well as to establish selective treatment protocols in a scientific manner. It is well known that muscular tension maintains a substantial role in the development of the pain–spasm circuit, which can be treated using techniques of self-regulation in the form of biofeedback. Traditionally, biofeedback has been associated with relaxation training as a means to lower the emotional arousal component involved in pain. However, based upon limited knowledge of the precise muscles involved in given syndromes, coupled with the lack of generalization of relaxation-oriented protocols, the development of effective biofeedback-assisted relaxation treatment protocols has been limited. The development of "static muscle scanning" techniques in the 1980s (Cram & Steger, 1983) allowed the practitioner to precisely map areas of chronic asymmetric muscle tension, better describing one of the characteristic of the pain syndromes. In addition, studies of the recruitment patterns (amplitude and timing) of selected muscles may show asymmetries of muscle function among synergists and antagonists, providing a stronger description of how pain creates and is associated with disordered movement patterns. Both the static and dynamic sEMG findings can serve as landmarks for potential biofeedback-assisted relaxation or muscle retraining sites, thus enhancing the efficacy of these endeavors.

TABLE 47.1
Electrophysiological Applications in Pain Management

If the History and Physical Examination Suggest	Select
Local nerve injury Entrapment syndrome Neuropathy	Nerve conduction studies
Radiculopathy Plexopathy Myopathy Neuropathy	Needle electromyography
Central pain	Somatosensory-evoked potentials
Muscle injury Disuse syndrome Muscle spasm Myofascial syndrome Fibromyalgia Postural disorder Psychophysiological state	Surface electromyography

The scientific community has always maintained the responsibility for providing objectivity in its endeavors. The techniques available utilizing surface electrodes can truly improve understanding of the functioning of the muscular system in a precisely documentable and reproducible fashion. The use of objective measures of muscular function can provide insights and direction for the treatment of the many millions of patients with syndromes ranging from headaches and temporomandibular joint dysfunction to diffuse, poorly understood myofascial syndromes.

Clinicians in the pain management arena recognize that more individuals today are suffering from myofascial disorders than in the past. An enhanced understanding of these disorders can greatly reduce the performance of surgical procedures that have always been considered acceptable treatment alternatives despite relatively poor success rates. Without doubt, knowledge of these disorders, derived

through surface electromyographic studies, can enhance the quality of medical care and can provide important diagnostic insights for the development of improved treatment protocols. The morbidity associated with invasive treatment approaches can be avoided.

SURFACE ELECTROMYOGRAPHY

Surface electromyography was not developed as an alternative or substitute for needle electromyography studies. It is erroneously believed by some that surface electromyography is a simpler, faster, and more cost-effective alternative to the performance of needle EMG. This, in fact, is not the case. The two technologies differ considerably. Needle electromyography is a procedure characteristically performed by neurologists, physical medicine specialists, and certain physical therapists and chiropractors. The technique involves the placement of needles, either bipolar (with two electrodes) or monopolar (one electrode) into selected muscle regions for the recording of electrical data in a relatively narrow circumscribed area. These techniques have little applicability for pain management unless one is treating a radiculopathic, neuropathic, or myopathic disorder. The most common application for needle electromyography in pain management today is for the documentation or correlation of a suspected radiculopathy. The typical parameters a needle electromyographer studies are based upon characteristic electrophysiological potentials that are recorded at or about the immediate region of the needle tip.

Needle EMGs study the topology of a single motor unit, while sEMG studies populations of motor units. By studying the muscular energy at this grosser level, the practitioner may begin to see the contributions and perpetrating factors in chronic pain through the quantification of muscle spasm, objective analysis of posture, assessment of emotional contributions, and the identification of faulty motor schemas and imbalances which become involved in the perpetuation of the disorder.

The clinical use of sEMG in the assessment of pain-related disorders was originally introduced by Edmund Jacobson in the 1930 as he began to study the effect of imagination on a variety of muscles. Janet Price in 1948 utilized multisite recording procedures and noted that muscle bracing patterns associated with chronic pain seemed to be asymmetrical, and eventually migrated to areas other than those of the original site of pain. Later, George Whatmore (1974), one of the students of Edmund Jacobson, saw disease as resulting from "dysponesis" or inappropriate muscular efforts. He conceptualized EMG activation patterns from the point of view of excessive bracing, the overrepresentation of emotional events, inefficient movements, or inappropriate attentional efforts. Wolf and Basmajian (1978) were one of the first teams to document a specific neuromuscular deficit in low back pain patients. Here, they noted the lack of excitation relaxation response in the erector spinae muscles of back pain patients. More recently, the work of DeLuca and his colleagues (1984) has focused on changes in the energy spectrum of the muscles in back pain patients. Using spectral technique, they have noted that these individuals tend to demonstrate a higher level of muscle fatigue compared to normals.

Surface EMG represents the summation of all of the alpha motor unit activity that reaches the recording electrodes. Typically, the electrodes are placed close together and the recording area is relatively small and specific. Rather than considering these recordings as representing innervations from specific nerve roots, it is more appropriate to think of this activity in terms of motor or muscle function. Such function is organized at multiple levels, including a segmental level.

Also, one should consider the dynamic interplay between the excitation associated with muscle spindle activity vs. the inhibitory influences of the golgi tendon organ. The gamma motor system modulates much of the sensitivity of this interaction and is partially regulated by the cerebellum. It also is excited by nocioception. These afferent fibers give rise to an excitatory push on the gamma motor system, providing the basis for "muscle splinting" around the injured area or joint. This also may modulate posture, potentially leading to learned alpha and gamma motor behavior and antalgic postures. If this postural adjustment is maintained over an extended period of time, trigger points as well as changes in the resting lengths of muscles will ensue. The patient will eventually learn to move differently, usually restricting his or her movement, while substituting inappropriate muscle groups (Lewit, 1985). Last, the pain patient may experience changes in emotional tone associated with pain. Recent evidence (McNutty et al. 1994) has demonstrated that the muscle spindle is activated by ANS activity associated with stress. Fear of pain may increase the resting tone in the muscle due to increased sympathetic tone. In addition, the patient may become anxious about his or her pain, and avoidant behavior patterns may develop. Problems of learned disuse of injured muscles or muscles associated with an injured or fixated joint may need to be addressed. All of the above-described changes in muscle function associated with pain can be documented using surface electromyographic techniques.

While needle EMG studies are very specific, it is now known that the recordings from one motor unit within a muscle are not a valid or general indicator of the status of the muscle itself. Thus, it is very difficult to accurately and reliably assess muscle function using needle EMG recording techniques. On the other hand, surface EMG seems to suffer from a lack of specificity to the precise motor units contributing to the recording.

This volume-conducted sEMG activity from distant muscles is thought to contaminate our confidence in the surface EMG recording.

However, careful placement of closely spaced electrodes, along with close observation of movement patterns associated with the EMG activity, can shed light on the source of the EMG signal. Specific isolated muscle testing may also clarify which muscles are contributing to the surface EMG recording.

An additional problem encountered in surface EMG is that of adipose tissue. The thickness of the adipose tissue may account for alterations of up to 20% of the EMG signal in the resting muscle and 15% in an active muscle. Careful assessment of skinfold thickness at the recording site to help quantify this factor should become part of the standard clinical procedure associated with surface EMG.

One should think of surface EMG as a gross motor rather than a fine motor assessment. Static assessments focus upon patterns of (antalgic) posture, while dynamic, movement-oriented sEMG evaluations explore the general firing patterns at the site(s) of the recording electrodes. Dynamic assessments can be performed to evaluate the neuromuscular system for synergy patterns, co-contractions, asymmetries, irritability, flexion–relaxation, muscle fatigue, faulty motor schemas, and associated emotional responses.

Finally, from an instrumentation point of view, the sEMG signal is processed using a differential amplifier. Only energy is unique to each recording electrode site is passed on for amplification, while all common energy (i.e., 60 Hz noise) is rejected. A bandpass filter is utilized to define the energy spectrum of interest. This commonly falls between 15 and 1000 Hz. It is important to note that the major portion of the EMG spectrum is below 80 Hz, and 97% of the signal lies between 5 and 500 Hz. Some commercial EMG biofeedback instruments utilize a very narrow 100- to 200-Hz filter. These filters were designed to facilitate clean, noiseless recordings, avoiding 60-Hz external interference and the biological artifacts of the heart. Bandpass filter considerations are of particular importance in the study of pain-related disorders because chronically fatigued muscles, such as those seen in chronic pain patients, tend to show a preponderance of low frequency signals. The very narrow bandpass 100- to 200-Hz filter would produce an underestimate of the actual level of muscle activity in these patients. In static evaluation procedures (muscle scanning), a narrow filter has been noted to lead to false negative conclusions (Cram, 1990).

Surface EMG Assessments of Muscle Impairment Syndromes

The concepts presented below may be studied in greater depth in *Clinical Applications in Surface EMG* by Kasman, Cram, and Wolf (1998). The seven clinical frameworks presented in Figure 47.1 all feed into a self-per-

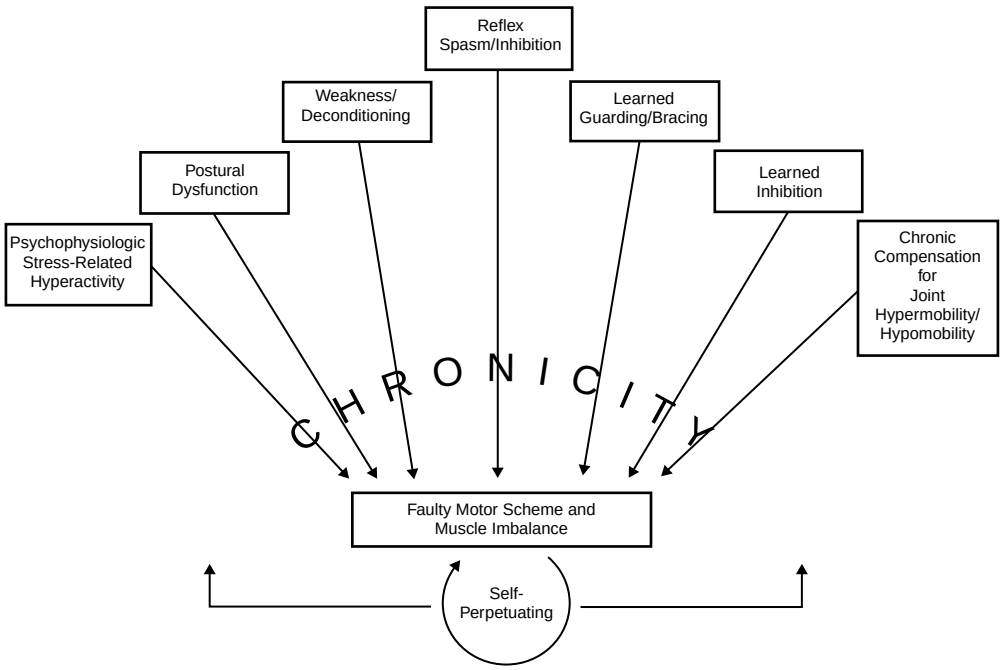

FIGURE 47.1 Factors contributing to the development of fault motor schema and muscle imbalances. (From Kasman, Cram, et al., *Clinical Applications in Surface EMG*, Gaithersburg, MD: Aspen Publishers, 1998. With permission.)

petuating faulty motor schema. And, just like elevations in blood pressure do not suggest the origin or etiology of the problem, alterations in sEMG activity need to be understood in a broader context. This chapter explores the possible contribution of each of the seven muscle impairment syndromes.

Elevation in sEMG Due to	Type of Impairment Syndrome
Phobic responses to stairs	Psychophysiological stress
Head forward position	Postural dysfunction
Fear of movement	Learned guarding
Herniated cervical discs	Reflex spasm
Facet blocks	Hypermobility of the cervical joints
Tightness of the upper trapezius relative to lower trapezius	Muscle imbalances

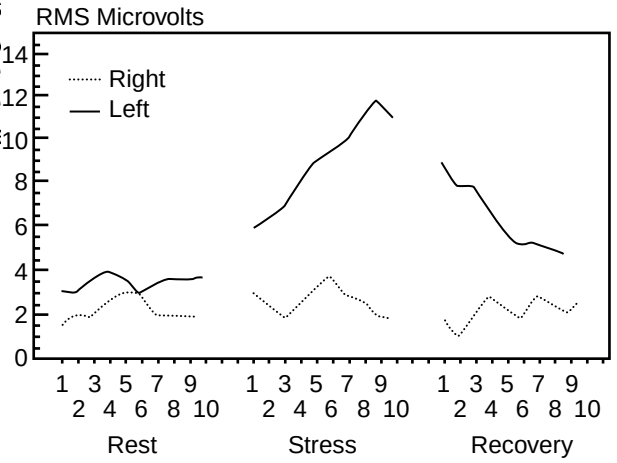

FIGURE 47.2 Stress response pattern in right upper trapezius. Note how the left aspect reacts to the stressor.

As an example, consider elevations in sEMG levels at rest in the upper trapezius of a patient after a fall down some stairs 6 months prior. These elevations may be due to one or more of the following elements:

Because the clinical syndromes presented here are not mutually exclusive, patients may exhibit qualities of one or more of the syndromes. But, once the etiology is better understood, sEMG retraining procedures (biofeedback) may become one of the treatment elements, one which may help restore the normal motor program that has been altered.

Muscle Impairment Syndrome 1: The Role of Psychophysiological, Stress-Related Hyperactivity

Here, sEMG activity at rest or during movement is elevated either due to general maladaptive coping to stressful situations or a conditioned emotional response to a traumatic event (Post-Traumatic Stress Syndrome).

For example, a patient 4 weeks post motor vehicle accident (MVA) who sustained a flexion extension injury to the neck and shoulder region provides a convenient example. Due to the emotional feature (PTSD) associated with the accident, traditional medical and physical therapies offered to the patient do not produce long-term gains. Clinically, a stress-profiling procedure may be conducted in which the offending muscle is monitored during a baseline recording (Figure 47.2), followed by a period of time in which the patient recalls in detail the events of the MVA. Changes in sEMG recruitment patterns noted during recall of the MVA scene (dysponesis, to use Whatmore's term) provide evidence as to this emotional component.

Once identified, a combination of sEMG "downtraining" and psychological therapy to treat the post-traumatic stress disorder should precede the more physically based therapeutic regimes. Such an approach would enhance the efficient use of clinical time and would greatly facilitate the clinical outcome.

Muscle Impairment Syndrome Type 2: Simple Postural Dysfunction

Here, aberrant motor activity is shown to be a direct function of posture. An example of head posture may be seen in Figure 47.3. The increased paraspinal muscle activity seen in this tracing is reduced as the head is moved from a head forward position to one in which the head is well positioned over its center of gravity. The initial sEMG elevation is associated with a head-forward position and is likely due to the increased load placed on the muscles due to the head being forward of its center of gravity. This increased load would also place untoward loading of the articular structures and chronically place the ligaments on stretch.

According to McKenzie (1981), this chronic physical stress on the soft tissue creates the foundations for pain. In addition, muscle length–tension relationships become inefficient. As the load moments are increased by lengthening the lever arm through which gravity acts, the normal force couples are disrupted and some muscles may recruit at an increased level, while the antagonists takes on a lesser role.

A typical clinical example would be a patient with headache and tension myalgia of the upper quarter and neck associated with work as a keyboard entry person. A postural examination of the patient showed that the patient sits with a head-forward position and with the arms extended slightly while typing. Retraining the patient to type with her head aligned over the spine, and with the elbows closer to her torso resulted in lower sEMG levels and, thus, less tension myalgia.

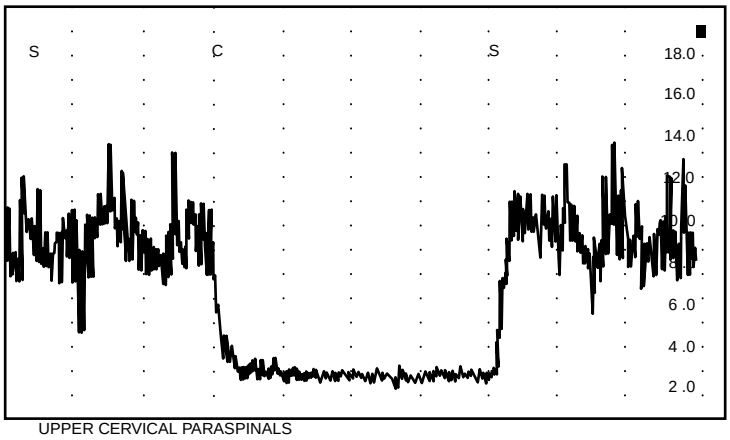

FIGURE 47.3 sEMG activity of the upper cervical paraspinal muscle recorded during a spontaneous forward head posture (S) and corrected postural alignment (C). (From Kasman, et al., Clinical Applications in Surface EMG, Gaithersburg, MD: Aspen Publishers, 1998. With permission.)

Muscle Impairment Syndrome Type 3: Weakness and Deconditioning

While muscle weakness may be associated with radiculopathies, plexopathies, neuropathies, or myopathies, the weakness/deconditioning syndrome referred to here involves simple muscle disuse due to immobilization after injury or surgery, or as the cumulative effect of poor motor habits and decreased activity. The condition may include atrophic loss of muscle cross-sectional area, inefficient vascularization, and compromised biochemical and physiological function (Davies & Sargent, 1975). There also may be a change or diminution in neural drive which accompanies changes in muscle tissue. The patterns of dysponetic sEMG activity may include decrements in peak torque, power output (i.e., inability to sustain force through ROM arcs), and impaired fatigue resistance.

Consider the case of a patient who has had his knee immobilized and weight-bearing restricted for 6 weeks after sustaining a leg fracture. The quadriceps will undergo disuse atrophy during the period of immobilization. Range of motion, strength, endurance, and functional mobility become impaired during the rehabilitation period. When the knee patient is cleared for active strengthening and is examined, obvious findings of weakness and deconditioning on the involved side are noted during physical examination. With sEMG monitoring, the quadriceps sEMG activity will differ between the involved and uninvolved lower extremities, with maximal effort sEMG activity decreased on the involved side. However, one should be aware that submaximal contractions may show increased activity on the involved side, presumably reflecting decreased neuromuscular efficiency. SEMG biofeedback training could be utilized to enhance the strengthening of the involved side.

Dysfunction Type 4: Acute Reflexive Spasm and Inhibition

Spasm is defined as an involuntary hypertonicity induced by the spinal reflex system (Kraus, 1988). Spasm is commonly triggered by noxious mechanical or chemical stimulation of the pain receptors within the muscle or the associated joint. Inhibition is a neurological suppression of muscle activity induced by pain and/or effusion (deAndrade, et al., 1965). It is driven, in part, by the golgi tendon organ and designed to protect the tendonous attachments and the joint.

Take an example of a low back pain patient with a bulging or herniated disc with pain in the right aspect of the low back, radiating down into the right hip and leg. A back patient with a known bulging or herniated disc has decreased range of motion of the torso and poor sitting tolerance. The patient might present with a flexed and laterally shifted trunk posture, and visibly and palpably elevated lumbar paraspinal tone. Pain is on the same side as the bulging disc. The pain is increased with sitting (supported or not), and the sEMG activation level also increases. Any movements, active or passive, of the lower extremity lead to an activation of the right erector spinae muscles. The pattern of spasm/activation during rest in the seated posture may be easily seen in Table 47.2, recorded in the "muscle scanning" procedure developed by Cram (1990).

An example of acute reflexive inhibition might be seen in a patient with a recent history of trauma and physical examination findings of swelling, tenderness, and inability to tolerate vigorous manual muscle testing of the lower extremity. sEMG monitoring would show a discrete focal drop in sEMG amplitude recorded from the quadriceps during a painful portion of the knee range of motion arc. The focal drop in sEMG activity in this case would be a consequence of neurophysiologic inhibition.

TABLE 47.2
Reflexive Muscle Spasm as Noted in a Muscle Scanning Protocol on a Low Back Pain Patient with Herniated Disk

	Sit		Stand	
Muscle Site	Left	Right	Left	Stand
Cervical	1.2	1.5	1.5	1.7
Trapezius	2.2	3.3	3.2	3.5
T1 Paraspinals	1.2	1.3	1.2	1.2

Abdominals	1.3	1.5	1.6	1.8

Note: The patient's pain is perceived on the left side of the back and hip.

* Indicates values are outside the normal and expected limits. (From Cram and Engstrom, 1986, Clinical Biofeedback and Health, 9(2), 106–116. With permission.)
(From Cram, J.R. (Ed.), 1990, Clinical EMG for Surface Recording, Nevada City, CA: Clinical Resources. With permission.)

Muscle Impairment Syndrome Type 5: Learned Guarding or Bracing

This pattern of neuromuscular activity differs from the reflex spasm model in that the pattern of muscle activity is learned or operantly conditioned rather than being strictly mandated by a reflex. The heightened muscle activity usually occurs upon movement or postural loading and is done in an attempt to avoid pain and the possibility of further injury. The activation pattern is seen on the side opposite the pain (contralateral) as the patient exhibits a learned disuse and inhibition of the painful side and a hyperactivity of the nonpainful side. This is one of the features which differentiates protective guarding from splinting or reflex spasm.

Consider the pattern of muscle activity for a patient with low back pain shown in Table 47.3. These sEMG data were collected done using the muscle scanning procedure mentioned above, in which the right and left aspects of multiple muscle groups were quickly sampled in the seated and standing postures. The patient has left-sided back pain which radiated down into the left hip and leg. Disc herniation is known not to exist. The pattern of activity shows increased sEMG activation on the side opposite of the pain, suggesting a protective guarding pattern. Here, the patient has learned to weight shift away from the pain (antalgic posture).

Muscle Impairment Syndrome Type 6: Learned Inhibition and Weakness

This syndrome is similar to the protective guarding and bracing model presented above. It differs in that it focuses on the "inhibition" side of the perspective. It is not uncommon, for example, for patients to learn not to move an injured or painful site. The less they move the muscle or joint, the less pain they feel. And through an operant process of negative reinforcement, they learn disuse. It is actually quite common in a unilateral neck/shoulder injury to see the injured side have normal resting tone while the uninvolved side is hyperactive at rest (protective guarding). But when the shoulders are elevated, for example, the injured side shows a hypoactive recruitment pattern, not reaching the same level of activation as the uninvolved side. It is this hypoactivity during strong recruitment that is referred to here as learned inhibition.

Here is another example. An otherwise healthy patient sustains recurrent strains of the hip adductor muscles while playing racquetball. The pain becomes severe and exacerbated whenever the adductor muscles vigorously contract during functional activities. To avoid the contraction-induced pain, the patient learns to reduce firing of the adductors while performing stressful physical activities. Over a period of time the altered patterns become unconsciously incorporated into the patient's selection of motor programs. Interestingly enough, the adductor sEMG amplitude of this patient appears symmetrical on both the involved and uninvolved side during walking and low level activities. In fact, when the patient is subjected to an unanticipated postural perturbation, the adductors are noted to recruit normally. The muscles are normally

recruited with postural reactions to help prevent a fall. However, during higher velocity and loading conditions such as sustained unilateral stance, lunging, or forma manual muscle testing, activity on the involved side appears to be markedly decreased and impaired.

Muscle Impairment Syndrome Type 7: Direct Compensation for Joint Hypermobility or Hypomobility

In this syndrome, the neuromuscular system compensat by attempting to stabilize lax joint structures, by affecting movement against joint stiffness, or by subserving linkec compensatory movements over kinetic chains (Hertling and Kessler, 1990). Although sEMG activity is aberrant, the primary problem is a biomechanical articular fault. The articular fault is causal to a compensatory motor control pattern, which may spontaneously resolve upon improvement in joint mechanics. Chronic joint dysfunction may lead to motor control problems that, themselves, contribute to deterioration of the kinetic segment and persist even after joint mobility improves. The distinction is made because if aberrant motor activity is felt to be directly compensatory to articular dysfunction, then biofeedback is not a first choice of treatment. The joint dysfunction should be addressed and then sEMG activity re-assessed.

An example of this may be seen in Figure 47.4. Here, a patient with jaw pain is found on physical examination to display hypomobility at the left temporomandibular joint (TMJ). There is a deviation of the midline of the jaw during opening and closing, and a palpable difference between the motions of the left and right mandibular condyles. As opening is initiated (or closing completed), the condyles are felt to spin in place. The condyles are then felt to translate forward as opening continues. This rolling/gliding relationship is necessary for normal jaw range of motion and is expected to be symmetrical at the left and right TMJs. In our case example, sEMG activity shows greater recruitment at the right masseter during jaw opening/closing range of motion. In this case, the right mandibular condyle translates a greater distance along the articular surface of the zygomatic process. The right masseter is activated to a greater degree to subserve the greater range of movement than the right TMJ. The fundamental problem, however, is not one of the right greater than left masseter sEMG activity, but one of the left less than right joint mobility. sEMG spontaneously becomes symmetrical once the left TMJ is mobilized with manual techniques or exercises.

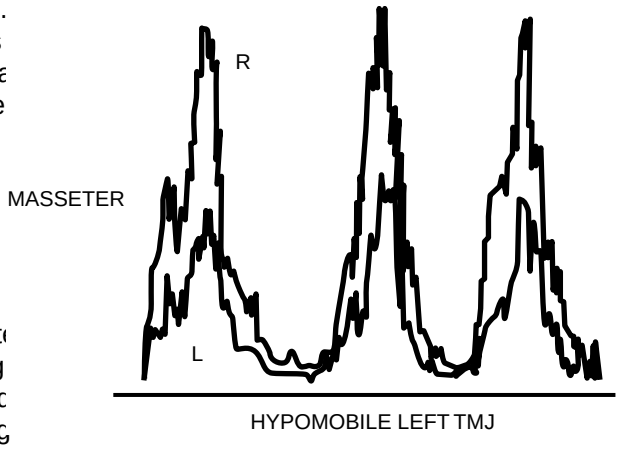

FIGURE 47.4 sEMG activity of the left (L) and right (R) masseter muscles recorded from a patient with left TMJ pain durig three repetitions of jaw opening and closing. Decreased left-side muscle activity was associated with hypomobility of the left joint. (From Kasman, et al, Clinical Applications in Surface EMG, Gaithersburg, MD: Aspen Publishers, 1998. With permission.)

The Final Common Pathway: Chronic Faulty Motor Programs

The final syndrome is an amalgamation and a perpetuation of all of the above syndromes. Here, we assume that the central nervous system learns to cope with pain, muscle weakness, joint instabilities, trigger points, myofascial extensibility issues, etc. As a result of this, there is a learned disruption of the normal agonist–antagonist–synergist relationships. The assessment (and treatment) of this broad syndrome requires sEMG monitoring along with assessment of coincident joint segment dysfunction, soft tissue dysfunction, and behavioral analysis.

Consider Figure 47.5. Here, a patient with chronic cervical paraspinal and suprascapular pain is examined. Motion takes place throughout the shoulder girdle to elevate the arms to the side (abduction). This includes upward rotation of the scapula, achieved by the coordinated actions of the upper trapezius, the lower trapezius, the lower fibers of the serratus anterior, and numerous other muscles with direct and indirect stabilizing roles. A motor program is a planned set of commands from the central nervous system that serves to coordinate the actions of muscles so that a specific goal is achieved, in this case shoulder abduction.

If an inefficient motor program is selected, then one muscle might contract with excessive or reduced tension relative to its synergist, resulting in abnormal loading patterns of both myofascial and articular tissue. With our patient example, it is observed that the sEMG activity of the upper trapezius is considered hyperactive, whereas the activity of the lower trapezius is inhibited. In addition, the patient has a poor ability to recognize these patterns of activation and tension and is unable to voluntarily activate the lower trapezius. Biofeedback may be used to re-educate the patient about his muscle function, and to develop a more appropriate motor program, one which includes the scapular stabilizers (lower trapezius) in arm movement patterns.

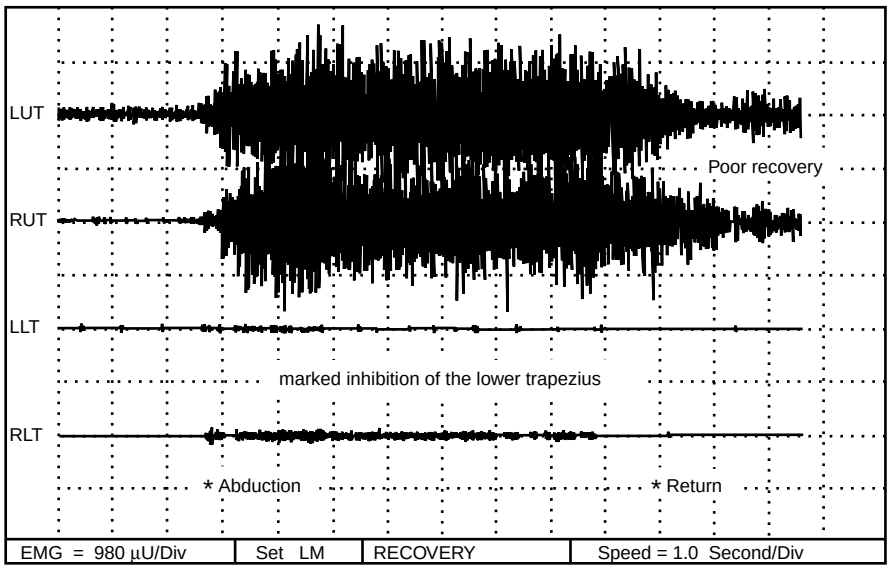

FIGURE 47.5 A grossly abnormal recording of the relations between upper and lower trapezius during abduction to 90°, in which the upper trapezius dominated over lower trapezius. (From Cram, J.R. and Kasman, G.S., *Introduction to Surface EMG*, Gaithersburg, MD: Aspen Publishers, 1990. With permission.)

sEMG RETRAINING AND BIOFEEDBACK TECHNIQUES

Once you understand how potential muscle impairment syndromes may be assessed using sEMG biofeedback techniques, it is useful to consider how the sEMG instrument may be used to treat these disorders. sEMG retraining or biofeedback techniques roughly fall into three clinical entities: downtraining (systemic relaxation), uptraining, and coordination training.

In the broadest sense, downtraining techniques are used to facilitate a reduction in muscles that are overactive. As noted above, they may be overactive for many reasons. If the etiology includes an element of emotions, then the downtraining usually falls under the rubric of systemic relaxation. But please note that some postural training procedures utilize downtraining, as do some ergonomic applications. Ettare and Ettare (1990), for example, have documented the benefits of a dynamic relaxation in which they teach patients to quiet their muscles quickly after every use.

Uptraining is actually easier to teach than downtraining, primarily because the patient is being asked to do something, to learn how to turn on or isolate a particular muscle or muscle group. This type of training is commonly done when working with inhibited muscles, or muscles weakened due to disuse or injury.

Coordination training is considered an advanced level of training and usually follows successful up- or downtraining. It entails trying to teach the patient how to obtain the correct balance of agonists/antagonists. This is more difficult because the cooperation of muscles may involve all three domains of posture, movement, and emotions.

Below, I describe some of the more common sEMG biofeedback procedures. Further examples and explanations of these biofeedback strategies can be found in Kasman, et al. (1998) *Clinical Applications for Surface EMG*, as well as Cram and Kasman (1998) *Introduction to Surface EMG*.

Training Technique 1: Isolation of Target Muscle Activity

Most sEMG biofeedback training strategies begin with assisting the patient to locate, proprioceptively, the dysfunctional muscle. The goal, here, is to learn to isolate it from other muscles. This means learning to contract it alone, and not in concert with surrounding or synergistic muscles. Visual feedback using time series displays of either a raw or processed sEMG signal is usually used to guide the patient's efforts. Figure 47.6 shows an example of training a patient to selectively contract the left lower trapezius (LLT) without creating a co-contraction in the right lower trapezius. As can be seen, the first four contractions are effective, but the fifth one begins to overgeneralize to the contralateral muscle. Through successive training attempts, the patient is taught to produce more and more effort to activate the muscle of interest, while simultaneously inhibiting associated or surrounding muscles. This task may involve open isometric contractions, resisted isometric contractions, open movement, and postural adjustments. After the patient has learned to isolate a particular muscle, then isolation training would proceed to other muscles. In the above example, once the left lower trapezius had been isolated, then the right lower trapezius would be attempted, followed by the left upper trapezius

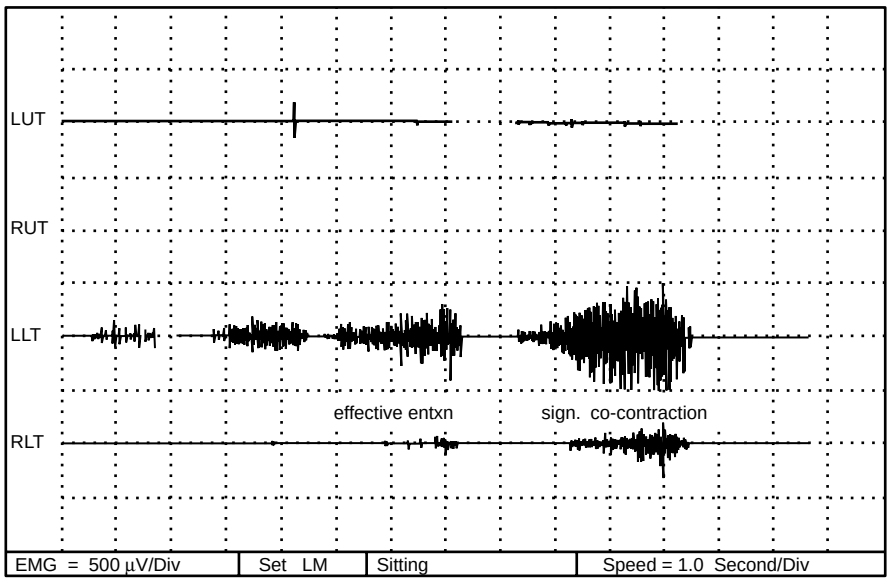

FIGURE 47.6 Isolated training example. Surface EMG recording from the right and left upper and lower trapezius during increasing efforts to recruit and isolate the left lower trapezius. Note that by the fourth attempted recruitment, the patient begins to contract the right lower trapezius along with the left. (From J.R. Cram and G.S. Kasman, *Introduction to Surface EMG*, Gaithersburg, MD: Aspen Publishers, 1990. With permission.)

and finally the right upper trapezius. After isolation is possible, then more advanced coordination training strategies may be employed.

Training Technique 2: Relaxation-Based Downtraining

Historically, sEMG biofeedback training was primarily used to assist in the cultivation of low arousal and relaxation (Basmajian, 1989; Gaarder and Montgomery (1977); Schwartz, 1995). Here, sEMG biofeedback is used primarily to treat the emotional layer of neuromuscular dysfunction. In general, the strategy is to use a general or systemic relaxation technique which is assisted by sEMG biofeedback. The feedback, then, is used to guide the success of the relaxation technique. Usually, broad regions or muscles involved in emotional displays (i.e., widely spaced frontal or trapezius placements) are monitored. Such placements take advantage of volume-conducted sEMG activity. However, it is not uncommon also to monitor the injured site and to assess and treat the emotional aspects of trauma. Patients are commonly provided with auditory feedback so that they can close their eyes during the relaxation procedure. Like a beacon, the tone is used to guide them to a more relaxed state on a moment to moment basis. In addition, a time series graph display, usually with a very long sweep time, may be used to see how the relaxation technique has worked over time. The goal is to see a general diminution of resting tone as the patient relaxes.

The selection of the specific relaxation technique depends upon the practitioner's training and the patient's tendencies. A patient who understands best the physical, concrete world might enjoy the systematic exploration of relaxation using "Progressive Relaxation" introduced by Edmund Jacobson (1976). Here, the patient is taught to tense and release muscles using a systematic step by step, muscle by muscle process. A patient who is more interested in how the mind affects the body might better enjoy an "Autogenics Training" program developed by Luthe (1969). Here, the patient is taught a series of very specific phrases or formulas to repeat. The autogenic phrases have been extensively studied and are known to specifically alter physiological functions. Or, a patient whose strongest attribute is visual representation might best enjoy a guided imagery such as those suggested in the writings of Peper and Holt (1993). Here, patients are asked to close their eyes and the therapist guides them through a relaxing experience, such as laying on the beach on a sunny day soaking in the warmth of the sun and the sand.

Training Technique 3: Threshold-Based Uptraining or Downtraining

Threshold-oriented sEMG biofeedback training utilizes a goal attainment model of training. This technique may be used to teach the patient to either turn on or off a particular muscle or general region. Here, the patient is presented with a highly smoothed and processed sEMG signal along with a visual and/or auditory marker set by the therapist. The marker or threshold is either a colorful line strategically placed within the time series scroll, or

an audio event (midi-tone or music), which is turned on or off when the patient meets the specified microvolt level or threshold.

The patient is instructed and shown strategies on how to exceed or fall below this marker. If the patient succeeds in his or her attempts to meet or exceed the threshold, the audio event is played, or the color of the sEMG tracing changes, or the therapist who is attending the training says "good" to reinforce the performance. Once the patient can meet or exceed the criterion set by the therapist 80 to 90% of the time, the therapist raises the threshold in the case of uptraining so that the patient must go to an even higher level of sEMG activity to obtain the threshold-oriented feedback reward. The opposite would be true, of course, for a downtraining protocol. If the patient is having a difficult time meeting the threshold at least 50% of the time, the therapist would change the threshold to afford a higher level of success.

This technique is well steeped in operant or behavioral psychology techniques. The threshold is systematically set and changed to shape and reinforce the patient's sEMG activity to the desired levels. Many computer-based biofeedback systems have been programmed to do this shaping strategy automatically.

Training Technique 4: Threshold-Based Tension Recognition Training

Threshold markers may be used in a variety of ways to shape desired sEMG behaviors. One of these behaviors is the ability to accurately perceive how tense or active the patient's muscle really is. As it turns out, chronic pain patients who have problems with muscle-oriented pain and tension, commonly have lost touch with the proprioceptive nature of what muscle tension feels like. In other words, they commonly don't know what normal feels like, or whether or not a muscle is tense.

The tension recognition technique differs from the uptraining and downtraining approach in that the threshold line now represents the targeted level of sEMG activity the patient is trying to match, rather than the point to exceed or fall below. Here, the patient is systematically trained to go to 5 microvolts, say, over and over and over again. The goal is to train the patient to know proprioceptively where 5 microvolts are from various resting levels and in a variety of postures. Such threshold training is thought to act like an anchor, allowing the patient to more accurately perceive whether his or her muscle activity is elevated above or relaxed below this threshold. Such sensory-based discrimination is very powerful. In one study on headaches (Cram, 1980), such a discrimination training approach was demonstrated to promoted longer-term therapeutic gains than did the downtraining or general relaxation approach described above.

Training Technique 6: Tension Discrimination Training

This procedure is a more advanced form of the threshold-based tension recognition training procedure. It differs only in that the patient is trained to discriminate multiple levels of sEMG activity rather than one. Figure 47.7 demonstrates the use of a visual template in the form of a staircase. Here, the patient is trained using a step template to systematically recognize five equally graded steps of sEMG activity. From a systems model, such

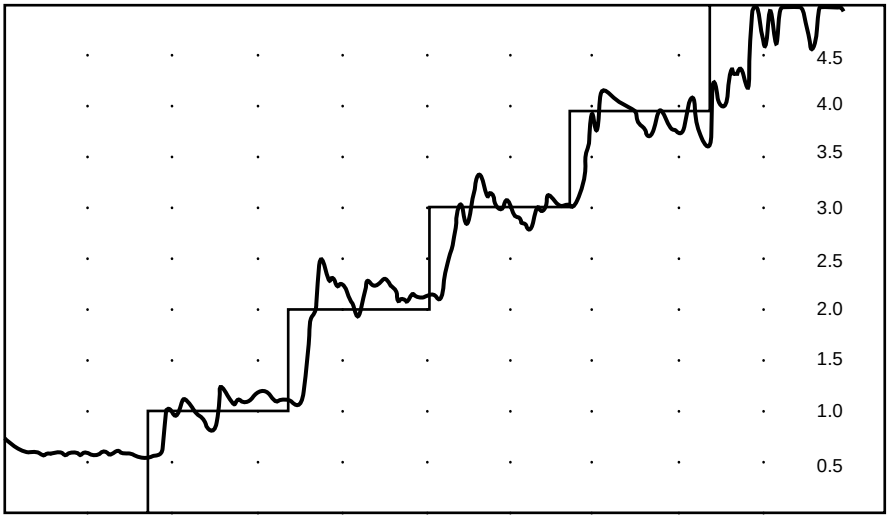

FIGURE 47.7 Tension discrimination training with the use of sEMG feedback from the upper trapezius, with an increase in task complexity from the single threshold model. The "staircase" template shown here is overlaid onto the graphic display. The patient is instructed to match the template as closely as possible. (From Kasman, G. S., Clinical Applications in Surface EMG, Gaithersburg, MD: Aspen Publishers, 1998. With permission.)

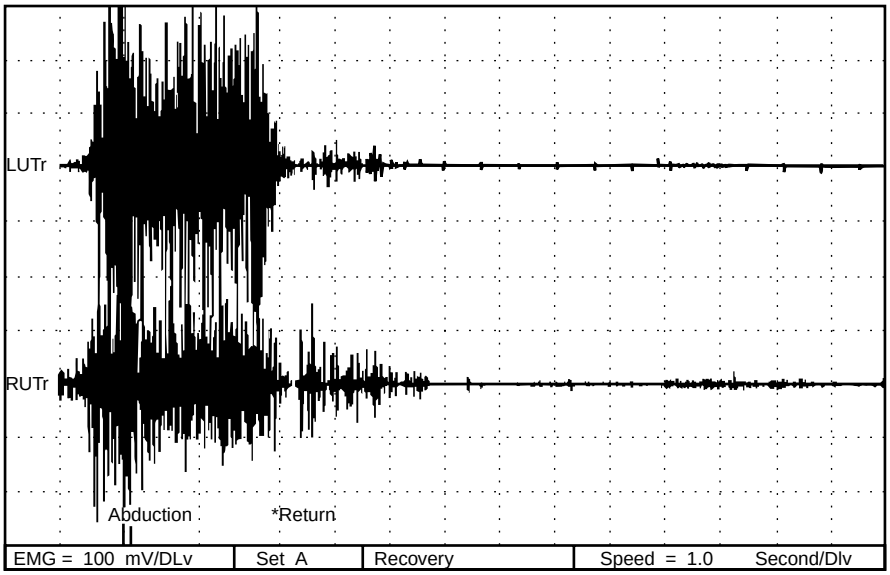

FIGURE 47.8 Surface EMG recording from upper trapezius during abduction of the arm to 90° and return. Note the presence of activity for 2 seconds following the return of the arm to the side. (From Cram and Kasman, Introduction to Surface EMG, Gaithersburg, MD: Aspen Publishers, 1990. With permission.)

proprioceptive knowledge of different levels of sEMG activity should allow the muscle to be regulated over a wider range of amplitudes.

Training Technique 7: Deactivation Training

Deactivation training is basic to all sEMG training procedures. In essence, it trains the patient to turn off the sEMG activity following activation. Figure 47.8 show a time series graph in which the patient exhibits spontaneous sEMG discharge for two seconds following the cessation of a movement. Figure 47.9 shows how the patient was trained using visually guided feedback to turn off the post-movement discharge immediately following the cessation of the movement.

As is well known, many repetitive strain disorders (RSI) are due to overuse. But what probably is not realized is that overuse is amplified by not letting the muscles rest between repetitions. Teaching a patient to turn off the muscle after each and every use has been found to be an effective method

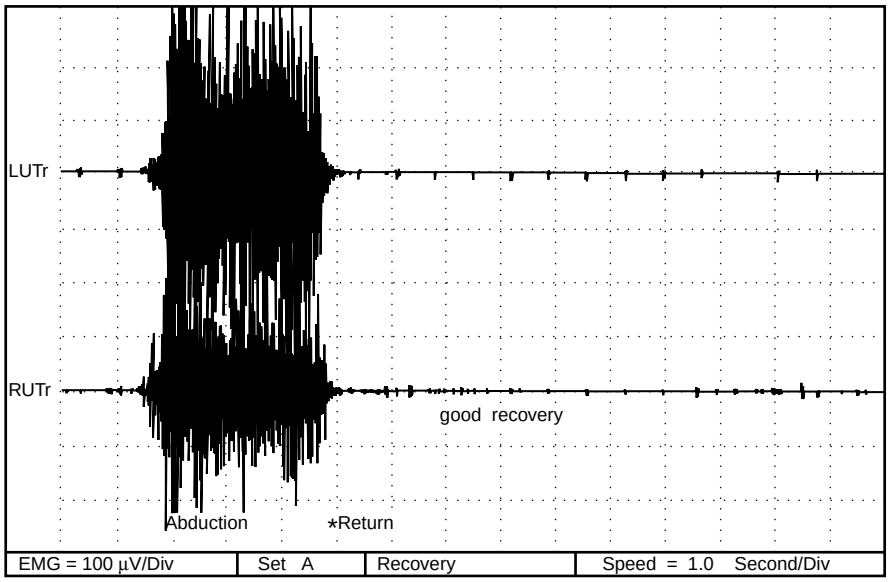

FIGURE 47.9 Surface EMG recording from upper trapezius during abduction of the arm to 90° and return. Here, the patient has been trained to quiet the muscles as quickly as possible following the cessation of movement. (From J.R. Cram and G.S. Kasman, Introduction to Surface EMG, Gaithersburg, MD: Aspen Publishers, 1990. With permission.)

for treating RSI. For a broader discussion of this type of procedure in clinical see Ettare and Ettare (1990).

Training Technique 8: Generalization to Progressively Dynamic Movement

Training in muscle control procedures usually begins in a static state. Isometric contractions are easier to produce and replicate than fully dynamic ones. But once they have been mastered, it is important to attempt to generalize them. This generalization typically involves larger and larger contractions, and faster and faster movements.

Training Technique 9: sEMG-Triggered Neuromuscular Electrical Stimulation (NMES)

This is a very sophisticated and powerful procedure which involves not only an sEMG instrument to monitor the electrical activity of the muscle, but also a microcurrent device to activate the muscle indirectly through the stimulation of the peripheral motor nerves (Baker, 1991). The procedure is very similar to the threshold-based uptraining one. The only difference is that when the patient reaches a predetermined (threshold) level of activity, the stimulation device is activated and full muscle recruitment is thereby electrically mandated. Usually this technique is used in very weak muscles. The threshold is initially set at a level which the patient can easily reach, but which is nonfunctional. When that threshold is met, a fully functional muscle contraction is created with the microcurrent device. Figure 47.10 shows an example of NMES training of the quadriceps muscle.

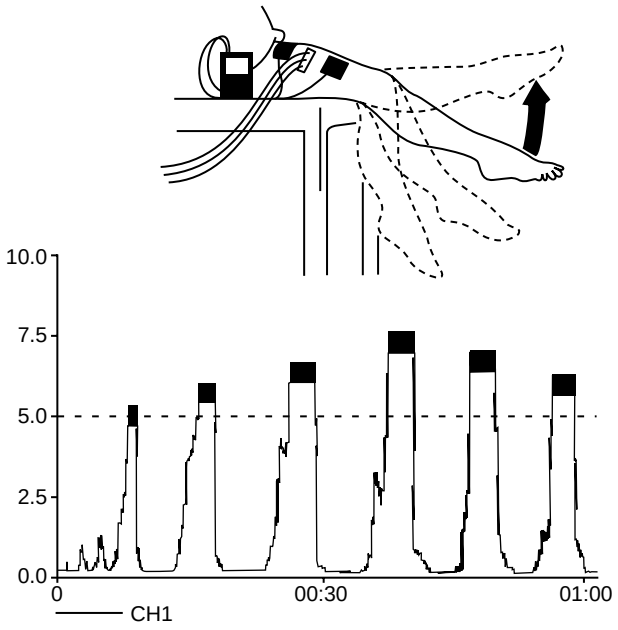

FIGURE 47.10 Standard sEMG-triggered NMES setup. EMG electrodes detect a voltage sum derived from muscle action potentials. The EMG signal is processed in a routine manner, and when the display magnitude exceeds a predetermined value, a relay causes a neuromuscular electrical stimulator to deliver current to the same muscle. The EMG display is nullified during the electrical stimulation because the device would record voltage associated with injection of artifact current, masking the small muscle action potentials. (From Kasman et al., Clinical Applications in Surface EMG, Gaithersburg, MD: Aspen Publishers, 1998. With permission.)

Training Technique 10: Left/Right Equilibration Training

Equilibration training is performed when the left and right aspects of homologous muscle pairs are observed to recruit in an asymmetrical fashion during a symmetrical tasks. For example, a symmetrical movement such as forward flexion of the head should bring about a symmetrical recruitment of the sternocliedomastoid muscles. An asymmetry of recruitment might come about due to a hyperextension injury to one side of the neck associated with a motor vehicle accident and the resultant flexion extension injury. The hyperextension injury leads to disruption of muscle spindle activity and long-term inhibited recruitment patterns within the injured muscle.

Equilibration training is designed to restore symmetrical sEMG recruitment patterns. It typically involves simultaneous recording from the right and left aspects of the homologous muscle pair. A processed sEMG signal is displayed on a time series display with the two channels of sEMG aggregated on the same screen using the same sensitivities and sweep times. In this way the symmetry of the activity of the two muscles can be easily seen. A skilled therapist will use a variety of therapeutic skills, such as uptraining the lower, more inhibited side to create greater symmetry of recruitment. The sEMG feedback guides that effort.

Training Technique 11: Motor Copy Training

This is a more advanced coordination training protocol. Here an sEMG recruitment pattern is created during movement. It is stored and later placed on the screen as a background template. The patient is then asked to use his or her own muscle effort during a live sEMG display to copy or follow the template.

Typically these types of procedures are done with patients who have unilateral weaknesses, such as stroke. The uninvolved side is then used during the desired movement to generate the template. The template from the uninvolved side is used teach how to use the involved side in a normalized fashion.

Training Technique 12: Postural Training with sEMG Feedback

This is a fairly straightforward procedure. Typically a time series scroll of the postural muscles of interest is provided. The therapist then assists the patient in obtaining a more natural or correct posture, and the sEMG feedback display demonstrates how the improved posture provides less work and stress on the musculoskeletal activity. In more complicated cases, the therapist might need to uptrain a weakened or unused set of muscles so that they may better play their roles in postural support.

Training Technique 13: Body Mechanics Instruction

This procedure is very similar to the postural training procedure, except this time the patient is doing more vigorous work. It usually involves a time series scroll of a processed signal from muscles that are either prime movers or stabilizers. Commonly, the patient is asked to do a task, such as lifting an object from the ground, and the therapist teaches standard body mechanics and observes how well the muscles recruit during the movement. Corrections and suggestions about the lifting technique might be given, and the lift tried again. The sEMG recording may be used to demonstrate how the new technique for lifting will reduce the probability of injury to the involved muscles.

Training Technique 14: Therapeutic Exercise Validated with sEMG Feedback

In physical medicine, patients are commonly given exercises by the therapist to strengthen a given muscle or muscle grouping. Occasionally, when given a therapeutic exercise, the patient inadvertently uses a muscle substitution pattern to create the desired movement pattern. When sEMG is used, a time series scroll showing the recruitment pattern of the prime movers and stabilizers of the exercise may be used to verify that the exercise is working on the desired muscles. If a muscle substitution pattern is noted, the patient may then be trained using the sEMG feedback to recruit the desired muscles for the given exercise.

Training Technique 15: Functional Activity Performance with sEMG Feedback

All of the prior training techniques lead to this procedure. It is essential to take an isolated training procedure and introduce it into real and varied life activities. Refinements of movement, posture, and emotional tone may be done during this time.

SUMMARY

In summary, we introduced sEMG as a procedure that may provide more beneficial information concerning chronic pain disorders than traditional electrodiagnostic tools. This is particularly true when the pain disorder involves muscles or myofascial pain. Seven muscle impairment syndromes were described, and the role of sEMG in their description and diagnosis was explored. A partial list of disorders with potential neuromuscular or musculoskeletal components includes tension headache, TMJ and myofacial pain disorders, post-traumatic stress disorder, cervical dysfunctions, shoulder girdle and upper extremity dysfunctions, low back dysfunctions, hip dysfunctions, knee dysfunctions, stroke, and urinary incontinence. These disorders are ones in which an sEMG assessment should be considered. In addition, these disorders may also be treatable, in part, using sEMG biofeedback. This chapter provided a description of 15 different sEMG treatment strategies relevant to the chronic pain patient. Formal "Application Guides" that describe clinical protocols for assessment and treatment of many of these disorders are available in Kasman et al. (1998). Please refer to this volume to understand these clinical concepts in further depth.

Six Diverse Acupuncture Techniques Useful in Pain Management

William D. Skelton, D.Ac.

INTRODUCTION

Acupuncture is a therapeutic modality that originated in China approximately 3000 years ago. It is the main component of traditional Chinese medicine, and serves as the basis of the physical and rehabilitative side of that system, one that is remarkable not only for acupuncture but in other areas as well. For example, a complete pharmacology was developed in the Sung Dynasty (960–1270 A.D.); a system of preventative medicine, including a nasal-inhaled smallpox immunization, was created in the 17th century; and a sophisticated form of forensic medicine was developed during the Warring States Period (475–221 B.C.).

Over the millennia the understanding and application of acupuncture have changed radically. At various times in China, this therapy has been adapted and modified to fit political structures, populist theories, philosophies, and belief systems. Various cultures have exerted their own influences to modify the practice of acupuncture, which is why there is Japanese acupuncture, French acupuncture, and others. In addition, the ongoing creative and experimental adaptations individuals have contributed to the practice of this therapy furthered the momentum of acupuncture's development. The result is a rich diversity of acupuncture styles and techniques.

The use of acupuncture in the United States has added its own unique mark on the profession and practice of acupuncture. While U.S. acupuncture can be traced back to the early 1800s, it was not until 1972 that the country as a whole became familiar acupuncture and its application. Since that time, acupuncture has steadily become less of an alternative to traditional Western medical treatment and more of a vital component of the U.S. healthcare system, particularly in pain management.

In this chapter I provide a short discussion of the use of acupuncture for the treatment of pain, followed by overviews of six specialized acupuncture techniques that are well suited for use in pain management programs. Although each of these techniques differs from what is typically thought of as a traditional acupuncture treatment, each can fit easily into a pain management program and yield impressive results. None of them rely as heavily on the Chinese biopsychosocial model for diagnosis; they do not try to treat the "whole" person, nor do they require the level of knowledge and skill that is needed to practice acupuncture as an independent approach to healthcare.

Following each overview is an example, or examples, of individual points that might be used in each technique for the treatment of an occipital headache and low back pain. The points listed do not constitute a treatment and are only examples of possible points. The point name or number is followed by a description of the location simply to orient the reader. For the sake of brevity and clarity, I have taken the liberty of selecting common points, giving a general location, and omitting mention of any special needle techniques such as angle, direction, insertion, or method of manipulation that might be indicated, because trained practitioners already have that knowledge.

Each of the acupuncture techniques described in this chapter is simple, effective, safe, and can be incorporated into virtually any program as either a stand-alone modality or as an adjunct to other traditional medical therapies.

0-8493-0926-3/02/$0.00+$1.50

Because of the variety of treatment options possible with these techniques, they easily accommodate the idiosyncrasies of a typical pain management program and those of the patients.

TREATING PAIN WITH ACUPUNCTURE

It is estimated that over 10 million acupuncture treatments are administered in the United States yearly. Acupuncture therapy has moved into the healthcare system on many levels, ranging from integrative health clinics to substance abuse treatment centers. The most common use, however, is in the treatment and management of pain.

Across the country, pain management clinics and pain treatment centers serving a wide variety of specialties, major hospitals, and medical school teaching clinics have added acupuncture therapy to treat pain associated with arthritis, headaches, back and spine problems, and other ailments. Besides being highly effective and clearly popular with patients, there are many advantages to using acupuncture in a pain management program. Two of the most important are that acupuncture is easily adapted to the needs of the program and patient and it is suitable for use in conjunction with the traditional therapies the program offers.

Efficacy

Studies have demonstrated that acupuncture is effective in treating pain. The 1997 National Institute of Health consensus statement on acupuncture stated that acupuncture may be useful as an adjunct treatment or an acceptable alternative or be included in a comprehensive management program for conditions including myofascial pain, fibromyalgia, osteoarthritis, low back pain, carpal tunnel syndrome, tennis elbow, and others.

Adaptability

The diversity of acupuncture techniques, such as the ones detailed in this chapter, enable a practitioner to treat a patient regardless of most limitations or restrictions such as implants, braces, wheelchairs, bandages, difficulty sitting or lying down, modesty, or any other barrier that might restrict treatment.

These techniques are easily adapted to the limitations of the pain management program. Often, programs are unable to provide the space or time required for a traditional acupuncture treatment, where a patient might occupy a room for 30 to 60 minutes. These techniques are ideal for group treatment settings, in which the shared results and a group dynamic can enhance the morale and response of the program participants. To reduce scheduling burdens and offer a wider variety of therapies, these techniques can be coupled with other therapies, such as physical therapy, occupational therapy, and counseling. This multimodality approach can produce impressive results, enabling patients to function at improved levels.

Acupuncture demonstrates additional benefits in pain management programs by treating the acute problems such as muscle aches, headaches, etc. that arise naturally or from the rigors of the program. On a more subtle level, acupuncture helps decrease depression, increase a sense of well-being, and improve patients' compliance with the requirements of their treatment programs.

CHOOSING A TECHNIQUE

Effective practitioners of acupuncture in pain management programs demonstrate a repertoire of techniques that range from those of modern acupuncture to those of traditional Chinese acupuncture. The treatment is tailored to the patient, the treatment setting, and the other therapies being administered to the patient. Because of these variables patients presenting with the same condition would typically receive very different treatments, even though the practitioner will probably be biased toward, and more comfortable with, particular treatment techniques.

The practitioner chooses an acupuncture technique or techniques based on the patient's constitution, physical condition, associated symptoms, emotions, and other biopsychosocial factors. Each treatment is also oriented to the disorder, the point in time of treatment, how chronic the condition is, the level or depth of the disorder, and the way the symptoms and signs change. The practitioner takes into consideration the depth, strength, and direction of the treatment techniques to determine which is appropriate.

Each of the techniques described in this chapter works on a different depth and requires a different perspective from the practitioner. In addition, each technique represents the practitioner's orientation to the patient; the choice of technique will also, in part, reflect the level of the practitioner's knowledge and understanding of the attributes that compose acupuncture.

THE SIX TECHNIQUES

Auricular Acupuncture

Auricular acupuncture is a rapid and highly effective microsystem based on a somatotopic representation of the ear as an inverted fetus (Figure 48.1). Thus, points on the earlobe correlate to the patient's head, and points on other parts of the ear correlate to the other parts of the patient's body.

Although auricular acupuncture treatment has been a part of traditional acupuncture therapy, it developed as a comprehensive system of diagnosis and treatment in the late 1950s. At that time a French physician, Paul

FIGURE 48.1 Somatotopic representation of the ear as an inverted fetus. (Courtesy of Carl L. Milton.)

Nogier, published his findings correlating specific sites on the ear to parts of the body. Now, throughout the world, there are many acupuncturists who only use auricular points for their treatments. The advantages of this system are that acupuncture points for only a small terrain need to be learned, and that the treatment procedure is simple and safe.

Auricular therapy can also be effective without needles, using a technique that involves taping a small surgical steel bead, resembling a BB pellet, onto various auricular points. The patient gently stimulates the bead by pressing on it periodically. Beads can be left in place for days, enhancing and extending the treatment. Self-application of the bead is not practical with auricular points, as it is with some of the techniques that follow, because the precise self-location of auricular points is difficult.

Auricular acupuncture is also amenable to other non-invasive treatment techniques that rely on the electrical stimulation of the points. Electric stimulation devices can assist practitioners in locating and electrically stimulating the auricular points as the therapy. These devices are widely available in the medical marketplace.

As with traditional acupuncture there are different levels of treatment possible with auricular acupuncture, ranging from symptomatic pain management to more complete utilization of the complex theories, techniques, and systems of acupuncture. In pain management, auricular points are very effective, simple to apply, and well tolerated by the patient. Additionally, using a deeper level of understanding of auricular therapy, points can be selected to treat mood, stress, emotions, and functional disorders. Such a wide variety of benefits is of significant value in a pain management program.

There are over 200 auricular acupuncture points that have been identified on each ear (Figure 48.2). They can be located by noting states of tenderness, measuring levels of electrical resistance, and noting abnormalities in coloration and morphological states.

In a pain management setting it is often most suitable to first select the appropriate points based on the pain being treated. The treatment technique for auricular therapy should produce a sensation of local soreness, warmth, or distention. Periodically, during the treatment, the needles are manually rotated or manipulated to reproduce these sensations. Electrostimulation applied to the inserted needle also can be beneficial for pain management.

Point Examples

- To treat occipital headache
  Point Name: Occiput (Figure 48.3)
  Point Location: Posterior and superior to the lateral aspect of the antitragus
  Point Name: Sympathetic nerve (Figure 48.3)
  Point Location: At the junction of the medial border of the helix and the infra-antihelix crus
  Point Name: Subcortex (Figure 48.3)
  Point Location: Anterior aspect of the inner wall of the antitragus
- To treat low back pain
  Point Name: Shenmen (Figure 48.4)
  Point Location: Medial and superior to the lateral angle of the triangular fossa
  Point Name: Lumbosacral (Figure 48.4)
  Point Location: On the medial border of the antihelix and level with the lumbar point
  Point Name: Adrenal (Figure 48.4)
  Point Location: On the inferior prominence of the tragus

Hand Acupuncture

There are two distinct systems of hand acupuncture: the Chinese system and the Korean system. They are both microsystems that reflect the anatomy of the patient and have points that influence all parts of the anatomy. Each system is distinguished by the point location, point indications, techniques of needle insertion, and the type of needles used.

The Chinese system of hand acupuncture is the oldest and easiest to use in a pain management program but it has limited application, because there are a limited number of points and areas of the body that it influences. The Korean system has far greater flexibility and scope, requires a deeper understanding of the system, and is more complicated to apply.

Both systems can easily be taught to patients for self-application of an acupressure device that stimulates the appropriate points without penetrating the skin. This approach can give patients a safe way to control their pain to some degree.

The Chinese System of Hand Acupuncture

In this system there are specific acupuncture points for the treatment of areas and functions of the body. The locations of points are easily found by using anatomical landmarks on the hand. The points are named according to the part of the body or a specific function or disorder that they affect or control.

In a pain management setting hand acupuncture techniques can be very effective and well tolerated by the patient. In general, point selection is symptomatically based. The treatments are usually contralateral, that is, left-hand points are used for right-sided problems. The needle is manipulated following insertion to generate a moderate to strong sensation. While the needles are in situ, the patient

is instructed to move and gently extend the area that is in pain or being treated. Electrostimulation of the hand acupuncture points can be appropriate for many cases.

Point Examples

- To treat occipital headache
- Point Name: Occiput (Figure 48.5)
  Point Location: On the midpoint of the ulnar side of the fifth finger at the level of the first interphalangeal joint
  Point Name: Lateral head (Figure 48.5)
  Point Location: On the midpoint of the ulnar side of the fourth finger at the level of the first interphalangeal joint
- To treat low back pain
  Point Name: Lumbar and leg #1 (Figure 48.5)
  Point Location: At the radial aspect of the tendon of the second extensor digitorum manus
  Point Name: Lumbar and leg #2 (Figure 48.5)
  Point Location: At the ulnar side of the fourth extensor digitorum manus
  Point Name: Vertebrae (Figure 48.5)
  Point Location: On the midpoint of the ulnar side of the fifth finger at the level of the metacarpophalangeal joint

The Korean System of Hand Acupuncture

Korean hand acupuncture was developed in the 1970s. It is a microsystem providing both a somatotopic representation of the human anatomy (Figure 48.6) and a representation of the traditional acupuncture system of points and meridians.

This system consists of a network of 14 micromeridians and 345 micropoints on each hand. The micromeridians and

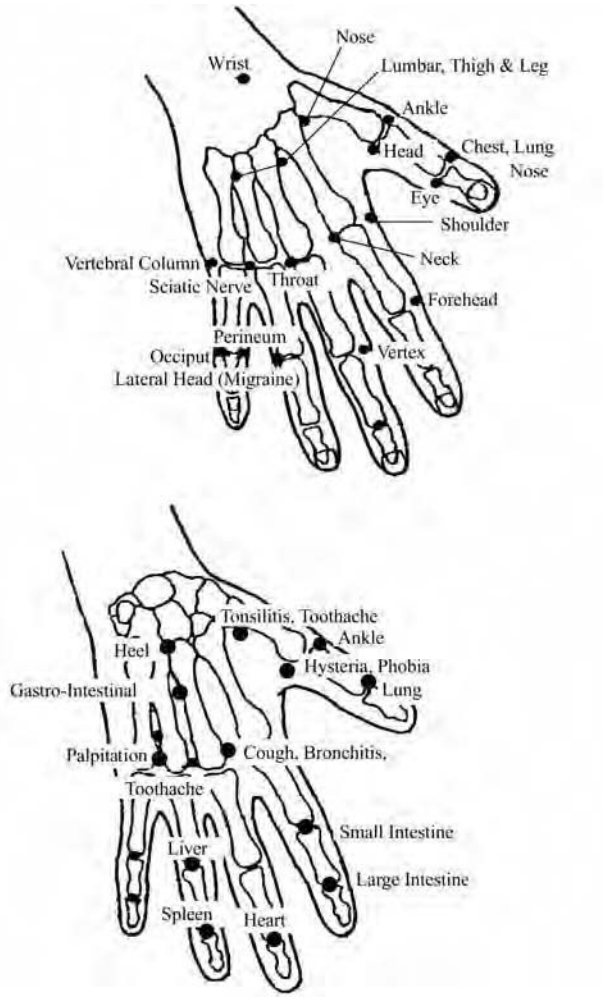

FIGURE 48.5 Chinese hand acupuncture. (Courtesy of Carl L. Milton.)

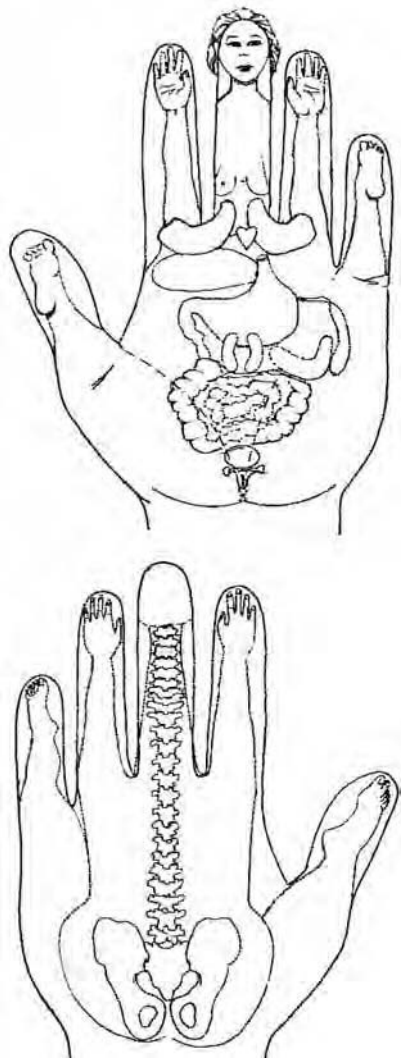

FIGURE 48.6 Korean hand acupuncture. (Courtesy of Carl L. Milton.)

the micropoints are, with some variations, analogous to the traditional acupuncture meridians, or channels.

As with traditional acupuncture there are different levels of treatment possible with Korean hand acupuncture. These range from a purely symptomatic treatment to ones that incorporate all of the complex theories and philosophies and point selections of traditional acupuncture treatment.

The easiest and most suitable level of applying Korean hand acupuncture for use in a pain management program is based on the somatotopic relationship of the hand and the whole body. Points are selected according to the anatomical location of the pain. Tiny needles, made specifically for this system, are inserted into the points and left for the duration of the treatment.

Point Examples

- To treat occipital headache
  Point Name: #3 Korean I micromeridian (Figure 48.7)
  Point Location: On the dorsal side of the hand lateral and medial to the midpoint of the crease of the distal interphalangeal joint of the third finger
  Point Name: #24 Korean B micromeridian (Figure 48.8)
  Point Location: On the dorsal side of the hand at the midpoint of the crease of the distal interphalangeal joint of the third finger
- To treat low back pain
  Point Name: #17–20 Korean I micromeridian (Figure 48.7)
  Point Location: On the dorsal side of the hand on the lateral and medial border of the distal half of the third metacarpal bone
  Point Name: #7 Korean B micromeridian (Figure 48.8)
  Point Location: On the dorsal side of the hand, over the third metacarpal bone near the delineation of the distal quarter of its length

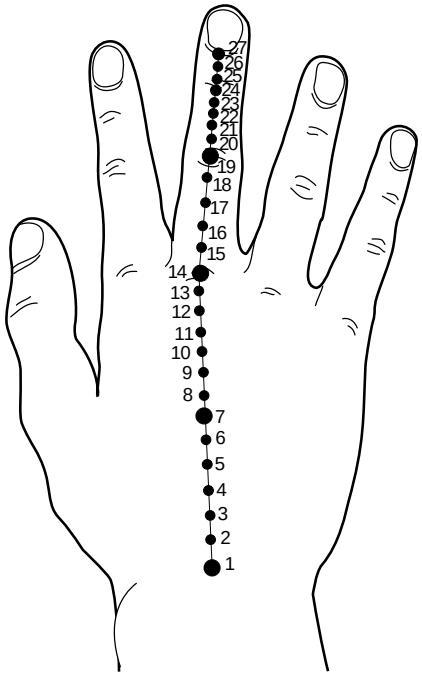

FIGURE 48.8 Points on the Korean B micromeridian. (Courtesy of Carl L. Milton.)

Head Acupuncture

Head acupuncture, also known as scalp needling therapy, was developed during the Chinese Cultural Revolution (1966–1976) and incorporates acupuncture techniques popularized during that period of history. The point locations and indications were developed in accord with the representative areas on the cerebral cortex.

In this technique a practitioner first identifies landmark lines along the scalp of the patient. The midline of the head is identified as going from the midpoint between the eyebrows and over the top of the head to the external occipital protuberance. The eyebrow-occipital line is identified as going from the midpoint of the eyebrow and across the temple to the external occipital protuberance (Figure 48.9). The motor area line is identified as going from a point located 0.5 cm posterior to the midpoint of

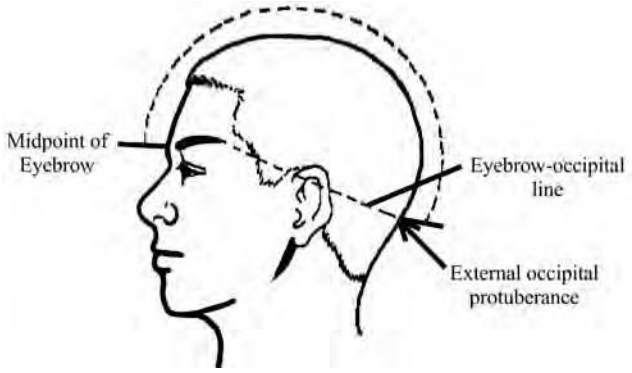

FIGURE 48.9 The eyebrow-occipital line. (Courtesy of Carl L. Milton.)

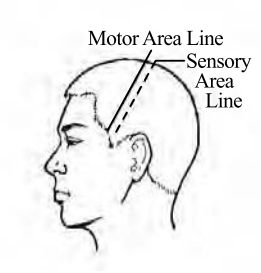

FIGURE 48.10 The motor area and sensory area lines. (Courtesy of Carl L. Milton.)

the midline across to the juncture of the eyebrow-occipital line and the temporal hairline (Figure 48.10). All measurements for other scalp acupuncture lines and point locations are made from these lines.

Typically, a treatment involves selecting the point located over the area of the cerebral cortex that corresponds to the problem. Additional points that have a related effect are often added to the treatment. Contralateral points are used for conditions affecting one side of the patient's body, while bilateral points are used for more general, bilateral, or systemic conditions.

After the appropriate point is located, the scalp over the point is lifted slightly using a pinching method and a needle is inserted under and almost horizontal to the scalp. The needle path follows the lines as measured from the landmarks. Once the needle is inserted to the proper depth, it is rotated 200 to 400 times per minute while maintaining its position at the desired depth. When the needle is applied properly a patient often notices sensations of heat, paresthesia, throbbing, or an involuntary movement in the limb that is being treated. Because there is a possibility that the patient will feel faint or light-headed from this treatment, it is best applied when the patient is in a fully supported position.

Head acupuncture therapy is the most difficult of the techniques discussed here to fit into a pain management program. It is time- and labor-intensive, and it requires precise point location and attention to needle technique. The sensations noted by the patient can be very strong. Patients tend to be less comfortable with this technique than the others discussed in this chapter, and therefore the technique is best suited for motor and sensory disorders of the limbs. The advantage to head acupuncture, however, is that it can produce results when the other techniques failed.

Point Examples

- To treat occipital headache
  Line Name: Sensory area line (Figure 48.10)
  Line Location: 1.5 cm posterior to the motor area line
  Needle Insertion: Upper fifth of the sensory area line
- To treat low back pain
  Line Name: Sensory area line (Figure 48.10)
  Line Location: 1.5 cm posterior to the motor area line
  Needle Insertion: Upper two fifths of the sensory area line
  Line Name: Leg and motor sensory area line (Figure 48.11)
  Line Location: 1 cm lateral to, and parallel with, the midpoint of the midline
  Approximately 3 cm in length
  Needle Insertion: The entire line

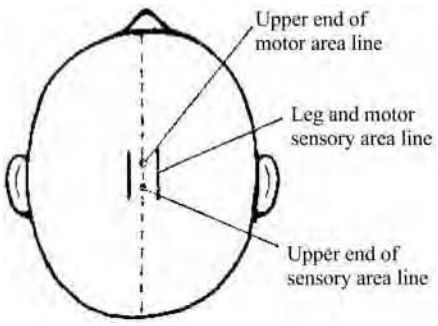

FIGURE 48.11 Leg and motor sensory area line. (Courtesy of Carl L. Milton.)

Distal Release Acupuncture Points

Distal release acupuncture points consist of traditional acupuncture points and also of special or extra acupuncture points that have a known effect on a specific area or function of the body. They are part of the aggregate body of knowledge of acupuncture and are used unconventionally, not following the traditional theories and rules of acupuncture. A skilled acupuncturist, over time, develops a repertoire of points that can be used in conjunction with the other levels of therapy.

These points are usually located on the opposite part of the body from the side being treated and are applied symptomatically. They are usually very tender when palpated, which is how most practitioners determine if the point is appropriate. The stimulation of these points is effective in relieving pain, releasing muscle tension, and improving range of motion. Patients are asked to move and stretch the area of pain while the needles are in place. The needles are periodically rotated to evoke a mild distension at the site of insertion.

In a pain management program these points can be utilized to provide fast relief of discomfort and limitations of movement brought on by the activities of the program. They are also useful when a practitioner is unable to treat an area due to the sensitivity of the area. These points can be used to sufficiently relieve discomfort so that a local treatment can be administered. These specialized points are especially useful when the patient is combining acupuncture with another therapy such as physical therapy or occupational therapy.

Point Examples

- To treat occipital headache
  Point Name: GB 40 (Figure 48.12)
  Point Location: Anterior and inferior to the lateral malleolus, in the depression lateral to the tendon
  Point Name: BL 60 (Figure 48.12)
  Point Location: At the midpoint of the space between the lateral malleolus and the tendon calcaneus
  Point Name: S I3 (Figure 48.13)
  Point Location: Proximal to the fifth metacarpal bone, on the medial edge of the palm where a crease forms when the hand is made into a fist
- To treat low back pain
- Point Name: Yaotongxue (Figure 48.16)
  Point Location: On the dorsum of the hand between the second and third, and between the fourth and fifth, metacarpal bones, half way between the transverse crease of the wrist and the metacarpophalangeal joint
  Point Name: SI 6 (Figure 48.14)

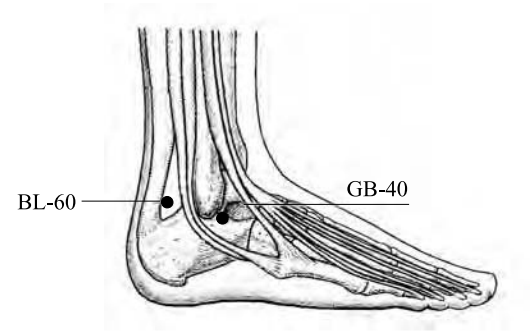

FIGURE 48.12 Acupuncture points GB 40, BL 60. Used to treat occipital headache. (Courtesy of Carl L. Milton.)

FIGURE 48.13 Acupuncture point S 13. Used to treat occipital headache. (Courtesy of Carl L. Milton.)

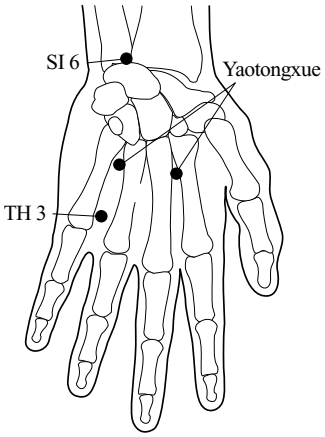

FIGURE 48.14 Acupuncture points Yaotongxue S 6. Used to treat low back pain. (Courtesy of Carl L. Milton.)

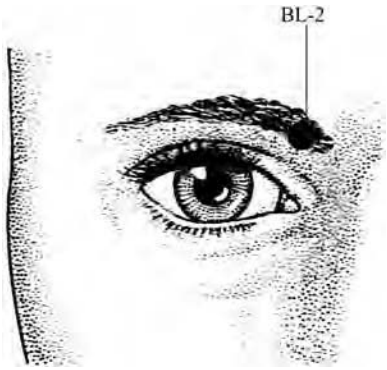

FIGURE 48.15 Acupuncture points B 12. (Courtesy of Carl L. Milton.)

Point Location: Found with the palm facing the chest, just above the styloid process of the ulna, and on its radial side

Point Name: BL 2 (Figure 48.15)

Point Location: At the medial aspect of the eyebrow, in the supraorbital notch

Myofascial Acupuncture

Myofascial acupuncture uses the complex network of acupuncture meridians as the primary basis for treating the body and relies strongly on a physical evaluation of the connective tissue of the body to assess how to go about treating the patient.

The physical evaluation frames the patient's condition in terms of myofascial causal chains that are broader in scope than referred pain patterns. These chains reflect the symptoms and expressions of the connective tissue and give insight to the assorted disorders that have been recorded as meridian symptomology in traditional acupuncture.

A skilled practitioner, using the image of the meridians as an overlay, evaluates a patient, visually noting factors such as gait, posture, and muscle tone. The practitioner manually examines muscle and tissue for indications of tension, painful loci, range of motion limitations, and any other unusual state. By adding the knowledge of the terrain of the meridians, the symptoms and signs from the evaluation are understood in the greater context of a multidimensional model of the body.

This model expands the practitioner's understanding of the interrelationship of the various regions of the body, specifically the upper and lower, front and back, left and right, and internal and external regions, and increases treatment options. More importantly, it provides a framework to understand the expressive paths of the complex emotional, visceral, and somatic interplay. This model has remained a valuable contribution to this style of therapy.

Myofascial acupuncture is exceptionally effective in a pain management program. It is very hands-on and demonstrates to the patient that the practitioner is in touch with the pain syndrome as a whole. During treatment, muscles are isolated and stimulated with needles to produce reactions that either mimic or radiate to the pain. Patients typically find it reassuring to know that their pain can be reached. In addition, the evaluation process takes into account the myriad physical, functional, and emotional symptoms that, while very real to the patient, have often been considered unrelated by other systems of thought. Consequently, this technique works extremely well as a strong adjunct to all other therapies, including counseling and psychotherapy.

In practice, this system bears a similarity to trigger point therapy in the selection of points according to muscle involvement. Many of these points tend to be spatially close to trigger points, and some of the muscle points are stimulated to release tension and pain. However, different from trigger point therapy, other acupuncture points relating to the involved meridians are included in various areas of the body as an integral part of the treatment plan.

Point Examples

- To treat occipital headache
- Point Name: GB 20 (Figure 48.16)

  Point Location: Between depression below the external occipital protuberance of the occipital bone and the mastoid process, between the trapezius and the sternocleidomastoid muscles, in the splenius capitis and the semispinalis capitis muscles

  Point Name: GB 21 (Figure 48.16)

  Point Location: In the trapezius muscle at the midpoint between the acromion of the scap-

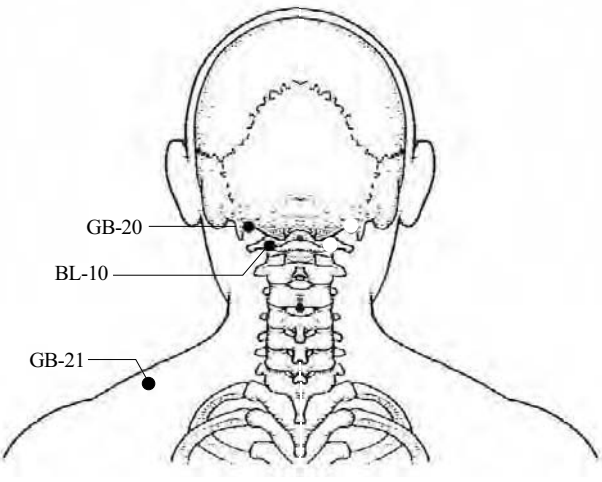

FIGURE 48.16 Acupuncture points GB 20, GB 21, BL 10. Used to treat occipital headache. (Courtesy of Carl L. Milton.)

ula and a point on the midline between the spinous processes of the seventh cervical and first thoracic vertebrae
Point Name: BL 10 (Figure 48.16)
Point Location: At the margin of the trapezius muscle and over the semispinalis capitis and splenius capitis muscles, aproximately 1.3 in. lateral to a point on the midline between the first and second cervical vertebrae
Point Name: TH 3 (Figure 48.14)
Point Location: Located on the dorsal side of the hand proximal to the metacarpophalangeal joint between the fourth and fifth metacarpal bones, in the fourth dorsal interosseous muscle
Point Name: BL 58 (Figure 48.17)
Point Location: In the gastrocnemius and soleus muscles, 1 in. inferior and lateral to the site where the two bellies of the gastrocnemius muscle separate when a patient is fully extending the foot
Additional Points: Various points that influence the posterior cervical muscles, occipitofrontalis muscle, the levator scapulae muscle and the trapezius muscle.

- To treat low back pain
  Point Name: BL 23 (Figure 48.18)
  Point Location: In the erector spinae muscles, 1.5 in. lateral to the lower border of the spinous process of the second lumbar vertebra
  Point Name: BL 47 (Figure 48.18)
  Point Location: In the latissimus dorsi and iliocostalis muscles, 3 in. lateral to the spinous process of the lower border of the second lumbar vertebra
  Point Name: BL 60 (Figure 48.12)
  Point Location: At the midpoint of the space between the lateral malleolus and the tendon calcaneus
  Point Name: S 13 (Figure 48.13)
  Point Location: Proximal to the fifth metacarpal bone, on the medial edge of the palm where a crease forms when the hand is made into a fist, in the abductor digiti minimi muscle
  Additional points: Various points that influence the superficial and deep paraspinal muscles

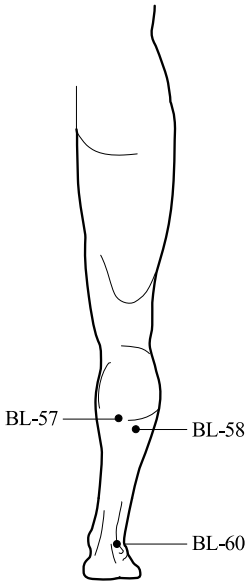

FIGURE 48.17 Acupuncture points BL 57, BL 58, BL 60. (Courtesy of Carl L. Milton.)

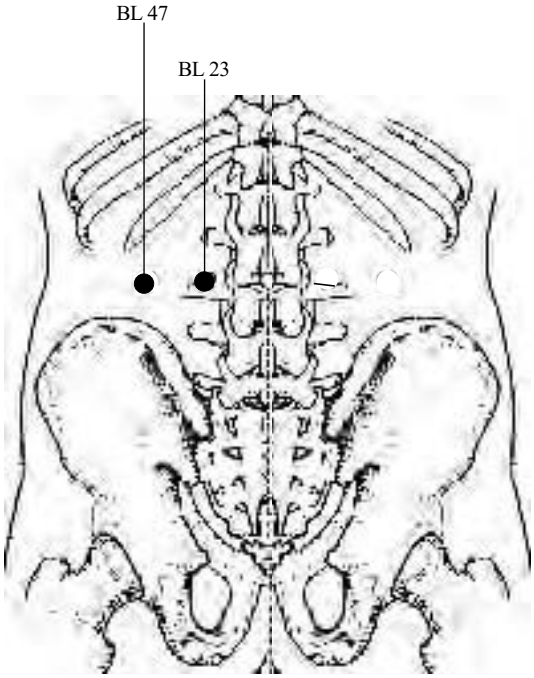

FIGURE 48.18 Acupuncture points BL 23, BL 47. Used to treat low back pain. (Courtesy of Carl L. Milton.)

CONCLUSION

It is likely that the use of acupuncture in pain management will continue to grow as a result of new research in the field, public awareness and acceptance, and its therapeutic flexibility. The techniques discussed in this chapter are a sampling of the ones being used in clinical practice. They serve to exemplify the breadth of the field of acupuncture and to demonstrate, by the nature of the technique, ways the therapy can be added to a pain management program or other treatment programs.

Tai Chi Chuan for Pain Management

Richard A. Peck, L.Ac., M.B.A. and Iva Lim Peck, L.Ac., Dipl.Ac., R.N.

INTRODUCTION

Tai Chi Chuan (a.k.a. T'ai Chi Ch'uan, Taijiquan) is an ancient Chinese martial art/exercise originally developed in the 13th century by Chang San Fang. Because of its underlying concepts of energy and its effect on the body, it has been incorporated into the overall system of Traditional Chinese Medicine (TCM). In the West it is often referred to merely as Tai Chi. This is somewhat erroneous because Tai Chi in Chinese refers to the symbols for Yin and Yang. It is more accurate to refer to it as Tai Chi Chuan, which means Grand Ultimate Boxing or Grand Ultimate Fist.

Originally, Tai Chi Chuan was a closely guarded secret reserved only for those within the Chen family. Since the 1800s it has evolved from the original Chen Style into many different styles (Yang, Wu, Sun, Hao) and is practiced by millions of people all over the world. Tai Chi Chuan is considered by many as one of the best low-impact exercises. Even though it is ancient, it fits well into our modern society. It can be practiced by anyone whether young or old, large or small, male or female. It does not require any special clothing nor does it require any special equipment. It is ideally suited for those with chronic pain.

Oriental Medicine: Background

To understand the underlying concepts of Tai Chi Chuan and how this ancient Chinese exercise is useful in pain management, one needs to have some understanding of the concepts of TCM.

Traditional Chinese Medicine is an energetically focused system of healing that dates back over 3000 years. One of the oldest references is the Huang Ti Nei Ching (Yellow Emperor's Internal Classic) which is composed of two separate books. The first is the Su Wen, which deals with physiology and pathology, and the second is the Ling Shu, which deals with the subject of anatomy and acupuncture. The estimated date of the writing is around 1000 B.C.

Most people in the West think of TCM as acupuncture. Acupuncture is only one part of Oriental Medicine. It is really a complex system of healthcare that includes acupuncture, moxibustion, dietary therapy, Chinese herbology, Tui Na (similar to massage), and exercises such as Tai Chi Chuan and Qi Gong (breathing exercises). For a traditionally trained Doctor of Oriental Medicine each of these modalities is as important as the other in the overall health of the patient.

Historically, the development of Oriental Medicine has been an evolutionary process. Ancient texts indicate and suggest that each part of TCM originated in a different part of China. Acupuncture originated in northern China, Chinese herbology began in the southern part, and Tai Chi Chuan originated in the central region.

It is believed that acupuncture was discovered quite by accident. There are numerous legends as to its discovery. The most popular one is an incident of an altercation between two groups of clansmen. One individual was struck in the shoulder by an arrow and his headache went away. The Chinese are great observers of nature. If there is one point that can relieve a physical problem, then there

0-8493-0926-3/02/$0.00+$1.50

must be more. Similar cause-and-effect situations were observed over the years and different pain problems were relieved. Initially, the development of acupuncture was limited to knowledge within a family that was passed down from father to son and generation to generation. Gradually, the knowledge was expanded and there were ancient writers like Chang Chung-Ching, who wrote the Shang Han Lun (Essay on Typhoid) (available in English) and Huang Fu-Mi, who wrote the Chia I Ching These and many other well-known physicians and historians throughout the centuries wrote manuscripts on the accumulated knowledge based on the observation and outcome experiences of their time. Many of these texts are still in existence today and have been translated, revised, or modified and are being used as text books in the teaching of Oriental Medicine.

Oriental Medicine: Concepts

The Chinese believe that there is an energy or vital life force in our bodies. This life force flows along predetermined pathways, which for our purposes we refer to as meridians. This vital life force is called Qi. It assumes many different forms. It comes to us genetically from our parents in what is referred to as Original Qi. It is in the food we eat and the air we breathe. It can also be enhanced by the exercise we do. For our purposes, we think of this life force collectively as that which gives energy to the various muscles, bones, and organs. The Chinese believe this is the vital energy that keeps us alive.

In a normal healthy person this vital energy flows continuously from one meridian to another and from one part of the body to another. The Chinese also believe that when the energy becomes blocked disease or pain problems occur. Let's think of the energy as a stream of water that runs continuously through the forest. If a tree or log falls over the stream, then the water is blocked and backs up forming a pond or a lake. In the human body, when there is an imbalance of energy flowing along the meridian it can be due to an internal problem or an external injury to a specific area of the body. The energy becomes blocked and backed up, quite often forming a tender point. If the problem is of short duration or is in an acute stage, the energy is probably no more than a small pond with minor consequences to the body. If the log across the stream or the energy is being blocked for an extended period of time, then the problem becomes chronic and we can think of this as a lake. It takes longer for the water to be drained out of a lake than a small pond. The same is said for energy blockage. In general, it may take longer to treat the chronic conditions than the acute conditions. The main objective of the Oriental Medicine practitioner is to identify and relieve the blockage of energy. This can be done by acupuncture, Chinese herbs, Tai Chi Chuan, etc.

ENERGY PATHWAYS

Each of our internal organs is associated with an energy pathway. For example, the heart has a meridian we can call the Primary Heart Meridian. The energy of the Primary Heart Meridian originates in the heart and branches internally in three directions. The first branch travels from the heart internally downward into the abdomen to connect with the small intestine meridian. The second branch travels upward and runs alongside the esophagus to connect with the eye. The third branch leaves the heart, enters the lung, and emerges through its external pathway at a point in the center of the axilla on the medial side of the axillary artery. This is the first acupuncture point of the Primary Heart Meridian system. From there it travels along the posterior and medial aspects of the upper arm down to the cubital fossa. From there it descends along the posterior and medial aspects of the forearm to the pisiform region and enters into the palm, and then goes to the tip of the medial aspect of the little finger, where it ends.

In addition to the Primary Meridian systems, there are two distinct secondary meridian systems. The first is the Connecting Meridian system, which connects one meridian to another, and the second is the Muscle Meridian system, which does not have acupuncture points but connects the energy along the muscular system. It is the Muscle Meridian system that is of primary importance to us. Each Primary Meridian has a Muscle Meridian. Thus, the Primary Heart Meridian has a Heart Muscle Meridian. The Heart Muscle Meridian follows along the same pathway as the Primary Heart Meridian system. It begins from the medial aspect of the small finger inserts at the wrist, then travels upward to the elbow where it again constricts. It flows upward across the chest where it constricts in the center of the chest before it descends into the abdomen. This Muscle Meridian system is the important factor in pain points, muscle pain, and the benefit from practicing Tai Chi Chuan.

TAI CHI CHUAN: DEVELOPMENT

Legend has it that Tai Chi Chuan and Qi Gong originated in the central part of China and more specifically on Wu Tang Mountain. Legends further attribute the creation of Tai Chi Chuan to more than one source. One of the most popular traditions is that in the 13th century a Taoist monk by the name of Chang San Fang watched an altercation between a snake and a crane and created the rudimentary basis of Tai Chi Chuan. Many of the movements of Tai Chi Chuan mimic the movements of animals or forces in nature and thus are named after the animal or natural occurrences. Within the various styles of Tai Chi Chuan there are individual postures in the exercise routine with names such as "Snake Creeps Down," "White Crane

Spreading Its Wings," "Carry Tiger to the Mountain," and "Wave Hands Like Clouds." Each of these movements mimics an animal or force in nature.

In performing the Tai Chi Chuan routine the whole body is slowly and gently stimulated along all the muscle groups, one after the other. The primary method of stimulating these muscle groups is through stretching that alternately contracts and relaxes specific muscles groups and balances the muscular activity throughout the body. The Muscle Meridian system of the body is continually being stretched. Because the Muscle Meridian system follows along the Pathway of the Primary Meridian System any movement will affect the energy flow along the various meridians. The movements of Tai Chi Chuan activate all the Muscle and Primary Meridians. The stimulation of one part of the body has an effect on another part of the body. This follows the concept of Oriental Medicine where an experienced practitioner will balance the energy flow in one part of the body knowing that it has an impact on another part of the body.

To further understand the role that Tai Chi Chuan plays in pain management, it is helpful for one to also understand some of the work done by Dr. Janet Travell and those who followed after her, and their continued work on the development and understanding of trigger points in myofascial release.

Briefly stated, Travell believed and demonstrated that within a muscle or muscle group one or more areas in the muscle group may be tender. The tenderness can be due to different reasons; however, the most common is from an injury to the muscle group. The injury causes the muscle to constrict or shorten causing a tender point. The tightness or spasm on a tender point in the muscle group can affect one or more areas of the body in the form of pain. This pain area usually is in close proximity to the Primary Meridian System and the Muscle Meridian System. If the tenderness can be relieved, it will have a positive and beneficial effect on the constricted muscle and pain pattern problem. The relief of the pain pattern through stimulation of the trigger point can come about through exercises (Tai Chi Chuan), massage, heat therapy, acupuncture, etc.

Tai Chi Chuan: Movement and Pain Relief

In Oriental Medicine spontaneous points that become sore are referred to as Ah Shi Points. The concept of Ah Shi Points was first put forth by Sun Si Mao (561–682) during the Tang dynasty. He believed that when soreness was felt as pressure was applied to a muscle an acupuncture point existed. The Ah Shi Points were used both for diagnostic purposes and for treatment. Many acupuncturists use the concept of Ah Shi Points to treat pain problems that lie along the pathway of the corresponding meridians. The Trigger Points of Travell in many instances correspond with the Ah Shi Points of Acupuncture.

Tai Chi Chuan is sometimes referred to as "land swimming" because the movements of Tai Chi Chuan resemble very closely the continuous movements of swimming. These continuous movements work differently than physical therapy. In physical therapy there is movement of one or more muscle groups; however, the Muscle Meridian and the Primary Meridian are not always stretched in their entirety. Physical therapy is often for an isolated area where the problem exists. When you look at the stretching movements of Tai Chi Chuan, there is a distinct difference. The movements stretch both the arms and legs along the entire pathway of the Muscle Meridian and Primary Meridian. The constant and smooth flowing movements of Tai Chi Chuan release the tender points identified by Dr. Travell and the Ah Shi Points of Traditional Chinese Medicine. When the tender points can be stretched and relaxed, the pain associated with these tender points will diminish or go away.

Research is now being done here in the United States and overseas to prove the benefits of daily Tai Chi Chuan practice. As one watches the graceful movements of Tai Chi Chuan it appears to be effortless, yet the slow and deliberate exercise has proven to reduce falls in the elderly. Those who practice the art find that their muscles become strong and they acquire substantial flexibility. The mind–body effects of Tai Chi Chuan provide an added boost to both the physical and mental health of an individual.

CONCLUSION

In conclusion, integrating daily Tai Chi Chuan practice into a pain management program will provide the stretching needed to relax the muscles and reduce the pain of many chronic pain patients. Like any form of therapeutic exercise, the only way to achieve optimum outcome is to learn the art from a qualified instructor, and practice it on a daily basis.

HISTORICAL OVERVIEW

It is commonly believed that some form of medicine was practiced by all cultures on the planet throughout the course of human history. Initially, however, it was not an isolated methodology. Rather, the promotion of health and the healing and cure of illness and disease were part of a larger system—a working and living portion of a culture's entire cosmological system that interwove spiritual beliefs, an explanation of the universe, the norms and values of the society of which it was a part, and even tasks of daily living.

Cosmological views such as these were often associated with the first form of religion known as animism (Harner, 1987). Animism as a religion is based on the belief that all things, living and nonliving, are alive and have a vital essence or a spirit that can be contacted. It is the view that there is more than just the physical self; an individual is part of a giant cosmic web in which all aspects are interconnected and the universe consists of a complex network of forms, energies, and vibrations. This animistic worldview was not contained to any one part of the world, nor to any specific indigenous culture. Each cosmological system acknowledged and called this vital essence, life force, or universal energy by a different name, including ruach by the ancient Hebrews, chi/ki in the Orient, mana in Hawaii, prana in India, huaca in Peru, and wakonda and manitou among some of the Native American tribes of North America (White & Krippner, 1997).

By the beginning of written history, several civilizations were practicing a form of energy medicine in which electrical and magnetic forces were employed to influence internal energy systems in the body. These energy systems were extensively documented, especially in India with the study of the chakra system and in China with detailed descriptions of the meridians. The use of energy fields in healing also was described in spiritual texts throughout the world, including the New Testament, where Jesus and others performed healings by laying-on-of-hands.

Classical literature indicates that the use of energy fields continued to be studied and named. In 500 B.C., Pythagoras called it vital energy (Brennen, 1993); Hippocrates, in his explorations, pointed out that "nature heals and not the physician," and referenced a vital energy force called the pneira. Paracelsus took this concept further, applying the principle of the archeus, or healing force, in his practice of medicine (Pierrakos, 1975). For the most part, to this point in history, medical paradigms and spiritual beliefs intermingled, and the belief in the existence of this vital energy held potential answers to the mysteries of both body and soul. However, with the advent of the Renaissance, a separation between religion and medicine began to develop, and the concept of animism as a cosmological framework was left to the uncivilized and heathen tribal people.

As the Age of Science and Reason blossomed during the 1600s, a greater understanding evolved in regard to electricity, magnetism, and biological processes. During this time two opposing schools of thought became recognizable. The first, mechanism, believed that life obeyed the laws of chemistry and physics and viewed living organisms as complex machines that were completely understandable by means of physical principles. The second school, vitalism, believed that life would never be explained by these physical principles alone and that there was a mysterious life force that was separate from the physical but impacted upon it (Becker & Marino, 1982).

0-8493-0926-3/02/$0.00+$1.50

In spite of this controversy, vitalists, including such individuals as Franz Mesmer, Samuel Hahnemann, and Luigi Galvani, continued to issue their findings that indicated the existence of a life force. With the discovery of electricity, some vitalists associated electrical fields with this life force and, between the late 1700s and the early 1900s, a variety of electrical healing devices were developed and widely used to treat a range of ailments (Geddes, 1984). Although broad-reaching claims were made, studies demonstrating their positive effects on health were inconclusive, resulting in condemnation by both the medical and scientific communities. During this same period, as research in biology, chemistry, and physics increased, vitalism as a school of science was dismissed as mere philosophical and esoteric speculation.

Even though vitalism was now on the fringe of the approved scientific paradigm, it never died out completely. Vitalistic-oriented beliefs and practices continued, often based on ancient beliefs, under such names as theosophy, metaphysics, and spiritual healing. Research also proceeded, although for the most part unacknowledged, in such areas as parapsychology and consciousness studies.

VARIANT SCHOOLS OF MEDICAL THOUGHT

Historically, then, it appears that our culture has evolved two seemingly opposing philosophical schools of thought in regard to medicine: Biomedicine and Energetic medicine.

Biomedicine is the formal name given for our current healthcare system in which the primary practitioners earn the degree of Medical Doctor (M.D.) or Doctor of Osteopathy (D.O.). Other names include *western*, *modern*, *orthodox*, *mainstream*, and *conventional*. As a school of thought, Biomedicine emphasizes that knowledge about the world, including nature and human nature, must be pursued by the following criteria:

- Objectivism. The observer is separate from the observed;
- Reductionism. Complex phenomena are explainable in terms of simpler, component phenomena;
- Positivism. All information can be derived from physically measurable data; and
- Determinism. Phenomena can be predicted from a knowledge of scientific law and initial conditions (Micozzi, 1996).

Within biomedical philosophy, illness and disease are viewed in the framework of what is known as "The Doctrine of Specific Etiology," or more simply, "The Biomedical Model". This model consists of two major postulates: first, that illness can be categorized into specific diseases characterized by identifiable organic pathology, and second, that each such disease has a unique primary cause (Werbach, 1986). In this medical paradigm, it is accepted that illness occurs due to organ malfunction, damage, or disturbance in the machinery of the body, and it is the physician's job to repair that machine. It utilizes, and is often also called, *allopathic medicine*, a term coined by Samuel Hahnemann and derived from the Greek *allo*, meaning "other" and *pathos*, meaning "feeling," to denote the standard practice of using medicines either to counteract symptoms or to produce an action unrelated to symptoms (Jacobs & Maskowitz, 1996).

A seeming dialectic to this approach is that of Energetic medicine, also known as Bioenergetic medicine, which has been defined in various ways. One definition states that "Energy medicine refers to therapies that use an energy field—electrical, magnetic, sonic, acoustic, microwave, infrared—to screen for and treat health conditions by detecting imbalances in the body's energy fields. Balance can then be restored using holistic therapies, or with treatment devices that rebalance the energy levels of the various fields" (Goldberg, 1993). Another viewpoint explains that "Energetic medicine can be considered to be a general term used to refer to many ancient and some modern medical practices which encompasses many different therapeutic disciplines but which views each as a separate entity with different mechanisms of action" (Becker, 1990).

According to these definitions, Energetic medicine can be considered an umbrella term to cover the wide variety of approaches to healing generally thought by Biomedicine to be vitalistic in theory and which are currently called alternative, unorthodox, integrative, complementary, or holistic. It also would include other approaches whose methodologies are based on Energetic medicine concepts, including spiritual healing, long-distance healing, laying-on-of-hands, psychic healing, shamanic healing, and specific ethnomedical traditions such as Kahuna, Curanderismo, and Native American healing.

Generally speaking, proponents of Energetic medicine believe that the body is more than a machine and that it is capable of healing itself. They also believe that the body also is capable of performing other actions that lie completely outside the realm of established science (Becker, 1990).

More specifically, utilizing the works of Lewis Mehl (1988) and Marc Micozzi (1996) as a basis, I have formulated what I consider to be essential aspects of an Energetic medical model. It consists of the following postulates:

1. The Body is an Energetic System.
   There exists, within the human body, a coherent and homeodynamic energetic system. Disruptions in the balance and flow of this bioenergy can potentially create an imbalance, and the system's response to energetic

imbalance over time can lead to perceptible disease within the body. Facilitating the body to restore its own energetic balance often can ameliorate symptoms and restore health.

2. Causal Factors of Energetic Imbalance are Multidimensional.
   Individuals do not exist in isolation but in relationship with the living universe around them. Understanding that potential causative factors exist that may be outside the realm of normal human perception, and that which is imperceptible to the human senses, are as important in illness and healing as that which can be measured and validated through the senses and current modes of research.
3. The Primary Focus is on the Individual.
   There is an emphasis on the whole person as a unique individual with his or her inner resources as well as his or her unique manifestation of imbalances.
4. Self-Healing is the Basis for All Healing.
   Treatment modalities utilized simply mobilize the body's inner healing resources. The ability to be well or be sick is largely tied to inner resources, but it is understood that other factors such as time and the external environment can impact on this ability in varying degrees.
5. Emphasis is on Wellness.
   Wellness is a focus on engaging the inner resources of each individual as an active and conscious participant in the maintenance of his/her own health. By the same token, the property of being healthy is not conferred upon an individual solely by an outside agency or entity, but results from the balance of internal resources with the external natural and social environment.
6. Health and Healing are Multifaceted.
   Awareness that health is more than the absence of disease and the potential for healing exists, and can impact upon, all levels of an individual's existence. Healing does not equal curing and, in this regard, it is possible for an individual to even approach death "healthy."

In general, "Energetic medical therapies focus either on energy fields originating within the body (biofields) or those from other sources (electromagnetic fields), and these therapies are intended to affect the energy fields … that surround and penetrate the human body" (National Center for Complementary & Alternative Medicine Website). Practitioners believe, then, that an appropriate therapy is one that either encourages the body's own energetic systems or adds external energy to these systems (Becker, 1990).

THE EVOLUTION OF BIOMEDICINE

It is agreed that some of the information derived from the Biomedical model has been both beneficial and effective, providing, for instance, an understanding of the basis of heredity and the ability to see on a cellular level as well as eliminating many major diseases that previously have been lethal. But this mechanistic approach has also fueled a growing tide of dissatisfaction, especially in medicine, where, in spite of all its benefits, its reductionistic approaches have the potential to demean and diminish the complexity of an individual. In this model, by identifying the patient as a diseased body, the whole does not even begin to equal the sum of its parts. Also, as Dr. William Tiller of Stanford University states: "For most of this century, science and medicine have seen health as being dependent upon the balance of body chemistry and the functioning of physical structures. However, attempts to treat illnesses and imbalances chemically often lead to unwanted side effects or the body becoming insensitive to the chemicals" (Goldberg, 1993). In addition, according to the United Nations World Health Organization (WHO), more than 70% of the world's population relies on non-allopathic systems of healing (Krippner, 1999), and Biomedicine is often ill prepared to meet the challenge posed by its encounter with different cultures and their systems of health and healing. These facts, among others, have created a growing interest in nonorthodox medical approaches and have led many health professionals to look beyond conventional drug-based therapies to the field of Energetic medicine.

Initially, medical interest focused on the magnetic fields around the body, but interest in biomagnetism spread widely in the Biomedical research community encouraging exploration of the role of other fields, including electricity, light, heat, gravity, kinetic energy, and sound. This expanding interest has led to the new emerging scientific discipline of Bioelectromagnetics or BEM. BEM is defined as "an interdisciplinary science at the interface of physics, biology, and medicine that deals with the effects of low-level electricity, magnetism and electromagnetic fields on life" (Rubik, 2001).

As inquiry led to a greater understanding about how electricity, magnetism, and other energy fields are created and utilized by living organisms, methods have been developed to measure energy fields within and around the human body. Contemporary medicine currently uses a number of electromagnetically sensitive instruments for diagnostic purposes, many of which are commonly known, including electrocardiogram for the heart

(ECG/EKG), electroencephalogram for the brain (EEG), electromylogram for muscles (EMG), electro-retinogram for eye movements, and magnetic resonance imaging for specific body parts (MRI). In addition, the S.Q.U.I.D. (superconducting quantum interference device) magnetometer is now widely used to map the biomagnetic fields produced by various organs and has led to new clinical instruments such as magnetocardiography and magnetoencephalography. Other diagnostic advances include the use of sensitive photometers and thermographic imaging techniques that can map the patterns of light and heat emitted by cells, tissues, organs, and the whole body, and the use of spectroscopy to reveal the energy emissions and absorptions of molecules, thereby revealing the roles of energy fields in molecular processes including hormone–receptor, antibody–antigen and allergic interactions (Oschman, 2000).

BEM FINDINGS AND THEIR POTENTIAL SIGNIFICANCE TO ENERGETIC MEDICINE

More recently, studies in the area of BEM have yielded significant findings potentially relevant to Energetic medicine. Some of the most pertinent are summarized below:

- Electrical currents flowing through tissues produce a magnetic field in the space around it, and changing, pulsing, or moving magnetic fields, in turn, produce an electrical current flow (Becker, 1990).
- Magnetic and electromagnetic fields have energy, carry information, and are the basis of many of the underlying control systems that regulate the complex chemical mechanisms within the body (Becker, 1990).
- Living organisms have biomagnetic fields around them that change from moment to moment in relation to events taking place inside the body (Oschman, 2000).
- Organisms are fundamentally bioelectric and emit low-level fields (Rubik, 2001).
- Organisms are sensitive to extremely low-level fields of electromagnetism (Rubik, 2001).
- The biomagnetic field of an organism extends some distance from the body surface and, therefore, the fields of two adjacent organisms will interact with each other (Chaitow, 1987).
- All electromagnetic fields are force fields that carry energy and are capable of producing an action at a distance (Becker, 1990).
- Living systems respond to external energy fields (Bialek, 1987).

ADDITIONAL VARIABLES RELATED TO ENERGETIC MEDICINE

The Living Matrix

Studies in both BEM and cellular biology indicate that an overall field also exists within the human body and that internal regulation mechanisms involve more than merely nerve impulses and hormones. Such research indicates that, from the skin to the innermost part of each cell, our entire system is covered with connective tissue internally linking it all together. This field, most commonly known as the living matrix, has no central aspect or part that is most basic; rather, it is "a continuous and dynamic supramolecular webwork extending into every nook and cranny of the body: a nuclear matrix within a cellular matrix within a connective tissue matrix. The properties of the whole network depend upon the integrated activities of all of the components, and effects on any one part of the system can, and do, spread to others"(Oschman, 2000).

An understanding of these integrative reactions may shed new light on some of the processes involved with various forms of Energetic medicine. This living matrix has been found to be simultaneously a mechanical, vibrational or oscillatory, energetic, electronic, and informational network (Pienta & Coffey, 1991), it being scientifically understood that vibratory properties include light, electric, magnetic, and electromagnetic energy, heat, gravity, kinetic (motion), chemical, and sound. Given this premise, restrictions in one part have consequences for the entire organism. For example, the structural system cannot be influenced without influencing the energetic/informational system and vice versa. In addition, it is well known that, in the body, each electron, atom, chemical bond, molecule, cell, tissue, and organ has its own vibratory character, with each molecule emitting a specific and precise characteristic energy spectrum creating, in effect, an electromagnetic "signature" or "fingerprint" unique to that molecule (Oschman & Oschman, 1988).

In lieu of these findings, it can be surmised that whenever the body is impacted upon, whether through touch, manipulation of the spine or soft tissue, movement, sound, light, heat, or application of a needle, magnet, laser beam, or electronic/electromagnetic device, this information is absorbed and transmitted through the matrix, creating an effect within the entire system. Also, because every substance contains unique electromagnetic and vibratory qualities, it would follow that the application or ingestion of any herb, essential oil, food, nutritional supplement, homeopathic formula, or even prescription drug would impact the system energetically.

Geomagnetic Interactions

It has long been accepted by indigenous cultures that an individual exists in relation to the surrounding world. In

some instances, such as with Oriental medicine, this concept forms the basis for treatment in which humans are considered as microcosms of the greater macrocosm with energetic interactions between the two influencing homeodynamic functioning.

The influence of external magnetic fields has been, and continues to be, controversial among scientists. However, as BEM findings indicate that organisms are sensitive to low-level electromagnetic fields and that they respond to external energy fields, there is a growing acceptance of the plausibility of these interactions. To date, a variety of physical and behavioral disturbances in the human population have been statistically related to disturbances in the Earth's electromagnetic field or to manmade interferences. Some physical disorders include cardiovascular problems, seizures, headaches, vestibular problems, intraocular pressure, and sleep disorders; behavioral changes have also been noted, including an increase in crime and aggression, anxiety, depression, and loss of attention and memory (Oschman, 2000; Becker, 1990).

The Heart, Emotions, and Immune Function

The heart has been shown to produce the strongest electrical and magnetic activity of any tissue in the body, and the biomagnetic field of the heart can be detected up to 15 ft away from the body (Baule & McFee, 1963). As such, it is the main source of our body's energy. In this regard, perhaps some of the most significant recent discoveries made in BEM research pertain to the relationships that have been found to exist in regard to electrical energy changes of the heart, emotions, and immune function.

It is known that the two branches of the autonomic nervous system, the sympathetic and the parasympathetic, regulate heart rate. Research has shown that mental stress and negative emotions, such as anger, increase the energy in the sympathetic nervous system and positive emotions, such as caring and compassion, increase the energy in the parasympathetic nervous system (Kamada, et al., 1992; Sloan, et al., 1994; Williams, et al., 1982). Along similar lines, particular emotional states have been correlated with measurable changes in the electrical energy spectrum of the heart. For instance, with the feeling of frustration, the heart rate varies somewhat randomly, a condition referred to as "incoherence." Various practices that intentionally focus attention on the area of the heart, while invoking sincere feelings of love and appreciation, lead to a more regular variation in heart rate, a condition referred to as "coherence." This regular variation reflects a balance and coherence between the heart rate and the rhythm of the sympathetic and parasympathetic nervous systems. With appropriate intention and training, a third state can be achieved that is referred to as "internal coherence." Here, the variation in heart rate decreases almost to zero. It is a calm, peaceful, harmonious, and highly intuitive feeling state, in which one becomes aware of one's electrical body and of the minute currents flowing throughout it (McCraty, et al., 1993; Rein & McCraty, 1993).

Additionally, studies in the field of psychoneuroimmunology, which explores the interactions and relationships between emotional states, behavior, neural and endocrine functioning, and immune processes, indicate that immune responses can be influenced by emotions. Research done over the last several decades, including a study published by Solomon and Moos as early as 1964, shows that a correlation exists between immunologic incompetence and specific emotional states such as anxiety and depression (Solomon & Moos, 1964). Based upon this research, it now becomes possible to see how emotional states, the heart, and the immune system are interrelated, and how emotional changes can affect multilevel functioning of not only an individual's internal system, but also his or her bioenergetic output due to the heart's extensive biomagnetic field, thus potentially affecting those around them.

CONSIDERATION OF BEM FINDINGS

If we consider the findings that have just been presented, we can begin to create an image of the human organism that differs from that of the biomedical model. What we have is a living energetic system existing within, and in relationship to, an energetic universe where everything is alive with its own unique vibration, where energy is being emitted and received, and where we are impacting and being impacted upon by all other energy sources in our midst or at an intentioned distance. It is a universe where each individual with whom we come in contact, whether we touch them or not, has an effect on us in a slightly different way, because what they are energetically emitting issues from their subjective emotional states, just as what we are emitting comes from ours—and these energy emissions can be consciously moderated.

If these BEM findings are indeed valid, then it appears that we may very well be circling back and are not truly at theoretical odds with the animistic-based cosmological systems of our ancestors and indigenous cultures the world over. In accordance with this view, we are, indeed, energetic beings living in a world of energy where everything is interconnected and interrelated. Following this, then, in considering the concept of Energetic medicine, we can see that Energetic medicine is not merely the use of electromagnetically sensitive methods and tools; we can see that, in a broad sense, all medicine is Energetic medicine. Whether it be those modalities deemed complementary or alternative or those considered biomedical and conventional, every

physical interaction and intervention will have corresponding energetic repercussions.

PAIN AND ENERGETIC MEDICINE

Pain is a high-priority symptom related to many illnesses, disorders, and injuries. In 1995, the U.S. Department of Health and Human Services found that more than 120 million persons were affected by pain with a cost of more than $100 billion in lost productivity and healthcare (Erickson, Wilson, & Shannon, 1995; Turk & Melzack, 1992).

In its definition of pain, the International Association for the Study of Pain includes actual or potential tissue damage as well as the emotional experience of pain. Understanding the multifaceted experience of pain becomes important in treatment. To mitigate their suffering, patients may turn to (other) therapies (incorporated within the realm of Energetic medicine) to reduce feelings of stress, anxiety, nervousness, agitation, despondency, lack of motivation, enjoyment, and lethargy (as well as physical symptoms). In this regard, one recent study indicated that from 30 to 70% of patients use alternative or complementary (energetic) therapies in hope of a cure or palliation of their pain [(Loitman, 2000).

The results of this study would indicate that Energetic medical modalities are being utilized within our population in the search for pain management or relief, and exploration of this field is both warranted and timely.

However, prior to further discussion, the following points must be made:

1. It is important to realize that, within the parameters of the Energetic medical model presented earlier, pain in and of itself is not the primary focus of treatment; rather, it is pain in the context of that specific and unique individual who is presenting.
2. In utilizing the definitions for Energetic medicine listed previously, it is clear to see that a vast array of techniques and modalities exist that potentially can be considered when treating pain. In addition, as a number of these have been utilized for many years, the literature and research findings are voluminous. Due to these facts, it should be noted that the approaches discussed are far from exhaustive and in-depth coverage of each modality/technique is beyond the scope of this chapter. The reader is recommended to explore references at the end of this chapter for further reading in this area.
3. Energetic medicine does not have to be viewed necessarily as an alternative to good conventional care, nor should it be in all cases. However, studies related to each of the techniques shown below indicate that these modalities can enhance positive patient responses, and many of them are often used either alone or in combination with one another as complements to conventional care. As in the utilization of any form of treatment, patients are advised to seek qualified and competent caregivers.

CATEGORIZATION OF ENERGETIC MEDICAL TECHNIQUES

In an attempt to present energetic treatment approaches in a coherent format, Dr. Robert Becker has provided a broad-based classification of techniques that are dependent upon the energy levels used, labeling them Minimal Energy Techniques, Energy-Reinforcement Techniques, and High-Energy Transfer Techniques (Becker, 1990). However, given the expansive nature of Energetic medicine, any attempt at categorization can be problematic, as not every technique can be accurately categorized this way and much overlapping can exist.

Minimal Energy Techniques

Minimal Energy techniques are defined as "techniques in which no external energy is administered to the body and in which the treatment methods attempt only to activate preexisting energetic control systems" (Becker, 1990).

Generally speaking, the purpose of these techniques is to facilitate the mind's capacity to affect bodily function and symptoms, and the one aspect common to all is that the conscious mind is being influenced in a desired direction, with the body then following (Becker, 1990). During the course of this process, commonly known as self-regulation, the conscious mind can control the autonomic nervous system. Self-regulatory techniques are based scientifically on psychophysiology, the study of relations between psychologic manipulations and resulting physiologic responses measured in the body (Sabo & Giorgi, 2000). In many cases, practitioners work with their patients, often explaining to them that they are going to facilitate their own healing by learning methods that will give them control over their own bodies. Strong evidence exists that such strategies can be useful in pain management (Patterson, et al., 1992). A number of these techniques, however, are based on ancient religious and cultural practices, still often used today, in which individuals attain an altered state of consciousness, unlocking healing powers within the mind and body.

Some examples of minimal energy techniques, and their potential benefits in the areas of pain management, are described below.

Relaxation Techniques

A variety of relaxation methods have been developed in the last century, and they typically fall into two categories: somatic relaxation refers to a method that emphasizes muscle relaxation through detailed observation and introspection of the body's kinesthetic sensations (i.e., purposeful relaxation of the muscles); cognitive relaxation refers to the use of a mental device (e.g., word, thought, sound, breathing) and the practice of a passive or nonjudgmental attitude to induce relaxation in the mind and body (Freeman, 2001). Clinical findings indicate that, as a group, relaxation methods can alter sympathetic activity and are effective in reducing chronic pain in a variety of medical conditions (Freeman, 2001). It is possible, too, that in acute pain situations, highly anxious patients might find some level of reduction not only in their anxiety, but also in response to their pain, although more research in this area is necessary.

Meditation

Meditation is defined as "the intentional self-regulation of attention, and a systematic focus on particular aspects of inner or outer experience" (Astin, Shapiro, & Schwartz, 2000). Many forms of meditation exist, both religion and nonreligion based, and in some cases it can fall under the designation of a cognitive relaxation technique (see above). Research indicates that meditation may be particularly effective in the treatment of chronic pain, and significant reductions have been seen in inhibition of activity due to pain, pain symptoms, psychological symptoms, and pain-related drug use (Kabat-Zinn, Lipworth, & Burney, 1985; 1987). Findings also suggest that meditation is effective in reducing symptoms of anxiety and treating anxiety-related disorders (Eppley, Abrams, & Shear, 1989; Edwards, 1991).

Biofeedback

Biofeedback is an operational term "that refers to a group of experimental procedures in which an external sensor is used to provide the organism with an indication of a state of bodily process, usually in an attempt to affect a change in the measured quantity" (Seifer & Lubar, 1975). The effects of this self-regulation have probably best been demonstrated in studies with yogis from India who were able to slow down respiration, control pain, stop bleeding, raise body temperatures, and speedily heal wounds with their wills alone. Biofeedback research at the Menninger Foundation and elsewhere has shown that some of this same power can be tapped in people with no yogic training (Becker & Selden, 1985).

Biofeedback principles have been used with different instruments to measure changes in muscle contraction, body temperature, skin conductivity, and brain waves. Studies conducted in a variety of settings indicate that biofeedback therapy may be beneficial in the management of chronic and acute pain and stress reduction (Lawlis, 2001a).

Hypnosis/Hypnotherapy

Hypnosis can be defined as "a state of attentive, focused concentration with suspension of some peripheral awareness" (Spiegel & Spiegel, 1978). Hypnotic techniques are said to induce states of selective attentional focusing or diffusion combined with enhanced imagery (NIH Technology Assessment, 1995). The history of the use of hypnosis and trance states is a long one, and there are currently a variety of schools of thought both as to its mechanisms of action and its therapeutic usage.

In general, it has been found that hypnotherapy can be used medically by helping a patient deal with the symptoms of disease, including his/her physiologic or emotional reaction to it, and it can also directly affect the illness and its course through the body. Research demonstrates effectiveness in reducing analgesic dependency, offering an alternative to anesthesia, and treating biologic mechanisms associated with such diseases as hypertension and terminal illness (Saicheck, 2000). Also, based on a review of research in the area of pain management and hypnosis, it can be concluded that hypnosis can be a valuable adjuvant therapy for the treatment of pain due to a variety of causes, including cancer, burns, and surgery (Freeman, 2001b).

Imagery/Guided Imagery/Visualization

Imagery is the thought process that invokes and uses the senses, including vision, sound, smell, and taste, and the senses of movement, position, and touch (Achterberg, 1985). Guided imagery refers to a wide variety of techniques, including simple visualization and direct suggestion using imagery, metaphor and storytelling, fantasy exploration and game playing, dream interpretation, drawing, and active imagination where elements of the unconscious are invited to appear as images that can communicate with the conscious mind (Rossman & Bresler, 2000). Also, in one visualization technique commonly used in healing, a patient is instructed to look inward into his or her body and, in the case of illness, to visualize the disease that is there, then visualize the body's defense system attacking, or affecting changes in, the diseased tissues.

The use of imagery is demonstrated to have definite effects on physiology, biochemistry, immune function, and brain-wave frequencies and, although clinical use of the many imagery techniques available varies, research studies have shown that imagery can impact positively on pain reactions and tolerance in cases of both acute and chronic pain (Freeman, 2001b). Imagery methods have also been

shown to facilitate psychophysiological relaxation (Zahourek, 1988) and alleviate anxiety and depression (King, 1988; McDonald & Hilgendorf, 1986; Schaub, B.G. & Schaub, R., 1990). Additionally, a specific imagery technique, known as mental rehearsal, has been utilized to help prepare patients for medical procedures, tolerate them more comfortably, and to relieve pain and secondary side effects, perhaps exacerbated due to heightened emotional states. Published outcomes are almost uniformly positive and include significant reductions in pain and anxiety, length of hospital stays, use of pain medication, and reported side effects (Freeman, 2001b).

Trauma Energetics/Energy Psychology

Energy psychology is based on the concept that while psychological and/or psychosomatic dysfunctions entail chemical, neurological, cognitive, and situational components, most fundamentally they are manifestations of specific biotic energy information or energy configurations that are expressed as diagnosable psychological or physical symptoms. In diagnosis and treatment, the energy psychotherapist relies on isolating where aberrant or destructive energy patterns are encoded within the cellular structures of the body, and then employs procedures to decode those bioenergetic patterns (McClaskey, 1999). Procedurally, a number of techniques are available for the energy psychotherapist to utilize to attain this end; these procedures include, but are not limited to, Eye Movement Desensitization and Reprocessing (EMDR), Traumatic Incident Reduction (TIR), Neuroemotional Technique (NET), Thought Field Therapy (TFT), and Visual/Kinesthetic Dissociation (V/KD).

Research findings in this area are currently insufficient to establish efficacy; however, both clinicians and patients have reported beneficial outcomes not only in the reduction of addictive behavior, anxiety, trauma-related stress, and psychological disorders, but also in the relief of acute and chronic pain. In instances of chronic pain, it has been found that the pain relief frequently improves over time, such that the treatments work faster and the therapeutic effects last longer (Gallo, 1999).

Energy-Reinforcement Techniques

Energy-reinforcement techniques are defined as "techniques in which external energies are administered to the body, but in amounts similar to those that the body itself uses in its energetic control systems; as such, they are seen as reinforcing an inactive or inadequate energetic control system" (Becker, 1990). According to Becker, the body's internal energetic control systems are subtle, and they operate with minute amounts of electromagnetic energy. The techniques in this category appear to work, then, by adding to or reinforcing the existing internal bioenergetic systems through the application of small amounts of external energy, enhancing the intrinsic energy-controlled systems of the body" (Becker, 1990).

It is within this category that the majority of research in Energetic medicine is found, and many Energetic medical approaches are considered to be energy reinforcing. It should also be noted that many other traditional medical systems have evolved over time, including Native American, Aboriginal, African, Middle Eastern, Tibetan, and Central and South American cultures, all of which have energetically based foundations of belief and healing practices; however, discussion of these systems lies beyond the confines of this chapter.

Below is a partial listing of more commonly utilized energy-reinforcing modalities and pain-related research findings.

Acupuncture/Traditional Oriental Medicine

This ancient system of healing emphasizes the creation, re-creation, and/or homeodynamic maintenance of the vital energy within an individual, known as chi (qi) or ki. It is based on the concept that imbalances of this energy, due to a variety of causes, can lead to illness and disease; diagnosis involves, among other things, the "reading" of this energy by palpation of radial pulses. Traditional Oriental medicine is an encompassing term that involves the use of methods and techniques including acupuncture, herbal medicine, Oriental massage, and various movement therapies, such as Tai chi and Qi gong. Acupuncture is the best known of these, and treatment consists of the stimulation of specific points in the body on specific pathways, primarily through use of a needle, although practitioners also utilize heat, pressure, friction, suction, or impulses of electromagnetic energy to stimulate the points. (Note: Electroacupuncture involves the use of external applications of electroenergy by means of various devices. It is considered at greater length in the next category.)

Some of the most important findings on the role of energy fields in health and disease have come from acupuncture research. Dr. Robert Becker's work in the area of bioelectromagnetism during the 1980s performed research on acupuncture points and meridians. He found that acupuncture points existed and that they had specific, reproducible, and significant elecrical parameters; he also found that acupuncture meridians had the electrical characteristics of transmission lines, while non-meridian skin did not (Becker, 1990). Further research also showed that acupuncture meridians are low resistance pathways for the flow of electricity (Reichmanis, Marino, & Becker, 1975).

Pain management is considered to be a major area for the application of acupuncture. However, a comprehensive acupuncture bibliography, prepared in response

to the 1997 NIH consensus development conference on its use, spanned the literature from 1970 to 1997 and identified 2302 citations in various categories. These categories, which encompassed a wide range of systems and disorders, included general pain, addictions, and psychiatric disorders; cardiovascular system; gastroenterology; genitourinary, pelvic, and reproductive systems; headache; low back, sciatica; lower extremities; neck and shoulders; nervous system; nausea, vomiting, and postoperative problems (Dean, Mullins, & Yuen, 2000). Acupuncture also has been shown to play an extremely important role in the prevention of illness and is utilized to facilitate personal transformational and spiritual growth processes as well.

Ayurveda

Considered India's traditional system of medicine, Ayurveda (meaning "the science or knowledge of life") is a comprehensive system of medicine that places equal emphasis on body, mind, and spirit. It is based on the premise that disease is caused by living out of harmony with our environment and each individual uniquely responds to this disharmony energetically; part of the diagnostic process includes "reading" of this energy in a way similar to Oriental medicine, although what is being read is considerably different. Treatment strives to restore this innate energetic harmony primarily through the use of diet, exercise, meditation, herbs, massage, chromotherapy, and controlled breathing techniques specific to each patient. Although little or no formal research has been conducted, there are many articles and studies in support of its efficacy, especially in cases of chronic conditions (Lad, 1999).

Homeopathy

Homeopathy is a systematic approach to healing formulated by Samuel Hahnemann in the 1790s that uses dilute or energetic forms of medicines to trigger an individual's innate capacity to heal. It works holistically, maintaining that disease is secondary to disharmony within the individual's system and that mental, emotional, and physical symptoms reflect this disharmony. Theoretically, it is based on the "Law of Similars," meaning that the same substance in large doses will produce the symptoms of an illness, but in very minute doses will cure it. In lieu of this, it is understood that the more dilute the remedy, the greater its potency. Homeopaths, therefore, utilize varying potencies of specially prepared plant extracts and minerals to stimulate the body's defense mechanisms and healing processes on whatever level is necessary to treat the specific illness. It is of interest to note that according to the World Health Organization, homeopathy is the second most used healthcare system in the world, primarily utilized in Europe; however, even in the United States, prior to the rise of allopathic medicine as a standard of care around the 1900s, 20 homeopathic medical schools were known to exist, with approximately 8% of all physicians utilizing it in their practices (Chapman, 1999).

Homeopathy is also often considered to be a form of what has been called vibrational medicine, and BEM findings may begin to provide an explanation of its mechanism of action. Diseases and disorders can alter the balance of the electromagnetic properties of molecules, cells, tissues, and organs. When this occurs, use of a specific drug sometimes can restore normal functioning; this is the basis for pharmacology (Oschman, 2000). However, vibrational medicines such as homeopathy demonstrate that similar or even better results can be obtained by providing the specific electromagnetic fingerprint or signature of a natural substance (Smith, 1994). In doing so, they can initiate a response in the defense and repair systems of the body and restore balance to the system without potential pharmaceutical side effects.

A review of clinical trials in homeopathy included 107 controlled trials that were published between 1990 and 1996. Although most trials were of poor quality, there was a positive trend; of the 107 trials, 81 demonstrated improvements in the treatment of headaches, respiratory infections, diseases of the digestive tract, postoperative infections and symptoms, as well as other disorders (Kleijnen, Knipschild, & ter Reit, 1991).

Biologically Based Therapies

This category encompasses a variety of naturally, pharmacologically, and biologically based products, practices, and interventions, many of which overlap with conventional medical usage, but which, by their nature, are appropriately considered as energy reinforcing. Examples of these include, but are not limited to, herbal therapies, orthomolecular and nutritional supplementation, chelation therapy, and special dietary therapies. Despite their diversity in historical usage, mechanisms of action, and clinical approaches, common aims are to control symptoms, promote health, and prevent illness. As therapies in this category have amassed volumes of literature, discussion of detailed findings is not possible, and the reader is invited to explore specific texts referenced at the conclusion of this chapter.

Chiropractic and Other Manipulative and Body-Based Therapies

Chiropractic is considered to be one of the major branches of Western medicine. The major difference between chiropractic and other forms of Western medicine is that chiropractic focuses on the spine as integrally involved in

maintaining health, providing primacy to the nervous system as the primary coordinator for function, and thus health, in the body. The goal of chiropractic is the maintenance of optimal neurophysiological balance in the body, which is accomplished by correcting structural or biomechanical abnormalities or disrelationships, and the primary method for accomplishing this balance is spinal manipulation, also known as the chiropractic adjustment (Lawrence, 1999). Although the use of manipulation is primary, chiropractic treatment also can include soft tissue techniques such as massage, and the use of ice, heat, ultrasound, traction, and electrical stimulation. A review of the research literature indicates that chiropractic treatment can be efficacious in treating low back, neck, and headache pain, although it is often utilized, with success, for some nonmusculoskeletal conditions as well (Freeman, 2001a).

Myriad other body-based techniques and methods also exist including, but not limited to, therapeutic massage, Shiatsu, acupressure, myofascial release, Feldenkrais, Alexander method, and Rolfing. Extensive subjective and clinical reports indicate that these and other methods can be beneficial not only for pain and stress reduction, but also to facilitate positive changes in body structure, associated soft tissue, and overall physiological functioning. (Please refer to the specific method in referenced texts for more detailed findings.)

Just as many forms of body-based therapies include the understanding that the whole system is impacted upon during treatment, body-oriented psychotherapies also have been developed that expand on the notion that the body–mind is interconnected and cannot be separated during the course of treatment. Candace Pert further explains this, incorporating bioenergetic aspects, when she states that "most bodyworkers and body psychotherapists take as fact that trauma is absorbed and stored in the body and can be unblocked by some corrective energyflow. Therapeutic massage can be so much more than increasing blood circulation in sore muscles; our concept of the psychosomatic network envisions memories stored in the body (the subconscious mind) in the form of alterations at receptor molecules which transduce chemical changes into ionic fluxes and thus the propagation of electromagnetic waves throughout the network which joins the nervous system, immune cells, gut, glands skin, etc." (Pert, 1999).

Spiritual Healing/Prayer

Spiritual healing is probably the oldest recognized form of energy-based healing and is defined as "the systematic purposeful intervention by one or more persons aiming to help (an)other living being (person, animal, plant, or other living system) or beings by means of focused intention, by touch, or by holding the hands near the other being, without application of physical, chemical, or conventional energetic means of intervention" (Benor, 1999). Prayer may be differentiated from spiritual healing in that, in most cases, it is performed singularly, and might instead be considered as a minimal energy technique. However, in those cases where group prayer is utilized as a healing modality, mechanisms of bioenergetic exchanges may occur.

Although efficacy is unpredictable, healers and those being healed report that pain is the symptom most responsive to spiritual healing, and emotional conditions, such as anxiety and depression, also often respond well (Benor, 1999). A number of studies have examined the effects of religion and prayer on health outcomes and results indicate that these factors were helpful for patients in coping with health problems, illness, and chronic disability that are unresponsive to medical treatment (Koenig, 2000). In addition, Elizabeth Targ and Fred Sicher (1998) published the results of a pilot study showing that advanced AIDS patients who received long-distance intercessory prayer improved their medical outcomes (Springer & Eicher, 1999). Other studies also indicate statistically significant effects of intercessory and remote prayer (Springer & Eicher, 1999).

"Hand-Mediated Energetic Healing Modalities" (HMEHM)

Victoria Slater has coined this phrase to refer to "healing methods in which a practitioner's hands are the medium of transfer or exchange of something that subjectively feels like energy, although there are some reports of feeling heat" (Slater, 1996). These modalities include new techniques, as well as modern variations of ancient indigenous practices found around the world, such as healing touch, therapeutic touch, polarity, touch for health, Reiki, and external Qi gong. Considered similar to spiritual healing in many aspects, these modalities generally are based on the belief in a universal healing energyflow with the premise being that it is either this healing force moving through the practitioner, or the individual healing force of the practitioner, that affects the patient. Practitioners are able to identify energy imbalances, often by passing their hands over the patient, and healing is promoted when the body's energies become balanced. Another similarity is that these techniques do not require direct physical contact, merely clear, focused intention. They do differ, however, from spiritual healing in that their effectiveness does not require professed faith or belief by either the practitioner or patient, and they are not typically performed within any religious context.

Although research on the objective physiologic causes and effects of these modalities is inconclusive, a review of related literature indicates that these prac-

tices can be effective in reducing pain, decreasing stress, depression, and anxiety, positively affecting blood level values, increasing healing rates and immune responses, and promoting relaxation (Slater, 1996). Due to the extensive research in this area, the reader is referred to related chapters in referenced books on complementary/alternative medicine for detailed studies.

Static Magnetic Field Therapy

Research by Robert Becker demonstrated that every nerve fiber in the body is completely encased in perineural cells and that this perineural system is sensitive to magnetic fields. This discovery helped to provide a basis for the use of magnets and biomagnetic fields in healing (Becker, 1990; 1991). In this category, a differentiation is made between the therapeutic use of static or permanent magnetic fields and other forms of electromagnetic therapies. Although theoretically the latter might be placed in this category as their usage is dependent upon devices that issue current, it is more appropriate that they be considered within the next category.

Static magnets have been used in a variety of ways, from placing small magnets over acupuncture points to the use of magnetic insoles, blankets, and beds—all aimed at balancing the body's electromagnetic fields, and thus affecting the functioning of the nervous system, organs, and cells. In regard to pain management, very little research has been documented. In one of the few double-blind studies with static magnetic fields, active and placebo magnets were applied over trigger points on 50 patients with pain; results showed significant reductions in pain (Vallbona, et al., 1997). Another study of fibromyalgia patients using tectonic magnetic mattress pads showed a significant improvement in physical functioning, decreased pain, and improvement in sleep (Colbert, et al., 1998).

Music/Sound Vibrations

In many cultures the use of music and sound has been found to create altered states and to promote healing, and it is now well known that the human body does respond to vibratory stimuli. Research shows that varying frequency, amplitude, and rhythm can elicit physiologic responses, affecting changes in heart rate, blood pressure, brain waves, the nervous system, and in muscles and other body tissues. Recent studies also indicate the efficacy of vibration and vibratory responses within the body to music or other sound waves in relief of both acute and chronic pain (Taylor, 1999).

Light Therapy/Phototherapy/Chronobiology

This energetic modality is defined as the therapeutic application of electromagnetic energy in the visible spectrum, using ultraviolet, bright white, colored, monochrome, or laser light, to treat a wide range of health disorders (Wallace, 2000). Based on the concept that varying colors and frequencies can affect the bioenergetic system and thus a number of bodily functions, treatment usually involves using various instrumentation that produces specific frequencies of light energy. It is performed most often by shining light/color on a person's entire body or specific parts; injecting specific irradiated pigments into cells, organs, or tissues that are then, in turn, irradiated with certain frequencies of light (photodynamic therapy); visualization of certain colors either within the body or as part of meditation to apply color to areas of the body; and/or irradiating water with a specific color for drinking (Wallace, 2000).

Research-based findings are currently somewhat limited; however, use of different forms of light therapy has been reported to yield positive results in the treatment of chronic and acute pain and inflammation, headaches, depression, immune and endocrine disorders, as well as in the areas of oncology and dermatology (Goldberg, 1993).

Aromatherapy

Aromatherapy is the therapeutic use of essential oils, absorbed via the skin or olfactory system. Essential oils are defined as steam distillates obtained from aromatic plants, or expressions from the peel of citrus fruits (Evans, 1994). Research indicates that aromatic molecules give off signals that travel to the limbic system that, in turn, is directly connected to those parts of the brain that control heart rate, blood pressure, breathing, memory, stress levels, and hormone balance. Findings show that essential oils, when inhaled, affect brain waves. Specific oils have a tranquilizing effect and work by altering the brain waves into a rhythm that produces calmness and a sense of well-being, while others work by producing a heightened energy response (Goldberg, 1993; 1997).

Although the properties of each individual oil appear to be understood, few studies have been done on the analgesic effects of essential oils. However, essential oils are frequently used for the topical treatment of various types of pain, including arthritis, cephalgia, and cancer, and can play a role in altering the perception of chronic pain. In a study, HIV-infected hospitalized children responded well to the chosen blends, helping to decrease the need for analgesic drugs. Some of the children said their pain had been relieved completely; in others, symptoms of chronic chest pain, muscle spasm, and peripheral neuropathy were eased (Buckle, 1999).

Related Research Findings

Although the scientific validity has been, and continues to be, questioned, studies of several of these energy trans-

fer modalities have brought forth interesting results, as shown below:

- Extremely large frequency-pulsing biomagnetic fields were discovered emanating from hands of therapeutic touch practitioners during therapy as determined by SQUID measurements. The signal pulsed at a variable frequency (i.e., sweeping or scanning through a range of frequencies) ranging from 0.3 to 30 Hz, with most of the activity in the range of 7 to 8 Hz. Nonpractitioners were unable to produce the same biomagnetic pulses (Zimmerman, 1990).
- Another study confirmed that an extraordinarily large biomagnetic field emanates from the hands of practitioners of a variety of healing and martial arts techniques, including yoga, meditation, and Qigong. The fields were measured with a simple magnetometer that indicated that these fields were approximately 1000 times stronger than the strongest human biomagnetic fields and the biomagnetic field pulsed with a variable frequency centered around 8 to 10 Hz (Seto, et al., 1992).
- The brain wave activities of various "healers" from around the world were studied and recorded by Robert C. Beck. Utilizing an EEG, he found that all the healers produced similar brain wave patterns when they were in their altered states and performing healings. Regardless of their beliefs and customs, all of these healers produced nearly identical EEG signatures with brain wave activity averaging about 7.8 to 8 Hz (Beck, 1996).

Although these studies did not document any clinical healing effects taking place during this projection of energy, the evidence does show that practitioners, in a variety of settings and using different modalities, emit powerful pulsing biomagnetic fields within a common, specific frequency. This frequency range corresponds to similar frequencies being tested in medical research laboratories for use in facilitating the healing process of certain biological tissues, with initial positive results (Sisken & Walker, 1995).

Additional studies on the effects of Qi gong also yielded notable results:

- A study of Qigong masters shows that they can project measurable amounts of heat from their palms, in addition to biomagnetic fields, which increases cell growth, DNA and protein synthesis, and cell respiration. They can also produce inhibiting qi, in which infrared energy is absorbed from the environment. This kind of qi slows metabolism (Muehsam, et al., 1994).
- Research has been performed employing a Qi gong master emitting external qi to a human being or a nonhuman organism while the effects are monitored under controlled scientific conditions. The results of these controlled Chinese trials demonstrated unexpected and unexplainable variations in the basic characteristics of most substances tested, ranging from radioactive materials to simple tap water. In addition, these external qi effects were noted at significant distances; for example, more than 10,000 miles between qi transmitter and receptor have been recorded, indicating that the matter–energy manipulation phenomenon is not limited to close proximity (Benford, et al., 2000).
- In regard to this latter finding, clinical research and other laboratory and cross-cultural studies also have demonstrated the ability to effect various physiological changes over long distances. Consistent with BEM findings that electromagnetic fields are capable of producing an action at a distance, bioenergetic effects appear to extend beyond hand-mediated practices. Findings such as these would support further clinical exploration of such well-known practices as remote visualization techniques and long-distance prayer.

High-Energy Transfer Techniques

High-energy transfer techniques are defined as those "in which electromagnetic energy is introduced or administered to the body in amounts that exceed those that naturally occur, in the sense that the normal system is replaced by this externally derived energy" (Becker, 1990). This category includes the use of a variety of diagnostic and treatment devices. For treatment purposes, the majority of electromagnetic (EM) therapeutic methods used in the United States are nonthermal in nature (causing no significant heating of the tissue) and generally utilize either pulsed electromagnetic fields (PEMFs), pulsed radiofrequency (PRF), or low-frequency sine waves, although others have also been utilized (Taylor, 1999).

Many electrical devices have been demonstrated over time to have beneficial medical applications. For instance, studies during the last several decades show that the use of transcutaneous electrical nerve stimulation (TENS), in which controlled, low-voltage electrical impulses are applied to the nervous system through electrodes, is beneficial for the control of acute and chronic pain. One of the accepted mechanisms of pain relief with the TENS unit is based on research indicating that increased endorphin production is derived from its use (Kahn, 1987).

It is estimated that there are more than 100 types of FDA-approved TENS units currently available, with each device offering some variances of wave forms and frequencies, although all operate on the same basis (Rubik, et al., 1992). Along similar lines, transcranial electrostimulation devices (TCES) and neuromagnetic stimulation techniques are being used to treat symptoms of depression, anxiety, seizures, and insomnia (Rubik, et al., 1992).

While traditional acupuncture is considered an energy-reinforcement technique, electroacupuncture—where either the needles are stimulated with varying frequencies/intensities of electricity or the acupuncture points are stimulated by electrical devices without the use of needles—is considered to be a high-energy transfer technique. Electroacupuncture is frequently used to enhance the analgesic effect in the course of a treatment, but is also utilized to create an anesthetic effect on specific body parts based on where the electrodes are placed. Studies utilizing electroacupuncture have shown it to be beneficial in the treatment of postoperative pain (Christensen & Noreng, 1989), renal colic (Lee, et al., 1992), and in the treatment of chemotherapy-induced sickness in cancer patients (Dundee & Ghaly, 1989).

Recently, medical research has revealed that magnetic fields can convert a stalled healing process into active repair. In regard to nonunion bone fractures, three types of applied electromagnetic fields are now known to promote healing: pulsed EM fields (PEMF) and sinusoidal EM fields (AC fields), DC fields, and combined AC–DC magnetic fields (Rubik, et al., 1992). Efficacy of EM bone repair treatment has been confirmed in double-blind clinical trials (Barker, et al., 1984; Sharrard, 1990), and clinical tests prove that PEMF therapy will jump-start bone repair (Bassett, 1995). In addition, PEMF therapy was found to be effective in reducing pain and improving function in osteoarthritis patients (Track, et al., 1994).

Research employing electric and magnetic fields on soft tissues has been reviewed by Sisken and Walker who observed that PEMF pulses not only accelerated the healing of soft tissue injuries, but also reduced swelling, diminished pain, increased tensile strength of ligaments, and accelerated nerve regeneration and functional recovery, among other findings. They found that to be effective PEMF pulses must be of low energy and extremely low frequency (ELF) (the ELF range is arbitrarily defined as frequencies below 100 hz) (Sisken & Walker, 1995). Short-wave pulsed radiofrequency (PRF) therapeutic applications have also been reported for the reduction of posttraumatic and postoperative pain and edema in soft tissue, wound healing, burn treatment, sprains and strains of the ankle, hand injuries, and nerve regeneration (Markoy & Pilla, 1995).

The use of electromagnetism is being studied for other medical benefits as well, including treatment of autoimmune diseases, immune restoration, additional areas of pain management, and in neurology. However, according to biomedical standards, there is currently no commonly accepted mechanism for electromagnetic field bioeffects, and analgesic action of electromagnetic frequencies is explained through enhanced endorphin production, as well as by anti-inflammatory and anti-edema activity and reduction in spasms (Serabek & Pawluk, 1998).

In addition to those electromagnetic devices currently either approved or pending approval by regulatory agencies, many others also exist that claim to perform a variety of procedures, including the diagnosis of energetic imbalances and the rebalancing of energy fields within the body, as well as facilitating healing in various ways. Despite claims regarding their efficacy, however, definitive documentation is lacking at this time, and clinical studies are continuing.

FUTURE IMPLICATIONS

As research accumulates in the areas of BEM, cellular biology, and quantum physics, new doors of understanding are opening, and work in the areas of energetics and bioenergetics may hold potential answers for continued expansion in the field of medicine. Some future implications of the use of Energetic medicine are considered below.

Prevention

In 1996, data showed that disease states can be detected by measuring changes in the electrical conductances of tissues, long before any structural abnormalities have occurred (Brewitt, 1996). In lieu of these data and similar research coming to light, we can begin to see the importance of Energetic medicine in the area of prevention. As Dr. Julian Kenyon states: "If pathological changes can be detected at the energetic stage, then diagnosis can be much earlier and also pathology at this stage is more easily reversible than when a lump has already appeared" (Kenyon, 1984).

While the current focus is on the healing of injuries and management of pain, it has also been found throughout time that Energetic medical techniques can be of profound significance even if no specific problem is present, and that the free flow of energy through tissues is essential not only for prevention of disease, but also for the promotion of optimal health. An individual who is healthy will not only be happier, but also less likely to have an injury or disease. Energetic medicine has shown that, in many cases, if problems arise, a person will be apt to recover more rapidly. Likewise, athletic, artistic, and intellectual performance can be enhanced when all of the body's communication channels are open and balanced. This point is well understood in many Energetic medicine practices, and people will often come in on a regular basis for what are called maintenance treatments or tune-ups.

Palliative Care

Both patients and physicians have reported dissatisfaction at what currently are often seen as the only answers to the question of how best to provide comfort at the end of life. When a cure is not possible, healing can still take place, and comfort comes in many forms. Energetic medical modalities are becoming viable options not only in pain management for the terminally ill, but also in reducing anxiety, creating a more peaceful outlook, and facilitating empowerment as death approaches.

New Medical Paradigm

Some researchers believe that Energetic medicine may be an important next step in medicine because it takes into account the entire individual. If utilized as a medical model, it would necessitate consideration of all bodily systems, including consciousness, as part of a patient's total experience in both the disease and the healing process (Lawlis, 2001a). In appropriate situations, specific energetic-based modalities also may be desirable over chemically based treatment because they can be generally safer to use, require less time for beneficial action, and dosage adjustment potentially could be determined with less risk of side effects. In addition, as research is beginning to indicate, specific forms of electromagnetic stimulation may be utilized for the regeneration of damaged tissue and bodily structures, for benefit in ameliorating specific symptoms, and for enhancing immunological functioning (Lawlis, 2001b).

CHALLENGES FACING ENERGETIC MEDICINE

Just as it has been established that extremely small amounts of electromagnetism have a variety of positive biological effects, some researchers make the argument that exogenous fields of energy administered to the body may have side effects of an undesirable nature. For example, as mentioned previously, research has shown that electrotherapy can be effective in some cases for chronic pain, to increase endorphin output, and to stimulate the healing of human bone fractures. Experimentation also has shown that exposing cancer cells to specific levels of DC current caused them to grow "at least 300% faster than the controls" (Becker, 1990). Findings such as these indicate the need for further inquiry and, as in the case of any new therapeutic modality, time must be afforded for the slow progression of discovery of benefits, consequences, and parameters. As clinical research of the properties, actions, effects, and interactions of both bioelectromagnetism and electromagnetic therapy continues, it is becoming evident that questions such as these are being addressed.

Even with the advent of extensive research of energy fields and their potential for medical benefits, there continues to be a great deal of criticism. The literature indicates that most criticism is centered around the fact that the human energy field cannot be adequately measured and, in many cases, the mechanisms of action and beneficial effects of energetic modalities have not been sufficiently explained, documented, and validated using current biomedical research standards. Study replication also has been found to be difficult, often yielding inconsistent findings; this may be because individuals are unique, and response to identical stimuli or testing methods may vary among individuals or over time with the same individual.

It is true that challenges exist in attempting to use conventional biomedical research methods to study Energetic medicine. A number of its practitioners and researchers feel that the randomized controlled trial is not always the most appropriate research methodology for energetically based treatments (Gatchel & Maddrey, 1998), many of which are based upon long-standing ethnomedical systems of knowledge. Clearly, it does not fit either the models of etiology and treatment or the current research models found in Western biomedicine. However, rather than dismissing the study of Energetic medicine, as has been suggested by some, consideration of alternative research methodologies is being initiated, including the use of case studies, experiential reports, and observational findings, all of which may provide valuable insights for both practice and research.

The study of biomedicine has been and continues to be an evolutionary process, changing as it embraces each new discovery. In the same regard, many BEM researchers are now beginning to expand what perhaps might be considered a limited and outmoded approach to scientific inquiry by suggesting the incorporation of a systems theory approach to the study of Energetic medicine. They believe that it may offer a plausible and acceptable scientific framework while accommodating the unique aspects inherently found in this form of medicine (Benford, et al., 2000). By definition, "systems at any level, whether physical, biological, social, and/or ecological, are open to information, energy, and matter to varying degrees and, therefore, interact with other systems to varying degrees" (Schwartz & Russek, 1997).

The core of systems theory, then, is dynamic interaction: systems do not simply act on systems; they interact with them in complex ways. As living systems are found to interact with other systems in ways previously uncomprehended, their study requires a focus to incorporate this information. Utilization of the systems approach to the study of Energetic medicine, then, may offer an exciting alternative to the current Biomedical model and an opportunity to begin to understand those aspects of life that exist outside of a reductionistic and mechanistic framework.

Qigong: A Paradigm Shift Tool for Pain Management

Linda C. Hole, M.D.

> Each person carries his own doctor inside him. They come to us not knowing the truth. We are our best when we give the doctor who resides within each patient a chance to go to work.
>
> Albert Schweitzer, M.D.

> When you have a disease, do not try to cure it — Find your center, and you will be healed.
>
> Chinese Proverb

INTRODUCTION: WHAT IS QIGONG?

Qigong is a 5000-year-old energy healing practice, an integral part of Chinese medicine, and is practiced by over 80 million people in China. For pain management practitioners in the New Millennium, Qigong is a paradigm shift tool that empowers both the patient and practitioner toward freedom from pain.

Clinical studies document that Qigong is remarkably effective in the treatment of pain, both acute and chronic. In the hands of a skilled practitioner, Qigong often gives dramatic, sometimes near miraculous results in pain relief, especially for those where all else has failed. Qigong not only empowers and frees the patient from pain, it is also simple to learn, practice, and apply, and is available to all.

Qigong is aligned with what Larry Dossey, M.D. heralds as New Era "non-local," "eternal" medicine vs. "internal" medicine (Dossey, 1999). Qigong takes mind-body medicine to the next step. Qi energy medicine is beyond mind, beyond body, beyond space, beyond matter, and transcends time. Qi healing may be long distance, spontaneous, and at times instantaneous.

Qi, pronounced "chee," is your breath, or your universal vital life force energy. Gong, pronounced "gung," is work, or practice.

As one of my Qi masters teaches, Qi is Greek for the letter chi, or the cross. Qigong is, thus, also the practice of standing centered between heaven and earth, and at the same time open to the universal "Christ force" healing energy, known in different cultures as *prana*, *shakti*, or *ki*. For some, Qi is simply the breath of God. Christ, of course, is the greatest Qigong master who ever lived.

Nearly every culture has some form of Qi energy healing practice. Modern day practices range from reiki, guided imagery, hypnotherapy, mindfulness stress reduction, reiki, and therapeutic touch, to shamanism and faith healing.

Qigong, however, is not a religion, is nondenominational, requires no particular set of beliefs, and again, is freely available to all. Qigong itself is simply the practice of gentle breathing, movement, stretching, and meditative exercises – exercises that open your body, mind, and spirit to the healing power and life-changing miracles of Qi.

Besides pain relief, Qigong strengthens your immune system, prevents aging and disease, relieves stress, reverses paralysis, increases energy, and promotes peak performance (Chow & McGee, 1994). Qigong practitioners routinely report profound healing and transformation on many levels: in health, relationships, personal and professional growth,

0-8493-0926-3/02/$0.00+$1.50

sense of well-being, plus a life of more love, light, joy, peace, abundance, laughter, freedom, and self-acceptance, qualities that in themselves help relieve pain.

Qigong, furthermore, potentiates the effectiveness of Western medications, alleviates side effects, and allows reductions in dosages (Sancier, 1999).

"Hard" Qigong includes performance miracles such as Qigong masters who light fluorescent bulbs and tubes, bend steel, break concrete slabs, and charge batteries with their bare hands. Some also can affect scientific instrument measurements, petri plate growth cultures, and kill laboratory cancer cells across a room (Eisenberg, 1987; Lee, 1999).

"Soft" Qigong superpower phenomena common to masters include medical X-ray vision, uncanny intuition, precognition, fingertip diagnosis, long-distance healing, and the ability to direct or emit Qi, with measurable physical results (Wen, 1998).

Medical Qi miracles include Qi-induced surgical anesthesia, spontaneous cancer remissions, reversal of paralysis, and Qi-induced changes in subjects' blood pressure, EEG, and blood levels of various neurotransmitters and hormones (Chow & McGee, 1994; Lee, 1999).

Wai Qi or "outer Qi," in the context of pain management, is when the practitioner brings about pain relief in the subject by emitting Qi. Qi may be emitted via your hand chakra, Lao Gong points, fingertips, and via mind over matter intention or Yi Nian.

Nei Qi or "inner Qi" is healing by cultivating your own internal Qi via simple breath, movement, and meditation exercises.

The discipline of Nei Qi is necessary for the practice of Wai Qi.

A Qigong master is someone who has cultivated both Wai Qi (outer) and Nei Qi (inner), and demonstrated significant Qi healing ability. One of our goals in this chapter is to take the mystique out of Qi healing. The miracles of Qigong are freely available to all. Within each and every one of you is a Qigong master.

THE SCIENCE OF QI

Does Qi really work? Is Qi real? How does Qi work? Cloaked in secrecy for centuries, and outlawed during the Cultural Revolution, Qigong underwent rigorous scientific scrutiny with the post-Cultural Revolution resurgence of traditional Chinese medicine as one possible solution to China's overwhelming health demands. Although the quality of the research is admittedly uneven, the data still clearly document that Qigong is remarkably effective in pain relief, and is real.

Does Qi Really Work?

A survey of clinical studies documents the effectiveness of Qigong, sometimes in combination with Chinese herbal medicine and/or acupuncture, in both acute and chronic diseases for relieving pain in arthritis (He, 1989), rheumatoid (Chen) and osteoarthritis (Omura et al., 1989); cancer (Chen, G.; Wang, S.; Wang, Ying); chest pain (Kazhuda); diabetic peripheral neuropathy (Feng et al.); disc disease (Lim, 1993; Lin, l988; Noda, 1993); dysmenorrhea (Huang, Cai, & Zhang, 1996); fibromyalgia (Singh, Berman, Hadhazy, & Creamer, 1998); knee pain (Nakagawa, 1988); low back pain (Lim, 1993); migraines (Pavek, 1988); neck pain (Liu, L., 1998); post-herpetic neuralgia (Omura, Losco, Omura, Takeshige, et al., 1992); trigeminal neuralgia (Tong, 1989); reflex sympathetic dystrophy (Wu, W., Bandilla, Ciccone, Yang, et al., 1999); shoulder pain (Shi, 1998; Wang, F., 1989), including frozen shoulder (Gao, Q., 1996); sciatica (He, 1989), soft tissue injuries such as sprains, strains (Enrico, K. & Enrico, D., 1993; Huang, R., 1989; Huang, X. & Cao, Q., 1993; Huang, Y., 1996); sports injuries (Cui, W., 1998); and pain secondary to surgical and/or traumatic scars (Ma, 1988), and pain secondary to vascular disease (Agish, 1998; Omura, 1990).

Studies also document the efficacy of Qigong in surgical anesthesia (Lin, H., 1988), and in pain relief of organic diseases such as cholelithiasis (Wang, D., et al., 1989) chronic atrophic gastritis (Qigong Science Research Group, 1988); coronary heart disease angina (Sun, Yuan, & Yang, 1988); gastritis (Wang, Y., 1989); irritable bowel (Pavek, 1988); gastric ulcer (Tong, 1989); and prostatitis (Tong, 1989). Omura and Sha report that Qigong is effective also in intractable pain (Omura, et al., 1992), and chronic pain syndromes (Sha, 1998). Quan notes that Qigong, used together with acupuncture, is significantly more effective than acupuncture alone, 94% vs. 55% for acupuncture alone for successful relief of pain (Quan, 1996).

Back and Disc Disease

Noda (1993) reports a 90% success rate in using a body manipulation Qigong approach to treat 2000 patients suffering herniated discs: 70% successful within one to two treatments, 15% with four to five treatments, and 5% requiring more than five treatments. For more than 600 patients suffering back pain, Lim (1993) reports a 98% success rate using Qi music tapes and Qi healing through the mind. Several of the patients avoided surgery. In a series of 292 patients treated with Qigong combined with Chinese and Western medicine, 274 for disc disease and 18 for chronic lumbrosacral pain, Liu (1988) reports a 97.7% success rate for cure and/or significant relief of symptoms.

Fibromyalgia

In 20 fibromyalgia patients who completed an 8-week mind–body protocol including weekly Qigong movement

therapy sessions, Singh et al. (1998) report significant pain reduction.

Frozen Shoulder and Tennis Elbow

Gao (1996) reported an overall effective rate using Qigong treatment for relief of symptoms 81.2% in 32 patients suffering a 1-week to 2-year history of frozen shoulder and tennis elbow: 6 patients (18.8%) with the first treatment, 7 patients (21.9%) with 2 to 5 treatments, 13 patients (40.6%) within 6 to 15 treatments.

Migraines

Pavek (1988) reports that in more than 40 patients suffering migraines, successful treatment with the psycho-emotional Qi approach reduced frequency from biweekly to episode intervals of over a year or more.

Coronary Heart Disease Chest Pain

In China, Qigong also is used to treat the pain of organic disease. Sun, Yuan, and Yang (1988) report a 100% success rate in relieving angina pain in 51 patients with diagnosed coronary heart disease, with documented electrocardiogram improvements in 94.12%.

Arteriosclerotic Lower Extremity Pain

Agishi (1996; 1998) in 37 patients with documented arteriosclerotic obstruction of their lower extremities reports that 93.8% experienced improvement in subjective symptoms; 89.6% experienced an "instantaneous" rise in lower extremity temperature following Qi treatments as documented by thermography; 75.6% experienced improvement in pulse amplitude documented by plethysmography; and 88.9% experienced increased dorsalis pedis and tibialis posterior blood flow documented by ultrasound.

Surgical Qi

Inosuke (1993) defines Qigong anesthesia as "the patient loses his consciousness when the Qigong master emits his qi to him." Lin (1988) reports 91.8% success in Qigong surgical anesthesia in 34 cases for thyroid tumor and cyst resections. Johnson (1998) finds that using Qigong pre-, post-, and intra-operatively reduces bleeding, enhances immune function, minimizes infections, accelerates recovery, and reduces pain. Of note, Machi and Chu (1996) report the synchronization between the subject and Qi master in stimulated Qi anesthesia of alpha and beta brain waves, and heart rate.

TABLE 51.1
Efficacy of Qigong in the Treatment of Pain Survey World Scientific Literature

	Author	No.	% Reporting Improvement in Symptoms
Back pain	Lim (1993)	600	98
Disc disease	Noda (1993)	2000	90
Disc disease and back pain	Liu (1989)	292	97.7
Fibromyalgia	Singh (1998)	20	Significant
Frozen shoulder and tennis elbow	Gao (1996)	32	81.2
CHD chest pain	Sun (1988)	51	100
ASCVD lower extremity pain	Agishi (1996; 1998)	37	93.8

Is Qi Real?

Subjects may experience Qi as sensations of heat, electric current, pressure, pulsing energy, involuntary movement, perspiration, tingling, relaxation of both body and mind, and pain relief; with simultaneous measurable changes in body temperature, skin temperature, blood pressure, heart rate, body secretions (Enrico, B., & Enrico, D., 1993; Lin, 1988; Nishimoto, 1996; Wu, 1989; Zhao et al., 1996), and over time, healthy weight loss (Wang, Y., 1995). Sancier (1994) reports in a pilot study of electrical conductivity of acupuncture meridians (EAV) that active Qi practice balances acupuncture meridians and internal organs.

Qi masters may experience in addition to the above a measurable increase in temperature of their Lao Gong hand points, an immediate increase in blood levels of ATP with the practice of Qigong exercises, and an immediate decrease in blood levels of ATP upon emitting Qi (Lee, 1999; Lin, H., 1988).

Emitted Qi from a Qigong master's hands has been documented in scientific laboratories to change the color of crystals, light fluorescent bulbs, increase the fluorescence of organisms by 68% (Lin, H., 1999), kill in vitro laboratory cancer cells, expose light-sensitive plates, and change magnetic fields (Lee, 1999).

Machi and Chi (1996) measured simultaneous physiologic changes in the subject and a Qi master emitting Qi to the subject. They report changes in electroencephalogram (EEG), electrocardiogram (EKG), galvanic skin resistance (GSR), and skin temperature, In both subject and Qi master, alpha waves increased, and beta decreased. Of note is that the heart rates became synchronized as well.

Non-local Qi, or Qi treatment at a distance, is possible by Yi Nian intention, or by inert materials, such as Qi-energized audiotapes, paper, metal, glass, stone, clothes, etc., into which a Qi master has emitted Qi. Omura (1990) reports that placing a (+) Qi stored material on an indicated

body area improves circulation, relaxes spastic muscles and vasoconstriction, reduces or eliminates pain, and enhances drug uptake. Lim (1993) and Nishimoto (1996) both use Qi-energized audiotapes in the treatment of pain with positive results.

Prestigious scientific laboratories in China, such as the National Atomic Energy Lab in Shanghai and the Space Science and National Electro-Acoustics Institute in Beijing, demonstrate that the Qi energy the Qigong masters emit is measurable as infrared, magnetic, static electric, and acoustical energy. Seto (1994) measured the magnetic field between the hands of healers to be in the range of 1 milligaus. Niu, et al. (1988) measured infratonic sound waves emitted by a Qi master in the range of 45 to 76 decibels, or 100 to 1000 times stronger than that emitted by an ordinary person (45 to 50 decibels). Via Kirilian photography, Lee (1999) exquisitely visually documents the effects of Qi.

The "How" of Qi

Zhang and other scientists document that emitted Qi raises potassium-medicated human skin pain threshold (Lin, 1988; Zhang, 1990). In a double-blind placebo-controlled study of 57 subjects. Lee and Wang (1993) demonstrate that infratonic Qi emitted by a Qigong Machine (QGM) significantly lowers the electrical activity of muscles, as measured by surface electromyelogram. Lin demonstrates increased immune activity with emitted Qi (Lin, H., 1988). Feng (1998) documents Qi-induced decreases in blood sugar levels in diabetics. Higuchi, et al. (1997) found that Qi meditation decreases blood levels of plasma cortisol, adrenalin, and dopamine, and changes levels of endorphins, suggesting that Qi meditation decreases sympathetic nervous system activity.

A number of studies document that Qigong increases blood circulation to the brain, to diseased or stressed tissue (Omura, Losco, et al., 1992), and to the nail folds of Qigong practitioners (Sancier, 1999). Liu reports that in 68 subjects Qigong exercises decrease blood levels of vasoconstrictor 5-hydroxy-tryptamine (5HT), and increases levels of norepinephrine and dopamine, with resulting vasodilation and increased blood flow. Increased blood flow both increases the delivery of oxygen, nutrients, and endorphins and the removal of metabolic waste products for pain relief (Lin, M., 1988).

Animal studies reveal that Qi is independent of placebo effect and provide more clues to the "how" of Qi. In rabbit experiments, emitted Qi induced a change in pulse, an increase in temperature (Lin, H., 1988), increases in osteogenesis osteoblast and osteoclast activity in bone injuries, increases in blood level of antibodies in infection, and changes in electroencephalogram (EEG) (Jia, Jia, & Lu, 1988; Lee, 1999). In guinea pigs, Ryu, et al. (1996) conclude that Qi somehow induces enhanced release of acetylcholine in the relief of muscle pain, possibly by a somato-autonomic effect from the anterior hypothalamus. In anesthetized cats, Liu demonstrates that emitted Qi still produces a change in ABER (Lee, 1999). Zhang, Chen, et al. (1990) also find that emitted Qi also depressed the cortical-evoked potential amplitudes elicited by other inputs as an index of response of the somatosensory cortex to pain in cats. In rats, Yang (1988a, 1988b) demonstrates that the analgesic effect of emitted Qi was inhibited by peri-aqueductal grey lesions (Yang, Xu, 1988; Yang, Guo, 1988). Both Zhang and Yang independently found inhibition of Qi analgesia by nalaxone, suggesting the involvement of endogenous opiates (Yang, Xu, et al., 1988; Yang, Guo, et al., 1988; Zhang, Chen, et al., 1990).

In a series of more than 20 subjects and with Qi masters Kong and Estes, we measured brain wave activity via interactive brain wave analysis (IBVA) induced by emitted Qi, and with Qigong exercises. We found that externally emitted Qi immediately decreases the subject's beta waves (12 to 30 Hz), which are associated with higher cognitive brain activity such as stress and/or concentration, and simultaneously increases alpha (8 to 12 Hz) and theta (4 to 8 Hz) waves. According to Dr. Kong, alpha waves are associated with a Qi healing state of mind, and theta waves indicate enhanced immune activity. An internal Qi state induced by the active practice of Qigong on the part of the subject gives like results (Hole, 1998a).

M. Liu (1988) in both controlled human and animal studies finds that emitted Qi enhances and synchronizes the subject's electroencephalogram (EEG) alpha rhythm. He also notes an increase in the EEG power spectrum with the most pronounced increase in the frontal lobe, inhibition of the cerebral cortex, excitation of the somatosensory cortex, and facilitation of the brainstem medulla and hypothalamus as measured by acoustic brainstem evoked response (ABER). Qi thus induces an alpha-state of deep relaxation, frontal lobe integration of autonomic function, and brainstem regulation of internal organs (Lee, 1999).

These studies clearly demonstrate that Qigong masters, without any voice, touch, or eye contact, can by Qi, induce changes in their subjects' brain wave activity for healing.

How does Qi work? Besides documented endocrine, immune, neurotransmitter, and circulatory changes, and deep relaxation, how does Qi work? The science of energy medicine is rapidly evolving. Gough (1999) suggests that nonlocal inputs, such as a healer's intention, has an impact on the DNA molecules themselves and on intercellular communication. Lee (1999) suggests that the DNA helix itself acts as a superconductor magnetic field detector and amplifier, and that this perhaps is how healers produce bioelectromagnetic energy.

How does Qi bring about healing? How does non-local external medicine work? How does prayer work? As with external medicine and prayer, the biophysics of exactly how Qi works is still somewhat of mystery.

SOME QI CLINICAL EXAMPLES

As with any Qigong practitioner, we see many miracles in our practice, especially with those who have found little or no relief elsewhere. A miracle, however, may be as ordinary as a smile or a teardrop.

Although Qi itself is still somewhat of a mystery, one of the goals of this chapter is to take the mystery out of the practice of Qi. Even with little or no previous experience, it is surprisingly possible to use Qigong to successfully relieve pain. While the discipline of daily Qi practice is mandatory for any serious practitioner, there are a number of easy-to-learn and apply Qi tools for pain relief. We present here some case studies and examples from our own experience in hopes of inspiring you to see for yourself that "Qi happens!"

Scanning and Directing Qi

Chronic back pain in an elderly man. Years ago, I brought my then-12-year-old son to his first introductory 2-hour Qigong workshop. He worked with an elderly gentleman suffering longstanding back pain. When I asked my son how the workshop was for him, to my astonishment he innocently replied, "Oh, you know that old man I worked with? Well, he was hot up top, nothing at the waist, then cold from the waist down … .. So I brushed him off up top, and packed him in at the waist. Then he was warm all over, and his back pain went away."

I have since attended and taught introductory Qigong workshops in which neophytes with no previous Qi training successfully treat those suffering chronic pain. The miracles of Qigong are available to you as well, for the asking.

Qi Breath

Headache in 49-year-old white male VA vet. I remember with fondness my first official Qigong patient. He was a steak-and-potatoes VA vet. He had suffered years of severe intermittent headaches, which had increased in severity and become constant over the last 5 weeks, to the point of waking him from sleep, and they were no longer relieved by narcotic pain medication.

I had just attended my first introductory 1-day Qigong workshop. I considered an MRI to rule out a brain mass, and decided in the meantime to teach him the simple mechanics of Qi breathing. Within minutes, he broke out in a grin, "What'd you do? My headache's gone!" That was nearly 5 years ago. The headaches he first presented with are still gone.

Migraines in 47-year-old white male blue collar worker. He complained of a lifelong history of constant pressure with episodes of spiking pain, nausea, vomiting, lachcrimation, and aura, growing progressively worse over the past year to the point of being unable to work for the last 1 to 2 months. He had no relief with demerol, stadol, codeine, norgesic forte, morphine, and neurology consult. With Qi breathing, his pain level went from a 10 to a 2 within minutes.

TMJ pain in a 45-year-old white female artist. One of my Qigong exercise class students found relief from her longstanding TMJ, unrelieved by dental consult, in the simple mechanics of Qi breathing. Specifically, she remembered on the in breath to connect her meridians, or energy circuits, by holding her tongue to the roof of her mouth.

Qi Centering

Cervical strain with radiculopathy in a 47-year-old singer status post-multiple injuries, including a motor vehicle accident (MVA) 3 years ago and a Labor and Industries claim as well. She complained of constant right upper extremity (RUE) pain and paresthesias, with no relief from medications or chiropractic treatment. With proper Qi posture and centering, she had her first night of sleep pain free.

Qi Exercises and Meditation

Radiculopathy in 49-year-old white female graphic artist with over a 7-year history C5–6 disc disease documented by MRI and neurology consult. She complained of several days of a "pinched nerve in my neck history," decreased mobility of right upper extremity (RUE), with paresthesias and pain radiating to RUE. With instruction for Qi exercises and meditation, her mobility was restored and pain relieved within minutes.

Degenerative disc disease in a 30-year-old white female law professional. One of my Qigong students wrote, "For years I suffered constant chronic back pain from degenerative disc disease. With one Qigong class and a 2-minute treatment, I am pain free." That was over a year ago. Where she once was a regular visitor to her chiropractor and the emergency room, she learned to control and relieve her pain with Qigong exercises and breathing.

Qi Pain Pictures

Arthritic toe pain in a 37-year-old white female ballroom dancer, documented by X-ray, unrelieved for years by NSAIDS and steroid injections. While working with her, images of a "steam roller truck" and a "dragon" came up, which she identified as her mother. By identifying the pain pictures, and moving the pictures of her toe, her pain was immediately relieved, and has not returned for months.

Qi Intention

Shoulder pain in Vietnam veteran with 20 years of no relief. My first experience of healing by intention was in a class with Prof. Tae Woo Yoo, O.M.D. Ph.D., internationally recognized as the founder of the Koryo Hand Therapy (KHT) acupuncture microsystem. Speaking no English, Professor Yoo drew the correct prescription on the chalk board, stroked the meridian on the chalk board in the correct direction, and the vet's pain was relieved. Professor Yoo then stroked the meridian on the chalk board in the opposite direction, and the vet's pain immediately returned. With the professor stroked the meridian on the chalk board once again in the correct direction, the veteran's pain was once again relieved.

Back pain in a middle-aged white female health professional. Once, after presenting at a medical headache symposium, a number of people lined up afterward for treatment. Short on time, I instructed a woman in line just to breath, and imagine or intend her pain away. Within minutes she thanked me, her pain gone.

Qi Nonlocal Healing

Frozen shoulder in 45-year-old Oriental female golfer with a 5-month history of progressive pain with little relief from orthopedic consult and physical therapy. Driving home from her appointment, she felt an incredible wave of energy freeing her shoulder from pain, and restoring her range of motion. Within days, she was discharged from orthopedic and physical therapy and went on to play tournament golf.

Qi Acupuncture

Cervical disc disease and Raynaud's syndrome in a disabled white female health professional. I "ran Qi" into her Koryo Hand Therapy correspondence neck area. Within minutes her pain was relieved, and for the first time in years, her hands were warm and pink. Months later, she thanked me because she'd been pain free since that one single treatment.

Sciatic pain for months in a renowned Native American female author. I applied fingertip Qi along her KHT bladder meridian. For the first time in months, she was pain free, and with the addition of a copper ring continued to be pain free for months afterward.

Eye pain in a 50-year-old Greek teacher. She complained of a 3-week history of eye pain with visual disturbance. Applying Qi to her KHT eye point, her pain was gone, and vision clear in minutes.

Qi, Intuition, and the Five Elements

Chest pain and pulmonary interstitial fibrosis with dyspnea in a 67-year-old retired white male. By KHT diagnosis, his element was metal. The element metal has to do with the emotions of grief, loss, regret, and giving too much of yourself away. In helping him intuitively recognize in himself the pain pictures of the element metal, he burst into tears, and both his chest pain and dyspnea were relieved within minutes.

Qi Love, Touch, and Hugs

Polymyalgic rheumatica and osteoarthritis in a 58-year-old white female chronic pain sufferer. With just a waiting room hug, her pain on three occasions was totally relieved.

THE WAY OF QI: SOME PRACTICAL PAIN RELIEF TOOLS FOR YOUR PRACTICE

There are hundreds of different Qigong schools, teachers, masters, and exercises. Following are some basic Qi tools and teachings that you can apply to your life and practice for immediate results.

Activating Your Qi

> Stressed is just desserts spelled backwards.
>
> Unknown

At the center of your palm is your hand-healing chakra Lao Gong point, or "old worker." It often appears as a contrasting lighter area at the center of your palm. In some paintings of saints, not only do the saints have halos, they also have golden beams of light, or Qi, coming out of their Lao Gong hand points.

To activate your Qi, rub your palms together back and forth at the Lao Gong points as if you're about to start a fire. What you feel between your hands is Qi. You may feel tingling, warmth, a magnetic force, or a palpable live ball of energy. The more you practice Qigong, the more open and clear you become, the bigger your healing ball of Qi grows, and the greater the miracles of Qi come through you.

Qi Centering: Standing Your Ground between Heaven and Earth

> Be still and know that I am
>
> Psalms 46:10

As in the Chinese character for emperor, or master, the Qi posture is standing centered and open, between heaven and earth, open to the heavens above and grounded to the earth below. Many people stand hunched over, carrying heavy burdens with the weight of the

world on their shoulders and back. Correct Qi posture is vital for the flow and release of Qi.

For Qi posture, plant your feet on the ground about shoulder width apart; roll your shoulders down and back to both open your heart chakra, and to allow your burdens to roll off your back; stand open and grounded between heaven and earth, then imagine a silver thread aligning, supporting, and stretching your spine between heaven and earth. Drop your center of gravity to your Dan Tian, the seat of energy 2 in. below your navel.

At your Hui Yin, or by the tip of your tail bone, give yourself a grounding cord to the center of the earth. "Turn on" your grounding cord, and ask it to draw out, like a magnet, and absorb whatever no longer serves you, whatever is keeping you from being who you truly are, and whatever is stopping you from being free of pain.

Open your Bai Hui, or crown, to the heavens above. Imagine a divine waterfall of light, or Qi, washing away and freeing you from whatever no longer serves you, keeping you from being who you are and without pain. Feel the silver thread aligning, supporting, and stretching your spine between heaven and earth, and feel the waterfall of light flowing down your back, to wash away your burdens, your past, and your pain.

Qi Breath: Open Heart of Compassion, Soft Belly of Letting Go

> One joy shatters a thousand griefs.
>
> Chinese Proverb

The Qi breath is going back to breathing as a baby breaths—open heart, soft belly via the diaphragm, and relaxing into the breath of God. Note that the words "spire" and "spirit" both come from the same root, spiritus. Notice how many people breathe very shallowly. Nonpermission and repressed pain such as anger, grief, and fear are among the causes of shallow breathing. Besides obviously providing the body more oxygen, and greater release of toxins, the deep diaphragm breathing of Qigong also facilitates the release of the emotional and spiritual pain underlying physical pain.

The Qi breath is with the open heart of compassion and soft belly of letting go. First remember to stand centered between heaven and earth in correct Qi posture. On the in breath, allow your soft belly to expand out, so that your diaphragm can fully open your lungs for a full deep breath. Draw the breath in through your nostrils down to your Dan Tian, again the center of energy 2 in. below your umbilicus. On the in breath, remember to hold your tongue to the roof of your mouth to complete the meridian energy circuits. Chest and shoulders remain still throughout the breath cycle. On the out breath, relax your tongue and belly. With a gentle smile of self-love and self-acceptance, breathe out through your mouth.

Energetically, for beginners, it's simplest to visualize breathing in and out of your heart. On the in breath, breathe in Qi as light and love. On the out breath, breathe out whatever no longer serves you, whatever is keeping you from being who you fully are, whatever is keeping you from being fully alive, and free of pain. As you breathe, imagine the Qi expanding in a golden ball of light to fill your heart, then your body, then your spirit, and continue expanding to protect and surround you throughout the universe.

Qi Exercises: Awaken Your Body, Awaken Your Spirit

> A day without dancing is a day lost.
>
> Unknown

Of the hundreds of different Qigong movement and stretching exercises, my favorite is free-form Qi dancing, or moving as the Qi moves you. For medical Qigong, the basic Chow Qigong set, is superb (Chow & McGee, 1994). The purpose of Qi exercises is to awaken your body and spirit; and to clear, open, and bring into harmony your energy channels for greater Qi, greater energy, greater awareness, greater healing, and greater healing ability.

A very effective and simple beginning Qi exercise is "shaking" Qigong, as the Quakers used to do. In Qi posture with the silver thread aligning and stretching your spine heaven to earth, grounding cord rooted to the center of earth, and crown open to the heavens, simply shake your body from head to toe, vertebrate by vertebrate. With a gentle smile of self-love, shake out all your worries, troubles, pain, and tension, and feel yourself becoming lighter.

Qi Meditation and Awareness

> 99% is awareness, the rest is gratitude, amusement, and letting go.
>
> Jim Self, Qi Master

Qi meditation centers on the breath; it quiets and stills the mind, body, and spirit; it is key to Qi healing and encompasses many of the same principles taught in Western schools of mindfulness stress reduction, visualization, focusing, hypnosis, transcendental meditation, and centering prayer. As in centering prayer, Qigong calls upon a greater energy, or universal Qi, for healing. The Qi exercises themselves prepare the body for the healing of Qi meditation.

With Qigong practice and meditation comes increased awareness, and the Qi meltdown effect. The walls burying unconscious pain melt, and you eventually

become aware of the wound to the psyche beneath the physical pain. With the release of the underlying pain picture, the physical pain is no longer necessary, and may clear as well.

In Qigong, bad, stagnant, or blocked Qi is the root cause of pain and dis-ease. One way of dispelling bad Qi is to simply replace it with good Qi. On the in breath, send a golden ball of Qi, of love and light, from your heart to any painful area, and breathe in good Qi. On the out breath, breathe out the bad, stagnant, or blocked Qi, and breathe out the pain. To prevent the bad Qi from reentering, always remember to fill the space where the pain and bad Qi used to be with good Qi.

Self-love, self-acceptance, self-forgiveness, and self-worth are core to Qi meditation and Qi healing. True self-love frees you to release pain, and to love, accept, forgive first yourself and then others. With each breath, give yourself a gentle smile of self-love and self-acceptance.

Other benefits of Qi meditation include learning how to stay centered amidst the chaos and stress of day to day living; the freedom to be who you truly are; inner peace, inner knowing, harmony with oneself and the universe; and the ability to move from your center with clarity and power— all of which help dispel pain.

The MicroCosmic Cycle and the Five Element meditations below are specific and fundamental to Qigong, and are both effective in pain relief.

Qi and the MicroCosmic Cycle

> Pain is removed when the block is eliminated.
>
> Traditional Chinese Medicine Principle

When practicing Qigong, visualize your Qi circulating in a MicroCosmic Cycle. On the in breath, visualize the Qi as light flowing from your Dan Tian, the seat of energy 2 in. below your umbilicus, down to your Hui Yin, or perineum, then up the Governing vessel energy channel along your spine, through the Three Gates, and up to your crown or Bai Hui. On the out breath, visualize the Qi flowing down the front of your body along the Conception vessel back to your Dan Tian.

The pelvic Lower Gate relates to fear, survival, sexuality, will power, and pelvic organs. The abdominal Middle Gate relates to power, control, resistance, judgment, empowerment, and abdominal organs. The thoracic Upper Gate relates to heart sadness and joy, speaking your truth, surrender to divine will, and thoracic organs. The Bai Hui or crown is your divine knowing and connection to the heavens.

As the Qi flows through the Three Gates, visualize the release of bad, stagnant, and blocked Qi, and see "good" Qi clearing, cleansing, healing, and filling all your energy channels, gates, chakras, and centers with light.

Qi and the Five Elements: Free Your Body, Free Your Spirit

> The root of all disease is spiritual … in the mind and the emotions.
>
> Tae Woo Yoo, O.M.D., Ph.D.

Patients often present with a purely somatic pain complaint, in stubborn denial of any possible underlying wound to the psyche. The physical pain points to a deeper psychospiritual pain, and is a call for help.

The body is about the five senses. The spirit is about the Five Elements: Fire, Earth, Metal, Water, and Wood. Each of the five elements governs a coupled yin-yang organ pair, each with a specific energy channel meridian map on the body. Each of the five elements also is associated with a specific set of emotions, and a whole set of other characteristics specific to the particular element as well—color, taste, season, etc. (see Table 53.1 in Chapter 53). The Five-Element location of the physical pain, the Five-Element color your patient chooses to wear, etc. all give you clues to the wound to the psyche underlying the physical pain.

The Five Element meditation helps release any pain associated with each particular element. Working with the Five Elements helps free the spirit to free the body, and is one of the most powerful, gentle, and effective tools in Qi healing.

Qi, Ego, Intuition, and Pain Pictures: Physician Heal Thyself

> E.G.O. stands for "Easing God Out"
>
> Unknown

The practice of Qigong brings increased awareness and intuition. Qigong masters commonly have "X-ray" medical intuitive vision, and in a moment know far more about the nuances of your life than an ordinary person could possibly know.

To clear the way for Qi, for your own inner knowing, or intuition, Qigong requires that you surrender all ego, both the big ego of arrogance and conceit, and the small ego of fear, unworthiness, and inadequacy. One also must surrender the judgment of ego: all negative thoughts, feelings, limiting beliefs, and pictures. Surrendering ego, judgment, fear, and negativity frees you to be an empty vessel for greater Qi and knowing.

Another way of opening to your intuition is simply asking. For example, ask what the pain means. We commonly say that something or someone is a "headache" or "pain in the neck." Ask who or what is the pain underlying the head ache or neck ache. Ask what the

pain in the body represents. For example, back pain may be about getting someone or something off "my back". A pain in the hip may be about fear of stepping forward. Pay attention also to the clues of the Five Elements. The Five Element location of your pain, the Five Element color you choose to wear, all point to the deeper Five Element wound to the psyche beneath the presenting physical pain.

As in guided imagery, we also call upon the inner knowing of the patients. Ask your patients who or what their physical pain is about. They may reveal a sometimes surprising self-realization and/or underlying "pain picture".

As you yourself become more intuitive and start "seeing" pain pictures in others, know that on some level every patient is a mirror for you. For every pain picture you recognize in someone else, you have within you a matching picture for your own pain. This is especially true for those to whom you feel a strong reaction. Know that every patient is a teacher, a mirror, a messenger, and a reminder of your own pain pictures asking for healing.

As Confucius taught, first you take care of yourself, then your neighbor, then your community, then the world. "Physician heal thyself" must come first. The freer and clearer you are of bad, stagnant, blocked Qi, and of your own pain pictures, the freer, clearer, and greater a vessel you become for Qi and healing.

Qi Dx, Rx, and Acupuncture: Scanning and Directing Qi

> The Way that can be spoken is not the Way.
>
> Lao Tze

For a more mechanical approach to Qigong relief of pain, "scanning" and "directing" Qi, and Qi acupuncture are easy to learn and apply, effective, and fun.

Scanning Qi. To scan or "diagnose" a patient's Qi, simply run your hands about 6 to 12 in. over the patient's body, and feel their energy field. Areas that seem hot and push your hands out have excess Qi. Areas that seem cold and pull in your hands have deficient Qi. Excess and deficient Qi are signs of pain, illness, or injury. As you scan, allow yourself to intuitively "see" pictures and "feel" emotions that have to do with the patient.

Directing Qi. For treatment, "brush away" the excess Qi, again the areas that feel hot, and/or push your hands out. "Pack in" with good Qi the deficient areas, again those which feel cold, empty, or pull your hands in. Simply brushing away and packing in Qi as indicated often give significant pain relief. The patient also may feel other sensations with the movement of Qi, such as warmth and tingling.

Qi Acupuncture. In our own practice, transmitting Qi via fingertips, or Wai Qi, to indicated acupuncture points and meridians for needleless Qi acupuncture can profoundly enhance treatment.

Qi, Love, Laughter, Hugs, Touch, Gratitude, Reframing, and the Inner Smile

> Love is the most important ingredient in healing.
>
> Effie Poy Yew Chow, Ph.D.

Qigong is an attitude. In Qigong, we reframe the challenges of life's day-by-day stresses and crises as opportunities to grow. The Chinese word for crisis translates as either "danger" or as "opportunity". In Qigong, we intentionally choose to reframe the challenges of life in a positive light, look for blessings in disguise, and simply give thanks.

"Negative thoughts can negate all healing" is a corollary Qigong teaching. One key in Qigong healing is moving from the Western left-brain problem-oriented approach of analyzing what's wrong to a more heart-centered approach of remembering, acknowledging, and giving thanks for the good. Rather than dwelling on and thereby reinforcing the negative, Qigong reframes life, and instead focuses attention and gives energy to the positive, thereby making way for healing and blessings to come.

On this level, Qigong is about looking for and framing the good, giving thanks for the good, and cultivating right thoughts and a positive mental attitude (PMA). Right PMA thoughts do not imply any judgment or condemnation. Right PMA thoughts are those that make your heart sing, give you something to live for, raise your Qi, help move your immune system toward healing, and melt away pain. In Qigong, an attitude of gratitude clears the way for healing and dispelling pain.

For parents, these concepts are obvious. Focusing on a child's negative attention-seeking behavior reinforces the behavior. Giving the child unconditional love, positive attention, and gratitude, within limits of heaven and earth, obviates the child's need for negative attention-seeking behavior, and plants the seed for the positive and good.

Pain is thus your body's negative attention-seeking behavior cry for help. Your symptoms are your friends. Instead of reacting in denial, fear, and/or resistance, what about thanking your body for asking for help, and asking your body what is it telling you? In Qigong, remember to give yourself an inner smile of self-love for you, for your pain, for your body, for your spirit. Unconditional love, and self-love, are vital in Qigong for healing and releasing pain.

Psychoneuroimmunology documents well the mind–body connection, and how your thoughts and emo-

tions affect your immune system. Other important Qigong PMA tools include laughter, hugs, touch, clear intention, letting go, and joy. As taught by Qi Master Effie Chow, Ph.D., we demonstrate via kinesiology and teach our patients the power of these PMA tools for their own self-healing and empowerment.

Empty Vessel, Be Still, Be Present, and Intention

> Your body is the vessel of your spirit—Honor It

For greater Qi healing, one must become a deep Empty Vessel through which greater love, light, Qi, and healing can flow.

One must Be Still, Be Present, and Be in his/her body. Healing does not occur in the past or in the future. Healing usually does not occur out of body. Qi healing occurs in the stillness of the present moment. One must let go of both the past and future, and be truly present in body in the still moment of now. Qi healing also requires that you honor your body with proper nourishment, rest, exercise, etc.

One must hold a clear intention, or "Yi Nian," of what he/she would like to create, whether it be wholeness, wellness, happiness, healing… or moving mountains. Hold your intention lightly and innocently, without ego or attachments. And lightly, with Qi, expect miracles.

True Qigong masters come from such a grounded, empty vessel space of centeredness, clarity, and surrender that the intention of their thoughts shapes reality. They simply command the universe and heal.

Living a Life Full of Qi

> Start the day with Love. Fill the day with Love. End the day with Love.
>
> Sai Baba

For committed Qigong students, Qigong is far more than simply a set of exercises. Qigong, at its highest, is a Way of Life.

The Way you think, the Way you relate to your loved ones, the Way you relate to your community, the Way you relate to the world, the Way you handle your emotions, the Way you care for your body, the Way you earn a living, the Way you stand in the universe, the Way you commune with nature, the Way you commune with God, the Way you Love — all determine your peace of mind, your state of health, pain, and Qi. The choices you make about Way you live determine how you live, how you age, how you love, and how healthy, happy, pain free, and well you are.

In the context of pain management and Qi, pain is a wake-up call to take an inventory of your life. For health, longevity, well-being, and a life free of pain and full of Qi, one must practice right living: right thoughts, relationships, love, livelihood, nutrition, exercise, practice, service, communion, etc.

The paradox, however, is that right living is about being rather than doing. The Qi practice of Right Living, or doing Qi, comes from the Qi practice of being in Qi: being centered, being still, being present, being true to your inner knowing, and being true to who you really are. Doing Qi without being in Qi is empty Qi. First be, then do.

INTEGRATING QIGONG INTO WESTERN MEDICINE: LOCAL VS. NONLOCAL MEDICINE

> White man get headache, take aspirin, get stomach ache.
>
> Unknown Medicine Man

Qigong is a paradigm shift tool for new era medicine. The traditional Western local medicine model is problem focused, problem solving, deductive, and defined by time and space. The Qigong nonlocal eternal medicine model is focused on remembering the good, giving thanks for the good, raising the Qi, inductive, and beyond time and space. Local medicine is organ centered, with some outside intervention as the cure. Qigong eternal medicine is Qi centered, and about one's relationship with oneself and the Universe.

In the Western local medicine, the power to heal is outside the individual. In the Qigong nonlocal eternal medicine model, we honor the individual's own inner knowing and power to heal. In local medicine, the cup is half empty. In Qigong eternal medicine, the cup is half full. Local medicine gives attention and energy to time and space limited problems. Qigong eternal medicine focuses attention and energy on the beyond time and space positive.

In Qigong, we simply "raise Qi," so that the problems simply melt away, and make room for the miracles to unfold.

There are many ways of integrating Qigong into your life, from the practice of simply remembering the breath to truly living a life full of Qi. The Qigong masters I most admire are full of light, love, joy, and amusement, and at the same time, are extraordinarily powerful healers. Teachers are valuable, and "When the student is ready, the master appears." Ultimately, however, Qigong is about you yourself connecting to your own "Be still and know that I am" healer within and universal Qi.

What more is there to say? Qigong changes lives and has made a tremendous difference in my life and in my practice of medicine. We humbly share these simple yet profound tools with you.

What words are there to express the look on a patient's face when, with a tool as simple as the breath, pain is relieved? What words are there to express how Qigong can transform your life, your practice, and the lives of your patients as well?

We invite you to take a minute to be still, go within, and see for yourself.

Koryo Hand Therapy: Modern Pain Management

Daniel C. Lobash, Ph.D., L.Ac.

Koryo Hand Therapy (KHT) is a natural, fast, effective, and safe energetic medicine system for reducing and eliminating pain. KHT is one of many increasingly popular microsystems for resolving pain and other functional problems. The microsystems commonly applied for the resolution of pain include the hand, ear, foot, scalp, iris, nose, and along the second metacarpal bone, among others.

Korean traditional medicine doctor, Tae Woo Yoo, O.M.D., Ph.D. developed the KHT system between 1971 and 1975. It is practiced throughout South Korea and the major text has been translated into six languages. It is a complete energetic medicine system based on the theory, principles, and methods of traditional body acupuncture. Each hand contains the information for the whole organism; that is, all of the structures of the body are represented on each hand. For example, the little finger on the right hand is related to the right leg.

In addition to body representation, all of the acupuncture meridians of the whole body are represented in a miniature but analogous form on each hand. Due to the relationship of the hand and the body, the hand can be used to access information about the condition of the systems of the body as well as provide a means to transmit information to the brain that will result in immediate or near immediate pain reduction.

SCOPE OF APPLICATION

KHT can be applied to any problem traditionally treated with body acupuncture. For purposes of this chapter, the materials presented are confined to pain reduction applications. Any pain, whether severe or low level, chronic or acute, can be successfully treated with KHT Correspondence Therapy. In fact, correspondence therapy is especially effective in creating near instantaneous pain relief. Examples of treatable conditions include neck pain ranging from that caused by accidents to sleeping in a draft; gallbladder-induced pain; pain due to stomach ulcers, gastritis, gas; back, shoulder, wrist, any joint pain, and in fact any pain anywhere in the body due to any cause.

SAMPLE CLINICAL CASES DEMONSTRATING THE EFFECTIVENESS OF CORRESPONDENCE THERAPY

Case 1. A 30-year-old patient had severe pain in the jaw, as shown in Figure 52.1, from dental work the previous day. Searching with a small probe located an exquisitely sensitive point on the jaw's corresponding area. Massage stimulation with the probe tip and a small metal pellet fixed to the skin with adhesive tape immediately reduced the pain 70% and the swelling by 50% within 10 minutes.

Case 2. An 80-year-old patient had suffered for 3 months with lower back pain resulting from twisting as she reached toward a top shelf. She had tried physical therapy and chiropractic, but had only temporary relief. One treatment relieved the pain immediately and it did not return. Shown in Figure 52.2 is the corresponding search area for the lower back.

Case 3. Migraine headache pain of a young woman was reduced by 50% through a simple instruction of where to press and self-massage on the corresponding area of the middle finger, as shown in Figure 52.3.

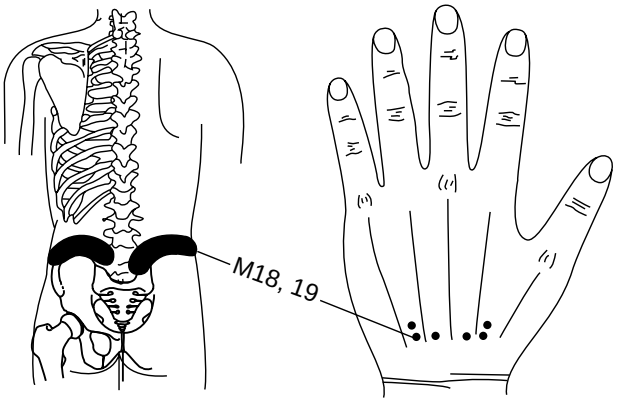

FIGURE 52.2 Patient with low back pain and where to press on the corresponding points of the hand.

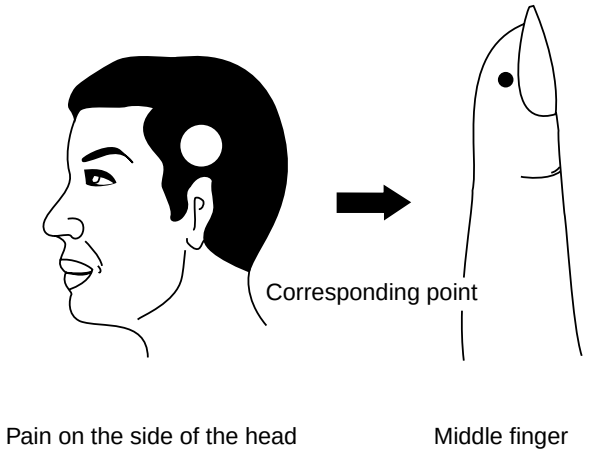

FIGURE 52.3 Patient with pain on the side of the head and where to press on the corresponding point of the middle finger.

UNIQUE CHARACTERISTICS OF THE HAND MICROSYSTEM

There are several characteristics of the hands that are useful to know and understand as diagnostic and treatment access points. Some of these characteristics also apply to other microsystems of the body.

1. Every pain or discomfort in the body is registered in the related microsystem of the hand.
2. Two common forms of registration that can be detected are reduced pain threshold to mechanical palpation and increased electrical conductance at the corresponding point.
3. Stimulation of the corresponding point has a unique capacity to signal the brain that, in turn, initiates a biochemical chain of events resulting in reduction of pain and inflammation at the corresponding point/area of the body. The action in most cases occurs instantaneously or within minutes. Shown in Figure 52.4 are several instruments used in corresponding point location and treatment.
4. A precise proportional relationship exists between the body structure and the image of the body as it is projected on the hand. Identification of the exact location on the body of pain enables finding the precise corresponding point on the hand.
5. Stimulation of corresponding points can be by means of mechanical pressure, electricity, and specially designed hand acupuncture needles; heat from burning moxa, tiny aluminum disks fixed over the corresponding points with adhesive tape; and several other appliances specially designed to stimulate hand points.
6. Mild stimulation of corresponding hand points results in effective body response. The degree of stimulation of corresponding hand points is minimal compared to that required for similar effects through body stimulation.
7. Areas of the body that are difficult or forbidden to treat in traditional body acupuncture can easily be treated on the hands. For example, it is possible to stimulate corresponding eye points on the hands but not on the body.

RELATIONSHIP OF THE HAND AND THE BODY

In Koryo Hand Therapy the hand is related to the body in a very precise pattern as shown in Figures 52.5 to 52.9 and as described below.

Each hand contains the information and structure for the whole body. This means that diagnosis and treatment

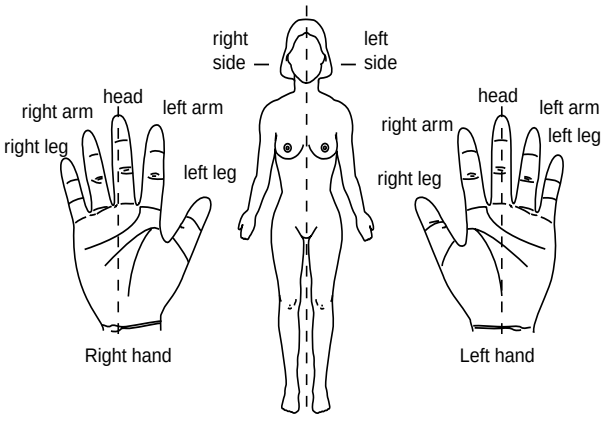

FIGURE 52.5 Frontal relationships. In the frontal view, the midline of the body is represented as the midline of the hands.

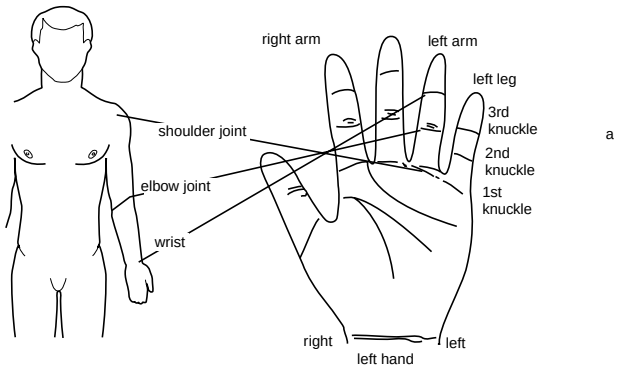

FIGURE 52.6 Pains on the anterior surface of the body are treated on the palm side of the hands. The arms correspond to the ring and index fingers.

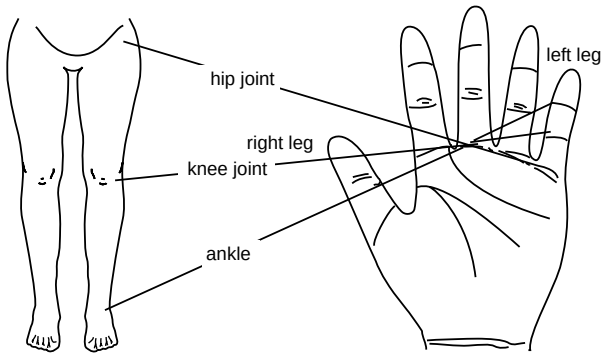

FIGURE 52.7 Pains on the anterior surface of the body are treated on the palm side of the hands. The legs correspond to the ring and little finger.

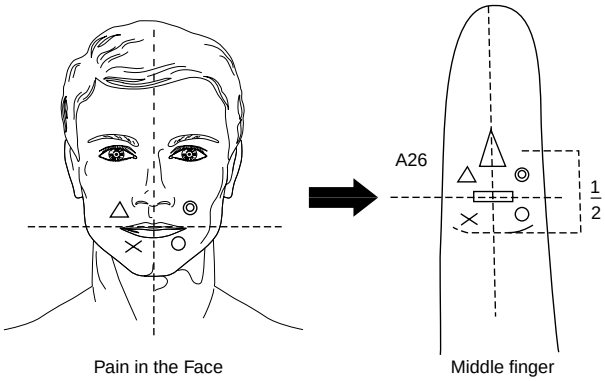

FIGURE 52.8 Pain in the face corresponds to the most distal phalange of the middle finger.

affecting the body could be done on either hand. The preferred treatment pattern, however, is to diagnose and apply stimulation to the hand on the problem side of the body. In the frontal view, the midline of the body is represented as the midline of the hands. The frontal relationships are shown in Figure 52.5.

Pains on the right side of the midline of the body are diagnosed and treated on the right side of the midline of the right hand and vice versa. The midline of the hand bisects the middle finger from the top to the base of the palm just above the wrist.

Pains on the anterior of the body are diagnosed and treated on the palm side of the hands. Pains on dorsal side of the body are diagnosed and treated on the dorsal surface of the hand. Pains on the sides of the body have correspondences on the sides of the hands and fingers.

The arms and legs correspond to the ring and little fingers, respectively, as shown in Figures 52.6 and 52.7. With reference to Figures 52.6 and 52.7, pains on the opposite surface of the body from that shown in the illustrations are found on the opposite surface of the hand. Pain in the face corresponds to the most distal phalange of the middle finger, as shown in Figure 52.8. Pain along the spine corresponds to the dorsal surface of the hand, as shown in the illustration of Figure 52.9.

These illustrations provide guidelines for locating the approximate area on the hands corresponding to pains in the body. The next section describes the process of locating corresponding points with precision.

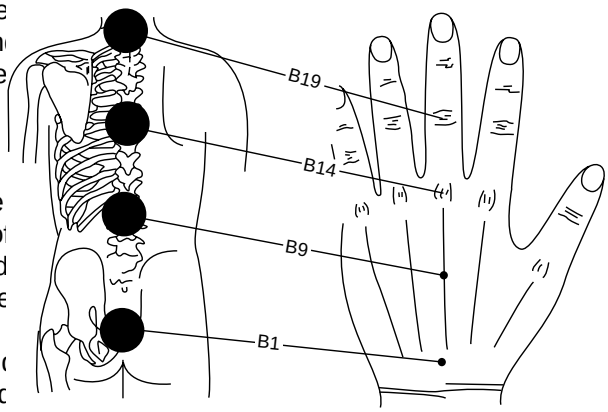

FIGURE 52.9 Pain along the spine corresponds to the dorsal surface of the hands.

LOCATING PRECISE CORRESPONDING POINTS

In order to achieve the maximum possible pain reduction, corresponding points must be located with great precision. This means that the maps of the body as shown above merely serve as guides to locating the approximately correct area. Then the precise points must be found exactly with a pressure probe and/or electrical point finder. Apply the following steps to locate the correct corresponding points:

1. Determine the exact locations of pain in the body. Ask the patient to be very precise in locating and pointing to the painful area. Then ask the patient to rate the discomfort level on a 10-point scale, where 0 is no pain and 10 is excruciating pain. If appropriate, establish range-of-motion limitations and ask the patient to notice the limitation, as well as noting it yourself.
2. Locate the approximate corresponding area on the hand where greater sensitivity is expected. Squeezing the client's hand at the expected corresponding area between your thumb and forefinger can do this. When the correct corresponding area is found, the client will tell you. Note that this is still only the approximate area. Now the search must be refined to locate the exact corresponding point.

3. To locate the exact corresponding point, a metal probe with rounded tips is desirable (Figure 52.4C). The reason for this is that the correct corresponding point can be located even a thousandth of an inch adjacent to the point currently being palpated. You must search in a very fine grid pattern until the exact point is located. When the correct point is stimulated, the client will definitely experience a sharp pain that is quite different from other points being probed.
4. As previously mentioned, the client will reflexively jerk a hand, lift a leg, grimace, squint, say "ahhh, ahhh, ahhh", etc.
5. There may be more than one corresponding point. All that are related to the current painful syndrome should be located and treated.
6. If the point cannot be located, then consider probing with more pressure. Consider that if there is a pain in the body, then there will necessarily be a corresponding point of greater sensitivity on the hand. Another strategy to locate difficult-to-find points is first to stress the painful body part by pressing, or having the client stress, the corresponding body part. This is generally only required in cases of low level, chronic pain.

STIMULATING CORRESPONDING POINTS

The choice and application of the best treatment method are the next steps. The major consideration is to stimulate the corresponding point. There are many strategies available.

1. Mechanical stimulation with a round-tipped, but pointed, probe is simple but does not have as long lasting an effect as other methods. However, the process of searching for and finding the corresponding point also stimulates the point. After this procedure, metal pellets, needles, electricity, and moxa can be added to enhance the effect.
2. Micro hand needles have been created that are thinner and shorter than typical 1/2-inch ear needles. The small size makes insertion nearly painless. The needles are typically inserted with a specially designed mechanical inserter that further reduces discomfort (Figure 52.4A). Needles are typically used for high-level, acute pain. The rule of thumb is that the more intense and acute the pain, the stronger the stimulation desired for greatest effect.
3. Metal pellets can be applied for most conditions. The general rule is to use pellets for chronic conditions, when a milder stimulation is desired, or if the client rejects the needle option, and with children. The pellet is actually shaped more like a small (1/8-inch diameter, approximately) flat disk made of aluminum with an antioxidizing coating. When it is affixed with tape over a corresponding point, it has a similar effect to a needle. The application is painless and the effect excellent. In KHT there are three sizes to accommodate larger corresponding areas, such as for lower back or stomach pain (Figure 52.4B).
4. Moxabustion is a traditional method of applying heat to acupuncture points as the method of stimulation. A small tube of either loose herbs prepared to a consistency similar to a cigarette or a special smokeless cylinder with the consistency of chalk is lit and burned. A cardboard insulator through which the heat penetrates through a small hole in the base limits direct contact with skin. Moxa on the corresponding points has the effect of increasing and evenly distributing blood circulation in the corresponding areas of the body. Moxa treatment is particularly indicated for "cold" diseases commonly found in gynecological conditions and where fatigue is a major factor, such as chronic fatigue and related immune-deficiency syndromes.
5. Microcurrent stimulation through an electronic point locator/stimulator designed for hand therapy is an excellent and fast method of treatment. One pole of the device, commonly the negative one, is held against the corresponding point and the positive pole is held opposite it on the hand. This treatment is commonly combined with pellet and or moxa treatment. First the microcurrent is applied and then the moxa and /or pellets are added.

DURATION OF EFFECTS AND FREQUENCY OF TREATMENT REQUIRED

Exact parameters here are difficult to establish, as each case is unique. However, this much can be said. With correspondence therapy, there is an immediate reduction of pain ranging from 40 to 100%. In acute pain conditions, such as a strained ankle, the effect is dramatic and one treatment may suffice. However, the effect, similar to body acupuncture, may begin to deteriorate in 12 to 48 hours. However, the pain level does not typically return to even close to its original level. In chronic conditions, the pain reduction may be only 20 to 40% and may require extended treatments. If significant structural change is the precipitating cause, such as stenosis, treatments may be only palliative and repeated treatments

will be required. It is impossible to state any reliable predictive conclusions. As a general rule, beginning treatments should occur two to three times per week for the first week, then two times per week and then once per week until the problem is fully resolved. The prognosis is more predictable after one treatment. The second and additional treatments yield less dramatic drops in pain level because the problem begins an immediate resolution with the first treatment. A course of treatment may be from one to ten treatments.

SELF-CARE

A benefit to the practitioner and the client is that many treatment strategies can be self-applied. Individuals can easily be taught to apply moxabustion in the form practiced in KHT. This is perhaps the number one effective home treatment. Moxa can be self-applied once or even twice per day and the additional benefit to the healing process is dramatic. This is especially helpful if the client cannot see the practitioner more than once per week. Moxabustion in the original form, which evolved over time with body acupuncture, consists of loose, finely shredded herbs rolled into a ball and placed on the top of a needle. The herb is lit and burns with an even and consistent heat that is transferred to the patient via the needle shaft. That same concept has been adapted to hand therapy, but in a smokeless, modern form.

Also, clients can be instructed about where to place pellets and where to apply mechanical stimulation and even simple massage. All of these forms of self-treatment supplement the work of the practitioner.

GOING BEYOND CORRESPONDENCE THERAPY

Correspondence Therapy is very effective but it does have limitations and in some cases stronger treatments are required. As was mentioned earlier in this chapter, in addition to the hand representing the entire body, each hand contains a set of micromeridians that is parallel, but not identical to, the body meridians in name and function. Often a pain in the body will reflect an energetic imbalance in the flow of energy through the organ–meridian complex. In order to affect the root cause of the pain, the energetic balance in the meridian flow must be reestablished. To accomplish this, the meridians must be stimulated in a specific way, as well as stimulation of the corresponding organ. In this case, most of the principles of meridian treatment common to whole body acupuncture can be applied to the hand micromeridians. By virtue of the existence of micromeridians, many treatment strategies can be applied that include

1. Simple meridian stimulation
2. Tonification and sedation of the energetics of specific meridians
3. Application of the principles of the eight extra meridians
4. Treatment plans based on the inborn constitutional patterns and other strategies unique to KHT.

All of the available options are not covered in this chapter due to space limitations.

RESEARCH STUDIES ON KHT

Many case studies and anecdotal studies have been conducted in Korea but none of them is available in English. In Japan, research was published by Professor Imura of the Department of Health that reported on the use of KHT for injuries. The results showed that there was a 19.5% placebo response to the stimulation of randomly selected points on the hand vs. a 69.5% positive response to the stimulation of the KHT corresponding points on the hands.

Dr. Roberto Jodorkovsky, M.D. recently conducted a pilot study. It showed a 96% positive response in a pediatric population. He diagnosed, treated, and followed a group of 106 of his pediatric patients over a 6-month period. The results of his study were reported in the Medical Acupuncture Journal 11(1), Spring/Summer 1999. The question he sought to answer was if Koryo Hand Therapy could be an effective therapeutic treatment approach in a suburban pediatric practice where standard Western medicine was combined with Koryo Hand Therapy.

The study group consisted of 106 pediatric patients who were a regular part of his practice and who ranged from 3 to 20 years of age. The kinds of conditions presenting included pain in the neck, shoulder, knee, hip, wrist, hand, back, ankle–foot, viral sore throat, head, nose, chest, as well as sinusitis, allergic rhinitis, recurrent abdominal pain, and asthma. Symptoms ranged from less than 1 day to greater than 6 months. The criteria for the success of a treatment for pain syndromes were that the condition resolved completely or was judged at least 50% better. The criteria for success of chronic nonpain syndromes were that specific medication usage was voluntarily reduced 50% and duration and frequency of relapses decreased.

The total number of treatments needed to meet these criteria was 132 for all 106 patients. The recovery rate was notable: 70% saw the improvement within 3 days and 52% saw improvement within 24 hours. For many, relief was virtually immediate.

Dr. Jodorkovsky reported that despite the limitations of an uncontrolled study of this nature, the results were so overwhelmingly positive that they more than made up for methodological and design deficiencies. At the present

time he is analyzing data from a more narrowly focused, blinded study of enuresis.

MAJOR BENEFITS OF KHT IN A PAIN MANAGEMENT PRACTICE

There are many obvious benefits to applying KHT in a pain management practice, including

1. Correspondence Therapy is very easy to learn; even children have been taught the fundamentals.
2. It is efficient, as diagnosis and treatment can take as little as 5 minutes.
3. Treatment can be completely painless, and in the case of the microthin needles inserted only 1 mm, nearly painless.
4. It is safe as needles in the hand cannot penetrate vital organs.
5. It is convenient to patients and practitioners, as clothing is not removed.
6. Pain reduction is immediate and is virtually guaranteed for a positive response.
7. It is acceptable to children, the needle phobic, and literally all ages.
8. KHT is an ideal adjunct to any other healing modality or it can stand alone as a complete energetic medicine practice.

HOW TO LEARN KHT

The Correspondence Therapy level or application can be learned in a variety of formats. In a 1-day seminar, with distance learning including a videotaped seminar, and eventually via the Internet. After 1 day of practice and learning the basics, practitioners are ready to treat patients.

Learning the entire scope of KHT requires attendance at a series of seminars on theory and practice. Learning the theory and concepts of KHT beyond Correspondence Therapy is made easier with a basic knowledge of Traditional Chinese Medicine theory. The entire scope of KHT includes

1. Micromeridian therapy
2. Eight Extraordinary meridian therapy
3. Five Element therapy
4. Hot/Cold therapy
5. Ring therapy
6. Designer Food therapy
7. Moxabustion therapy
8. Birth Constitution therapy

Included in the aforementioned are many different treatment and combination treatment strategies.

WHO PRACTICES KHT

At the present time in the United States, practitioners include physicians in many specialties, nurse practitioners, nurses, acupuncturists, chiropractors, physical therapists, massage therapists, holistic health practitioners, and at the basic level even interested lay people. KHT has been taught throughout the world and the basic text has been translated into six languages including English, German, Russian, Japanese, French, and Spanish.

In summary, the key words that exemplify Korean Hand Therapy are effective, efficient, safe, acceptable, and economical.

Koryo Hand Therapy for Pain Relief

Linda C. Hole, M.D.

> A wise man should consider that health is the greatest of human blessings, and learn how by his own thoughts to derive benefit from his illness.
>
> Hippocrates

INTRODUCTION

Koryo Hand Therapy (KHT), a hand acupuncture microsystem developed by Dr. Tae Woo Yoo, O.M.D., Ph.D. of Korea, is a remarkably effective and powerful tool for pain management that is based on a simple systematic relationship between your body's acupuncture meridians and corresponding hand "map".

KHT is noninvasive, painless and effective without needles, has no significant side effects, often gives immediate and dramatic results within minutes, and is easy to both learn and apply. KHT is recognized worldwide for its elegant methodical simplicity, immediate onset of action, and often instantaneous, near-miraculous results. KHT is especially a godsend for those who have found little or no relief elsewhere.

Qi is your breath, your universal vital life force, or the healing energy transmitted via Qigong, a 5000-year-old energy medicine healing system from China. Qi enhances your KHT treatment, and gives even more remarkable results in pain relief.

Dr. Yoo, the internationally renowned acupuncturist who discovered KHT, considers KHT a gift of God. In his own words, he describes the birth of KHT:

> One autumn night in 1971 I was awakened from sleep by a severe pain in the back of my head. For some reason, I found myself staring at the back of my middle finger, and it occurred to me that there might be a point there to treat the pain. I proceeded to stick my finger with the tip of a ballpoint pen, and indeed found a particularly painful area. I then proceeded to insert a needle in this sensitive spot, and my God the headache was gone. The speed and degree of pain relief was overwhelming. I mentally visualized the tip of my finger as possibly representing the head of the human body, and wondered whether there was a relationship of the rest of the hand with the whole of the human body.

In this chapter, we focus on KHT, and build on Chapter 52, the introductory chapter on Koryo Hand Therapy by Dan Lobash Ph.D., L.Ac. and on Chapter 51 on Qigong by this author.

Although KHT is based on the same principles as Traditional Chinese Medicine (TCM) acupuncture, KHT requires no TCM, acupuncture, or Qigong training to learn or apply. For those with TCM experience, practitioners find KHT superior for:

- Greater efficacy, depth, and breath, with results even when all else has failed
- Immediate onset of action, with results usually within minutes
- Far more efficient in the amount of time required for treatment
- Far simpler to learn and apply
- Essentially no side effects
- Noninvasive and painless; no needles are required
- Empowers patients in self-care, and to become free of dependence on habit-forming medications

0-8493-0926-3/02/$0.00+$1.50

One great advantage of KHT is its simplicity. We routinely teach KHT to our patients for self-care. We've even taught children how to effectively use KHT to successfully treat family and friends. In this chapter, we hope you will be inspired to see for yourself what KHT can do to ameliorate pain.

CLINICAL SCOPE AND STUDIES

In our medical practice, we have found KHT effective in the treatment of a wide range of pain disorders including acute injuries, arthritis, bone pain, cancer, carpal tunnel syndrome, chest pain, disc disease, dysmennorhea, fibromyalgia, fractures, hypothalamic syndrome, headaches, migraines, myopathies, neuralgias, pelvic pain, peripheral neuropathies, radiculopathies, RSD reflex sympathetic dystrophy, RSI repetitive stress injury, sciatica, shingles, shoulder pain, frozen shoulder, soft tissue and sports injuries, surgical postoperative pain, chronic pain, and intractable pain.

Roberto Jordokovsky, M.D., a pediatrician, reports in a 1999 pilot study for the AAMA and the Journal of Physical Medicine[1] on 106 children and adolescents treated with KHT. For the 65% with painful acute conditions, e.g., sprains, back pain, headache, etc., he observed a nearly 100% positive response within one treatment session, and no side effects. For the 35% with chronic conditions, he noted significant improvement over time with repeated follow-up treatments.

Patrick Mok, M.D., anesthesiologist and pain management specialist, reports his findings on the treatment of neuralgia and myopathy. "Practically all patients will have positive results with KHT to different degrees, usually within 3–4 treatments … (with) significant pain alleviation of varying degrees and duration, abolishment of acute exacerbations, and enhanced medication effect, with decreased doses of medication required … and a documented case of return to normal levels of CPK."[2]

With controlled studies in English in progress, KHT medical doctors and practitioners across the country report similar results.

THE SCIENCE OF KHT

A punch biopsy of any part of your body gives a hologram of your body. Cells, by their embryological cellular "memory," remember their origins and how they relate to the whole. Other well-documented acupuncture microsystems include the scalp, eyes, ears, tongue, face, and foot. For every body pain, there is a sensitive correspondence KHT point on the hand. The KHT hand microsystem is one of the most powerful for pain relief.

Studies by Dr. M.H. Cho and Dr. Y. Mitsuo demonstrate that stimulation of KHT hand points induces an increase in temperature of predicted KHT corresponding body parts. Professor Yoo (1976, 1977) further reports that stimulation of KHT hand points increases electroencephalogram alpha waves.

In acupuncture, Dr. Bruce Pomeranz, professor of physiology at the University of Toronto, did the classic studies demonstrating that acupuncture stimulates the release of endorphins, dinorphins, serotonin, and norepinephrine. Acupuncture research also documents vasodilatation, and increased blood levels of enkephalins, mRNA, prostaglandins, and other anti-inflammatory agents.

KHT TO GO: SOME CASE EXAMPLES

KHT is so simple and fun to apply, with such immediate results, that we routinely give impromptu "curbside" treatments almost everywhere we go. With KHT, it is not uncommon for patients to require only a single treatment for long-standing relief. In hopes of inspiring you to explore KHT for yourself, we share here some case examples, with more clinical examples and treatment details to follow in the "How" section of this chapter (see also, Qigong Chapter 51, Qi Acupuncture section).

Headache

A middle-aged blue-collar worker complained of severe headaches. As I applied needles to his sensitive KHT correspondence hand points, he burst out with a series of very loud vocal four-letter expletives, for the whole office and waiting room to hear. Then with a sigh of relief, "Whew! That sucker did it! — My headache's gone".

Surgical Pain

At the registration tables of a medical meeting, a fellow attendee complained of acute incisional postoperative pain. When we found the corresponding hand KHT painful point, he literally dropped to his knees in surprise. We applied simple fingertip Qi and pressure to the KHT correspondence hand point, and his incisional pain was relieved.

Disc Disease

We visited a family friend the night before his scheduled surgery for his herniated disc. We found him at home lying on the floor, with porta-potty at side, having signed himself out of the hospital against medical advice. With a single several minute treatment, he returned to work within 2 weeks.

KHT LEVELS OF TREATMENT

KHT levels of treatment range from simple to elegant. The most straightforward for beginners are the Correspon-

dence, Basic, and Meridian levels of treatment. The Mo and Yu points, and Dr. Yoo's Formulary are also helpful. For more complex and chronic pain disorders, deeper treatment is necessary, such as the Three Constitutions, Five Elements, or Birth Constitution Biorhythmic approach. Combining different levels of treatment gives even more effective results.

- **Correspondence**. This is the simplest level of treatment to learn, usually gives immediate and effective results, and when augmented with Qi, at times even long-lasting results. Simply find the corresponding or sensitive points on the hand to ease the body pain.
- **Basic**. This basic set of points energizes the three vital "heaters" or "burners," upper, middle, and lower, and may be used as a foundation for any KHT treatment.
- **Meridian**. Use an acupuncture atlas to find the acupuncture meridian location of the pain. Balancing the meridians balances the internal organs, and thereby helps dispel the pain.
- **Three Constitutions**. There are three fundamental "Constitutions" in KHT theory: Yang, Yin, and Kidney. The "Extraordinary" points free constitution-level blockages, and thus also pain. Use in combination with Correspondence, Meridian, and Five Elements treatments.
- **Five Elements**. Each yin–yang organ pair has an Element. Balancing the Five Elements gives a deeper level of treatment for pain relief.
- **Mo and Yu Points**. Each organ has a control gathering front Yin "Mo" and back Yang "Yu" point. These points in combination with other levels of treatment potentiate pain relief.
- **Biorhythmic and Birth Constitution**. Each person's date and time of birth determine his or her Five Element "core" Three Constitutions diagnosis.
- **Formulary**. A cookbook approach, which includes specific prescriptions based on Dr. Yoo's years of experience, is especially useful for those new to KHT.
- **More KHT Tools**. Connecting Meridians, Four Gates, Hot vs. Cold, Long vs. Short Lever, Long Distance, Pendulum, Upside Down points, the Four Lifesaving points, Three Emergency Points, Four Gate points, Four Spiritual Points, Eight Extraordinary points, Twelve Source points, Five Su points, and Special Points for Nervous Disease are more KHT tools available—all superbly effective for pain relief, and simple to learn.

KHT METHODS OF TREATMENT

Ways of stimulating KHT hand points include

- Mechanical pressure, e.g., with a ball point pen, or special KHT probe
- Pressure pellets, with negative silver- and positive gold-colored pellets
- Magnets, with negative north poles, and positive south poles
- E-Beam microcurrent electrical stimulation, with negative and positive leads
- Needles, with polarity by color, and/or slant of needle
- Moxa, or heat stimulation—a must for those with deep or chronic illness
- Qi-KHT fingertip pressure with Qi
- Five Element ring therapy, silver and gold colored
- Five Element food therapy formulas for each element
- Yi Nian, or "Clear Intention", or simply visualizing the correct treatment.

Negative, or silver-colored, pellets, magnets, needles, and rings sedate and calm. Positive, or gold-colored, materials tonify and strengthen.

Five Element ring therapy, and Five Element food therapy are deeper methods of balancing the internal organs of the Five Elements. Just holding the correct specially formulated Five Element food packet, or wearing the Five Element ring on the correct finger may relieve the pain.

Simultaneous Qi emission with any method potentiates the treatment results.

Some Precautions

Bad effects may occur if one overtreats, especially with magnets. Pressure points left too long, and or applied with overzealous pressure may damage the skin. Misdiagnosing and applying the entirely wrong prescription, especially when using the Three Constitutions Extraordinary Points, may rarely cause dizziness, nausea, and even fainting, for which the antidote is to immediately remove the points. There are also the obvious precautions with pregnancy, and possible burns with moxa. KHT, however, is by and large very forgiving, and when practiced correctly, has essentially no side effects.

How Do I Learn and Apply KHT?

The best way to learn KHT is to simply start experimenting with the hand points. Sometimes when we teach an introductory workshop, we invite an audience participant

to find the KHT pain relief points on a volunteer. The incredulous looks on their faces when the pain disappears are priceless.

THE HOW OF KHT: SOME KHT PAIN RELIEF TOOLS

The practice of KHT is simple. KHT hand points become sensitive in correlation to the pain in the body and internal organ imbalance. Simply stimulating the indicated Correspondence, Basic, Meridian, Three Constitutions, Five Element, and/or Mo and Yu points gives pain relief.

Incorporating Qi into the treatment augments the pain relief, regardless of the specific method of stimulating the indicated hand points. When you apply Qi to indicated KHT hand points, your patient may experience an electric tingling or warm sensation in the corresponding body part, and sometimes even break out laughing.

We usually use the ipsilateral hand to treat pain. Treat the right hand for a right-sided pain, the left hand for a left-sided pain. For severe conditions, we sometimes use the contralateral hand, or "long lever." The contralateral long lever applies more healing force than the ipsilateral short lever.

The more sensitive distal points on the fingers are used for the acute conditions. The more proximal points on the fingers are used for chronic conditions.

Correspondence Therapy

The Correspondence Level of treatment is the most direct first-step KHT approach to pain. For a step-by-step guide to the Correspondence Therapy, see Dr. Lobash's Introductory Chapter 52.

In general, the palmar surface of your hand corresponds to the anterior or "Yin" surface of your body: face, chest, abdomen, knees, etc. The dorsal surface of your hand corresponds to the posterior or "Yang" surface of your body: occiput, spine, buttocks, achilles tendon, etc. Each finger corresponds to a limb, with the middle finger representing the spine and head. Each finger joint corresponds to a body joint.

The sensitivity of the correspondence point is in direct relation to the severity pain of the affected body area. Stimulating the correspondence point alleviates the presenting pain. The correspondence point itself will become less sensitive as the body pain is dispelled.

Correspondence Therapy Clinical Example

Chronic Pain in a 42-year-old C6–7 quadriplegic, who complained of long-standing neck, shoulder, and lower extremities unrelieved by opiates. Simple fingertip Qi applied to his KHT correspondence point for his trapezius muscles gave immediate relief of his shoulder pain.

Yi Nian Clear Intention

Yi Nian clear intention is visualizing the specific KHT prescription itself, and the pain-free result you like to achieve. The mere clear intention of seeing your patient free from pain may give remarkable results. This level of treatment is an example of what Larry Dossey, M.D. heralds as New Era "nonlocal" medicine.

Yi Nian Clear Intention Clinical Example

For a veteran who complained of over 20 years of intractable shoulder pain, Professor Yoo drew the correct KHT prescription on the blackboard, a simple arrow, then stroked the arrow on the blackboard in the correct direction of the meridian flow necessary to relieve the pain—and the patient's pain was immediately relieved. To prove the phenomenon, Professor Yoo then erased the blackboard, drew the prescription again, stroked the arrow on the blackboard in the opposite direction, and the his pain returned. Professor Yoo then erased the blackboard one last time, drew the correct prescription once again, stroked the arrow on blackboard in the correct direction, and the veteran's pain was gone.

Basic Therapy

The Basic points may serve as a foundation for any KHT pain relief treatment, in that they energize and balance the three "heaters" and the internal organs. The Lower Heater controls pelvic excretion and reproduction. The Middle Heater controls abdominal organs and digestion. The Upper Heater controls the heart and lungs, circulation, and respiration. Regular use of the Basic Treatment points for health maintenance results in more restful sleep, increased energy, vitality, alertness, sexual energy, and overall sense of well-being.

Three Constitutions Therapy

There are three basic "constitutional excess syndromes" in KHT theory: Yang Excess, Yin Excess, and Kidney Excess. Constitution Level treatment is appropriate for both acute and chronic pain, and is usually necessary for organic and chronic pain. An imbalance or blockage at a Constitution Level may contribute to pain. Freeing the imbalance and blockage frees the pain.

Within each constitution, there are two types: Yang and Yin. In Yang types, the excess organ is a hollow Yang organ, and the carotid pulse is greater than the radial. In Yin types, the excess organ is a solid Yin organ, and the radial pulse is greater than the carotid.

One way of diagnosing the constitution is by palpating the abdomen. For each syndrome, there is a specific abdominal TCM point: Stomach 25 for Yang Excess Syndrome, Spleen 15 for Yin Excess Syndrome, and Conception Vessel 4 for Kidney Excess Syndrome. Kidney Excess Syndromes also may be tender at Stomach 25 and Spleen 15 as well. For each of the three syndromes, there are specific sets of Extraordinary points for treatment: one set for Yang types and another for Yin types.

Yang Excess Syndrome

Patients are characteristically thin, conciliatory, kind, and are the most responsive to treatment. The major excess organs are the large intestine, liver, and heart. They are prone to dizziness, headaches, nervousness, fatigue, low back pain, sciatica, hemiplegia, and impotence. Their conditions are aggravated by excessive drinking, sexual indulgence, emotional stress, imbalanced diet, and overeating.

Yin Excess Syndrome

Patients are usually overweight, often "greedy", tend to be big eaters and sleepers, and are slower to respond to treatment. The primary excess organ is the spleen. They are especially prone to neuralgias: trigeminal neuralgia, intercostal neuralgia, and lower extremity neuralgias, progressing to loss of sensation. They are also prone to headaches, especially migraines, seizures, paralysis, and stroke.

Kidney Excess Syndrome

These patients by nature like to save and spare, are preoccupied with their own troubles, tend to right-sided disorders, and are prone to disc disease and paralysis, plus allergic, rheumatic, and autoimmune disorders. The excess organ is the kidney, and they are the most difficult to treat.

Three Constitutions Clinical Example

Once when I was presenting at a medical symposium, a young woman with a 6-month history of a constant headache volunteered herself before the full audience for pain relief. I applied only the four indicated Three Constitutions Extraordinary points, and her headache was gone.

Meridian Therapy

Meridian therapy is a safe and gentle method of controlling the six solid Yin, and six hollow Yang organs of TCM. Each meridian governs one organ of a pair of coupled solid Yin and hollow Yang organs, each with its own specific body surface dermatome-like area.

With hands raised up to the heavens and the palm Yin surface facing forward, the Yang meridians run on the lateral and posterior Yang back surface of the body, and flow from heaven to earth. The Yin meridians run on the medial and anterior Yin surface of the body, and flow from earth to heaven.

Upper extremity pain may result from imbalances in the coupled Yin–Yang organs: lung–large intestine, heart–small intestine, pericardium–triple heater. Lower extremity pains results from imbalances in the coupled Yin–Yang organs: liver–gall bladder, spleen–stomach, and kidney–bladder.

The imbalances are excess or deficient organs. In the coupled pairs of organs, excess in the yang organ means deficiency in the coupled yin organ. Pain is usually secondary to the excess organ.

For meridian level treatment of pain, first determine the location of the pain on the body, then which meridian controls the specific body area, and the meridian's organ. Next, sedate the excess organ via its meridian, or tonify the coupled deficient organ. Sedate by running microcurrent or Qi against the flow of the meridian. You may use Qi to sedate by simply stroking your fingertip against the direction of the meridian flow. Tonify by running microcurrent or Qi in the same direction as the flow of the meridian. Tonify via fingertip Qi by stroking the KHT micromeridian in the same direction as meridian flow.

Current runs negative to positive with pellets, and north to south with magnets. Thus, one may also use pellets and magnets to tonify and sedate. Gold- or silver-colored rings on the correct fingers continue the tonification or sedation.

For pain, simple sedation of the indicated meridian usually gives some immediate relief. For a depleted patient with a low energy level, for example, someone suffering cancer pain, tonifying the coupled deficient organ is a better choice.

As a practitioner, you can almost simply show your patient an acupuncture atlas, ask the patient to point to the affected body area, then treat the indicated meridian according to the diagram.

Meridian Therapy Clinical Examples

Sciatica for months in a renowned author. I applied fingertip Qi to sedate her bladder meridian. I stroked her 5th finger dorsal midline along her KHT bladder micromeridian, from distal tip to proximal metacarpal joint, then gave her a pinky copper ring to continue bladder sedation tonification at home. For the first time in months, she was pain free, and continued to be pain free for months afterward.

Carpal tunnel in a young woman with adult-onset diabetes. Carpal tunnel in KHT is often a pericardium meridian imbalance. With a single KHT treatment, her

TABLE 53.1
The Five Elements

Element	Wood	Fire	Earth	Metal	Water
Color	Green	Red	Yellow	White	Black
Emotion	Anger	Joy	Thinking	Grief	Fear
Direction	East	South	Center	West	North
Climate	Wind	Hot	Damp	Dry	Cold
Taste	Sour	Bitter	Sweet	Pungent	Salt
Orifice	Eyes	Tongue	Mouth	Nose	Ear
Tissue	Tendon Vessels	Blood	Muscle	Skin	Bone
Yin/Yang	Liver	Heart	Spleen	Lung	Kidney
Organ	Gall Bladder	Small Intestine	Stomach	Large Intestine	Bladder

physical therapist noted an increase in both muscle strength and mass.

Headache in a 23-year-old computer wizard camp director, who complained of long-standing frontal headache radiating to vertex. Dx: Gall bladder deficiency. Rx: Sedate liver. Result: Headache relieved.

Five Element Therapy (see Table 53.1)

We introduced the Five Elements in Chapter 51 on Qigong. When other levels of KHT treatment are insufficient to fully alleviate the pain, go to the Five Elements, a deeper more profound level of treatment.

There are Five Elements: Fire, Earth, Metal, Water, and Wood, each of which governs a pair of coupled Yin and Yang organs. Each element has a whole set of element-specific characteristics: color, emotions, sound, taste, direction, etc.

The Five Elements themselves are governed by a "Mother Son" Nourishing Cycle, and by a Control Cycle. For each meridian there are specific Five Element points. In Five Element therapy, we pick tonifying and sedating points according to the principles of the Mother-Son Nourishing and Control cycles. Five Element therapy may bring to light the deeper psychospiritual pain picture underlying the surface physical pain.

When patients present with a physical pain, they often deny any related deeper pain. Five Element therapy dispels the physical pain in part by addressing the underlying psychospiritual pain as well. Giving patients feedback on their Five Element diagnosis helps them become aware of the deeper wound underlying their physical pain. With this awareness, there are often tears of release, signifying a more profound, and sometimes life-changing, healing.

Five Element Clinical Examples

Intercostal neuralgia in a 46-year-old female professional artist. Heart sedation relieved her pain. The Fire, or heart, emotion is sadness. Her underlying pain was deeply suppressed Heart Sadness over the death of her father.

Left sciatica in a 30-year-old health professional. Left bladder sedation relieved her pain. On the right, she had large intestine excess. Water, with the emotion fear, is the bladder element. Metal, with the emotion grief, is the large intestine element. Her underlying issues were grief over her father's illness, and fear that he may die.

Combined Levels of Treatment

Although simple Correspondence Therapy may give immediate and dramatic results, and is adequate for simple and/or acute pain, other levels of treatment are necessary for deeper pain. For organic and/or chronic pain, our approach is to first diagnose and balance the Three Constitutions, then address the Five Element organ imbalance underlying the presenting pain.

Chronic and Organic Pain Clinical Examples

Diabetic Peripheral Neuropathy in a 53-year-old white CEO with constant pain and numbness, especially of left upper extremity, sleepless even with medication. Dx: Left and right Yang syndrome, with large intestine and bladder excess. Rx: Sedate large intestine and bladder excesses. Result: pain relieved, and sensation returned.

Herpetic Neuralgia in a 29-year-old health professional with acute herpetic trigeminal neuralgia, onset after death of a loved one, in tears with pain, unable to open mouth, chew, or smile. Dx: Left Yin syndrome with spleen and lung excess, right Yin syndrome with gall bladder and bladder excess. Rx: Sedate excess organs. Result: Left office with full range of motion of mouth, and happy smile as well.

CONCLUSION

KHT is a truly effective, easy-to-learn, rewarding, and paradigm shift tool for empowering New Era medicine

pain management. The look on a patient's face, with the realization that the presenting symptom is suddenly gone, is again priceless—sometimes amazement, sometimes disbelief, sometimes pure relief, sometimes laughter, sometimes tears of release and gratitude.

My hope in sharing these tools with you is to give you a taste of what's possible, and encourage you to explore KHT for yourself, and see what a tremendous difference KHT can make in your own life, in your practice, and in the lives of your patients.

Bruce Hocking, D.Ac.

FOREWORD

The social and human costs of chronic pain are staggering. During the 20th century, chronic pain has disabled millions of people, costing hundreds of billions of dollars in rehabilitation and lost productivity in addition to untold human suffering (Statistics Canada, 1992). According to some statistics, 80% of these payments have been made for patients with neuromyofascial pain. For the future, there is little evidence to suggest that the rate of growth of chronic soft tissue pain conditions will decrease or even plateau.

Today, doctors and patients can choose from a variety of treatments, though surgery and prescription drugs are the most popular avenues in the United States. The major disadvantage associated with drugs or surgery is that they do not always solve the root problems; rather, they mask pain or surgically remove local pathology. Pharmaceuticals occasionally are effective, but can result in unpleasant interactions and side effects to a degree that reduces the quality of life for those who ingest them on a long-term basis. Moreover, the risks associated with drugs and surgery are not always outweighed by the benefits, as many patients actually feel worse.

A number of complementary and alternative modalities (CAMs) have been promoted as solutions to fill the void left by allopathic medicine. However, their relative efficaciousness may be regarded as sporadic. Progress in identifying a broader range of therapeutic benefits of CAMs has been hindered by considerable infighting among different disciplines, to a degree reminiscent of a quest to be the first to race up the hill, plant a flag, and claim victory in a winner-takes-all contest. While natural solutions do offer some relief in the battle against chronic pain, long-term victory appears elusive when approaching a patient with a single modality or treatment philosophy.

The development of Electro-Therapeutic Point Stimulation (ETPS) therapy represents a turning point in the fight against chronic pain. Where surgery and prescription drugs fall short, ETPS provides nonsurgical, noninvasive treatment of chronic neuromyofascial pain. ETPS does not replace, nor does it dispute the validity of conventional medicinal approaches. Rather, ETPS recognizes that all therapeutic approaches must be examined to determine the most efficacious treatment for the patient. ETPS also recognizes that different therapies produce different responses and that the key to understanding the source of a patient's chronic pain is to perform an overall mechanical and neuropathic analysis of the body. This analysis helps to identify problematic areas that contort the body, resulting in asymmetrical posture and motion, physical conditions that ETPS therapy believes can lead to degenerative changes and chronic pain throughout the body.

INTRODUCTION

ETPS neuropathic therapy is a hybrid modality used in the treatment of neuromyofascial pain. In its most basic form, ETPS therapy applies brief, staged, concentrated stimulation to points relating to different therapeutic systems. Patient assessments are performed at the end of each stage to determine therapeutic effectiveness. Through a series of systematic and reproducible protocols, the diagnosis and treatment of root causes of soft tissue pain can be completed with a high degree of accuracy.

0-8493-0926-3/02/$0.00+$1.50

The theoretical underpinnings of ETPS therapy are based on sound medicine, firmly grounded on the principles of acupuncture, osteopathic trigger points, neuromuscular and neural therapies. As such, the constituent elements of ETPS therapy are not new. Its unique contribution to pain relief, however, comes from the synthesis of different approaches, combining the therapeutic "pearls" of trigger, motor, and acupuncture points with a mechanical analysis of the body. The result is a simple, easy-to-use series of protocols.

By following the recommended protocols, physicians are able to identify which stage(s) is/are most responsible for contributing to a patient's pain condition. Stages deemed ineffective in producing positive therapeutic responses are eliminated from future treatments. Those stages producing positive responses are examined diagnostically to determine interrelationship(s) with the patient's condition and are integrated into future protocols.

ETPS therapy does not isolate or treat a pain condition; rather, it is used to determine how the patient's overall body mechanics and neuropathic/radiculopathic manifestations can be combined with acupuncture and trigger points to produce unique protocols. These protocols bridge many different treatment philosophies to provide therapeutic responses where other modalities fail to achieve successful results. Because it is effective in the diagnosis of root causes of pain, ETPS therapy can serve as an invaluable tool for all types of physicians in their efforts to substantiate current treatment and as an integrative tool for current protocols.

The therapeutic benefits of ETPS are based on four different physiological principles.

1. Circulation response. Increasing or decreasing circulation (called "chi" in Eastern therapies) can benefit the patient in a manner similar to the application of heat (vaso dilation) and ice (vasoconstriction) in Western medicine.
2. Autonomic/parasympathetic response. A medium for chronic pain, the Autonomic Nervous System (ANS) covers over 90% of the body and consists of the sympathetic and parasympathetic nervous systems. ETPS stimulation of parasympathetic "gates" can have a calming effect on the body, providing the patient with immediate and long-lasting relief from pain, anxiety, and insomnia.
3. Endorphin response. Endorphins are similar to morphine in their ability to reduce pain, but are thousands of times stronger and do not produce harmful side effects. Endorphins may be released through concentrated low-frequency ETPS stimulation of neural points causing the pituitary to secrete endorphins, thereby releasing adrenal cortico-atrophic hormone (ACTH) and hydrocortisols for acceleration of soft tissue repair.
4. Myofascial release. Chronic pain is known to originate in neuropathy, or functional alterations of the peripheral nervous system (PNS). Neuropathy is always caused by muscle contraction, while radiculopathy is neuropathy at the spinal root. Relaxing contracted muscles relieves impingement of the nerves, reduces heightened sensitivity of pathways, and improves the patient's ROM.

The balance of this chapter, divided into two main sections, provides an overview of ETPS therapy. Part A describes the six pillars of ETPS therapy, the core foundation of knowledge upon which the synthesis of different modalities is built. They are (1) acupuncture; (2) the relationship between radiculopathy and neuropathy and chronic pain; (3) the relationship between dermatomes and chronic pain; (4) the relationship between gait and chronic pain; (5) the relationship between scar therapy (neural) and chronic pain; and (6) ETPS stimulation. Based on this body of knowledge, Part B describes several ETPS protocols, all of which use an approach to treatment that allows therapists to diagnostically isolate and treat chronic pain concurrently.

ETPS therapy has proven successful in the treatment of various indications. These include back and neck pain, whiplash, TMJ, fibromyalgia, neuropathies, migraines, headaches, sport injuries, carpal tunnel, failed backs, postoperative radiculopathy, plantar fasciitis, frozen shoulder and shoulder pain, tennis elbow, and most other neuromyofascial pain syndromes. Due to the limitations of this forum, the description of ETPS therapy and related treatments will focus on back and neck pain, fibromyalgia, and plantar fasciitis protocols.

PART A: THE SIX PILLARS OF ETPS THERAPY

Acupuncture

In order to utilize ETPS protocols effectively, therapists must have a basic, practical understanding of acupuncture. Long regarded as an effective modality for the treatment of pain, acupuncture contributes four key dimensions to the development of ETPS protocols: the release of endorphins, key acupuncture points, a numbering system for point location, and the movement of circulation and energy. Each dimension is discussed below.

The Release of Endorphins

Acupuncture has been scientifically proven to release endogenous morphines from the anterior pituitary (Andersson,

1999; Augustinsson, et al., 1977; Cheng, McKibbon, Roy, & Pomeranz, 1980; Fisher, 1992; Martelete & Fiori, 1985; Pomeranz, 1981). Once released, internal morphines stimulate the release of ACTH and glucocorticoids, natural hormones that accelerate soft tissue healing. These powerful nonaddictive opiates are circulated throughout the body to relieve pain and remain elevated for a period of 12 to 72 hours. All acupuncture points can release endorphins as long as a proper therapeutic response is achieved with needles or low frequency stimulation. ETPS therapy activates endorphin response for overall pain relief through the application of low-frequency endorphin-releasing parameters to ETPS protocols (Christopher, Lorenzo, Zirbs, Chantraine, & Visher, 1992; Lehmann, Russell, Spratt, Liu, Fairchild, & Christensen, 1986; Pomeranz & Niziak, 1987).

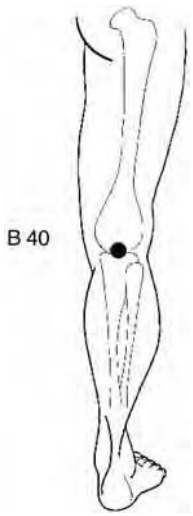

FIGURE 54.1 B 40 is a distal acupuncture point that influences proximal low back pain.

Key Acupuncture Points

Key acupuncture points are utilized for their beneficial therapeutic effects on the body. Distal points located on the extremities are stimulated to produce proximal pain relief and have been integrated into ETPS protocols to enhance pain relieving benefits. Four examples of distal points related to the treatment of back pain are described below.

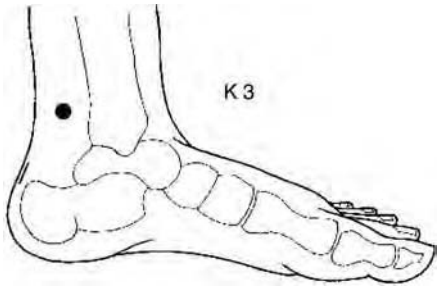

FIGURE 54.2 K 3 is a distal acupuncture point for low back pain. Very effective for sciatica patients with pain aggravated in the morning.

- B 40 (Figure 54.1). An effective low back pain point integrated into circuits with ETPS back pain protocols to produce a highly effective therapeutic stage. Located on the midline of the transverse knee crease.
- K 3 (Figure 54.2). Is circulated with L4-L5 segmental levels for back pain that is worse in the morning. Located halfway between the apex of the medial malleolus and the Achilles tendon.
- B 60 (Figure 54.3). A powerful sciatic point circuited with L4-L5 segmental levels for afternoon back pain. Located halfway between the apex of the lateral malleolus and the Achilles tendon.
- Gb 34 (Figure 54.4). An influential point for muscles, tendons, and tissues that should always be incorporated into the first stage of a standard protocol because of its ability to reduce muscular hypertonicity and spasticity throughout the entire body. Applying ETPS therapy to this acupuncture point is an absolute must for therapists who perform manual or soft tissue therapy on patients. Located inferior and posterior to the head of the fibula.

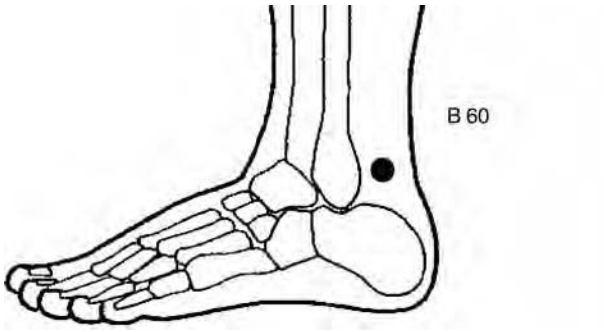

FIGURE 54.3 B 60 is a distal acupuncture point for low back pain. Effective for sciatica patients reporting aggravation in the evening.

Meridian Numbering System for Point Location

Soft tissue research suggests that there is a strong therapeutic connection between trigger, motor, and acupuncture points and a low level of skin resistance (Gunn & Millbrandt, 1976; Hartley, 1989; Low & Reed, 1994; Robinson, MacKler, & Snyder, 1995; Travell & Simons, 1992). For this reason, ETPS therapy uses the acupuncture meridian numbering system to assist in point location. In addition, the meridian system facilitates greater anatomic specificity when locating trigger points compared to palpation.

FIGURE 54.4 GB 34 is the myofascial release point, also known as the physical therapy point in acupuncture. Applied in circuits for myofascial release of receptor muscles.

To demonstrate the advantages of the meridian numbering system, consider acupuncture point Gb 21 and the upper trapezius trigger point. Although physically the same point, locating Gb 21 through the acupuncture meridian system is generally easier and will result in a more exact positioning compared to efforts to identify the upper trapezius trigger point through palpation alone.

Circulation and Energy

Blood and circulation in ETPS therapy are assumed to be in line with the concept of chi in acupuncture. Chi is a difficult concept to translate into English, but can be described as flowing energy, vitality, or life force. In the Oriental concept of medicine and the human body, the maintenance of health is achieved by releasing blocks, often caused by muscular tension, that restrict the flow of positive (yang) and negative (yin) energy. Many ailments, including neuromyofascial pain, are thought to be symptomatic of restricted or unbalanced chi.

Much of the skepticism with chi in Western culture largely centers on the inability of modern science to quantify this energy force. Rather than casting doubt on the existence of chi, the lack of recognition reflects the inflexibility and underlying hubris of modern Western paradigms. Acceptance of chi is not a prerequisite for practicing ETPS therapy; however, an open mind to its potential healing power is necessary.

ETPS adopts a simplified approach to chi. Positive or negative polarity (vasodilative or vasoconstrictive therapy) may be applied to trigger or acupuncture points depending on the historical response of the condition to heat and ice. Excessive or hyperfunctioning conditions usually respond better to vasoconstrictive therapy, while deficient or hypofunctioning conditions respond better to vasodilative therapy.

The circulatory setting is especially important with some chronic pain categories, such as fibromyalgia and reflex sympathetic dystrophy, where the traditional vasoconstrictive approach to pain therapy is poorly tolerated by patients. The therapeutic versatility necessary to treat positive and negative polarity is accomplished with ETPS' neuropoint stimulator, which has a current reversal function.

The importance of polarity in the treatment of pain should not be discounted. Based on our clinical experience, there appears to be a 70:30 split in the chronic pain population; approximately 70% of patients respond better to vasoconstrictive therapy (sedation), while 30% respond better to vasodilative therapy (tonification). With ETPS stimulation, therapists have the option of easily incorporating these ancient, but powerful healing philosophies into treatment protocols increasing flexibility and individualizing the therapy to better suit patient needs.

The Relationship between Radiculopathy, and Neuropathy and Chronic Pain

Neuropathic Therapy

ETPS therapy has achieved significant success in relieving pain by integrating acupuncture philosophies into pain protocols. However, a singular reliance on acupuncture for treatment was found to be insufficient in addressing a number of neuropathic and mechanical issues. For instance, acupuncture offers no clear direction for the treatment of impinged nerves, nor does it integrate dermatomes and neuropathic pain patterns into protocols. Through years of experience, ETPS therapy has found that neuropathy plays a role in chronic pain and that its treatment through ETPS therapy can, in some cases, reduce or eliminate the need for drugs and surgery.

The introduction of neuropathic pain therapies into ETPS protocols greatly enhanced the understanding and therapeutic outcomes of chronic pain syndromes. The theories of radiculopathy and neuropathy suggest that nociception and inflammation are not the catalysts for chronic pain syndromes. Instead, the root of many chronic pain syndromes appears to be neuropathy and the muscular contractions causing neuropathy.

The cause of neuropathy is thought to be severe muscular contraction, that is, muscles that have contracted and remain contracted in the absence of action potential. Radiculopathy, defined as neuropathy at the nerve root, seems to have the strongest influence on chronic pain syndromes. Radiculopathy impinges nerves at the root and causing abnormal functioning of the pathways as well as the muscle tissue they innervate. In this way, radiculopathy creates an increased susceptibility to injuries along the dermatomes to the nerve endings.

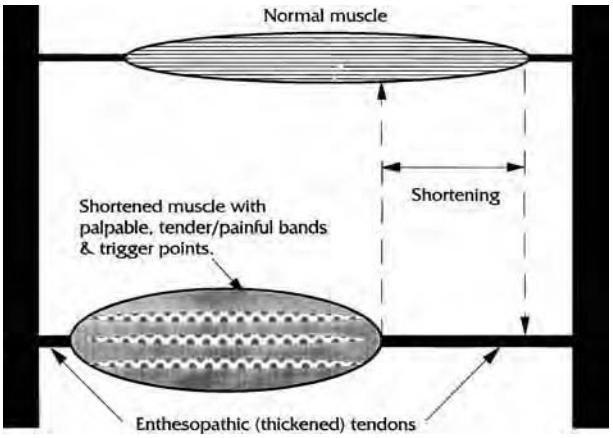

FIGURE 54.5 Top muscle illustrates muscular homeostasis. Lower muscle indicates muscle shortening, stretching of the tendons, and straining of the joints.

ETPS electrical stimulation produces a myofascial release of contracted muscles. When muscles contract and remain contracted, there is an electrical depolarization within the muscle (Fambrough, Hartzell, Powell, Rash, & Joseph, 1974; Becker & Selden, 1987). ETPS direct current stimulus creates an electrical loop within the muscles, enabling electrical repolarization and thus relaxation of the muscles (Figure 54.5).

Radiculopathy and Chronic Pain

Poor postural lifestyle and repetitive strain motions, usually occurring while playing sports or in the workplace, contribute to a pooling of "micro" injuries in the paraspinal muscles. If a sufficient number of micro injuries build up over time, a relatively minor movement by the patient can initiate paraspinal muscular contraction severe enough to produce radiculopathy and chronic pain (Bradley, 1974; Gunn, 1980; Gunn, et al., 1976; Gunn, et al., 1978; Gunn & Milbrandt, 1976; Loh & Nathan, 1978; Sola, 1981; 1984; Thomas and Ochoa, 1993).

Radiculopathy caused by paraspinal muscular contraction is believed to affect the ANS by impinging nerves at the nerve root, usually proximal to the dorsal/ventral rami juncture. Nerve impingement reduces the flow of motor impulses throughout the nerve pathway. According to Cannon's Law of Denervation (Cannon & Rosenbluth, 1949), a reduction of motor impulses through a nerve pathway produces disuse sensitivity and abnormal behavior within the receptor organ or tissue.

Radiculopathy influences tissue throughout the entire dermatome by reducing the flow of motor impulses at the nerve root. Nerve impingement and radiculopathy also influence distal pain by elevating acetycholine (ACH) and adrenaline levels throughout the pathways (Cannon & Rosenbluth, 1949), thereby increasing susceptibility to extremity muscular contraction (i.e., neuropathy). The environment created by increasing susceptibility to extremity neuropathy also increases susceptibility to distal injuries. Based on this series of relationships, it should be apparent that the treatment of most distal injuries must include an examination of the spine. In other words, if the spine significantly contributes to distal injuries, it should be a focus in pain therapy.

If paraspinal muscular contractions (radiculopathy) contribute significantly to distal pain and/or disease, then the release of paraspinal muscles through ETPS therapy should provide relief to distal pain disorders. Therefore, stimulating the paraspinal "Back Shu" points, which directly influence radiculopathic segments, can relax contracted muscles to a degree sufficient to reduce nerve impingement and allow the increase of motor impulses throughout the nerve pathways.

Manifestations of Radiculopathy and Neuropathy

Back Shu points are located paraspinally at the level of the spinous process interspace. Segmental levels with radiculopathy should be selected according to the following manifestations:

- Bilateral signs of trophedema are usually located at segmental levels L1–S3. Trophedema is a collagenic change in the skin that occurs when impinged nerves reduce the flow of motor impulses through pathways. Trophedema may be located with the "skin rolling" test, which will clearly identify the location in relation to nontrophic skin (Figure 54.6). Another manifestation, sudomotor, can be identified visually because it produces general warmth and sweating in the vicinity of radiculopathy. Trophedema and sudomotor manifestations are commonly located in the lumbar sacral segmental levels of L1–S3. Once the radiculopathic segments have been identified, they are correlated via dermatomes to distal injuries/pain conditions to determine root involvement in chronic pain conditions.
- Motor bands may be palpated paraspinally throughout contracted muscles, usually T2–T12. Cross-fiber palpation will easily identify thick, ropy bands within paraspinal muscle bellies that often run the entire length of the muscle.
- Posterior and lateral neck creasing at segmental levels, usually C2–T1 (Figure 54.7). Skin creasing suggests that some degenerative changes have occurred in the neck at the related segmental level. Occasionally, major creases will occur at every correlating segmental level on the neck.

FIGURE 54.6 Illustration of trophedma (physical manifestation of nerve impingement, called radiculopathy) as demonstrated using the "skin rolling" test.

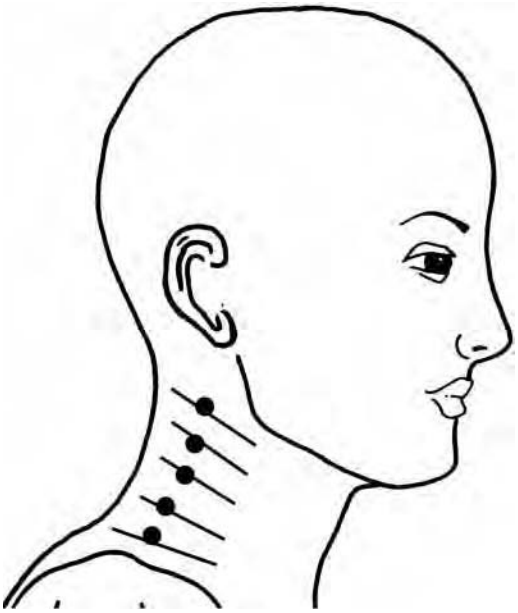

FIGURE 54.7 Illustrates lateral creasing in the neck and the suggested location of myofascial release points throughout tight motor bands. DO NOT apply microcurrent stimulation anterior to the corner of the jaw (over the carotid sinus).

Sympathetic Deregulation with Parasympathetic Points

The ANS comprises the sympathetic and parasympathetic nervous systems. Both neuropathy and radiculopathy stress the ANS by producing nerve impingement. Nerve impingement blocks the flow of motor impulses and deprives an organ or tissue of excitatory input (e.g., neural impulses) for a period of time causing disuse supersensitivity. Supersensitive nerve pathways and innervated structures react abnormally to stimuli, causing patients to perceive more pain than is actually being created (Bradley, 1974; Gunn, 1980; Gunn, et al., 1976; Gunn, et al., 1978; Gunn & Milbrandt, 1976; Loh & Nathan, 1978; Sola, 1981; 1984; Thomas and Ochoa, 1993).

Neuropathy, and radiculopathy in particular, increases the upregulation of the sympathetic nervous system by reducing the flow of motor impulses, making treatment difficult due to the patient's high sensitivity levels. Parasympathetic points treated with vasoconstrictive therapy deregulate the sympathetic nervous system, thereby permitting a more aggressive and proactive approach to patient treatment. Key parasympathetic points are as follows:

- Lu 9 (Figure 54.8). A powerful vascular/parasympathetic point. Located on the transverse wrist crease, in the hollow on the ulnar side of the radius bone.
- P 6. A good nausea and parasympathetic point. Located three fingers proximal from the most distal wrist crease, deep between the palmaris longus and flexor carpi tendons.
- H 7. A good mind-calming and parasympathetic point. Located on the transverse wrist crease, in a hollow on the radial side of the thick, flexor carpi ulnaris tendon.
- Sp 6 (Figure 54.9). An immune, parasympathetic, and distal pain point for perineum. Located four fingers superior to the medial malleolus and posterior to the tibia bone. Press against the posterior edge of the tibia bone to find this tender point properly.

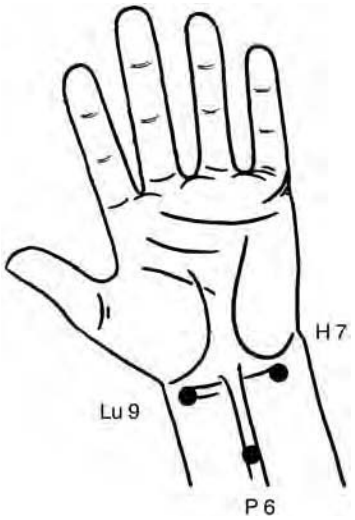

FIGURE 54.8 Three upper limb parasympathetic points Lu 9, P 6, and H 7, used to deregulate the autonomic nervous system (ANS), permitting continued therapy on supersensitive patients.

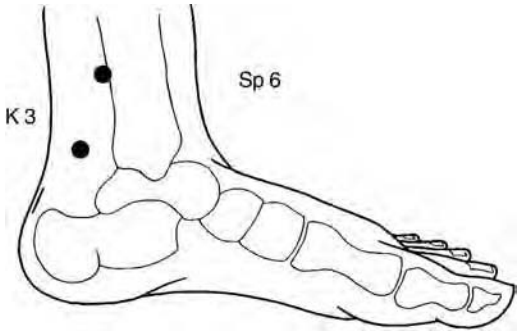

FIGURE 54.9 Sp 6 and K 3 are lower limb parasympathetic points for deregulation of lower viscera, again, permitting continued therapy on sensitive patients.

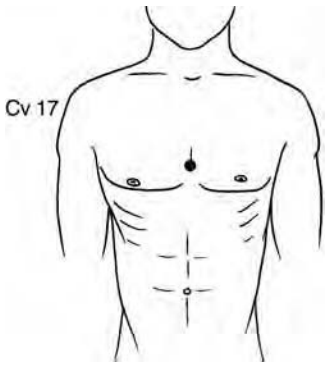

FIGURE 54.10 Acupuncture point for body calming. Also called "sea of tranquility". CV 17 should ONLY be treated on severe pain patients, and only AFTER all the above points have been treated.

- K 3. A low back pain, congenital energy, and parasympathetic point. Located in the hollow midway between the medial malleolus and the Achilles tendon. Used for morning back pain, circuited with B 25 (L 4–L 5 interspace).
- Cv 17 (Figure 54.10). A respiratory and parasympathetic point. Located on the midline of the sternum, horizontal with the fourth intercostal space.

The Relationship between Dermatomes and Chronic Pain

The application of ETPS therapy requires an inspection of dermatomes for their interrelationship with segmental levels. This important inspection will provide evidence in determining if radiculopathy is contributing to a pain condition. Distal injuries are correlated first with their dermatomes and second proximally to the segmental levels that innervate the dermatomes. ETPS stimulation to paraspinal points that influence the dermatomes and nerve pathways will relax contracted muscles, allowing for increased motor impulses throughout pathways, improved nerve regeneration, and reduced pain levels (Figure 54.11).

There are three ways to integrate the nerve root with pathways and dermatomes: segmental nerve root and paraspinal stimulation, nerve pathway treatment, and integrative circuits and nerve ending treatment using distal dermatome and acupuncture points.

Paraspinal Point Location

Radiculopathy and nerve impingements often occur paraspinally at the segmental nerve root and innervate the injury or pain area. Locating and treating paraspinal points corresponding to radiculopathic segmental levels is an important step in the application of ETPS protocols.

These paraspinal points are located approximately 1 in. bilateral to the midline on the medial border of the erector spinal muscles ridge. When stimulated, they provide a relaxing effect on the deep paraspinal muscles of semispinalis, longissimus, and iliocostalis, all of which influence the entire spinal column and the extremities through the dermatomes. One of the most successful applications of this ETPS paraspinal therapy is at the L 4–S 2 segmental levels, which innervate the lower limbs and feet. Paraspinal stimulation of L 4–S 2 segmental levels can provide significant pain relief to the vast majority of patients suffering from lower extremity pain such as plantar fasciitis, peripheral neuropathy, metatarsalgia, and heel spurs.

The integration of paraspinal segmental points into the clinical pain setting is an effective therapy. Pain must travel through the pathways and all pathways are connected to the spinal cord. Spinal Back Shu points are selected according to neuropathic manifestations

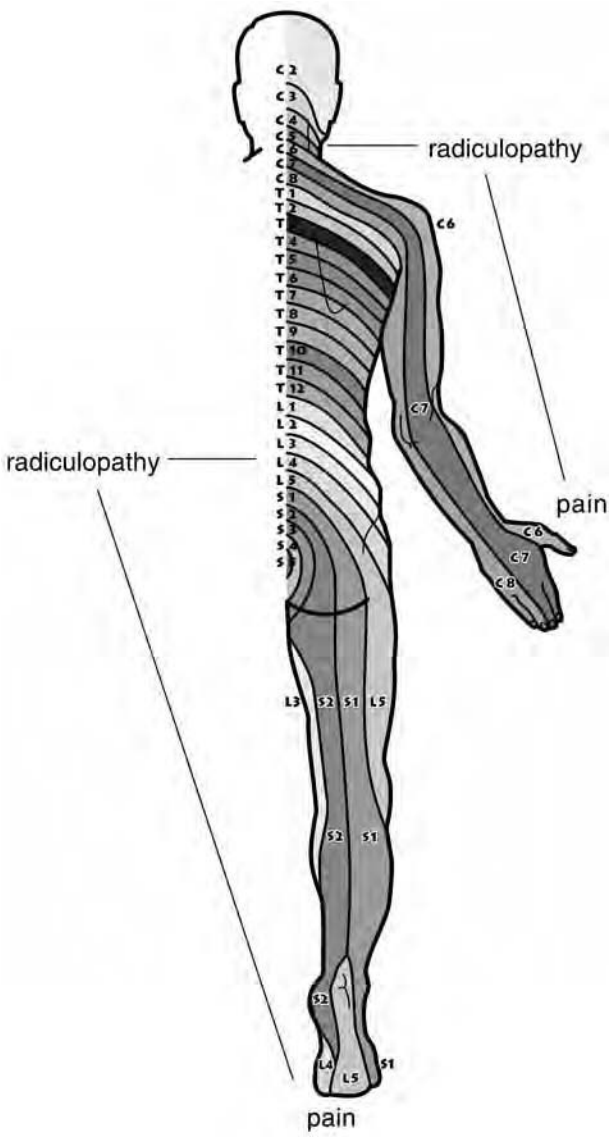

FIGURE 54.11 Illustrates nerve root impingement called radiculopathy, influences distal pain throughout the extremities.

observed at the segmental levels that innervate the injury or pain syndrome. Different manifestations will affect different segmental levels. Brief stimulation of these spinal points with ETPS therapy provides an easily integrated, diagnostic, and effective approach to chronic pain management.

Integrative Neural Circuits

Circuits have been used in acupuncture therapy for centuries. A circuit consists of a series of stimulated points integrated into a single treatment to produce enhanced therapeutic benefits. In ETPS therapy, selected acupuncture, trigger, and motor points are circuited for their ability to isolate nerve pathways and relax specific muscles and groups of muscles. Segmental level L 2–L 3 has, for instance, a strong analgesic relationship with the lumbar region. In traditional acupuncture, this segmental level relates to the kidneys, widely regarded as powerful organs in pain therapy, which indirectly influence the spinal column. Paraspinal points at segmental level L 2–L 3 (B 23 in acupuncture) are circuited with B 40 (a distal acupuncture point for the lower back) to produce a powerful analgesic response for lower back pain.

Another circuit combines segmental levels L 4–L 5 (B 25 in acupuncture) with the important low back pain point B 60 (lateral malleolus). B 60 strongly influences the L 5 dermatome, and produces a strong analgesic response in sciatic patients when circuited with the L 4–L 5 nerve roots. This circuit is ideal for patients whose pain gets progressively worse throughout the day.

The circuit L 4–L 5 (B 25) and K 3 (medial malleolus, opposite B 60) provides another opportunity to individualize pain treatment to meet patient needs. This circuit is ideal when sciatic/low back patients display morning pain and stiffness that may or may not improve throughout the day. Recognizing that patients with morning back pain and stiffness often display weak kidneys, circuiting B 25 and K 3 treats the kidneys by helping to relieve stiffness and stimulate nerve roots, thereby addressing radiculopathic and energetic contributions to injury. (See Figure 54.12.)

In ETPS therapy, there are numerous circuits that produce outstanding responses. A therapist who possesses a working knowledge of dermatomal patterns and extremity acupuncture points may use this understanding to create integrative circuits. Circuits are created between the dermatomal nerve root (spinal points) and any major trigger/acupuncture points located distal to the injury. These circuits permit therapists to release individual or groups of muscles in one application, ultimately saving manual therapists time and effort.

Integrating Dermatome Points

The final approach to integrating segmental/dermal therapy is the treatment of dermatome points located on the lateral and medial side of the nail base at the tips of the fingers and toes. All dermatomes and meridians connect the extremities with the midline. Therefore, if stimulation is applied at the nerve root to alleviate distal pain, stimulation may also be applied to the extremities to alleviate proximal pain. Stimulation is applied to dermal points on the fingers and toes relating to pain along dermatomes and meridians. In our experience dermatome point stimulation has been found to be a successful treatment for a significant percentage of patients who are unresponsive to nerve root and pathway treatments and an integrative adjunct to improve outcomes. (See Figure 54.13.)

Successful applications of this circuit are often applied on the feet. Segmental levels L 4–S 2 innervate the feet

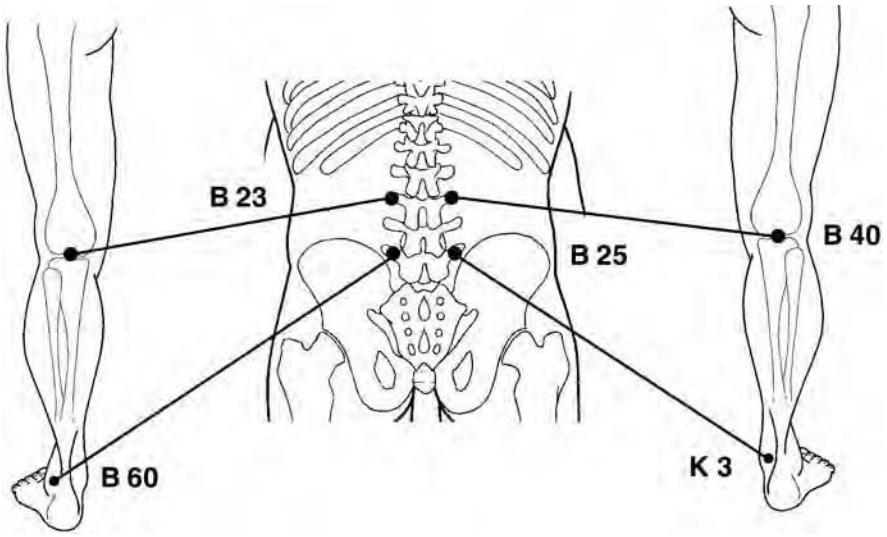

FIGURE 54.12 Illustrates neural circuits performed in ETPS therapy. Circuits B 23–B 40 are treated bilaterally to reduce upper leg pain and calm nerve pathways resulting from radiculopathy. Circuits B 25–K 3 are integrated bilaterally for back patients with pain aggravation in the morning. Circuits B 25–B 60 are integrated bilaterally for back patients with pain aggravation in the afternoon or evening.

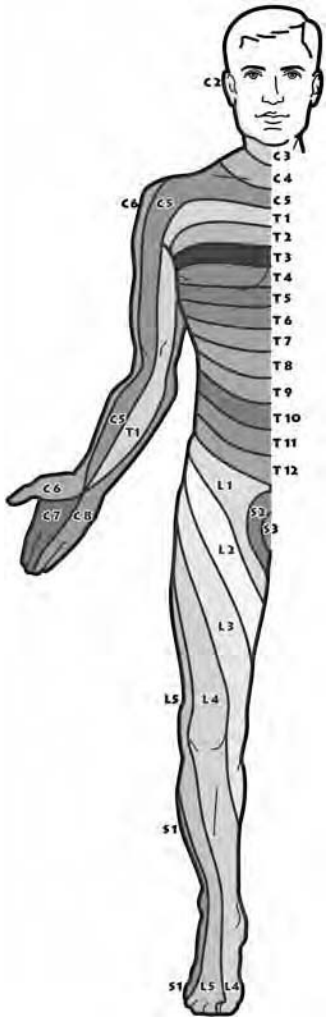

FIGURE 54.13 Illustration of the segmental dermatomes.

with the fourth and fifth toes representing the L 5 and S 1 dermatomes. These two points may be stimulated with ETPS individually to produce an effective analgesic response in the lower back. More importantly, these dermal points also represent the end of the two acupuncture meridians, the gallbladder and the bladder, both of which have a strong influence over hip and back pain. Gb 44 is located on the fourth toe and B 67 is located on the fifth "baby" toe. Proximally following the meridians, the gallbladder meridian influences the lateral leg and hip region, while the bladder meridian influences the spine. Therefore, these two points may be used to diagnostically determine root causes of low back or hip pain. If Gb 44 is more sensitive than B 67, the piriformis–iliotibial fascial muscles (and, therefore, the gait) are more likely to be responsible for a patient's back pain. If B 67 is more sensitive, local spinal pathology, such as a bulging disc, is most likely responsible. Through years of ETPS experience, the sensitivity of these two points has proven to be an accurate diagnostic indicator of pain, mechanical imbalances, or neuropathy along the meridian or the muscles that intersect the meridian. (See Figure 54.14.)

Myofascial Release with Dermatome Therapy Points

The cross integration of dermatomal points with acupuncture meridians displays the flexibility of ETPS therapy. Dermatome points correspond strongly with jing well points, acupuncture points used to treat acute diseases in related organs. Dermatome point stimulation also is an effective treatment for myofascial release of muscles relating to, or intersecting with, correlating meridians. The integration of dermatomal and jing well points has proven successful in the treatment of hard to reach muscles, such as the psoas, and difficult injuries, such as adductor groin. Far from experimental, this technique has been applied for decades in many therapies, including Electro Acupuncture According to Voll (EAV) therapy, with much reported

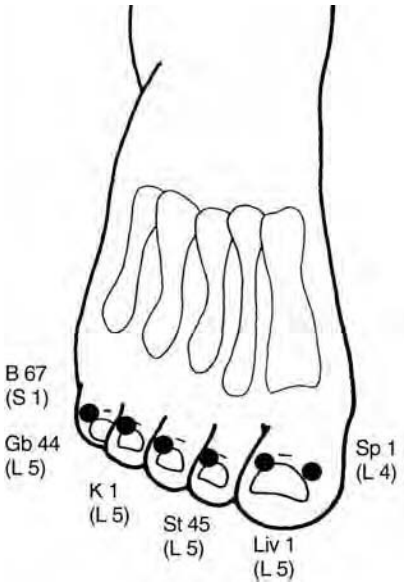

FIGURE 54.14 Distal acupuncture points that correspond to the segmental dermatomes. Located at the base of the nail, on the illustrated side.

success. The example described below, focusing on the stomach meridian and the psoas muscle, demonstrates an effective application of this approach.

There is a strong myofascial/therapeutic relationship between the psoas muscle, the stomach meridian and the corresponding jing well point. If the stomach meridian is followed proximally from the distal end at St 45 (located on the lateral base of the second toenail), the meridian travels through the quadriceps and intersects the psoas muscle (Figures 54.15 and 54.16). Stimulation of St 45 provides effective myofascial release of the corresponding ipsilateral psoas muscle. Widespread success of this technique has been witnessed at ETPS workshops and reported through clinical feedback, with approximately 80% myofascial release occurring within minutes of treatment. This unique ETPS response can save manual therapists a significant number of hours of therapeutic work in addition to rescuing patients from the agony of deep manual therapy.

Another therapeutic pearl is the stimulation of Sp1 (L 4 dermatome point located at the medial nail base of the first toe) for groin pain. Traditionally used for acute menstrual cramping, this technique has proven successful in relieving pain associated with difficult to treat adductor groin injuries in ETPS therapy. In many cases, successful results have been achieved within minutes of treatment.

The integration of dermatome points provides one of the simplest approaches to the treatment of pain. With a working knowledge of dermatomal patterns and acupuncture meridians, a therapist can quickly treat any proximal segment or muscle with the related dermal points.

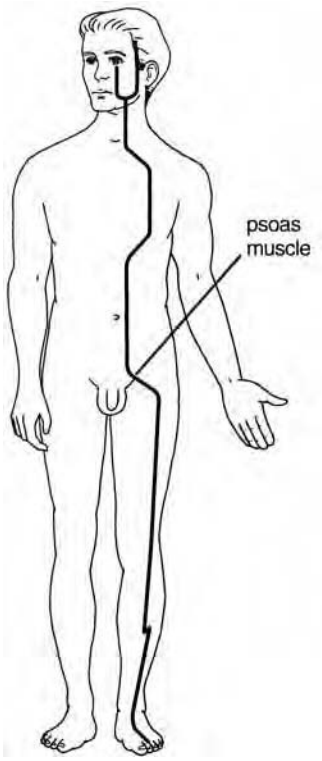

FIGURE 54.15 Illustrates the stomach meridian and the anatomical location of the psoas muscle.

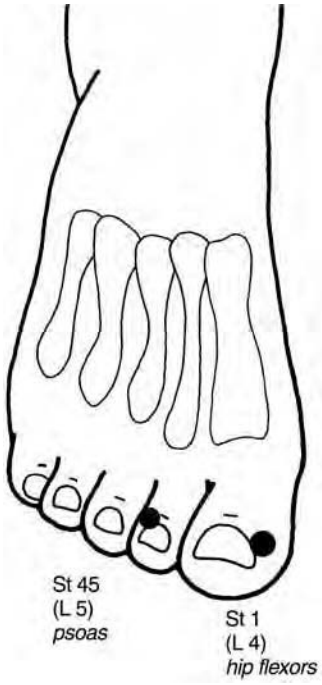

FIGURE 54.16 Illustrates the integration of acupuncture "jing well" points with meridians for myofascial release of psoas and hip flexor muscles.

The Relationship between the Gait and Chronic Pain

For many years, different fields of science and meridian research have studied the mechanics of the human body in order to identify potential relationships with chronic pain. Based on our experience with ETPS therapy, there appears to be a causal relationship between the gait and several chronic pain syndromes. In more precise terms, body asymmetry produces an irregular gait that stresses the ANS, which in turn causes pain (Figure 54.17).

"Gait" refers to the postural positioning of the iliac crest and its subsequent relationship to the spine and lower limbs. A positive right gait will, for instance, produce a shortened right leg and a length discrepancy between the two legs. Leg length discrepancy (LLD) leads to asymmetrical movement with a disproportional amount of body weight shifted to the longer and often weaker leg (Figures 54.18 and 54.19).

Positive gait irregularities also stress the spine to produce misalignment of the segments, asymmetrical movement, and paraspinal degenerative changes. These mechanical imbalances precipitate muscular contractions and radiculopathy (Friberg, 1983; Yochum & Barry, 1994). Radiculopathy leads to denervation supersensitivity of the nerves and an upregulation of the sympathetic nervous system. Thus, radiculopathy not only contributes to and perpetuates chronic pain, but also can serve as the major precipitator of chronic pain syndromes in many cases.

After studying hip positioning and mechanical relationships to the gait, there appears to be a neuropathic and, therefore, myofascial component to asymmetrical positioning. If contracted, the piriformis muscle, and its specific attachments, may be responsible for gait misalignments. Viewed through the ETPS framework of analysis, the trochanter will be pulled upward (superiorly) in the acetabulum if the piriformis contracts, thereby producing a positive, or higher, hip on one side. This imbalance in turn pulls up the femur to create a LLD. Therefore, the first step in treating gait imbalances should be a manual correction of the gait and LLD after a visual inspection has been completed.

Current therapeutic solutions to LLD include lifts and orthotics. The problem with these solutions is that they do not specifically address the root causes of LLD. The dominant one-sided nature of the human body, combined with the prevalence of repetitive-action lifestyles, places stress on the piriformis muscle resulting in contraction. If true, leg length corrections that do not address the gait may actually contribute to poor body mechanics and a continued stressing of the ANS.

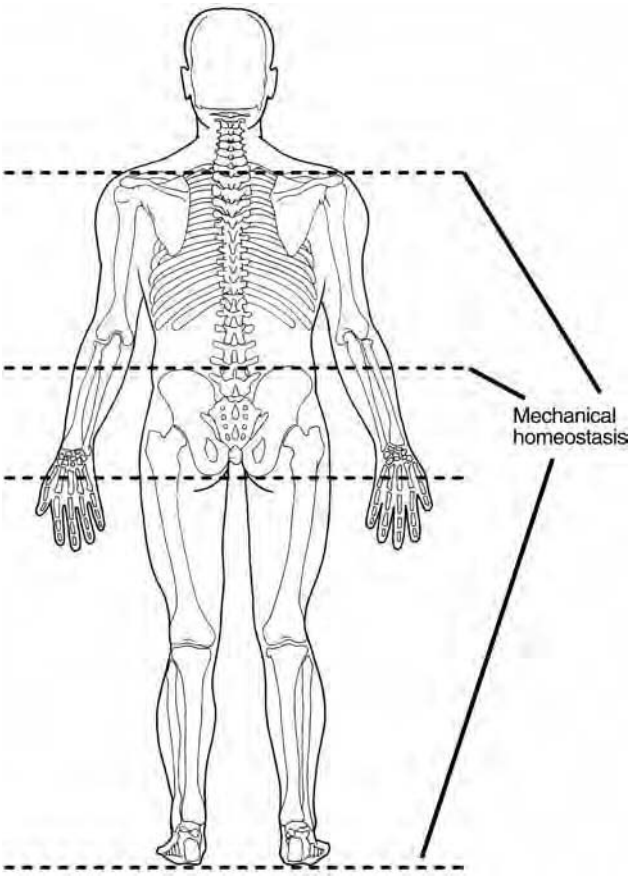

FIGURE 54.17 Mechanical homeostasis, as seen by level hip, shoulders, and trochanters.

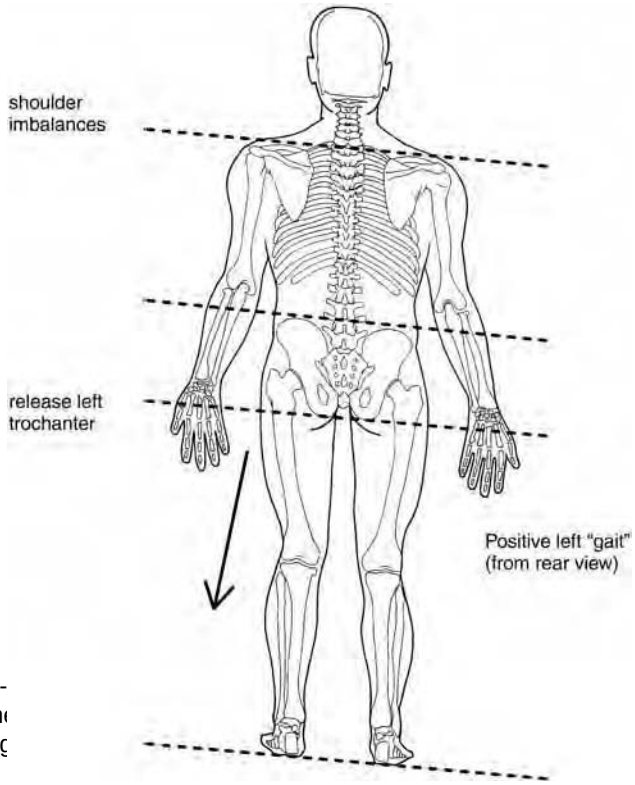

FIGURE 54.18 Illustrates superior movement of left trochanter in the actetablum. This is often due to contraction of the piriformis muscle, which precipitates mechanical imbalances of the shoulders and hips, and leg length discrepancy of the left leg. Called a positive "left" gait.

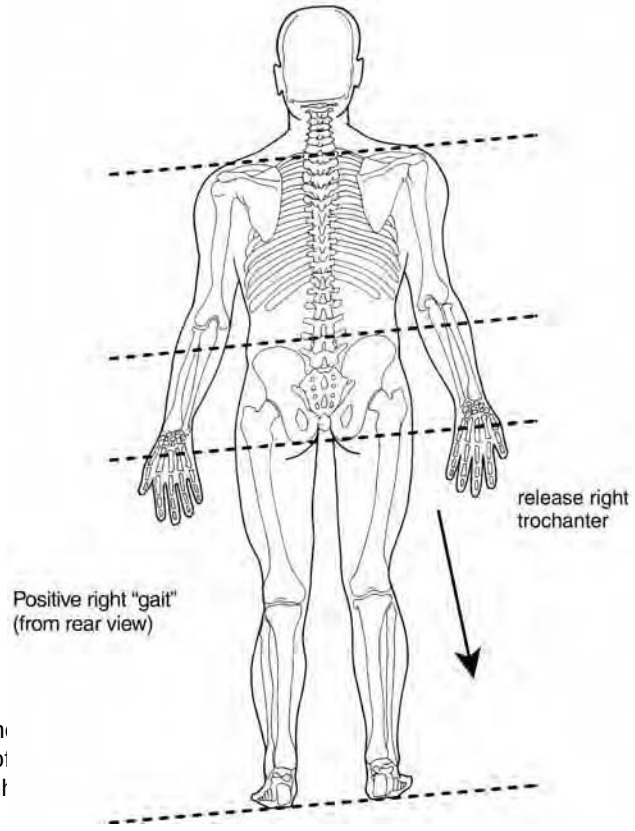

FIGURE 54.19 Illustrates superior movement of right trochanter in the acetablum. This is often due to contraction of the piriformis muscle, which precipitates mechanical imbalances of the shoulders and hips, and leg length discrepancy of the right leg. Called a positive "right" gait.

Manual Piriformis Stretch

In ETPS therapy, a specific manual therapy called a piriformis stretch is performed in order to properly reposition the trochanter in the acetabulum; in other words, realign the hip and pelvis. Stretching the piriformis until the trochanter and acetabulum restore proper gait balance will produce symmetrical leg lengths and mechanical homeostasis throughout the body. With the patient in the prone position, approach from the right (R) side, place your R hand on the superior angle of the trochanter at a 45% angle. Lift the leg 6 in. above the knee with the left (L) hand and abduct the leg to a 30% angle or until trochanter becomes prominent on the R hand.

In one motion, rotate your R hand medially and use the L hand to gently lift the R leg on midline (beside the L leg). If properly executed, this piriformis stretch places the trochanter in the proper anatomical location creating hip, spine, and mechanical symmetry throughout the body. In some cases, the shortened leg is so badly displaced in the trochanter that this realignment technique will make the shorter leg longer than the other one. For this reason, the piriformis stretch should always be performed bilaterally to ensure symmetry of the hip and pelvis. The importance of symmetry throughout the hip and pelvis region in general, and the piriformis stretch in particular, cannot be understated in the fight against chronic pain.

Myofascial Release of Piriformis Using Circuits

After achieving mechanical repositioning, a myofascial release on the piriformis must be completed to prevent the leg from recontracting and producing the same positive gait and LLD. Without this release, a repetitive lifestyle would constantly pressure the piriformis to recontract, thereby misaligning the gait and creating the conditions for the cycle to reappear.

Two circuits will release the piriformis, hip, and lateral thigh muscles (Figure 54.20). The first is the piriformis–IT circuit. To start, palpate cross-fiber at the superior angle of the piriformis muscle. Thick motor bands are often easily palpated where piriformis glute min/medius meet. Apply one circuit to the most tender trigger point found within the motor bands; the other circuit should be applied to the trigger point of the iliotibial band (found at the end of main rae with hands at the side (Gb 31 in acupuncture). Simultaneous stimulation of these two points often provides a strong myofascial response between the hip and lateral thigh muscles, creating immediate pain relief. It also allows the piriformis muscle to relax and facilitates proper positioning of the trochanter in the acetabulum.

Piriformis–Gb 34 is the second circuit. For this treatment, keep one modality on the same tender piriformis trigger point as above. The other modality is placed on Gb 34, the acupuncture point responsible for relaxing muscle tissue (inferior and posterior to the head of the fibula). This circuit performs an overall myofascial release and often relaxes muscular tissue not released in the first circuit.

To perform a myofascial release, two circuits must be created. The first is a circuit between the superior angle of the piriformis trigger point and the middle of the IT band (acupuncture point Gb 31). The second circuit is performed between the superior angle of the piriformis trigger point and the myofascial acupuncture point Gb 34 (inferior/posterior to head of fibula). These two circuits, performed bilaterally, are effective in maintaining a myofascial release of the piriformis and related gluteal and hip muscles responsible for gait misalignment.

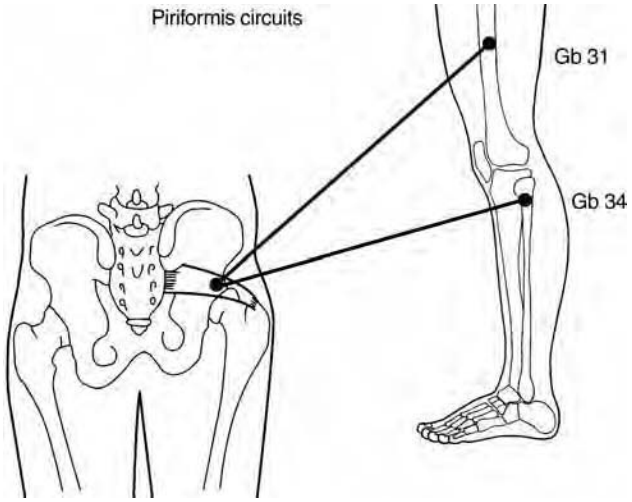

FIGURE 54.20 Piriformis circuits are performed to produce myofascial release of hip and leg muscles responsible for gait imbalances. They are applied bilaterally after mechanical realignment for optimal, lasting results.

The integration of a piriformis stretch/release is an important part of ETPS protocols. Its introduction can significantly improve soft tissue and mechanically based therapeutic outcomes of any pain program. Once learned, the stretch can be applied in seconds and should be integrated into any pain management protocol.

The Relationship between Scar Therapy and Chronic Pain

Occasionally, patients may continue to suffer from pain after receiving treatment based on the above-mentioned therapeutic steps addressing the mechanical and myofascial components of chronic pain. Therefore, other sources of pain, such as neural therapy, have been included in ETPS protocols to treat scars throughout the dermatomes and meridians.

Neural therapy, the stimulation of scars for pain reduction and homeostasis, has been an accepted and proven form of neuromyofascial pain therapy for years. Neural therapy theory suggests that scarring restricts the flow of energy, disrupts the lymphatic and circulatory systems, and interferes with muscle energy and mechanical stability of the body. All of these systems are affected adversely when a scar influences the dermatome or meridian to which it is connected.

For unresponsive pain conditions, inspection for distal scarring along the dermatomes or distal/proximal scarring along the meridian can be helpful in determining where to treat the pain condition next. If a scar is located in the corresponding dermatome or meridian, ETPS stimulation along the scar perimeter can provide immense relief to suffering patients. This approach is especially effective if there is extremity joint scarring, especially around the ankle and knees.

Based on current medical knowledge, it is not clear why scar stimulation is an effective form of treatment for some patients. One leading theory suggests that neural therapy "breaks up" the collagenic tissue surrounding the scar. Intermittent stimulation of the scar perimeter, sometimes called "surrounding the dragon," is thought to break up scars, thereby permitting an increase in the functioning and homeostasis of the lymphatic, energetic, neural, and circulatory systems. Irrespective of the pathology, scar treatment has been found to reduce local pain. The stimulation of scars relative to the injury via dermatomes and meridians has produced impressive therapeutic responses with some hard-to-treat chronic local pain as well as discomfort along the dermatome and meridians

Application of ETPS Stimulation

Traditional stimulation of trigger motor and acupuncture points includes invasive techniques such as acupuncture and hypodermic needles and noninvasive modalities such as TENS and microcurrent stimulation. Both TENS and microcurrent stimulation may be applied with traditional pads or via point stimulation. Truly integrative therapies, such as ETPS, employ potent, versatile, and patient-friendly stimulation. Based on these criteria, an initial treatment utilizing invasive needles is relatively less productive because it damages tissue and requires a recovery and/or an incubation period of 20 to 30 minutes to determine therapeutic efficacy. In contrast, ETPS therapy often can generate positive results in a matter of minutes.

ETPS therapy is best applied with noninvasive direct current (DC) stimulation. Alternating current (AC) is ineffective because it does not produce the square wave necessary for the stimulation of an endorphin response (Christopher, et al., 1992; Lehman, et al., 1986; Pomeranz et al., 1988; Pomeranz & Niziak, 1987). Furthermore, AC cannot by definition produce a monophasic pulse, a form of stimulation that can be reversed in order to produce the highly sought after vasodilative and vasoconstrictive responses (Bronzino, 1998). DC also is favored for its ability to repolarize contracted muscle tissue, a necessary physiological response for the release of myofascial tension. Finally, DC stimulation is preferred because it produces few, if any, adverse side effects. With no significant iatrogenic responses, noninvasive and concentrated DC stimulation can be used to treat multiple systems at one sitting, thereby creating an opportunity to outperform traditional needle therapies that concentrate on one system in each treatment. The result is greater therapeutic versatility and productivity.

ETPS applies DC microstimulation in stages to determine the root cause of chronic pain syndromes. Concentrated DC microstimulation, applied by a point stimulator, is the only modality that can produce therapeutic responses quickly enough to eliminate or include therapeutic systems in future treatment protocols. Traditional TENS, applied by pads, is far too inefficient a stimulation to produce beneficial therapeutic response in a short period of time (Cheng & Pomeranz, 1986; Gadsby & Flowerdew, 2000). Therefore, pad stimulation is not the desirable modality for ETPS therapy.

PART B: ETPS INTEGRATIVE PROTOCOLS

ETPS integrative protocols combine the therapeutic efficacy of acupuncture, intramuscular therapy, and neural therapies. As a rule, a mechanical neuropathic assessment is performed and stimulation is applied in stages in order to isolate fascial, neural, or meridian systems and to determine and treat the root cause(s) of neuromyofascial pain. The application of these different integrative therapies, methodically and in stages, to isolate different therapeutic systems provides a window of opportunity for healthcare practitioners (HCP) to diagnose soft tissue pain.

The first step in the treatment of any chronic pain condition is to assess and apply the ETPS Standard Protocol. The ETPS Standard Protocol is designed to address body mechanics, radiculopathy, and spine therapy as well as fascial contractions responsible for positive gait and body misalignment. ETPS therapy initially assumes that chronic pain syndromes have a precipitory influence from the hip misalignment and lower back radiculopathy. Therefore, the Standard Protocol will identify or eliminate the nerve root, gait, and body mechanics as major contributors to the chronic pain condition.

Depending on the results of the initial assessment, one or more specific sets of protocols may be performed. The Standard Protocol is described below as well as protocols for back pain, neck pain, fibromyalgia, and plantar fasciitis.

Standard Protocol

1. Assess patient for gait and radiculopathic irregularities.
   The first step in standard protocol is to assess the patient in order to determine the degree of discomfort, range of motion or injury, degree of disability, and level of pain. Identify gait imbalances through iliac crest levels and leg length discrepancies. Select vertebral segments that display radiculopathic manifestations of trophedema and sudomotor responses.
2. Manually release gait and stretch piriformis.
   Manually release the gait using the piriformis stretch (as described in Part A). Start with the side with the positive (or higher) gait and the shorter leg. Perform stretch bilaterally.
3. Treat radiculopathy at levels identified in Step 1 with a paraspinal release using Back Shu points.
   These points are located at each segmental level at the spinous process interspace (SPI), approximately 1 in. bilateral at the medial border of the erector spinal muscle ridge (two fingers bilateral from midline).
   The simultaneous application of two ETPS modalities to these bilateral spinal points provides an exceptional myofascial release of the paraspinal muscles that precipitate radiculopathy and nerve impingement. If ETPS therapy is applied to a series of spinal points correlating to an area of radiculopathy that innervates distal pain or injuries, the entire pain condition may be treated (Figure 54.21).
4. Release piriformis with fascial circuit Piriformis–IT band, Piriformis–Gb 34.
   Release fascia responsible for gait misalignment by performing a fascial circuit between any tender motor bands palpated throughout the piriformis muscle, the IT band point (Gb 31), and the myofascial point Gb 34 (Figure 54.22). Ask the patient to sit up slowly and then slide off the table, placing both feet on the ground at the same time (to prolong treatment outcome).
   The Standard Protocol effectively treats lower back radiculopathy and fascial components of gait and overall mechanical imbalances. Many pain conditions throughout the body may be effectively treated with the Standard Protocol, suggesting that radiculopathy and gait imbalances are major contributors to the chronic pain cycle.

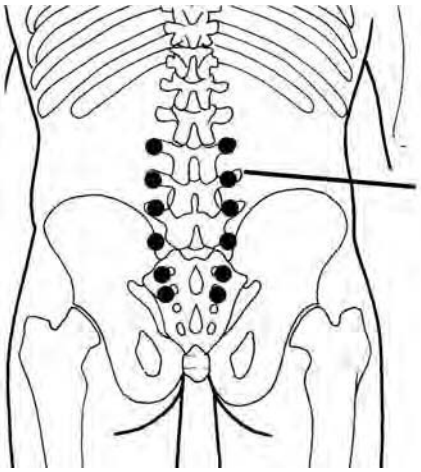

FIGURE 54.21 Illustrates paraspinal points treated in areas of trophedema (nerve root impingement), identified during skin rolling test (see Figure 54.6).

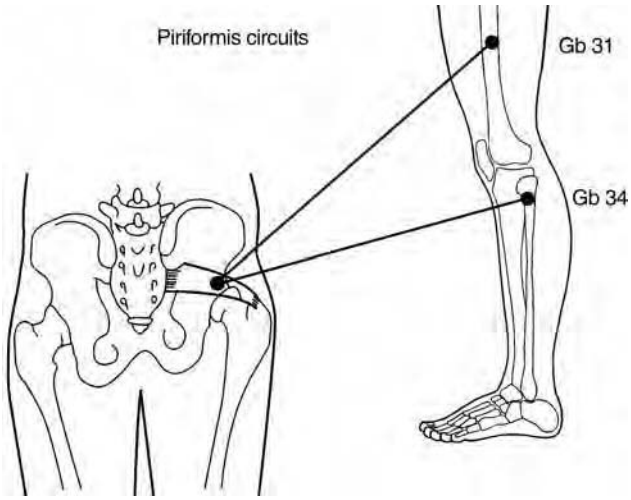

FIGURE 54.22 Piriformis circuits are performed to produce myofascial release of hip and leg muscles responsible for gait imbalances. Applied bilaterally after mechanical realignment for optimal, lasting results.

Other Integrative Protocols

ETPS integrative protocols go beyond standard procedures with the inclusion of segmental levels, fascial planes, and acupuncture-trigger points that work well for individual pain conditions. Additional circuits, fascial groups, and modalities are included on a step-by-step basis with an assessment performed at the end of each step or stage.

ETPS protocols are designed to integrate different philosophies and apply treatments in stages to determine the root cause of pain. Once the root causes have been determined, continued treatment may be applied to areas known to produce therapeutic responses. If applied properly, ETPS therapy can diagnosis the root cause of pain with a significant degree of accuracy, thus assisting all HCP in the treatment of chronic soft tissue pain.

In ETPS therapy, the patient is assessed before and after each therapeutic stage to determine the degree of success. With several therapeutic stages in back pain, it is possible to determine which segmental levels, muscle dermatomes, and meridians are responsible for the patient's pain in approximately 10 to 15 minutes. Generally, one or more stages will produce pain relief for the majority of patients, thus indicating which dermatomes, segments, muscles, and meridians should be investigated further as the source of chronic pain. Stages that produce minimal or negative responses (i.e., the patient and pain are noticeably worse after treatment) should be eliminated in future treatment episodes. Using this therapeutic process of elimination, therapists can investigate and treat patients at the same time, ultimately producing faster and more effective outcomes. After assessing the exact points and therapeutic systems using the ETPS elimination process, concentrate only on those stages that produce positive therapeutic benefits.

Presented below are four additional protocols for the diagnosis and treatment of back pain, neck pain, fibromyalgia and plantar fasciitis.

Back Pain Protocol

Step 1 Apply Standard Protocol.

Assess patient after each of the following stages.

- Check gait–piriformis.
- Inspect for signs of neuropathy and radiculopathy, especially between L 2–S 2.
- Manually release gait.
- Perform paraspinal release at segments with trophedema (–ve).
- Circuit piriformis–IT Band (–ve) and piriformis–Gb 34.

Step 2 Stimulate circuits designed to treat the nerve pathway or meridian involved with injury.

Perform these circuits bilaterally with patient lying in the prone position. Ask patient to sit up and dismount with both feet landing on the floor at the same time. (See Figure 54.23.)

- Circuit L 2–L 3. Interspace with B 40 (low back pain distal point) and treat with negative (vasoconstrictive) polarity.
- Circuit L 4–L 5. Interspace with B 60 (anatomic and acupuncture trigger point) for patients whose pain becomes more severe throughout the day.
- Circuit L 4–L 5 with K 3 (kidney source point) for patients with back pain and stiffness that is most severe in the morning.

Step 3 Stimulate sacral triangle and dermatomal points for lateral hip release and spinal pain.

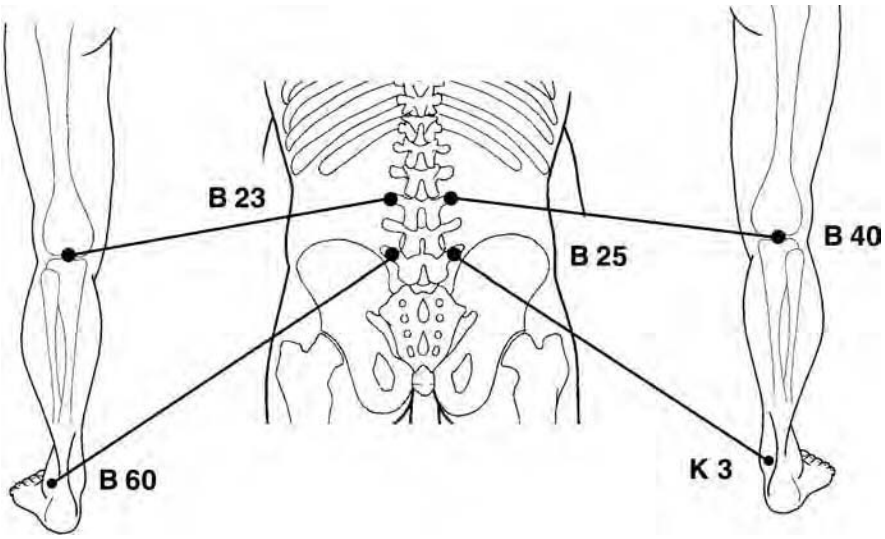

FIGURE 54.23 Neural circuits performed between paraspinal nerve root points and key distal acupuncture points to reduce upper leg pain and calm nerve pathways resulting from radiculopathy. Circuits B 23–B 40 are treated bilaterally. Circuits B 25–K 3 are integrated bilaterally for back patients with pain aggravation in the morning. Circuits B 25–B 60 are integrated bilaterally for back patients with pain aggravation in the afternoon and evening. Apply vasoconstrictive ETPS therapy.

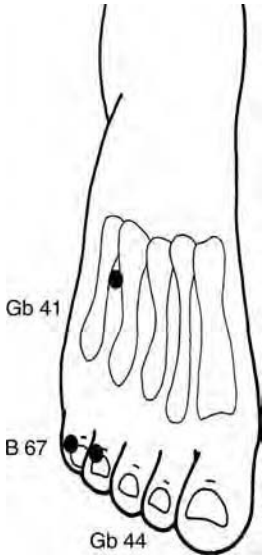

FIGURE 54.24 Distal acupuncture points B 67 and Gb 44 are combined with GB 41 to produce "sacral triangle." These points are treated to reduce proximal nerve root pain and for myofascial release of hips in stage three (3) of back pain protocol. Apply vasoconstrictive ETPS Therapy.

If success is limited in the first two steps, Step 3 can often provide immense relief to patients. Stimulation need only be applied for 20 to 30 seconds on the proper dermatome point in order to provide relief. Based on our experience using ETPS therapy, a significant number of patients with back pain will respond only to Step 3. Treat the distal dermatome points involved with painful or radiculopathic vertebral segments, and the posterior/lateral muscles believed to be involved with mechanical gait imbalances.

- Sacral triangle includes B 67, Gb 44, and Gb 41. B 67 (located at the base of fifth toenail on the lateral side) and Gb 44 (located at the base of the fourth toenail lateral side) correlate to S 1 and L 5 dermatomes and nerve roots. Gb 41 is located at proximal end of the fourth and fifth tendons (Figure 54.24).

The application of ETPS dermatome points can produce useful information.

i. Are stimulated nerve endings most effi-cacious in the treatment of proximal pain?
ii. Are the hip and gluteal muscles responsible for back pain? If true, Gb 41 and Gb 44 will be sensitive.
iii. Is spinal injury or disc bulge responsible for back pain B 67? If true, the spine will be tender.

Step 4 Dermatomal points for anterior hip flexors.

Located at the lateral side of the base of the second toenail, St 45 isolates the treatment release of the psoas and hip flexor muscles (Figure 54.25). With some pain patients, the psoas muscle may be contracted alone or with the piriformis muscle. If pain continues to persist after Steps 1 to 3, a quick stimulation of St45 (second toe base nail lateral side) will reveal if the psoas muscle is contributing to the pain condition. Patients

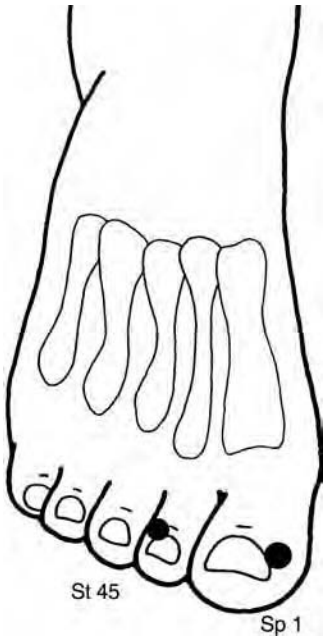

FIGURE 54.25 Illustrates the acupuncture jing well points Sp 1 and St 45 used ipsilaterally for the myofascial release of the psoas and hip flexor muscles. Apply vasoconstrictive ETPS therapy.

FIGURE 54.26 Tender points are treated at the end of ETPS protocols for additional pain relief. They are identified by the patient and treated in short intense bursts with ETPS stimulation. Apply vasoconstrictive ETPS therapy.

should be assessed between treatments of both the R and L points to determine which psoas muscle is most involved in the injury. This step is integrated to include both posterior and anterior hip stabilizing muscles in order to determine if they individually or collectively contribute to the patient's chronic pain state.

Step 5 Neural therapy.

Application of ETPS stimulation to scars that intersect with, or are located in, the dermatomes or on meridians that relate to pain is an effective approach to more complex pain conditions. Inspect for scarring, either surgical or injury related, distal in the dermatomes to the injury and distal proximal to the injury/pain along the meridian. For back pain, inspect for scars along the lateral anterior knees and paraspinal back. If scars exist, stimulate briefly (10 to 15 seconds) at 1/8-inch intervals surrounding the scar. This process has produced effective responses with many patients.

Step 6 Tender points.

Tender trigger points are treated as a last step in the therapy because ETPS assumes that all pain is referred from another anatomical area of the body. Therefore, the treatment of local pathology is secondary to root sources of pain (i.e., body mechanics and radiculopathy). However, local pathology can exist and the tender trigger point(s) may be identified by the patient and treated by the therapist after Steps 1 through 5. After identification, apply brief ETPS stimulation of 15 to 20 seconds per point. This technique has proven successful in alleviating the majority of any pain that remains. (See Figure 54.26.)

Neck Pain Protocol

Step 1 Apply Standard Protocol.

Pay special attention to radiculopathy at the L 2–L 3 interspace levels, as they have a strong influence on neck pain.

Assess patient after each of the following stages.

- Check gait–piriformis.
- Look for signs of neuropathy and radiculopathy, especially at the L 2–L 3 level.
- Manually release gait.
- Perform paraspinal release at segments with trophedema (-ve)
- Circuit pirformis–IT Band (–ve) and piriformis–Gb 34.

Step 2 Posterior neck and trapezius release.

- Paraspinally release cervical neck at level of crease identified in Step 1. This step is designed to diagnose and treat the posterior muscles of the neck involved with injury.

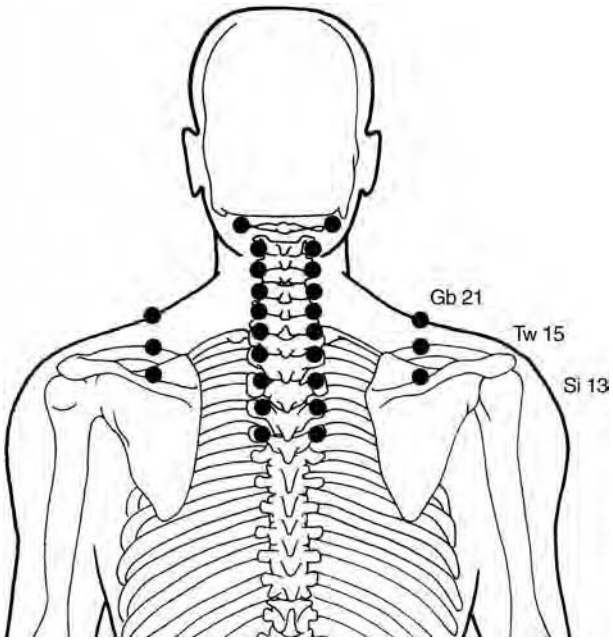

FIGURE 54.27 Illustrates the posterior paraspinal neck points and the trapezius myofascial release points. A positive therapeutic response indicates involvement of these segments and muscles with the injury. Apply vasoconstrictive ETPS therapy.

- Stimulate Gb 21, Tw 15, and Si 13, designed to release the trapezius, rhomboid, and supraspinatis muscles (Figure 54.27).

Step 3 Lateral neck release.

- Laterally release neck, palpating for motor bands. Stimulate the motor bands at the level of the horizontal neck creases. All contributors to neck and limb disorders, stimulation of these areas is designed to release the scalenes, levator scapula, and splenius capitus muscles (Figure 54.28).

Step 4 Distal point for the neck.

- Si 3: Posterior muscles of the neck. Located at the medial end of the distal transverse palm crease. Note: locate and treat this point with the fist clenched (Figure 54.29). This is the first point to treat when there is a wry neck or torticollis. Treat bilaterally.

Step 5 Dermal points for the neck.

Treat these points first if patient's neck is hypersensitive (i.e., postaccident/whiplash or postoperative). If not hypersensitive, follow protocol order.

- Li 1: Designed to release SCM ipsilaterally. Located at the radial side of the base of the index fingernail (Figure 54.30).
- Si 1: Designed to release ipsilateral scalenes. Located at the lateral side of the base of the little fingernail (fifth metacarpal).

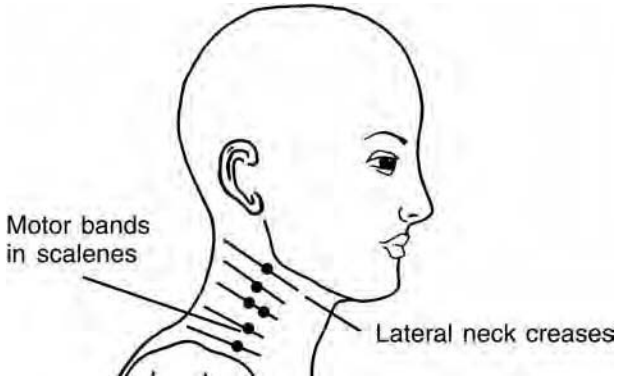

FIGURE 54.28 Illustrates lateral neck muscles and suggested location of myofascial release points throughout tight motor bands points. Release these with ETPS stimulation for highly effective relief of upper extremity pain. DO NOT apply microcurrent stimulation anterior to the corner of the jaw (over the carotid sinus). Apply vasoconstrictive ETPS therapy.

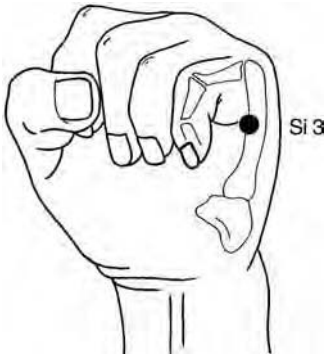

FIGURE 54.29 Confluent acupuncture point Si3 displays influence over the posterior neck and spine. Often highly sensitive on patients with posterior disc problems. Treat bilaterally, apply vasoconstrictive ETPS therapy.

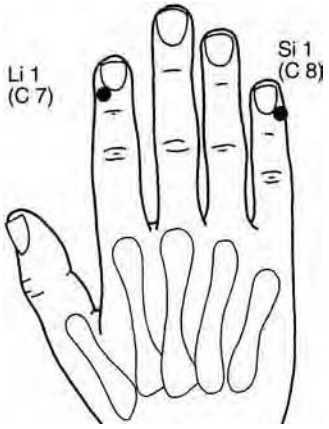

FIGURE 54.30 The hand illustrates the integration of acupuncture jing well points for myofascial release of Sterno Cliedo Mastoid (SCM) using Li 1 and the scalene muscles using Si 1. Treat bilaterally, applying vasoconstrictive ETPS therapy.

Step 6 Neural therapy.

Inspect for scarring, either surgical or injury, distal in the dermatomes from C 5-1 or along any upper limb meridians. For neck pain, inspect for scars around the elbow and wrist.

Step 7 Tender trigger points.

Ask the patient to identify any local tender points remaining in the cervical region. Apply ETPS therapy to these points, usually trigger points (TPs) or acupuncture points (APs) throughout injured tissue. Brief stimulation of 15 to 20 seconds per point has been successful in alleviating the majority of any pain that remains.

Fibromyalgia Protocol

Step 1 Treat the parasympathetic points (-ve).

Treat the following parasympathetic points. Assess the patient after each stage.

- Lu 9 (Figure 54.31): A powerful vascular and parasympathetic point. Located on the transverse wrist crease, in a hollow on the ulnar side of the radial bone.
- P 6: A good nausea and parasympathetic point. Located three fingers proximal from the most distal wrist crease, deep between the palmaris and flexor carpi tendons.
- H 7: An excellent mind-calming and parasympathetic point. Located on the transverse wrist crease, in a hollow on the radial side of the thick flexor carpi ulnaris tendon.
- Sp 6 (Figure 54.32): An immune, parasympathetic, and distal pain point for perineum. Located four fingers superior to the medial malleolus and posterior to the tibia bone. Note: Press directly against the bone to find this point.
- K 3: A low back pain, congenital energy, and parasympathetic point. Located in the hollow midway between the medial malleolus and Achilles tendon. Also used for morning back pain and circuited with B 25 (L 4–L 5 interspace).
- Cv 17 (Figure 54.33): A respiratory and parasympathetic point. Located on the midline of the sternum, horizontal with the fourth intercostal space.

Step 2 Apply Standard Protocol.

Assess patient after each stage.

- Check gait–piriformis.
- Look for signs of radiculopathy (motor bands), especially at T 9–10 levels.
- Manually release gait.

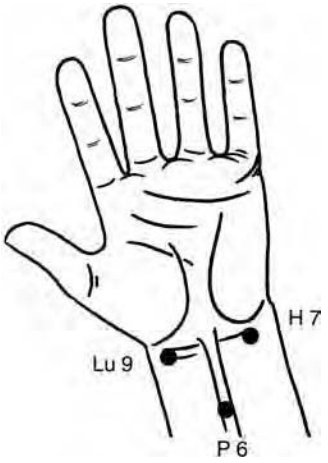

FIGURE 54.31 Three upper limb parasympathetic points Lu 9, P 6, and H 7, used to deregulate the Autonomic Nervous System (ANS), permitting continued therapy on supersensitive patients. Treat bilaterally, applying vasoconstrictive ETPS therapy.

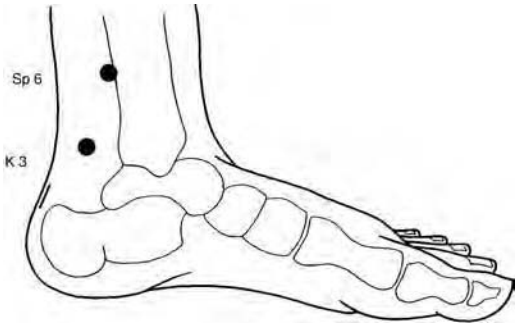

FIGURE 54.32 Sp 6 and K 3 are lower limb parasympathetic points, used for deregulation of lower viscera, permitting continued therapy on sensitive patients. Treat bilaterally, applying vasoconstrictive ETPS therapy.

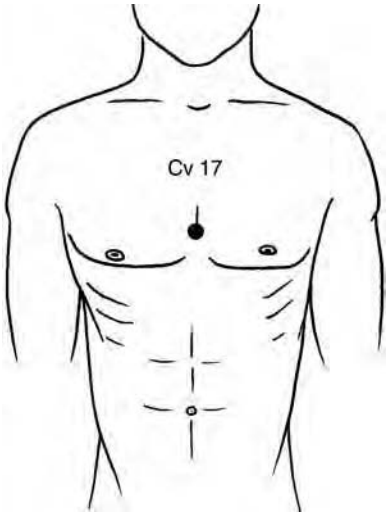

FIGURE 54.33 Acupuncture point for body calming. Also known as "sea of tranquility", Cv 17 should ONLY be treated on severe patients, and only AFTER all the above points have been treated.

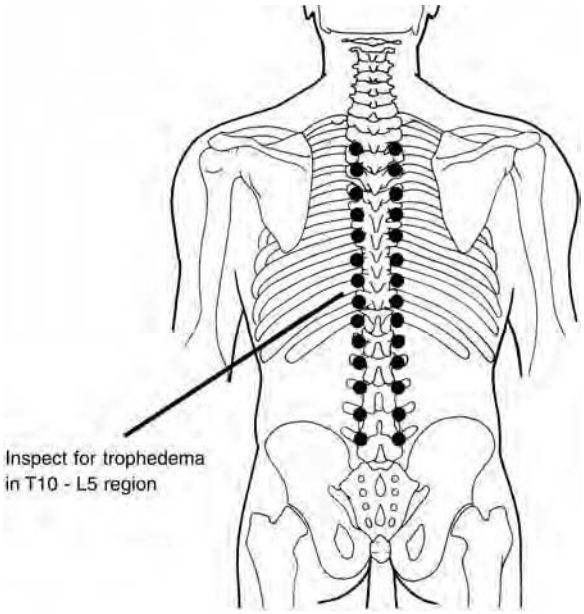

FIGURE 54.34 Palpate for paraspinal motor bands throughout the thoracic region. Release identified motor bands with paraspinal points. Apply vasodilative ETPS therapy.

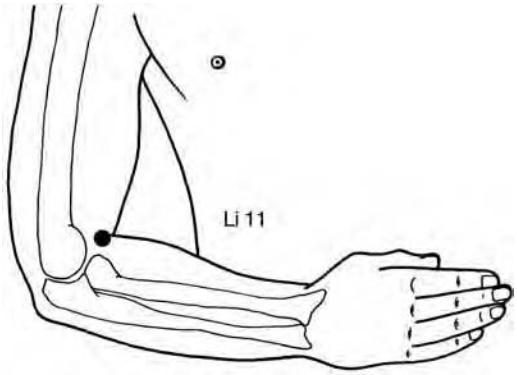

FIGURE 54.35 Homeostatic acupuncture point Li 11. Apply vasoconstrictive therapy to right arm and vasodilative therapy to left arm.

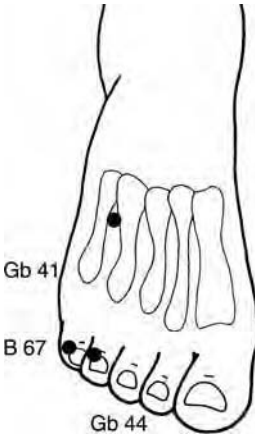

FIGURE 54.36 Sacral triangle may be treated with vasoconstrictive ETPS stimulation for additional relief beyond steps 1 to 3. Note the audible differences between B 67 and GB 44. A high pitch with GB 44 denotes hip and fascial pain root, and a high pitch with B 67 denotes spinal radiculopathic involvement in pain cycle.

- Perform paraspinal release from T 10–S 2 (+ ve) encompassing segments with trophedema (Figure 54.34). Note: Use positive polarity for paraspinal stimulation.
- Circuit pirformis–IT Band (–ve) and piriformis–Gb 34.

Step 3 Homeostatic point Li 11 (–ve).

If success is limited in the first two steps, Step 3 can often provide relief to the patient. Stimulation needs to be applied only for 20 to 30 seconds on the proper dermatome point in order to provide relief. It is located at the lateral end of the transverse elbow crease, with the elbow semiflexed (Figure 54.35).

Step 4 Sacral triangle B 67, Gb 44, Gb 41 (–ve) (Figure 54.36).

Isolate the treatment release of the psoas muscles. With some patients, the psoas muscle may be contracted alone or with the piriformis muscle. If pain still exists after Steps 1 through 3, a quick stimulation of St 45 (second toe base nail lateral side) will reveal if the psoas muscle is contributing to the pain condition.

Patients should be assessed between treatments of both the R and L points to determine which psoas muscle is most involved in the injury. This step is integrated into this protocol to include both posterior and anterior hip stabilizing muscles to determine if they individually or collectively contribute to the patient's chronic pain state.

Step 5 Release tender trigger points.

As noted earlier, tender trigger areas are treated as a last step in ETPS therapy because it is assumed that all pain is referred from another anatomical area of the body (Figure 54.37).

Ask the patient to identify tender points and apply ETPS therapy to these points (usually TPs or APs throughout injured tissue). Brief stimulation of 15 to 20 seconds per point has proven successful in alleviating the majority of any pain that remains. After each stage, stop and assess patient. Treat all points bilaterally.

Plantar Fasciitis Protocol

Step 1 Apply Standard Protocol.

Assess patient after each stage.

- Check gai–piriformis.
- Look for signs of neuropathy and radiculopathy.
- Manually release gait.

FIGURE 54.37 Two to three tender points may be identified by patient and treated AFTER the previous steps are completed. Do not apply stimulation to more than three tender points, as aggravation of symptoms is common with excessive stimulation.

- Perform paraspinal release from L4–S2 (encompassing segments with trophedema) (Figure 54.38).
- Circuit pirformis–IT Band and piriformis–Gb34

Step 2 Myofascial release of fascial overlay throughout calf muscles.

B57 (Figure 54.39): Located at the muscular junction of the Achilles tendon, this is an excellent point for releasing the entire calf area.

Step 3 Treat local points for pain relief.

- K 3 (Figure 54.40): The best point to treat for patients who display a stiff back in the morning. Located in the hollow between the medial malleolus and the Achilles tendon.
- K 5: Located one thumb's width below K 3.
- K 6: Located in the hollow just below the medial malleolus.
- B 60 (Figure 54.41): Located in the hollow between the lateral malleolus and the Achilles tendon. Very tender on sciatica patients.
- B 62: Located in the hollow just below the lateral malleolus.

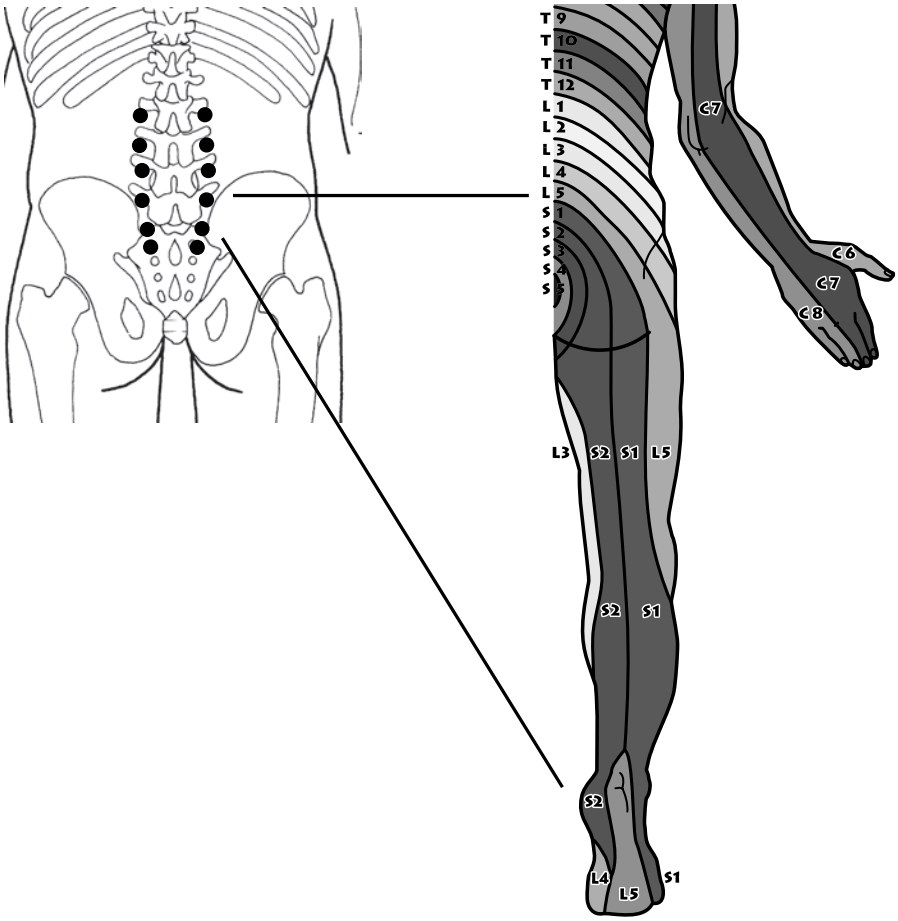

FIGURE 54.38 Inspect for trophedema at segmental levels L 4–S 2, as identified with skin rolling test (see Figure 54.6). Paraspinal release with vasoconstrictive ETPS therapy.

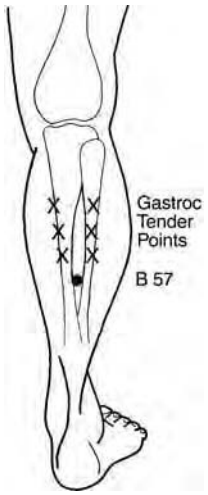

FIGURE 54.39 Release acupuncture point B 57 and tender points located throughout motor bands (identified through palpation) using vasoconstrictive ETPS therapy.

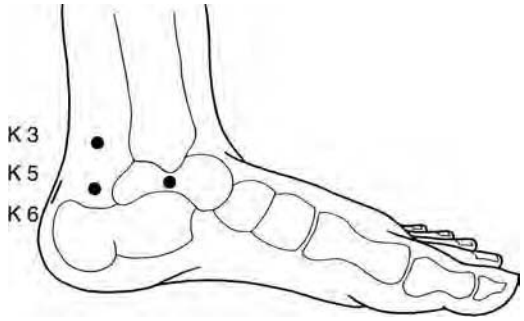

FIGURE 54.40 Local medial acupuncture points K 3, K 5, and K 6, which are treated for additional relief from plantar fasciitis pain. Treat with vasoconstrictive ETPS therapy.

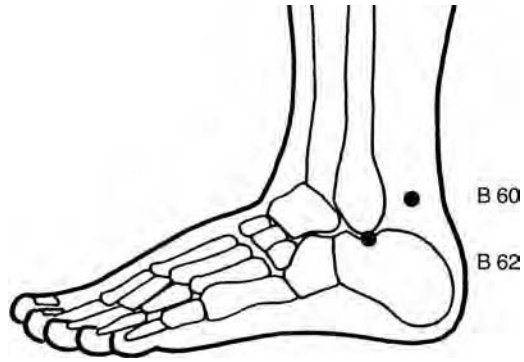

FIGURE 54.41 Local lateral acupuncture points B60 and B62, which are treated for additional relief from plantar fasciitis pain. Treat with vasoconstrictive ETPS therapy.

Step 4 Treat dermatome points.

- B 67 (Figure 54.42): At the base of the baby toenail, on the lateral side. Innervation, S 1
- Gb 44: At the base of the fourth toenail, on the lateral side. Innervation, L 5.

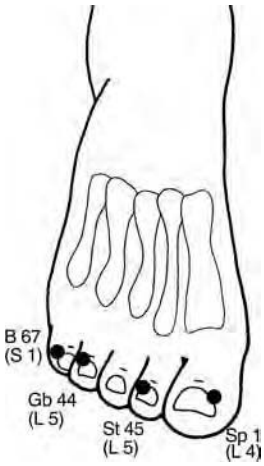

FIGURE 54.42 Distal jing well acupuncture points Sp 1, St 45, Gb 44, and B 67. Treat for additional relief of plantar fasciitis pain using vasoconstrictive ETPS therapy. Note: Audible differences between points and correlate to dermatomes for clues to root causes of pain.

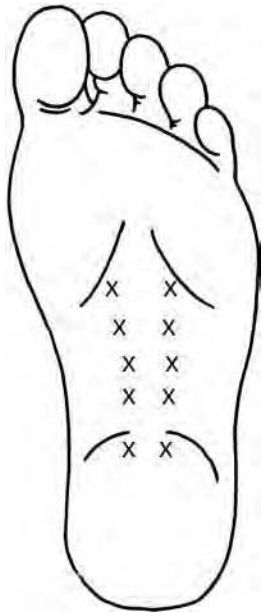

FIGURE 54.43 Apply vasoconstrictive ETPS therapy to tender points identified by patient on plantar region of foot.

- St 45: At the base of the second toenail, on the lateral side. Innervation, L5.
- Sp 1: At the base of the big toenail, on the medial side. Innervation, L 4.

Step 5 Tender trigger points.

Ask the patient to identify tender points and apply ETPS therapy to these points, (usually TPs or APs throughout injured tissue). Apply brief stimulation of 15 to 20 seconds per point (Figure 54.43).

CLINICAL RESEARCH STUDY

In a pilot study on carpal tunnel syndrome recently completed at the Canadian Centre for Integrative Medicine, Markham, Ontario, Dr. Gordon Ko (physiatrist, American Association of Electrodiagnostic Medicine) recorded improvements in five consecutive patients who completed ETPS (one time per week for 4 to 6 weeks). Using the Neuromax 1004 (including skin temperature measurements), the pre- and post-treatment median nerve latencies and amplitudes improved (9 hands). The mean scores are listed below with range in brackets.

Mean Values	Pre-Treatment	Post-Treatment
Distal motor latency	4.61 msec (3.8 to 6.0)	4.22 msec (3.7 to 5.9)
Sensory onset latency		
Palmar	1.98 msec (1.5 to 3.0)	1.81 msec (1.5 to 2.9)
2nd and 3rd digits	3.13 msec (2.5 to 4.2)	2.93 msec (2.5 to 3.6)
Sensory amplitudes		
Palmar	37.0 uV (19.3 to 99.0)	44.5 uV (29.3 to 120.3)
2nd and 3rd digits	13.6 uV (5.0 to 22.7)	16.7 uV (5.3 to 26.0)

Clinical improvement was reported in all patients without any significant adverse effects. One patient with severe CTS who completed the "Dash" (Disabilities of the arm, shoulder, hand) survey demonstrated marked improvement with a pre-score of 20/100 and a post-score of 1.7/100 (a higher score indicates increased functional limitations). Prior to treatment, the patient's right-hand sensory responses were absent. After treatment, palmar and third digit responses were measurable.

Further research is required to verify the efficacy of treatment and supporting data. A call for patients is now under way to proceed with a larger controlled study with Dr. Gordon Ko at the University of Toronto.

ETPS NEUROPATHIC THERAPY CASE STUDY

A case study of the benefits of ETPS neuropathic therapy on 345 chronic pain patients was performed. Patients were all over the age of 65, and divided into two groups: one group treated daily for 3 weeks; one group treated themselves weekly for 3 months. Assessments were performed at the beginning and end of each time frame.

Mean scores improved in both groups without any adverse side effects. A significant improvement was reported in the mean score with patients listed below:

Mean Values	Pre-Treatment	Post-Treatment
Average pain score: Daily n = 293	7.48/10 (9.9 to 5.8)	2.99/10 (6.3 to 1.5)
Average pain score: Weekly n = 52	6.13/10 (8.5 to 4.2)	2.35/10 (6.8 to 0.5)

Clinical improvement was reported in all patients without any adverse side effects. Further research is required to verify the efficacy of treatment and the accuracy of the supporting data.

CONCLUSION

ETPS therapy incorporates acupuncture, osteopathic, trigger point, neuromuscular, and neural therapies into simple, easy-to-use protocols. With this approach, it is possible to integrate different philosophies and access a wide variety of soft tissue pains using one modality. With back pain, an exceptionally common condition, each stage in an ETPS protocol treats a specific pathway, group of muscles, segmental levels, acupuncture meridian, or scar. Through this step-by-step elimination process, it is possible to identify and treat those levels, muscles, or meridians at the root of a patient's pain.

Although ETPS therapy has been able to make modest breakthroughs in the diagnosis and treatment of chronic pain through its synthesis of different modalities, additional research is required to advance the body of knowledge. Perhaps an even greater challenge than pure research is the need for competing disciplines to work cooperatively by reducing the barriers that compartmentalize medicine. Drawing from the Oriental paradigm, the advancement of knowledge and the pursuit of truth begin with questions, rather than proclamations of answers. This paradigm is the foundation of ETPS therapy. "How can the constituent elements of medicine be combined to advance the treatment of chronic pain?"

Magnetic Biostimulation in Peripheral Neuropathy

Michael I. Weintraub, M.D., F.A.C.P., F.A.A.N.

INTRODUCTION

For more than 2000 years, interest in the health effects of magnets on biological processes has been explored and debated in the scientific community. The public has perceived that magnets are an important source of natural energy and good health and has created a worldwide demand, spending more than $500 million in the United States and Canada and $5 billion worldwide in sales last year. Anecdotal endorsements by more than 70 sports figures in golf, baseball, tennis, football, etc. have also enhanced utilization. As we enter the new millennium, there has been a shift in focus. Rather than ignoring it, the public's and medical community's interest and curiosity about the subject of alternative medicine has heightened. What are the facts and what is fantasy? This chapter explores the topic of magnetic therapy in terms of static magnets, mechanisms of biological effects, and current investigations. While time-varying magnetic field (electromagnetic) devices are mentioned, a comprehensive discussion is beyond the scope of this chapter.

HISTORICAL PERSPECTIVE:

Man's fascination with magnetism is a historical blend of science, sensationalism, quackery, fashion, and controversy. However, it is a story worth telling because it provides insights into how contemporary American society deals with the current surge of interest in alternative medical therapies.

For an excellent review of the background history, the article by Mourino is exceptionally informative (Mourino, 1990). Claims of magnetic healing have been traced for more than 2000 years. The term "magnet" was probably derived from Magnes, a shepherd, who legend states was walking on Mount Ida and was suddenly drawn to the Earth by the metallic tacks in his sandals. He dug to ascertain a cause, and in the process, discovered magnetite, the mineral lodestone containing a magnetic oxide of iron (Fe_3O_4). The ancients also called these Herculean stones, lodestones, or live stones as they were meant to "lead the way". The observations that lodestones could attract iron filings and that amber rods rubbed with fur could attract paper and other objects were considered manifestations of the same phenomena. Thus, magnetism and electrostatic attraction were considered similar mechanisms and this closeness is reproduced throughout subsequent history of the subjects (Mourino, 1991; Geddes, 1991; MacKlis, 1993; Armstrong & Armstrong, 1991). Because history has a way of repeating itself, distinct footprints can be easily traced.

Briefly, the ideas expressed by the ancient Greek and Roman civilizations represent the historical origins of "invisible movement of matter." Plato, Euripides, and other individuals attributed various powers to magnets and sensed that the lodestones could be put to practical use, e.g., building boats with iron nails and also destroying them by closely putting them against the magnetic mountains of rocks, etc. Healing properties of lodestones and amber were attributed to soul and by 200 A.D., Greek physicians were prescribing amber pills to stop

0-8493-0926-3/02/$0.00+$1.50

hemorrhage and magnetic rings were sold in the markets of Samothrace in an attempt to cure arthritis. In 1289, Peter Peregrinus is credited with writing the first major treatise on magnetism. Lodestones were thought to have strong aphrodisiac powers, curative powers for gout, baldness, arthritis, and even the power to draw poison from wounds. His work also contains the first drawing and description of the compass in the Western world.

The Middle Ages was a dark period for science and an astounding number of beliefs and myths were attributed to magnets. For example, it was stated that magnets could draw gold from wells and that an antidote for magnets was garlic. In the 16th century, Paracelsus investigated the medical properties of lodestones in the treatment of diseases such as epilepsy, hemorrhage, and diarrhea. Paracelsus was a physician and alchemist who denounced Galenic medicine and made public displays of burning books, etc. He combined mysticism with practical issues and became very controversial. One of his major points was "that every person is a magnet" that can attract good and evil and is an important "elixir of life." By the middle of the 16th century, attempts were made to separate the magnetic phenomena from the "amber effect." William Gilbert, physician to Queen Elizabeth I of England (1533–1603), wrote his classic text "deMagnete" in 1600, describing hundreds of detailed experiments on electricity by using amber and electrons. He also described terrestrial magnetism by using the compass and the Earth as a magnet. He debunked many quack medical uses of magnets and was responsible for laying the groundwork for future research and study.

Thomas Brown continued this attack on popular magnetic salves and remedies and suggested that their putative healing power was due only to the incorporated herbal and mineral compounds. He performed experiments demonstrating that lodestones retained their magnetism and that garlic could not destroy them and that diamonds did not impede them. It should be noted that in the nearly 100 years after the publication of Gilbert's book, no major advancements were made in the study of magnetism. In the early 18th century, significant interest in electricity and magnetism arose. An electrostatic engine was invented in 1705 by Francis Hauksbee. He mounted a glass globe on a spindle and rotated it with great speed while a woolen cloth was pressed against it by a strong, brass spring. Hauksbee discovered that this apparatus could produce a strong, electric charge that could be transferred to other objects by means of a metal chain (wire) connected to fine metal points suspended just above the surface of the glass globe. This produced electrical shocks, and by 1743 showmen were traveling throughout Europe with their electrical machines and even went to the English New World (American colonies), giving people shocks for a small fee. Fortuitously, in that year in Boston, Benjamin Franklin observed an electrified boy exhibition by an itinerant electrician that roused Franklin's interest in electrical and magnetic phenomena. In fact, much of the current nomenclature of electrical terminology, such as charge, discharge, condenser, electrical shock, electrician, positive, negative, plus, and minus, originated with Franklin. Magnetism was not Franklin's major research area; and he distinguished himself in his studies of electrical fluid and charges. According to him, all matter contains a magnetic field that is uniformly distributed throughout it. When an object is magnetized, the fluid condenses in one of its extremities. That extremity becomes positively magnetized while the donor region of the objects becomes negatively magnetized. The degree to which an object can be magnetized depends on the force necessary to start the fluid moving within it.

Across the continent in Europe, Father Maximilian Hell was effecting medical cures with artificial lodestones, i.e., pieces of iron that had been strongly magnetized through a process developed during the period 1743–1751. His student, Anton Mesmer, obtained a supply of these magnets and began to apply them to his patients. Many patients were experiencing hysterical or psychosomatic symptomatology and, consequently, Mesmer's cures were "astounding" and spectacular. His results were principally due to the power of suggestion, and he began to experiment with other objects such as nonmagnetic materials, i.e., paper, wool, silk, and stone. Mesmer reasoned that he was not dealing with ordinary mineral magnetism but with a special kind that he named "animal magnetism." He theorized that ill people could overcome a disease by "mesmerizing" their body's magnetic poles to induce a crisis, often in the form of convulsions "so as to restore their health and harmony." In a single, short year, mesmerism and mesmeric cures became the rage of Vienna. In 1775, Mesmer published his first medical treatise on the medicinal uses of the magnet. Mesmer's exaggerated claims of success bordered on the theatrical and forced the Royal French Academy of Science to convene a special study in 1784. This panel included Anton Lavoisier, J.R. Guillotin, and Benjamin Franklin. In a controlled set of blind experiments in which patients were exposed alternatively to a series of magnetic or sham-magnetic objects and were asked to describe their sensations, the Committee decided that the efficacy of the magnetic healings seemed to reside entirely within the mind of the patient, i.e., power of suggestion in susceptible or naive individuals. Based on these findings in France, mesmerism soon came to symbolize medical quackery and was scorned. Mesmer's theories were declared fraudulent. The French Revolution subsequently occurred in 1789 and Mesmer left France in disgrace.

Credit for discovering the true nature of electromagnetism goes to Hans Christian Oersted (1777–1851). He noted that a compass needle was deflected when a

current flowed through a nearby wire. He carried out some experiments and found to his astonishment that not only did a current-carrying wire exert a force on a magnet, but a magnet also exerted a force on a coil of wire carrying electric current. The coil acted like a magnet, behaving as if it possessed magnetic north and south poles. Magnetism and electricity were somehow connected. It was Oersted who was instrumental in creating the proper scientific environment that led to further progress. Subsequently, the pace of scientific research on magnetism skyrocketed. Society embraced the application in the treatment of illness which led to commercial enterprises. The alleged benefits of magnetotherapy were summarized in a mail-order pamphlet printed in 1886 and distributed by Dr. C. J. Thatcher. He explained how magnetic healing provided pain "a road to health without the use of medicine and dependent upon the magnetic energy of the Sun." He believed that the iron content of the blood made it the primary magnetic conductor of the body. The most efficient way to recharged the blood's magnetic field was through the use of magnetic garments, and Thatcher's Chicago Magnetic Company produced over 700 individual magnetic devices and garments. The complete set was said to "furnish full and complete protection of all the vital organs of the body."

He was dubbed by Collier's Magazine "The King of Magnetic Quacks." By the late 19th Century and early 20th Century, the medical establishment was beginning to accept the role of electromagnetic approaches to the treatment of some diseases. In fact, one of the standard medical textbooks from the period devotes an entire chapter to the use of galvanism and electromagnetic fields in the treatment of neurologic disease. However, there were numerous skeptics who provided contradictory data making it difficult for the medical establishment to either restrict or condone the practice of magnetic healing. Thus, magnetic devices were sold without regulation. In 1896, D'Arsonval placed his head inside a magnetic coil which caused phosphenes (stimulation of the retina). However, many people date the era of modern magnetic stimulation from the clinical reports of Bickford and Fremming (1965) who were able to twitch skeletal muscles by magnetic stimulation of peripheral nerves. Subsequently, Barker (1975) and McLean, Holcomb, Wamil, et al. (1995) at the University of Sheffield (1986) developed the first commercial magnetic stimulator. As might be expected, stimulation using magnetic coils for the central and peripheral nervous systems, has been worldwide for more than a decade and has created a new discipline both for diagnosis and therapy. Similarly, the development of Nuclear Magnetic Resonance (MRI) led to imaging research applied to biological systems. Hydrogen, sodium, and phosphorous were studied. Tissues have a specific signature" and these techniques have been further refined and are used by the neurological community on a daily basis.

The use of pulsed electromagnetic fields (PEMF) is another form of electromagnetic energy that influences biological changes. This has been investigated specifically at the cellular membrane level with ion flux as well as stimulating osteoblasts in nonunion fractures. It also has been approved by the FDA for incontinence and healing of nonunion fractures. Exposure to various EMF, i.e., high-voltage power lines, microwaves, has generated fears of lymphoblastic leukemia and other malignancies. This issue was discussed in the Archives of Physical Medicine and Rehabilitation by Vallbona, Hazelwood, and Jurida (1997).

DEFINITIONS

Types of Magnetic Fields

There are two broad groups of magnetic fields: static and time-varying. In time-varying suprathreshold magnets high-current electrical pulses pass through a coil of wires inducing a magnetic flux which does not attenuate as it passes through tissues. The magnetic pulse then induces a proportional electrical field in an opposite direction to the current in the coil. Repetitive electrical stimulation of the cerebral cortex has long been known to interfere with cerebral processing and is the basis for electroshock therapy. Similarly, single-pulse transmagnetic stimulation (TMS) of the motor cortex can disrupt neural function. Thus, noninvasive stimulation of the human cortex and peripheral nervous system can be safely utilized to measure function and may have a profound impact therapeutically. Depending upon the pulse frequency (1 to 5 Hz), the excited axons may have excitatory or inhibitory effects which may be distant or local. While it is beyond the scope of this chapter, suffice it to say that TMS is a young science that is being explored in movement disorders, psychiatric disease, epilepsy, speech disorders, behavior and spinal cord dysfunction, etc. (Pascual-Leone, Valls-Sole, & Brasil-Neto, et al., 1994; George, Lisanby, & Sackheim, 1999). This is a painless and reliable approach that does not require direct skin contact and produces the same results as standard electrical stimulation. Because of the strengths of these suprathreshold magnetic fields, numerous biological reactions can occur and are described later.

Static or permanent magnets for the management of pain are commercially available in various magnetic configurations, sizes, and compositions. Manufacturers have created devices from neodymium, ceramic, iron, plastiform, barium ferrite, etc. These are weak devices usually measured in gauss or Tesla. There are two specific types of magnets described as unipolar (north or south) or bipolar. The term "bipolar" refers to magnets that at the surface have alternating north and south poles

in a concentric pattern or grid. Other patterns developed are called multipolar with triangular arrangements of alternating north and south poles. Each proponent of their configuration has made claims as to the "best and most efficacious design", but no large-scale clinical studies exist comparing one design to another. However, laboratory analysis explored and tested this issue in a 1995 study at Vanderbilt University. McClean and co-workers (1995) demonstrated an enhanced effect of multipolar magnets on sensory afferent firing (pain axons) compared to unipolar or bipolar designs. Beneficial effects from permanent magnets have been attributed to penetration of the field which is proportional to the strength of the magnetic field at the surface. It is also a function of the size of the magnet. It is well-known that magnetic fields lose their intensity as they penetrate body tissues. Thus, it is important to keep these devices firmly affixed to the skin surface for maximal penetration. Gaussmeter recordings taken at increasing distances from a magnetic surface demonstrate a rapid decrease in gauss strength and penetration with distance. Thus, the field density at the target area is probably more clinically relevant than the magnetic reading at the surface of the skin. The strength and force of any magnet are designated as its gauss rating. This represents the energy field at the topmost center of the magnet, the energy field declines with distance. Most commercial magnets have 300 to 600 gauss strength but not all brand of magnets are equivalent in depth penetration and each manufacturer makes its own claim. Specifically, in the utilization of bipolar magnets, it has been suggested that there is spatial cancellation from the adjacent opposite poles producing no active magnetic field penetration to the target region.

Duration of Contact

This has not been scientifically confirmed. Valbonna, et al., (1997) utilized bipolar magnets for 45 minutes in post-polio syndrome whereas Collacott, Zimmerman, White, and Rindone (2000) used bipolar magnets for 18 hours per week. Weintraub (1998; 1999), utilized multipolar magnetic devices (475 gauss) constantly 24 hours per day. One manufacturer, Magnetherapy, Inc., recommends using a unipolar magnet for a minimum of 8 hours per day with continuous application until pain has been relieved.

Precautions

Static magnets are thought to be safe and are not regulated by the FDA. However, all manufacturers have cautioned about their use during pregnancy because there is no available information regarding the role of magnetic fields in pregnancy and/or on the fetus. Individuals who wear a pacemaker or electronic implants also should not use these devices. Patients with open and fresh wounds also are cautioned against wearing these devices.

MECHANISMS OF THE BIOLOGICAL EFFECTS OF MAGNETIC FIELDS:

The exact mechanisms of the interaction of magnetic fields with biological tissues resulting in functional changes are presently unknown. Electromagnetic fields (EMF) are known to alter biomolecular DNA synthesis, cell proliferation, membrane calcium fluxes, and cell surface properties in vitro (Cleary, 1995). The principle site of biophysical interaction leading to cell functional alterations is most likely the lipid membrane surface where EMF may affect the ability of ion pump enzymes to move calcium, sodium, and potassium ions across the cell membrane (Blank & Soo, 1993). Magnetic fields also may alter the equilibrium between cell death and proliferation via modulation of calcium influx (Fanelli, Coppola, Barone, et al., 1999). An excellent overview of the biological effects of electromagnetic fields is found in a two-volume publication edited by Carpenter and Ayrapetyan (1994). Adey (1981) demonstrated that at the cell surface, ionic phenomena arise producing transmembrane signaling. Thus, at the atomic level, there are disordered free radicals which reflect the level of involvement with generation of electromagnetic signals (Adey & Chopart, 1987). Adey also has identified glycoprotein strands protruding through cell membranes, which he feels act as antennae or tissue components of electromagnetic fields traveling along cell surfaces. This produces transduction with an intracellular cascade of metabolic, messenger, and cell-growth regulating enzymes. This is an athermal interaction at the atomic level. He has noted that disordered, free radicals are associated with oxidative stress, diseases including Parkinson's, Alzheimer's, and coronary artery disease, aging, cancer, and diabetes mellitus. Observed biological effects of imposed fields point to a needed mechanistic basis, beyond the fabric of biomolecules in physical processes at the atomic level. It is well-known that free radicals are usually unstable and highly reactive and are capable of abstracting electrons from surrounding lipids, proteins, or DNA molecules, thus inducing cellular changes and damage. Adey further suggests that nitrous oxide is the specific agent involved and further theorizes that magnetic benefit occurs at the level of free radicals with the splitting of nitrous-oxygen bond (NO). Thus, ion parametric resonance theory has been attributed to biological effect.

Cope (1973) also indicates that at the atomic and subatomic levels there have been changes in biological systems. It is his premise that microregions exist within

cells and molecules and are sensitive to external magnetic fields (both low and high). Such interactions can lead to changes in enzymatic reactions, cellular potentials, conduction velocity, etc. Nordenstrom (1983) proposed that the endothelial lining of the cardiovascular system serves as a conduit for the transmission of electrical energy throughout large regions of the body. Thus, it is not inconceivable that a magnetic field from either a permanent magnet or electromagnetic device can induce electric current in vascular elements in one region of the body, etc., which in turn could be transferred to other regions.

The biologic phenomenon that is responsible for altering rates of wound healing with pulsed electromagnetic fields (PEMF) exposure as well as improvement in stress incontinence is not well understood. However, the FDA has approved its utilization. Both human and animal studies indicate increased peripheral blood flow resulting from such an exposure. Specifically, changes occur in fibroblast concentration, bursting fibers, and collagen at wound sites, again attributed to increased blood flow (Bassett, Mitchell, Norton, et al., 1979; Pujol, Pascual-Bolz, et al., 1998). Some authors feel that water plays a major role in explaining the therapeutic effects of magnetic fields. While this mechanism is clearly applicable in MRI, it also needs further assessment in the laboratory. Beall, Hazlewood, and Rao (1976) demonstrated cyclical changes in the physical state of water, with water being most organized in an S-phase due to exposure to magnetic fields.

Jacobson and Yamanashi (1995) explored biophysical interactions that might explain electromagnetic inducement of oncogenes. The final product of the study was the production of a testable theoretical model with a magnetotherapy mechanism wherein physiologic magnetic fields may be directed from an exogenous source through the patient, producing changes in the lattice structure of normal genes. This research suggests effects of magnetic therapy that go well beyond changes in blood flow.

A blockade of action potentials of cultured sensorineurons by small static magnetic fields has been previously reported by McLean, et al. (1995). The exact mechanism of the interaction of magnetic fields with biological tissues resulting in functional changes is unknown. Previously, Weintraub (1998; 1999) hypothesized that C-fibers are influenced by constant contact with static magnets leading to a reduction of burning and painful symptoms in the feet. This probably involves the potassium (K^+) internal rectifying channel (Horn, Quasthoff, & Grafe, et al., 1996). Thus, there is a repolarization or a hyperpolarization that develops due to constant exposure.

Currently, blood flow studies in response to static magnetic fields (unipolar, bipolar, and multipolar) utilizing laser-Doppler perfusion measurements are currently in progress. Thus, from a clinical perspective, objective data may be obtained that can be extrapolated to look at specific dosing of magnetic fields, frequency and duration of utilization, as well as a spatial coverage.

Despite laboratory attempts to identify a mode of action, a large clinical study of cohorts with detection of biological markers ultimately will determine if there is a legitimate role of magnetic therapy in pain medicine.

The safe application of electromagnetic fields has been attested by the World Health Organization (WHO) (1987) which reported that all the available evidence indicated the absence of any adverse effects on human health due to exposure to static magnetic fields up to 2 Tesla.

As we enter the 21st Century, we see that history has indeed repeated itself, but with more progress. Previous applications of permanent magnets have been utilized by Weintraub (1998; 1999) as well as Vallbona, et al. (1997) and Collacott, et al. (2000) with varying results. To any serious student of medicine and neurology, skepticism should be maintained in view of the absence of large longitudinal, randomized, placebo-controlled trials. An open mind is necessary. Science still does not have all the answers!

MAGNETIC STIMULATION IN DIABETIC PERIPHERAL NEUROPATHY: A NOVEL APPROACH

It has been estimated that 16 million Americans suffer from diabetes mellitus. Most represent adult-onset Type II noninsulin-dependent (90%) and 10% have Type I insulin-dependent diabetes mellitus. The Diabetes Control and Complications Trial (1988) identified risk factors associated with the development of diabetic neuropathy that include degree of hyperglycemia, duration of diabetes, age, male sex, and height. Other complications of retinopathy and nephropathy also are associated with these same risk factors and may coexist with neuropathy. Thus, over 60% of individuals with diabetes mellitus suffer some form of neuropathy (peripheral and/or autonomic or combination) and in most, the ensuing symptoms are serious enough to interfere with daily activities. Diabetic peripheral neuropathy represents a spectrum from clinically silent to a progressive axonopathy of the dying-back type characterized by myelinated fiber loss and reduced fiber regeneration with sprouting. Usually, the neurological examination reveals blunted sensation to pin prick, vibration, position, and temperature, and usually blunting and/or absence of deep tendon reflex response. Motor weakness may also be present. Neurological complications occur equally in Type I and Type II diabetes mellitus. Quantification of the above process by nerve conduction velocity and quantified sensory testing (QST) (Dyck, O'Brien, Kosambre, et al., 1993) iden-

tifies if the symptomatology is primarily secondary to small unmyelinated C-fibers (dysesthetic pain, warm thermal perception, autonomic function) or large-fiber damage (deep-seeded gnawing pain, altered position, and vibration). Also, loss of sympathetic regulation of sweat glands and local blood flow leads to skin dryness, cracking, and ultimately secondary local infections leading to amputation (Low, Caskey, Tuck, et al., 1983).

Dysesthetic symptoms remain a refractory problem and are notoriously difficult to treat with conventional pharmacologic agents and the patient often becomes disabled. Disappearance of pain occurs and is misinterpreted by patients as improvement, whereas it signifies that the neuropathy is progressing. This should serve as a warning sign for more frequent foot care because this scenario often leads to amputation.

Numerous pathogenic mechanisms have been offered including metabolic, vascular, autoimmune, sorbitol toxicity, etc. Despite hundreds of millions of dollars of research, there is no specific etiology accepted. Presently, it is considered a heterogenous disease with various aspects of pathology and pathogenic mechanisms.

A number of treatments have been used in an attempt to reverse and halt diabetic peripheral neuropathy, but only strict glycemic control has been found effective (Low & Dotson, 1999). Similarly, despite hundreds of millions of research dollars, associated peripheral vascular disease and impaired wound-healing results in more than 200,000 cases of foot ulcers and about 100,000 amputations per year. Despite over $1 billion in research, effective therapy for the prevention and treatment of diabetic peripheral neuropathy is not currently available.

Most research has focused on pharmacologic approaches for pain relief by blocking central or peripheral transmission pathways. But, the optimal drug has yet to be developed. Troublesome side effects also are a significant problem. Therapeutic options with conventional pharmacologic agents are, therefore, limited. Thus, alternative therapies directed at slowing or halting the process become attractive. Anecdotal reports over the past 2000 years have suggested that the application of static magnets in painful areas of the body can reduce discomfort; however, these claims have not been scientifically validated. As we enter this new millennium, a great opportunity exists to critically evaluate new and novel therapeutic approaches.

Prior pilot studies using commercially available multipolar magnets (475 gauss) resulted in unexpected pain relief in individuals with diabetic peripheral neuropathy and peripheral neuropathy from other etiologies. A follow-up pilot study looked at the potential role of placebo response and the results indicated that the pain relief benefit was not placebo. The fact that nerve conduction studies and SSEP, which measured large A-fiber conduction serially over 4 months, did not demonstrate any significant change, suggested that the pain modifying benefit was secondary to C-polymodal receptor afferent modulation. In view of the fact that burning was extremely sensitive to magnetic application, it only reinforced this as a theory. Consequently, a larger longitudinal study was required in an attempt to statistically determine if magnetic stimulation is a legitimate therapy.

Nationwide Randomized Placebo-Controlled Study

In July 1999, a multicenter, randomized, double-blind placebo-controlled study was started in the United States. A cohort of 300 cases with Stage II/III DPN (Dyck, Kratz, Karnes, et al., 1993) was enrolled and observed for a 4-month period. Both examiners and patients were blinded. One group wore magnetic foot devices (475 gauss) constantly over a 24-hour period whereas a control group wore a similar appearing sham device. Baseline parameters of numbness, tingling, and pain were measured three times per day on a VAS scale of 0 to 10 as well as nocturnal interruption secondary to foot pain and foot discomfort after a standardized 10-minute exercise. Baseline nerve conduction velocity and/or Quantified Sensory Testing (QST) of C- and A-fibers or sympathetic skin response (SSR) are to be taken.

Several sites with special interest in autonomic functions, blood flow, intraepidermal nerve fiber assessment, microneurography, and threshold electrotonus are also being performed serially. Currently, there are 115 sites in all 50 states including Washington, D.C. and Puerto Rico. All seven Podiatric Medical Centers in the United States are participating as well as the five largest foot and ankle centers. Of the neurological university centers, over 60% of the examiners are Chairpersons, Professors, or Chiefs of Neuromuscular Division. In an attempt to complete the study by March 2001, additional community investigative sites of practicing Board Certified Neurologists with expertise in electrodiagnostic studies were added. There also is close community collaboration with endocrinologists and physical medicine and rehabilitation specialists. This diabetic cohort of 300 patients represents the mosaic of the United States population as regards racial representation with Native Americans, Asiatics, Hispanics, African-Americans, and Caucasians. It also will demonstrate how university and community investigators from several disciplines can work together and produce a quality study. Biological markers are actively being sought in an attempt to identify the proposed mechanism of effectiveness. It is hoped that this study will validate the two prior pilot studies. But, irrespective of the results (positive or negative), it needs to be published. The public spent $500 million in the United States and Canada in 1999 and

over $5 billion worldwide for magnetic devices. Thus, the legitimacy of their use needs to be determined from a scientific standpoint. This study also will determine the role of placebo as well as the role of A- and C-fibers in response to constant magnetic field stimulation. The results may also suggest, too, that further clinical improvement can arise with increased Gaussian strength or improved steep field penetration or combination therapy with drugs.

If indeed this study is positive, it suggests the need to prophylactically wear these devices when diagnosed with diabetes mellitus prior to the emergence of clinical symptoms. It also would suggest a positive effect on wound healing.

Magnetic therapy is currently riding the crest of the tidal wave of public enthusiasm for alternative medicine. This current scientific endeavor will definitively determine if there is a legitimacy to static magnetic fields in diabetic peripheral neuropathy (DPN).

In conclusion, at this time, the best defense against DPN is maintaining optimal glucose control. This slows the onset and progression not only of neuropathy but other complications. Despite the functional benefits and dramatic pain relief reported with the two prior studies (75 to 90%), it is important to underscore that while these results are provocative, they must be considered anecdotal due to small sample size. The current nationwide initiative and its results will be eagerly anticipated because this will be a definitive study. Also important is that this study considers C- and A-fiber function over a 4-month period. Several blinded cases have demonstrated significant electrophysiological changes correlating with improved clinical status. These results must be duplicated. Healthy skepticism by the medical community still needs to prevail until the results of this definitive, randomized placebo-controlled study is completed.

Manipulation under Anesthesia: An Anthology of Past, Present, and Future Use

Robert C. Gordon, B.S. (Ed.), B.S. (Bio.), D.C., D.A.A.P.M., Anthony Rogers, M.D., Daniel T. West, D.C., Robert S. Matthews, M.D., and Mathew R. Miller, P.Ac.

The purpose of this chapter is to enlighten the reader about the treatment of manipulation under anesthesia (MUA). The chapter covers the anthology of MUA from the historical past to its present day usage. We present a basis for using the MUA procedure when manipulative therapy is the therapy of choice, but when conservative office manipulative therapy has had only minimal effect. The focus is on adaptation of this modality into pain management practice when neuromusculoskeletal conditions are being treated. We do not hold MUA out as an all-inclusive treatment modality that is going to replace all forms of treatment for neuromusculoskeletal conditions. We also make no implied reference to any guarantees that if you use MUA you will obtain the same results as have been historically achieved by other MUA practitioners. We do, however, suggest that this modality has been successful with certain types of conditions, later referenced, when other modalities have not. Because this modality has had some success during the years it has been used, this form of therapy needs to be considered as part of the pain management algorithms being considered for neuromusculoskeletal conditions when manual therapy is the therapy of choice.

HISTORICAL PERSPECTIVE

MUA has been used with great success by osteopathic, chiropractic, and orthopedic professionals since the late 1930s. Siehl and Bradford (1952) speak of Pershing International Clinic, which reported 200 cases treated with this modality in 1938. Results indicated that there was a 94 to 97% recovery rate for the conditions treated with the MUA technique. But we can really go back to some of the earliest times when we consider both manipulation and anesthesia. Early Egyptian scrolls and drawings depicted manipulation being used along with herbs to relax the body. Even the earliest of cave drawings showed forms of manipulation being used to cast out evil spirits." The point is that the use of manipulation and anesthesia predate many of the medical models referenced for the time when manipulation and medicine were first reported. In this section we present a historical anthology of the MUA procedure to lend support to the concept that this procedure has been used for many years. It is not meant to document every article written about this procedure, but instead to give a validated perspective from many sources concerning the multidisciplinary approach of this procedure.

Over the past 60 years, the MUA procedure has come under scrutiny from both the scientific community and insurance carriers. The words "safe" and "effective" have been thrown about with little regard to their full meanings in interpreting the procedure they are discussing. A new procedure that has very little history of use certainly would be classified as having questionable clinical validity. In the medical field, any potential procedure must undergo months of testing with controlled studies to validate its clinical therapeutic value. This is especially true when new procedures that may mean life or death for patients are found to be clinically significant. It is important to investigate these new procedures so that the patients we treat may benefit from everything available

0-8493-0926-3/02/$0.00+$1.50

to them, especially if the new procedures may save their lives. An investigational trial of all procedures must take place to determine if a procedure has clinical significance and whether it is safe for use and effective in procuring results. To become safe and effective, the new procedure must show a record of success, must be able to be duplicated by other practitioners, and must obtain clinically satisfactory results from patients undergoing the procedure. It must have been used by practitioners throughout the country for conditions shown to respond similarly to the procedure, and it must have been used with enough success to warrant its use as an alternative to other procedures if it is used as an intervention rather than other forms of therapy. This sounds much like the same requirements for inclusion in the AMA CPT codes of reimbursable procedures ("Introduction and Instruction for Use", 2000).

Because manipulation under anesthesia has been used as an alternative to prolonged conservative manual therapy and surgical intervention since the late 1930s, and because MUA has been completed on well over 20,000 patients since that same time (number of procedures is based on literature review and clinician interview throughout the United States and United Kingdom), and because the procedure has been used with regularity on the same types of conditions with similar results over that same time period, it falls within the parameters for being both a safe and an effective procedure (Hunter, 1974).

Literature reviews, which have been completed on numerous occasions by many authors, indicate that a considerable body of material has been written on the subject of manipulation under anesthesia, including references in manual therapy texts. I quote from some of these original articles. Clybourne (1948) states:

> I have had the opportunity to use manipulation under anesthesia on a sufficiently large number of cases to realize its scope and limitations. The type of case most amenable to treatment by manipulation is that in which the main pathological cause is the interference with joint motion by the presence of adhesions.

According to Siehl and Bradford (1952), a review of 100 MUA procedures on 87 cases indicated the "method was first used on those cases which were not responding or were responding very slowly to usual manipulative management."

Siehl (1963) states

> A conservative regime which includes manipulative treatment of the lower lumbar intervertebral disc syndrome under anesthesia eventuates in a significantly high percentage of satisfactory results to warrant its use as an essential part of conservative therapy.

Siehl presented an 11-year study of 723 cases treated with MUA at the annual meeting of the American Osteopathic Academy of Orthopedics, Bal Harbour, Florida, October 31, 1962.

Lindemann and Rossak (1959) concluded in the same paper presented by Siehl (1962):

> In our opinion, it is not permissible to regard the reposition under anesthesia without further ado as technical blunders. ..It deserves its place in the scale of the orthopedic therapeutic measures for the treatment of the protrusion and the dorso-lateral prolapse in the lumbar region. For the forms of the sciatic syndrome which are evoked through the dorso-lateral compression working on the nerve roots, the reposition under anesthesia is harmless and presents absolutely an acknowledged and trustworthy procedure in treatment.

In an early presentation at the 39th Annual Session of The American Congress of Physical Medicine and Rehabilitation (1962) Ronald Barbor, M.D. of London, England expressed the essence of the controversy surrounding the use of the MUA procedures we use today when he wrote:

> Manipulation is a word used to mean passive movement, forced movement, mobilization, or stretching. Manipulation carried out while the patient is anesthetized, as done by orthopedic surgeons is reputable, but manipulation done on a conscious patient is disreputable in the eyes of the medical profession, because this is the method used by osteopaths and chiropractors.

Because this concept of the right professional providing the right procedure is still employed today by most insurance companies, the MUA procedure has not been given the proper opportunity to prove its efficacy with the frequency that it should, based on the data from the clinical outcomes seen throughout the country (West, Mathews, Miller, & Kent, 1999). Documentation of the safe and effective use of MUA was evident early when Soden (1949), described the reason for the use of anesthesia during manipulative therapy by writing:

> The answer to the question of "why anesthesia" lies not only in the successful clinical results, but also in the physiology of anesthesia. According to Dr. William Baldwin (Professor of Physiology at the Philadelphia College of Osteopathy), general anesthesia carried well into the surgical stage causes the abolition of reflex response due to a slowing of the reflex arc, and an accompanying change in the graded synaptic resistance at the segmental level. Therefore, due to these factors, postural tonus of the muscles is abolished. With the removal of this postural tonus, there is lost the muscle function of joint stabilization

> and the splinting action of the muscles of the joint structures. The loss of these factors of muscular function is desirable in producing joint motion by manipulative procedures, especially when there has been present, previously, a reflexly maintained increase in the postural tonus.

This theory has been the foundation of the MUA technique for many years, but, of course, now with the advancement and use of new medicines, anesthesiologists are able to place patients in conscious sedation, which, when performed properly, can allow the joint to be mobilized without putting the patient under general anesthesia, which also allows for end range appreciation in joints, joint capsules, and appeneuroses (Ettema & Huijing, 1990). In fact, there are really no facilities that I know of in the country that are still inducing general anesthesia for this procedure. That change alone makes for a safer physiological environment for the procedure to be completed.

Krumhansl and Nowacek in Grieve (1986) make the following comment:

> The importance of fascial lengthening, tendon stretching and ligamentous mobilization are as important as the realignment of joints. Patients with long-standing, intense pain resulting from motor vehicle accidents, industrial accidents and severe falls gradually compensate. Eventually even the 'normal' joints of the spine and proximal extremities become involved. Most frequently there develops a zig-zag pattern of muscle tightness and locked facets, either in individual segments or in groups. Manipulation under anesthesia is a final step in a long sequence of medical and physical treatments for patients who have endured prolonged and intractable pain and who have not responded to the more conventional methods of treatment. It is neither new nor revolutionary. Orthopaedic surgeons in the United Kingdom have practiced it for many years. Osteopaths in the United States have relied on its efficacy. A few American orthopaedists have incorporated this approach into their treatment regimes (Stoddard, 1969; Fisher, 1948; Mennell, 1960).

Rumney (1968) states

> Manipulative therapy to the musculoskeletal system under anesthesia has a definite place as an elective modality. Manipulation of the joints of the spine and the appendages under anesthesia has been carried out by orthopedic surgeons for many years, in both the osteopathic and allopathic professions.

Beckett and Francis (1994) reported on a controlled study of MUA completed by Chrisman, Mittnacht, and Snook (1964) that included 39 patients who all had low back pain, sciatica, and positive findings on at least one sciatic nerve stretch with at least one reflex, motor, or sensory deficit finding. Using guidelines from an earlier study by Mensor (1955), 27 of the 39 patients had positive myelograms for disc herniation. The average duration of the symptoms was 6 years, with a range of 10 days to 25 years. For their last attacks of back pain, these patients had received conservative management including heat, analgesics, muscle relaxants, bracing, flexion exercises, and rest. These patients then received MUA. A similar group of 22 patients received the same conservative care but no MUA. Chrisman, et al. (1964) reported that "the effects of the MUA were frequently dramatic and more than one half of the patients reported their sciatic symptoms lessened within 24 hours." Using Mensor's criteria (1955), Chrisman, et al. (1964) reported that 21 of the MUA patients had excellent or good outcomes at 5 to 10 months follow up, 4 patients had fair outcomes, and 14 patients had unsatisfactory results. Overall, they reported that 51% of the patients with an unequivocal picture of ruptured intervertebral disc unrelieved by conservative care had good or excellent results after MUA (Beckett & Francis, 1994). The 22 non-MUA patients did poorly (no mention of specific results or testing methods) and 16 eventually required surgery (Chrisman, et al., 1964). The findings of Chrisman, et al. (1964) were consistent with the findings of Mensor (1955) in the earlier study.

H.A. Williams (1998), past president, Council on Chiropractic Orthopedics, ACA, states the following in a three-part article in the *ACA Journal of Chiropractic*

> Manipulation under anesthesia as a procedure appears to be well within the province of chiropractic. Traditionally, chiropractics' goal has been to restore and maintain the welfare of the human body. In my opinion, MUA fits within that goal since the responsible chiropractor is concerned with appropriateness, necessity, utility, identifiable goals and objectives, utilization standards, protocols, indications, contraindications, patient needs, patient selection, patient safety, defensive practices, collaboration and a (currently limited) scientific basis (Bilkey, 1993)

P.E. Greenman (1992) observes that

> manipulation while the patient is under anesthesia is an old widely recognized procedure in musculoskeletal medicine. It is used for treating acute and chronic musculoskeletal conditions with significant biomechanical dysfunction unresponsive to conservative therapy.

C.G. Davis (1996) states:

> Manipulation under anesthesia (MUA) has been used successfully for many years in treating acute and chronic musculoskeletal conditions that have been unresponsive to other types of care. The purpose of anesthesia is to obliterate the responses to pain and the

> muscle spasm that may limit other forms of conservative care from being successful.

In the same article as above, Davis quotes Morey (1975): "manipulation with the patient under anesthesia should be performed by graduate manual medicine practitioners who have a high level of skill and have been trained in structural diagnosis and manipulative treatment." Davis goes on to expand upon the concept of being trained in manipulative therapy by specifically relating to his state of California and its interpretations of those practitioners who are educated to perform manipulations of any kind:

> The capacity to perform manipulative therapy is defined by statute and in California, manipulative therapy can be performed by a physician, including a medical doctor, an osteopath, or a chiropractor. Additionally in the state of California the Attorney General has stated that the adjustment in manipulation of hard tissue, that is bones and bony structure, is particularly a chiropractic technique. Shekelle, Adams, Chassin, Hurwitz, and Brook (1992) report from a RAND study found that 94% of the manipulative therapy performed in the United States is by chiropractors. As part of the chiropractic education there are over 600 hours of basic instruction for manipulative therapy with an additional 8 months of internship (LACC Class Catalog, 1982) with additional training in proctoring requirements to perform manipulation under anesthesia (Davis, 1996).

This statement is true relative to all chiropractic colleges and most states with regard to application by professionals who perform manipulative therapy.

Gordon (1995) wrote:

> Standard Chiropractic services include procedures which specifically move articulations to promote the healing process, increase flexibility, correct a subluxation complex and provide holistic concepts in healthcare. Chiropractic care has been healing the world for the past 100 years and has literally cured the world of many of its ills. With the introduction of MUA, we have another avenue to try if the patient falls into MUA categories before referral is necessary. The basic concept behind mobilization, manipulation, and adjusting procedures while the patient is under a sedative/hypnotic is to increase articular, ligamentus, tendenous and muscular flexibility that has not been achieved in the office routine. Standard chiropractic techniques are used but the physiological state of the patient is changed, and the procedure is done in a different environment. Even with the enhancement of physiotherapy, many cases don't respond in the office, and it's only with the physiological change that the body can respond and the fixation be altered so the patient receives relief. Many chronic cases are candidates for the MUA procedures and they tend to respond extremely well.

Gordon, Hickman, & Gray (1999) state:

> MUA has been recorded to have been successful as far back as the late 30's by the osteopathic profession. The anesthetics used were not as sophisticated, and the techniques were not what has been considered by manipulative therapy literature as site specific (Kleyhans, Terrett, Glasglow, Twomey, & Schull, 1985). The purpose of using MUA is to provide mobilization, manipulation and adjustments of the spinal motion units and the surrounding soft tissue in an atmosphere where there is a decrease in muscle splinting and contracture and where the patient's apprehension about the maneuver lessens. It is also used because the patient is more responsive to manipulative procedures than in an office setting. When used on properly selected patients it is more cost effective and more productive to the patient's return to normal lifestyle than prolonged conservative care or possible surgical intervention (Gordon, 1993).

West, et al. (1999) wrote:

> Manipulation under anesthesia (MUA) is the use of manual manipulation of the spine combined with the use of general anesthetic. The addition of anesthetic allows for the benefits of manipulation to be shared with those patients who cannot tolerate manual techniques because of pain response, spasm, muscle contractures, and guarding. MUA uses a combination of specific short lever arm manipulations, passive stretches, and specific articular and postural kinesthetic integrations to obtain a desired outcome (Gordon, 1993; Wiesel, Boden, & Feffer, 1994; Wyke, 1972).

West, et al. continue the discussion on manipulation under anesthesia by describing the anesthesiology part of MUA.

> There has been much discussion regarding the use of general anesthetic in the performance of MUA. Issues discussed include the depth of consciousness associated with general anesthesia, the inability of the patient to give pain feedback or resist over zealous manipulation, and the intrinsic guarding mechanism of voluntary/involuntary muscle fibers, which protect the elastic barrier in the conscious patient.

To address these concerns West, et al. make the following points:

> First, only highly skilled graduate practitioners who have trained in structural diagnosis and manipulative treatments should perform these procedures. And secondly, the advent of newer, short-acting, highly titratable, and completely reversible intravenous anesthetics allow for controlled anesthesia depths, preservation of patient pain response, as well as significantly reduce morbidity and mortality rates.

Several references in the above literature have related to the use of general anesthetics with the MUA procedure. As this procedure has evolved into what is practiced today, we have found that the same or better response to MUA could be achieved using conscious sedation. Most of the procedures currently done in the United States use conscious sedation. (See the "Conscious Sedation" section of this chapter.) The anesthetics utilized are short acting and can be titered to allow for patient response, yet allow for a protective level that permits the doctor to complete the manipulative technique without putting the patient at a point where tissue damage will occur. All of the articles that have been reviewed point to the fact that manipulation under anesthesia has been not only used for a number of years, but also has been investigated both clinically and scientifically. Today, with the advent of newer medications employed with anesthesia and the formation of a national association, the National Academy of MUA Physicians (1995), in October of 1995, the procedure of manipulation under anesthesia is being recognized as a real alternative to prolonged conservative care and possible surgical intervention (Gordon, et al., 1999). The National Academy of MUA Physicians has established standards and protocols for the primary practitioner doing the manipulation under anesthesia (who, in most instances, is a chiropractic physician), has established standards for anesthesia, for nursing, and for the facilities where MUA is performed. These standards and protocols have started to be endorsed throughout the United States primarily by state boards. Most of the state boards of chiropractic have adhered to the provisions in their state laws, which state that procedures taught by CCE-accredited chiropractic colleges fall within the scope of practice of a chiropractic physician. A couple of the states have adopted a policy relative to manipulation under anesthesia, directing specific language to their scope of the practice. The North Carolina Board of Chiropractic Examiners released a position statement in August 1994 that stated:

> Manipulation of a patient under anesthesia by an MUA trained chiropractor is within the scope of chiropractic in North Carolina. MUA is an exceptional combination of effective pain management procedures that has expanded the options to help relieve persistent pain. MUA is not an experimental procedure. It is well established within the chiropractic and medical communities and the utilization of MUA has been enhanced by the professional cooperation of these two procedures (Williams, 1998).

SCIENTIFIC SUPPORT

The MUA procedure is used to alter adhesions and correct joint dysfunction caused by chronic connective tissue scarring and/or joint fixation from disuse following injury or repetitive trauma causing pain. The procedure also is being employed in acute care with medical intervention to decrease the time it takes to overcome certain neuromusculoskeletal conditions. The procedure is directed at altering adhesions by stretching tissues while the patient is under conscious sedation or in concert with joint injection. The most widely accepted theory for the results obtained by using this technique is that as the practitioner uses the MUA techniques, the forces and concurrent responses to those forces cause desired changes in mechanoreceptors and, thus, neurological changes through the joints and joint capsules. By stretching the muscles surrounding the joints, adhesions that are built up in the muscle fibers from disuse in the injured area are altered to give the connective tissues and joints more mobility and, secondarily, increase flexibility. References indicate that if continuous linear force is used to prolong a period of sustained stretch, the stretch reflex in the muscle spindle, the Golgi tendon response, is reversed so that instead of an immediate counter-reaction contraction called a holistic response stretch, the muscle can be stretched into an altered disuse plastic deformans state (Alter, 1988). If the disuse or altered plastic deformans state is attained in the disuse range of the injured elastic range of the muscle(s) being stretched, there is a good chance that permanent change will occur. If this same range was achieved in the normal muscle and joint end range, plastic deformans would result in strain and potential for tearing of the muscle. But, if we consider that most muscles are in a shortened state from disuse after an injury, and that the cross-bridging normally responsible for creating muscle contraction is in a state of contracture, the ability to stretch the muscle beyond this state is a considerably significant part of the MUA technique. We feel this is occurring because the patient who undergoes the MUA procedure has a definite increase in range of motion with very little, if any, microtrauma. And if proper follow-up post-MUA therapy is performed (Gordon, 1993), the increase in range of motion is permanent in 85 to 95% of the cases (Gordon, 1993; Lindemann & Rossak, 1959; West, et al., 1999). If completed properly with the properly selected patients, MUA is one of the more gentle forms of manipulative techniques.

Reference has always been made to properly selected patients and those same references have also stressed the importance of properly trained practitioners.

> No amount of experience in the office setting will qualify a physician for manipulation of the patient under anesthesia. No hospital should permit the physician to perform such manipulation until he has been observed and has received supervision and the approval of an experienced operator who himself has been previously approved by certification and hospital proficiency standards (Siehl-Bradford, 1952).

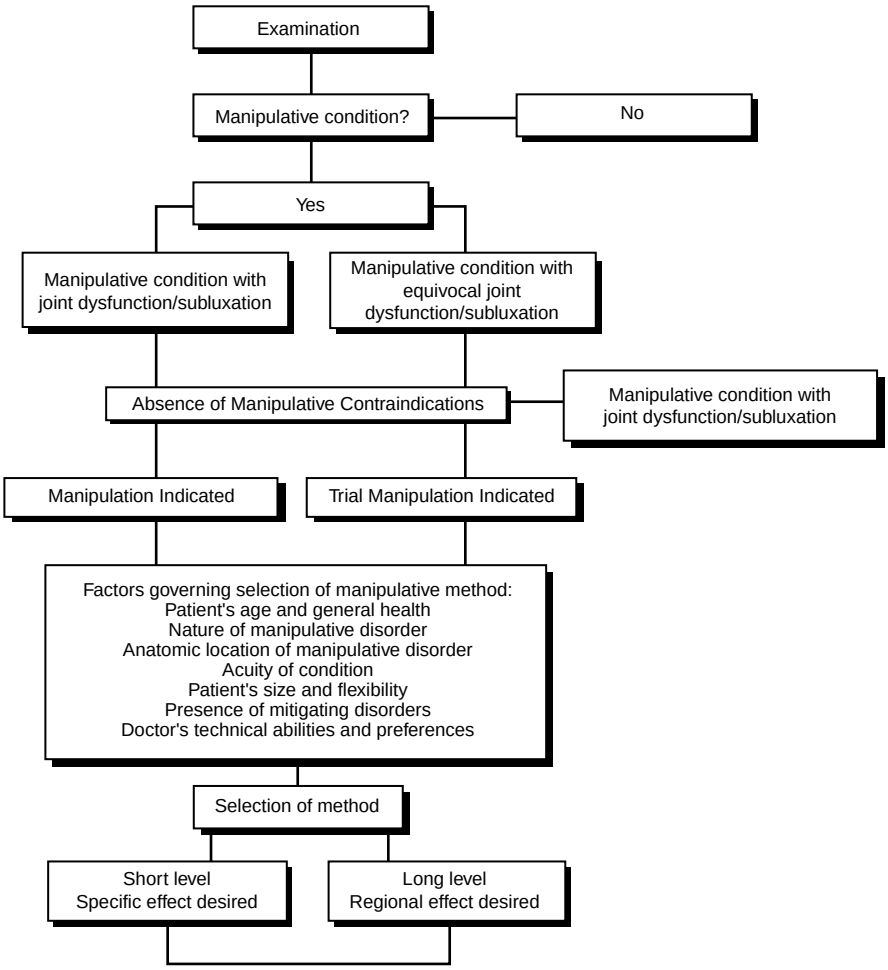

FIGURE 56.1 Spinal manipulation therapy pathway. (From Gordon, R., West, D., Mathews, R., Miller, M., and Kent, G. (1995). Standards and Protocols. Manchester, MO: The National Academy of MUA Physicians. With permission.)

The basis of change achieved when using the MUA technique makes it mandatory that the practitioner be properly trained to perform this technique. It is not a technique that just anyone can perform with success and the more training the practitioner has in the art of manipulation, the better prepared he or she is to successfully complete this procedure. In the past 40 years or so, chiropractors have had more education in manipulation than other professionals and, therefore, have also been the practitioners of choice for those considering MUA.

MUA has been used historically for both acute and chronic conditions. The concept of acute care, however, takes on a different meaning when we speak of MUA. Acute refers to severity, not time, as it pertains to MUA. By this we mean that many conditions have recurrent acute exacerbations over the course of the treatment period. This is determined by the patient's perception of pain, and is measured subjectively by the doctor using a visual analogue scale and patient questionnaire instruments. Measurement in improvement in many facilities is objectively obtained by using MRI, EMG, Functional Capacity testing, and videofluoroscopy.

The use of MUA is in itself traumatic on a microtrauma scale, and increasing the inflammation by stretching and articular manipulations during the MUA procedure would tend to increase this inflammatory response, so we don't normally use MUA on acute traumatic cases. There are instances, however, when the patient has unrelenting pain that is interfering with activities of daily living (ADLs). In these instances, the team that would provide the MUA procedure might evaluate whether the patient could be brought into the MUA program using MUJA (manipulation under joint anesthesia) to gently stretch out the areas to try and give the patient some relief through the benefits of increased circulation from passive stretching, injectable medications, and decreased inflammatory response.

The National Academy of MUA Physicians (1995) has established parameters for acute care MUA that state that MUA/MUJA is a proper progressive alternative if forms of manipulative treatment and medical

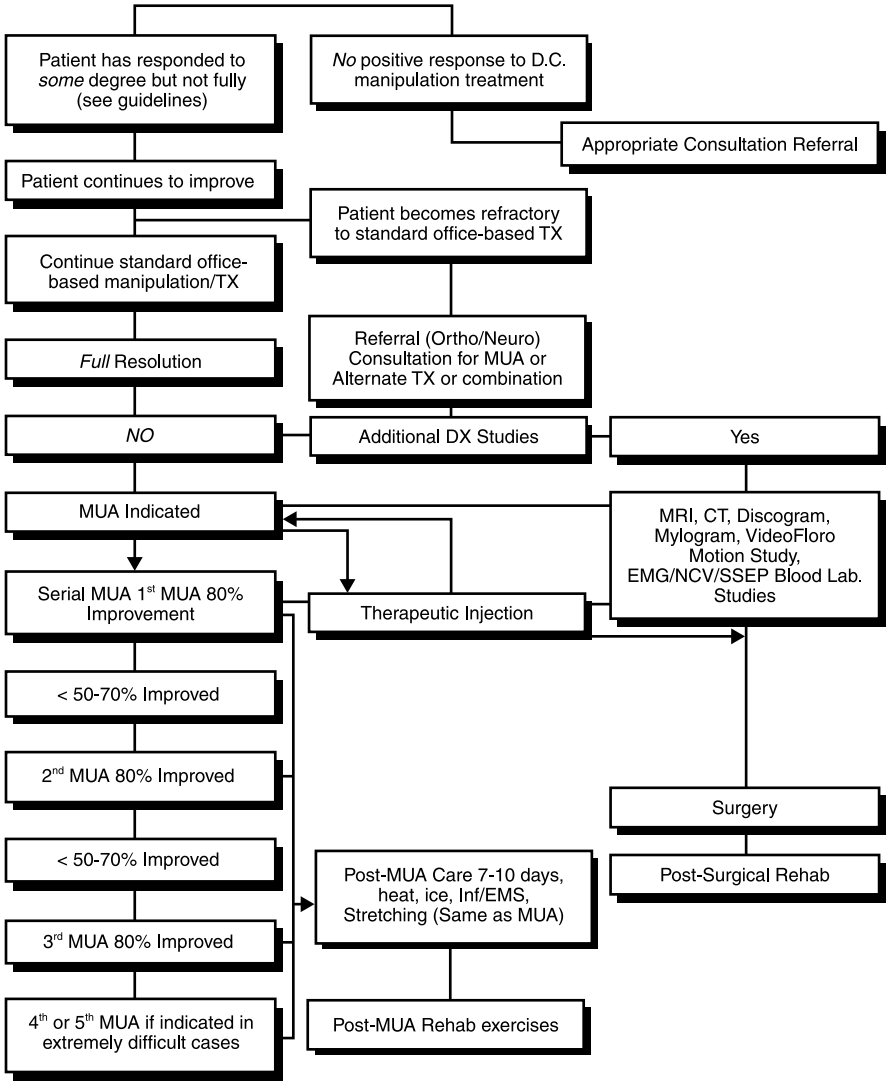

FIGURE 56.2 MUA pathway. (From Gordon, R., West, D., Mathews, R., Miller, M., and Kent, G. (1995). Standards and Protocols Manchester, MO: The National Academy of MUA Physicians. With permission.)

pharmocologic intervention for a period of 2 weeks have been tried and had little effect with minimal change and progressive deterioration. This treatment would vary from the normal MUA and involve coordination with the medical team member and involve pain management combined with manipulative therapeutics. It has been established that when this acute traumatic care stage has been reached, it usually takes only one MUJA to bring the patient back to the conservative office program (Gordon, 1993).

MUA vs. MUJA

The use of these techniques has advanced the broader based MUA technique even more in the last 4 to 5 years. MUA is a common technique for alteration of joints, joint capsules, and muscle tissue using stretching and articular manipulation under conscious sedation.

MUJA, or manipulation under joint anesthesia/analgesia, has advanced into the field in the past 4 or 5 years as an alternative to conscious sedation by using joint injection to decrease the inflammation in the joint, anesthetize the joint, and manipulate the joint to provide mobilization and flexibility while decreasing joint irritation.

Acute Care MUA

MUJA is used for acute care MUA and is being put forward by the concept that relief from intractable pain (pain, neuromusculoskeletal in origin, with no relief) could be provided by injection into the affected joint, with mobilization and manipulation used secondarily to diffuse the

injected medicine and help eliminate the inflammatory reaction in the affected joints (Dreyfuss, Michaelsen, & Horne, 1995).

Reasons for MUJA

Early mobilization of the involved joints, despite otherwise intractable pain and/or muscle spasm, reduces compressive forces on the discs, facet capsules, and nerve roots (which would cause additional scar tissue if left untreated), thereby allowing nutrients and fluids into the area of the lesion and helping the body heal itself more naturally and rapidly.

MUJA Results

In Acute Care MUA, MUJA reduces:

- Excessive scar tissue build-up
- The chance for muscle contracture
- Duration and frequency of regular outpatient spinal manipulative therapy
- The percentage of resultant permanent impairment

MUJA in Chronic Care

MUJA has been used to affect joint involvement in chronic neuromusculoskeletal conditions. Injection into the involved joint to determine the pain location has been utilized for many years as both an objective diagnostic tool and a therapeutic tool. It is employed in conjunction with the injection to improve joint mobility. The same standards of care and protocols are followed when patients are chosen for the MUJA procedure as for the MUA procedure. The conditions treated with MUJA are somewhat the same as MUA, with the exception being more joint involvement as compared to myofascial and/or muscular involvement.

The majority of MUA candidates historically have been those patients who suffer from chronic joint restriction due to fixation from disuse following trauma. This syndrome sets up a vicious cycle that Michael Alter (1988) calls the "self-perpetuating cycle of muscle spasm." In this cycle, the patient undergoes a form of trauma, which can be caused by direct contact or through repetitive incremental injuries. These injuries then set up pain stimuli, inflammation, emotional tension, sometimes infection, temperature variations, and eventual immobilization from disuse. As the cycle proceeds, it sets up reflex muscle contraction which, if gone untreated, progresses to muscle contracture. This, in turn, progresses to restricted movement and fixation in the joints, which has a direct effect on what Wyke (1972) calls "dysfunctional postural kinesthetics". Wyke refers to a disturbance in postural kinesthetics resulting in altered mechanoreceptor response. Typically, Types I, II, and IV mechanoreceptors are concurrently involved, setting up a cycle of trauma-induced altered posture affecting movement, which then stimulates nociceptive response.

Using the MUA technique, we complete stretching maneuvers and mobilization techniques coupled with specific adjustive techniques to help alter adhesion accumulation that has been laid down by the body as connective tissue protective mechanisms to prevent further damage to the areas involved. Because new medications allow us to perform this technique while the patient is in conscious sedation, we can provide progressive linear forces to these areas and alter these adhesions without tearing tissue in the process. Because these medications allow the patient to relax and not respond with immediate muscle contraction when pain is perceived, we are able to perform these maneuvers so that end range is not lost. The natural protective mechanisms are present but are slowed down temporarily, and pain is perceived, but not remembered (Gordon, 1993). By completing the MUA procedure as a team, with the anesthesiologist as a very valuable member who provides just the right medications to allow this physiological change from the normal office manipulative therapy program, the certified MUA doctor is able to accomplish considerably more with MUA than if the same patient were to undergo these procedures in the office setting without the conscious sedation. The most important concept here is that if the patient were able to recover in the office setting without the use of conscious sedation, the patient would not have been a candidate for the MUA procedure in the first place.

Serial MUA

MUA as performed today is completed in a 2- to 4-day continuous program. The procedure is repeated every day with same-day follow-up care given in the facility or the doctor's office 1 to 2 hours after the actual procedure. The reason for doing the procedure in a serial fashion is to alter the adhesion formation present during the remodeling phase of the inflammatory cycle into a phase where permanent change is made. The procedure is done in small increments each day to effect change rather than in 1 day and possibly causing inflammatory exacerbation. Kotlke (1971) indicates that if altered, an adhesion will begin to re-form in 24 to 48 hours. Serial MUA and post-MUA therapy are performed every day to prevent re-formation of connective tissue adhesions after alteration.

The MUA Procedure (Gordon, 1993)

The patient is draped in the appropriate gowning and is taken by gurney or led walking to the operative area and asked to lie supine on the operating table. The patient is then placed on the appropriate monitors for conscious sedation as established by ASA standards. When the

patient and doctor are ready, the anesthesiologist will administer the appropriate medications to assist the patient into conscious sedation using medications that allow the stretching, mobilization, and adjustments necessary for the completion of the outcome the doctor desires.

The Cervical Spine

The patient's arms are crossed and he or she is approached from the cephalad end of the table. Long-axis axial traction is applied to the patient's cervical spine and musculature while counter-traction is applied by the first assistant, who then is positioned to stabilize the patient's shoulders in order to use the counter-traction maneuver. Traction in the same manner is then applied in a controlled lateral coronal plane bilaterally, and then in an oblique manner by rotating the patient's head to 45° and elevating the head toward the patient's chest. This is also accomplished bilaterally. The patient's head is then brought into a neutral posture and cervical flexion is achieved to traction the cervical paravertebral muscles. The cervical spine is then taken into a rotatory/lateral (bone setting) traction maneuver to achieve specific closed reduction manipulation of the vertebral elements at the level of articular abnormality on one side and again using the same technique on the opposite side, if indicated, at the level of articular abnormality. During this maneuver, a low velocity thrust is achieved after taking the vertebrae slightly past the elastic barrier of resistance, and into the para-physiologic space. (Cavitation may or may not be achieved.)

The Thoracic Spine

With the patient in the supine position on the operating table, the upper extremities are flexed at the elbow and crossed over the patient's chest to achieve maximum traction of the patient's thoracic spine. The first assistant holds the patient's arms in the proper position and assists in rolling the patient for the adjustive procedure. With the help of the first assistant, the patient is rolled to his/her left/right side, selection is made for the contact point, and the patient is rolled back over the doctor's hand. The elastic barrier of resistance is found and a low velocity thrust is achieved using a specific closed reduction anterior to posterior/superior manipulative procedure. This maneuver is referred to as an anteriority adjustment.

The Lumbar Spine

With the patient supine on the procedure table the primary physician addresses the patient's lower extremities, which are elevated alternatively in a straight leg-raising manner to approximately 90° from the horizontal. Linear force is used to gradually increase the hip flexion during this maneuver. Simultaneously, the first assistant applies a myofascial release technique to the calf and posterior thigh musculature. Each lower extremity is independently bent at the knee and tractioned cephalad in a neutral saggital plane, lateral oblique cephalad traction, and medial oblique cephalad traction maneuver. The primary physician then approximates the opposite single knee from his/her position from neutral to medial slightly beyond the elastic barrier of resistance. (A piriformis myofascial release may be accomplished at this time.) This is repeated with the opposite lower extremity. Following this, a Patrick-Fabere maneuver is performed up to and slightly beyond the elastic barrier of resistance.

With the assisting physician stabilizing the pelvis and femoral head (as necessary), the primary physician extends the right lower extremity in the saggital plane, and while applying controlled traction gradually stretches the para-articular holding elements of the right hip by means of gradually describing an approximately 30 to 35° horizontal arc. The lower extremity is then tractioned straight caudad and internal rotation is accomplished. Using traction, the lower extremity is gradually stretched into a horizontal arch to approximately 30°. This procedure is then repeated using external rotation to stretch the para-articular holding elements of the hips bilaterally. These procedures are then repeated on the opposite lower extremity.

By approximating the patient's knees to the abdomen in a knee–chest fashion with the knees separated to avoid abdominal pressure, the lumbo-pelvic musculature is stretched in the saggital plane, by both the primary and first assistant, contacting the base of the sacrum and raising the lower torso cephalad, resulting in passive flexion of the entire lumbar spine and its holding elements beyond the elastic barrier of resistance. With the patient's lower extremities kept in hip/knee flexion, the patient's torso is secured by the first assistant and the lumbar fasciae/musculature elongated obliquely to the right of midline, in a controlled manner up to and beyond the elastic barrier of resistance. (Cavitation may be noted.) This is repeated on the opposite side.

With the use of the undersheets, the patient is carefully placed in the left/right decubitus position and positioned so that the lumbar spine overlays the kidney plate to the point where the lumbar spine attains the horizontal, and is derotated to avoid facet imbrication. The patient's body is stabilized by the first assistant. The knee and hip of the upper leg are flexed and the lower leg stabilized in the extended position by the first assistant. Segmental localization of the appropriate lumbar motion units is made by the primary physician and the elastic barrier of resistance found. A low-velocity impulse thrust is applied to achieve cavitation. (If desired, the PSIS is then adjusted on the opposite side with the patient in the same position as above.)

The patient is then repositioned supine by means of the undersheets. With appropriate assistance, the patient is transferred from the procedure table to the gurney and is returned to the recovery room, where appropriate equipment is utilized to monitor vital signs. The IV is maintained up to the point where the patient is fully alert and stable, and the patient is then transferred to a sitting recovery position and given fluids and a light snack. Following this, the patient is discharged with appropriate home instructions (Gordon, et al., 1999; Gordon, 1993). (Note: It must be emphasized that all pathology has been ruled out, and proper patient selection has taken place.)

CONSCIOUS SEDATION*

This is a brief overview of conscious sedation, which is used in the MUA and MUJA procedures. It is not intended as an anesthesia "how to" course but instead provides an understanding of the term "conscious sedation" and the usual medications used in delivering this type of anesthesia.

Pre-Operative Considerations

Anesthesia can be divided into 3 classifications: general anesthesia, MAC (monitored anesthesia care), and local. General anesthesia is placing the patient into an altered level of consciousness so that his/her vital reflexes are severely depressed or absent. The patient is usually unconscious, cannot cooperate, and is prone to airway obstruction. Local anesthesia consists of injecting local anesthetic agents into the area to be operated on. MAC can be both conscious or unconscious sedation and can be a continuum between the two; however, the goal for MU(J)A is conscious sedation.

Conscious sedation is produced by the administration of pharmocologic agents. A patient undergoing conscious sedation has a depressed level of consciousness but retains the ability to independently and continuously maintain a patent airway and respond appropriately to physical stimulation and/or verbal commands. The medications and dosages utilized for conscious sedation are not intended to produce deep sedation or loss of consciousness. Practitioners of conscious sedation should be ACLS trained and comfortable with airway management and resuscitation.

The objectives of conscious sedation are altering of the level of consciousness and mood, maintaining consciousness and cooperation, providing relaxation and amnesia, and elevating the pain threshold, with minimal variation of the patient's vital signs. The patient should be easily aroused from sleep, have purposeful responses to verbal communication and tactile stimulation, and should be able to return to ambulation in a short period of time, with the duration of amnesia also falling within the duration of the procedure.

The undesirable effects that one is trying to avoid are a deep unarousable sleep, respiratory depression, airway obstruction, apnea, decrease in vital signs (bradycardia, hypotension, etc.), agitation and combativeness, and loss of pain reflexes.

Pre-procedural evaluation of each patient is mandatory and can be done by the patient's primary care physician and/or anesthesiologist. Acute, unforeseen medical problems can arise previous to the procedure or even the day of the procedure and may necessitate postponement. However, standard pre-operative practices should be in place that allow for the identification of chronic conditions or significant items in the patient's medical history, which can then be addressed prior to the day of the procedure. The patient should have a complete medical history and physical including drug allergies, previous experience with sedation and/or anesthesia, pertinent laboratory and X-ray results, and medications the patient is taking. The patient will then be given an ASA (American Society of Anesthesia) classification, which ranges from Class 1 to Class 6. Most patients will fall between Classes 1 to 3 (1 = normal health, 2 = mild systemic disease, and 3 = severe systemic disease).

The day of the procedure, the patient will be seen by the anesthesiologist and all data will be reviewed including the patient's NPO status. If everything is in order, the patient will be taken to the operating or procedure room and placed on the procedure table. Monitors including blood pressure, EKG, and pulse oximetry will be placed. IV access will be established so that the sedating agents can be given. After baseline vital signs have been established, the patient will begin to be sedated and the procedure can then begin. The sedation is usually accomplished by a combination of benzodiazepines, narcotics, and ultrashort-acting hypnotic agents. Variability in pain tolerance and medication requirements is great, and the range of responses to the various medications can be dramatic; therefore, titration of the various agents is the key to optimum sedation.

Pharmacology of Medications (Commonly Used Sedating Agents)

Benzodiazepines provide sedation and amnesia but are not analgesic or anti-emetic. The common medications in this class in order of duration are midazolam (Versed), diazepam (Valium) and lorazepam (Ativan). The adverse effects are respiratory depression, hypotension, bradycardia, and hypoventilation and are potentiated by narcotics.

Narcotics provide analgesia and this is more pronounced if given before a painful stimulus. The common medications in this class in order of duration are Alfentanil, fentanyl (sublimaze), meperidine (Dem-

* Contributed by Anthony Rogers, M.D.

erol), and morphine. The adverse effects are respiratory depression, apnea (potentiated by benzodiazepines), bradycardia, hypotension, pruritis, nausea/vomiting, and urinary retention.

Barbiturates provide sedation and hypnosis. The common medications in this class are propofol (diprivan), methohexital (brevital), and ketamine (dissociative agent). The adverse affects are respiratory depression, apnea, tachy/bradycardia, hypotension, and pain on injection.

There are two reversal agents in use, one for the narcotics and one for the benzodiazepines. The duration of action is usually shorter than those being reversed, so caution should be given to resedation and the patient should be closely monitored. The agents are naloxone (narcan), which is used in the reversal of narcotics and flumazenil (romazicon), which is used in the reversal of benzodiazepines. There is no reversal agent for the barbiturates.

The post-operative course should be short if the sedation was titrated and the shorter-acting agents were used. With a combination of versed and propofol most patients are awake and alert within 5 minutes after the procedure and are able to be discharged within the shortest period of time, usually a half hour, but this may vary from center to center.

ANESTHESIA RECORD*

A standard example of a medication dose record might be

Sex: Male	Chief Complaint: Cervicogenic Headaches
Age: 44	Paracervical myospasm
Wt.: 187 lbs.	Paralumbar myospasm
	Lumbar disc dysfunction
Nonsmoker	Nature of Condition: Chronic
NKA Treatment Modalities:	SMPT; PT; Pharmacological intervention; 3 Epidurals
No Prescription or OTC Meds	
ASA Class 1	
No Relative Med. Hist.	
Onset: MVA–4/20/96	
Anesthesia Record:	40 mg propofol
	50 mcg fentanyl
	2 mg versed

Patient was supplemented with 20 mg propofol one time during the 15-minute procedure.

The usual initial dosage range for MUA at this facility has been

25–50 mg propofol
50–100 mcg fentanyl
0–2 mg versed

Supplemental doses of propofol vary depending on patients weight and response and are titered accordingly.

INDICATIONS AND CONTRAINDICATIONS

The indications and contraindications for MUA are based on conditions that would ordinarily be indicated for manipulation or contraindicated for manipulation. The addition of contraindications for anesthesia becomes part of the equation because of the use of manipulation with conscious sedation. The following list is composed of conditions that have been recorded historically as successfully treated with MUA, or have been contraindicated for the use of MUA. The list is evolutionary; as more becomes known about this procedure, both parts of the list will grow in length.

Indications	Contraindications
1. Bulging protruded, prolapsed, or herniated discs without free fragment and not surgical candidates	1. Any form of malignancy 2. Metastatic bone disease 3. TB of the bone 4. Acute bone fractures
2. Frozen or fixated articulations	5. Direct manipulation of old compression fractures
3. Failed low back surgery	
4. Compression syndromes with or without radiculopathies caused from adhesion formation, but not associated with osteophytic entrapment	6. Acute inflammatory arthritis 7. Acute inflammatory gout. 8. Uncontrolled diabetic neuropathy
5. Restricted motion, which causes the patient pain and apprehension, but manipulation is the therapy of choice	9. Syphilitic articular or periarticular lesions 10. Gonorrheal spinal arthritis 11. Advanced osteoporosis (as indicated diagnostically)
6. Unresponsive to manipulation and adjustment when they are the treatment of choice	12. Evidence of cord or caudal compression by tumor or disc herniation (Note: Use a 5~~8~~ mm in L/S bulge or 3~~5~~ mm in C/S as a guide for further investigation prior to recommending MUA in these areas.)
7. Unresponsive pain, which interferes with the function of daily life and sleep patterns but falls within the parameters for manipulative treatment	
8. Unresponsive muscle contracture that is preventing normal daily activities and function	13. Osteomyelitis 14. Widespread staph/strep infection

* Case presented courtesy of The Center for Special Surgery at Hawthorne, John Tauber, Administrator; Dave Hershan, M.D., Anesthesiologist.

9. Post-traumatic syndrome injuries from acceleration/deceleration or acceleration/deceleration types of injuries which result in painful exacerbation of chronic fixations
10. Chronic recurrent neuromusculoskeletal dysfunction syndromes, which result in a regular periodic treatment series and are always exacerbation of the same condition
11. Neuromusculoskeletal conditions that are not surgical candidates but have reached maximum medical improvement (MMI), especially with occupational injuries
15. Sign/symptom of aneurysm
16. Unstable spondylolysis

COMPLICATIONS

As with any procedure, when addressing the safe and effective nature of the procedure, it is also necessary to discuss complications from that procedure as well as concern regarding those complications. Phil Greenman (1992) states that

> temporary flare-ups of symptoms after the procedure have been reported by several patients. This flare-up is attributed to stretching of the adhesion and mobilization of inflamed soft tissue joints. It is easily controlled with appropriate post-operative care. Serious complications have been rare.

He quotes Poppen (1945) who reported in 1945

> two cases of paralysis after manipulation by competent orthopedic surgeons with the patient under anesthesia. This complication occurred in a population of 400 cases of intervertebral disc disease. It appears that serious complications can be avoided by appropriate patient selection, suitable operative technique by a competent practitioner, and consideration for the contraindications and potential complications.

Davis (1996) notes:

> because of the range of possible adverse reactions, cases must be carefully selected. (Referring to cervical MUA) Success is directly related to the skill of the anesthesiologist in providing the appropriate sedation and the operator's manipulative skills. Data on complications from cervical MUA are not available. However, the relevant values for severe complications for all cervical manipulations have been estimated at between 1 in 380,000 to over 1 in one million (Eder & Tilscher, 1990; Terrett & Kleynhans, 1992). Deaths from chiropractic cervical manipulations are rare (Terrett, 1988). General anesthesia has a higher risk of about 1 death per 200,000 for ambulatory surgery (Liu, 1992). Though it is possible that the vertebral artery can be compressed or damaged with manipulation throughout the cervical spine this has generally been reported in the first three segments. Between the C1-C2 transverse process the vertebral arteries are relatively fixed at the C1-C2 transverse foramen, therefore rotation will produce stretching of the vertebral artery. At C2-C3 level, compression may be due to superior articular facet of C3 on the ipsilateral side of head rotation, and the C1 transverse process can compress the internal carotid artery. An important point to make here is that lateral flexion on the neck apparently has little effect on vertebral artery blood flow in most cases suggesting little stress on the artery.

The procedure of manipulation under anesthesia of the cervical spine is completed with low-velocity, high-amplitude thrusting procedures that put very little torsion into the cervical spine. The primary focus of MUA in the cervical spine is axial and lateral tractioning and oblique tractioning with articular cavitation occurring generally during the stretching maneuvers (Gordon, et al., 1999; Gordon, 1993). Also, currently, with the use of conscious sedation rather than general anesthesia the patient is able to discern pain, although neuro-perception is slowed down, and retain end range of muscles and joints during the MUA procedure. This allows for full stretching maneuvers and articular cavitation without the inherent risk of vertebrovascular accident, tissue rupture, or joint dislocation. Patients also have undergone prerequisite conservative care for at least 4 to 6 weeks and usually several months prior to having an MUA. Because the force form of manipulation is high velocity, low amplitude, if damage to the spinal segments, vertebral arteries, or tissue were going to occur, it certainly would have happened during the first manipulative therapy program. Again, this is why a regime of conservative manipulative therapy before considering the MUA procedure is recommended and also why there are very few recorded instances of tissue damage, injury, or CVAs from MUA. As with any technique using forms of anesthesia, there are inherent risks that are part of this procedure. But historically there have been very few reports of damage from the MUA procedure and most of those were either from medication reaction or because the procedure was performed by uncertified, unskilled practitioners.

The safety and the effectiveness of manipulation under anesthesia have been widely proven by clinical documentation. The above-referenced articles and information all relate to the educational standards necessary to perform this procedure, proper patient selection for the procedure,

and then proper follow-up care once the procedure has been completed. The standards also apply to physician training to provide proper diagnostic and examination procedures prior to having the patient undergo manipulation under anesthesia. If all of these areas are followed properly, the MUA procedure is safe to perform. It has been completed on several thousand patients and the effectiveness has greatly outweighed any minimal risks from the types of anesthesia used. All of the malpractice insurance carriers for the chiropractic profession, the osteopathic profession, and the medical profession cover these types of physicians for MUA. If there were any question regarding the safety and effectiveness of this procedure, insurance carriers would not cover physicians under malpractice parameters.

Pulsed Signal Therapy: A Practical Guide for Clinicians*

Richard Markoll, M.D., Ph.D.

> Before the next century is out of its infancy, physics will be as important in the treatment of disease as pharmacology and biotechnology are today. ... The future holds exciting and rewarding prospects for those ... who use their diverse knowledge and skills as teams to forge the principles for a new era of medical therapeutics. Without interdisciplinary effort, however, success will be elusive. ... Herein lies our challenge.
>
> C. Andrew L. Bassett

A DESCRIPTION OF THE SERVICE

The development of Pulsed Signal Therapy (PST™) was initiated 3 decades ago following proof that pulsed electromagnetic fields (PEMF) could promote the healing of bone fractures and reports that they could also relieve pain due to osteoarthritis and traumatic joint damage. Because most of these latter claims were based on anecdotal observations and different PEMF devices had varied characteristics, an effort was made to determine whether a pulsed electromagnetic field with specific parameters might provide superior and more consistent results. The normal stimulus for cartilage production and bone formation results from piezoelectric signals that generate a "streaming potential" in the extracellular matrix when skeletal structures are subjected to physical pressure. Bones that are immobilized in a cast for long periods of time become demineralized, and conversely, it has been shown that regular exercise helps build stronger bones. Because this restorative electrical signal is impaired in osteoarthritic joints, it seemed logical to attempt to define and accurately reproduce this natural physiologic stimulus so that similar benefits could be achieved in affected tissues not subjected to any load. Basic science research that focused on physical chemistry as well as clinical trials conducted between 1973 and 1988 confirmed the validity of this approach. Since then, the ability of PST to relieve osteoarthritic pain and improve mobility has been unequivocally verified in double-blind and open label clinical trials of over 100,000 patients with osteoarthritis of the knee and other joints. This noninvasive treatment is not associated with any pain or discomfort and long-term follow-up confirms sustained efficacy as well as an absence of any adverse side effects.

More recently, PST has been found to be effective in temporomandibular joint syndrome (TMJ), tinnitus, which is difficult to cure, and periodontal disease, an established risk factor for heart attack and stroke. PST is currently administered at over 500 sites in 16 countries, where it is reimbursed by fiscal intermediaries and governmental agencies because of its proven cost effectiveness and safety record. Many facilities are located in clinics associated with academic medical institutions or respected hospitals, such as The American Hospital in Paris. PST presently is approved only for veterinary use in the United States.

* The Publisher and American Academy of Pain Management cannot assume responsibility for the validity of all materials contained in this chapter or for the consequences of their use. Pulsed Signal Therapy is presently approved only for veterinary use in the United States.

The PST device consists of a control box connected to a ring-shaped coil that emits a proprietary pulsed electromagnetic field. Different coil sizes have been developed to treat peripheral joints (knees, shoulders, and wrists), the spine (cervical, thoracic, and lumbar vertebral bodies), tinnitus and dental disorders, and for veterinary applications as illustrated in Figures 57.1 through 57.4.

The joint to be treated is placed inside the coil and exposed to PST, usually for 1 hour on 9 consecutive days, interrupted only by a weekend. It is important to emphasize that PST is a patented procedure that should not be confused with PEMF devices that make similar claims but have scant supportive scientific clinical or basic research data

FIGURE 57.1 Osteoarthritis of the knee.

FIGURE 57.2 Tinnitis.

THE HISTORY OF THE SCIENCE

The Yellow Emperor's Canon of Internal Medicine, which dates back 4000 years, describes how lodestones applied to acupuncture points could be used to relieve pain. Cleopatra allegedly wore one on her forehead while sleeping to prevent aging. In the Middle Ages, lodestones were also ground up to make powders to be applied as a magnetic salve to promote wound healing. Paracelsus believed they could be ingested to treat everything from diarrhea and epilepsy to various types of hemorrhage. By the middle of the 18th century, more powerful carbon-steel magnets that could be made in different shapes corresponding to any organ or structure in the body that required treatment became available. Magnet mania swept through Europe and France due to Mesmer, who used various magnetic paraphernalia in his salon to increase the flow of "animal magnetism," which could cure anything. Although Mesmer was discredited, the popularity of magnets steadily increased in the United States. By the beginning of the 20th century, magnetic insoles, rings, belts, girdles, caps, and other apparel were sold to cure everything from athlete's feet and baldness to menstrual cramps and impotency. The use of magnets to relieve pain declined with the advent of drugs and surgical procedures that could provide proven benefits. Over the past decade, they have become popular again because of stronger and smaller neodymium products that are easier to apply, and aggressive marketing by manufacturers eager to capture part of the estimated billion dollar worldwide market. While some studies do suggest that permanent magnets may relieve the pain of diabetic neuropathy, post-polio syndrome, and carpal tunnel syndrome, the action mechanism is obscure and there is little evidence of sustained benefits.

It is not clear when electricity was initially used to treat illness, but the electric catfish, which is indigenous to the Nile, is portrayed in Egyptian mural paintings that date back to 4000 B.C. The first recorded medical application was in 46 A.D. by Scribonius Largus, a Roman physician who used a live torpedo fish to treat a patient with gout, and who also wrote that headaches and other pains could be cured by standing in shallow water near these electric fish. The powerful South American electric eel was introduced in Europe in 1750 and people flocked to be treated with its "natural" electricity. The invention of the Leyden jar around the same time dramatically demonstrated the ability of stored electricity to produce muscle contractions, and as batteries were progressively improved during the 19th and early 20th centuries, numerous types of "medical coils" increasingly appeared. Electromagnetic therapy was viewed as a legitimate subspecialty, much like the rapidly growing fields of

FIGURE 57.3 TMJ and periodontal disease.

FIGURE 57.4 Veterinary applications.

radiology and radium therapy and was used by over 10,00 physicians and countless others to treat almost every typ of pain or functional complaint. There were numerous instruments with names like "The Dynamiser" and "Oscil-loclast", based on theories that each organ and person we "tuned" to a specific wavelength that could rejuvenate them. Claims were frequently made by charlatans to promote the sale of worthless devices. The 1910 Flexner report, which stated that there was no scientific basis for any of these outlandish and fraudulent claims, and the introduction o X-ray and electrocautery instrumentation that provided proven benefits, led to their gradual demise. However, as with permanent magnets, there also has been a recent res gence of various types of "electromedical" devices that continue to make unsupported claims.

Pulsed electromagnetic fields have been used to tre nonunion bone fractures for several decades, with a rela-tively consistent success rate of 70 to 80% in several countries. (Bassett, Pilla, & Pawluk, 1977; Brighton & Pollack, 1985). In 1979, the FDA approved certain PEMF devices for the treatment of fractures that failed to unite satisfactorily within 9 months. This approach has bene-fited hundreds of thousands of patients including some where nonunion had persisted for 15 or more years despite surgical and other interventions. In 1990, approval was granted for failed spinal fusions of any age.

PST is based on the application of a very specific type of pulsed electromagnetic field to bone and adjacent tis-sues. The PST device generates a pure magnetic field out-put signal that employs direct current with unidirectional biological frequencies below 30 Hz. The "waveform" is quasi-rectangular with measured field strengths generally below 2 mT or 20 Gauss. The system is controlled through a pulsed unidirectional magnetic DC field with multiple output frequencies implemented via a free-wheeling diode to optimize the inductance characteristics. Various fre-quency/amplitude combinations are switched over auto-matically and transmitted under continuous control during the treatment period. Induction of treatment takes place during the first 10 minutes, followed by a combination of pulsed signals that delivers the therapy over the remaining 50 minutes. PST differs from conventional alternating-cur-rent magnetic field therapies such as the Krause-Lechner type system as illustrated in Figure 57.5.

This system coil delivers an alternating-current magnetic field that generates a sinusoidal waveform. This signal does not conform with what normally takes place in the body, because electrical activities in all living organisms follow only direct-current-oriented processes. PST also differs from other pulsed electromagnetic field (PEMF) approaches that utilize a direct-current-oriented signal transmitted at a spe-cific intensity and a particular frequency that remains con-stant during treatment, as illustrated in Figure 57.6.

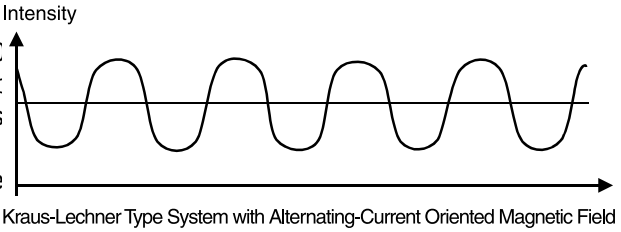

FIGURE 57.5 Krause-Lechner type system.

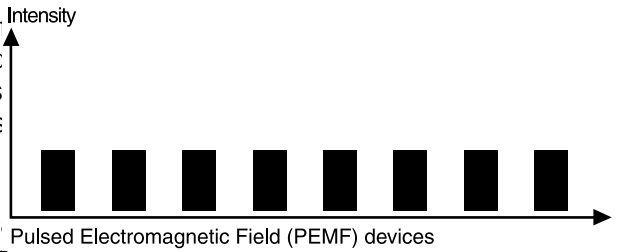

FIGURE 57.6 Conventional PEMF.

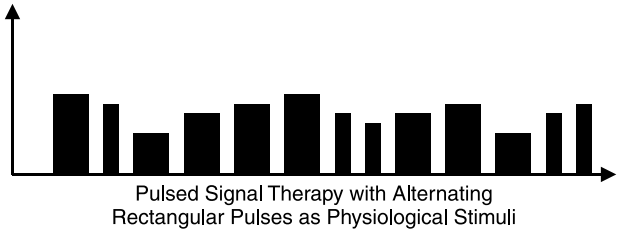

FIGURE 57.7 Pulsed signal therapy (PST).

While standard pulsed electromagnetic field devices do deliver a direct current signal, it never varies in either amplitude or frequency, which is also inconsistent with electrical signaling in living organisms. In contrast, pulsed signal therapy delivers changing pulsed electromagnetic signals in an alternating fashion that mimics signals generated in the body that are known to stimulate chondrocyte activity. The intensity of these rectangular pulses lies predominantly in the range of 0.5 to 1.5 milliTesla with relatively low frequencies that range from 10 to 20 Hz, as shown in Figure 57.7. The low biological frequencies and energy field strength at which PST operates is in a physiologic range, which helps explain why treatment is both effective and safe.

The most important distinction between patented PST and other electromagnetic therapies that are often in the public domain lies in proprietary specific amplitude, frequency, and repetition parameters. These have been designed to simulate physiological electrical signals in order to reproduce their biological benefits. PST's patented signal (pulsed DC magnetic field 0.28 W., max. 20 gauss; 5–24 Hz; quasi-rectangular waveform) is the only electromagnetic stimulus with proof of efficacy in rigorously controlled clinical trials, as well as safety based on long-term follow-up. In sharp contrast to other devices making similar claims, the proposed mechanisms of action also are supported by extensive in vitro and other basic science research studies. The studies of Gierse, Breul, Faensen, and Markoll (in prep.). demonstrated that human chondrocyte cell cultures exposed to the specific electromagnetic fields generated by PST attained statistically significant higher mitosis rates than chondrocytes in untreated cultures (nearly twice that of the control group). Nerucci, Marcolongo, and Markoll (2000) demonstrated that PST enhances proteoglycan concentration in human chondrocyte cultures. These in vitro findings support one of the proposed action mechanisms believed to be responsible for the benefits of PST as illustrated in Figure 57.8.

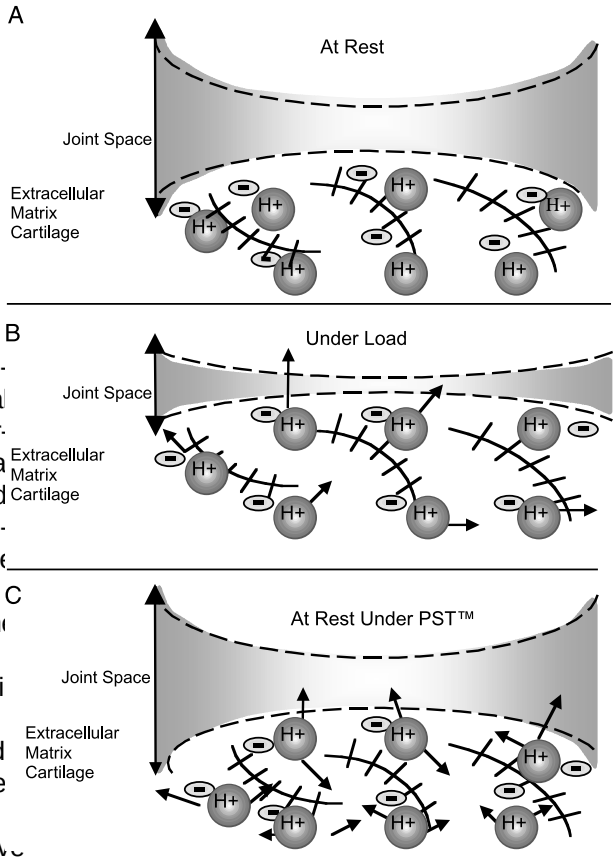

FIGURE 57.8 Action mechanism of PST. (A) Extracellular matrix at rest. An equilibrium exists between hydrogen and negative charges in the extracellular matrix, and there is no streaming potential of ionic flux as in (B) and (C). (B) Extracellular matrix under pressure. When the joint space is compressed as a result of physical pressure, a streaming potential is created as fixed negative charges in fluid are forced out of hydrogen protons to move into the joint space. (C) Extracellular matrix, as in (A), with PST. A similar streaming potential can be generated in the resting state by PST. This is from the forced movement of hydrogen protons, which results in alternating energies stimulating chondrocytes in matrix connective tissue. PST stimulates physiological streaming potentials as in (B).

NEED FOR THE THERAPY

Osteoarthritis currently affects 20.7 million Americans and its prevalence is expected to increase to 40 million within the next 20 years. It is responsible for 7 million physician visits and 3 million hospitalizations per year, with annual medical costs averaging $2655.00 (Gabriel, Crowson, Campion, & O'Fallon, 1997). Sales of products to treat osteoarthritis in the world's seven major pharmaceutical markets (United States, France, Germany, Italy, Spain, United Kingdom, and Japan) totaled approximately $1.6 billion in 1998, and according to one recent report, are forecast to leap to more than $4 billion in 2008 (The Marketletter, 1999). Nonsteroidal anti-inflammatory drugs (NSAIDs) are among the most commonly prescribed medications in the United States, accounting for more than 70 million prescriptions per year. Approximately 14 to 20 million patients take an NSAID on a daily basis (Statistical Bulletin, 1992). This figure is not inclusive of over-the-counter use of nonste-

roidal anti-inflammatory drugs, estimated to be greater than 26 billion tablets per year. This number has grown steadily since NSAIDs first became available without a prescription in 1983, and as the use of aspirin as a cardioprotective agent has increased.

According to the Food and Drug Administration, NSAIDs cause more adverse drug reactions than any other class of drugs. Harmful kidney, central nervous system, and hematologic effects can occur, but gastrointestinal (GI) complications are far and away the most common and serious. The prevalence of endoscopic evidence of gastric ulceration is estimated at 10 to 20% and most of these patients have no prodromal symptoms or warnings that there is any problem (Hochberg, et al., 1995; Henrietta, 1999). There are approximately 200,000 hospitalizations a year due to NSAID-related GI bleeding and ulcer complaints. Up to one in ten patients taking NSAIDs will suffer some serious gastrointestinal complication causing 70,000 hospitalizations and 10,000 to 20,000 deaths each year (Fries, 1991). The economic impact of these complications has been estimated at approximately $1.5 to 4 billion annually (Smalley & Griffin, 1996; Smalley, et al., 1996). The significance of this is underscored by the advent of COX-2 inhibitor NSAIDs, which have fewer GI complications but are not significantly more effective in relieving pain and are much more expensive. Both Celebrex® and Vioxx®, the only two currently approved in the United States, easily surpassed Viagra® as the best-selling medication within the first 12 months of their introduction.

Numerous nonprescription drugs and nutritional supplements for the treatment of osteoarthritis are popular and a variety of medical and surgical approaches are also available. Some of these are summarized and compared to PST in Table 57.1.

This is not intended to be a comprehensive list of therapies for osteoarthritis but rather an indication of the diverse treatments available. For example, as this chapter was being completed, there was a report that Cat's Claw, a popular herbal treatment, had been shown to be equally or more effective than a prescription NSAID for osteoarthritis in a European double-blind study. However, the drug is not available in the United States and there are other questions about the validity of the study. Similarly, permanent magnets are widely used to treat pain but I am not aware of any studies showing them to be effective in osteoarthritis. It is important to emphasize that unlike PST, most of these and other popular remedies provide inconsistent benefit and must be used on an ongoing basis.

Joint and adjacent soft tissue damage due to trauma is also a huge and growing problem that responds to PST. According to the Institute for Preventive Medicine in Ann Arbor, Michigan, "Sports injury is the most under-recognized major public health problem facing the world community. In addition to being an enormous public health issue, injuries continue to usurp our limited healthcare financial resources" (Nicholl, Coleman, & Williams, 1995). Numerous reports confirm that joint pain resulting from some sport injury affects millions of people of all ages all over the world. In England and Wales alone, there are 29 million sports incidents per year that require new or ongoing treatment (Bijur, 1995). An Albert Einstein College of Medicine study estimates that every year there are close to 4.5 million sports and recreation injuries to American children and adolescents alone (Madhok, 1993).

INDICATIONS AND CONTRAINDICATIONS

While the vast majority of clinical trials have been devoted to osteoarthritis, PST also has been found to be effective in relieving pain and disability due to trauma, temporomandibular joint disease, tinnitus, periodontal disease, carpal tunnel syndrome, osteoporosis, tendonitis and convalescence following surgical repair of ligaments, fresh bone fractures, aseptic necrosis, fibromyalgia, sciatica, post-polio syndrome, migraine, metatarsalgia, acute burns, immune deficiency disorders, drug resistant epilepsy, diabetic neuropathy, herniated disc and Dupuytren's Contracture, as are discussed in the following section. There are no known contraindications to pulsed signal therapy, and it has been used successfully in hemophiliacs with joint problems. Although there are no reported adverse effects in patients who are pregnant or have implanted pacemakers, treatment is avoided because of potential medical-legal problems.

RESULTS TO DATE

Double-blind clinical trials and other open label randomized studies conducted in the United States, Canada, France, Italy, and Germany over the past decade are summarized in Table 57.2. The protocol initially used 30-minute treatment periods for 18 days, but it was subsequently found that a 1-hour treatment for 9 days was more effective. Administering therapy for 1-hour twice a day for 5 successive days because of time constraints also has had good results, but there are insufficient data to determine whether this might be a satisfactory option.

The initial double-blind studies in the United States were conducted in three treatment centers and reported in the Journal of Rheumatology (Trock, et al., 1993; Trock, Bollet, & Markoll, 1994). Pain was evaluated using WOMAC and later OMERACT III validated instruments of outcome measures. Functionality was measured using WOMAC and modified Ritchie scales, as well as global evaluations of improvement by the patient and examining

TABLE 57.1
Osteoarthritis Treatment Modalities Compared with PST

Treatment Common Home Remedies	Duration of Relief	Adverse Side Effects
	External Application	
Heat	Several hours	None
Heat and cold	Several hours	None
Paraffin baths	Several hours	None
Rest and exercise	Several hours	None
Capsaicin (hot pepper)	Variable duration when effective	Burning sensation at site of application
Dimethyl sulfoxide (DMSO)	A few hours	Garlic odor to breath
	Oral Administration	
Glucosamine; chondroitin sulfate preparations	Effective for several hours in some double-blind studies but not others; must be taken continuously	Concerns about possible development of insulin resistance and/or diabetes
Methyl sulfonyl methane (MSM) and various herbal products	Variable and no good double-blind studies; must be taken continuously	None
Homeopathic preparations	Unknown; no good double-blind studies	None
Nonprescription NSAIDs and analgesics	2–8 hours; requires chronic administration	Gastrointestinal ulcerations, bleeding, kidney, and liver complications
	Prescription Medications	
NSAIDs	3–12 hours; requires chronic administration	Gatrointestinal ulceration, bleeding not uncommon (see text); may also affect the rate at which damaged cartilage regenerates
Glucocorticoid steroids	4–8 hours depending on dose; requires chronic administration	Fluid retention, gastric ulceration, diabetes
Codeine and its congeners	4–6 hours; requires chronic administration	Dependency and addiction
Viscosupplementation-hyaluronic acid (HA) injection	Up to 6 months	Long-term effects not known and benefits are controversial
Chondrocyte culture implantation	Variable and still experimental	Very expensive and long-term benefits or complications not known
	Surgical Procedures	
Arthroscopy	Variable depending on condition	Soft tissue, bone, and articular complications, as well as unexplained pain occur; in one study of 71 patients, there were 82 complications in 50 wrists
Osteotomy	Variable depending on condition	Negative side effects often outweigh benefits Decrease in muscle mass
Resection	Variable depending on condition	Negative side effects often outweigh benefits; rehabilitation required
Arthrodesis	Variable depending on condition	Negative side effects often outweigh benefits; loss of flexibility
Total joint replacement (Arthroplasty)	Approximately 10 years, but may be risky if done more than once	Long rehabilitation, not long lasting enough for younger people
	Electrical Stimulation	
Transcutaneous electric nerve stimulation (TENS) and cranioelectricalstimulation (CES)	Variable and requires multiple treatments if effective	None; does not affect cartilage loss which will cause pain to recur
High voltage pulsed galvanic stimulation (HVPGS), interferential electrical stimulation, MENS (minimal electrical noninvasive stimulation)	Variable but not long lasting and requires repeated treatment	None; does not affect cartilage loss which will cause pain to recur
Pulsed signal therapy	Sustained pain relief and cartilage growth continues after treatment	None

physician. It should be emphasized that only qualified physicians and health professionals are licensed to administer PST and only after they have satisfactorily completed training in our treatment protocol with each specific device. This includes detailed instructions on how to conduct a double-blind trial, as well as obtain an accurate history, and perform a thorough physical examination before and after treatment. For the past decade, all therapists also have been required to use our specially developed computer software program called "VITAL" (Visual Therapy Log) which captures all relevant follow-up details using a form of WOMAC evaluation criteria. A recent analysis of data obtained from monitoring 70,000 patients through our VITAL program confirms sustained benefit and no evidence of long-term adverse effects. Ongoing clinical studies are outlined in Table 57.3.

It should be noted that Tables 57.2 and 57.3 refer only to clinical trials dealing with osteoarthritis. Numerous studies have been performed or are in progress for a variety of the disorders.

Because PST was designed to repair and restore any type of connective tissue damage, we have explored its use in a variety of disorders including.

Trauma

In May 1990, we initiated a 4-year study of 1000 patients under the auspices of a Yale University teaching hospital in Connecticut. Several hundred patients with various sport injuries resulting from swimming, bowling, bicycling, jogging, tennis, basketball, baseball, golf, skiing, ice skating, boxing, gymnastics, handball, hockey, karate, mountain climbing, soccer, track and field, wrestling, as well as others sustained by fire and police personnel were included. Because most of the patients were relatively young and healthy, they responded very rapidly to PST compared to our experience with elderly patients with chronic diseases. Since 1996, we have developed a large number of sports-type injury clinics in Europe and Asia. Currently, PST is available to most European soccer players within their clubs' medical facilities. Following a request, PST also was made available for German Field and Track athletes at the Sydney 2000 Olympic Games.

Tinnitus

Tinnitus is a common disorder characterized by a ringing, buzzing, or other persistent sound described as everything from a teakettle's whistle to the test tone for the Emergency Broadcast System. It can have many causes, is sometimes associated with dizziness or other neurological complaints, and it is estimated that more than 50 million Americans are affected. While there is no cure, one authority believes that tinnitus patients should be treated as if they had chronic pain. In a study of 160 adults with severe tinnitus reported at a recent meeting of the American Academy of Otolaryngology, it was emphasized that subjects additionally complained of stress, anxiety, fatigue, and depression, symptoms also common in patients suffering from chronic pain, and our experience has been similar. We conducted three prospective clinical trials in Berlin, Nuremberg, and Munich, Germany using untreated patients (population at large) as a control. A total of 199 patients were treated, 128 females and 71 males ranging in age from 17 to 78 years (mean age 57 years). Patients suffering from long-standing chronic tinnitus (Grades, II, III, or IV) who had failed to respond to various types of therapies were randomly selected. Treatment consisted of 12 1-hour PST sessions conducted over a 2-week period. Using validated measurement instruments based on the accepted Goebel-Hiller Protocol developed at the University of Tübingen, all patients were evaluated before and at the end of treatment, and 6 and 12 weeks after the treatment. Data on hearing loss and other relevant parameters were also obtained. A gratifying and progressive trend of improvement was reported at the end of treatment and 6 weeks later. Final evaluation 12 weeks following treatment revealed that 26% were unchanged, 52% were very significantly improved, and 22% were now completely symptom free. No adverse side effects were reported or noted. Almost three out of

TABLE 57.3
Clinical Studies Currently in Progress

Study Design	Facility	Study Director(s)	Size	Publication	Results/Notes
Study of the clinical effect of PST in trials of the synovial liquid in osteoarthritis of the knee	Auguste-Victoria-Hospital Berlin, University of Erlangen	Detlef Schuppan Michael Faensen Richard Markoll	40	Study in progress, to be submitted for publication	Study began: December 1998 End date: December 2001
Trial of the medium-term effect of PST therapy vs. placebo in osteoarthritis of the knee	Prof. Kahan, Hospital Rangueil, Toulouse E. Vignon, Hospital E. Herriot Lyon	André Kahan	230	Study in progress, to be submitted for publication	Study began: September 2001 End date: Spring 2002

four stated that they were very satisfied and would definitely recommend PST, including some in the group who reported no change. Many in the significantly improved cohort reported a loss or diminution of high-frequency pitch ringing or replacement by a low-frequency hum that was much less disturbing.

Much larger European studies are in progress and a pilot study of 100 patients has been agreed upon in the United States. Presently, an extended multiphase clinical study, under the auspices of the Medical Director of the German Tinnitus League, is in progress. The first phase of the study was completed and evaluated at the end of 2000 and demonstrated significant results in the same etiology domain as previously observed.

Temporomandibular Joint Disorder (TMJ)

During follow-up evaluation of patients who were treated for osteoarthritis of the cervical spine, it was noted that a significant number of patients indicated that their temporomandibular joint disorder (TMJ) complaint also improved. Based on these observations, we completed a pilot study of 30 patients who reported an 80% improvement in their TMJ symptoms. Based on these encouraging results, a randomized prospective, double-blind study of 120 patients was undertaken in patients with varied TMJ complaints at five European centers. Statistically significant improvement in pain and mandibular mobility was confirmed. Another double-blind study of 102 patients at the University Dental Clinic in Greifswald, Germany, and a third study at the Freie Universität Berlin reported similar improvement. As a result of the above studies, PST was recently approved for the treatment of tinnitis and TMJ disorders by appropriate European regulatory bodies in accordance with the International Medical Device Directive and the International Organization for Standardization (ISO) 9000. I should add that following a detailed audit of our Munich facility, PST received ISO 9001 and EN 46002 certifications for standards for quality. The company also received the CE mark in 1998 after demonstrating compliance with the Medical Device Directive. The ISO 9000 is a required certification for medical devices that corresponds to FDA approval in the United States.

Periodontal Disease

An open label clinical study was undertaken in 1999 at the Rothlauf Dental Clinic in Munich, Germany. Sixty patients with chronic periodontal gum disease were enrolled. Significant improvement was documented clinically and objectively with X-ray studies in all patients. Gingival pockets were not as deep and periodontal tissue became thicker. A subgroup of patients who had a routine scraping and cleaning procedure within 2 years of receiving PST showed the greatest improvement. The objective video and/or X-ray has been described as "remarkable." A clinical study of human patients at the University of Milan is now in progress and will be completed toward the end of 2001. Ongoing studies at the University of Modena have confirmed efficacy in an animal model of periodontal disease.

Carpal Tunnel Syndrome

A pilot study involving 45 patients with intractable symptoms demonstrated relief of pain and a full return to all normal activities within 3 weeks of completing a series of treatments, thus avoiding surgery. A clinical study in the United States of patients with intractable pain is currently underway to document improvement and explore possible mechanisms of action.

Tendinitis and Ligamentous Damage

Our experience has consistently been that tendinitis due to rotator cuff injury or golfer's elbow responds dramatically within 3 weeks. A surgical procedure is the treatment of choice for repairing a torn anterior cruciate ligament in the knee, and full recovery generally requires 6 to 8 months of rehabilitation. In more than two dozen patients who received PST immediately after

such surgery, full recovery was obtained within 3 months. Meniscal tears also respond well.

Osteoporosis

In one controlled study of 100 women aged 55 to 75 with X-ray evidence of moderate to advanced osteoporosis, the mean increase in bone density was greater than 25% following PST treatment.

Fresh Bone Fractures

While most bone fractures heal within a few weeks, spiral and various compound fractures may require casting and extensive rehabilitation for more than 3 months. We have treated a wide variety of fresh fractures, and our experience has been that the time required for casting is reduced by more than half.

Aseptic Necrosis

Aseptic necrosis of bone is a painful problem that does not respond to medication. Surgery is costly, usually only partially effective, and entails a long period of convalescence. We have treated aseptic necrosis since 1990, and in one study of 17 patients, 15 showed marked improvement, particularly with respect to relief of pain.

Fibromyalgia

Fibromyalgia is characterized by the constant presence of widespread pain so severe that it often is incapacitating. Signs and symptoms include muscle pain, aches, stiffness, disturbed sleep, depression, and fatigue. In the United States, 5 million people may be afflicted with its symptoms. It has been estimated that 15 to 20% of patients seen by U.S. rheumatologists may have fibromyalgia. The disorder shares many of the symptoms of myofascial and chronic fatigue syndrome and primarily affects women aged 25 to 50 years. Our experience has been that PST treatment relieves the signs and symptoms of fibromyalgia in over 80% of severe cases.

Post-Poliomyelitis Syndrome

Post-poliomyelitis syndrome is manifested by complaints of joint pain and difficulty walking that may surface decades after an attack of poliomyelitis. In a study of five such patients who received a course of 18 PST treatments, all had relief of pain and ambulation was significantly improved. In one patient who had not been able to bend her ankle or walk without a marked limp for 62 years, range-of-ankle-motion returned to 60% of normal, her limp disappeared, and she was able to discard her cane and return to an active social life, including dancing.

Sciatica

Sciatica is a term used to describe severe referred pain in the leg and often due to pressure on the sciatic nerve from pathology in the lumbar region. Our experience has been that PST treatment can provide significant improvement within 2 or 3 weeks.

Metatarsalalgia

Metatarsalalgia is a general term used to describe pain in the ball of the foot due to a variety of disorders such as Morton's neuroma, or atrophy of the plantar fat pad. In more than 50 patients with metatarsalgia who had received 15 to 18 PST treatments, over 80% were pain free or only had a slight twinge once in a while.

Plantar Fasciitis

This problem is due to soft tissue inflammation in the foot which also causes severe pain when attempting to walk. Our experience in over 40 patients with nonspecific fasciitis shows dramatic improvement with complete recovery and an absence of pain following a standard course of PST treatment.

Acute Burns

A European study of 23 acute burn patients demonstrated that reepithelialization occurred in less than 50% of the anticipated time following a course of PST treatment.

Immune Deficiency Disorders

An open-label European study of 25 patients with neutropenia or pancytopenia due to immune system dysfunction showed significant improvement that persisted for up to 1 year in some instances. While anecdotal, treating hematologists were impressed with these results.

Drug-Resistant Epilepsy

Three patients with drug-resistant epilepsy were treated in an uncontrolled study. Complete neurological evaluation was obtained prior to and 1 and 3 months following PST treatment. All the neurologists concluded that their patients had experienced such significant improvement that a large pilot study is planned with a more specific protocol and parameters.

Diabetic Neuropathy

Diabetic Neuropathy is a serious complication of diabetes mellitus manifested by pain and tingling and a loss of sensation. There is no treatment for this disorder, which

often leads to severe foot infections and amputation of various portions of the lower extremities. In one study of 17 patients with well-documented diabetic neuropathy, 16 reported marked improvement and an increase in quality of life following PST treatment because they had regained the ability to engage in many daily activities that were previously difficult or impossible.

Migraine

In a pilot study of seven patients with a long history of migraine headaches, 15 PST treatments were administered over a 3-week period. A 9-month follow-up of five patients revealed a mean average of less than one attack per month per patient over this time period. These results were so impressive that a larger double-blind study is planned.

Avascular Necrosis and Ankylosing Spondylitis

This disorder also respond well to PST. We have treated 100 patients with bilateral avascular necrosis of the neck of the femur in the past 2 years, with remarkable relief of symptoms as well as objective evidence of radiological improvement. Ankylosing spondylitis is another indication for PST and treatment is targeted to the source of the referred pain rather than its location.

Back and Neck Pain

Due to herniated disk, spondylolisthesis, and other lumbosacral problems can improve significantly following PST treatment. A double-blind study of 176 patients, 81 with cervical spine and 86 with knee complaints reported in the Journal of Rheumatology (Trock, Bollet, & Markoll, 1994) reported marked improvement following nine PST sessions with an absence of pain and a return to normal activities 4 to 6 weeks following treatment.

Dupuytren´s Contracture

In its early stages Dupuytren's Contracture responds to PST and can significantly shorten the recovery period following surgical procedures.

In addition to the above, a variety of other disorders have responded to PST. In 1996, we treated a 15-year-old girl with a tentative diagnosis of osteochondritis dissecans who was unable to walk without assistance or crutches. She received the standard program of nine consecutive sessions over a 10-day period. On the 14th day, she was able to walk for short periods without crutches and progressively improved so that 3 weeks later, she was able to join a walking tour in Greece. Although advised not to participate in any strenuous hiking activities, she was able to keep up with the group climbing hills and tough terrain with no difficulty. She has not received any additional treatment, and she was able to enter a course in karate training later in 1996, and subsequently achieved Black Belt status. At present, she continues to pursue an unusually active life with no orthopedic complaints.

PREDICTIONS

This chapter began with C. Andrew L. Bassett's emphasis on the "vast interdisciplinary gap between biophysics and medicine" and the need for physicians to have more basic science education. The importance of this component has now been recognized, as relevant courses in physics are increasingly being integrated and introduced into the medical curriculum. This is vividly illustrated by the clinical benefits of PST, which is based entirely on solid physical chemistry research.

In a 1993 article, Bassett also made the following prediction:

> Against this background, it is clear that the physical control of certain pathologic states with selected time-varying magnetic fields can be highly effective, safe and economic in comparison to present treatment methods. As in vitro (tissue culture) and in vivo (animal) studies progress, substantial biomechanistic data support a rational expansion for clinical investigation to include PEMF use for speedng nerve repair for benefiting cardiac ischaemia (i.e. heart attacks), and for controlling loss of function following a cerebral vascular accident (stroke). Experimental results, also, suggest that conditions as diverse as adult onset diabetes and cancer deserve the concerted research attention of the bioelectromagnetics community.
>
> C. Andrew L. Bassett, 1993

Andy Bassett, a good friend who was very supportive of our research, unfortunately did not live long enough to see his prophecy fulfilled well ahead of schedule. Along with Bob Becker and others, he pioneered the use of electromagnetic fields for the treatment of fractures that failed to unite, and stimulated many others to explore the use of electromagnetic fields for diverse clinical disorders. Pasche (1999) has proven the efficacy and safety of low energy emission fields (LEET) for the treatment of insomnia and anxiety disorders in rigidly controlled double-blind polysomnography studies at major sleep centers. Other forms of cranioelectrical stimulation can markedly improve depression and repetitive transcranial magnetic stimulation (rTMS) has been particularly effective in patients resistant to medication. Sodi Pallares (2000) has demonstrated remarkable reversal of metastatic malignancies and

terminal cardiomyopathy with a combined magnetotherapy–metabolic regimen.

These and other observations, such as Liboff's (1985) ion cyclotron resonance studies, are difficult to explain in terms of Newtonian physics. They appear to defy the laws of thermodynamics because these feeble forces produce nonthermal effects that do not appear to involve caloric exchange. However, as Rosch and Adey (1999) have proposed, they do become comprehensible from a quantum physics perspective, and are consistent with an emerging paradigm of energy medicine that views communication in the body at a physical/atomic level rather than the current chemical/molecular model.

Life on earth evolved under constant geomagnetic influences, so it should not be surprising that all living cells, tissues, and organs are sensitive to electromagnetic systems" with specific electrical or magnetic resonance characteristics. Becker (1990) has shown that our bodies exhibit a positive polarity along the central axis, and a negative polarity in peripheral structures. He also has demonstrated that this polarity is reversed in hypnosis and anesthesia, as well as following an injury that creates a positive potential at the trauma site. He believes that this reversal of polarity generates a microcurrent of injury that is conducted through Schwann and glial cell sheaths surrounding neurons, which act to initiate repair and regenerative processes. Nordenstrom (2000) has proposed that there is a local build-up of positively charged ions following injury that creates an electrical voltage potential between opposite ions that are separated. Much as occurs in a battery, this energy can be tapped once the circuit is closed to permit the flow of electricity between these charged areas. The speed, versatility, and integration of these activities suggest the existence of the biologic equivalent of electrical systems composed of electrodes, switches, amplifiers, resistors, and capacitors that can store and regulate energy flow, which he refers to as "Biologically Closed Electrical Circuits" (BCEC). Based on this, he has developed a very effective treatment program for metastatic lung tumors that has now been replicated by others in tens of thousands of patients all over the world.

As enthusiasm for "electroceuticals" grows, there will undoubtedly be claims of other therapeutic triumphs. There are already reports of benefits for patients with everything from Alzheimer's and Parkinson's disease to multiple sclerosis, migraine, and epilepsy. Unfortunately, it may be difficult to distinguish between approaches that are authentic and promising and are supported by a scientific rationale, and others based on anecdotal reports and speculation by well-meaning but misinformed zealots. In addition, entrepreneurs and charlatans eager to cash in on the growing popularity of bioelectromagnetic medicine who may take advantage of desperate patients for whom conventional medicine has little to offer. As their efforts are shown to be worthless, there is apt to be a rising tide of resentment from the public as well as the scientific community, with the danger that the baby will be thrown out with the bathwater.

TABLE 57.4
Questions to Ask When Evaluating Electromagnetic Devices Claiming to Relieve Pain or Provide Other Benefits

1. Have rigidly supervised double-blind studies been conducted in a clearly defined and properly selected patient cohort under the auspices of a university medical center or affiliated teaching facility?
   YES___
2. Are the individuals conducting the study and the supervising Scientific Director of the organization offering the therapy qualified scientists with appropriate academic or other medical credentials, as opposed to salespeople or engineers?
   YES___
3. Have follow-up studies been performed that demonstrate long-term sustained benefits, safety, and absence of adverse side effects?
   YES___
4. Have any supportive basic science studies been performed at university-affiliated or recognized research centers by appropriately qualified scientists?
   YES___
5. Have the results of clinical trials and supportive basic science studies been published in established peer reviewed medical and scientific journals as opposed to popular lay publications, other media presentations, or self-serving press releases?
   YES___
6. In addition to Institutional Review Board approval, has an academic or other appropriate teaching facility reviewed and signed off on the study protocol and the results that were obtained?
   YES___
7. Has the device or procedure been patented, and if so, are these merely simple design patents as opposed to process patents that cover the technology?
   YES___
8. Is there a definitive database that can be made available to provide background information that explains the biological effects of the therapy being offered?
   YES____

One way to prevent this when evaluating various claims is to ask the questions in Table 57.4 and compare the responses with PST.

PST can answer a resounding YES to all of these. Our experience has been that others can respond satisfactorily to only one or two, and in some cases none. There is little doubt in my mind that bioelectromagnetic therapies will be increasingly incorporated into mainstream medicine in the millennium, if we can separate the wheat from the chaff. As Andy Bassett predicted, this has already started to occur and some current standard treatments are likely to be supplanted.

This "energy medicine" paradigm also may provide important insights into how acupuncture, homeopathy, the laying on of hands, faith healing, placebos, as well as prayer can relieve pain and provide other rewards. Pfeiffer (2000) has already demonstrated with Kirlian photography that there are marked differences in energy levels before and after treatment with PST. Similar approaches may lead to a greater understanding of how we can communicate with other living systems to improve health and harmony in nature. As Jules Henri Poincaré noted this should be the goal of the true scientist:

> The scientist does not study nature because it is useful; he studies it because he delights in it, and he delights in it because it is beautiful. If it were not beautiful, it would not be worth knowing, and if nature were not worth knowing, life would not be worth living.

ACKNOWLEDGMENT

The author wishes to acknowledge with gratitude the cooperation and participation of Professor Paul J. Rosch, M.D., President, The American Institute of Stress; Theresa K. Toohil, Ph.D., Information Management Consultant, and Stacy L. Candia, Administrative Associate.

Infrared Photon Stimulation: A New Form of Chronic Pain Therapy

Jacob Green, M.D., Ph.D., Deborah Fralicker, R.N., D.C., William Clewell, Ph.D., Earl Horowitz, D.P.M., Timothy Lucey, B.S., Victor John Yannacone, Jr., J.D., and Constance Haber, D.C.

INTRODUCTION

In this chapter we report our experiences with the subjective amelioration of diverse painful conditions by means of infrared photon stimulation. The use of infrared photon stimulation devices at classical acupuncture treatment points and directly over the painful areas was successful in several diverse groups of patients suffering chronic pain. No deleterious effects were detected in more than 500 infrared exposures among any of the normal control subjects and diverse patient groups.

BACKGROUND

In one study of 25 patients complaining of painful feet, 21 with chronic painful diabetic neuropathy, and 4 with painful nondiabetic neuropathy (Green, Horwitz, Fralicker, Ossi, Briley, & Lucey, 1999), infrared photon stimulation resulted in significant amelioration of pain according to a patient visual analog scale. Warming of previously cold painful feet as a result of infrared photon therapy was identified in a large percentage of cases with neuropathy. Participating patients also assessed infrared photon stimulation treatment to be significantly beneficial on a Likert (Leikert) Scale evaluation.

Infrared photon stimulation was first applied to asymptomatic volunteer subjects in single sessions repeated over a period of 3 to 6 weeks at a dedicated multidisciplinary neurologic/pain rehabilitation center. Recordings of any neurovascular change of each sham or infrared energy application session in the control subject group were made by high-resolution dynamic digital infrared imaging (Green, 1989; Green, 1993; Green, Leon-Barth, Kohli, & Green, 1989).

Seven normal control subjects did not have any immediate or delayed deleterious effects attributable to the infrared photon therapy.

Those patients with positive assessment of the infrared photon therapy by patient visual analog pain scale correlated most closely with those who had the most profound physiological changes demonstrated on high-resolution, dynamic digital infrared imaging (Figures 58.1a,b).

In a second study (Fralicker, Green, Clewell, Ossi, & Briley, unpublished), 74 chronic myofascial pain patients who on high-resolution, dynamic digital infrared imaging initially exhibited a significant increase in infrared radiation from a focal area of the skin were observed to have less infrared radiation from the skin at those sites, and a more harmonious and congruous pattern of infrared radiation on side-to-side comparison following infrared photon therapy. The change in infrared radiation pattern was an objective measure of positive effect attributable to the infrared photon stimulation treatment (Figure 58.2)

Similarly, almost all patients reported a significant decrease in pain on their visual analog pain scales and also a positive assessment of the procedure by Likert (Leikert) scale assessment. Independent chart review

showed no increase in pain medicine use occurred in this patient study group.

Patients afflicted with complex regional pain syndrome, type I (previously known as reflex sympathetic dystrophy) (Rowbotham, 1998) have been notoriously difficult to treat. Current theory hypothesizes that the common pathophysiologic process is reduction of the regional vascular supply with resultant tissue ischemia, which, in turn, leads to continued nociception.

One recent consideration for the change in nomenclature from RSD to CRPS (complex regional pain syndrome) was microangiopathy. M. Stanton-Hicks, Janig,

FIGURE 58.2 Before and after needleless acupuncture treatment. Top images are before treatment and bottom images are immediately after treatment.

Hassenbusch, Haddox, Boas, and Wilson (1995) reported that microangiopathy of the affected limbs (van der Laan, ter Laak, Gabreels-Feston, Gabreels, & Goris, 1998) was pathologically verified in amputations done on a number of RSD patients.

A significant clinical review of 824 patients was done by Hooshmand and Hashmi (1999) who found that the complex regional pain syndrome is characterized by hyperpathic allodynic pain, vasomotor dysfunction, flexor spasms, inflammation, and limbic system dysfunction. They concluded that casting, amputation, and elective surgery are high on the list of aggravating factors.

We report here the use of infrared photon stimulation in chronic regional pain syndrome (Green, Fralicker, Clewell, Horowitz, & Lucey, 1999). In a single patient with reflex sympathetic dystrophy (complex regional pain syndrome) (Green, 1993), we observed progress toward more normal symmetry in the infrared energy radiation signature. Although a single patient report, it appears to be significant in that we have again corrected the autonomic-sympathetic dysfunction characterized by a well-defined asymmetrical infrared energy radiation pattern with documented change toward a more normal infrared radiation signature following infrared photon therapy.

MODE OF ACTION

Our observations suggest that the bioelectrochemical physiological reactions proceeding continuously in living creatures at all levels from their electron transfer during oxidative phosphorylation in intracellular organelles to the conduction of signals along axons and the transfer of physiologically active materials throughout the entire body by means of the vascular and lymphatic systems acquire information from and transfer information to the autonomic-sympathetic nervous system (Yannacone, personal commun.). That information can be monitored in real time as it modulates the radiation of infrared energy from the skin to the environment (Christoph, Strasser, Eiswirth, & Ertl, 1999).

Our experience with the use of infrared photon stimulation in treating chronic pain has created a bridge between the qualitative and almost mystical character of Eastern medical practices such as acupuncture, acupressure, and Nei Qong and the more quantitative technologically driven traditions of Western medicine.

It appears that application of infrared energy at classical acupuncture points can, under appropriate conditions, have significant impact on autonomic-sympathetic

activity and that application of infrared energy to the surface of the skin may influence bioelectrochemical physiological processes far removed from the site of application.

Our observations indicate that the meridians or great channels for rapid transfer of energy within the human body that are at the heart of Chinese medical theory, seem to actually exist and, at least in the functional sense, may behave as a kind of biological "superconducting pathway" or physiological "wormhole" linking organs and organelles to expedite physiological processes (Yannacone, personal commun.).

Our observations also suggest that infrared energy radiated from the skin is subject to modulation by physiological processes far removed from the site of the radiation and that the skin behaves as a kind of antenna transferring information from organs and organelles deep within the body during the process of radiating infrared energy (Yannacone, personal commun.). Observing such infrared radiation can provide a means of monitoring physiological function in real time (Yannacone, personal commun.).

It appears that portions of the infrared energy absorbed by or transmitted through tissue can affect bioelectrochemical physiological processes locally, regionally, and at a distance, resulting in clinical improvement (Karu, 1987).Infrared photon stimulation appears to be of significant value in the treatment of chronic pain of a neuropathic and neuromuscular character and represents an alternative to opioid analgesics (Figures 58.3 and 58.4).

It has been suggested that neuromodulation or neuroaugmentation may well be more effective in pain relief than direct electrical stimulation by means of implanted or external electrical stimulators (Melzack & Wall, 1965; Melzack, Stillwell, & Fox, 1977). Consideration of acupuncture as a neuromodulation technique for pain control was described in 1992 by Ng, Katims, and Lee, and by Helms in 1998.

Our observations have begun to establish a theoretical foundation for consideration of effects attributable to acupuncture and acupressure (Yannacone, Green, & Hobbins, private commun.).

DATA PRESENTATION AND REVIEW

Better overall Likert (Leikert) scale assessment of treatment effectiveness was noted in those patients whose infrared energy radiation signatures became more coherent. Note, however, high-resolution, dynamic digital infrared imaging revealed that not all treated patients demonstrated "normal" infrared energy radiation signatures, indicating that underlying pathophysiological processes may still be continuing.

Clinical outcomes of infrared photon therapy in patients with neuropathy involving the lower extremities are summarized according to patient judgment in Table 58.1 (21 patients with diabetic neuropathy, 4 with nondiabetic neuropathy, and 7 control subjects without neuropathic features or pathognomonic infrared energy radiation signatures). Statistically significant decreases in the patients' reported levels of pain were achieved, along with patient assessment that the treatment was effective. Infrared energy radiation signatures became more coherent and moved dramatically toward the normal controls.

Seventy-four patients with myofascial pain treated with infrared photon stimulation, first at established acupuncture treatment sites and then over the painful region identified by the patients, experienced significant changes in the asymmetry of their infrared energy radiation signatures (Green, 1993). Statistically significant changes were attributed to infrared photon stimulation therapy.

While suggesting that infrared photon stimulation at classical acupuncture points is effective in myofascial pain therapy, we have taken the liberty of identifying those classical acupuncture points in a manner we believe to be more consistent with the conventional anatomical nomenclature of Western medicine (see Figure 58.5).

DISCUSSION

Many patients complaining of chronic pain (lasting longer than 6 months) are seen by physicians each day. Despite myriad scientific advances and new invasive procedures, minimal improvement has been noted in many of those suffering chronic painful conditions. These patients often turn to alternative medicine and seek unconventional treatment.

Our prior unsuccessful attempts to treat chronic painful conditions by means of early commercial photon stimulators were described previously (Green, 1998). In this chapter, we summarize our success with infrared photon stimulation in conjunction with high-resolution, dynamic digital infrared imaging. We consider this technology along with real-time monitoring suitable for effective outpatient treatment of chronic pain. We are satisfied that by careful and thoughtful application of infrared photon stimulation we can significantly influence the autonomic-sympathetic nervous system and visualize and document these changes using high-resolution dynamic digital infrared imaging.

Successful therapy for chronic pain is economically important. In 1994 Liberty Mutual received 119,000 claims for back pain alone (Webster & Snook, 1994). Multidisciplinary pain clinics are expensive with an estimated outpatient therapy cost in 1995 of $4746 per patient. Outpatient treatment appears to be less expensive, however (Kee, Middaugh, Pawlick, & Nicholson, 1997). Medical costs directly and indirectly attributable

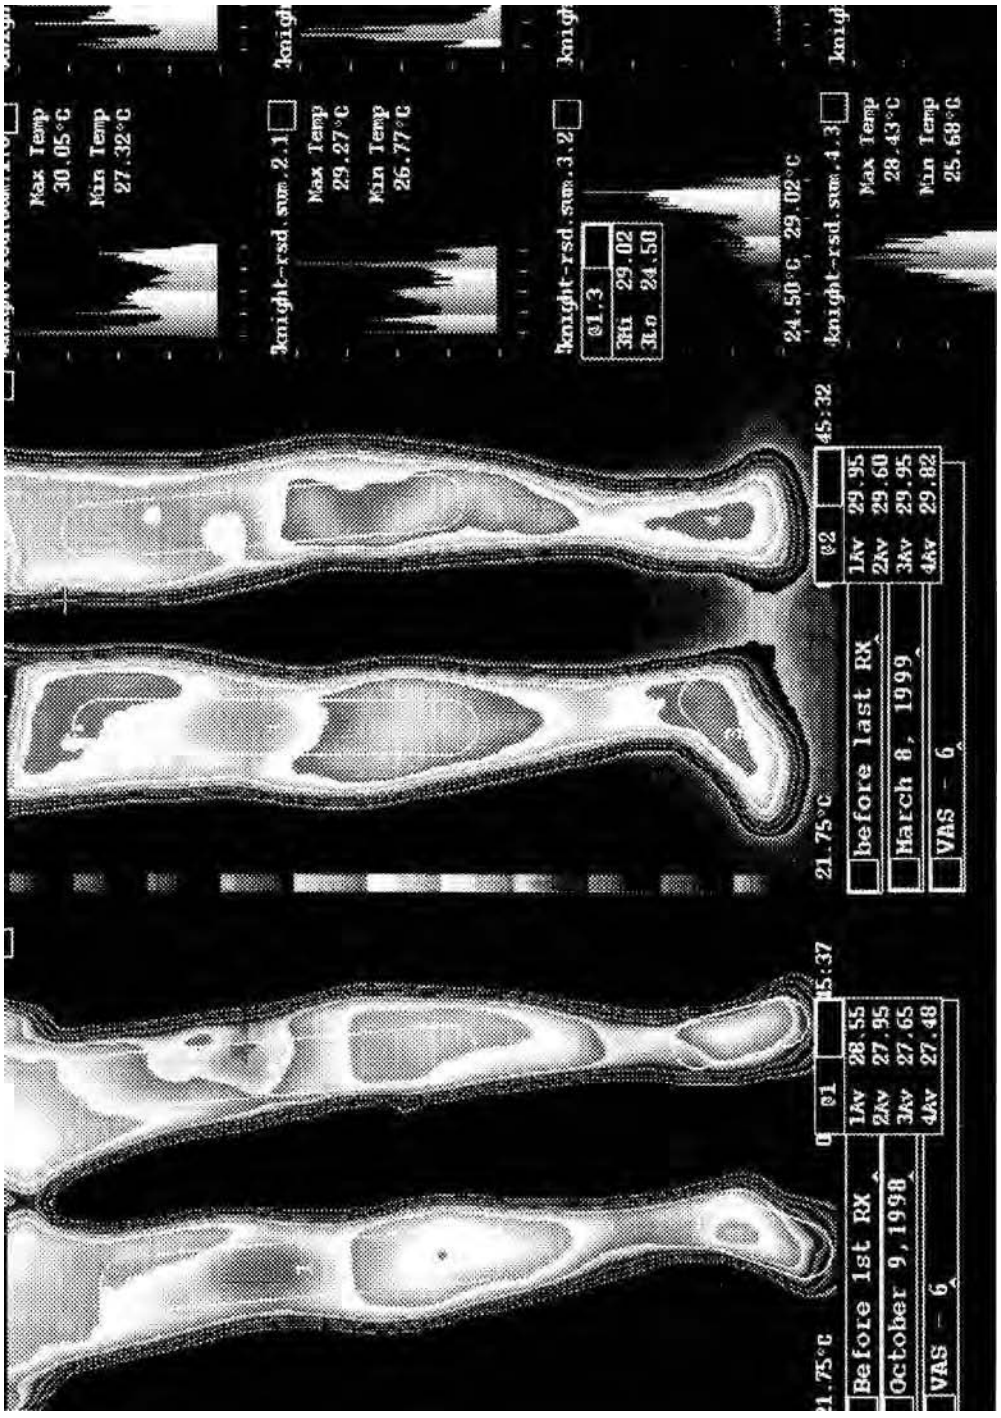

FIGURE 58.3 Infrared, chronic regional pain syndrome, before and after therapy.

FIGURE 58.4 Typical photon stimulator.

to chronic, episodic, and recurrent back pain treatment are estimated to be $50 billion a year (Frymoyer, Katz and Bahril, 1991).

The effectiveness of longer-term treatments, including supervised education in a back school, objectively led to significantly fewer re-injuries (Brown, Sirles, & Hilyer, 1992). Alternative adjunctive treatments including back belts to reduce injuries have also been (minimally) effective (Mitchell, Lawler, Bowden, Mote, Asundi, & Purswell, 1994). Various and sundry treatment programs for chronic back pain including exercise (Feine, Widmer, & Lund, 1997), and splinting (McMillas & Blasberg, 1994; Wright & Schiffmn, 1995) have been evaluated. Continued excitability of peripheral tissue and central neural excitability together may contribute to the persistence of soft tissue pain (treatment failures) in post-trigger point injection cases. Electrical stimulation of myofascial trigger points has also been used successfully as still another treatment for chronic recurrent back pain (Airaksinen & Pontinen, 1992). Any improvement in chronic recurrent back-pain treatment will be of great economic significance.

LASER THERAPY

It is important to recognize that the infrared photon therapy discussed in this chapter is not laser therapy. It is not the low-level laser therapy (LLLT) reported in the literature (Gam, Thorsen, & Lonnberg, 1993). The mode of action of infrared photon therapy seems to be significantly different and the results have been considerably more promising.

An assessment of laser therapy for musculoskeletal disorders was carried out in a meta analysis of randomized clinical trials and reported by Beckerman, de Bie, Bouter, De Cuyper, and Oostendorp (1992) who found no clear relationship between laser energy dosage and outcome in the 36 reviewed and published clinical trials involving a large number of patients. On average, however, laser treatment was more effective than just placebo. The conclusion was that laser seemed to have a substantial therapeutic impact on rheumatoid arthritis, post-traumatic joint disorder, and myofascial pain.

TMJ and degenerative joint disease therapy with laser have been studied and laser therapy was found to be effective in the management of the pain associated with rheumatoid arthritis and degenerative TMJ disease (Bertolucci & Grey, 1995). Mulcahy and others, however, believe that no therapeutic effect of laser treatment exist and that the positive outcomes reported were merely placebo (Mulcahy, McCormack, McElwain, Wagstaff, & Conroy, 1995).

Alternative therapies including Qi Gong energy and electrical fields were reported by Omura and Beckman (1995); however, improved circulation and enhanced drug uptake were thought responsible for the positive outcomes.

Yang, Guyuang, and Chang (1995) successfully utilized an assessment of brain magnetic field changes evoked by acupuncture treatments using a SQUID (superconducting quantum interference device) biomagnetometer to assess 12 subjects. Posterior neck treatments using 100-W LLLT in another study (Wong, Lee, Zucherman, & Mason, 1995) reported rapid alleviation of pain and tingling in the arms.

A subjective positive result, i.e., decreased symptomatology, was reported following acupuncture therapy in

TABLE 58.1
Clinical Outcomes via Patient Judgment

Number of Patients	Type of Group	Appointment VAS (pain)	Leikert Scale (overall opinion)	
			First	Last
23	Diabetic neuropathy (all types)	5.6	4	8.1
4	Nondiabetic neuropathy	5.1	2.5	7
7	Control Group	1.7	0.7	5

Scale: 5 = Neutral

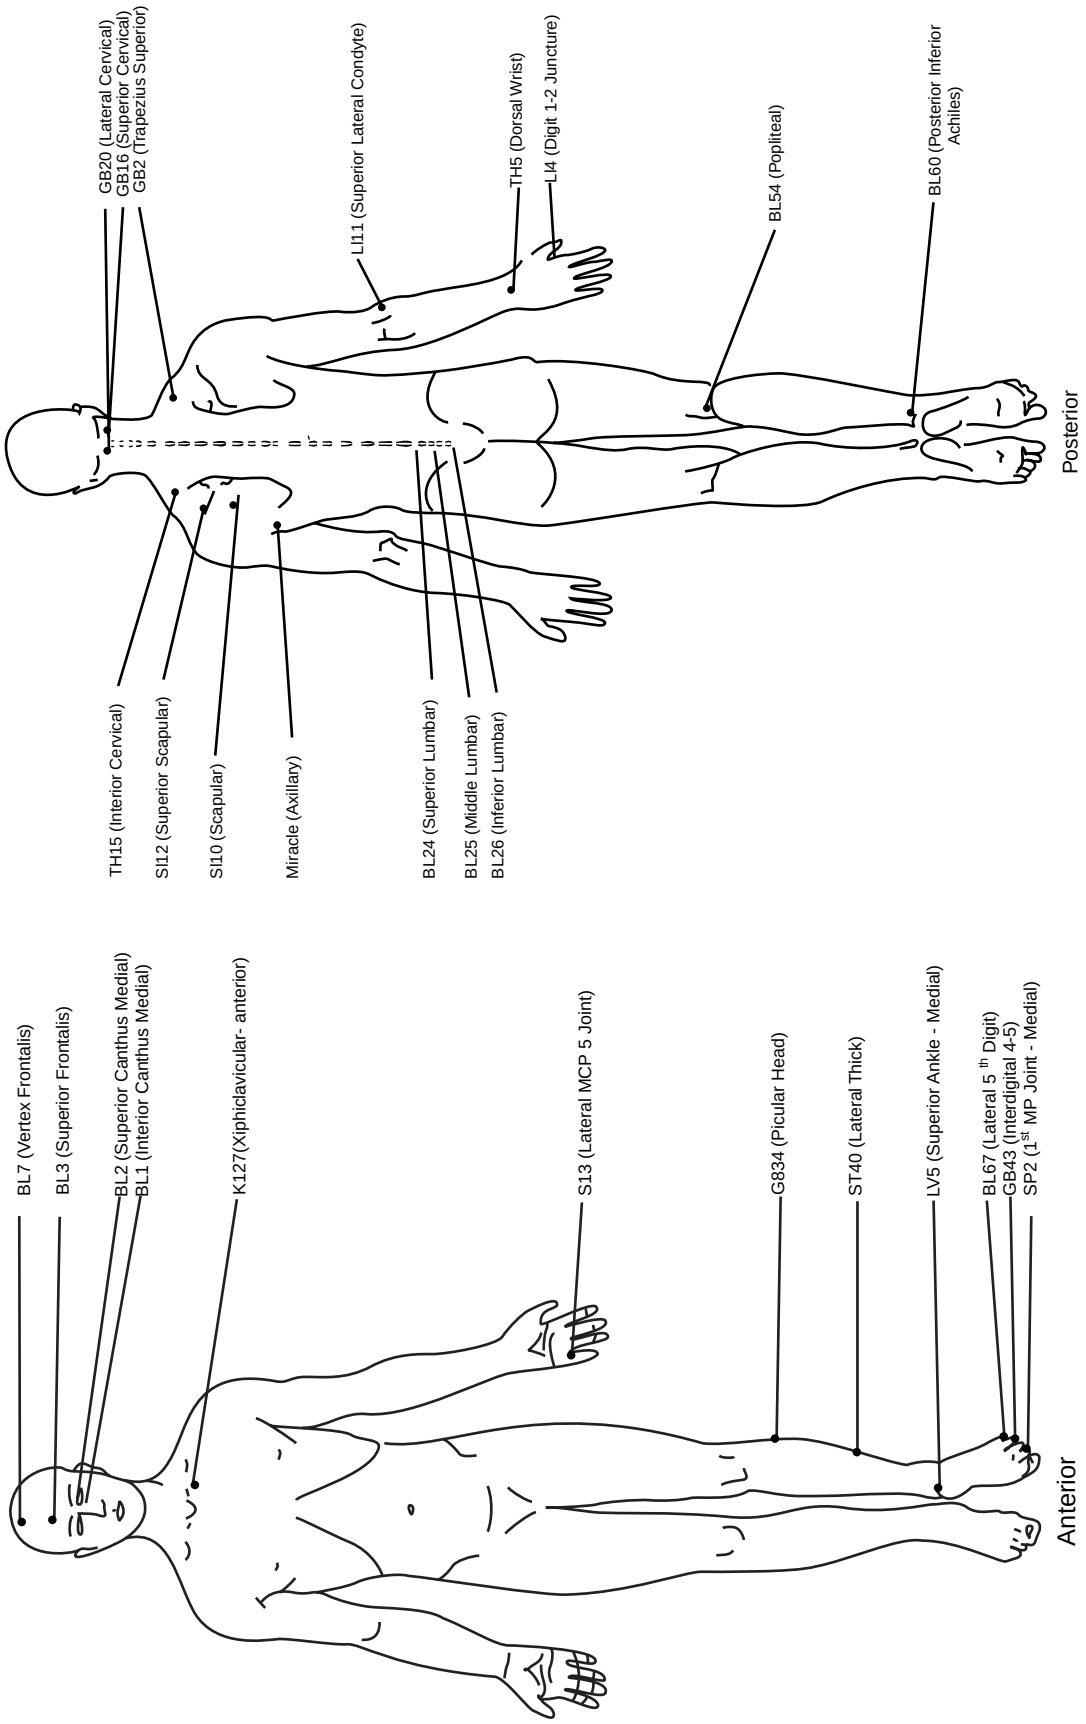

FIGURE 58.5 Traditional acupuncture points in designation (old). New designation (anatomical) appears in parentheses.

temperomandibular joint (TMJ) pain, myofascial pain, and occlusal splint (Johansson, Wenneberg, Wagersten, & Haraldson, 1991). Occlusal lifting (a TMJ treatment) did alleviate muscle tension in a study of silver spike joint electrotherapy and other modalities (Sugimoto, Konda, & Shimahara, 1995).

A number of studies involving lasers as surgical instruments for removal of tattoos have been published (Alfelberg, Bailin, & Rosenberg, 1986; Fitzpatrick & Goldman, 1994; Reid, Miller, Murphy, Paul, & Evens, 1990; Taylor, et al., 1990). Others have treated and reported on the treatment of Nevus of Ota with therapeutic lasers (Geronemus, 1992; Watanabe, et al., 1994). Cutaneous pigmented human lesions have been successfully destroyed by lasers (Anderson & Parrish, 1983; Kilmer, Goldberg, & Anderson, 1994; Tan, Morelli, & Kurban, 1992). Port-wine nevi have been treated by various laser techniques (Garden, Polla, & Tan, 1988; Tan, et al., 1989).

Other articles describe the application of physical modeling for optimal treatment protocol development and the application of various wavelengths for more specific laser treatment (Van Gemert, 1991): Q-switched ruby laser and Q-switched YAG laser (Alster, 1995; Gonzalez, Gange, & Momtaz, 1992), cool lasers and flash pump-pulsed dye laser in the treatment of various skin lesions (Chess & Chess, 1993; Fitzpatrick, Lowe, Goldman, Borden, Behr, & Ruiz-Esparza, 1994), and various precise laser treatments using specific identified tissue parameters (Svaasand, Norvang, Fiskerstrand, Stopps, Berns, & Nelson, 1995).

The diffusion of light in turbid material and reflections has been considered in other laser treatment protocols (Ishimaru, 1990). Major international symposia have been held on the diagnostic and therapeutic uses of lasers (Steiner, 1989).

Treatment by means of lasers of different wavelengths and variable energy output characteristics have been considered in several literature reviews (Fitzpatrick, Goldman, & Ruiz-Esparza, 1993; Polla, Tan, Garden, & Parrish, 1987). Similar diverse technical considerations of light distribution in the skin were made for therapeutic sources of infrared light emission therapy (Miller & Veitch, 1993).

In the search for other modalities in the treatment of chronic pain, Waylonis, Wilke, O'Toole, Waylonis, and Waylonis (1988) reported on the clinical responses to various therapy modes (utilizing a McGill Pain Questionnaire), but no particular advantage of neon laser therapy was reported in this single study.

Innovative considerations for photon therapy included skin-contact monochromatic infrared irradiation therapy (Thomasson, 1996) and photothermal sclerosis of leg vein problems (Goldman & Eckhouse, 1996).

Various proton and photon energy beams have been used along with a so-called Monte Carlo model for photon irradiation for cancer patients (Hug, Fitzek, Liebsch, & Munzerider, 1995; Lovelock, Chui, & Monahan, 1995).

REVIEW SUMMARY AND CONCLUSIONS:

It appears that infrared photon stimulation carries with it a significant potential for amelioration of the chronic pain characterized by autonomic and neurovascular abnormalities demonstrable by means of high-resolution dynamic digital infrared imaging. Further research and continued treatment of patients with infrared photon stimulation are clearly indicated and warranted. We are now exploring applications of infrared photon stimulation for treatment of chronic myofascial back pain conditions.

Physical Therapy and Pain Management

C. Kumarlal Fernando, M.A., L.P.T.

Physical agents such as sunlight, water, mud baths, and mineral baths have been used as therapeutic agents for the management of pain since ancient times. Today, in the modern world, physical therapists trained in the use of physical agents such as electricity, sound, magnetism, water, and exercises use sophisticated equipment for pain management and the treatment of musculoskeletal and neurological problems. However, the physical agents and modalities themselves are not the complete answer to the problem. Physical exercises, combined with other modalities, help the whole patient and return the patient to normal activities of daily living.

Pain is as old as life itself. It is subjective and defies description. The concept of pain includes, first of all, a sensation evoked by harmful or potentially harmful stimuli, and second, a reaction to this primary sensation. These reactions are threefold: physical, rational, and emotional.

Individual biorhythms, changing continuously during the day, the month, and the year, have an effect on the experience of pain. Women tolerate potentially painful stimuli when ovulating or when they are premenstrual. Most pain is worse in the evenings, perhaps partly due to absence of the distractions of the day, but also due to increased activity of the sympathetic nervous system, which is highest in the evening when body temperature is highest. In controlled experiments, where the stimuli are kept constant, the experience and presence of pain vary from person to person. According to Mersky (1979), "Pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage." According to this definition, pain has psychological as well as physiological aspects and, therefore, the whole person, rather than a body part, must be treated. Otherwise, only a part of the pain will be eased.

Physical therapy treatment for pain is designed to combat the physiological aspects of pain such as tissue damage, inflammation, ischemia, edema, defects of reduced physical and metabolic activity, and trauma.

But if strategies in the management of pain are to be truly effective, it is important for physical therapists to understand that both physical and psychological components are needed. Melzack (1973) states, "The puzzle of pain, as we have seen, is far from solved and there are few problems more worthy of human endeavor than the relief of pain and suffering."

However, in treating the acute stages of pain, techniques aimed at the physiological aspects are very effective. It is important to realize that the optimal management is entirely different for acute and for chronic pain. Acute pain is the kind of severe pain that, for classification purposes, lasts less than 7 days. Subacute pain lasts from 1 week to 3 months; chronic pain, longer than 3 months (Mooney, Modic, & Brown, et al., 1988).

Prior to the treatment process, and before the application of any physical agent, a thorough evaluation of the patient must be performed. This chapter describes the various modalities that I employ and how I combine them in the management of pain. The physical agents involved are interference current (medium frequency), transcutaneous electrical stimulation, iontophoresis, superficial heat and cold, ultrasound, phonophoresis, shortwave therapy, therapeutic exercises, deep friction, and traction techniques. Each of these modalities is described in the section on Treatments.

0-8493-0926-3/02/$0.00+$1.50

EVALUATION OF THE PATIENT

Prior to treatment of any patient, the physical therapist must evaluate that patient with regard to the pain problem. As a part of the general examination, a thorough history is taken with attention directed to the particular part of the body involved. A majority of the patients will have had their problems diagnosed by their referring physician. But if the diagnosis has not yet been made, a physical evaluation and general history are recorded. The first step is to map out the painful area as accurately as possible. For this, the patient is given a diagram of the body and asked to mark the places where pain is present. Then further examination focuses on skin changes, muscle changes (such as guarding, spasms, and tenderness), joint changes, temperature changes, soft tissue swelling, crepitus, range of motion measurements, limitation of activities, and weakened muscles. Maneuvers that cause pain, pressure on trigger points, neck movements, and maneuvers that relieve pain are considered. Such clinical measurements as straight leg raise, range of motion, and joint and muscle strength are obtained. From these studies a decision is made regarding the goals of treatment and appropriate techniques to meet those goals.

The evaluation of a patient is carried out according to the following protocol: patient history, observation, examination, special tests of reflexes, joint movements, and muscle strength. The patient history must include a complete medical history. The emphasis in the case must be placed on that portion of the assessment having the greatest clinical relevance. Important data in the history are the age and occupation of the patient; whether the problem began gradually or suddenly; whether the patient experienced this condition previously; whether the patient experienced any trauma; the intensity, duration, and frequency of pain; whether the pain is constant, periodic, or occasional; whether it has moved or spread; whether it is associated with rest, certain postures, certain functions, or time of day. Is the pain nerve pain, which tends to be sharp, bright, and burning in quality and usually runs along the nerve? Is it bone pain, which tends to be deep, boring, and very localized? Or is it muscular pain, which tends to be diffused, aching, poorly localized, and may refer to other areas of the body. Muscle pain is usually dull and hard to localize, and is often aggravated by injury.

Some of the questions asked during the patient's history taking are: What type of sensation does the patient feel? Are there pins and needles, abnormal sensations, or tingling? Do the joints lock or are they unlocking? Are there changes in the color of the limb, ischemic changes, loss of hair, or abnormal nails of the hand or foot? In observing the patient, the physical therapist must look for any fractures, scoliosis, kyphosis, muscle wasting, size of the limbs, shape, color, temperature, any scars, texture of the skin, any crepitus on movement, any swelling, any heat or redness, the patient's facial expression, lack of sleep, and whether the patient moves around or walks abnormally.

EXAMINATION

First, the patient's active movements, then passive movements, and last, resistive movements are each tested several times to see whether the symptoms increase or decrease and whether there is weakness. Muscles are tested manually and range of motion noted. The patient's active movements help in diagnosing any problems with the contractile substance, and passive movements helping diagnose problems with the ligaments and the inert substances. Finally, special tests are done to check on the particular system that is at fault. For instance, straight leg raise is performed for back problems and draw testing is performed for knee problems.

After the examination is evaluated, goals of treatment and a treatment plan are established and the patient is treated accordingly. I wish to stress that a single treatment modality is very rarely the answer in the management of pain. The treatment procedure entails modalities, exercises, and home programs, combined to help the patient get better. It is important to know that a single modality, even if it gets rid of the pain, is not a treatment by itself if the patient is not able to return to normal activities of daily living. For instance, a patient with tennis elbow may be treated with ultrasound or phonophoresis and the pain relieved. But when the patient returns to playing tennis, this again causes microtrauma in the common extensor tendon and the condition recurs. Therefore, the treatment must first eliminate the pain by using ultrasound or phonophoresis and cold packs, and then exercises must be started in order for the patient to strengthen the muscles to ensure that they are not torn again. The various modalities are explained in the following section.

TREATMENTS

Hippocrates cautioned his students and colleagues to observe carefully, proceed slowly, and exercise restraint in treatment, a philosophy expounded in the injunction: "First, do no harm" (Gordon, 1949). With this in mind, physical therapists treat patients conservatively and cautiously with much restraint. Most patients treated for pain by physical therapy are patients with low back pain. It is particularly important in view of the multiplicity of possible causes of backache that an exact diagnosis be established prior to treatment, if possible. Today, with MRI, CAT scan, and myelography, disc disease can be diagnosed very easily. Most back pain is due to disc lesions, which, properly treated with physical therapy, can be helped. Indications for the use of physical modalities are

symptomatic pain relief, relief of muscle spasm, strengthening and endurance training, increase of spinal mobility or joint mobility, and postural re-education.

Rest

The first modality of treatment is rest. For sufferers of acute pain, bed rest is the most frequently prescribed treatment. It must specifically entail rest for the affected body part. Relief is obtained by unloading the spinal segment or the joint involved. If it is the spine, the intradiscal pressure is decreased. In the case of compression of a spinal nerve, edema of the perineural sheath is thought to be the reason for the pain (Bell, et al., 1984), and bed rest allows the edema to subside, thus contributing to the relief of pain. The required length of bed rest is disputed for patients with acute backache. Many practitioners believe a minimum of 2 weeks is needed, but some maintain that 2 days may be sufficient in some cases. Deyo and Rosenthal (1986), for example, have shown that 2 days of bed rest can be just as effective as 7 days. But to push a patient who is in severe pain with only 2 days of bed rest could, in fact, cause harm. Most authorities still advocate 2 weeks of bed rest initially, followed by gradual movements and strengthening. The length of bed rest prescribed — from 2 to 14 days — depends mostly upon the patient, the symptoms, and the severity of the pain. In chronic pain, however, bed rest is not the solution because it may result in muscle atrophy and generalized deconditioning.

Heat Therapy

Heat therapy is used as an adjunct to other types of treatment. Superficial moist heat is relaxing, soothing, and pleasant. Moist heat produces vasodilatation that allows rapid removal of cell metabolites from the tonically contracted muscles, thereby achieving therapeutic effects (DeLateur, 1982). A nonspecific counter-irritant, moist heat also contributes to analgesia, which, according to Lehman, et al. (1958), is produced by an increase in the pain threshold.

The rationale for using moist heat is mainly to relax superficial muscles and also to prepare the skin for subsequent physical agents. In addition to hot packs, moist warm towels, water bottles, infrared lamps, and paraffin wax baths are used for acute and chronic pain conditions.

In chronic pain conditions, hydrotherapy can be effective because of the buoyancy of the water and the counter-irritant phenomenon. The buoyancy of the water counteracts the effects of gravity which diminish the weight-bearing stress on the lumbar spine, thereby reducing pain. The temperature of the water also relaxes and sedates the muscles and joints so that the patient can much more easily perform the exercises in the water.

Cryotherapy

Ice cools the superficial layer of the muscle, which decreases muscle spasms and elevates the pain threshold. Because of this, the analgesia and muscle relaxation will last longer. Also, the counter-irritant effect of ice further contributes to the analgesia (Lipold, et al., 1960).

Deep Heat

Shortwave diathermy and ultrasound are two methods of applying effective deep heat therapy in the treatment of pain conditions.

Ultrasound

The ultrasound generated in the United States produces sound waves at the frequency of one megacycle per second. For clinical application, a transmission medium is always required. Generally, the ultrasound waves are transmitted via water, oil, or transmission gel. It has been suggested that about 50% of the ultrasound is transmitted to a depth of 5 cm (Goldman & Heuter, 1956).

Deep tissues, such as joint capsules and deep muscles, can be treated with ultrasound. Homogeneous substances, like subcutaneous fat and metal implants, absorb less energy than muscle, so ultrasound produces very little increase in the temperature of these materials. Therefore, patients with implants can be treated with ultrasound in the kinds of treatment situations where one must be very careful. A physiological effect of ultrasound is to decrease the level of cortisol. Painful nerves and nerve plexors have been found to increase the level of cortisol, and because ultrasound is a strong anti-inflammatory substance, its use decreases inflammation due to trauma. Ultrasound, therefore, can be used in the treatment of lumbosacral nerve root irritation, nerve root impingement, and various types of neuritis (Touchstone, et al., 1963). Ultrasound also affects joint capsules and ligaments, increasing their range of motion. Muscle spasms of a localized nature can be effectively treated with ultrasound, which increases temperature in the muscles, by about 1 to 2°C. Ultrasound is contraindicated in pregnancy, in malignancies, in bone overgrowth, and in patients who cannot perceive pain and heat.

Shortwave Diathermy

Large body parts such as the back and thigh, and deep areas such as the hip, can be treated with shortwave diathermy. Shortwave equipment produces high-frequency electromagnetic waves, having a length of 11 m and a frequency of 27 megacycles. Shortwave diathermy with condenser electrodes uses the electrical components of the electromagnetic waves, and shortwave diathermy with induction electrodes uses the magnetic components

of the electromagnetic waves. The effect is deep tissue penetration and heating. Greater heating of fat or muscle is achieved with condenser electrodes. When heat is needed in deep joints such as the hip, condenser shortwave therapy is more effective. Induction electrodes are used for superficial heating and muscle tends to become warmer than fatty tissue. Therefore, induction coils are used for the treatment of superficial muscles and joints. The thermal physiological effects of shortwave diathermy are elevation of muscle temperature to 42°C after a 20-min application, and increased blood flow into the heated muscle. A concurrent increase in metabolism and relaxation of contracted fiber is experienced. In Reynaud disease and other vascular conditions of the extremities, an increase of blood flow can be brought about by heating the abdominal area. Shortwave diathermy is used mainly for reduction of effusion in arthroscopic surgical knees and for osteoarthritis of the knee, where it is very effective. It is contraindicated if the patient is pregnant or has a pacemaker or a metal implant.

Iontophoresis and Phonophoresis

The introduction of various ions into the tissues beneath the skin via electricity is called iontophoresis. Phonophoresis is the driving of ions into the tissues via ultrasound. Using a sound applicator, various medications can be driven into the tissues to a depth of about 5 cm (Griffin & Karselis, 1997).

Hydrocortisone and Lidocaine

Hydrocortisone and lidocaine are two medications used in phonophoresis to treat the pain of musculoskeletal conditions. Hydrocortisone in a 1 or 10% concentration is used in both acute and chronic pain conditions such as bursitis, tendonitis, and neuritis. Before phonophoresis or iontophoresis is applied, the patient's complete history must be reviewed to avoid choosing any medication to which the patient is allergic. Iontophoresis is used in cases of neck and back pain, arthritic conditions, bursitis, rotator cuff, and tendonitis. Physiological effects of the direct current alone are known and are utilized in the technique of iontophoresis. The positive pole alone produces an acid reaction and tends to decrease nerve irritability. The negative pole cathode is alkaline and tends to increase nerve irritability.

Interference Current Therapy (ICT)

Medium Frequency Electrical Therapy

Interference current therapy was developed by the Austrian physicist, Nemec. Two electrical currents, each with a different frequency, 4000 and 4100 Hz, are applied to the skin through surface electrodes and an interference pattern is established at the intersection of the two currents, The result of this interference pattern is that the targeted tissue receives a net frequency of 100 Hz of low frequency current. The main advantage of this type of current is that is penetrates the skin with very little resistance and, hence, less intensity output is required. Also, this low frequency current produces superficial muscle contractions and tends to depolarize the muscle membrane to a great extent. Moreover, motor nerves and sensory nerves are more readily depolarized at lower frequencies. Therefore, deep stimulation of muscle and nerve is possible by the selective application of ICT using from 1 to 100 Hz. At frequencies of 0 to 10 Hz, motor nerves are readily depolarized and muscle contractions initiated. This frequency can be used muscle contraction, for muscle relaxation, muscle strengthening, and muscle reeducation. Also, smooth muscles surrounding blood vessels reportedly respond well to stimulation at these lower levels, which can be used in such situations as sympathetic reflex dystrophy. ICT also allows the therapist to effectively reduce and treat edema in acute conditions, and pain relief is possible from frequencies of 1 to 100 Hz. The specific features of interference current are no polar effects, as pure sinusoidal current is used; stimulation of cell division; increased adenosine released through depolarization of the cell membrane leading to adenosine triphosphate; improved microcirculation due to increased adenosine release; and ATP splitting, which results in an increase of free phosphate ions found for mineralization (Hausner, 1982).

Transcutaneous Electrical Nerve Stimulation (TENS)

In 46 A.D., Scribonius Largus described the use of the torpedofish, an electric eel, to control pain. This was the beginning of the technique of electrical stimulation for the relief of pain. TENS uses electrodes to stimulate the skin in the treatment of acute and chronic pain conditions. In 1967, Drs. Shealy and Mortimer (1970) developed a dorsal column stimulator for surgical implantation in patients with chronic intractable pain. At the time, they used TENS as a screening device for their patients. Eventually, they eliminated the surgery because they found that the screening process alone brought relief. At that point, TENS, as an alternative method of pain management, became a reality. In addition, Drs. Melzack and Wall's Control Therapy of Pain Perception convinced the medical community of the benefits of electrical neuromodulation of pain. The physiological basis for the treatment is the stimulation of large myelinated afferent fibers, which at the level of the spinal cord tend to block the passage of painful impulses carried by smaller unmyelenated afferent fibers. TENS can be used with a pulsed alternative current wave of 0.1-ms duration, frequency of approximately 100 Hz, and variable

voltage to the point of tingling or parasthesia, but not pain. In my practice, 75% of patients require a high width with a low rate for about 2 to 6 pulses per second, and the other 25% require a high width with a high rate, with an amplitude such that they can feel the tingling on the muscle contraction. Obviously, TENS is not used alone. TENS is used with other modalities described later in this chapter. A great many studies are known to have proven the effectiveness of TENS in acute and chronic conditions.

Ultrasound in Conjunction with Muscle Stimulation

Ultrasound is used in conjunction with muscle stimulation to treat muscle spasms, softened scar tissues, and microscopic fibrous tissue adhesions. Electrical stimulation by mechanically pumping the muscle being treated promotes the removal of the products of that muscle's increased metabolism. Ultrasound with muscle stimulation is mainly used in muscle splinting, guarding, or muscle spasms to help restore the muscle to its normal function, thereby breaking the cycle of muscle spasm and pain.

Audiovisual Neuromuscular Re-Education and Electromyographic Biofeedback

Audiovisual neuromuscular re-education and electromyographic biofeedback are techniques used for the evaluation and treatment of patients as well as for muscle re-education. These techniques are adjuncts to therapies commonly used in rehabilitation medicine. For two of the problems treated, the three main techniques are inhibition of spasticity, recruitment of motor units, and muscle relaxation. These three techniques are used in combination or alone, depending on the problem. EMG feedback is used for patients with muscle spasms of unknown etiology causing pain. In physical therapy, these are usually chronic back pain problems. The management of chronic pain with EMG feedback can be effective for those patients who are in severe pain due to muscle spasms. These spasms aggravate pain and set up a vicious cycle of muscle spasm, pain, and movement (Fernando & Basmajian, 1978).

Lumbar Traction

This system involves positioning the patient with knees and hips bent at 90° and pelvis tilted to decrease lumbar lordosis. A rope attached to a belt around the patient's pelvis is draped over the top of a triangular frame. The patient pulls on the rope to lift the pelvis off the floor. This system can be used in the hospital as well as in outpatient programs. According to Cottrell (1981), relief is experienced in 97% of acute and 94% of chronic low back pain.

Twomey applied 9 kg of traction to L1, S2 cadavers spines and measured an average overall increase in spine length of 8.7 mm (Cottrell, 1985; Twomey, 1985). In addition to the relief of back pain due to bulging disks or protrusion of the nucleus pulposus, there are other benefits. For instance, when the facet joint has become restricted in motion by impingement of the meniscus, capsulitis, or free bodies, traction can release the impinged facet joint and help relieve the muscle spasm. Also, as rapid stretching of skeletal muscles causes reflex excitation, the more prolonged stretching produced by traction is relaxing. This is one of the reasons for using traction. It has been said that stretching by traction stretches the mechanical receptors of the disc, which exerts a beneficial effect on some patients (Cyriax).

Studies by Ramos and Martin (1994) of the Department of Neurosurgery of McAllen Texas, studied intradiscal physical pressure during vertebrae decompression. Transducers were placed in the L4, L5 disc under A-P and lateral fluoroscopy. With the catheter in place, the patient was placed prone on a VAX-D table. Various decompression tensions from 50 to 100 lb were applied. The distraction tensions and intradiscal pressure changes were noted.

Intradiscal pressure was significantly reduced to minus 150 to 160 mm of Hg.

In numerous studies, this was not shown in conventional tractions studies; on the contrary, many traction devices actually increase intradiscal pressure.

The capillary pressure in the vertebral body is greater than the intradiscal pressure; it negates oxygen diffusion to the disc, which, in turn, impedes healing.

Contraindications for Traction

Contraindications for traction include spine infections, spine malignancies, cord completion from central disc herniation, vascular disease, acute inflammatory arthritis, pregnancy, uncontrolled hypertension, and claustrophobia. It also is contraindicated in patients with ligament disruption or dislocation fractures.

Deep Friction

A penetrating massage technique is required to treat deep seating lesions. Given properly, deep friction has a fourfold effect. It induces (1) traumatic hyperemia, (2) movement, (3) increased tissue perfusion, and (4) mechanoreceptor stimulation. For deep friction to be effective the right spot must be found, and the friction must be given across the fibers composing the affected structure. The friction must be given with sufficient sweep and must reach deeply enough. In the case of tendons around a sheath, the tendons must be kept taut. The ideal treatment lasts from about 2 to 20 min daily and from 2 to 7 days depending on the condition. The ordinary conditions

treated by deep friction are muscular lesions, tenderness of sheaths, long-standing scars, muscular tendinous junction lesions, tendons without a sheath (as in tendonitis or tennis elbow where the short tendon or the supraspinatus tendon is strained), recent strains, and chronic sprains. Contraindications include inflammation due to bacteria, traumatic arthritis of the elbow joint, ossification or calcification (in soft structures), bursitis, rheumatoid types of arthritis, and pressure on nerves. According to Dr. Cyriax (1975), deep friction is very effective and when properly used with other techniques, the results are excellent. I have used deep friction with success in tennis elbow, muscular tendinous lesion, rotator cuff lesions, and other muscle conditions.

Exercise Therapy

The many types of exercise therapy are divided into active and passive. The active are divided into assisted, resistive, and free. It is very important that exercise therapy be prescribed properly and administered by those who know the treatment protocols and programs. It is useless to give a patient a list of exercises to be done at home, or to tell the patient to walk or swim, with no direction or teaching by a physical therapist. In the overall management of pain, exercise therapy is the most important part of the treatment program. The modalities only lower the pain threshold or minimize the pain, but it is up to the physical therapist to strengthen muscles, increase joint range, and by the use of prescribed exercises and therapeutic programs, to get the patient back to normal activities of daily living and to a normal holistic state as soon as possible. Therefore, the management of pain is really exercise therapy in combination with modalities, not modalities alone. There are many different kinds of exercises including isometric, isotonic, isokinetic, etc. Sophisticated equipment may be used. As mentioned, low back pain is the condition seen by physical therapists in at least 70% of the cases of pain management. Exercise therapy to minimize back pain aims to improve flexible strength and endurance, and to return the patient to activities of daily living and normal functions. Exercises can reduce pain by stretching muscles in spasm and also can minimize the possibility of recurrence of low back problems. Various exercise programs can help the back by helping its nutrition, which will modulate pain and improve spinal biomechanics. The three most commonly used types of exercises are hyperextension, extension, and flexion.

Principles of Muscle Rehabilitation

The three major principles of muscle rehabilitation are (1) specificity, (2) overload, and (3) provision of optimal condition for performance (Malone, 1988).

Specificity

If a muscle is trained for strength, then improvement is only in strength and not in other parameters. If the training is limited to a specific range, then the strength gains are significant only in that range. If the strength gains are obtained by isometric exercise, then the strength during dynamic exercise is minimal. And, if the strength gains are obtained by dynamic exercise that is concentric and eccentric, then the isometric improvements are minimal (Lindh, 1979).

Slow speed exercises do not stimulate muscles to the extent that fast speed exercises do. During fast contractions, firing rates of motor units are greater than in slow contractions (Sale, 1987).

Overload

Muscle strength improvement is directly proportional to the overload applied to the muscle. Maximum loading increases maximal activation of prime movers and, hence, produces muscle hypertrophy. A muscle can be overloaded in two ways: (1) by increasing resistance, and (2) by performing submaximum contractions to the point of fatigue.

Extension and Flexion Exercises in the Management of Low Back Pain Due to Intervertebral Disc Lesions

Clinicians have held widely diverse views on which therapeutic exercises should be prescribed to patients with low back pain. Authorities such as Williams (1965), Cailliet (1966), and Rowe (1960) emphasized exercises that strengthen the flexors of the spine, while others, such as Mock and Armstrong, advocated exercising the flexors as well as the extensors of the lumbar spine.

Although advocates of the different procedures claimed success with their particular techniques, no studies were published to verify their claims. Then Sarno and I studied various techniques, and based on our studies, recommended that for people with this problem, all muscle groups, including the iliopsoas, should be strengthened. I developed exercises and techniques based on my studies and those of numerous investigators all over the world. I have been giving these exercises—extension as well as flexion—to back patients since 1968 (Fernando and Sarno, 1970).

Rationale for Exercise Treatment for Low Back Pain

Where backache is due to intervertebral disc lesions, as soon as the acute episode subsides, exercise therapy should be commenced. The aim of treatment is to minimize intradiscal pressures by using nonweight-bearing positions within the patient's pain-free range of movement. This is important, as a rise in intradiscal pressure in patients with

a herniation could lead to protrusion of the nucleus pulposus, which could then impinge on the sinuvertebral nerve or its branches that innervate the posterior longitudinal ligament, the outer layer of the annulus, and the synovial joints, thereby giving rise to pain and its resulting clinical syndrome. Nearly 50% of all intervertebral disc lesions are posterior. Only about 10 to 12% of such lesions are posterolateral, which type can give rise to a radiating pain in the lower extremities. The aim of treatment is to stabilize the lumbar spine so as to avoid recurrence of herniation, irritation, pain, and muscle spasm. This rationale was originally expounded by Morris and Bressler (1961), and then by Armstrong (1964), and later by Lucas (1973). I expanded their ideas based on my studies and the reports of other investigators all over the world (Fernando & Sarno, 1970; Fernando, 1974).

By itself, an isolated ligamentous spine fixed at its base will collapse under a force as small as 4.5 lb. The stability of the lumbar spine is dependent upon two muscle systems: the extrinsic stabilizers and the intrinsic stabilizers.

The extrinsic stabilizers of the lumbar spine are comprised of all the muscles surrounding it. Its intrinsic stabilizers are the ligaments and intraabdominal pressures. To improve these systems and thus stabilize the lumbar spine, several important physical therapeutic measures can be undertaken:

- Strengthen the abdominal muscles
- Strengthen the back extensor muscles
- Strengthen the iliopsoas group

By strengthening the abdominal and back extensor muscles we not only strengthen the extrinsic stabilizers, but also increase the integrity of the intrinsic stabilizers, namely, intraabdominal pressure, which opposes the forces on the lumbar spine and, thus, minimizes them.

By strengthening the iliopsoas group, the extrinsic stabilizers are strengthened. The fact that this group of muscles weakens in patients with low back pain indicates that this procedure is necessary.

The majority of patients treated by physical therapists have low back pain, and at least 90% of back problems referred to physical therapy are due to intervertebral disc lesions. These patients can be divided into three categories: (1) back pain alone, (2) back pain with referred pain into the buttock and thigh, and (3) pain below the knee with or without back pain or neurological signs. In addition to the disc, other structures produce back and leg pain, such as tendons, ligaments, fascia, and facet joints. However, on the basis of current information, the disc remains the primary structure thought to be responsible for low back pain, particularly when sciatica is present (Mooney, Modick, & Brown, 1988).

In addition to these three categories, patients can also be divided according to the duration of the pain: (1) acute pain of 7 days or less, (2) subacute pain of 1 week to 3 months, and (3) chronic pain of longer than 3 months (Mooney, et al.). I believe that the majority of patients referred to physical therapy who linger longer than 3 months have pain due to disc lesions and not chronic pain due to unknown or idiopathic conditions. New studies clearly show that chronic pain is due mainly to disc problems that have gone undetected (Grubb, et al., 1987). For many years, practitioners have manipulated and immobilized backs for the facet joint. But again, studies show that manipulating the facet joint does not open up the facet nor relieve the pain. The facet phenomenon (McFadden & Taylor, 1986) is secondary to the disc; therefore, it is dangerous to manipulate or mobilize the patient (Butler, et al., 1990). Furthermore, no studies indicate that manipulation is effective in disc disease (Doran & Newell, 1975; Glover, Morris, & Kholsa, 1974; Godfrey, Morgan, & Schatzker, 1984; Hoehler, Tobeis, & Buerger, 1981; Paris, 1983; Sims-Williams & Young, 1978).

All exercises are performed in nonweight-bearing positions, and within the patient's pain-free range of movement. This is important, as in nonweight-bearing positions, intradiscal pressures are kept low, and thus the chances of the nucleus pulposus protruding and irritating sensitive structures are minimized. In the beginning, all exercises are performed isometrically, and then later, progress is made to isotonic movements still within the patient's pain-free range of movement. If complete rehabilitation is the goal, the patient eventually should be able to perform through the entire normal range of motion (Fernando, 1974).

The treatment plan for category 1A is bed rest for 2 to 7 days or more, depending on the severity of the pain, followed by hot packs, neurostimulation if there is muscle spasm or listing, back exercises, and a TENS electrical stimulator. At the end of 7 days, when the pain subsides,

TABLE 59.1
Classification of Clinical Categories of Lumbar Disc Disease

1A) Acute low back pain
2A) Acute low back pain with thigh pain referred
3A) Acute low back pain with lower leg pain nerve root irritation
1B) Subacute low back pain
2B) Subacute low back pain and thigh pain referred
3B) Subacute low back pain and leg pain nerve root irritation
1C) Chronic low back pain
2C) Chronic low back pain and thigh pain referred
3C) Chronic low back and lower leg pain nerve root irritation

From Mooney, et al. (1988). In Frymoyer, J. & Gord, F.L. (Eds.). New perspectives on low back pain. (With permission.)

strengthening exercises can begin for abdominals, back extensors, leg musculature, etc. For category 1B, after 7 days the treatment is the same as for 1A, with increasing activity on bicycle and treadmill. All the exercises should be done in the patient's pain-free range. In category 1C, patients have pain of 3 months duration, and strengthening exercises, endurance exercises, and range-of-motion exercises continue. However, patients properly treated in the A and B stages should not reach stage C or the 3-month period. Hence, the chronic low back pain due to a disc lesion can be cut short if the patient is treated adequately in stages 1A and 1B. I have seen many patients in the 1C stage who were not treated properly in 1A and 1B. At this point, modalities can be used to break the vicious cycle of spasm and pain and then the strengthening exercises can be continued. In addition to the treatment programs, the patient must be taught correct techniques for lifting and performing other activities of daily living to avoid back problems. Instruction in the proper use of tables, chairs, and beds should be included.

1A) Acute Low Back Pain

The patient rests from 2 to 7 days, or longer, depending on the pain. While the patient rests, hot packs, ultrasound, or neurostimulation, depending on muscle spasm and list, can be used. A TENS unit for 6 to 8 hours per day also can be used. When the pain subsides, which may be on the 3rd, 4th, or 5th day, pelvis tilt and back extension exercises can be started, depending on the evaluation. If both exercises are painful, they must not be done. If extension exercises are painful, they must not be done. Whatever is NOT painful is done. It is also important to begin with isometric rather than isotonic exercises in the early stages, then gradually to build up to isotonic and isokinetic, again depending on the pain. All exercises are performed within the pain-free range and in reclining positions to minimize intradiscal pressures. As the patient progresses, exercises can be done sitting or standing. As part of the program, patients should be taught back-protective techniques, back school techniques, walking, and swimming.

2A) Acute Low Back and Thigh Pain Referred

The program is much the same as in 1A, but back traction is also used. In the Cottrell System, a very simple positional device is used for 30 minutes twice a day in the early stages. As time goes on, when the pain down the thigh subsides, its use is decreased to once a day. Exercises are then performed and modalities applied, depending on pain and spasm. If no spasm is present, ultrasound can be used. If spasm is present, neurostimulation or interferential therapy can be used. Both are effective in reducing spasm. TENS also is used 6 to 8 hours daily and the patient is cautioned not to use the unit while driving, lifting heavy objects, or performing other activities of daily living.

3A) Acute Low Back Pain, Lower Leg Pain, Nerve Root Irritation

Again, bed rest, back traction, (90/90 Cottrell System), TENS, cold packs, interferential therapy, or neurostimulation are used, then exercises are begun depending on whether pain is present. The object is to minimize positions that increase intradiscal pressures and cause protrusions of the nucleus pulposus that impinge on nerve or pain sensory structures.

In my experience over the last 32 years, I have used this technique to treat thousands of patients with excellent results. Rarely was there a need for surgical intervention. In the subacute and acute stages, the treatments are much the same. As I mentioned, no patient should ever become chronic if treated in the manner described. The patients who come for treatment after 6 months of pain are patients with disc lesions that have not been diagnosed properly, and have not been treated properly (Grubb, et al., 1983). As with a subacute patient, we progress toward strengthening, back-protection techniques, back school, and the modalities mentioned, with emphasis on walking and relaxation exercises.

Treating disc lesions is simple and effective and I have found no need for esoteric treatment techniques such as mobilization or manipulation. These can be dangerous and have no place in the treatment of disc lesions. If something goes wrong, paraplegia, further disc lesions, or exacerbation of present problems could ensue.

Surgery is a last resort for a disc lesion. Studies by Weber (1983) show that 10 years after treatment, whether the treatment is conservative or surgical, the results are the same. Now, one may well question: Why have surgery with its attendant risks if, at the end of 10 years, the results are the same whether surgically treated or conservatively treated with physical therapy?

The latest data as presented by Taylor, Deyo, Cherkin, et al. (1994) revealed that in 1990, the rate for surgery in the United States was 131 per 100,000 patients. Another study comparing the rates of back surgery in 13 countries reveals that the U.S. rate is at least 40% higher than any other country, and more than 5 times that of Scotland and England. The reason for this was explained as cultural differences and practice patterns.

Electromedicine: The Other Side of Physiology

Daniel L. Kirsch, Ph.D., D.A.A.P.M.

A fresh look at physiology is needed to better understand the primary medical complaint of pain. Universities are still teaching their students that life is based on a chemical model. Rather than view life processes on a chemical basis alone, it is more realistic to view them on an electrochemical basis. All atoms are bonded electrically. This is a basic foundation necessary to understand electromedicine that is taught during the most elementary training in the basic sciences. Further in our rudimentary training we learned that there are voltage potentials across the membrane of all cells. All standard physiology textbooks define the Nernst and Goldman Equations to determine membrane and action potentials. They do not, however, speculate on the staggering significance of these facts.

If batteries are placed in series, their voltage potentials are combined. A simple remote-control device may use three 1.5-V batteries to produce the 4.5 V needed to operate a television. The human body has trillions of cells, each having a 10- to 200-mV potential across their membranes. The overall electrical potential in humans is 2×10^4 V/mm (Kitchen & Bazin, 1996). All good scientists should ask themselves why we find electricity so prevalent in biological systems.

It is already established that bioelectricity plays a major role in physiology. Robert O. Becker, M.D. has spent more than 30 years attempting to determine how trillions of cells with hundreds of subtypes can function harmoniously in the form we call human. The result of that inquiry is a complete revolution in our previous concepts of biology (Becker, 1983).

Becker (1982) found that electromagnetic fields control all living processes. The earliest concept of such field effects can be traced back to ancient China. Traditional Oriental medicine is based on the controlling power of ch'i (Qi) or ki energy; a concept that predates electricity but appears to be analogous (Kirsch, 1978). Chiropractic also developed based on a similar observation termed innate intelligence by Daniel David Palmer in 1895 (Palmer, 1910). Indians use the term prana to represent the same concept. Allopathic practitioners are limited to the vague notion of homeostasis.

In Western civilization, the first documented use of electricity to manage pain was by the physician Scribonius Largus in 46 A.D. (Tapio and Hymes, 1987). He claimed that just about everything from headaches to gout could be controlled by standing on a wet beach near an electric eel. Not surprisingly, attempts at producing pharmaceutical preparations from dead eels proved ineffective. In 1791, Luigi Galvani discovered that electrical impulses could cause muscle contraction (Smith, 1981). By 1800, Carlo Matteucci showed that injured tissue generates an electric current (Becker and Marino, 1982). The discovery of alternating current by Michael Faraday in 1830 opened the door to the development of manmade devices as sources of electricity. Over 10,000 medical practitioners in the United States alone made use of electrotherapeutic modalities until publication of the 1910 Flexner report, which stated that there was no scientific basis for electromedicine at that time. Flexner's report was originally prepared by the American Medical Association and sponsored by the Carnegie Endowment for the Advancement of Teaching (Walker, 1993). Since the Carnegie family was heavily invested in the young pharmaceutical industry, it is no wonder their report declared allopathic medicine superior.

Since then, arguably the greatest development in the field of electromedicine was when Becker (1961) electrically induced limb regeneration in frogs and rats as a model

0-8493-0926-3/02/$0.00+$1.50

to study bioelectrical forces as a controlling morphogenetic field. Regeneration represents a return to embryonic control systems and cellular activities within a localized area. It can, therefore, be considered a more accessible and more observable form of morphogenesis. The complexity of instructions required to designate all of the details to recreate a finished extremity is impossible to transmit by previously understood biochemical processes alone.

Becker (1983) proposed that a primitive direct current data transmission and control system exists in biological systems for the regulation of growth and healing. His studies of extraneuronal analog electrical morphogenetic fields have eliminated any rational arguments against the importance of bioelectricity for all life processes. Becker has laid the groundwork for the medical professions to start to evolve toward a more reasonable integrated view of biology incorporating our understanding of both biochemistry and biophysics.

Björn Nordenström, M.D. (1983, 1998), former Chairman of the Nobel Assembly, also has proposed a model of bioelectrical control systems he calls biologically closed electric circuits (BCEC). The principle is analogous to closed circuits in electronic technology. Nordenström's theory is that the mechanical blood circulation system is closely integrated anatomically and physiologically with a bioelectrical system.

Nordenström hypothesizes that ionic and nonionic compounds interact in a way that makes selective distribution and modulation of electrical and other forms of energy possible throughout the body, even over long distances. The biological circuits are switched on by both normal electrical activities of the organs and pathological changes, such as tumor, injury, or infection. Like Becker, Nordenström views bioelectricity as the primary catalyst of the healing process.

Using the vascular interstitial system as an example, Nordenström postulates two branches of this system. The first branch, the intravascular system, proposes that walls of blood vessels act as insulators, much like cables in a battery system. The electrical resistance of the walls of the arteries and veins is 200 to 300 times greater than the blood within.

Delayed available energy, or potential energy, is carried by blood cells that bind oxygen, as well as other chemicals such as glucose, neutral fat, nonpolar amino acids, etc. These are all noncharged packages of energy that arrive at specific sites and are released primarily by reduction/oxidation. Nordenström terms these ergonars. The intravascular plasma acts as the conductor, where ions such as sodium, calcium, and chloride supply immediately available energy to the system, primarily by electrophoresis. Nordenström calls these ionars.

The second branch addresses the interstitial system. The tissue matrix acts as an insulator while the interstitial fluid acts as a conductor.

Capillary membranes are the main components that close the system. These membranes act as junctions between the interstitial and vascular fluids, allowing exchange of ionars and ergonars along gradients of electrical potential.

This theory represents a comprehensive attempt to describe functions of anatomical components in terms of electromagnetic forces, rather than limiting them to chemical interactions. Nordenström further theorizes that similar closed circuit systems exist in the urinary and gastrointestinal systems. Using electrical intervention, Nordenström (1984, 1989) reversed terminal cancer in most of his patients as clinical proof of his theories. Several other researchers are confirming the value of electromedicine for the treatment of cancer (Pallares, 1998; Lyte, et al., 1991; Morris, et al., 1992; Sersa, et al., 1992; and Belehradek, et al., 1981).

The medical community has barely taken notice of these remarkable theories. Few practitioners are even aware of the works of Becker or Nordenström. Nordenström is familiar with this type of ignorance. In the 1950s he pioneered a series of remarkable innovations in clinical radiology (including percutaneous needle biopsy) that were considered radical at the time, but are routinely employed by every major hospital in the world today.

Lack of updated education of healthcare professionals is the main stumbling block to acceptance of the modern theories and practice of electromedicine. The other problem is the wide variety of technologies available. At present, there are well over 100 different models of transcutaneous electrical nerve stimulation (TENS) devices in the marketplace and an increasing number of other electrical devices. Most healthcare practitioners who want to utilize such technology have received little or no training in electrobiology or electrical technology. Hence, when it comes to making an educated decision on what type of instrument to choose for a practice or a particular patient, practitioners are often overwhelmed when meeting with an electromedical sales representative. Purchase decisions are frequently made based on lack of knowledge, misinformation, unsubstantiated claims such as testimonials not backed by solid research, or price. If a device is effective in only 2% of the population, treatment of 1000 patients can result in 20 testimonials. The plural of anecdote is not data. Accordingly, healthcare professionals should rely only on evidence-based technologies supported by double-blind research.

BASIC PRINCIPLES

The basic unit of energy is the electron. In 1600, William Gilbert coined the word electricity (Bauer, 1983). Using sulfur and friction to generate electricity, Guericke found that it had several properties in common with magnetic

forces, such as repulsion/attraction, transference of properties, and opposite poles. Faraday termed the positive pole the *anode*, meaning "upper route" and the negative pole *cathode*, or "lower route". Electrons flow from negative to positive, or cathode to anode.

Fluid-based biological systems are conductive media. Blood, water, and lymph all conduct electricity. Various molecular ions, such as calcium, sodium, and chlorides, carry current. When current is carried by ions, electrolysis occurs. In this process, electricity breaks the conducting fluid down into its components. In the case of water, electricity reduces the H_2O molecule into its components of two atoms of hydrogen and one of oxygen. The half-reaction for the formation of water is $\frac{1}{2}O_2 + 2H^+ + 2e^- \rightarrow H_2O$. The resultant voltage released at a pH of 7.0 is 0.816 V (Segel, 1975). This process occurs within all types of tissue (e.g., nerves, muscle, bone, etc.) throughout the body.

Many interactions of this nature are highly complex and not yet thoroughly understood. Certain types of electrical stimulation have caused neurotransmitters to be manufactured and released. Some of these treatments are even considered to be frequency specific, but there is still a lot to learn before we can specify the biochemical effects of frequencies, or any other individual aspect of a waveform.

Waves and Pulses

In fluids, such as water, the sinusoidal wave is the only basic waveform. However, with electrical technology, different shaped waveforms can be built. These are often referred to as *square*, *rectangular*, *triangular*, *sawtooth*, etc. In actuality, they are composed of thousands of waves known as harmonics. A collection of harmonics within a single electrical activity is called a *pulse*.

Frequencies (Hz) and Pulse Repetition Rates (PRR)

Pulses are measured in cycles moving through a medium in 1 second. One cycle per second is also called *Hertz* (Hz). In electrical devices, pulses have frequencies. Just as the collection of harmonics is called a pulse, total frequencies (built by the resonance of harmonics) is referred to as the *pulse repetition rate* (PRR). It is the speed at which the pulse moves. For example, a 1 Hz pulse will have harmonic frequencies that build the pulse, ranging from 1 Hz to hundreds of thousands of Hz and beyond, theoretically to infinity. This is often a source of confusion, not only among practitioners, but also among manufacturers of devices as well. In engineering terms, the term *frequency* should only be used with a pure sinewave. Only in this one case, frequency is the same as the pulse repetition rate. With any other waveform (e.g., square, rectangular, triangular, etc.) there is an infinite number of harmonic frequencies generated within each pulse.

The interplay of harmonics identifies a given musical instrument as a particular aural experience. Some people prefer the sound of a specific note on a piano, while others would rather hear the same note played on a violin. Although the note is the same in each case, the harmonics vary. The interplay of harmonics in electromedicine is essential in affecting the results of a given treatment. With this in mind, we can begin to understand why one electromedical device may work for one patient, yet provide poor results for another. If we could predict what harmonics each tissue needed at a given time, we could design devices that would provide more consistent results in pain management, healing, altering consciousness, and regulating biological processes in general.

The body accepts frequencies and pulse repetition rates in a nonlinear, differential manner. For example, low frequencies penetrate greater depths of tissue than high frequencies. Higher frequencies are auto-shielding; that is, they are limited in penetration because the resistance of tissue acts like a faraday cage, forming eddy–repulsion. This eddy current produces a back electromotive force and blocks the penetration. The reflection of input signals in any conductor (in this case the body) is a mirror image of the opposite phase. The higher the frequency, the greater the rejection and the shallower the penetration. Complex frequencies interact in the body causing a diffuse spread of current.

A nonlinear electrical device is called a *diode*. A diode conducts current of one polarity far greater than the opposite polarity. Most living tissue exhibits nonlinear characteristics, functioning somewhat like diodes.

With square and rectangular waves, a shotgun-like distribution of thousands of frequencies occurs simultaneously within each pulse, like buckshot scattering over a wide area. A sinewave, on the other hand, is more like a bullet from a rifle, which must strike a target accurately to be of use. Our present knowledge of electrophysiology is not sufficient to determine the optimum frequencies for specific tissue responses; therefore, the use of sinewaves is not recommended.

Pulse Width

The length of time a pulse lasts is called *width*. This is usually measured in microseconds. Pulse width really refers to the time the wave is active. This is important with respect to how a given tissue may be affected, and is part of a hypothetical window of optimal electric stimulation.

The body responds to the peak of electrical signals and to the number of electrons in that signal. The maximum charge per pulse is measured in microcoulombs, which is the total energy of each pulse. The definition

of a coulomb is the quantity of electric charge carried by 6.25×10^{18} electrons. Returning to our bullet analogy, we can see that a .22 bullet has less energy than a .45 bullet because it is lighter. While the .22 might go faster, the .45 can knock down a bigger target with its increased energy. Consider each spike a bullet and the pulse width the energy carried by that bullet. Taking our analogy a step further, the velocity of the bullet is the voltage, while the mass of the bullet is the energy, measured in microcoulombs.

Biphasic Signals

Because ions dissociate by electrolysis in the presence of electrical current, living tissue can become polarized in a direct current field. This can cause conflict in neural tissues. Therefore, modern stimulators usually provide alternating or biphasic (also known as bipolar) current. That is, current that reverses polarity each half cycle. This is called a zero net current. If the current continued to flow in the same direction, polarity stress could result in irreversible tissue damage.

As an analogy, picture a group of soldiers marching across a bridge. Before they get to one side, an about-face order is given and they return. Before they reach the opposite side, another about-face order is given, and so on, so that they never actually reach a side. By going back and forth, biphasically, there is no net electron flow across the bridge and no soldiers are added or subtracted. They never get across the bridge to cause an irreversible balance in the status quo. Accordingly, a biphasic current does not add electrons to the body; it simply moves them back and forth.

Amperage, Voltage, and Resistance

Electricity travels in a circuit. The number of electrons moving per unit of time is called amperage. Amperage is a measure of the amount of current. Voltage is a measure of the pressure in the circuit. Resistance to the electron flow in the circuit is measured in ohms. A classic analogy of this is water flowing through a garden hose. The amount of water in the hose corresponds to the amperage. The water pressure corresponds to the voltage. The hose can take only so much water pressure at a given time. Any more pressure or water will be met by more resistance from the hose. This concept is mathematically stated by Ohm's law of E = IR, where E (electromotive force) is the voltage, I is the current, and R is the resistance. One can increase the current and decrease the voltage by decreasing resistance, just as more water can pass with a lower pressure through a fire hose than through a garden hose. Similarly, more current can pass through a larger diameter wire or through a highly conductive metal such as copper. In both cases, the thicker wire and more conductive metal have lower resistance.

In the case of a human body, resistance is determined by factors such as fluid content, general health, skin thickness, amount of oil on the skin, temperature and humidity in the air, etc. If a person has a higher resistance, less current will flow through. However, voltage can be increased to maintain the desired level of current. The better electromedical devices deliver a constant current by self-adjusting voltage as skin resistance changes.

Conductivity

Skin resistance is several thousand ohms (as high as 100,000 Ω when dry). Wet skin can be as low as 1000 Ω. Resistance between the hand and foot excluding skin resistance is as low as 500 Ω. Overall, tissue conductivity is proportional to its water content as can be seen in Table 60.1.

TABLE 60.1
Water Content of Various Tissues

Tissue	Water Content
Skin	5–16%
Bone	5–16%
Fat	14–15%
Brain	~68%
Muscle	72–75%

CLINICAL ASPECTS OF ELECTROMEDICINE

The correct form of electromedical intervention will often have a profound and usually immediate effect on pain. Although caution is advised during pregnancy for liability purposes and the possibility of inducing a miscarriage, and electrical stimulation should not be used on patients with demand-type cardiac pacemakers manufactured prior to the electromagnetic compatibility standards that went into effect in 1998, there are no known significant lasting adverse side effects to therapeutic electromedical technology. There are, however, a number of contraindications as listed below.

General Overview of Benefits

1. Low incidence of adverse effects.
2. Relatively easy to learn.
3. Can be administered by paramedical personnel.
4. Expands the practitioner's clinical capability.
5. Enhances the total efficacy of clinical efforts.
6. An alternative therapy in cases refractive to conventional methods.
7. Eliminates or reduces the need for addictive medications in chronic pain syndromes.

8. May be applied on a scheduled basis or PRN.
9. Some modalities produce cumulative effects.
10. May be self-administered by patients for palliative care.
11. Noninvasive therapies are less liable to result in malpractice claims than many conventional procedures.
12. Highly cost effective.

General Overview of Contraindications, Precautions, and Adverse Effects

1. Possible interference with pre-1998 demand-type pacemakers. Also, other implanted devices such as defibrillators, morphine pumps, artificial joints, joint screws, etc.
2. Strong stimulation or pressure from probes placed directly on the carotid sinus could result in vaso–vagal syncopé.
3. Some modalities may cause skin reactions (redness through actual burns) due to excessive stimulation, prolonged use of direct current (or polarity imbalance), or simply sensitive skin.
4. Direct currents can cause electrochemical damage (i.e., chemical burns).
5. Contact dermatitis or disease transmission due to unclean electrodes.
6. Electric shock hazard due to device malfunction or improper use.
7. Many modalities contraindicated for use around heart.
8. Most modalities contraindicated for use on head.
9. Excessive stimulation may produce muscular soreness or spasm, or exceptionally vigorous muscle stimulation can cause muscle or joint damage.
10. Some modalities can cause cardiac fibrillation.
11. Shock hazard from sudden interruption of current in some modalities.
12. The use of most modalities has not been researched in pregnancy (possible physiological implications, such as miscarriage; and unsubstantiated legal arguments in case of developmental defects).
13. Masking of pain that may serve as a protective mechanism.
14. Masking of pain that may hinder or delay diagnosis.
15. Some devices can raise or lower blood pressure.
16. Patients may not be able to drive or operate heavy machinery during or after use.
17. Some devices may cause headaches, vertigo, or nausea.
18. Sensations experienced by the patient can cause anxiety, or panic attacks due to fear of electricity.
19. Some devices may cause vasodilation which would be contraindicated in some people due to hemophilia or thrombosis (may detach thrombus).
20. Spreading of acute inflammation due to muscle pumping action.
21. Some devices may increase injury if used for recent traumatic injuries.
22. Some modalities must not be used over the spine.
23. Some devices may be contraindicated in malignancy (while others are designed to treat cancer).
24. As in drugs, tolerance is the biggest problem of most modalities, such as TENS.
25. Metal electrodes may be toxic. Electrode materials may be driven through the skin through iontophoresis.
26. Electricity passing through any substance produces heat. For human skin 1 mA/cm^2 is just below the level at which cell damage due to heat is produced. Higher currents may damage cells (Becker, 1990).

Indications and Contraindications for Specific Electrotherapy Modalities

The following tables may be used as general guides to determine which modality might be prescribed for a given diagnosis. However, this information is far from complete, and certainly will not, in itself, suffice as a complete course in electromedicine. The reader should keep in mind the above list of general contraindications, precautions, and adverse effects, and that quality, consistency of the outputs, and other factors vary widely among products. This information is culled from the author's 3 decades of training and experience in electromedicine as well as that of several other leading authorities (Becker, 1990; Benton, Baker, Bowman, & Waters, 1981; Jaskoviak & Schafer, 1993; Kirsch, 1999; Kitchen & Bazin, 1996; Low & Reed, 1994; Nelson & Currier, 1991; Thuile & Kirsch, 2000).

Auriculotherapy

Treatment of ear acupuncture points for pain management and systemic disorders (all acupuncture applications).

Uses low frequency 0.5–320 Hz, < 2 S, < 500 mA.

Cranial Electrotherapy Stimulation (CES)

Treatment of the brain for pain, stress, anxiety, depression, insomnia, and addictions when treated at lower or mid-brain levels (ear lobes). Also may be useful to treat organic brain disorders (e.g., stroke, Parkinson's disease, multiple sclerosis, etc.) when treated on top or above ears. Remove earrings and hearing aids.

Uses low-frequency biphasic currents of 0.5–100 Hz, < 2 S, < 1.0 mA.

Indications		Contraindications
Addictions (alcoholism, cigarette withdrawal, cocaine, heroin, marijuana, methadone, opiates, polysubstance abuse, withdrawal)	Learning disorders	Patients prone to vertigo
	Multiple sclerosis	
	Muscle tone/movement/tremor	Pregnancy
	Obsessive-compulsive disorders	
	Pain (systemic, idiopathic, delusionary or hallucinatory)	
Anxiety	Phobia	
Attention deficit disorder	Parkinson's disease	
Bronchial asthma	Phantom limb syndrome	
Cerebral palsy	Raynaud's disease	
Chronic fatigue syndrome	Reaction time, vigilance	
Closed head injuries	Reflex sympathetic dystrophy	
Cognitive dysfunction	Rehabilitation (systemic disorders)	
Dental analgesia	Stress	
Depression	Stroke	
Eating disorders	Temporomandibular joint disorder	
Fibromyalgia syndrome		
Headaches		
Insomnia		

Cryotherapy

Ice, cold packs, vapocoolant sprays, cold therapy, cold immersions, and cryokinetics. This is included here in opposition to hyperthermia treatment that is a given therapeutic factor of some electromedical modalities.

It takes about 15 minutes for ice to reduce skin temperature from 84 to 45°F, 60 minutes to decrease subcutaneous tissue from 94 to 70°F, and about 2 hours to decrease intramuscular temperature from 98 to 79°F. Use of cold for more than 30 minutes may cause temporary nerve palsy.

Indications		Contraindications
Inhibits bleeding after acute trauma	Angiomas	Raynaud's disease
	Boils and carbuncles	Coma
Reduces pain and reduces the accompanying reflex muscle spasm in acute musculoskeletal injuries	Febrile states	Rheumatoid arthritis and gout
	Herpes blisters	Cryesthesia (e.g., tooth decay)
	Sprains and strains	Paroxysmal cold hemoglobinuria
	Tumors	
	Varicose ulcers	
	Warts	
Decreases blood flow to areas of acute inflammation		
Spasticity		
Burns		
Closed pressure sores		
Reduces adverse tissue changes and relieves pain in the first-aid treatment of insect and snake bites		

Electroacupuncture

Pain management, vasodilation, nausea, healing (all acupuncture applications).

Uses low frequency 0.5–100 Hz, 0.2 mS, at microcurrent to TENS-like amplitudes.

Faradic

Functional electrical stimulation (FES) provides tetanic contractions of denervated muscles. Used for impaired movement, muscle strengthening.

Uses low frequency 30–100 Hz, 0.1–1 mS, biphasic currents applied to motor points.

Indications	Contraindications
Brachial plexus injury	Areas of diminished sensation
Difficulty in voluntary movement (post-stroke or head trauma)	Beyond the flexibility of implanted prosthesis
	Metastatic carcinoma
Facilitation of voluntary motor function	Over metallic implants
	Over open wounds
Guillian-Barré syndrome	Over or through heart
Maintaining or increasing range of motion	Pacemakers
	Pregnancy
Muscle spasticity	Transcranially
Muscle strengthening	
Orthotic training	
Rehabilitation of muscles (post-orthopedic surgery, spinal injuries)	

Galvanic

Neuralgia, circulation disorders, myalgia (denervated muscle), alleviates pain, promotes healing. Used for forcing chemicals through the skin via iontophoresis.

Negative electrode (cathode) is generally thought to promote healing; however, recent evidence indicates that the driving electric force of the degrading, energy-liberating, catabolic process of injury undulates from anodic into cathodic phases, attenuating toward a state

of equilibrium ("healing") as is the case with all spontaneous reactions (Nordenström 1983). Biphasic devices are safer and may actually be better for promoting healing.

Galvanic currents are continuous direct currents of < 0.33 mA/cm^2.

Primary Effects of Direct Currents

Type of Effect	Anode (+)	Cathode (–)
Physiochemical	Attracts acids	Attracts alkaloids
	Repels alkaloids	Repels acids
	Attracts oxygen	Attracts hydrogen
	Corrodes metals by oxidation	Does not corrode metals
Physiological	Hardens scar tissue	Softens tissues
	Decreases nerve irritability	Increases nerve irritability
	Dehydrates tissue	Congests tissues
	Produces vasoconstriction	Produces vasodilation
	Retards bleeding	Enhances bleeding
	Produces ischemia	Produces hyperemia
	Tends to be analgesic	Tends to increase pain at low intensities
		Germicidal effects

Indications	Contraindications
Acute trauma	Carotid sinus area
Adhesions	Impaired cutaneous sensation
Arthritis	Near the heart
Intervetebral disc syndromes	Over any metallic implant (e.g., joints, pins, or IUD)
Joint pain	Over scars and adhesions
Neuritis	Pacemakers
Myalgia	Pregnancy
Sciatica	Transcranially
Sprains and strains	Treatment on a metallic table

High Voltage Pulsed Galvanic

Vasodilation, healing of superficial wounds, reduction of edema, pain management, muscle stimulation.

Uses low frequency 200 Hz typical (< 1 kHz), < 500 V, 1.2–1.5 mA, 1–600 mS.

Indications	Contraindications
Adhesions	Areas of diminished sensation
Circulatory stasis	Metallic implants
Edema	Metastatic carcinoma
Muscle spasm	Over or through heart
Muscular atrophy	Over open wounds
Pain	Pacemakers
Passive exercise	Pregnancy
Restricted joint movement	Transcranially
Trigger points	

Interferential

Pain due to traumatic injuries, post-operative pain, joint conditions, myalgia and tendinitis, bursitis, edema, hematoma. Nerve blocks via Wedensky Inhibition occur when the frequency of the stimulation is faster than the frequency of the action potential (due to its shorter wavelength), because the nerve cannot recover. With continued stimulation, the nerve becomes partially insensitive. The maximum frequency of an action potential lasting 10 mS is 100 Hz.

Generally uses medium frequency combination of 4000 and 4100 Hz = 100 Hz, at 4–15 mA.

Indications		Contraindications
Anterior tibial syndrome	Myositis	Abscess
Bursitis	Neuralgia	Anxiety
Bronchial asthma	Neuroma	Carotid sinus area
Capsulitis	Osteoarthritis	Circulation block
Causalgia	Pain	Heart area
Cholecyctitis (chronic)	Periarthritis	Hyperpyrexia
Effusions	Phantom limb pain	Menstruation
Epicondylitis	Post-traumatic edema	Metastatic carcinoma
Facial palsy	Prostatitis	Pacemakers
Fibrositis	Psoas syndrome	Pregnancy
Frozen shoulder	Rheumatic disorders	Thrombophlebitis
Hematoma calcification	Sciatica	Transcranially
Hemiplegia	Shoulder–arm syndrome	Tuberculosis
Herpes zoster	Spasm	Varicosities
Incontinence	Spondylitis	
Intermittent claudication	Sprains and strains	
Intervertebral disc syndrome	Spurs	
Ischialgia	Stiffness	
Joint deformity	Sudeck's atrophy	
Low back pain	Synovitis	
Lymphedema	Thoracodynia	
Myalgia	Trigger points	
	Vasospasm	

Laser ("Cold Laser")

Nanosecond pulse widths, usually 500–5000 Hz, 15–25 W (< 25 mW actual). Avoid eyes.

Indications	Contraindications
Bursitis	Near eyes
Degenerative joints	Over thyroid gland
Diseases of the oral cavity (stomatitis, post-extraction problems, ulcers, herpes labialis)	Over pacemakers
	Pregnancy
	Tumors
Post-operative or -traumatic musculoskeletal complaints	
Scars	
Ulcers (decubitus and herpetic)	

Microcurrent Electrical Therapy (MET)

Acute, chronic, and post-operative pain, initiating and accelerating healing.

Often references Arndt's Law: Weak stimuli excite physiological activity, moderate stimuli favor it, strong stimuli retard it, and very strong stimuli arrest physiological activity. At 500 μA adenosine triphosphate (ATP) increases by 500%, but drops below baseline above 5 mA (Chang, Van Hoff, Bockx, et al., 1982). At 100–500 mA, amino acid transport rises 30 to 40% above controls.

Uses low-frequency biphasic currents of < 2 S, 0.3–100 Hz, < 1 mA.

Indications		
Systemic Pain	**Head and Neck Pain**	**Abdominal Pain**
Arthritis	Cervicogenic headache	Bladder pain
Bursitis	Cluster headache	Bowel stasis
Cancer	Dental disorders (periodontal and orthodontic pain)	Diverticulosis
Causalgia	Facial palsy	Dysmenorrhea
Cholecyctitis (chronic)	Migraine	Labor
Decubital ulcers	Sinusitis	Post-operative pain
Effusions	Sprains and strains	Prostatitis
Fibrositis	Suboccipital headaches	
Hematoma calcification	Tinnitus	
Hemiplegia	Temporomandibular joint disorder	
Herpes zoster	Tension headache	
Ischialgia	Torticollis	
Lymphedema	Trigeminal neuralgia	
Multiple sclerosis	Whiplash	
Myalgia		
Myositis		
Neuralgia		
Neuroma		
Osteoarthritis		
Pain (systemic and idiopathic)		
Phantom limb syndrome		
Post-traumatic edema		
Raynaud's disease		
Rheumatoid arthritis		
Scars		
Synovitis		
Trigger points		

Back Pain	**Lower Extremity Pain**	**Upper Extremity Pain**
Coccydynia	Ankle pain	Carpal tunnel syndrome
Failed back surgery	Anterior tibial syndrome	Epicondylitis
Intercostal neuralgia	Foot pain	Frozen shoulder
Intervetebral disc syndrome	Fractures	Hand pain
Low back pain	Joint mobilization	Peripheral nerve injury
Lumbrosacral pain	Knee pain	Shoulder–arm syndrome
Radiculitis	Passive stretch pain	Sprains and strains
Spasm	Sciatica	Subdeltoid bursitis
Sprains and strains	Sprains and strains	Wrist pain
Thoracodynia	Spurs	
Whole back pain	Tendonitis	
	Thrombophlebitis	

Contraindications		
Carotid sinus area	Demand type pacemakers	Pregnancy

Russian Stimulation

Muscle stimulation primarily for post-operative rehabilitation.

Uses medium frequency 2500–4000 Hz, 50 Hz, 0.2–0.4 mS

Shortwave Therapy (Diathermy)

Increases elasticity in connective tissue (particularly skin), muscles, ligaments, and joint capsules. Generally used for vasodilation, wound healing (use only after 2 to 4 days), arthritis, bursitis, sinusitis, tendonitis, contusion, rupture, fracture, hematoma, herpes zoster, neuropathy, deep muscle pain and spasm.

Diathermy creates heat but does not depolarize nerves.Remove all metals to a distance of at least 1 m. Contraindicated if there is any implanted metal. Patients should be dressed in a gown with a towel under the electrodes.

Uses high-frequency >300 kHz, short wavelengths 3–30 m. Typically, 27.12 MHz, 65–400 mS, 32 W average (< 200 W).

Indications	**Absolute Contraindications**	**Relative Contraindications**
Amenorrhea	Fractures (recent)	Areas of decreased vascularity
Brachial plexus neuritis	Hearing aids	Arteriosclerosis (advanced)
Bronchiectasis	Hemoptysis, epitaxis, melena, and other hemorrhagic tendencies	Hypothermesthesia
Bronchitis	Malignancy	Infants and debilitated elderly
Bursitis (subacute and chronic)	Menstruation	Intrauterine device (metallic)
Colic	Metallic dental appliances and fillings	Metallic buttons, zippers, hairpins, buckles, clasps, keys, knives, etc.
Contusions	Metallic implants	Nondraining cellulitis
Dislocations	On a metal table	Osteomyelitis
Diverticulitis	Over adhesive strapping	
Dysmenorrhea		
Epicondylitis		
Fibrositis		
Fibrous fixation/ankylosis		

Furuncle/carbuncle	Over casts	Osteoporosis (advanced)
Hypertonia	Over moist dressings	Over growing epiphyseal plate
Intercostal neuralgia	Pacemakers	Patients on anticoagulants, cortisone, gold therapy
Ischialgia (chronic)	Peptic ulcers	Peripheral vascular disease (occlusive)
Intervetebral disc syndrome	Pregnancy	Poliomyelitis (acute stage)
Low back pain	Pyretic states	Polyneuritis with impaired circulation
Mastitis	Rheumatoid arthritis (acute)	Suppurating inflammatory process
Myalgia	Septic arthritis (acute)	Thrombosis
Myositis	Tuberculosis (pulmonary or joint)	Transcranially
Neuritis		Varicose veins
Osteoarthritis		
Pelvic inflammatory disease (subacute, chronic)		
Pleurisy		
Prostatitis		
Pyelitis (subacute, chronic)		
Rheumatoid arthritis (subacute, chronic)		
Sprains and strains		
Tenosynovitis		

Transcutaneous Electrical Nerve Stimulation (TENS)

Acute, chronic, and post-operative pain.

Uses low-frequency biphasic currents of 75–400 mS, 50–150 Hz, < 100 mA.

Indications		
Systemic Pain	**Abdominal Pain**	**Back Pain**
Bursitis	Bladder pain	Coccydynia
Cancer	Bowel stasis	Intercostal neuralgia
Causalgia	Diverticulosis	Intervertebral disc syndrome
Ischialgia	Dysmenorrhea	Low back pain
Neuralgia	Labor	Lumbrosacral pain
Osteoarthritis	Post-operative pain	Radiculitis
Passive stretch pain		Sprains and strains
Rheumatoid arthritis		Thoracodynia
Synovitis		Whole back pain
Lower Extremity Pain	**Upper Extremity Pain**	**Contraindications**
Ankle pain	Carpal tunnel syndrome	Metallic implants
Foot pain	Epicondylitis	Metastatic carcinoma
Fractures	Frozen shoulder	Near carotid sinus area
Joint mobilization	Hand pain	Over or through heart
Knee pain	Peripheral nerve injury	Pacemakers
Sciatica	Sprains and strains	Pregnancy
Sprains and strains	Subdeltoid bursitis	Transcranially
Tendonitis	Wrist pain	
Thrombophlebitis		

Ultrasound

Promotes blood circulation; improves metabolism, muscle relaxation, pain control; increases elasticity of connective tissues. Used to treat tendon adhesions and scars, post-traumatic injuries, binding tissue contractions (scars), Dupuytren's Contracture, bursitis, capsulitis, tendonitis, and chronic open wounds. Micromassage, microdestruction, and heat generation.

May cause mechanical or thermal tissue damage. Overdose may decrease blood sugar levels, cause fatigue, nervousness, irritability, constipation, and a tendency to catch cold. Do not use over pregnant uterus, heart, testicles, spine, areas of thrombophlebitis, infections.

High frequency mechanical vibrations using piezoelectricity > 20 kHz (typically between 0.8 and 3 Mhz) and 0.1–3 W/cm^2.

Indications		Contraindications
Bursitis (subacute, chronic)	Sprains and strains (subacute, chronic)	Acute infection
Calcific bursitis	Sudeck's atrophy	Areas of thermohypersthesia
Causalgia	Tendonitis (subacute, chronic)	Near hearing aid
Decubital ulcers	Trigger points	Near malignant lesions
Fibrositis (subacute, chronic)	Varicose ulcers (chronic)	Near metallic implants
Fibrotic polymylosis		Near pacemakers
Herpes zoster		Occlusive vascular disease
Joint contractures		Over bony prominences
Myalgia		Over epiphyseal plates of growing children
Neuralgia		Over nerve plexuses
Osteoarthritis		Over suspected embolus
Painful neuroma		Over the eye
Periarthritis (nonseptic)		Over the heart
Radiculitis (subacute, chronic)		Over a pregnant uterus
Raynaud's disease		Over the reproductive organs
Rheumatoid arthritis (subacute, chronic)		Over spinal cord after laminectomy
Scars		Radiculitis (acute)
Shoulder–hand syndrome		Tendency to hemorrhage
Spondylitis		Transcranially

SUMMARY

One must stray from the routine procedures of today in order to create the advances of tomorrow. There is still a lot to learn about bioelectricity and electromedicine. In

order to do so, we must first acknowledge that there is another side of physiology. Everyone concerned about health should demand widespread access to conservative, safe, alternative care. To lessen human suffering is a notable goal. That we have not been able to achieve enough of this to date without causing undo harm is a good indication that the answers must lie elsewhere. Biophysics must be better understood to realize the actual basis for the control of the regulatory processes of life.

Even at its present state of evolution, electromedicine offers an unprecedented conservative, cost-effective, fast, safe, and powerful tool in the management of the pain patient. As such, it should be the first priority on the list of treatment options.

A Practical Protocol for Electromedical Treatment of Pain

Daniel L. Kirsch, Ph.D., D.A.A.P.M.

If there were pharmaceutical products that could control people's physical pains more than 90% of the time and were safe enough to use as often as necessary without causing any significant side effects, physicians would prescribe them often. If those drugs could also calm people who were seriously clinically anxious or depressed, while being safe enough for people who are only a bit stressed, they would be the most widely prescribed drugs on Earth. If those same drugs could also heal broken bones and close wounds, the pharmacies could not possibly stock enough of them.

What if there is something that could do all these things and so much more, but is not a drug? What if there is a treatment that is so safe it could be used daily to control pain and stress-related diseases. What if it is also so inexpensive that once purchased for a fraction of the cost of conventional care, it will cost almost nothing to use? There is. New forms of electromedicine offer all this and more.

Change has always fought its way into the healthcare system slowly. A mere 100 years ago it would have been considered quackery to propose that invisible little germs could cause disease. Even after the discovery of bacteria, for 35 more years most doctors refused to believe that washing their hands before surgery would make much of a difference. Yet progress in medicine occurred as we developed tools to look deeper into the body, and to see smaller particles. We even speak of subatomic particles, such as electrons, which could both cause disease in the form of free radicals and cure known diseases as well as functional disturbances of the body and mind. We have learned to appreciate the power of physics in our lives with convenient technologies such as microwave ovens and cellular telephones. Today, our daily lives are increasingly more influenced by electronics than chemistry.

As we begin this new millennium, we rely on various forms of technology to diagnose our patients, both locally through an ever-increasing armamentarium of devices, and even over long distance with telemedicine. But we also can treat our patients with new technologies for a variety of disorders with remarkable and unprecedented safety and efficacy.

Most systems of healthcare have historically been based on biophysics. Acupuncture is an obvious example. Chinese call the electrical properties of life Chi energy, Japanese call it Ki, Indians call it Prana, and chiropractors call it "innate intelligence". Even homeopathy is based on the energetic residual of the chemical after it has been so diluted that chemists question its continued existence. Western allopathic medicine stands alone in reliance on synthetic chemical treatments and invasive procedures, many of which impose a risk worse than the disease for which it is offered. In fact, conventional medical care is the third leading cause of death in the United States with at least 225,000 people dying annually from iatrogenic conditions (Starfield, 2000).

Change takes time in medicine as in any established system. There are strong controlling economic influences and long-standing institutions that will always argue for the status quo. Yet people are more educated and informed about healthcare than ever before. With that comes concern over side effects of dangerous treatments. Why do

0-8493-0926-3/02/$0.00+$1.50

we not try the most inexpensive and conservative treatments first, instead of last? When that treatment is based on sound electromagnetic principles, most physicians are surprised to discover that, while not a drug, the results are often more immediate and spectacular than one can imagine. Also, unlike drugs, the results are usually long lasting and cumulative.

While electromedicine has been practiced in some form for thousands of years, research and clinical usage in electromedicine are expanding as never before in history. Perhaps even more than any other therapeutic option, electromedicine is now used routinely by a growing number of practitioners from all of the healthcare professions, as well as by patients themselves at home. Only the United States Food and Drug Administration (FDA) restricts the sale of electromedical devices for use by or on the order of licensed healthcare practitioners. All other countries allow people to purchase therapeutic electromedical devices over the counter for their own personal use. Electromedical modalities are easy to use, relatively safe, and the newer technologies, such as microcurrent electrical therapy and cranial electrotherapy stimulation, have proven efficacy unprecedented by any prior form of medical intervention.

One word of caution, though: Medicine is still a science. Modern electromagnetic therapies have attracted many charlatans. Simply said, not everything is equally safe and effective. Rely only on evidence-based technologies.

MICROCURRENT ELECTRICAL THERAPY

Joseph M. Mercola and Daniel L. Kirsch (1995) coined the term "microcurrent electrical therapy" (MET) to define a new form of electromedical intervention using biocompatible waveforms.

Patrick DeBock (2000), a physiotherapist at the University of Antwerp in Belgium, recently compared MET with TENS based on the Eight Parameter Law which covers every possible influence in electrotherapy. In his conclusion, DeBock states, "MET has a completely different mechanism, which at this time is not fully understood, but works on a cellular level … It looks as if TENS is going to lose this competition … MET will, in most cases, be much more satisfying than TENS because of the longer lasting and more intense effects."

A growing body of research shows the effectiveness of MET to do more than control pain. It can actually accelerate and even induce healing. When a wound is dry, its bioelectric current flow is shut off. Eaglstein and Mertz (1978) have shown moist wounds to resurface up to 40% faster than air-exposed wounds. Falanga (1989) found that certain types of occlusive dressings, like Duoderm, accelerate the healing of wounds. It is probable that these dressings achieve their effects by promoting a moist environment (Kulig, Jarski, Drewek, et al., 1991). The moisture may allow endogenously produced current to flow more readily through the injury, and thus promote wound healing. Electrical stimulation of the wound has a similar effect, and also tends to increase the amount of growth factor receptors, which increases the amount of collagen formation (Falanga, et al., 1987).

Electricity was first used to treat surface wounds over 300 years ago when charged gold leaf was found to prevent smallpox scars (Robinson, 1925). There are several recent studies supporting the beneficial effects of treating wounds with an artificial current (Goldin, et al., 1981; Jeran, et al., 1990; Jeran, et al., 1987; Mulder, 1991). Experimental animal wound models in the 1960s demonstrated that electrical intervention results in accelerated healing with skin wounds resurfacing faster, and with stronger scar tissue formation (Assimacopoulos, 1968; Carey & Lepley, 1962).

Assimacopoulos (1968a) published the first human study using direct current for wound healing. He documented complete healing in three patients with chronic leg ulcers due to venous stasis after six weeks of electrical therapy. One year later Wolcott, Wheeler, and Hardwicke (1969) published the most frequently cited work in the history of electrical wound healing. They used direct currents of 200 to 1000 μA on 67 patients. Gault and Gatesn (1976) repeated the Wolcott and Wheeler protocol on 76 additional patients with 106 ischemic skin ulcers. Rowley, McKenna, Chase, and Wolcott (1974) studied a group of patients having 250 ischemic ulcers of various types. These included 14 symmetrical control ulcers. The electrically stimulated ulcers had a fourfold acceleration in healing response compared to the controls. Carley and Wainapel (1985) performed one of the only studies on this subject with equal and randomized active and control groups. All of these studies documented significant accelerated healing from electrical stimulation.

One additional consistent observation in these studies was a reversal of contamination in the wounds. Wounds that were initially contaminated with *Pseudomonas* and/or *Proteus* were usually sterile after several days of MET. Other investigators also have noticed similar improvements and encourage the use of this therapy as the preferred treatment for indolent ulcers (Alvarez et al., 1983; Barron & Jacobson, 1985; Kaada, Flatheim, & Woie, 1991; Lundeberg, Eriksson, & Malm, 1992). Additionally, no significant adverse effects resulting from electrotherapy on wounds have been documented (Weiss, et al., 1990). A review of the literature by Dayton and Palladino (1989) shows that MET is clearly an effective and safe supplement to the nonsurgical management of recalcitrant leg ulcers.

Some of these studies used unipolar currents that were alternated between negative and positive based on various criteria. Some researchers initially used negative current

to inhibit bacterial growth and then switched to positive current to promote healing. To date no study has compared this variable of MET. However, there is some compelling basic science research, and one animal study, suggesting that a biphasic waveform, which provides both negative and positive current, may be better in that it both sterilizes the wound and promotes wound healing (Stromberg, 1988; Windsor, Lester, & Herring, 1993).

In the 1960s Robert O. Becker (1985) demonstrated that electrical current is the trigger that stimulates healing, growth, and regeneration in all living organisms. He found that repair of injury occurs in response to signals that come from an electrical control system, and suggested that this system became less efficient as we age.

Becker developed his theory of biological control systems based on concepts derived from physics, electronics, and biology. He postulated that the first living organisms must have been capable of self-repair, otherwise they never would have survived. The repair process requires a closed-loop system. A specific signal is generated, called the current of injury, which causes another signal to start repair. The injury signal gradually decreases over time with the repair process, until it finally stops when the repair is complete. Such a primitive system does not require demonstrable consciousness or intelligence. In fact, many animals actually have a greater capacity for healing than humans.

Science has amassed a vast amount of information on how the brain and nervous system work. Most of this research involves the action potential as the sole mechanism of the nerve impulse. This is a very sophisticated and complex system for the transfer of information. It is helpful to compare this conceptualized concept of the nervous system to a computer.

The fundamental signal in both the computer and the nervous system is a digital one. Both systems transfer information represented by the number of pulses per unit of time. Information also is coded according to where the pulses originate, where they go, and whether or not there is more than one channel of pulses feeding into an area. All our senses (e.g., smell, taste, hearing, sight, and touch) are based on this type of pulse system. Like a computer, the nervous system operates remarkably fast and can transfer large amounts of information as digital on-and-off data.

It is unlikely that the first living organisms had such a sophisticated system. Becker believes they must have had a much simpler mechanism for communicating information because they did not need to transmit large amounts of sophisticated data. Accordingly, they probably used an *analog* system. An analog system works by means of simple DC currents. Information in an analog system is represented by the strength of the current, its direction of flow, and slow wavelength variations in its strength. This is a much slower system than the digital model. However, the analog system is extremely precise and works well for its intended purpose.

Becker theorizes that primitive organisms used this analog type of data transmission and control system for repair. He postulates that we still have this primitive nervous system in the perineural cells of the central nervous system. These cells comprise 90% of the nervous system. The perineural cells have semiconductor properties that allow them to produce and transmit nonpropagating DC signals. This system functions so vastly differently from the "all or none" law of propagation of the nerve action potentials that Becker called this the fourth nervous system.

This analog system senses injury and controls repair. It controls the activity of cells by producing specific DC electrical environments in their vicinity. It also appears to be the primary primitive system in the brain, controlling the actions of the neurons in their generation and receipt of nerve impulses. Accordingly, as knowledge of this aspect of our nervous system is uncovered, another mystery of brain physiology may be explained, including the regulation of our consciousness and decision-making processes. Given this understanding, the application of the correct form of electrical intervention is a powerful tool for treating pain, initiating the endogenous mechanisms for healing, and altering states of consciousness.

Chang, Van Hoff, Bockx, et al. (1982) proposed another mechanism for MET. Their research showed that microcurrent stimulation increased adenosine triphosphate (ATP) generation by almost 500%. Increasing the level of current to milliampere levels actually decreased the results. Microcurrent also was shown to enhance amino acid transport and protein synthesis in the treated area 30 to 40% above controls.

It would be helpful to review the cellular nature of an injury to fully appreciate the importance of Chang's research. Becker (1985) has shown that trauma will affect the electrical potential of cells in damaged tissues. Initially the injured site has a much higher resistance than that of the surrounding tissue. Basic physics dictates that electricity tends to flow toward the path of least resistance. Therefore, endogenous bioelectricity avoids areas of high resistance and takes the easiest path, generally around the injury. The decreased electrical flow through the injured area decreases the cellular capacitance (Windsor, et al., 1993). As a result, healing is actually impaired. This may be one of the reasons for inflammatory reactions. Pain, heat, swelling, and redness are the characteristics of inflamed tissues. Electricity flows more readily through these hot inflammatory fluids.

The correct microcurrent application to an injured site augments the endogenous current flow. This allows the traumatized area to regain its capacitance. The resistance of the injured tissue is then reduced, allowing bioelectricity to enter the area to reestablish homeostasis. Therefore, microcurrent electrical therapy can be viewed as a catalyst helpful in initiating and sustaining the numerous chemical and electrical reactions that occur in the healing process.

When a muscle experiences trauma it goes into spasm to protect itself. This decreases its blood supply, reducing the amount of oxygen and nutrients that reach it. The decreased circulation causes an accumulation of metabolic waste products. This acts as noxious input resulting in pain.

Adenosine triphosphate is an essential factor in the healing process. Large amounts of ATP, the cell's main energy source, are required to control primary functions such as the movement of vital minerals, like sodium, potassium, magnesium, and calcium, into and out of the cell. It also sustains the movement of waste products out of the cell. Injured tissues are deficient in ATP.

As MET restores circulation and replenishes ATP, nutrients can again flow into injured cells and waste products can flow out. This is necessary for the development of healthy tissues. As ATP provides the energy tissues require for building new proteins, it also increases protein synthesis and membrane transport of ions.

Survey Results

Two surveys were recently conducted on a total of 3000 people using Alpha-Stim™ technology employing the combined treatment protocols of MET and CES as presented here.

Healthcare practitioners completed a post-marketing survey of 500 patients in 1998 (Kirsch, 1999). There were 174 males, and 326 females, ranging from 5 to 92 years old. Outpatients accounted for 479 of the forms, while 21 were hospitalized at the time of treatment. Treatment was satisfactorily completed by 197 (41%) of the patients with 207 (43%) still receiving treatment at the time of the survey. Ten patients discontinued treatment because they thought it was not helping them, and three more discontinued due to undesirable side effects. An additional 13 terminated treatment when their insurance ran out and they could no longer pay for treatment; 20 patients moved out of the area while treatment was in progress or discontinued treatment for other, unstated reasons.

Negative adverse effects were all rare, mild, and self-limiting, with 472 (94.4%) reporting none. Six (1.2%) reported vertigo as a side effect and 2 (0.4%) reported nausea, either of which normally occurs when the current is set too high or in patients with a history of vertigo. Only 3 (0.6%) reported skin irritation, and 1 (0.2%) each reported anger, a metallic taste, a heavy feeling, or intensified tinnitus. These generally receded or disappeared as soon as the current was reduced.

The most important aspect of this survey was the results reported as a degree of improvement in the seven symptoms present in most patients for which MET and/or CES is prescribed; i.e., pain, anxiety, depression, stress, insomnia, headache, and muscle tension. The treatment outcome was broken down into response categories beginning with [it made the condition] "Worse," and progressing up to "Complete" improvement or cure. As in pharmaceutical studies, a degree of improvement of 25% or more was considered to be clinically significant. The data for all 500 patients reporting on multiple symptoms are summarized in Table 61.1.

In addition, 2500 patients were surveyed through a form attached to warranty cards (Smith, 2001); 1411 (72.40%) of the patients were female; ages ranged from 15 to 92 years old with a mean of 50.07 years. The length of use ranged from the minimum of 3 weeks which was

Note: Total N = 500 patients with multiple symptoms.

the only inclusion criterion, to a maximum of 5 years in two cases. The average period of use reported was 14.68 weeks or approximately 3.5 months. Of 1949 primary pain patients, 1813, or 93.02% rated their improvement as significant, and these findings correlate well with the physicians' survey of 500 patients where 90.91% of 286 pain patients were observed to have significant improvement. The data for all 2500 patients reporting on multiple symptoms are summarized in Table 61.2.

BASIC TREATMENT PROTOCOL FOR MICROCURRENT ELECTRICAL THERAPY (MET)

The following section is intended as a practical guide for clinicians to utilize the principles discussed in this chapter. The methods of treatment provided herein have been developed by the author based on 3 decades of experience in electromedicine. The reader is cautioned to remember that not all brands of microcurrent devices are equally efficacious. Always check the manufacturer's specific instructions before using a medical device. As medicine is not an exact science, the author cannot assume responsibility for the clinical efficacy of, or liability for, the methods and treatments found in this text.

Step One: History and Brief Exam

It is important to take a comprehensive history and do a brief analysis of the patient's current condition before beginning each session of MET treatment. A diagnosis is not enough. One should determine when the pain first presented, its frequency, duration, intensity, limitations-of-motion, positions which exacerbate the pain, and any precipitating factors. Ask about the specifics of previous treatments and details of all surgical scars and traumatic injuries. Microcurrent electrical therapy is a very holistic procedure. It may be necessary to clear the body of any and all electrical "blocks" in order to achieve the best results. Even brief 10- to 20-second treatments of other problems and/or old injuries may reverse a refractory case.

Immediately before each treatment determine the patient's present pain level, and positions that exacerbate the pain. Ask the patient to rate his or her present pain on a scale of 0 (no pain) to 10, with 10 being excruciating, debilitating pain. Tell the patient to consider 10 as "the worst this condition has been." Also note any immediate limitations-of-motion, positive orthopedic and neurologic test findings, and objective signs of psychological distress. Because the results of MET can be seen after only a minute or so of treatment in most people, these indicators are necessary reference parameters to determine effectiveness throughout a single treatment session.

Adjust the Settings

Use 0.5 Hz frequency most of the time. It is unusual ever to need other frequency settings. However, if 0.5 Hz does not work, and a number of electrode placements sites have been attempted, try 1.5 Hz; 100 Hz sometimes produces faster results when treating inflammatory articular problems (e.g., arthritis, bursitis, tendonitis, etc.). However, 100 Hz does not contribute much to long-term results so treatment should always be completed using a low frequency. Set the current intensity level at the highest comfortable position, which is usually 500 to 600 μA for probes, although sometimes less for the silver electrodes used with MET. Do not use standard TENS electrodes except in the initial treatment of hypersensitive patients. Carbon TENS electrodes have a resistance of about 200 ohms, while silver electrodes have a resistance of about 20 ohms. Only silver electrodes will work effectively with MET devices.

When using probes, first fix new felt electrodes and saturate them with an appropriate electromedical conducting solution. Then apply firm pressure, but less than what would cause more pain. Tap water does not work well in some places anymore because of recent advances in desalination during water processing. Saline solution may be used if a conducting solution is not available.

For extremely hypersensitive people, such as fibromyalgia patients, it is better to start with a minimal amount of current. Even low-level MET currents may be uncomfortable in some patients. For these patients it may be necessary to initially reduce the conductivity by using more resistive electrodes. Over the course of a few weeks, the therapeutic dosage of electricity can gradually be increased. Start with standard carbon electrodes, followed by silver electrodes, then probes with tap water, until the area is desensitized enough to use probes with conducting solution. Fortunately, this is rarely necessary. Most people will not even feel MET stimulation at a current of 600 μA.

Basic Treatment Strategy

There are only a few principles one must remember when treating patients with MET. The patient should be in a relaxed position to receive maximum beneficial effects. For example, do not let patients help with the treatment of their hands by holding up their arms, which would cause the arm muscles to tense. In this case, it is better to place both hands on a table.

The most important variable is the position of the probes, or silver electrode pads. Place the probes, or pads, in such a way that if a line were drawn between them, the line would travel through the problem area. Keep in mind that the body is three-dimensional. Therefore, many possible lines can be drawn through the problem area. Some lines will work much better than others. The correct electrode location is the one that works. However, the one

TABLE 61.2

that works may be transient, working well one day, but ineffective another day. As the problem begins to resolve, the electrode locations may require frequent adjustments.

A common mistake made by clinicians familiar with traditional TENS is placing the electrodes on each side of the spine for back pain. This is a two-dimensional

approach. With such a placement, microcurrent will travel just under the skin between the electrodes and never reach the spine. Nor can the electrodes be effectively placed "between the pain and the brain." These are common placements for TENS electrodes, but MET is not TENS. A better way is to place one electrode next to the spine at the level where the problem is, and the other on the contralateral side, anteriolaterally (front and opposite side). A line drawn between those will go right through the spinal nerves. Next, reverse the sides. Then follow up by doing another set of contralateral placements one spinal level above, and one below the problem to accommodate overlap in the dorsolateral fasciculus.

Always treat bilaterally. Bilateral treatment includes the spinal cord, thereby involving dermatomes, myotomes, and sclerotomes. Also, if the problem is within the axial skeleton and the contralateral side is ignored, there is a good chance that the primary location of a pain problem will be missed. Pain often presents itself on the tense side, which may be compensating for muscular weakness on the other side.

Quick Probe Treatments

When using probes, set the timer on a probe setting, or if one is not available, treat about 10 seconds per site. In other words, move the probes to the next location every 10 seconds. Consider one treatment "set" to be 12 to 20 of these 10-second stimulations, each at a different angle of approach. The first set should take about 2 minutes, but then additional treatment may be done at 1-minute intervals. The patient should be reevaluated between each set.

The protocol involves four steps:

1. First treat in a large "X" manner over a wide area holding the probes so that the current is directed through the problem area. An example of this strategy for knee pain would be to first make the large X by treating from the medial, superior thigh to the lateral foot, then lateral at the hip to the medial foot.
2. Treat with smaller Xs, or a "star" (*) closer and directly around the involved knee (e.g., two obliques, one or two medial–lateral, one or two anterior–posterior, etc.).
3. Treat the opposite knee for at least 20 seconds (one X), even if it is asymptomatic.
4. Connect the two knees by placing a probe on each knee at least four times.

The above example takes 2 minutes. A big X beyond the area (20 seconds), a star through the chief complaint (40 seconds), treat the opposite side with one small X (20 seconds), and connect the two sides (40 seconds). Then reevaluate the pain based on the original criteria.

If the pain is gone, stop for the day. If it is reduced, ask the patient to point to where it hurts with one finger and treat for another minute or so directly through the area of pain, which may have moved after the original 2-minute treatment.

Think in terms of symmetry. Look, palpate, and otherwise examine areas above, below, and to the left and right of the primary area undergoing treatment. Always treat the opposite side and connect both sides.

Silver Self-Adhesive Electrodes

These are used following the same strategy as the probes, except for a longer period of time. The probes and brief electrode treatments assume MET is working as a catalyst for the patient's own bioelectrical system, whereas keeping electrodes in place can be viewed as using MET to augment endogenous bioelectricity. For optimum results, silver electrodes also may be moved around the problem area. Whereas the probes are used for 10 seconds a site, silver electrodes should be left at each location for at least 5 to 10 minutes. Some cases will require an hour or even several hours of stimulation daily. Accordingly, silver electrodes are best used for home care. However, if brief stimulation works, do not continue treatment at that session. More is not better when using MET technology to manage pain!

When to Stop

Reevaluate the patient after the 2-minute protocol using the original criteria. It is not enough to ask if the patient feels better, ask for a specific percentage of how much better. If the patient has difficulty with a 0-to-10 scale, to facilitate communication, ask, "If you had a dollar's worth of pain when we began, how many cents do you have left?" Also, reexamine for improvement in objective signs, such as range-of-motion increases, etc. Stop when the pain is completely gone, or when the improvement has reached a plateau after several treatment sets. Continuing to treat the area at this time may cause the pain to return! If the pain is gone, it is far better to stop treatment for that day even if the patient only had 1 or 2 minutes of treatment.

If the patient can no longer identify any pain, but complains of stiffness, this indicates that it is time to stop treatment for the day. Microcurrent may not reduce residual stiffness. Post-pain stiffness usually wears off by itself. Yoga, Tai Chi, or simple stretching exercises are good means of controlling chronic stiffness.

Although most patients will have an immediate response to treatment, in some the effects will be delayed, continuing to improve over a day or two after the treatment. In these patients relief will generally occur 1 to 3 hours post-treatment or even as late as the

next morning. Some patients will experience a cumulative effect, continuing to improve over time. Patients who experience a delayed effect are more difficult to treat due to lack of immediate feedback. Usually, patients who experience a delayed effect from microcurrent treatment also have a delayed effect with anesthetics. Ask the nonresponsive patient if his or her dentist had to wait more than 10 minutes after injecting anesthetic prior to doing dental procedures. Because treating patients who exhibit delayed responses can be viewed as a type of "blind" treatment, one must rely on experience with other patients who exhibited an immediate response in order to develop the skills to treat those few who have a delayed response. A post-treatment diary is also helpful in analyzing the response of these patients.

Follow-Up

Most patients should be given at least three to seven treatments before evaluating their responses to microcurrent electrical therapy. It helps to explain to the patient that the effects of MET treatment are cumulative. Like antibiotics, one must take several doses over a period of time to get results. Although results will usually be seen during or subsequent to the first treatment, the longevity of the results can only be evaluated after a series of treatments. Fortunately, most patients will experience long-lasting results. However, in some cases the results will plateau to a similar time period regardless of treatment. For example, a patient may only get 1 or 2 days of relief no matter what combination of treatment strategies is employed. For these, and cases of severe pathology, the effectiveness may be only short-lived, so a MET device should be prescribed for home care. After an initial series of up to ten clinical treatments, a good rule of thumb is to prescribe a unit for anyone with a chronic condition who requires more than one or two palliative treatments per month, and for patients who have progressive pathologies. When used at home, after an initial series of 1 or 2 weeks of daily treatments, treatment every other day usually provides better results than daily treatment.

Tips for Limited or Poor Results

While a good MET device will be at least somewhat efficacious on more than 90% of the population when used correctly, MET will not work for everyone. In cases where there are no results at all, a few things should be considered. Dehydrated patients may not respond well. Patients should be advised to drink at least eight to ten glasses of water daily. Nutrition is certainly a factor. A poor diet does not provide the necessary building blocks to reinstate homeostasis.

Also, preliminary observations suggest that people who have had a significant exposure to strong electrical current may be poor candidates for MET. This means that they either have been held by electrical current at some time in their life, or have been treated with mA TENS or similar modalities for a prolonged period of time, usually years. There have even been a few reports of failures in patients who were struck by lightning. Brief exposure to very high levels of electricity is not as bad as longer exposure to any level of electricity. Such patients need to be treated for a longer period of time.

Aside from hydration and nutrition and electrical shock, the primary reversible reason patients fail to respond to treatment is that they have some sort of a blockage somewhere on or in their body that is resisting endogenous electrical flow. This is usually something superficial, like a scar or old injury. It need not be anywhere near the patient's primary problem. Identify all scars by taking a very thorough, persistent history, and examining the patient completely. All scars are important no matter how old or how far they are from the chief complaint. Scar tissue impedes the systemic flow of endogenous bioelectricity because it is a poor conductor of electricity. Accordingly, scar tissue may interfere with the patient's entire bioelectrical system. If scars are present they should be treated with silver electrodes for 10 minutes per scar, at least four times. Simply cover the scars with the electrodes, or for large scars, place the electrodes on the ends of the scars. This may be done 4 days in a row or there can be a short interval of up to a few days between the treatments. Some people report that it helps to repeat this procedure after a month or so.

During treatment for scars the person may experience a significant surge of energy. This can be viewed as if an electrical "bioresistor" has broken down, reestablishing the normal flow of bioelectricity. After scar therapy, patients will often report feeling half their age. Because people have nothing with which to compare their life experiences, they usually attribute the subtle effects of scars on their electrical system as normal aging. Be aware that this treatment will often also increase pain, because the whole body and mind "wake up," including the painful part. However, in nearly all cases, when this happens the painful area can then be successfully treated. Always schedule enough time to treat the pain after a scar treatment, so the patient will not need to endure even a temporary increase in pain.

If all the scars are treated and there are still no results, or if there are poor results, a few other options still exit. Question the patient about old injuries that may not have healed properly. These also could be electrical blocks and should be approached in the same way as scars. Consider treating the primary complaint at a lower current setting of 100 μA with silver electrodes for 60

minutes or more. Slightly higher pulse repetition rates (e.g., 1.5 Hz) may produce results in some people when the 0.5 Hz fails, but this is rare. For more information about treating scars, or how to determine which scars to treat, physicians and dentists may contact the American Academy of Neural Therapy through their Web site at www.neuraltherapy.com.

SAMPLE PROTOCOLS

The following illustrated sample protocols may be used as a guide for treatment using MET.

Head Pain Protocol

SAMPLE 1 (See Figure 61.1): Head Pain

Include the temporomandibular joint (TMJ), neck, and shoulders.

1. Above the ear to the tip of the contralateral shoulder. Reverse sides.
2. Across the shoulders by treating bilaterally across the distal tips of the acromions.
3. A few "X" patterns across back of neck.
4. From one TMJ to the other.
5. Temple to ipsilateral masseter muscle. Reverse sides.
6. About 1 minute through the primary area of involvement.

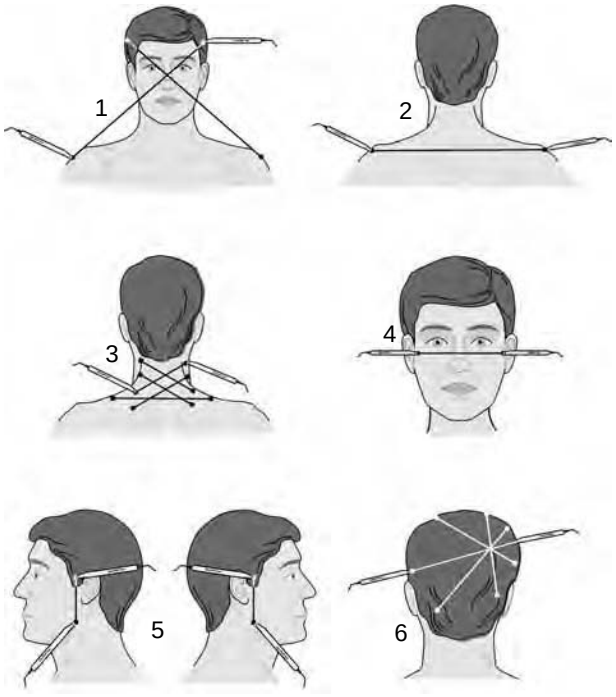

FIGURE 61.1 Head pain protocol.

Balance out contralateral side by treating any mirror areas not already covered.

Note: Reduce the current as necessary to avoid vertigo. Treating near the eyes may cause the patient to see flashing lights due to stimulation of optic nerve. Patient may also taste metal fillings when treating across oral cavity. None of these conditions is harmful.

Sinus and Ocular Pain

SAMPLE 2 (See Figure 61.2): Sinus and Ocular Pain

Begin sinus and ocular pain treatment using the above protocol for head pain.

7. Treat sinuses when indicated, above and below eyes, or from side to side (see notes in head pain section). The patient should be able to breathe more clearly immediately after treatment.
8. For ocular headaches, treat behind eyes by placing probes on each temple, lateral to the lateral canthus of the eyes, and across each eye (one at a time) at the bridge of the nose to the lateral canthus.

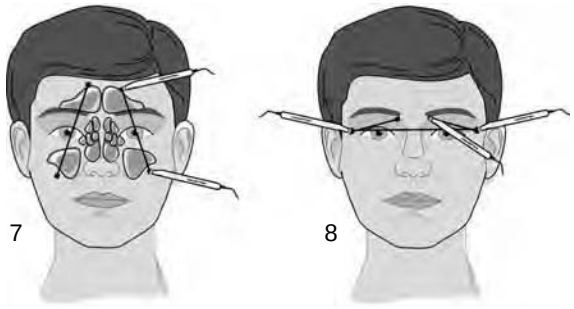

FIGURE 61.2 Sinus and ocular pain protocol.

Temporomandibular Disorder

SAMPLE 3 (See Figure 61.3): Temporomandibular Disorder (TMD)

Begin temporomandibular disorder treatment using the above protocol for head pain.

7. A star pattern across TMJ. Reverse sides.
8. Connect the TMJ with the sternocleidomastoideus (SCM) muscles, below the mastoid, and along the clavicular and sternal branches. Reverse sides.

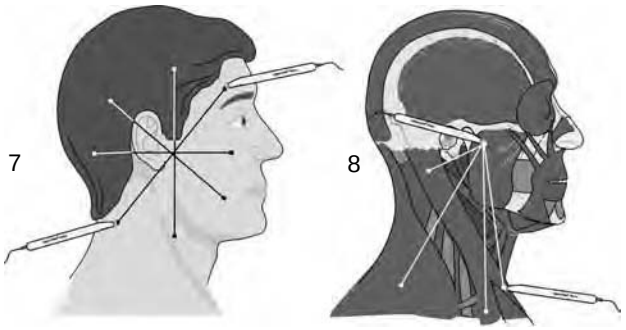

FIGURE 61.3 Temporomandibular disorder (TMD) pain protocol.

to the webs between the fingers in addition to local treatment at the wrist.
3. Treat the area corresponding to the area of pain on the other upper extremity for 20 to 40 seconds.
4. Connect the two upper extremities by placing one probe on each in several symmetrical places encompassing the pain area for 40 seconds to 1 minute.

Lower Extremity Pain Protocol

SAMPLE 5 (See Figure 61.5): Lower Extremity

1. First make the large "X" by treating from the medial, superior thigh to the lateral foot, then the lateral hip to the medial foot.
2. Complete 40 seconds to 1 minute of smaller Xs closer to and directly around the hip, knee, ankle, foot, or other area of pain.
3. Treat the area corresponding to the area of pain on the other lower extremity for 20 to 40 seconds.
4. Connect the two lower extremities by placing one probe on each in several symmetrical places encompassing the pain area for 40 seconds to 1 minute.

Upper Extremity Pain Protocol

SAMPLE 4 (See Figure 61.4): Upper Extremity

1. First make the large "X" by treating from the anterior shoulder to the posterior hand, and the posterior shoulder to the anterior hand.
2. Complete 40 seconds to 1 minute of smaller Xs closer to and directly around the shoulder, elbow, wrist, hand, or other area of pain. For carpal tunnel syndrome (CTS) or repetitive strain injury (RSI), treat superior to the elbow

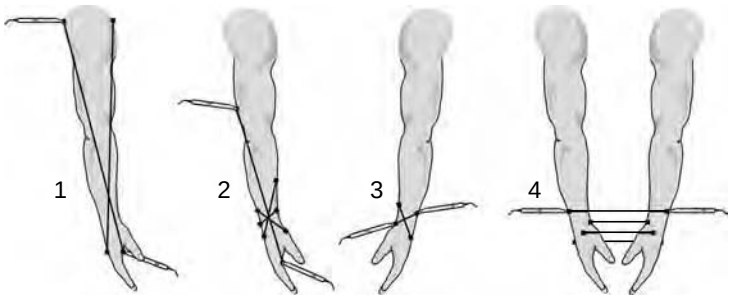

FIGURE 61.4 Upper extremity pain protocol.

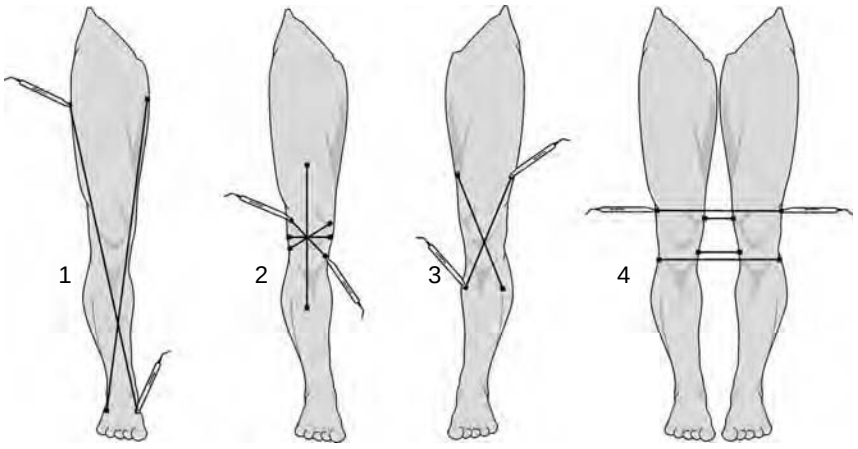

FIGURE 61.5 Lower extremity pain protocol.

Back Pain Protocol

SAMPLE 6 (See Figure 61.6): Back Pain

1. Anterior between the trapezius muscle and the clavicle connected to the contralateral posterior hip. Reverse sides.
2. Then place one probe next to the spine at the level where the problem is, and the other on the contralateral side, anteriolaterally (front and opposite side). A line drawn between those will go right through the spinal nerves. Reverse the sides. Repeat contralateral placements one spinal level above, and one below the problem.
3. Also treat across the vertebrae, from each side of the body through the problem area, above, and below.
4. For low back pain with sciatic radiculitis, connect various levels from L3 to L5 about 1 inch lateral to the spine with the ipsilateral, posterior leg at 4- to 6-inch intervals with the last, most inferior placement at the lateral foot (or just past where the pain radiates).

CRANIAL ELECTROTHERAPY STIMULATION

Cranial electrotherapy stimulation (CES) is the application of low-level, pulsed electrical currents (usually not exceeding 1 mA), applied to the head for medical and/or psychological purposes. It is used primarily to treat both state (situational) and trait (chronic) anxiety, depression, insomnia, stress-related and drug addiction disorders, but it is also proving indispensable for treating pain patients (Kirsch & Smith, 2000; Lichtbroun, Raicer, & Smith, 2001; Thuile & Kirsch, 2000).

Drs. Leduc and Rouxeau of France were the first to experiment with low-intensity electrical stimulation of the brain in 1902. Initially, this method was called electrosleep

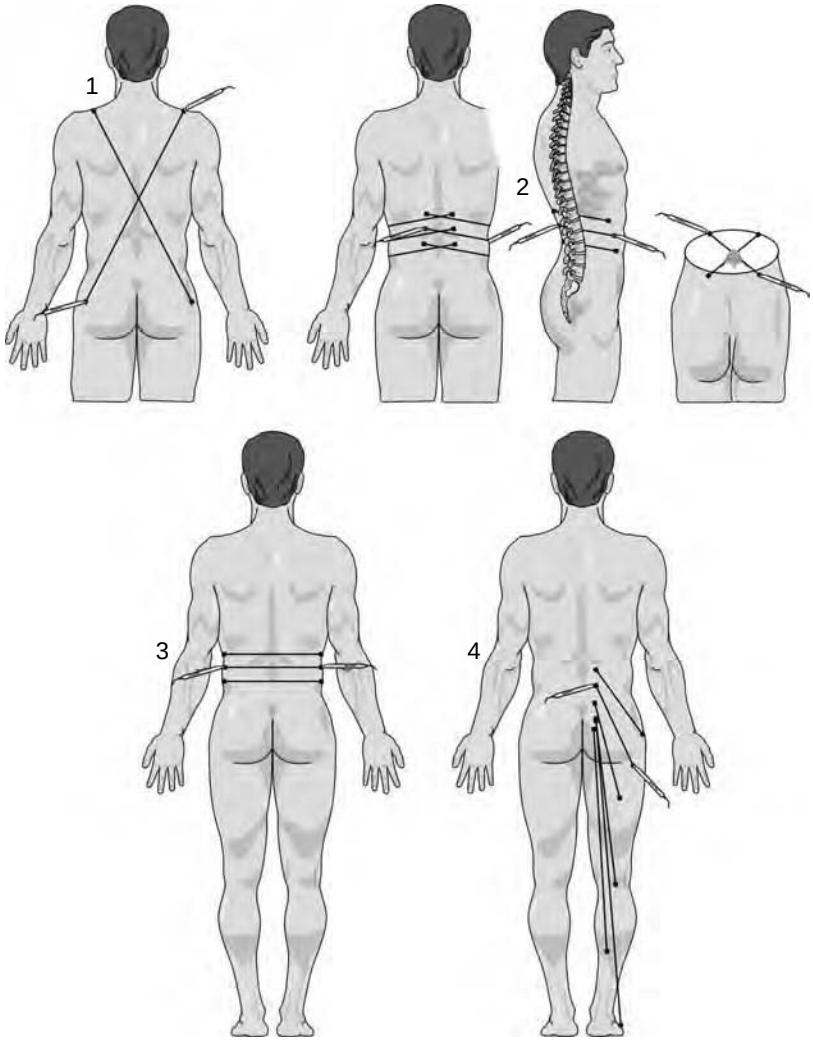

FIGURE 61.6 Back pain protocol.

as it was thought to be able to induce sleep. Since then it has been referred to by many other names, the most popular being transcranial electrotherapy (TCET) and neuroelectric therapy (NET). Research on using what is now referred to as cranial electrotherapy stimulation (CES) began in the Soviet Union during the 1950s.

Cranial electrotherapy stimulation is a simple treatment that can easily be administered at any time. The current is applied by easy-to-use clip electrodes that attach on the ear lobes, or by stethoscope-type electrodes placed behind the ears. In the 1960s and early 1970s, electrodes were placed directly on the eyes because it was thought that the low level of current used in CES could not otherwise penetrate the cranium. This electrode placement was abandoned more than 20 years ago. Recent research has shown that from 1 mA of current, about 5 $\mu A/cm^2$ of CES reach the thalamic area at a radius of 13.30 mm which is sufficient to affect the manufacture and release of neurotransmitters (Ferdjallah, Bostick, Jr., Francis, Jr., & Barr, 1996).

Anxiety reduction is usually experienced during a treatment, but may be seen hours later, or as late as 1 day after treatment. Although in some people it may require a series of 5 to 10 daily treatments to be effective. Severe depression often takes up to 3 weeks to establish a therapeutic effect.

Cranial electrotherapy stimulation leaves the user alert while inducing a relaxed state. Psychologists call this an alpha state. The effect differs from pharmaceutical treatment in that people usually report feeling that their bodies are more relaxed, while their minds are more alert. Most people experience a feeling that their bodies are lighter, while thinking is clearer and more creative. A mild tingling sensation at the electrode sites also may be experienced during treatment. The current should never be raised to a level that is uncomfortable. One 20-minute session is often all that is needed to effectively control anxiety for at least a day, and the effects are usually cumulative. If the patient can only tolerate a small amount of current (< 200 μA) due to vertigo or nausea, more time is required. Cranial electrotherapy stimulation also may be used as an adjunct to anxiolytic or antidepressive medication, but the dosage of medication should then be reduced by approximately one third. It is also proven to be an effective complimentary treatment along with psychotherapy, biofeedback training, and surgical anesthesia (Kirsch, 1999). For people who have difficulty falling asleep, CES should be used in the morning to avoid the possibility of increased alertness that may interfere with sleep.

Most people can resume normal activities immediately after treatment. Some people may experience a euphoric feeling, or a state of deep relaxation that may temporarily impair their mental and/or physical abilities for the performance of potentially hazardous tasks, such as operating a motor vehicle or heavy machinery, for up to several hours after treatment.

At present, there are over 100 research studies on CES in humans and 20 experimental animal studies (Kirsch, 1999). No significant lasting side effects have ever been reported. Occasional self-limiting headache (1 out of 450), discomfort or skin irritation under the electrodes (1 out of 911), or lightheadedness may occur. A rare patient with a history of vertigo may experience dizziness for hours or days after treatment.

Most cranial electrotherapy stimulators are limited to 600 μA. To put this into perspective, it takes one half of an ampere to light an ordinary 60-watt light bulb. To truly compare the work done per second by these two different currents, we must multiply the currents by the respective voltages that drive them. The product of current $\times$ voltage is a measure of the rate of generation of energy, and is referred to as the power output. By definition, when a device outputs 1 ampere of current with a 1-volt driving force, the power output of the device is 1 watt. Therefore, a device producing a maximum output of 600 μA is limited to about 11,000 times less power than the light bulb: (600/1,000,000) amperes $\times$ 9 volts = 0.0054 watts. Some people do not even feel this amount of current.

As in many areas of biology and therapy, the evidence of CES effectiveness is empirical. It is generally believed that the effects are primarily mediated through a direct action on the brain at the limbic system, the hypothalamus and/or reticular activating system (Brotman, 1989; Gibson & O'Hair, 1987; Madden & Kirsch, 1987). The primary role of the reticular activating system is the regulation of electrocortical activity. These are primitive brainstem structures. The functions of these areas and their influence on our emotional states were mapped using electrical stimulation. Electrical stimulation of the periaqueductal gray matter has been shown to activate descending inhibitory pathways from the medial brainstem to the dorsal horn of the spinal cord, in a manner similar to endorphins (Ng, Douthitt, et al., 1975; Pert, Dionne, Ng, et al., 1981; Salar, Sob, et al., 1981). Cortical inhibition is a factor in the Melzack-Wall Gate Control theory (Melzack, 1975). Toriyama (1975) suggested it is possible that CES may produce its effects through parasympathetic autonomic nervous system dominance via stimulation of the vagus nerve (CN X). Taylor (1991) added other cranial nerves such as the trigeminal (CN V), facial (CN VII), and glossopharyngeal (CN IX). Fields, Tacke, and Savana (1975) showed that electrocortical activity produced by stimulation of the trigeminal nerve is implicated in the function of the limbic region of the midbrain affecting emotions. Substance P and enkephalin have been found in the trigeminal nucleus, and are postulated to be involved in limbic emotional brain structures (Hokfelt, Ljungdahl, et al., 1977). The auditory-vertigo nerve (CN VIII) must also be affected by CES, accounting for the dizziness one

experiences when the current is too high. Ideally, CES electrodes are placed on the ear lobes because that is a convenient way to direct current through the midbrain and brain stem structures.

From studies of CES in monkeys, Jarzembski, Sanford, and Sances, Jr. (1970) measured 42 to 46% of the current entering the brain, with the highest concentrations in the limbic region. Rat studies by Krupisky (1991) showed as much as a threefold increase in β-endorphin concentration after just one CES treatment. Pozos, Richardson, and Kaplan (1971) conducted mongrel dog research that suggests CES releases dopamine in the basal ganglia, and that the overall physiological effects appear to be anticholinergic and catecholamine-like in action. Richter, Zouhar, Tatsuno, et al. (1972) found the size, location, and distribution of synaptic vesicles were all within normal limits after a series of ten, 1-hour treatments in Rhesus monkeys. Several studies in stump-tailed macaques and humans revealed a temporary reduction in gastric hypersecretion (Kotter, Henschel, Hogan, et al., 1975; Reigel, Dallmann, Christman, et al., 1970; Reigel, Larson, Sances, Jr., et al., 1971; Wilson, Reigel, Unger, et al., 1970).

A recent review by Kirsch (1999) of 106 human studies involving 5439 subjects (4058 receiving cranial electrotherapy stimulation, while the remainder served as sham-treated or placebo controls) revealed significant changes associated with anxiolytic relaxation responses such as lowered reading on electromyograms (Forster, Post, & Benton, 1963; Gibson, & O'Hair, 1987; Heffernan, 1995; Overcash, & Siebenthall, 1989; Voris, 1995), slowing on electroencephalograms (Braverman, Smith, Smayda, & Blum, 1990; Cox, & Heath, 1975; Heffernan, 1996; Heffernan, 1997; Krupitsky, 1991; McKenzie, Rosenthal, & Driessner, 1971; Singh, Chhina, Anand, et al., 1971), increased peripheral temperature, an indicator of vasodilatation (Brotman, 1989; Heffernan, 1995), reductions in gastric acid output (Kotter, Henschel, Hogan, et al., 1975), and in blood pressure, pulse, respiration, and heart rate (Heffernan, 1995; Taylor, 1991).

The efficacy of CES has also been clinically confirmed through the use of 27 different psychometric tests. The significance of CES research for treating anxiety has been reconfirmed through meta-analyses conducted at the University of Tulsa by O'Connor, Bianco, and Nicholson (1991), and by Klawansky, Yeung, Berkey, Shah, et al. (1995) at the Department of Health Policy and Management, Harvard School of Public Health.

Seventeen studies conducted follow-up investigations from 1 week to 2 years after treatment (Brotman, 1989; Brovar, 1984; Cartwright, & Weiss, 1975; Flemenbaum, 1974; Forster, et al., 1963; Hearst, Cloninger, Crews, & Cadoret, 1974; Heffernan, 1995; Hochman, 1988; Koegler, Hicks, & Barger, 1971; Magora, Beller, Assael, & Kenazi, 1967; Matteson, & Ivancevich, 1986; Moore, Mellor, Standage, & Strong, 1975; Overcash, 1999; Patterson, 1988; Smith, 1999; Turaeva, 1967; Weiss, 1973). Sixteen of 16 (100%) reported that at least some of the subjects had continued improvement after a single CES treatment, or a series of CES treatments. The other follow-up report only commented on safety (Forster, et al., 1963). None of the 17 studies revealed any long-term harmful effects.

When restricted to anxiety populations or studies that measured for physiological and/or psychological changes in anxiety, there are 40 scientific studies of CES involving 1385 patients. Thirty-four of the 40 (85%) studies reported efficacious results in the treatment of anxiety. Five of the studies on CES (all using the Alpha-Stim) support the effectiveness for managing anxiety during or after a single treatment (Gibson, & O'Hair, 1987; Heffernan, 1995; Smith, 1999; Voris, 1995; Winick, 1999).

None of the 6 of 40 (15%) anxiety studies categorized by the authors as having negative or indeterminate results were recent; 5 were done in the 1970s, and one in 1980. Three showed both actual treatment and sham groups to improve significantly, most likely because both groups were also taking medications (Levitt, James, & Flavell, 1975; Passini, Watson, & Herder, 1976; Von Richtofen, & Mellor, 1980). One was a depression study in which the author noted that acute anxiety was not relieved and again, the study did not control for medications (Hearst, et al., 1974). One reported no significant change on anxiety or depression scales, but subjective insomnia improved ($P < .05$) during active treatment (Moore, et al., 1975). Only one study conducted on a population of insomniacs, with an average duration of symptoms for almost 20 years, did not show any significant change at all in any parameters (Frankel, Buchbinder, & Snyder, 1973). [Perhaps the device used in Frankel's study was defective.]

Cranial electrotherapy stimulation has been well researched and clearly proven to be the most effective, and safest method of treatment for anxiety, and anxiety-related disorders. It is also highly effective for depression and insomnia, muscle tension, fibromyalgia, and headaches. As an increasing number of patients seek alternatives to the side sfects and potential addiction to mood-altering pharmaceuticals and controlled substances, CES offers a viable solution. It is easy enough to offer CES in a psychologist's, dentist's or physician's office, clinic, or hospital, and chronically stressed patients will find it cost-effective over time to own their own CES device.

INDICATIONS

In addition to the primary claims for anxiety, depression, insomnia, and pain, CES has been researched with significant results for many other conditions. Smith and Shiromoto (1992) showed it to be highly effective in blocking fear perception in phobic patients. Favorable

results also have been reported for labor, epilepsy, hypertension, surgery, spinal cord injuries, chronic pain, arthritis, cerebral atherosclerosis, eczema, dental pain, asthma, ischemic heart disease, stroke, motion sickness, digestive disorders as well as various addictive disorders including cocaine, marijuana, heroin and alcohol abuse (Brovar, 1984; Daulouede, 1980; Feighner, Brown, & Olivier, 1973; Gomez & Mikhail, 1978; Overcash & Siebenthall, 1989; Patterson, 1983; Schmitt, Capo, Frazier, & Boren, 1984; Smith, 1975; Smith, 1982; Wharton, McCoy, & Cofer, 1982).

Reflex sympathetic dystrophy (RSD) and fibromyalgia syndrome (FS) are two significant pain diagnoses from primary central and autonomic nervous system etiologies that respond best to CES (Alpher & Kirsch, 1998; Lichtbroun, Racier, & Smith, 1999). Adding somatic treatment with MET to these two conditions does not seem to improve the outcomes.

Besides specific pathological disorders, there are a growing number of studies being conducted that show increases in cognitive functions. Michael Hutchison (1986) discussed several mind-enhancement techniques in his book *Megabrain*, devoting Chapter 9 to CES as a tool for attaining higher levels of consciousness. Sparked by Hutchison, Madden and Kirsch (1987) completed a study that demonstrated CES is a useful tool for improving psychomotor abilities. Smith (1999) demonstrated that CES significantly improved stress-related cognitive dysfunction, such as attention deficit disorder (ADD), after only 3 weeks of treatment, and maintained the effect through an 18-month follow-up assessment.

Methodology

Cranial electrotherapy stimulation devices are generally similar in size and appearance to TENS units, but produce very different waveforms. Standard mA-current TENS devices must never be applied transcranially. CES electrodes can be placed bitemporally, forehead to posterior neck, bilaterally in the hollow just anterior to the mastoid processes, or through electrodes clipped to the earlobes. The ear clip method, developed by the author, is the easiest and possibly most effective electrode placement.

The electrodes must first be wet with an appropriate conducting solution. When using ear clip electrodes, apply them to the superior aspect of the ear lobes, as close to the jaw as possible. Start with a low current and gradually increase it. If the current is too high the patient may experience a painful stinging sensation at the electrodes, dizziness, or nausea. If any of these three symptoms arise, immediately reduce the current and the symptoms will subside in a few moments. After a minute or two, try increasing the current again, but keep it at a comfortable level. It is okay for the patient to feel the current as long as it is not uncomfortable.

The ideal treatment time is 20 to 60 minutes, but some patients may achieve the full benefits of a CES treatment within 10 minutes. Many dentists use it instead of nitrous oxide gas to help relax patients during dental procedures (Winick, 1999). Sometimes these dental procedures last for hours with the patient undergoing CES treatment the entire time.

Although CES treatment is indicated for insomnia, because of the increased alertness some patients find it difficult to fall asleep immediately after a treatment. Accordingly, it is recommended that CES be used at least 3 hours before going to bed. Also, in most cases after daily treatments for the first week or two, treating every other day is usually more effective than daily treatment.

The CES Experience

During the treatment, most patients will experience a subjective change in body weight. They may feel heavier at first and then lighter, or they may feel lighter initially. The patient may feel worse during the heavy cycle and this feeling can last for hours or even days in rare cases unless extra treatment time is given. Therefore, it is important to continue the treatment if the patient feels heavier at the end of the allotted time, even if it has already been 20 minutes or more. Continue for at least 2 to 5 minutes after the patient feels lighter. Not all patients will be aware of these weight-perception changes.

Following CES, most people feel better, less distressed, and more focused on mental tasks. They generally sleep better and report improved concentration, increased learning abilities, enhanced recall, and a heightened state of well-being.

Psychologists first described these general feelings during the 1970s as an alpha state of consciousness. Meditation, biofeedback training, relaxation instructions, chanting, hypnotherapy, and certain religious rituals also produce such states. This is not the same as the alpha brain wave frequency of 8 to 13 Hz. Often, practitioners are confused by device representatives who claim that their particular devices will output and entrain a brain to the alpha frequency. There is no evidence to support that CES devices work on an entrainment principle.

Contraindications

There have not been any significant lasting harmful side effects reported in any of the research literature from either MET or CES. As with all electrical devices, caution is advised during pregnancy, and with patients using an older model (pre-1998) demand-type pacemaker. In addition, it is recommended that patients do not operate complex machinery or drive automobiles during and shortly after a CES treatment.

SUMMARY

Microcurrent electrical therapy and cranial electrotherapy stimulation are electromedical modalities that use low level currents that usually do not exceed 1 mA. Beneficial effects have been reported for a wide variety of pain, psychological distress, and addiction-related disorders.

Pain is a complex process encompassing the entire nervous system. To achieve optimal results through electromedical intervention, the peripheral and central nervous systems should both be treated. Cranial electrotherapy stimulation induces a relaxed, alert state. It is a primary modality effective for controlling anxiety, depression, insomnia, and generalized stress ubiquitous in pain patients. In addition, there is mounting evidence that CES can enhance cognitive functions. Because of its safety and effectiveness, the combination of MET and CES used with the protocols described here is highly recommended for a broad range of pain and stress-related disorders.

Pain, Disease, and Suicide

Blake H. Tearnan, Ph.D.

NATURE OF THE PROBLEM

Incidence

There are over 30,000 completed suicides in the United States each year. Most successful suicides are carried out by men, but women attempt suicide more often (National Center for Injury Prevention and Control, 1999). Suicide is currently the third leading cause of death among young adults ages 15 to 34, and in the United Kingdom, suicide is the second most common cause of death in this age group after motor vehicle accidents (Williams, 1997). Recently, the Surgeon General identified suicide as one of the top public health concerns in the United States (Parker, 1998). Overall, suicide accounts for nearly 9% of males and 4% of females in loss of years of life before the age of 65. This figure is similar for most Western countries (Williams, 1997). Clearly, suicide represents a major health concern.

Risk Factors

Extensive research has been done to identify risk factors associated with suicide in the general population. Some of the more consistent findings include increased rates for men by a factor of nearly 2 to 1 in most countries and 5 to 1 in Finland (Sainsbury, Jenkins, & Baert, 1981). Whites in the United States are also approximately twice as likely to commit suicide as blacks or other nonwhite groups, and this difference is particularly associated with the older age group. The exception to this finding is that suicide is particularly high in young Native Americans (Williams, 1997).

Most studies have found the presence of psychiatric disturbance and/or substance abuse increases the risk of suicide in all populations (Williams, 1997). For example, it is a well-established fact that suicidal behavior is particularly associated with major depression. Other findings have shown suicidal risk is greater in Protestants than other religious affiliations including Catholics and Jews. However, in general, churchgoing is associated with decreased risk of suicide, possibly related to increased social supports (Williams, 1997).

The incidence of suicide in various social classes also has been studied. One investigation of social classes in England and Wales found the risk of suicide was greater in the professional and unskilled classes (Charlton, Kelly, Dunnell, Evans, Jenkins, & Wallis, 1992). Comparatively fewer suicides were found in lower-level professional and executive, skilled and partially skilled classes. However, the highest risk was found among individuals who had no occupation at all. Studies conducted in the United States have shown that people in the lower classes living in substandard housing have proportionately higher rates of suicide (Charlton, et al., 1992). The exception is African-Americans living in poor communities. Williams (1997) concluded that this result was possibly related to the strong social ties within the African-American community.

It is clear economic conditions, particularly unemployment, increase the risk of suicide. Generally, men who are unemployed and seeking employment are at two to three times greater risk. Boor (1980) found that among suicide victims, the rate of unemployment was 50% across several studies.

There have been numerous studies on suicide related to lifespan issues. In most all Western countries, suicide is extremely uncommon in young children but rises steadily after puberty with the risk increasing with age (Buda & Tsuang, 1990). Recent studies have confirmed

0-8493-0926-3/02/$0.00+$1.50

earlier investigations, but in men rather than women, where the rates actually have decreased in recent years (Kaplan & Sadock, 1996). The rates of suicide in younger men appear to be rising, and recent studies have shown a slight decline in the suicide rate among older people. Williams (1997) explains the rise in suicide in young males as caused by the increase of working class men who are unemployed and may be experiencing significant economic hardship. This group is also most likely to abuse alcohol and other drugs.

Medical Illness as a Risk Factor

Perhaps more than any other factor, medical illness is associated with an increased risk of suicide (Druss & Pincus, 2000). Psychological autopsies performed on completed suicides have found general medical disorders substantially raise the risk for completed suicide. Several other studies have shown certain medical illnesses are associated with unusually high rates of suicide. For example, the risk of suicide among epileptic patients is 4 times greater than the general population and 25 times greater for temporal lobe epileptics (e.g., Rosenfeld, Breitbart, Stein, et al., 1999; Chochinov, Wilson, Enns, & Lander, 1998). Also, people suffering from peptic ulcer, Huntington's chorea, spinal cord injuries, AIDS, and those undergoing renal dialysis experience higher rates of suicide compared to the general medical population.

Cancer is particularly associated with an increase in suicide. Although the overall incidence is low, patients with cancer are at two times increased risk for committing suicide when compared to the population at large (Fox, Stanek, Boyd, et al., 1982). One study examining male cancer patients (Marshall, Burnett, & Brasure, 1983) showed there was a 50 to 100% greater likelihood of suicide among male cancer patients when compared to the general population. For women, the risk was increased by 30 to 50%. Suicidal behavior is particularly prevalent immediately following the diagnosis of cancer and in the beginning of treatment for men (Fox, Burnett, & Brasure, 1983). Apparently this difference in sexes disappears roughly 2 years after the diagnosis.

Investigations have identified several factors that are likely to increase the risk of suicide in cancer patients. These include significant disability, delirium, prognosis, disfigurement, feelings of hopelessness, and pain (e.g., Allebeck & Bolund, 1991; Hietanen & Lonnqvist, 1991; Chochinov, et al., 1998). History of psychiatric disturbance, poor family support, psychological disorder, especially depression, substance abuse, pain, and family history of suicide all may be additional risk factors for cancer patients but are not specific to cancer.

In a recent study, Henderson and Ord (1997) studied 241 patients who were diagnosed with head and neck cancer. They studied these patients over a 5-year period between 1991 and 1996. The patients' medical charts were examined to identify patients who had committed suicide, had expressed suicidal intent, or refused therapy preferring to die. The results showed 1.2% of their sample committed suicide. Two patients admitted to suicidal intent and an additional four patients refused treatment. They concluded that head and neck cancer patients have some of the same risk factors as other cancer patients but appear particularly prone to suicide because there is often significant disfigurement after treatment, and many of these patients use alcohol, have poor social support and may become socially isolated because their speech apparatus interferes with speaking. In addition, these patients also report other changes in quality of life including decreased smell, interference in taste for foods, and inability to chew foods and swallow.

It is interesting to speculate that some somatic diseases, like cancer, may pose a greater risk of suicide because of the alteration of certain neurochemical processes such as the availability of serotonin or by some other mechanism (Stenager, Stenager, & Jensen, 1994). The problem is compounded by the use of various medications that can precipitate mood disturbance and cognitive impairment and by various medical illnesses that can cause an organic mood disturbance, not necessarily by altering brain chemicals but by some other pathway.

Studies have shown the risk of suicide rises in patients with a general medical illness, even when co-morbid factors, such as depression or pain, are controlled for. In one study, Druss and Pincus (2000) showed a significant association between various medical conditions and suicidality that persisted after adjusting for depressive illness and alcohol use. In this investigation, the authors examined the presence of a medical illness in more than 7500 individuals, ages 17 to 39 years of age. They administered the Diagnostic Interview Schedule as part of a national survey. The information collected from this survey included any incidence of lifetime suicidal ideation and suicide attempts. Also assessed were common medical illnesses, presence of major depression and alcohol usage. One purpose of the study was to determine if there was a relationship between medical illness and suicidality after controlling for psychiatric morbidity. The results show 16% of the respondents without medical illness described suicidal ideation at some point in their lives; whereas, individuals with a general medical condition reported a 25% lifetime incidence of suicidal ideation. The figure was as high as 35% in those individuals who reported two or more medical illnesses. The sample on the whole reported a 5.5% incidence of attempted suicide whereas 9% of the respondents with a medical illness made a suicide attempt and 16% of those with two or more medical conditions had attempted suicide. After controlling for major depression and alcohol use as well as certain demographic characteristics, the results showed

that the presence of a medical condition predicted a 1.3 times increase in the likelihood of suicidal ideation. Certain medical illnesses showed a much higher increase in the incidence of suicidal ideation. For example, cancer and asthma were each associated with more than a four-fold increase in the likelihood of a suicide attempt.

Although medical illness by itself is associated with an increased risk of suicidality, clearly when co-morbid psychiatric conditions, such as depression and substance abuse are present, along with a number of demographic and lifespan issues, the risk increases dramatically (Williams, 1997). Persistent pain is another factor in the medically ill patient that can raise suicidal risk. This was demonstrated clearly by Stenager et al. (1994) who examined a sample of suicide attempters admitted to a department of psychiatry. Each patient underwent a structured interview examining a multitude of factors that may have led up to the suicide attempt. The results show 52% of the patients were shown to have a somatic disease, and 21% were taking analgesics daily for pain. The patients experiencing a physical illness differed from other suicide attempters on a variety of measures including depression scores, age, pain, and the presence of psychoses. The authors noted fewer of the physically ill subjects reported significant psychopathology, and those with significant pain were more often depressed and abused medications. They concluded the risk of parasuicide for subjects with a physical illness, but without depression, was significantly less. In a smaller sample of successful suicides, they noted the subjects were older and there was also a tendency toward painful somatic diseases and depression increasing the risk for suicidality.

Venkoba (1990) reviewed the literature on the relationship between somatic disease and suicide. The investigation included examining the association between pain from physical illnesses, like duodenal ulcer, and suicide. Some of the conclusions reached indicated patients suffering from physical illnesses associated with pain, especially when scores on depression and hopelessness were high, were associated with significantly increased suicidal behavior.

In a 5-year follow-up study, Nielsen, Wang, and Bille-Brahe (1990) also concluded that depression and physical illness represented the greatest risk for suicide. In addition, they showed that subjects reporting no depression and pain contacted their primary care providers more often before attempting suicide. Obviously, patients with a somatic illness and depression are especially susceptible to suicidal behavior. This is particularly true for older patients with painful somatic diseases and depression.

The relationship between somatic disease and suicidality is clear. Patients with a variety of illnesses are at increased risk, and the problem is compounded by a number of factors including depression, pain, and lifespan. These findings also extend to chronic, nonmalignant pain patients. Studies have shown that these patients are at greater risk for depression and suicide than the general population. Fishbain, Cutler, Rosomoff, and Rosomoff (1997) examined 18 studies that looked at the association of chronic pain and suicide. He concluded that suicidal ideation, suicidal attempts, and suicide completions are commonly found in chronic pain populations. He also noted that chronic pain patients usually show other suicidal risk factors, especially depression. He concluded that chronic pain is a significant suicide risk factor. He cautioned that a careful search for co-morbid risk factors needs to be accomplished when evaluating the chronic pain patient.

In summary, it is well-established that one of the most significant risk factors for suicide is somatic illness. Medical illness is associated with 30 to 50% of attempted and successful suicides. Certain medical conditions such as cancer epilepsy, AIDS, spinal cord injuries, and chronic pain pose increased risk. In most cases, the co-occurrence of depression, especially associated with feelings of hopelessness, increases the risk of suicide. Evidence from various studies indicates that although medical illness poses a significant risk factor for suicide, rarely does the patient attempt or commit suicide in the absence of a psychiatric disorder.

Understanding Pain, Suffering, and Suicide

Medical illness increases the risk for suicide. There are a number of factors that appear to compound the problem including pain, especially chronic pain, and depression associated with feelings of hopelessness. Efforts to understand the relationships among pain, depression, and suicide have traditionally relied upon the biomedical model. This disease model of pain has been useful for promoting the development of various analgesic medications and neuroablative techniques that have shown some success in pain management.

Biomedical Model

In the strictest sense, the biomedical model posits that pain results from a disturbance in nerve pathways, and pain intensity is presumed to be a function of the degree of physical damage. Pain is conceived as a closed, unmodulated, unidirectional system. The affective quality of pain is thought to be incidental to the underlying disease and strongly correlated to the signal intensity of pain. The degree of disability associated with pain is considered directly proportional to the underlying impairment, and changes in disability, depression, and suffering occur by reducing the signal intensity of pain. Dramatic displays of pain behavior associated with few physical findings are often attributable to psychological overlay, and pain is viewed as symptomatic and never a problem in and of itself.

Limitations of the biomedical approach are numerous, especially when applied to the understanding of persistent pain of a nonmalignant nature. Studies conducted as far as back as the 1950s show pain and the disability and suffering associated with it, are often poorly correlated to biological disturbance (Melzack & Wall, 1983). How patients interpret and apply meaning to their pain, and the social and environmental factors with which they come in contact also have been shown to affect pain and the suffering associated with it (Melzack & Wall, 1983).

Biopsychosocial Model

The biopsychosocial model (Turk & Waddell, 1992) maintains that pain usually is initiated by nociception with accompanying sensory perception, but pain is also influenced by emotional, social, and environmental factors. In this conceptualization, each factor interacts in complex ways to affect pain. It carries with it the overriding assumption that changing the pain experience requires attention to multiple influences.

The biopsychosocial model also assumes that the affective quality of pain is not simply an incidental response to pain, but is related to multiple factors such as how the pain is interpreted, the social consequences of the pain, pre-morbid psychological vulnerabilities, perceived loss of self, and so forth.

Disability and Suffering Defined

Disability and suffering are often poorly related to underlying physical impairment, especially in chronic pain (Turk & Waddell, 1992). According to the biopsychosocial model, this finding can be easily assimilated because non-physiologic influences are recognized to affect disability and suffering, such as fear of pain or type of job. Clearly, reducing pain does not always decrease disability and suffering. Because physical disturbance, disability, and suffering are often poorly related due to multiple physical, environmental, and social factors, it is erroneous to attribute the lack of any clear relationship to so-called psychological overlay.

Suffering and the disability associated with pain from the perspective of the biopsychosocial model exert independent influences on pain and, as emphasized above, are not incidental to physical impairment. This has important implications for the understanding of pain and in the treatment of depression and prediction of suicidal risk associated with pain. If suffering and disability are simply consequences of underlying organic pathology and related proportionally to the degree of physical disturbance, then treatment efforts directed at symptomatic relief of pain to affect a change in suffering and disability would be effective. However, clearly this has been shown not to be the case (Turk & Waddell, 1992).

Suffering is defined as "a state of severe distress associated with events that threaten the intactness of the person. It occurs when an impending destruction of the person is perceived; suffering continues until the threat has passed" (Cassell, 1982). According to Fordyce (1988), this definition emphasizes the anticipatory nature of suffering and events that are likely to precipitate threats to the self or the intactness of the person. In other words, suffering is an emotional experience triggered in anticipation of events the person perceives as potentially threatening. Although related to the signal intensity of pain, suffering is independent. For example, a patient with chronic pain may experience persistent pain related to a number of underlying pain mechanisms, including disc disruption. The suffering expressed by the patient is related to the sensory experience of pain triggered by the disc pathology, but is also affected by the understanding the patient has about the pain, fear of pain and re-injury, possibly the type of job to which the patient is expected to return, and what the patient thinks may happen in the future as long as the pain persists. Suffering is diminished not simply by affecting a change in pain intensity, which is often not possible, but by reducing the perceived threat associated with pain the patient is experiencing. This could be as direct as educating the patient more effectively about the underlying nature of the pain problem and offering reassurances that being bound to a wheelchair is not likely to happen if a modicum of activities are initiated.

Fordyce (1988) observed that clinicians often confound pain and suffering. This carries with it important implications because it places paramount importance on correcting the physical disturbance before the relief of pain, as well as suffering, can occur. As Fordyce wrote, "Suffering behaviors may occur for many reasons and may have little or no relationship to nociception."

Like suffering, disability, or the patient's diminished capacity, is frequently unrelated to nociception, especially in chronic pain (Turk & Waddell, 1992). Patients are disabled for a variety of reasons including physical impairment. But, patients are also disabled because of fear, uncertainty associated with pain, and co-morbid factors such as depression. Turk and Waddell (1992) in a series of studies showed that the correlation coefficients were minimal to modest at best among various medical conditions and expressed disability. In lower back pain, they found a 0.5 correlation and in arthritic conditions only a 0.3 correlation between underlying damage and disability.

The Role of Cognitions and Emotions

It should be clear by now that cognitive factors play an important role mediating in pain perception and the expression of suffering and disability. One of the first studies demonstrating the influence of beliefs, including attributions in pain, was conducted by Henry Beecher

(1959). He showed wounded soldiers requested far fewer narcotics and reported less intense pain experiences when compared to civilian post-surgery patients. Beecher concluded after interviews with the soldiers that the meaning of pain was entirely different for them. If they survived the battle, it meant a ticket home and out of the range of danger. In other words, they attached a different meaning to the pain experience than civilians who may have interpreted the pain as a nuisance and a disruption of daily activities (Fordyce, 1988).

There are countless other studies showing how patients interpret their pain experiences and that the meaning they give to their pain affects not only pain perception, but also disability and suffering levels (c.f., Wall, 2000). In particular, patients who perceive greater levels of threat, more ambiguity, and feel more vulnerable, possibly related to a loss of self-control and the inability to cope, express more distress. This can translate into heightened levels of pain-related suffering and disability (Chapman & Gavrin, 1999).

Underlying the experience of pain and influencing in part all the different facets of the pain experience, especially levels of suffering, is the emotional tone of the patient. Patients who are more anxious and depressed cope more poorly with pain and with the problems a medical illness presents. Depression is a common consequence of persistent pain (Fishbain, 1999). It compounds the problem of pain by heightening a sense of threat leading to increased levels of suffering (Tearnan & Lewandowski, 1992). Depression also increases fatigue and contributes to lowered self-confidence for managing day-to-day problems.

Conceptual Framework

Medical illness raises the risk for suicide because somatic disease, especially associated with persistent pain, strains coping abilities. This increases the likelihood that the patient will attribute failures to cope to personal inadequacies, and uncertainty about the future and worries about the medical condition will cause further loss and deterioration of the self. This often leads to feelings of depression, especially in individuals sensitive to loss of control (Duggleby, 2000). Depression heightens the sense of vulnerability because a failure to cope is thought to be more probable. Threat is judged more significantly when a sense of vulnerability increases, leading to increased suffering. Feelings of hopelessness result from the belief that suffering will never stop and, as a result, nothing positive will ever come of the future. Suicide is in response to a belief of hopelessness (Chochinov, et al., 1998). Death is seen as an option to end the suffering and prevent a future without hope.

Evidence for this conceptual understanding of how suicide may result from a medical illness is based on a number of studies including investigations showing a strong link between pain and the later development of depression (Fishbain, et al., 1997). Suffering as it relates to the expectation of threat was first talked about in the pain literature by Fordyce (1988), but was borrowed originally from social psychology (Higgins, Bond, Klein, & Strauman, 1986) and work by Cassell (1982) suggesting psychological distress and emotional upheaval occur when events threaten the intactness of the person.

The relationship between psychological distress and suffering also was demonstrated by Tearnan and Lewandowski (1992). They showed that chronic pain patients consistently identified certain factors when asked to report what they were most concerned about when their pain increases. These included the expectation that the pain will negatively impact others, contribute to a loss of productivity, cause physical harm, lead to psychological problems, and cause more pain. These five groupings were supported in factor analytic studies sampling over 600 pain patients. The patients scoring high on all concerns, conceptualized collectively as pain suffering, expressed more depression and distress in general. They also reported more problems associated with overall pain and disability, especially activity interference.

According to Chapman and Gavrin (1999), suffering represents "a disparity between what one expects of oneself and what one does or is. A serious disruption in the psychosocial trajectory of human life, such as the onset of uncontrolled pain, can cause such a disparity and thereby compel changes in a sense of self." For example, the development of a painful shoulder would probably have little impact on a man working in a sedentary capacity but could be devastating to a professional football player "because it affects what he or she is and can hope to be in the future" (Chapman and Gavrin, 1999).

Patients with persistent pain, largely as a result of trying to cope with the various stressors a somatic illness can cause, can become consumed by negative events they anticipate will occur in the future (Fordyce, 1988). This is fueled by the often ambiguous nature of physical illness and the inability of the medical system to assist patients in coping more effectively with a pain problem that is unlikely to dissipate completely.

The suffering that results from medical illnesses with persistent pain occurs as a consequence of self-blame for failure to adequately cope and for trying to fight against the onslaught of numerous stressors patients frequently feel ill equipped to manage (Chapman & Gavrin, 1999), particularly those patients prone to feel out of control.

It should be mentioned that even though depression resembles suffering because both are associated with negative thoughts, feelings of exhaustion, and general psychological impairment, suffering is not a pathologic state (Chapman & Garvin, 1999). Depression, unlike suffering, is associated with self-blame and self-depreciation.

A considerable body of research has shown that hopelessness is correlated highly with suicidal ideation in general medical patients and is a significant predictor of eventual completed suicide (Chochinov, et al., 1998). Physical disease by itself is seldom decisive for the suicidal act (Williams, 1997). Also, depression has been defined differently by various investigators but is generally associated with measures of discouragement and pessimism and is not based fully on medical prognosis. Chochinov et al. (1998) defined hopelessness as encompassing the capacity to find purpose in living. Patients experiencing medical illnesses who have lost the capacity to believe the future will change will generally express hopelessness and are at increased risk for suicide.

In an important review by Hall, Platt, and Hall (1999), 100 patients who made severe suicide attempts were studied. They were interviewed by the authors, and their charts carefully reviewed. All patients required treatment in the emergency room or were admitted to intensive care or a surgical unit of a large urban hospital. Results from the study suggested that the symptoms most predictive of severe suicide attempts were beliefs of hopelessness and insomnia; severe, relentless anxiety, often with intermittent panic attacks, depressed mood, recent conflict or loss, and alcohol abuse. The majority of the patients developed symptoms within 3 months before the suicide attempt, and most had experienced a significant loss. The majority of the patients attempted suicide impulsively. Interestingly, the majority of the patients described fleeting, intermittent, transient but not disturbing thoughts of suicide and no persistent thoughts of a plan. Particularly relevant to this discussion was that 41% of patients had some type of chronic medical illness. Most of the patients had never attempted suicide before and 88% had sought counseling from a healthcare provider in the month prior to the attempt.

Physician-Assisted Suicide

End-of-life issues have become increasingly important as attention shifts from curative to palliative care for patients nearing the end of life. Issues of withdrawing or withholding life support treatment and the legalization of physician-assisted suicide in Oregon have stimulated discussions among many health professionals and represent a significant challenge to groups traditionally concerned with preserving rather than facilitating death. The ethical and moral dilemmas faced by healthcare professionals are outside the scope of this discussion. Instead, a brief review of issues important to pain, depression, and hopelessness are presented as explanations for why patients request assistance from the physician to end their lives prematurely.

Physician-assisted suicide remains a controversial issue, but one that has been discussed more openly in the past decade (Cohen, Steinberg, Hails, Dobscha, & Fischel, 2000). Disagreements largely revolve around whether patients who request end-of-life measures have reached this decision through rational thought processes or are their requests triggered by pathological depression (Cohen, et al., 2000). The available data are not conclusive enough to settle the issues physicians must confront in deciding whether or not to actively end a patient's life or discontinue treatment. However, several well-controlled studies have recently shown that patients who request physician-assisted suicide score high on formal measures of depression and hopelessness (Shuster, Breitbart, & Chochinov, 1999). Unfortunately, physicians often place very little emphasis on ruling out depressive illness, considering depression a natural consequence to terminal illness (Haghbin, Streltzer, & Danko, 1998). This is particularly disconcerting because a substantial minority of physicians report a lack of confidence in diagnosing depression, and many admit to discomfort making a psychological referral (Haghbin, et al., 1998).

There are many healthcare professionals who believe the rational decision to end life occurs in only a minority of patients and palliative care efforts need to be made before any decision to hasten death is reached. This includes assessment of depression and hopelessness. Studies in Oregon show that patients who died through physician-assisted suicide were 7.3 times more likely than controlled patients to be concerned about loss of independence and 9 times more concerned about loss of bodily function, suggesting anxiety and possibly depression in the generation of decisions to end life (Cohen, et al., 2000).

In the area of pain control, studies have shown patients who request physician-assisted suicide do so because of depression and helplessness rather than from physical pain (e.g., Emanuel, Fairclough, & Emanuel, 2000; Emanuel, 1997). Depression can be caused in part by poor pain control but is often related to a multitude of other factors supporting discussions made earlier on pain, suffering, and disability. In one large study van der Maas, van Delden, and Pijnenborg (1992) showed only 5% of the euthanasia cases were motivated solely by pain. Another study by Emanuel and Emanuel (1998) found patients experiencing pain were no more likely to request euthanasia than those without pain.

Discussion and Treatment Implications

Medical illness is a significant risk factor for suicide, particularly in patients who are depressed and expressing beliefs of hopelessness. The presence of pain compounds the problem and may increase the likelihood of suicide.

It is important healthcare providers learn to formally assess and screen for depression and beliefs of hopelessness in general medical populations, particularly in

patients with medical conditions where persistent pain is present. Studies have shown that when less formal screening is provided, even professionally trained mental health professionals often have difficulty recognizing the presence of depressive symptoms and hopelessness (Haghbin, 1998).

It is important to also recognize in the assessment process that a general medical illness increases the likelihood of suicide but having more than one physical illness raises the risk of suicide substantially (Druss & Pincus, 2000). Even when depression and alcohol use are adjusted, the relationship between medical illness and suicidality persists. As Druss and Pincus suggest, perhaps depression and alcohol use do not necessarily mediate the relationship between suicide and medical illness. Possibly other intermediate factors, such as disability, disruption of social supports, and chronic pain, may make an individual regard his life as no longer worth living.

It is worth emphasizing that while studies have shown that depression and suicide are related, most patients admitting to suicidal behavior do not meet criteria for major depression. This strongly suggests assessing for suicidal ideation and intent, aside from examining for signs of depression (Druss & Pincus, 2000).

It is imperative that healthcare professionals, not just mental health professionals, talk openly about depression, death, and suicide with their patients. There is no evidence these discussions will trigger suicidal behavior (Henderson & Ord, 1997). In fact, more evidence exists that these discussions help correct misconceptions, establish a strong rapport between the clinician and patient, and improve a patient's sense of personal control (Henderson & Ord, 1997).

In cases where a patient admits to thoughts of suicide, either through formal screening or in discussions with the patient, referral to a psychologist, psychiatrist, or other appropriate mental health professional should be made. The discomfort many health professionals feel about initiating this type of referral needs to be addressed, mostly by the professional, because, as the author generally has found, if talked about in an open and honest manner, patients are not offended or upset but generally see the importance of addressing psychosocial issues.

Thoughts of suicide and the risk of suicide should be assumed by the clinician when working with the medical patient experiencing persistent pain. Addressing the problem directly, assessing for it aggressively in an open and honest manner, and applying solid pain management techniques in an interdisciplinary setting, including attention to behavioral medicine issues, are appropriate measures for dealing with the potential problem of suicide. This requires attention to effective pain management practices, including educating the patient about better ways to manage and cope with pain, reducing the ambiguity and uncertainty about the future and the medical illness associated with the pain, eliminating medications likely to precipitate depression and confusion, and encouraging the patient to increase levels of activity using the skills of pacing.

It is important that under certain circumstances extraordinary measures be taken to prevent the possibility of suicide, particularly when patients express depression, beliefs of hopelessness, excessive alcohol use, and are reporting severe levels of anxiety and/or panic attacks. Recent losses of close personal relationships, global insomnia, and a sense that the medical condition is deteriorating are signs of which the clinician needs to be particularly aware. In addition, patients out of work and unable to find jobs, patients who are unskilled and feel disenfranchised, and mothers with few social supports are particularly prone to attempt suicide (Williams, 1997).

An examination of the many risk factors for suicide reveals the prevalence of these signs within the pain population. Although single-modality, unidimensional treatment approaches might be appropriate for short-term transient pain, they are inappropriate for persistent pain, especially because pain is rarely a symptom that exists in isolation. For the nonmalignant chronic pain patient, education, attention to emotional factors, focus on function rather than cure, and attention to other problems such as sleep disturbance, are important in managing pain and should reduce the risk of suicide. These same general treatment recommendations are suitable for the cancer patient, except the physician should make every effort to prevent the pain and to relieve it promptly. Also, fears about cancer need to be addressed and, like the nonmalignant pain patient, what patients think about is important, especially in efforts to alleviate their fears and correct misconceptions.

It is helpful to conceptualize pain as a stressor that can promote a destructive stress response, leading to a variety of physiologic, cognitive, and behavioral consequences such as fatigue, myalgia, and impaired cognitive functioning (Chapman & Gavrin, 1999). Addressing the pain problem by reducing the stress of pain and its consequences can involve reducing the unpleasant sensation of pain, altering the perception of unpleasantness or the consequences of loss that are associated with pain, and modifying the body's response to the stress through medications or relaxation. Developing skills to manage the stressors more effectively, including pacing of activities, interacting more effectively with physicians to participate in care, and understanding the mechanism of pain also may be important.

The essential focus of treatment, however, starts with the recognition that the problems medical patients in pain present with are not alleviated by attention just to the sensation of pain. They are best dealt with when attention is directed to a multitude of other factors. It is up to the clinician to formulate what problems are best managed to effect a change in patients. For example, in certain

patients, treating the depression and beliefs of hopelessness with cognitive restructuring techniques might be the most effective approach, whereas other patients might benefit more from reducing their fears through simple physical therapy activities. Still, in other patients, attention to social factors and isolation might be the best approach to affect change in mood, pain, sleep, and hopefully suicidal risk.

Whatever specific treatment measures are applied to affect change, it is important that they sustain hope, reduce uncertainty, contribute to pain acceptance and, in some cases, encourage patients to turn their attention to spiritual needs (Duggleby, 2000).

Assessing the Veracity of Pain Complaints and Associated Disability

Michael F. Martelli, Ph.D., Nathan D. Zasler, M.D., F.A.A.P.M.&R., F.A.A.D.E.P., C.I.M.E., D.A.A.P.M., Keith Nicholson, Ph.D., Treven C. Pickett, A.B.D., Psy.D., and V. Robert May, Rh.D.

INTRODUCTION

Evaluation of pain complaints and pain-related disabilities presents a significant diagnostic challenge. In cases of clear, severe, and/or functionally disabling physical pathology and pain, the evaluations and opinions of most healthcare practitioners are fairly consistent. In most cases, however, where physical findings are less clear, practitioners who specialize in pain and disability assessments may express widely varying opinions. Medical evidence is often problematic or disputable and the relationship between physical findings and subjective report is frequently weak. Pain, ultimately, is a subjective complaint that is difficult to verify or refute (Hall & Pritchard, 1996; Merskey, 1986). Finally, despite recent biopsychosocial and psychophysiologic advances in terms of understanding, simplistic and dichotomous conceptualizations remain overly represented (Martelli, 2000).

Traditionally, pain and pain-related disability evaluations have been conducted by such specialists as physiatrists, orthopedists, neurologists, neurosurgeons, psychiatrists, psychologists, and neuropsychologists. Further, diagnosis and treatment are the presumed reasons for assessment, and the estimation of frank malingering, as well as significant exaggeration of symptoms, is generally estimated to be less than 20% (Martelli, Zasler, Mancini, & MacMillan, 1999). A recent review by Fishbain, Cutler, Rosomoff, and Rosomoff (1999) indicates that malingering might be present in between 1 and 10% of chronic pain patients, but there are significant problems with the reliability of any such estimates and an absence of reliable methodologies for detecting malingering in chronic pain patients. However, it should be noted that pain evaluation referrals also frequently involve such contexts as healthcare insurance policy coverage, disability insurance policy application, social security disability application, personal injury litigation, workers' compensation claims, functional capacity evaluations, and determination of capacity for work. In these medicolegal situations, the incidence of symptom exaggeration and malingering may be significantly higher (Rohling & Binder, 1995; Binder & Rohling, 1996).

Importantly, the evaluation of pain complaint and pain-associated functional impairment and disability may be one of the more confounded and misunderstood areas of healthcare-related work. The task of making determinations regarding pain severity, impact, and related functional impairment and disability is fraught with potential obstacles and pitfalls. This is, of course, due to the poorly understood and complex nature of the deficits involved, as well as the lack of formal, scientifically validated conceptual models and "rating systems." Disentangling the multiple contributors to subjective pain experience and associated functional disability requires careful scrutiny.

Chronic pain patients may present with some response bias to report pain or related disability. In the present chapter, response bias is defined as a class of behaviors that reflects less than fully truthful, accurate, or valid

0-8493-0926-3/02/$0.00+$1.50

symptom report and presentation. Importantly, response bias is a ubiquitous phenomenon affecting almost any domain of human self-report. However, in the context of medicolegal or insurance presentations, with which this chapter is primarily concerned, the prevalence or importance of such bias becomes more acute (Rohling & Binder, 1995; Binder & Rohling, 1996; Youngjohn, Burrows, & Erdal, 1995). Given frequent financial and other incentives to distort symptoms and performance during examinations conducted in medicolegal or insurance contexts (i.e., healthcare policy coverage, disability insurance, social security disability, personal injury litigation, workers' compensation claims, functional capacity, and work evaluations), assessment of examinee veracity and motivation to provide accurate and full effort during assessment becomes critical. The importance of detecting response biases or invalid symptoms is crucial with regard to increasing the likelihood of diagnostic accuracy. Accurate diagnosis is prerequisite to provision of appropriate and timely treatment and prevention of iatrogenic impairment and disability reinforcement; it is also critical to appropriate legal compensation decisions.

Medicolegal and insurance assessments, with their significant consequences of determination decisions regarding impairment and disability, require the following in order to ensure validity: (a) an accurate assessment of possible response bias to report pain or related disability; (b) an accurate assessment of attribution, i.e., whether pain and related problems are correctly being attributed to the compensable cause; and (c) sensitivity, specificity, utility, and ecological validity of assessment measures.

Blau (1984; 1992) has expounded on the importance of determining response biases and measuring true levels of impairment in medicolegal situations. Essentially, in this arena, an alleged victim of a wrongful act or omission attempts to establish (a) causality in order to demonstrate entitlement to compensation for damages, which is awarded based on (b) level of damages suffered. In cases of less obvious, clear-cut, and significant trauma with psychologic, neurologic, or soft tissue damage, causality and level of current and future damages are more difficult to prove and expert evaluation and opinion are heavily relied upon for making legal determinations. In the parallel insurance situation, the insured attempts to access entitlements to healthcare treatment and disability benefits, and expert evaluation and opinion are relied upon for making policy determinations. In both cases, financial and other incentives clearly represent motivational factors that increase the likelihood of response bias in the form of exaggerated or feigned symptoms.

EXAMINING PATIENT RESPONSE BIASES

Examinee response bias, or predilections toward less than fully valid, accurate, and effortful behavioral responses, can take several forms. Bias ranges from interpretations of symptoms that may be minimized to exaggerated or feigned, and that may be accurately or inaccurately attributed to different events. For instance, pre-existing symptoms may suddenly be attributed to an accident, symptoms previously not noticed suddenly may be given such vigilant attention that attention and anxiety alone produce significant increases, or an accident may cause an aging person to do a self-inventory of health that reveals symptoms due to aging that were present but previously minimized. Further, a heightened awareness or vigilance effect can lead to focusing and sensitization to problems which would otherwise be innocuous. In addition, environmental realities also exert influence over response to injury and symptoms. For example, the vastly different consequences for diagnoses of cancer vs. mild traumatic brain injury or back injury produce differential reinforcement; the former is clearly undesirable and negative, while the latter can result in highly desirable monetary compensation.

Martelli et al. (1999) reviewed the literature and found that the following injury context variables were associated with poorer post-injury adaptation and recovery, and increased likelihood of response bias.

1. Anger or resentment or perceived mistreatment
2. Fear of failure or rejection (e.g., damaged goods; fear of being fired after injury)
3. Loss of self-confidence and self-efficacy associated with residual impairments
4. External (health, pain) locus of control
5. Irrational fear of injury extension, reinjury, or pain
6. Discrepancies between personality/coping style and injury consequences (e.g., very physically active person with few intellectual resources who has a back injury)
7. Insufficient residual coping resources and skills
8. Prolonged inactivity resulting in disuse atrophy
9. Fear of losing disability status, benefits, and safety net
10. Perceptions of high compensability for injury
11. Preinjury job (task, work environment) dissatisfaction
12. Collateral (especially if "silent")
13. Inadequate and/or inaccurate medical information
14. Misdiagnosis, late diagnosis, or delays in instituting treatment
15. Insurance resistance to authorizing treatment or delays in paying bills
16. Retention of an attorney
17. Greater reinforcement for "illness" vs. "wellness" behavior
18. Dichotomous (organic vs. psychologic) conceptualizations of injury and symptoms

These variables represent vulnerability factors that can reduce effective coping with post-injury impairments and increase the likelihood of maladaptive coping and response bias.

Importantly, these variables are not mutually exclusive, and, as with the variables presented below, more than one can contribute to symptom report and presentation

Additional review of the literature, balanced with clinical experience, identifies the following significant sources of response bias that can be seen during examinations (Martelli, 2000).

1. Cultural Differences. For example, many non-Western cultures mix emotional and physical pain and symptoms at a conceptual and phenomenological level. Also, some cultures see failure to impose severe penalty/extract significant compensation for harm as a sign of weakness and disgrace in God's eyes.
2. Reactive Adversarial Malingering (RAM) based on fear, mistrust of the opposing side, dishonesty, or mistreatment (e.g., from assumed "facts" in many work settings and cultures, including plaintiff attorney groups) resulting in a deliberate pendulum-like overplaying of symptoms. This may be especially characteristic in persons/groups with tendencies toward suspiciousness, including immigrants, outsiders, or those who feel chronically underprivileged.
3. Conditioned Avoidance Pain-Related Disability (CAPRD), or roughly, phobic or extreme anxiety reactions wherein activity (mental or physical) is associated with anticipation of an exacerbation of pain, with such stress possibly resulting in an actual exacerbation. Kinesiophobia and cogniphobia are two types.
4. Desperation Induced Malingering (DIM) or Desperation Induced Symptom Exaggeration (DISE), e.g., insecure immigrant workers, aging workers, tired workers, workers insecure about work changes, immigrants who tried introjection and feel resentful that they were not rewarded, persons who recently climbed back on the horse only to get knocked off again without belief they can climb back in the saddle one more time, workers fearing their own limited or declining abilities, real or imagined abuse from employers, family, etc., immigrants who feel rejected by the culture and feel entitled, immigrants who feel disillusioned because the new land was not everything they had hoped — i.e., those who believe this to be a viable solution to a desperate situation. Probably also included are those making desperate pleas for help and who, upon confronting tests that seem different and maybe easier than the real-life situations where they have problems, reduce effort to highlight their problems.
5. Sociopathic, Manipulative, and Opportunistic (SMO) types. These rather self-explanatory styles can be found in all groups.
6. Passive Aggressive or Impatient or Rebellious types, representative of those who resent others not listening to them and believing them at face value, and resent imposed evaluations or doctor's visits, especially ones that examine psychological function or motivation. They may play games with doctors by withholding or undermining procedures or treatments, and may especially alter performance or play games on tests that seem nonchallenging or unrelated to real life situations.
7. Psychologically Decompensated types, i.e., the extremely dysfunctional patient who is usually easily recognizable.
8. Those who don't take our examinations or tests as seriously as we do. The authors have some very limited but relevant survey data suggesting that plaintiffs may take our examinations a little more seriously than defendants. In contrast, weathermen seem to be taken more seriously than independent examiners by persons who have not graduated high school, while independent examiners seem to fare better with those who have been to college.

Importantly, a too often overlooked form of bias is one that is iatrogenic to the nature of the insurance and adversarial legal system. In an effort to elucidate expectancy influences and bias for persons sustaining injuries, Martelli, Zasler, and Grayson (2000) collected survey attitudinal data from professionals who work with injured Worker's Compensation (WC) patients. A summary of the preliminary data is offered in Table 63.1, broken down by the three sample groups: (1) disability evaluators, comprised of physicians, chiropractors, physical therapists, and vocational evaluators; (2) staff from a rehabilitation neuropsychology service; (3) attendees at a case management conference, including over 50% WC case managers. These data are quite compelling. Overall, approximately 25% of WC patients are believed to be exaggerating or malingering, with higher rates evidenced by WC case managers. This suggests a general skepticism and distrust faced by injured persons during evaluations. In contrast, the majority of professionals filling out the survey believed they would be treated unfairly by the WC system if they were injured, suggesting a general skepticism and distrust of the extant systems that fund evaluation and treatment of injury and disability.

TABLE 63.1
Survey of Attitudes Regarding Worker's Compensation (WC)

	Respondent Sample (%)		
Question	Disability Evaluating Professionals (N = 17)	Medical Psychology Service Staff (N = 7)	Case Managers (N = 16) (including 7 WC employees)
% Injured workers who fake/exaggerate/malinger	19.2	24.7	28.5
% Injured workers that WC insurance treats < fairly	49.2	62.5	23.2
% Employers who treat injured workers < fairly	53.5	41.2	32.7
Likelihood your employer would treat you < fairly	43.75	54.2	46.4
Likelihood WC would treat you if injured < fairly	60.0	65.9	48.9

Despite the preliminary nature of these data derived from small samples and the fact that generalizability across situations cannot be assumed, they nonetheless seem compatible with the levels of diffuse distrust observed by the authors in medicolegal situations. These data highlight the importance of considering the much different set of motivational factors that operate on examinees that present to independent evaluation. In addition, they strongly argue for deliberate and thorough preparation of examinees prior to the examination.

In an interesting theory about a major type of response bias in chronically disabled workers, Matheson (1988; 1990; 1991a; 1991b) conceptualized a "symptom magnification syndrome" based on a careful analysis of injured industrial workers. He defined this syndrome as a conscious or unconscious self-destructive (e.g., blocks return to productive activity) and socially reinforced pattern of symptoms, which are intended to control life circumstances of the sufferer, but which impede healthcare efforts. He further defines three major subtypes, and provides classification guidelines for evaluation via observation during performance of simulated work tasks completed within functional capacity evaluations. The Type I "refugee" is defined as displaying illness behavior that provides escape or avoidance of life situations perceived as unsolvable. Somatization, conversion, psychogenic pain, and hypochondriacal disorders are conceptualized as extreme subcategories for this type. The Type II "game player" employs symptoms for positive gain. Although this type seems associated with the psychiatric diagnosis of malingering, Matheson argues that true malingering is a medicolegal concept, while Type II symptom magnifying is a treatable self-destructive syndrome. The Type II "identified patient" is motivated by maintenance of the patient role as a means of life survival. Associated psychiatric diagnoses include factitious disorder (May, 1999).

Main and Spanswick (1995) also examined simulated or exaggerated incapacity in persons claiming physical disability. They identified a list of features associated with simulated or exaggerated incapacity. Features identified as primarily suggestive of simulated or exaggerated incapacity included

1. Failure to comply with reasonable treatment
2. Report of severe pain with no associated psychological effects
3. Marked inconsistencies in effects of pain on general activities
4. Poor work record; history of persistent appeals against awards
5. Previous litigation

Features identified as not primarily suggestive included

1. Mismatch between physical findings and reported symptoms
2. Report of severe or continuous pain
3. Anger
4. Poor response to treatment
5. Behavioral signs/symptoms

A brief review of important sources of bias, or threats to objectivity, which require assessment during evaluation of physical, sensory, and neurocognitive impairments follows.

Attribution and Bias

Examinee attribution bias can confound accurate diagnosis. Examples include mistaking clinical entities like depression or sleep disturbance and concomitant physical, memory, or motivational problems for physical injury and pain-related sequelae. This can occur due to misattribution or over-attribution or retrospective attribution, or illusory correlation, or heightened awareness due to vigilance biases. Importantly, conditions like depression and sleep disturbance are reversible and may have even been present pre-injury without producing significant limitations. Furthermore, these factors may be interacting with true physical injury symptoms to increase distress, prolong impairment, and interfere with recovery. Finally, such factors as

presence of vigilance to symptoms can increase physiologic arousal and lead to increased symptomatology and perceptions of impairment, in a vicious cycle.

Examiner misattribution can similarly occur. Only methodical medical and psychological assessment can differentiate sequelae secondary to, for example, brain injury from chronic pain. Tendencies toward over-diagnosis of brain injury-related disorders by brain injury specialists given abnormal neurocognitive findings and/or nonspecific somatic complaints not exclusively pathognomonic of brain injury can be avoided only through careful differential diagnosis. Brain injury specialists sensitized to neurologic symptoms have been observed by the authors to misdiagnose chronic pain sequelae as post-concussive symptoms, which may result in iatrogenic impairments associated with an escalation of medical costs, prolongation of inappropriate treatment, and eventual failure that produces helplessness and chronic disability (e.g., nonresolving post-concussive disorders) and misperceptions in the injured person. Conversely, similar observations have been made for psychiatrists and psychologists prone to infer psychiatric etiologies for all pathology, including pain and physical injury sequelae (Main & Spanswick, 1995; Martelli, Zasler, & Grayson, 1999a).

The Response Bias Continuum

As indicated above, for the purposes of this chapter, response bias is defined as any behavioral predisposition involving less than fully truthful, accurate, and valid symptom report and presentation. This includes less than fully effortful behavioral responses displayed on formal and informal interview and examination procedures. Formal assessment of response bias, which is frequently lacking or only haphazardly attended to in most clinical examinations, represents the only assurance that clinical exam findings are accurate and valid reflections of pain severity, frequency, and functional impairment levels. Response bias appears best conceptualized on a continuum that extends from

1. Denial and unawareness of impairments,
2. Symptom minimization,
3. Symptom magnification/exaggeration to
4. Frank malingering.

Denial and unawareness refer to either psychologic or organic phenomenon wherein impairments are underappreciated due to dysfunction of brain operations subserving awareness or psychological repression to guard against distressful realizations. Symptom minimization is a related, but more consciously motivated desire, and usually involves an attempt to minimize the impact of undesirable functional restrictions or distress (Martelli, et al., 1999a).

Symptom magnification, in contrast, refers to exaggeration of impairment and can occur in relation to multiple factors and serves a wide range of psychological needs (e.g., efforts to legitimize latent dependency needs, resolve pre-existing life conflicts, retaliate against employer or spouse or other, reduce anxiety, exert a "plea for help", or solicit acknowledgment of perceived difficulties). Symptom exaggeration always promotes passivity and helplessness and an external locus of control and is a significant impediment to rehabilitation (Martelli, Zasler, & Grayson, 1999b).

Symptom exaggeration also can occur in patients with premorbid histories of psychologic problems who "latch on" to a specific diagnosis that not only becomes responsible for all life problems, but also promotes passivity and helplessness and an external locus of control. When patients are assessed for claims of major disability following uncomplicated mild whiplash or soft tissue injuries, inorganic contributors should be closely scrutinized. Depression, post-traumatic stress disorders, anxiety conditions, and other psychiatric syndromes generally have a favorable psychological and functional prognosis given timely and appropriate assessment and treatment. Misdiagnosis of these conditions serves to promulgate misperceptions and amplify functional disability and healthcare costs.

Malingering, as defined in the DSM-IV (p. 683) (American Psychiatric Association, 1994) is "…the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives such as avoiding military duty, avoiding work, obtaining financial compensation, evading criminal prosecution, or obtaining drugs." Malingering should be suspected if any combination of the following is noted:

1. Medicolegal context of presentation
2. Marked discrepancies between claimed stress or disability and objective findings
3. The presence of Antisocial Personality Disorder

Therefore, measures of malingering, or deliberate symptom production for purposes of secondary gain, should always be administered in cases of medicolegal presentation, suspicion of any disincentive to exhibit full effort, or suspicion of sociopathic personality disorders.

According to Lipman's typology (1962), malingering can be categorized into four categories: (1) fabrication of nonexistent symptoms; (2) exaggeration of symptoms that are presented as worse than in actuality; (3) extension of symptoms that have actually improved or resolved; and (4) misattribution or fraudulent attribution of symptoms to an injury when they actually preceded, postdated, or are otherwise unrelated. Notably, exaggeration is considered much more frequent than fabrication, while more than one category can occur in a single person. Finally,

as Miller (2001) notes, different combinations of types can occur in persons with more than one problem (e.g., chronic pain, PTSD, post-concussion syndrome), which can further co-occur with other psychological syndromes (e.g., somatoform and personality disorders).

Identifying Response Bias

The difficulty with defining pain, actual accentuation of the pain response (e.g., hyperpathia) seen in some chronic pain problems, response bias to reported pain, and its possible deception, makes the assessment of pain-related complaints extremely challenging. Pain, defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage (Merskey, 1986), is a complex multidimensional subjective experience mediated by emotion, attitude, and perception. Unlike other modalities, it is not possible to devise simple signal detection paradigms for the evaluation of response bias given that this is a subjective experience with no clear objective referents, especially in the case of chronic pain associated with actual injury and nociception or abnormal function of the nervous system. Clearly, multiple variables may impact on pain reporting and behavior. For example, arousal, stress, tension, and anger all may exacerbate subjective reporting of pain and pain behavior, as may depression, through effect on physiologic function. Psychoemotional and psychosocial concomitants of chronic pain must also be appreciated, including loss of self-esteem, lowered frustration tolerance, depression, sexual dysfunction and decreased libido, and anger and guilt. Further, situational factors make additional contributions to pain-related complaints. The context of an exam, however, typically requires that psychological and physical pain factors be addressed individually, despite the fact that these components are typically inextricably intertwined with one another, as well as such affective conditions as depression and anxiety.

Physicians should be familiar with exam strategies designed to evaluate disorders with (a) probable "functional" components, or symptoms that seem more strongly associated with psychosocial vs. structural factors, as well as (b) feigned symptoms, including bedside exam techniques for physical and cognitive "malingering." Examples include such strategies as Hoover's test for evaluation of malingered lower extremity weakness, sideways/backward walking for assessment of feigned gait disturbance, and a positive Stenger test on audiologic assessment for nonorganic hearing loss. Other tests that might be of value in the context of response bias detection on the physical examination include Mankoski maneuver, strength reflex test, arm and/or wrist drop test, hip adductor test, axial loading test, Gordon-Welberry toe test, Bowlus and Currier test, Burns bench test, Magnuson test, among others [(Babitsky, Brigham, & Mangraviti, 2000); see also Table 63.3 for a relatively comprehensive listing].

Some major exam findings that are inconsistent with structural lesions include patchy sensory loss, pain in a nondermatomal distribution, nonpronator drift, and/or astasia-abasia. Motor and other impairment inconsistencies that fluctuate or disappear under hypnosis, drug-assisted interviews or "presumed" nonobservation may certainly increase the index of suspicion regarding nonorganicity, although exceptions to this rule do exist. Faked hemiparesis is typically more common on the left side, perhaps due to the fact that most persons are right-hand dominant. Consistency regarding laterality of symptoms, particularly with referred pain and/or neurologic impairment, should be evaluated.

Clinicians evaluating chronic pain must be familiar with psychosocial syndromes that may present as pain, including

1. Factitious disorder, or the intentional production or feigning of physical symptoms, or exaggerated expression of physical conditions in order to adopt a sick role
2. Somatoform disorders, characterized by preoccupation with physical symptoms and pain that exceeds possible organic pathology
3. Hypochondriasis, or preoccupation with pain as part of a conviction that it is a part of a pernicious disease process
4. Conversion disorder, or the expression of frank psychiatric disorder via some symbolic transformation

Clinicians should also be familiar with symptoms related to pain imperception. Pain complaints should be assessed, in part, when of CNS origin as opposed to psychogenic, by concurrently assessing temperature perception, given that the same neural pathways mediate these sensations. When temperature sensation is preserved in the presence of a loss of pain sensation, after either brain or spinal cord injury, the deficit is not likely to be organic (the loss should occur contralateral to and below the level of the lesion). This point also belabors the fact of understanding the neuropathology/pathology of the lesion based on imaging studies and the implications that these findings have for anticipated clinical exam findings. Alleged pain imperception can be evaluated, as can any impairment for that matter, with appropriately designed forced choice testing. Additionally, examiners should realize that alleged pain imperception or loss of sensation is difficult to fake upon repeated bilateral stimulation. This is due to the fact that examinees who exaggerate rely on subjective strategies rather than truly responding to the strength of the stimuli. Therefore, assessments such as Von Frey hairs could be utilized in the aforementioned

scenario to provide further objective evidence of feigned sensory deficits.

It is worth emphasizing that the presence of structural inconsistencies, a nonorganic syndrome and/or response bias does not necessarily exclude the diagnosis of another organic syndrome. This certainly complicates the process of disentangling multiple clinical entities that sometimes coexist. Unfortunately, the science and art of methodic differential diagnosis are too often underappreciated in the evaluation process (Martelli, et al., 2000).

A relevant screening procedure frequently used by physical therapists, doctors, and chiropractors for estimating when psychological factors are significantly influencing pain-related responses is the assessment for Waddell Nonorganic signs (Waddell & Main, 1984; Waddell, Main, Morris, Paoloa, & Gray, 1984; Waddell, 1999). These are listed below:

Screening for Nonorganic Response Bias: Waddell Signs

1. Overreaction
   Guarding/limping, bracing, rubbing affected area, grimacing, sighing.
2. Tenderness
   Widespread sensitivity to light touch of superficial tissue.
3. Axial loading
   Light pressure to skull of standing patient should not significantly increase low back symptoms.
4. Rotation
   Back pain is reported when shoulders and pelvis are passively rotated in the same plane.
5. Straight leg raising
   Marked difference between leg raising in the supine and seated position.
6. Motor and sensory
   Giving way or cog wheeling to motor testing or regional sensory loss in a stocking or nondermatomal distribution (rule out peripheral nerve dysfunction).

Additional nonorganic signs include lower extremity giving way, no pain-free spells in the past year, intolerance of treatments; and emergency admissions to hospital with back trouble.

Importantly, the presence of Waddell or other nonorganic signs does not exclude physical components as the cause of low back pain. Rather, they suggest only that psychological factors appear to be influencing the patient's responses and behavior. Notably, physical and psychological findings are not mutually exclusive, and psychological factors may more often be a result of low back pain than a cause (Simmonds, Kumar, & Lechelt, 1998). Further, recent reports strongly demonstrate the relationship between high levels of anxiety and nonorganic responses during physical exams in chronic low back pain (Hadjistauropoulos & LaChapelle, 2000). As such, the importance of minimizing anxiety-related response bias during exams should, therefore, be emphasized with regard to optimizing accurate performance and assessment. Clinicians should familiarize themselves with the wide variety of simple yet effective anxiety management interventions.

With regard to assessment of psychological/psychiatric, somatic, and neuropsychological impairments, including chronic pain, response bias represents an especially important threat to validity. Because these assessments usually begin with an interview about self-reported symptoms and subsequently rely heavily on standardized measures of performance on tests which are variably normed, their validity requires the veracity, cooperation, and motivation of the patient for obtaining valid performance measures. Recent evidence, however, strongly suggests that patients seen for presumptive injury-related impairments over-report preinjury functional status (Lees-Haley, Wil-liams, Zasler, Margulies, English, & Steven, 1997). This is especially true with post-concussive and pain related deficits because these symptoms often appear with similar frequency in the general population (Lees-Haley & Brown, 1993). In addition, the demonstrated ability of physicians and psychologists to accurately detect malingering in examinations and test protocols has been less than impressive (Hall & Pritchard, 1996; Loring, 1995). Nonetheless, various instruments, techniques, and strategies are available that have demonstrated at least some utility in detecting response bias, especially malingering, as a means of increasing confidence in appropriate motivation during examination, and hence the validity of assessment findings.

In Table 63.2, a general summary of hallmark and selected signs of response bias are presented. The signs are predicated on examination of inconsistencies and can certainly be applied to most aspects of comprehensive medical and psychological evaluations for chronic pain.

In Table 63.3, a summary of some very specific response bias detection measures and strategies, along with guidelines, is presented in an integrated format. Importantly, these strategies are presented as illustrations of indicators of important information for interpreting examination findings and test data within a larger context of multidisciplinary evaluation for chronic pain. This approach integrates contextual information, history, behavioral observation, interview data, collaborative data, and personality data with measures of effort or performance (or symptom exaggeration or malingering) and physical examination, medical and neuropsychological examination performance data. This approach potentially offers increased reliability with regard to estimating the degree to which an examinee is responding truthfully and exerting full effort or withholding or distorting effort or performance, and the degree to which specific and general test results from multiple assessment areas are reliable and valid and reflect true abilities.

TABLE 63.2
Response Bias: Hallmark Signs

1. Inconsistencies within and between the following (given absence of significant psychiatric, attentional, comprehension, or other disorders where inconsistencies are not uncommon):
   a. Reported symptoms
   b. Examination/test performance
   c. Clinical presentation
   d. Known diagnostic patterns
   e. Observed behavior (in another setting)
   f. Reported symptoms and exam/test performance
   g. Measures of similar abilities
   h. Similar tasks or tasks within the same exam or test (especially when difficult tasks are performed more easily than easy ones)
   i. Different examination sessions
2. Grossly impaired performance and extreme complaints
   a. Poorer performance and more extreme complaints vs. established expectancies or normative data for similar injury/illness
   b. Very poor performance on easy tasks (especially when presented first)
   c. Failing tasks that all but severely impaired perform easily
3. Lack of specific diagnostic signs of impairment
4. Specific signs of exaggeration/dissimulation/malingering on psychological testing
   a. Minnesota Multiphasic Personality Inventory (MMPI/MMPI-2) Original and additional validity scales: L, F, Fb, Fp, Ds, K, TRIN, VRIN, F-K, Fake Bad, etc.
   b. Personality Assessment Inventory (PAI) Validity scales (inconsistency, infrequency, positive and negative impression management) and 8 malingering and 6 suspected malingering patterns
   c. Pain Assessment Battery (PAB): Symptom magnification, extreme beliefs frequency and other "validity" indicators
   d. Millon Behavioral Health Inventory (MBHI) validity scales (3)
   e. Hendler (i.e., Mensana Clinic) Back Pain Test: scores of 21–31 (exaggerating)
   f. Cognitive malingering detection tests (e.g., memorization of 15 items test, Digit Recognition Tests, Computerized Assessment of Response Bias, Word Memory Tests, Word Memory Test, Word Completion Memory Test, etc.).
5. Interview evidence
   a. Nonorganic temporal relationship of symptoms to injury
   b. Nonorganic symptoms, or symptoms that are improbable, absurd, overly specific, or of unusual frequency or severity (e.g., triple vision)
   c. Disparate examinee history/complaints across interview or examiners
   d. Disparate corroboratory interview data vs. examinee report
6. Physical exam findings
   a. Nonorganic sensory findings
   b. Nonorganic motor findings
   c. Pseudoneurologic findings in the absence of anticipated associated pathologic findings
   d. Inconsistent exam findings
   e. Failure on physical exam procedures designed to specifically assess malingering

Empirical support exists indicating that each of these indicators has some utility in detecting dissimulation or suboptimal effort.* Examining the pitfalls and limitations of each of these procedures, both conceptual and methodological, is well beyond the scope of this chapter. However, increasing evidence exists for improved discrimination and increased reliability when multiple measures are employed. The conceptual approach offered by the proposed Motivation Assessment Profile (MAP) is one where behavioral observation, interview, collaborative, historical, personality, and contextual data with neuropsychological and medical performance data and measures of effort or performance (or response bias) are integrated as an optimal method for estimating the degree of effort or performance and the degree to which test results are reliable and valid and reflect actual abilities. Notably, in evaluation of response bias and malingering, as in evaluation of pre- and post-injury status, the following investigative tools may be used in conjunction with interviews and examination and testing: (1) school records; (2) medical records; (3) driver records; (4) service and criminal records; (5) employment records; (6) psychological/psychiatric records and reports; (7) interviews with family members, friends, teachers, and employers, etc.; (8) any other available materials (e.g., from attorneys through formal discovery).

Importantly, the strategies and guidelines offered in Table 63.3 are presented as important indicators for

* See starred references.

TABLE 63.3
Response Bias Detection Measures and Strategies

Pain Assessment Measures with Built-In Response Bias Indicators	
Pain Assessment Battery (PAB), Research Edition	Symptom Magnification Frequency (SMF) > 40%
Proposed clinical hypothesis procedure evaluating	Extreme Beliefs Frequency (EBF) > 35% Four other "validity" indicators (i.e., alienation, rating percent of max, % extreme ratings (2 scales))
Millon Behavioral Health Inventory (MBHI)	Elevations on 3-item validity scale
Hendler (i.e., Mensana Clinic) Back Pain Test	Scores of 21–31 (Exaggerating) Scores > 31 (Primary psychological influence)
Medical Indicators	
Hoover's test	Test for malingered lower extremity weakness associated with normal crossed extensor response
Astasia-abasia	"Drunken type" gait with near-falls but no actual falls to ground
Nonorganic sensory loss	Patchy sensory loss, midline sensory loss, large scotoma in visual field, tunnel vision
Nonorganic upper extremity drift	Long tract involvement results in pronator type drift; proximal shoulder girdle weakness and malingering typically present with downward drift while in supination
Stenger's Test	Test for malingered hearing loss during audiologic evaluation
Gait discrepancies when observed vs. not observed	If organic, should be consistent regardless of whether observed or not
Gait discrepancies relative to direction of requested ambulation	Gait for a patient with hemiparesis should present similarly in all directions; malingerers do not as a rule practice a feigned gait in all directions
Forearm pronation, hand clasping, and forearm supination test for digit/finger sensory loss	Malingered finger sensory loss is difficult to maintain in this perceptually confusing, intertwined hand/finger position
Pain vs. temperature discrepancies	Because both sensory modalities run in the spinothalamic tract, they should be found to be commensurately impaired contralateral to the side of the CNS lesion
Lack of atrophy in a chronically paretic/paralytic limb	Lack of atrophy in a paralyzed/paretic limb suggests the limb is being used or is getting regular electrical stimulation to maintain mass
Impairment diminishes under influence of sodium amytal, hypnosis, or lack of observation	All these observations are most consistent with nonorganic presentations including consideration of malingering or conversion disorder
Incongruence between neuroanatomical imaging and neurologic examination	Lack of any static imaging findings on brain CT or MRI in the presence of a dense motor or sensory deficit suggests nonorganicity
Arm drop test	An aware patient malingering profound alteration in consciousness or significant arm paresis will not let his own hand, when held over his head, drop onto his face
Presence of ipsilateral findings when implied neuroanatomy would dictate contralateral findings	An examinee claiming severe right-brain damage who claims right-eye blindness and right-sided weakness and sensory loss
Tell me "when I'm not touching" responses	An examinee with claimed sensory loss who endorses that he does not feel you touch him when you ask him to tell you "if you do not feel" this.
Lack of shoe wear in presence of gait disturbance	An examinee with claimed longer term gait deviation due to orthopedic or neurologic causes should demonstrate commensurate wear on shoes (if worn with any frequency)
Calluses on hands in "totally disabled" examinee	An examinee who is unable to work should not present with signs of ongoing evidence of physical labor
Assistive device "wear-and-tear" signs	In any examinee using assistive devices for any period of time, e.g., cane, crutches, there should be commensurate wear on the device consistent with the claimed impairment and disability
Mankopf's maneuver	Increase in heart rate commensurate with nociceptive stimulation during exam (some controversy exists on whether this always occurs)
Lack of atrophy in a limb that is claimed to be significantly impaired	If side-to-side measurements and/or inspection do not bear out atrophy consider other causes aside from one being claimed

continued

TABLE 63.3 (CONTINUED)
Response Bias Detection Measures and Strategies

Sudden motor give-away or ratchitiness on manual strength testing	Considered to normally be a sign of incomplete effort or symptom exaggeration
Weakness on manual muscle testing without commensurate asymmetry of DTRs or muscle bulk	Suggests simulated muscle weakness if longstanding
Toe test for simulated low back pain	Flexion of hip and knee with movement only of toes should not produce an increase in low back pain
Magnuson's test	Have examinee point to area several times over period of examination; inconsistencies suggest increased potential for nonorganicity
Delayed response sign	Pain reaction temporally delayed relative to application of perceived nociceptive stimulus
Wrist drop test	In an examinee with claimed wrist extensor loss, have him pronate forearm, extend elbow, and flex shoulder … if upon making a fist in this position he also extends wrist, then nonorganicity should be suspected
Object drop test	Examinee claims inability to bend down yet does so to pick up a light object "inadvertently" dropped by examiner
Hip adductor test	Test for claimed paralysis of lower extremity, similar to Hoover test yet looks for crossed adductor response
Disparity between tested range of motion (ROM) and observed range of motion of any joint	When ROM under testing is significantly disparate (e.g., less) from observed, spontaneous ROM, suspect functional contributors
Straight leg raise (SLR) disparities dependent on examinee positioning	Differences in SLR between sitting, standing, and/or bending may suggest a functional overlay to low back complaints
Grip strength testing via dynamometer	Three repetitions at any given setting should not vary more than 20% and/or bell-shaped curve should be generated if all 5 positions are tested
Sensory "flip" test	Sensory findings should be the same if testing upper extremity in supination or pronation or lower extremity in internal vs. external rotation, differences may suggest a functional overlay
Pinch test for low back pain	Pinching the lumbar fat pad should not reproduce pain due to axial structure involvement; if test is positive, suspect a functional overlay
Personality Instruments with Built-In Response Bias Designs	
Personality Assessment Inventory (PAI)	Inconsistency (INC), Infrequency (INF), Positive Impression Management (PIM), and Negative Impression Management (NIM) scales. 8 score patterns thought to comprise a Malingering Index (Morey, 1996). > 2 patterns malingering suspected > 4 patterns likely malingering
Minnesota Multiphasic Personality Inventory (MMPI-2)	Validity indices (L, F, Fb, Fp, Ds, K, VRIN, TRIN), F-K (Gough, 1954) The Fake Bad Scale (Lees-Haley, 1991) Compare subtle to obvious items Rogers et al. (1994) – cutoff scores: Liberal: 1. F-scale raw score > 23 2. F-scale T-score > 81 3. F-K index > 10 4. Obvious– subtle score > 83 Conservative: 1. F-scale raw > 30 2. F-K index > 25 3. Obvious– subtle score > 190
Qualitative Variables in Assessing Response Bias	
Time/response latency comparisons across similar tasks	Inconsistencies across tasks
Performance on easy tasks presented as hard	Low scores or unusual errors
Remote memory report	Difficulties, especially if less than recent memory, or severely impaired in absence of gross amnesia

TABLE 63.3 (CONTINUED)
Response Bias Detection Measures and Strategies

Personal information	Very poor personal information in absence of gross amnesia
Comparison between test performance and behavioral observations	Discrepancies
Inconsistencies in history and/or complaints, performance	Inconsistencies across time, setting, interviewer, etc.
Comparisons for inconsistencies within testing session (quantitative and qualitative)	A. Within tasks (e.g., easy vs. hard items) B. Between tasks (e.g., easy vs. hard) C. Across repetitions of same/parallel tasks (rule out fatigue) D. Across similar tasks under different motivational sets
Comparisons across testing sessions (qualitative, quantitative)	Poorer/inconsistent performance on re-testing
Symptom self-report: complaints	High frequency, severity of complaints and higher frequency, severity vs. significant other report or other collaborative report
Main & Spanswick, 1995	Failure to comply with reasonable treatment Report of severe pain with no associated psychological effects Marked inconsistencies in effects of pain on general activities Poor work record and history of persistent appeals against awards Previous litigation
Symptom self-report: early/acute vs. late/chronic symptom complaint	Early symptoms reported late or acute symptoms reported as c
Response to typically helpful pain interventions	Failure to show any pain relief to at least one of the following: biofeedback, hypnosis, mild analgesics, psychotherapy, relaxation exercises, heat and ice, mild exercise Failure to show any pain relief in response to TENS
Assessment of Cognitive Effort: Performance Patterns on Existing Psychological/Neuropsychological Tests	
Full scale IQ	Low (vs. expected, estimated, etc.)
Arithmetic and orientation scale performance	"Near-miss" (Ganser errors)
WMS-R Malingering Index: Attention/Concentration Index vs. Memory Index	Attention–concentration index score < general memory index (AC-GMI)
Grip strength	Unusually low w/o gross motor deficit
Recognition memory (California Verbal Learning Test (CVLT))	< 13
Rey Complex Figure and Recognition Trial	Atypical recognition errors (> = 2); recognition failure errors
Word Stem Priming Task Performance	Poor or unusual performance
Specific Cognitive Effort/Response Bias Measures	
Word Memory Test (WMT)	< 50% chance responding
Test of Memory Malingering (TOMM)	< 50% chance level responding
Dot Counting Test (DCT)	Correct/incorrect responses
Computer Assessment of Response Bias (CARB)	< 89% raises suspicion
Rey Memory for 15 Items Test (MFIT)	Lezak (1983), < 3 complete sets, < 9 items
Symptom validity testing (SVT)	< 50% chance level responding

interpreting examinee data. Integration of contextual information, history, behavioral observation, interview data, collaborative data, personality data, with measures of effort or performance (or symptom exaggeration or malingering) and examination and test performance data provides the best information for estimating, for instance, the degree to which a person was responding truthfully and exerting full effort, and the degree to which test results are reliable and valid and reflect actual abilities and current status.

It also should be noted that the necessary recent increase in attention to response bias assessment has been accompanied by frequently haphazard and overzealous application of poorly validated detection models and single assessment procedures regarding malingering. Further, some alarming trends have appeared that do not objectively or critically evaluate the weaknesses, as well as strengths, of these procedures. Based on a critical evaluation of the current state of the art, it appears that many common assumptions about response bias detection and malingering measures should be considered myths (Martelli, Zasler, Mancini, et al., 1999). Importantly, malingering (1) should not be considered dichotomous, or EITHER/OR (i.e., present/not; malingering/not); (2) should not be considered something that clinicians can reliably or validly assess with any high degree of certainty, even when serious efforts are made; and (3) should not be considered a discrete entity that symptom validity tests (SVT) measure.

TABLE 63.4
General Weaknesses of Response Bias Assessment Measures

1. Psychometric research inadequacies (e.g., basic test construction issues such as reliability, validity, as well as convergent and divergent validity studies are poorly addressed).
2. Limited generalizability of analogue research (i.e., simulated malingerers vs. externally or criterion-validated malingerers, unknown differences between simulated and real malingerers; cf. studying serial killers this way), as well as tendencies for measures with good discrimination to show less effectiveness in cross-validation and follow-up studies.
3. Variable group membership (i.e., wide variability in samples for both simulators and symptom/disorder groups).
4. Differential vulnerability to response bias (i.e., some tests are more obvious while others are more subtle).
5. Questionable generalizability of findings (i.e., from one measure to any other (response bias or real) test, or to actual symptoms, or across time; conversely, good effort on a response bias measure does not necessarily predict response on any other measure).
6. Absence of mutual exclusivity (i.e., poor effort can occur in presence of real disorder, symptoms).
7. "Law of the instrument" operational definitions wherein malingering becomes what malingering tests measure. Specifically, the definitions of "effort," and validation studies to examine the construct are missing. Further effort cannot be assumed uniform for mild traumatic brain injury (TBI), chronic pain, and depression diagnoses, for nonlitigating and litigating, etc.
8. Effects of fatigue, pain, disinterest, non-attended (computer) administration, mixing real tests and SVTs in a battery with unknown face validity, and other factors, on response bias tests, are not understood and have not been addressed.
9. Exclusive or even primary reliance on any current SVT/Index or combination potentially violates APA ethics and APA Standards for Educational and Psychological Tests with regard to making a diagnosis of malingered pain or in making decisions about recommending treatment termination, due to limited reliability and validity data.
10. Frequently high misclassification rates (i.e., false positive) when these are assessed through record review and detailed analysis.
11. Problems associated with inaccurate assumptions of nonorganic conditions based on inconsistencies or absence of findings. Notably, recent advances in our relatively poor understanding of pain and its mechanisms and associated sequelae have implicated central nervous system effects in many such cases. A growing body of evidence strongly associates central nervous system effects, especially central sensitization phenomenon, in cases where peripheral findings are inconsistent, weak, or even apparently nonexistent (Jay, Krusz, Longmire, & McLain, 2000; Miller, 2000; Nicholson, 2000; Nicholson, in review; Mailis, Papagapiou, Umana, Cohodarevic, Nowak, & Nicholson, in press).

A specific method of response bias assessment that is worth mentioning is SVT, which typically refers to a forced-choice technique originally designed for assessing effort or symptom validity with respect to nonorganic blindness (Pankratz, 1988). This technique has been extended to assess effort in purported sensory loss and, more recently, memory complaints (Colby, 2000). The typical SVT paradigm involves presentation of a stimulus, followed by a distraction, and then presentation of the original stimulus with a novel stimulus with instruction to identify the original stimulus. With regard to memory assessment, a series of words is presented for recall and, following a delay, each word is presented with a sham, with the subject instructed to select the previously presented word. In the case of visual or sensory assessment, the simplest procedure entails exposing the subject to a series of visual or sensory stimuli (e.g., pinpricks while blindfolded, asking whether or not he or she perceived each. Performance is then compared with chance, which is the worst possible expected performance if sensory function or ability is completely absent. Below chance (i.e., below 50%) performance across a sample of numerous trials indicates negative bias and indicates that the symptom is feigned. Such performance provides strong and unambiguous evidence of conscious dissimulation or symptom malingering, because worse- than-chance performance requires recognition and suppression of true responses.

A summary of some of the major problems with extant response bias procedures is offered in Table 63.4 to (1) emphasize the necessary caution with regard to overinterpretation of response bias procedures; (2) emphasize the importance of employing multiple data sources and making thoughtful inferences only after integration of thorough historical information, interview, assessment, behavioral observations, collaborative interview, and data sources, and so on (Martelli, 2000).

Table 63.5 is presented to further caution against simplistic and dichotomous conceptualizations with regard to diagnosis, Table 63.5 is presented. Notably, this table represents just 64 of the possibilities with regard to injury-related presentations. The range of possibilities represented span from (a) persons with real, uncomplicated disorders with impairments on exam and in functional status, without exaggeration on either (but possibly minimization or denial) to (b) persons with no real physical pathology or impairments, but who exaggerate or feign impairments on exam and functional status.

Necessarily, a cautious approach is indicated with regard to estimating the probabilities regarding presence or absence of physical impairment and response bias. However, in many cases, it is not sufficient to integrate data from multiple sources and make inferences about which of the 64 possible combinations is most likely. Descriptive characterization is often relevant. For

TABLE 63.5
Diagnostic Realities in Assessment of Chronic Pain

Real Physical Pathology		Residual Functional Impairments		Residual Impairments On Exam, Testing	
1. Yes		1. Yes, and exaggerated		1. Yes, and not exaggerated	
2. Mixed		2. Yes, and not exaggerated		2. Yes, and exaggerated	
3. Indeterminate		3. No, and exaggerated		3. No, and exaggerated	
4. No		4. No, and not exaggerated		4. No, and not exaggerated	=
4	×	4	×	4	64

instance, if a person has both physical pathology and exaggeration, inferences must be generated about not only the degree of physical impairment, but also the degree of awareness of exaggeration on the part of the subject. Has the person adopted a sick role, and talked themselves into believing they cannot perform certain tasks or lack certain abilities (e.g., somatoform disorder), with conscious withholding of effort due to intending to demonstrating what they believe to be true disabilities? Or, are they less conscious and aware, as in a conversion disorder? Or are they completely aware, but coping in a way that may be adaptive as in the case of an aging worker with a chronic history of back failures who may be shy, have low self-esteem and self-confidence; be disconnected from or less than well liked by his/her employer, against the backdrop of believing that another back injury is inevitable and cumulatively painful and disabling, that uncomfortable interactions with others may be required, that the company sometimes forces previously injured workers, that the company did not make obvious safety precautions to prevent the individual's injury; and that no other job options are realistic?

CONCLUSIONS

To summarize, the major response bias detection strategies presented in Table 63.3 provide an illustrative summary of a constellation or profiling approach to response bias detection strategy use that relies on assessing relevant information for interpreting examination data. This conceptual model is also a methodological approach for constructing a profile of motivation and response bias, which (a) incorporates a wide array of findings from common instruments and procedures during evaluation; (b) summarizes empirically supported indicators with at least some purported utility in detecting suboptimal effort; (c) despite numerous pitfalls and limitations of each of these procedures, both conceptual and methodological, offers improved discrimination and increased reliability given multiple measures; (d) integrates behavioral observation, interview, and collaborative, historical, personality, and contextual data with medical examination and psychological performance data and measures of response bias, as an optimal method for estimating the degree of effort or performance and the degree to which examination findings are reliable and valid and reflect actual abilities; and (e) allows estimation of motivation by incorporating currently available instruments and methods and the available published research for direct and indirect measurement of motivation and response bias.

Notably, these strategies are not offered individually and, again, are not intended to support a simple dualistic model that assumes examinees either try hard or malinger, or that evidence of less-than-full effort on any one test necessarily implies absence of impairment in other areas of examination or in real world abilities. Although they also are not offered with specific guidelines (e.g., failure on any one, or any two, or any three, etc. represents inadequate performance, or symptom exaggeration or malingering), they are offered with the suggestion that (a) examination performance can be influenced by multiple factors including a desire to be completely truthful and perform with full effort; (b) the degree of truthfulness and effort exerted on examinations exists on a continuum (vs. a dichotomy) and can be estimated by the extent to which indicators of unreliable report and poor/inconsistent effort are present; (c) reliability and validity of examination findings are dependent on relative assurances of full effort; and (d) interpretation and diagnostic impressions are dependent upon reliable and valid examination results.

It should be emphasized that "failure" on one measure of response bias or malingering does not mean that the entire set of complaints is biased or malingered. Ethical guidelines universally caution against overzealous interpretation of limited test data. In fact, the only reasonable evidence of certain or definite malingering is confession or admission. A secondary form of evidence, although somewhat less than perfectly reliable, is when the person or examinee is detected, via surveillance, performing an act he or she reported was absolutely impossible to perform under any circumstance.

It should be noted further that a great disparity exists between the adversarial legal process and the responsibility of attorneys to be client advocates vs. the dispassionate, objective scientific ethics expected and required of psychologists and physicians. The danger of attorney

"coaching" based on utilization of this material cannot be underestimated. This, of course, would then represent a form of "stealth" threat to the validity of examination data. This threat, or expected consequence of collision between disparate legal and scientific ethics, has recently been documented in a national publication noting a case of attorney-client coaching (Youngjohn, 1995). However, compared to simpler models where only a couple of isolated response bias measures are used, it seems extremely unlikely that the multiple measures, such as those outlined in the MAP approach, could be understood and manipulated.

Finally, enhancing response bias detection as a means of optimizing interpretability of examination results, critical as it is, should not be considered the half-step. Decreasing response bias must certainly be considered a more efficacious and economic approach to enhancing utility of medical and psychological assessments.

The following explicit and comprehensive recommendations for enhancing motivation, assessing response bias, and increasing efficiency, utility, and ecological validity of examination procedures are offered (Martelli, et al., 1999b).

Recommendations for Enhancing Validity in Chronic Pain Assessments

1. Establish rapport and attempt to establish a working relationship with patients. Even in cases of independent examinations where the referral source and expectation are extremely adversarial, valid data collection requires a collaborative effort. Be on guard by addressing potential sources of bias directly, and providing feedback, education, and clarification.
2. Prepare patients and examinees before beginning examination and testing. Employ understanding, as well as education, in order for examinees to be prepared to respond truthfully and to the best of their abilities. Emphasize that the procedures and tests do not always measure everything, but that they do assess poor motivation or effort. Emphasize that interview data, corroborative data, and functional abilities are just as important as examination data.
3. Spend time with patients/examinees and try to get to know them from a motivational, emotional status, personality, and coping style perspective. If motivation seems poor, confront and attempt to elicit more valid responses vs. ignore and/or proceed with collecting invalid data and/or attempting to interpret data of questionable validity. Such questioning of motivation/effort should not involve a "gotcha" attitude. We can't assume that everyone takes our tests seriously, will be as forthcoming, honest, or effortful as we would like, will not doubt our procedures or try to emphasize their problems, or that we won't have to work at getting them optimally motivated.
4. Ensure that important general situational and psychosocial variables affecting motivation are adequately assessed during an interview that is concluded prior to examination procedures. Specifically, assess the impact of anger or blame and feelings of resentment or victimization (Rutherford, 1989), as well as the other variables shown in the literature to be associated with poor recovery and adaptation to impairments (Martelli, Zasler, & Grayson, 2000).
5. In addition to emotional and motivational issues, always assess interest/disinterest in the examination and testing procedures process, and any obstacles or impediments to optimal effort and performance. Always assess anxiety level and ensure that measures are taken to minimize its effect and potential interference with valid assessment.
6. Rely primarily on M.D.s and Ph.D.s for all aspects of examination, including interviewing and testing, with limited use and reliance on technicians. Experienced M.D.s and Ph.D.s who conduct interviews, examinations, and test administration are infinitely more capable of
   a. Integrating history, interview, personality, and emotional assessment data and inferences, with more sophisticated clinical observations during examination;
   b. Adapting more creative modifications of testing procedures given suspicion of low motivation, as well as modifications to the testing process (e.g., provision of corrective feedback, instruction, anxiety reduction interventions) to increase motivation and optimize effort;
   c. Benefiting from the probability that examinees will be less likely to believe they can "fake out the doctor";
   d. Avoiding the possibility of symptom exaggeration owing to fear that a technician or inexperienced clinician will miss legitimate problems.
7. Differentially utilize instruments with built-in response bias or symptom validity measures. Most major objective personality measures, some of the newer domain-specific pain assessment measures, and some neuropsychological measures (e.g., Memory Assessment Scales (Williams, 1992), and the Rey Complex Figure Test and

Recognition Trial (Meyers & Meyers, 1995)) provide simulator performance data.

8. Apply multiple strategies for assessing motivation, especially when cutoff score approaches are employed, and include qualitative and qualitative measures. Integration of contextual information, history, behavioral observations, interview and collaborative data, and personality and coping data with measures of effort or performance and current test data, provides the best information for estimating the degree of effort exerted, and the degree to which test results are reliable and valid.
9. Vary the response bias measures and procedures that are employed in order to prevent dilution of utility. Notably, publicizing of these tests has led to increased recognition by potential defendant attorneys, litigants, support groups, Internet groups, etc.
10. Promote development of assessment procedures with built-in response bias or symptom validity measures and develop built-in measures for existing assessment procedures.
11. Employ more sophisticated and less dichotomous continuous conceptualizations of motivation and response bias using multiple independent measures and estimated effort. Employ a reasonably sophisticated model that conceptualizes motivation and effort as continuous variables that can vary across tests, settings, and occasions. Utilize and devise models that measure degree of apparent motivation and effort, using multiple data sources, and estimate confidence levels in inferences given consideration of the multiple factors that contribute to test results. Employ similarly sophisticated models for assessing persistent impairments, adaptation to impairments, disability, and so on. Probability statements based on multiple meas-ures are probably best.
12. Do not freely share relevant trade secrets (e.g., information about response bias tests, or known patterns of performance on procedures and instruments) with referral sources, attorneys, and nonphysicians and nonpsychologists. They often adhere to a completely different set of professional ethics.
13. Remain aware that in science and medicine things are rarely either–or, clear cut, or unidimensional. Avoid simplistic conceptual models that are compatible with dichotomous approaches to assessing motivation/effort and malingering. Such approaches usually rely on cutting scores for one or two measures. Note that cutting scores by their nature (Dwyer, 1996) always entail judgment, inherently result in misclassification, impose an artificial dichotomy on essentially continuous variables, and "true" cut scores do not exist.
14. Promote utilization of independent examinations by clinicians who actually spend a significant portion of their time treating the type of patient being assessed. This helps assure more adequate clinical skills for accurate diagnosis and understanding, including detection and appreciation of suboptimal performance, as well as collection of internalized tracking data to validate previous inferences across time, and continuous self-correction and increased collection of internalized norms regarding ecological and predictive validity of available assessment measures.

Psychoneuroimmunology

Jan M. Burte, Ph.D., D.A.A.P.M.

Historically, the study of mind/body interaction can be traced to early Greek physicians. Indeed, when one begins a search of its earliest origins, one inevitably is led to Hippocrates and Galen of ancient Greece. To the ancient Greeks, emotions were seen to play a significant role in the progress and maintenance of diseases. What today is known as tuberculosis was described symptomologically by Hippocrates and prescribed to have its etiology in stress. However, the importance of the role of the mind in maintaining health has passed through many significant perceptions since that time. Until recently, post-Descartian thinking resulted in the mind's role in immune functioning being allocated to the periphery of medicine.

Masek, Petrovicky, Sevcik, Zidek, and Frankova (2000) pointed out that psychoneuroimmunology (PNI) was comprehensively described only as recently as 20 years ago. They go on to define PNI as the bidirectional communication between the central nervous system (CNS), neuro-endocrine system, and immune system. With a return to examination of the interactive role of the central nervous system, the endocrine and immune systems came a new field currently labeled PNI. Many definitions of PNI are available, depending on the emphasis or direction of the pathways particular fields of researchers choose to emphasize.

One definition offered by Paul Martin (1998) is "the field of scientific research that is concerned with the complex interrelationship between the psychological and emotional factors, the brain, hormones and immunity and disease."

The purpose of the chapter is to offer the following: First, a basic understanding of precisely which pathways are considered in PNI. For example, what are the biological immune responses (cortisol levels, cytokines levels, natural killer-cell levels, etc.) that are affected by environmental and internally mediated stress? Second, to restate the question often raised by clinicians, "Does statistical significance (i.e., changes in hormone levels) assume clinical relevance (i.e., a clinical change in the immune system's protective potential)?" Third, if we accept that stressors experienced through conscious awareness and judgment impact the immune system, what can be done to reduce those stressors?

A discussion of treatment modalities is offered, and finally, hope for a united direction for future research unifying the basic sciences (statistical analyses) and the applied sciences (clinical relevance). What then do we know about the integrative reaction of the CNS and the immune response?

Stress, via bidirectional interactions between the central nervous system, endocrine system, and immune system, impacts the hypothalamic, pituitary, adrenal (HPA), and the sympathetic adrenal medullary (SAM) axes, can induce modulation of the immune system and, thereby, defense against infectious agents and health (Yang & Glaser, 2000).

In a review of research articles, Sali (1997) notes that stress increases the risk of viral infection. Stress and depression can depress immunity, whereas stress reduction enhances immunity. Sali points to outcome data on improved cancer prognosis by enhanced immunity resulting from stress reduction. Spiegel (1999) found increased survival rates in breast cancer patients who attended stress reduction groups or programs. Further, Van der Pompe, Anoni, Visser, and Garsseri (1986) suggested the importance of psychotherapy and psychological resiliency in breast cancer survival. Utilizing a twin study model (124 normal adult twin pairs; Hickie, Bennet, Lloyd, Heath,

0-8493-0926-3/02/$0.00+$1.50

and Martin 1999) found a positive genetic relationship between psychological distress and immunity. They concluded that genotype may play a significant role in the reactivity of the immune system to stress. Garssen and Goodkin (1999) suggest that some evidence has been found that a low level of social support and a tendency toward helplessness and repression of negative emotions are factors that promote cancer progression but not cancer initiation. These same factors are also symptoms commonly associated with depression. Further, Christiansen, Edwards, Wiebe, Bonotsch, McKelvey, Andrews, and Lubaroff (1996) found that immunosuppression (NKC activity) could be positively impacted by self-disclosure of traumatic or stressful experiences.

A question is then raised: "Does a correlation exist between depression, suppressed immunological functioning, and the elevation of underlying disease processes to a level above threshold (i.e., the symptomatic expression of herpes or the increase in joint counts in rheumatoid arthritic patient)?" Research continues to support the concept that stress plays a significant role in exacerbating pathophysiology. Berin and Perdue (1997) note that reported stress often precedes relapses in patients with inflammatory bowel disease or irritable bowel syndrome and that CNS and immune-mediated pathophysiology as expressed by changes in the epithelium may exist.

Stress and pain also have been demonstrated to adversely affect endocrine and immune function in regard to postsurgical wound healing, with greater fear or distress prior to surgery being associated with slower and more complicated postoperative recovery (Kiecolt, Glaser, Page, Marucha, MacCallum, & Glaser, 1998) and to small punch biopsy wound healing in caregivers as demonstrated by increased healing time and lower cytokines (IL–1) levels (Glaser, 1996). In regard to posttraumatic patients, Klapheke (2000) suggested that their depression should be seen as a contributory factor to the net state of immunosuppression in transplant patients

PSYCHONEUROIMMUNOLOGY AND PAIN

The impact of pain on immune functioning has been studied extensively in animals, but more recently the role of various types of pain on immune function has been examined. Kremer (1999) notes that surgery negatively affects immune function, and that pain has a deleterious effect on immune function. Via neuroendocrine pathways, depression, stress, and pain can be viewed as psychoneurological phenomena. He suggests that treatment of postoperative pain must be included in the recovery process because of its psychoneural immunological impact on the patient.

In a study to assess acute pain impact on immune levels in 10 HIV^+ and 10 HIV^- patients, Eller (1998) found no significant difference between groups. However, significant changes in state anxiety, systolic blood pressure, diastolic blood pressure, and CD4+ lymphocyte numbers were associated with levels of perceived pain intensity to a cold pressor test.

In extreme situations where physical trauma and pain are severe, the body releases endogenous opioids which reduce the perception of pain and have pain-relieving actions. However, as a result, the immune activity of natural killer cells and lymphocytes is reduced.

This raises the issues of placebos and other treatments that work by altering the individual's perception of pain without actually providing an external source of analgesia. If, in fact, they operate as some believe by triggering pain-relieving opioids, do they then represent a two-edge sword which offers pain relief, thus, diminishing the immunosuppressant levels of IL-6 and cortisol while possibly decreasing tumor suppression by lowering NKC and certain lymphocyte activities?

Another issue about pain is its controllability. Laudenslager (1983) found that lack of control vs. control over pain induced by electric shock determined lymphocyte responsiveness of rats. This may also explain the more recent findings of researchers that depression (learned helplessness) with regard to pain may be significantly related to dysfunctional reciprocal relations between neuroendocrine and immune function (Geiss, Varodi, Steinback, Bauer, & Anton, 1997).

The patient's perception of the controllability of pain and level of optimism may also play a significant role in the impact that pain has on immune functioning. In an examination of pain patients suffering with temporomandibular pain and dysfunction syndrome, immune functioning was not impacted compared to controls. However, patients who scored high on measures of "demoralization" (low self-esteem and perceptions of helplessness and hopelessness) demonstrated significant decreases on measures (Marbach, Schleifer, & Keller, 1990).

In a review article, Page and Ben-Eliyahu (1997) note that the immune system plays a role in controlling the spread of cancer and that perio-operative pain relief improves immune status and health outcomes. They suggest that sufficient evidence exists to view pain as a pathogen in and of itself that is capable of facilitating the progression of metastatic disease via immunosuppression.

Along similar lines, a study by Parker, Smarr, Anglone, Mothersead, Lee, Walker, Bridgers, and Caldwell (1992) utilizing the Beck Depression Inventory, the Arthritis Helplessness Index, and the Arthritis Impact Measurement Scales (AIMS) pain score in conjunction with immunophenotypic analyses of peripheral blood lymphocytes found that the percentage of HLA-DR + cells in the peripheral blood and helplessness related to joint count in rheumatoid arthritis (RA) patients. Further, joint count had an effect upon depression and depression affected the perception of pain,

demonstrating the interrelationship among psychological factors, immunologic activation, and disease activity in RA. Zautra, Hoffman, Potter, Matt, Yocum, and Castro (1997) also found that interpersonal stressors were associated with increased disease activity in a study of 41 rheumatoid arthritic women.

Affleck, Urrows, Tennen, Higgins, Pav, and Aloisi (1997) examined sedimentation rates, an indication of systemic inflammation and soluble interleukin-II receptors (a marker of immune system activation known to correlate with the RA disease activity). For RA patients, they found that daily event stressors were associated with increased joint pain (regardless of mood) and decreased joint inflammation (reduced levels of soluble interleukin-II receptors).

Another issue that often is raised is the impact of acute stressors on individuals who are experiencing chronic life stressors. It would seem that individuals who are experiencing chronic life stress might be more vulnerable to the impact of acute stressors. The importance of this is apparent when we look at disease onset rates in more vulnerable populations, such as the infirmed, ill, or impoverished, who may be experiencing higher levels of chronic life stress. Indeed, Pike, Smith, Hauger, Nicassio, Patterson, McClintick, Costlow, and Irwin (1997) found that individuals experiencing chronic life stress demonstrated greater subjective stress, higher peak levels of epinephrine, lower peak levels of beta endorphin and of NK cell lysis and NK cell distribution to a mild acute stressor than did controls. These changes persisted beyond termination of the stressor and sympathomedullary recovery. It reinforces the concept that those already suffering, often the case in chronic illness or injury patients, are most vulnerable to further immunosuppression from acute stressors.

In the case of traumatic injury, Schrader (1996) suggests that the individual's psychologic and physiologic states may alter the immune system and decrease immunity as measured by serum cortisol levels, and further, that the perception of diminished control and subjective stress may contribute to immune changes when combined with the immunosuppressive effects noted with regard to pain, suggesting that the state of significantly decreased immunity needs to be addressed from a psychological, controlled coping skill, and pain management approach.

Interestingly, research suggests when the stress is consistent with the stressor (perhaps demonstrating better coping skills by the individual), immunological changes are less severe than when the stress experienced is greater than expected from the trauma. Solomon, Segerstrom, Grohr, Kemeny, and Fahey (1997) found that earthquake survivors who manifested acute psychological reactions to a realistic degree given the life stress experienced less disruption of an aspect of immunity (lymphocyte subsets – total T[CD3+] helper T[CD4+] cytotoxic T[CD3+ and CD8+] 19+) and natural killer cell (NK; CD3– CD16+ sign CD56+) as well as lymphoid cell mitogenesis (PHA and DWM) and NK cell cytotoxicity than those who had more severe reactions or who repressed their stress reactions.

Adaption to stress and its impact on the immune system may be somewhat more complicated. Kelly, Hertzman, and Daniels (1997) have suggested that PNI measures may act as markers to adaption to socioeconomic and psychosocial stressors.

There appears to be significant evidence that psychological stress contributes to immunological suppression (Biondi & Annino, 1997). However, there is less compelling evidence suggesting that immunosuppression may result in mental disease. However, recent research identifies the hypersecretion of IL-2 in schizophrenia and IL-6 in depression. Muller (1997) suggests that cytokine changes resulting from stress impacting the immune system may play a role in psychiatric disorders. Further, Dabkowska and Rybakowski (1994) suggest that the immune system may play a role in increasing vulnerability to psychiatric disorders.

Given the interactive nature of PNI, it is evident that a relationship exists between emotional disorders such as depression and alterations in the response of the immune system. However, as Kaye, Morton, Bowcutt, and Maupin (2000) point out, the associations and relevance of these alterations with regard to health and illness are not yet fully determined.

Anyone who has spent a night in pain or stressed knows the impact that either can have on sleep. Hall, Baum, Buysse, Prigerson, Kupfer, and Reynolds III (1998) report that sleep has been demonstrated to be a significant factor in the stress/immune relationship of NKC number and functions.

Severity of pain was also a factor. This suggests that clinicians must be aware of the patient's mental state and take into account immunological susceptibilities in those patients who present with significant levels of emotional demoralization (chronic pain syndrome) when invasive potentially immunosuppressant interventions are considered.

In fact, an optimistic outlook may protect the immune system from the negative impact of stress. First-year law students evaluated at the onset of the semester who were found to manifest a more optimistic attitude had more helper T-cells (T-cell increased 13%) and higher natural-killer cell cytotoxicity mid-semester than their pessimistic peers (T-cell dropped 3%). This led to the suggestion that the optimist's attitude protected their immune functioning (Segerstrom, 1998).

Another important question often asked is, "Does stress impact sufficiently enough on the immune system to create a health risk?" Glaser (1996) found studying antibody responses to flu-vaccinated Alzheimer's disease patients' caregivers and to Hepatitis B-vaccinated medical students that their findings indicated psychological

stress may be able to alter a person's response to a vaccine and, therefore by implication, his or her risk to infection by a live virus. Koenker (2000) states that psychological stress sufficiently impacts the immune system to raise catecholamine and CD9 levels and increases the risk of viral infection-released histamines which trigger severe bronchoconstriction in asthmatics. It also alters insulin needs, increasing the risk for diabetes mellitus; alters acid concentrations in the stomach contributing to peptic and stress-ulcers and ulcerative colitis; and increases plaque buildup in arteries thus adding to the risk of angina and heart attack. (Elliott & Eisdorfer, 1982; Lieberman, 1974).

As we continue to learn about complex PNI interactions our views of the forms of intervention and pharmocotherapies may significantly change. Masekt, Petrovicky, Sevcik, and Zidek (2000) point out that the data strongly suggest that in the very near future we will not only better understand the very complex communication between mind and body, but also have completely new types of compounds become available.

Vedhara, Fox, and Wang (1999) raised the question as to whether in vitro statistically significant results can be equated to in vivo immune outcomes. Although not yet completely answered, significant in vivo research is present, as evidenced by the plethora of treatment outcome studies represented in the literature. These studies suggest the presence of a PNI effect.

TREATMENT

Having reviewed the mechanisms and correlations between the psyche (mind), and neuro (brain/endocrine) and immune system, and seeing that a bidirectional relationship exists, we next should review what forms of intervention have been applied in treating various conditions. One might feel initially tempted simply to try to correlate treatments with conditions/diseases, but this would undermine the very essence of the psychoneuroimmunological model which seeks to approach immunosuppression from a more holistic framework. Perhaps the best title for all interventions which utilize this model is the one proposed by Biondi and Zannino (1997) who refer to such interventions as psychoimmunotherapy, namely, the application of conjoint psychological intervention in pathologies such as tuberculosis, herpes simplex virus, and HIV. Coyle (1996) offers a similar concept of psychoneuroimmunology in the treatment of multiple sclerosis.

An important issue rises, however, but the point of intervention. Hiramoto, Solvason, Hsueh, Rogers, Demissie, Hiramoto, Gauthier, Lorden, and Ghanta (1999) state

> Psychoimmunology has been credited with using the mind as a way to alter immunity. The problem with this concept is that many of the current psychoimmunology techniques in use are aimed at alleviating stress effects on the immune system rather than at direct augmentation of immunity by the brain. They raise the question as to whether the mind can, via conditioning, be trained to remember an output pathway to raise immunity.

If so, then it lends increased credibility to the mind-control components promoted in Eastern philosophies and healing arts.

Further, as we break down the concept of training pathways, one is presented again with questioning to what extent conditioning is behaviorally mediated via the build-up of neural pathways or unconsciously mediated via imagery-based internal experiences.

Let us first examine the different modalities utilized and presented in the literature concerning stress reduction as a means of enhancing immune function. Stress management represents a broadly defined treatment orientation encompassing a huge variety of treatments. The singular underlying common goal is to bring about either objectively or subjectively reported changes in the patient's experience of stress. However, as has been frequently noted in the literature from Selye (1956; 1976) to the present, not all stress is negative, and although general stress values have been numerically quantified (Holmes and Rahe 1967), not all events maintain equal stress values for all individuals. In addition, factors such as the ability to control the stressors (Schrader, 1996; Kiecolt, et al., 1998; Kaye, et al., 2000; Laudenslager, 1983), support systems (Spiegel, 1999), chronicity of the stressor (Pike, et al., 1997), and adaptation to the stressors (Kelly, et al., 1997) may play a significant role in the impact of stress on immunological functioning and responsiveness to treatment.

Some of the treatments that have sought to address the effects of stress include biofeedback, hypnosis, cognitive behavioral, behavioral approaches, exercise, nutrition, physical manipulation, yoga, and a host of other techniques including laughter therapy, dance, and the arts. What almost all of these approaches have in common is that they seek to change the patient's (assuming he or she is ill at this point) appraisal of the stressors that preceded the influence of immunodepression, the stressors associated with his/her appraisal of the illness and treatment. This typically includes the patient's stability to control pain and the degree to which he or she is limited or disabled by the illness or pain, as well as the stressors associated with the patient's appraisal of future functioning and/or mortality.

In essence, stress combined with a stress-prone personality leads to physiological and hormonal consequences which deplete the immune system. This opens the door for possibly increased susceptibility to or maintenance of illness. Ultimately, the presence and impact of

that consequent illness, especially if pain is concomitant, can easily become a stressor unto itself and further mitigate stress-induced immunosuppression. In this model, then, a downward spiral of health requiring significant multimodal intervention is required if we are to reverse its direction.

BASIC STRATEGIES OF CHANGE

Biofeedback

Biofeedback as a form of intervention provides the patient with an increased sense of control over physiological responsivity to stressors. Through monitoring their EMG, EEG, and/or thermal responsiveness to covert and/or overt stimuli, patients can learn to significantly reduce physiological reactivity. Biofeedback can be especially useful in reducing arousal responses to conditioned stressors such as finger sticks, nausea associated with chemotherapy, and stress-induced cervical headaches associated with environmental queues (i.e., entering a hospital).

In addition, by experiencing feedback on their physiological functioning, patients who have been educated about the concept of PNI can gain an increased sense of control (previously noted as extremely important) over their physiological responsiveness and, thereby, over their environmental stressors. It provides for the generally positively perceived concept of "learning and mastery" to be placed back into the patient's hands. For example, even patients who feel little control over their illness and/or pain can gain some emotional and/or pain relief by focusing on minor successes in controlling physiological changes during biofeedback. Immediate biological biofeedback may be especially helpful with patients who evidence low to moderate levels of hypnotizability, whereas highly hypnotizable patients appear to benefit more from delayed biological feedback. In delayed biofeedback, information is provided after several minutes of self-hypnosis training in order to shape and confirm the efficacy of the self-hypnosis training (Wickramasekera, 1999).

Within the thermal biofeedback approach, one goal is to teach the patient to lower sympathetic nervous system activity level through autogenic hand warming. Additionally, a quieting of the muscular armoring through EMG biofeedback can benefit patients by reducing stress-induced pain as well as pain-induced stress. The relaxing of the physiology and musculature is then enhanced with EEG biofeedback where patients can induce increased alpha and beta wave activity, thereby seeking to incur a quieter mental and emotional state. Alterations of cognitions, beliefs, and perceptions can be achieved via the association of altered physiological states with new concepts and coping thoughts. Bibliotherapy in conjunction with the biofeedback, which includes educating the patient about the benefits controlling stress responses has upon their limbic system (increasing NKC activity and possibly reducing mutagenic effects), helps the patient tangibly connect with intervening in his or her own treatment (Davis, 1986).

Cranial Electrotherapy Stimulation (CES)

With patients having difficulty achieving therapeutic levels of alpha states, even with biofeedback, cranial electrotherapy can assist by passing microcurrents through the cranial area via electrodes attached to the earlobes. CES stimulation has been shown to be helpful when utilized for emotional distress such as depression and anxiety by teaching the patient how to achieve a relaxed, quieted but alert state. While CES has not been found traditionally to be useful in treating stress-related disorders, recent studies have begun to demonstrate its effectiveness. Research has also demonstrated utility in pain management. By passing microcurrents through affected pain regions, patients report significant reductions at the sites of their pain. By combining CES with microcurrent stimulation at pain sites patients can reduce emotional distress and physical discomfort (Kirsch, 1999), thereby positively impacting upon the pain and emotional components of the PNI triad. The pain relief associated with microcurrent stimulation may provide the patient with an increased sense of control over pain and a smoothing of EEG peaks (associated with pain) when emotional and physical complaints are conjointly present (Hefferman, 1997). Because this treatment can often be self administered by the patient, it further enhances their sense of self-efficacy. It has little or no documented negative interactions with other forms of treatment.

Visualization/Imagery

Visualization has been conceived as the active process by which we "voluntarily and intentionally instruct the body." Whereas imagery is the spontaneously occurring "appearing in unconsciousness" modifier, qualifier, or belief emerging from the unconscious (Norris, 2000). Visualization represents how we ingest the world around us and what we then transfer to our unconscious or cognitive processing mind. Imagery represents how we interpret that information from the perspective of our internal beliefs and knowledge base. It represents "what does that visualization mean to me?" Perhaps more succinctly stated, as clinicians, we can guide patients into varying visualizations but the imagery is the process within them, their "experience" of the visualization. Through the use of imagery, patients can learn to change their outlooks for the future, and for the illness process. This has been shown to be tremendously helpful in improving clinical outcomes.

Pioneering in the use of imagery in fighting cancer in works such as Love, Medicine, and Miracles (Siegel, 1986) helps patients develop a sense of personal efficacy

in dealing with their illnesses, and enhancing the PNI triad. Visualization can help patients focus on the events they are experiencing in the process of working through their illnesses.

An excellent example of the use of imagery applied to the treatment of severe and chronic illness, especially cancer, is the program developed by Mitchell Gaynor, M.D. In his book, *Healing E.S.S.E.N.C.E.*, he details the use of imagery throughout seven steps toward healing experiences, see, surrender, empower, nurture, create, embody (Gaynor, 1995). Even patients with no prior experience with imagery can develop a practical and useful means of controlling illness and enhance the healing process.

Whatever the name, mental imagery (Moye, Richardson, Post-White, & Justice, 1995), guided imagery (Giedt, 1997), relaxation imagery (Andrews and Hall, 1990), and autogenic training (Benor, 1996) have been shown to be immuno-enhancing. In a somewhat more extreme example of drug-induced imagery states, Roberts (1999) found that entheogen-induced mystical and peak experiences may boost the immune system.

Hypnosis

Hypnosis is arguably the most effective approach in unifying the different aspects of the PNI triad. In ways, hypnosis may encompass many of the other approaches previously mentioned. Hypnosis can have a positive effect on illness by intervening at several levels including symptom alleviation, emotional stabilization, stress reduction, self-image enhancing, and self-efficacy empowering. It also can be employed in directly attempting to enhance endocrine responsiveness and CNS reactivity as well as pain control. Kalt (2000) states that "techniques which attempt to influence the mind fall into the theoretical categories of passive, active, or targeted approaches, each of which may carry varying degrees of importance in immuno-enhancement."

Hypnosis has often been segregated into three general orientations. These include direct, indirect, and nondirective approaches. The following is a brief discription of each approach and its utility in PNI intervention.

Traditional Approaches of Direct Suggestion with Formal Induction

In these approaches, general trance depth is considered to be important in symptomological change, or behavioral changes are given as a directive from the therapist. Although imagery may be employed, it is often the hypnotherapist's conceptualizations that direct the patient's internal experience. Direct hypnotic approaches have been effectively used, especially in situations where the patient either is strongly invested in turning over control to the therapist (i.e., pain management) or where the patient enters the therapeutic setting with significantly impaired feelings of self-empowerment or self-efficacy.

The need to feel that "the therapist is hypnotizing them" provides an initial sense of being taken care of, which may be critical to some patients, especially those deeply ingrained in the medical model. Issues of suggestibility and susceptibility are often raised when arguing the effectiveness of traditional hypnotherapeutic interventions.

With regard to pain management, significant support exists for the importance of the hypnotic suggestibility of patients. Highly suggestible patients demonstrate significantly greater pain tolerance (DePascalis, Magurano, & Bellusci, 1999; Farthing, Venturino, Brown, & Lazer, 1997; Rainville, Carrier, Hofbauer, Bushnell, & Duncan, 1999; Sandrini et al., 2000; Zachariae, Anderson, Bjerring, Jorgensen, & Arendt-Nielsen, 1998) and postoperative recovery than less suggestible patients (Defechereuz, Meurisse, Hamior, Gollogly, Jorus, & Faymonville, 1999; Mauer, Burnett, Oullette, Ironson, & Dandes, 1999). Other studies have demonstrated that the ability to be hypnotized may be less of a factor especially in emergency room settings where an increase in hypnotic susceptibility may be induced by the trauma (Pebbles-Kleiger, 2000).

Indirect Approaches

Currently, one of the most commonly utilized indirect hypnotic approaches is Ericksonian hypnosis. Ericksonian hypnosis promotes the idea of trusting in the patient's unconscious to deal with issues that arise. By its very nature, Ericksonian hypnosis employs a psychoimmunotherapeutic bent. Through the use of metaphor, storytelling techniques, and indirect suggestion, the patient is asked to seek what internal images or associations arise while in a hypnotic state in order to bring about emotional and psychotherapeutic change (Erickson, 1980). Distraction and dissociative suggestions have been utilized with pain patients within the Ericksonian model (Burte, Burte, & Aroaz, 1994). The therapist often acts in a reflective manner, guiding the patient into a deepening understanding of the spontaneously generated images by applying metaphors or stories to relay the hypnotic suggestion while allowing the patient to integrate the message into his or her own schema. The therapist helps the patient to understand the nature and origin of his or her symptoms, whether emotional, physical, or physiological. Ericksonian approaches have been extensively employed in the treatment of medical illness both symptomologically and etiologically (Erickson, 1986).

Simonton and Henson (1992) utilize hypnotic approaches in helping patients learn how to increase their ability to heal (enhance their PNI triad). Visualizing their bodies fighting illness by generating increased T-cells (i.e.,

little white Pac men eating the cancer) or visualizing bronchial dilation or shunting off blood flow to a tumor are examples of but a few of the plethora of indirect hypnotic applications patients can utilize.

Nondirective Approaches

The new hypnosis initially developed by Araoz (1985) presents a somewhat different model than either the traditional (direct suggestion) or Eriksonian models (indirect suggestion). The new hypnosis utilizes the symptoms brought to the session by the patient as the means of entering the patient's "inner state". A process of observing the patient's somatopsychic behaviors (i.e., hair twirling, fist clenching), and psychosemantic expressions (i.e., "he turns my stomach") within the framework of how these actions are manifested through the visual, auditory, olfactory/taste, proprioceptive, and kinesthetic senses is initiated. Patients are then led into their own inner awarenesses. They are encouraged not to judge or critique what arises. Often the patients gain new insights into the process, which affects their interpretations or reactions to stressors.

At this point, patients are given the opportunity to "visualize and introduce changes that promote greater well-being." Perhaps most critical in the PNI framework is the concept of negative self-hypnosis (NSH). Patients often find that they maintain negative self-hypnotic statements such as broad concepts of "I can never overcome this illness, it is going to kill me" to more minute specific beliefs about their illnesses or stressors.

The goal in applying the new hypnosis or any hypnotic intervention is to be able to intervene and exchange those negative self-hypnotic beliefs for positive self-hypnotic beliefs (PSH). This is best accomplished when, through the hypnotic experience, the patient feels a change that comes from changes in his or her inner awareness and belief system. For example, a patient who was experiencing chest pain of a nonorganically based nature, reported that in trance, due to unresolved issues with his father he became aware of the pain as an image of his father's fist squeezing his heart. Upon imaging a conversation where he resolved these issues and could see his father stroking his heart, the pain abated (Burte, 1989).

In situations where pain or stress has a clear etiological basis, the new hypnosis has been employed in developing coping skills, visualizing analgesia, or promoting positive internal representation for changes in biophysiology (Burte et al., 1994).

Eye Movement Desensitization and Reprocessing (EMDR)

An interesting new approach, known as EMDR, has been employed with trauma patients. It demonstrates some promising results. Perhaps of most significance in PNI is the concept of repressed trauma as a possible precursor to immunosuppression.

Group Therapy

Extensive work has been conducted on the impact of group therapy and stress management on immunosuppression. David Speigel's (1999) work with breast cancer patients demonstrates the efficacy of group support as does the work of other researchers who have found subsequently that group therapy can enhance life expectancy and functioning of patients with HIV and other immunosuppressant disorders. It appears that group therapy offers patients a sense of cohesiveness and an opportunity to express their negative emotions and beliefs while simultaneously helping them develop a better mental attitude and coping skills which, in turn, appears to enhance immune system functions.

Societal isolation and self-imposed feelings of family isolation (even at times when under the best of supportive conditions) negatively impact the PNI triad in the chronic pain and chronically ill patient (Hitchcock, 1998). Lack of family coherence, at times present with severely ill patients, emphasizes the importance of group therapy as an outlet for these patients. It provided a sense of coherence and support that they cannot obtain from their families or personal support networks. A review of the literature appears to suggest that a diverse range of therapeutic/support groups may be effective, and, in fact, it may be merely the intangible element of not facing adversity alone that enhances immune functioning. Stress management, pain management, coping skills development, dance, acting "as if" group laughter, supportive nondirective groups, all appear to contribute positively to patient well-being and demonstrate PNI enhancement.

Meditation

Role Play and Dance

Another technique found to impact the immune system includes meditation, which via the pineal gland influences melatonin levels, which, in turn, have been shown to modulate the progression of breast and prostate tumors (Coker, 1999). In addition to covert techniques such as meditation, the mere outward expression or acting/modeling of happy behaviors have been found to stimulate endorphins and enhance immune system function (Anderson, 1997). This may be especially helpful when it is difficult to convince patients of the impact of their negativistic thinking. At such times, perhaps we can encourage them to act as if" they were happy in order to bring about immunological changes. Still other researchers have found that dance therapy (Hanna, 1995) may improve patient immune functioning possibly by providing proprioceptive feedback and feelings of self-efficacy and physical self-control during those times.

A variety of other modalities too far reaching to encompass in this brief chapter also deserve mentioning as they are represented in the PNI literature. Behavioral approaches (Caudell, 1996; Cottraux, 1993;), diet and psychological health (Miller, 1996; Norris, 2000), healing energy (Wright & Sayre-Adams, 1999), laughter and music (Bittman, 2000; Strickland, 1993), and exercise (LaPierriere, Ironson, Antoni, Schneiderman, Klimas, & Fletcher, 1994) have been demonstrated to provide positive changes, although further investigation of their mechanisms is necessary.

Physical manipulative techniques that directly affect the physiology and nerve transmission, such as chiropractic massage therapy (Homewood, 1981; Rich, 1999) may bring physical and restorative relief and provide pain control (with or without opioids). These are but a few approaches that may promote healing via reducing stress, reducing pain, or enhancing patient efficacy.

A word of caution is raised by Greer (1991), who notes that within the PNI model of intervention, one must be on guard that a "blaming the victim" mentality is not promulgated inadvertently. Emphasis should be on positive change, not responsibility for creating one's own impaired status. Any intervention that increases the individual's sense of control of his or her environment or pain level reduces stress, enhances optimism and self-efficacy, impacts the PNI triad proactively, and may promote increased health by reducing immunosuppression (Burte, 2000).

"Goodbye" said the fox. "And now here is my secret, a very simple secret. It is only with the heart that one can see rightly. What is essential is invisible to the eye." "What is essential is invisible to the eye" the little prince repeated so that he would be sure to remember (Antoine de Saint-Exupéry, 1943).

> Whosoever is spared personal pain must feel himself called to help in diminishing the pain of others.
>
> Albert Schweitzer

INTRODUCTION

Pain is doubtless one of the most illusive and complicated aspects of life, particularly for the practicing health professional. From the inception of recorded human history everyone from the afflicted to sages, philosophers, theologians, and magicians have attempted to enlighten us regarding this condition. We are now wise enough to know that what we are currently recording will no doubt also be shown to be just as naive in years to come. Yet, despite this, we must try to consolidate what we know in an attempt to help those living in this era of history. We now know enough to see pain as more than a result and more than a syndrome. It is doubtless an illness all its own. Portenoy (1996) conceptualized longstanding pain associated with tissue damage as far more disabling than the injury itself.

Whereas "pain" has traditionally been thought of as a result of distress, usually with physical etiology, we now recognize many kinds of pain arising from multiple, singular, and combined sources. Whereas physical pain continues to be our greatest challenge in the medical world, other disciplines have joined to remind us of emotional pain and spiritual pain. We have come to recognize the interconnection of these kinds of pain and the reciprocal nature of the origins and amplifiers of pain. We have come to see that physical pain can be reduced or increased by emotional and spiritual pain and vice versa. The latest version (1995) of Roget's Thesaurus classifies pain as a physical experience, as does the Sixth Edition (2000) of The Columbia Encyclopedia. Our definitional literature has not caught up with the experiential world.

Practitioners are now challenged to preserve good pain while attempting to eliminate bad pain. Someone has said that without pain we could die without knowing that we were sick. Therefore, there is good pain, i.e., that pain which triggers action to protect the body and mind. However, there is also bad pain that produces more pain and suffering. Sometimes the signals of these two kinds of pain become confused and produce even greater suffering and actually escalate simple neuropathic pain into allodynia, the normally nonpainful stimulus that is perceived as painful, and is probably psychologically mediated. The possibility that such pain is psychologically mediated does not, however, mean that the pain is psychosomatic (psychologically induced) or only imagined. The etiology of pain and the mediation of pain are not the same. The origin of a neurological message and the transmission of that message are not the same thing. Pain may be caused by psychological stimuli or the stimulus may be transmitted neurologically, or in variations and combinations. Allodynia may truly be somatopsychic and real regardless of the mechanism that produced the final perceived sensation (Iadarola & Caudle, 1997).

Because pain is highly individualized and individually reported, it is possible that a practitioner could unwittingly create a state for future serious injury

0-8493-0926-3/02/$0.00+$1.50

because of neuropathic reporting and the subsequent alleviation of good pain. Illustrative of this are the persons who have been delivered from headache only to die from undiagnosed brain tumors. When healers are instructed by the Oath of Hippocrates to do "no harm", they must first recognize that the remediation of pain, in and of itself, although seemingly a noble gesture, may in truth not always be the most beneficial goal of treatment. Every quadriplegic knows that the absence of pain is a serious detriment to one's health.

Pain is a multichannel warning system within the human body. It is transmitted via many different pathways and culminates in the body's awareness that something is wrong. However, pain is more than a warning system. It is frequently an entity in itself that precludes normal thought and physiological functions. Illustrative of this are conditions such as post-herpetic neuralgia, a condition in which the nervous system continues to emit painful messages long after the actual viral infection has been arrested. When this is the case, the pain becomes both the etiology and the result of a condition that is definable as a separate and distinct illness.

THE CHALLENGE OF PAIN MEASUREMENT AND ASSESSMENT

One of our greatest unsolved problems in dealing with pain is our inability to see or measure it. We are getting closer to understanding substance P and its binding receptor NK-1. The release of neuroactive substances such as glutamate, calcitonin, along with substance P and substance K combines with biochemical mediation of nociceptive neurons, producing a perceived and probable actual change in the neurogenic recognition and transmission of the stimulus, which is ultimately experienced as pain. Good pain and bad pain are by all probability "attenuated by different toxin-ligand molecules" (Iadarola & Caudle, 1997).

There have been several attempts to measure pain, however, none has proven valid. The Gaston-Johansson Pain-O-Meter and the Gaston-Johansson Pain-O-Meter Visual Analogue Scale are attempts to quantify and identify levels of pain (Sittner, Hudson, Grossman, & Gaston-Johansson, 1998). In the final analysis, the only reliable measurer of pain is the person experiencing it. Pain is most accurately measured by descriptors such as "burning", "lancinating", "stabbing", "aching", "throbbing", etc. The perception of pain measurement on a scale of one to ten is probably as beneficial to most practitioners as anything. The patient can then indicate if the remediation is providing a lesser or greater scale score. Perception, in truth, is everything when it comes to the phenomenon of pain.

Doubtless one's level of consciousness is related to one's perception of pain. Qualia are the philosophically designated intrinsic properties of conscious experience. However, any health service provider who has worked with unconscious patients knows that even in the state of deep coma patients respond to deep pain, proving that consciousness is not a necessary requirement for pain perception. The qualia become beneficial in diagnosis and treatment of illness because they provide us with the descriptors, and the descriptors have common and frequent relationships to certain physiological conditions. Certainly the more accurately a patient can describe the pain, the more likely the physician will be able to provide the correct remedy.

Descarte believed that pain was a simple mechanism of action–reaction. As simplistic as this description is, the vast majority of persons who adhere to Western medical thought maintain a view that is not very different. The rapidly growing body of literature regarding pain is proving that pain is not simply an action–reaction phenomenon but a complex neural, chemical, anatomical, emotional, and cultural mixture. Most health service providers, even in the Western world, have given up the Cartesian mind/body separation, but we as yet have insufficient practitioner understood knowledge of the complex mechanisms we know are present but as yet unexplained.

Pain and suffering are not synonymous although often companions. Culturally mediated experiences of the same kind of stimuli produce different levels of perceived suffering. Athletes, martyrs, and mentally ill and hypervigilant persons have been reported to experience severe traumatic stimuli that under other conditions and in other cultures are reported as very different levels of suffering. There is no absolute correlation between the actual stimulus of pain and the reported level of suffering. Persons experiencing coma, yoga, hypnosis, and other states of altered consciousness have shown the presence of pain stimulus without the recognition of such by the person experiencing it. The attempt to measure pain by its consequent manifestations of suffering are, therefore, without scientific or experiential bases (McQuillen, 1991).

The aspect of suffering has been coupled with the degree to which the etiology of the pain is perceived to be a threat to the patient as a person. This has also been called one's "Total pain" (Cassel, 1982). It stands to reason that a threat of change or loss of life can markedly impact the meaning and, therefore, the attention paid to said stimulus, with the ultimate stakes of an impaired quality of life, which could result in social isolation, occupational difficulties, and financial hardship to name but a few. This can stand as a true test of a person's character, possibly adding kindling to underlying dysfunctional character traits, which could lead to a multitude of poor choices.

INDIVIDUAL DIFFERENCES IN PERCEPTION

There are only minor and poorly substantiated differences in each gender's perception of pain. These vague and nonscientifically based reports tend to indicate that much additional study is needed before one can conjecture regarding gender-related pain (Marble, 1999). Kelly (1999) asserts that because women probably experience pain more frequently than most men, they feel pain more keenly, yet women have a lower threshold for pain than men. The research is scant and far from scientifically based on this subject.

Children are most interesting in their reactions to pain. They tend to relate pain to various actions done to them, and they tend to see all pain as bad. As children mature, differentiate pain and its severity into various categories. Young children see pain as having an "owie," or being "stuck or poked", or simply that it "stings" or "burns". We, of course, know that young children do not relate causality to consequence in the same fashion as do older children or adults. It only goes to reason that they would perceive pain as whatever is present in the end state. Much the same as the child who spills the milk says, "the milk spilled", the child in pain says simply that it "hurts" (Woodgate & Kristjianson, 1996).

The same ambiguity is present in attempting to differentiate the experience of pain by ethnicity. A recent study reported that white persons reported less "severe disabling pain and withstood more pain for longer intervals than blacks" (Pirisi, 2000). Numerous studies have demonstrated that responses and expressions differ greatly from one ethnicity to another; however, studies do not exist that clearly demonstrate that the variations of response are due solely or primarily to ethnicity (Chapman, Toru, Martin, Tanaka, Okazaki, Colpitts, Mayero, & Gaghardi, 1982; Clark & Clark, 1980; Morse & Morse, 1988; Woodrow, Friedman, Seigelaub, & Collen, 1972). Generalizations abound regarding certain ethnic responses to pain, however, solid research is lacking to establish any such claims.

There is an emerging literature regarding the responses of older people to pain. Ruzicka (1998) reports that the beliefs of elders modify the experience of pain considerably. She found that "Pain is common and older people are expected to put up with it", and "Searching for the meaning in the pain experience is important, and often a review of past personal experience is the method used to attach meaning to the experience", and that elders are reluctant to express pain. There is doubtless a critical element present regarding the experience of pain and the willingness to complain about it. This is most probably a result of culture rather than age.

CHANGING PERCEPTIONS

Pain is more strongly linked with emotion than any other area of perception (Matlin, 1988). A visual perception, such as a beautiful sunset, exists out there in the environment and, therefore, can be a common or shared experience with another individual. In contrast, a perception of pain, such as a toothache, is a much more in here experience, within the confines of our bodies; therefore, such an experience is difficult to convey to others (Verillo, 1975).

Pain is a subjective experience depending on the nature of the perception of the individual; therefore, the experience of and response to a given painful stimuli can change as the perception changes. Cornock (1996) pointed out a few of the many factors that may affect a person's perception of any given painful stimulation. He included cultural factors, the context in which the pain occurs, expectations, emotions, motivations, personality, past experiences, and preparations. To understand these as some of the contributing influences of the net experience a person has provides the clinician with key elements for addressing a person's past experiences to help change the present perception of a painful process.

Interestingly, pain research has investigated essentially every aspect covered in a basic college psychology course, including learning and motivation, psychophysics and perception, brain and behavior, memory and cognition, individual differences, development, personality, psychological disorders, and social behavior (Craig & Rollman, 1999). To truly understand a pain process holistically, one must understand physiology, psychology, sociology, and spirituality. Since Melzack and Wall (1965) published their Gate Control theory, a watershed of different types of nontraditional treatment methods has been forthcoming because of the suggestion of various modulation of pain in concert with traditional allopathic medicine. For the first time, it became apparent that the sufferer had some degree of control over the pain processes associated with his/her given affliction, with proper education and work.

A greater sense of personal control over somebody can have great influence on the impact of his/her perception. Much like the elephant who has learned he can't break free from his shackles, even though the claims are oftentimes much smaller chains than what were originally used, the individual with an external locus of control, dependent on others to take care of his/her ills, often will lack the confidence to break free from the confines of the condition. This often will lead to a less proactive and sedentary, unhealthy lifestyle, which does not promote healing.

Likewise, a sense of self-efficacy is closely related to an internal sense of control. Self-efficacy originated with Albert Bandura and is defined as "an individual's sense of their abilities, of their capacity to deal with the partic-

ular sets of conditions that life puts before them" (Reber, 1995). Obviously, learned helplessness can be the net result of a poor sense of self-efficacy. Knowing this may be a normal reaction of individuals suffering from painful conditions, work geared toward self-confidence, personal controllability, and an internal locus of control may prove fruitful for many patients. It is important to remember, however, that some individuals need their pain. It gives them focus, attention, and reinforcement that may be beyond the scope of the clinician to understand.

Cornock (1996) outlined four major nonpharmaceutical approaches that can be used to help alter the patient's perception of pain. Please refer to the psychological technique chapter of this text for a more comprehensive understanding of these concepts. These include:

1. Information control. Through open communication of pain and its underlying conditions, some of the mystery is eliminated, thus alleviating the fear of the unknown.
2. Behavior methods. Through operant models of conditioning, desirable behavior is reinforced and positive change is rewarded. Relaxation and biofeedback also may be used to reduce tension and stress that may contribute to pain.
3. Cognitive approaches. These work to replace maladaptive thoughts, provide nonpain imagery, and refocus attention.
4. Hypnosis. A modality used for many different problems through relaxation, the placebo effect, and possibly the effect of the clinician on the patient.

With the successful use of one or several of these techniques, pain can be managed effectively by changing the perception of the ongoing physiological pain.

TWO MAJOR TYPES OF PAIN

Nociceptive pain was defined by Pasero, Paice, and McCaffery (1999) as "pain resulting from the ongoing activation of primary afferent neurons by noxious stimuli. The nervous system is intact." Furthermore, Portenoy (1996) added, it tends to be commensurate with the degree of ongoing tissue damage from an identifiable peripheral lesion that involves either somatic or visceral structures." Somatic pain is generated from muscle, skin, joint, connective tissue or bone, oftentimes has an achy or throbbing quality and is often easily localized. Visceral pain arises from visceral organs such as the pancreas and the GI tract.

Nociceptive pain (visceral or somatic in nature) has four basic processes. Transduction is the conversion from one energy to another. This is a peripheral process that begins with a mechanical, thermal, or chemical stimulus, and causes some degree of tissue damage. This injury to tissues produces the release of algogenic (pain-causing) substances that promote immune functioning and inflammation responses, and activate pain receptors. The algogenic substances include serotonin, bradykinin, and histamine, but this process also involves the production of other substances such as substance P and prostaglandin.

This nociceptive pain process triggers an action potential, sending messages toward the central nervous system. Transmission is the movement of pain impulses from the site of transduction to the brain. This phase begins in the dorsal horn of the spinal cord, triggers the release of substance P among other chemicals, sending this impulse to the brain. Perception is the process of recognizing, defining, and responding to pain, our conscious experience of the pain. Last, modulation is the activation of descending pathways that exert inhibitory effects on the cells responsible for pain transmission. This occurs, in part, with the release of endogenous opioids, serotonin, and norepinephrine (Pasero, et al., 1999).

The second major type of pain is neuropathic pain, defined as pain initiated or caused by a primary lesion or dysfunction in the nervous system. Within neuropathic pain, there are two distinctive types: centrally generated pain, initiated or caused by a primary lesion or dysfunction in the central nervous system, and peripherally generated pain, caused by primary lesion or dysfunction in the peripheral nervous system (Pasero, et al., 1999). Science has explained fairly effectively the physiology of pain processes, although work is certainly not complete in this area. Modern theories such as Melzack's Neuromatrix theory may be more thoroughly understood through a working knowledge of preceding basic theories.

THEORIES OF PAIN

Specificity Theory

The specificity theory was greatly influenced by the writings of René Descartes. Pain and touch sensors on the skin are wired to a pain center in the brain through specific receptors and pathways, similar to the visual system (Matlin, 1988). The painful stimulus was theorized to travel directly to the brain, and any emotions displayed as part of the experience were in response to the original stimulus. The theory assumes the intensity of the pain is directly proportional to the amount of damage and because pain is neural, it results in triggering irritation of specific neural pathways.

There is a fundamental fault with this theory regarding the denial of the emotional aspect of the pain experience, and considers only biological factors. Chemical blocking and surgical severing of nerve tracts oftentimes fail to eliminate pain. Additionally, the existence of pain in conditions with no apparent physiological bases cannot be

explained. For example, there is no way to account for the soldier who feels no pain from injuries until after an intense battle. There is an organic basis for pain; there is just no conscious awareness until the person has time to focus on it.

Pattern Theory

This theory suggests that the pattern of nerve endings determines sensation due to pain spots in the tissue which, through summation, produce nerve activation. The intensity and frequency of a stimulus (known as pattern of the stimulation) determine to what extent (if at all) it will consciously be perceived as painful. Each receptor does respond to many different types of stimulation, but that response is greater to some stimuli than others. Therefore, a receptor, which responds vigorously to touch, may still respond to a hot stimulus, but less vigorously, even less so to painful stimuli and very little to cold stimuli. Ultimately, the brain was thought able to interpret a code in terms of the relative strengths of the receptors' responses (Matlin, 1988). The weakness of this theory has to do with the fact the focus was on sensation, while ignoring the variables of the perception of pain.

Operant Behavior Model

Fordyce (1976) introduced this new mindset by describing the operant factors that occur in chronic pain. Central to this theory are behavioral manifestations rather than the sensation of pain. It suggests pain behavior, such as excessive rest, overuse of pain medications, verbal complaints, protective behaviors, limping and bracing, although initially useful in combating pain, may be positively reinforced by spouses and healthcare providers. The behavior may be maintained further by the avoidance of activity which may test the waters too much, putting the individual at risk of having the noxious stimulation return.

Well behaviors, such as exercise and work, may not be sufficiently reinforcing and the pain behaviors may, therefore, be maintained. The operant conditioning model focuses on overt manifestation of pain and suffering expressed as pain behaviors such as limping, moaning and avoiding activity. Emphasis is placed on the communicative function of these behaviors" (Turk & Gatchel, 1999). The psychological factors involved in the chronic pain patient are considered only reactions to painful stimuli, rather than affecting the perception directly.

Cognitive Behavior-Transactional Model/Stress–Diathesis Model

This more recent theory is heavily influenced by social learning and cognitive theories and the great importance the family or support system plays in the manifestation of a chronic pain condition. The major emphasis concerns the social context in general and the family context in particular. Just as in the Stress–Diathesis model, a framework exists in every individual, including the biological (CNS neurobiological), behavioral, cognitive, and affective domains, that results in coping techniques by the individual that may be positively or negatively reinforced by the family or support system. This is similar to the operant conditioning model regarding the importance of significant others, but the family is viewed as a more active participant in the evaluative response to the adequacy of coping strategies and the individual's ability to effectively meet the challenges of his or her given condition.

Schemas, described as relatively fixed beliefs about the world, develop in family systems. These have a significant effect in specific appraisals regarding the pain patient's condition, and may affect the individual's ability to deal effectively with the condition and help determine the level of adaptation. Past failure to deal effectively with one's condition can enhance the perceived threat of the condition, which could lead to interoceptive focus on the symptoms, heightening the level of perceived pain, and increasing disability and affective distress (Turk & Gatchel, 1996).

The cornerstone of the Stress–Diathesis model, as previously mentioned, includes biological, psychological, and social factors. Simply put, preexisting personality features place the individual at risk of maladaptive response to a painful condition. This places stress on the person, thus influencing the interrelationship between the neurobiological and psychological variables, which can lead to vulnerability. This vulnerability can result from the crossover of several domains, including cognitive perceptions of controllefficacy, affective depression which leads to anxiety and fear, behavioral declines in functional activity and, finally, family and social interactions that may significantly influence pain expression.

Stimulation-Produced Analgesia (SPA)

This is a pain modulation theory largely based on stimulation-produced analgesia through the production and utilization of endogenous opiates, such as endorphins and enkephalins, for the modulation of pain. The opioid peptides largely associated with pain are enkephalins, beta-endorphins, and dynorphins. It is thought SPA as well as opiate analgesia operate in part through descending control of spinal and trigeminal nociceptors (Basbaum, 1983). With discovery of these endogenous opiate-like substances, the scientifically based suggestion could be made that the brain itself can produce substances that can act to modulate the perception of pain.

Gate Control Theory and Three Dimensions of Pain

A multitude of different theories about pain and its processes has existed since antiquity. It was not until Melzack and Wall published their Gate Control Theory in 1965 that science could understand the pain process from the perspective of descending nerve pathways originating from higher regions and acting via the midbrain and medulla, affecting the perception of pain by inhibiting the transmission of signals through the substantia gelatinosa of the dorsal horn in the spinal cord.

They considered pain to have three dimensions: sensory-discriminative (thought to provide information regarding the nature of the noxious stimulus), motivational-affective (the reactive component of the process, with importance in both acute and chronic pain and mediated by polysynaptic afferent pathways thought to be interconnected between the brain stem reticular activating system and the limbic system), and cognitive-evaluative (the meaning of a given pain can profoundly alter its sensory experience) (Portenoy, 1996). It is these three areas that are the bases of the widely used McGill Pain questionnaire.

Physiologically, three variables control the gate. Aδ-fibers (sharp pain), are small fibers and travel at a slower conduction velocity than those of the Aβ-fibers. C fibers (dull pain) are unmyelinated afferent neurons, with slow conduction velocity. Both the C and Aδ-fibers tend to open the gate by obstructing or inhibiting the special gate neurons of the substantia gelatinosa. Finally, Aβ fibers (messages of light touch) are large fibers with much faster conduction velocities than the previous two.

It is theorized that besides the modulation of the pain signal by the stimulated Aβ-nerve fibers our conscious experience of pain intensity is affected not only by the magnitude of the pain stimulus but also by concentrations of chemical regulators, namely, the endogenous opiates in two major classes: enkephalins and endorphins (Coren, Ward, & Enns, 1999). Willer, Dehen, and Cambier (1981) found the effects of psychological stress when subjects anticipating painful shocks triggered the endogenous opiate system to protect the individual from the forthcoming pain. Similarly, it has been that found women have an increased pain tolerance in the last 2 weeks of pregnancy, presumably to ready them for the upcoming painful events (Cogan & Spinnato, 1986).

Neuromatrix

Neuromatrix as proposed by Ronald Melzack in the 1990s expounded upon the influential gate control theory. It considers pain a multidimensional experience characterized by the "body–self neuromatrix" in the brain, which are considered genetically (but modified by sensory experience) determined neurosignature patterns of nerve impulses. These patterns may be triggered with or without actual sensory inputs; therefore, providing an explanation for the mystery of the perception of pain sometimes present in individuals devoid of pathology or injury.

It proposes that the output patterns of the neuromatrix activate perceptual, homeostatic, and behavioral programs after injury or pathology or as a result of multiple other inputs that act on the neuromatrix (Melzack, 1999b). Pain then can be viewed as an output of an extensive neural network in the brain instead of as a much more complicated process than simple injury, inflammation, or other pathology. Stress is a major triggering factor in this theory, due to the complex processes required for the body to restore homeostasis. Chrousos (1992) defined stress as a state of threatened homeostasis, that is, a disruption by stressors of physiological processes such as blood sugar level and body temperature that are normally maintained at a fixed, delicately balanced set point. Therefore, a disruption of homeostasis due to a stressor (physical or psychological) activates programs of neural, hormonal, and behavioral activity.

Indeed, the neuromatrix theory considers five basic types of inputs that produce the unique neurosignature outputs. These include "(1) sensory inputs (cutaneous, visceral and other somatic receptors); (2) visual and other sensory inputs that influence the cognitive interpretation of the situation; (3) phasic and tonic cognitive and emotional inputs from others areas of the brain; (4) intrinsic neural inhibitory modulation inherent in all brain function; (5) the activity of the body's stress-regulation systems, including cytokines as well as the endocrine, autonomic, immune and opioid systems" (Melzack, 1999a).

PAIN THRESHOLD VS. PAIN TOLERANCE

There is no denying the subjectivity of pain. The response in given individual has is an intensely personal experience, and therefore, cannot be predicted with certainty. There are times when seemingly innocuous stimuli are perceived as excruciating, whereas quite severe injuries can produce almost no perceived sensation to the individual.

Obviously, this poses a great challenge to the healthcare professional during the assessment. It is important to be mindful of the inherent difference of pain threshold vs. pain tolerance. When considering pain and sensation as a process, there are many aspects, which are fairly consistent and reproducible from person to person, and from the same person over time. Pain threshold is scientifically based, quantifiable and reliable. It has been defined as the intensity of a stimulation at which a subject says, "It's painful" half the time and "It's not painful" half the time (Matlin, 1988). Threshold is variable across the body as evidenced by neurologists' two point discrimination test. More pain receptors means greater dis-

crimination of the presented stimulus, and a lower pain threshold.

The great challenge is that pain tolerance has so many variables and elements. Not only does it vary between individuals, but within the same individual at different times. What possible factors can account for the high variability in the tolerance of pain over time? Turk and Flor (1999) point out that an injury to the nociceptive transmission system or to the activity of the modulatory system can lower pain intensity. There may also be abnormal neural activity, which may produce hypersensitivity creating a self-sustaining process started by the original injury. Examples of such processes may be seen in phantom limb pain, neuropathic pain, or complex regional pain.

Finally, psychological factors may affect normal responses to pain, and yield quite variable and unpredictable responses. One of the most important factors when considering the tolerance and general perception of pain is the *meaning* of the pain to the sufferer. Needless to say, a painful condition associated with a minor injury or temporary illness will likely be a much different experience than similar pain levels associated with more severe life-altering conditions.

CONCLUSION

There is considerable evidence that the expression of pain follows social modeling, cultural expectations, and religious beliefs. Stoicism, hysteria, athletic endurance, and numerous other designations of discomfort accompany lifestyles and life expectations. It has been observed that wealthy persons expect to be able to "buy relief" from pain, and that athletes view pain as the only way to gain. Winners in athletic endeavors often express the pain of overexertion or injury differently if they win or lose the contest. The pain from muscular irritation and other physical states resulting from "practice" becomes dissociated a part of their experience. Religious persons have been known to welcome pain as a believed prelude to rewards in the after life. Pain is not universally perceived the same, expressed the same, nor is it treated the same. For these and myriad other reasons, pain continues to be our most illusive encounter with human existence.

Screening for Alcohol and Other Substance Use Disorders*

Nick J. Piazza, Ph.D.

Alcohol and other drug use are primarily or secondarily implicated in a large number of medical problems, including pain (Kitchens, 1994). Undetected and untreated alcohol or other substance use disorders can have a significant effect on a patient's response to treatment as well as treatment compliance. Adger and Werner (1994) stated that healthcare professionals "should screen all patients for [substance] use and determine the need for further assessment and intervention." Failure to at least screen for a substance use problem could lead to misdiagnosis, and failure to provide the patient with the most appropriate care.

Adger and Werner state that the goal of screening is to determine the likelihood that a problem exists and whether further assessment is needed. They believe that all patients should undergo screening for alcohol or other drug problems. If a screen is positive, then the Health Care Provider (HCP) should refer the patient for a detailed substance use assessment, and initiate prevention or treatment measures where appropriate.

Assessment is a lengthier, more involved process usually conducted by personnel specifically trained in substance use disorders. The purpose of assessment is to "determine the extent of the problem, explore coexisting medical and psychiatric conditions, and assist in treatment planning" (Adger & Werner, 1994). Most HCPs feel competent to screen for a substance use disorder; however, they may prefer to refer the patient to a specialist for assessment.

CHARACTERISTICS OF A GOOD SCREEN

There are a number of characteristics that help determine whether a screening procedure is of value. The most important characteristics are sensitivity, specificity, validity, reliability, and cost-efficiency.

Sensitivity and Specificity

Sensitivity refers to the proportion of individuals correctly identified as positive for a particular condition or disorder. In this case, sensitivity would refer to the percent of individuals correctly identified by a particular screen as having a substance use disorder. A screen with good sensitivity is important because it can tell us who needs to be referred for a more complete evaluation, who may not respond to medications or therapies as expected, or who may be malingering or drug-seeking.

Specificity refers to the proportion of individuals correctly identified as negative or as not having a substance use disorder. The value of a highly specific screen is that it can tell us who is least likely to have a substance use disorder. A screen with good specificity can tell us when it is unnecessary to expend valuable time or resources evaluating patients for a condition they most likely do not have.

Salaspuro (1994) noted that a good screen should not overidentify individuals as having a problem (i.e., false positives) nor should it overidentify individuals as being problem-free (i.e., false negatives). A high false-positive

* Portions of this chapter were excerpted from Piazza, N.J., Martin, N., & Dildine, R. (2000). Screening instruments for alcohol and other drug problems. *Journal of Mental Health Counseling, 22*, 218–227. With permission.

0-8493-0926-3/02/$0.00+$1.50

rate would mean that valuable time and resources were expended on individuals who, in fact, did not have a substance use disorder, while a high false negative rate means that individuals went untreated because they were not detected by screening.

Validity and Reliability

Validity refers to a screening instrument's ability to measure what it purports to measure. Valid screening procedures for substance use disorders should accurately discriminate true positives and true negatives from false positives and false negatives. A number of threats to validity exist including standardization on a too small sample, using a screen on individuals who were not part of the standardization group, using a screen for purposes other than those for which it was developed. A perfectly valid instrument would achieve a value of 1.0. Screening instruments for substance use disorders can range from lows of about 0.4 to highs of 0.9 or better.

Reliability refers to the consistency with which an instrument measures the variable or condition of interest. A reliable screen will yield consistent results across individuals and, more importantly, across time. Conversely, an unreliable instrument yields different results each time it is administered. Technically, it is not possible to have an unreliable screening procedure that is valid. Validity is dependent on the stability of the results obtained.

As with validity, reliable screens should approach a value of 1.0. Most screening instruments report test–retest reliability because this measures the stability of results over repeated administrations of the procedure. Questionnaire-based screens often will report internal consistency or alpha reliability. High internal consistency or alpha values mean that the items on the questionnaire are highly intercorrelated and most likely measure the same variable or condition.

Cost-Efficiency

Cost-efficiency implies that the benefits of using the screening procedure are greater than the costs. Using an inexpensive but poorly constructed screen with low sensitivity and specificity may prove to be more costly over time because resources are wasted on false positives and false-negative patients go undetected and untreated. In addition, screening all persons in a population for a low prevalence disorder may add considerable cost to treatment while benefiting only a few individuals.

LABORATORY OR BIOLOGICAL SCREENING PROCEDURES

Laboratory Tests

Laboratory tests, especially liver enzyme tests, have long been used as a means to screen for potential alcohol abuse. Fleming (1993) identified four useful laboratory measures. These include measuring levels of gamma-glutamyl transferase (GGT), mean corpuscular volume (MCV), alanine aminotransferase (ALT), and aspartate aminotransferase (AST). Fleming (1993, p. 231) selected these tests because they "measured direct hepatic and hematopoietic cellular alcohol toxicity." Fleming notes that the sensitivity of these screens ranges from 20 to 90%, with GGT levels the most sensitive of the four measures.

O'Connor and Schottenfeld (1998) recommend testing for carbohydrate-deficient transferrin in addition to the measures listed above. They report that carbohydrate-deficient transferrin levels have a "sensitivity of 58 percent to 70 percent and a specificity of 82 percent to 98 percent for the detection of heavy drinking or alcohol abuse" (O'Connor & Schottenfeld, 1998).

Blood-Alcohol Concentration (BAC)

BAC is a measure of the percent of alcohol concentrated in a volume of blood. The BAC is sometimes alternatively referred to as the blood-alcohol level or BAL. The procedure involves drawing a sample of blood and analyzing the sample to determine how much alcohol is present. Persons with a BAC of 0.1% or higher are considered too intoxicated to drive in 34 states, the District of Columbia, and Puerto Rico; 16 states and all the provinces in Canada have set their legal intoxication limit at 0.8% (Harley Owners Group, 2000). The validity and reliability for this test are sufficiently high that BAC is accepted as evidentiary of intoxication in a court of law. It has been the author's experience that any BAC over 0.15% in an adult is suggestive of alcohol abuse or dependence, while a BAC of 0.2% is almost always associated with alcohol dependence.

Urinalysis

Many drugs are broken down or metabolized in the liver. The by-products of liver metabolism are called metabolites. The kidneys filter these metabolites from the blood supply, and then dump them in the urine where they are expelled during urination. It is possible to determine whether a patient has recently ingested a drug by examining the urine for the presence of these metabolites. This procedure is commonly known as urinalysis.

Urinalysis actually consists of two tests. The first test is known as the enzyme multiplied immunoassay technique or EMIT. The strength of an EMIT is its specificity. A negative EMIT fairly conclusively indicates that the patient's urine is relatively free of drug metabolites. An EMIT's sensitivity, however, is sufficiently poor that a significant proportion of individuals will be false positives. Consequently, it is necessary to run a second measure—a gas chromatography/mass spectrometry (GC/MS)—to confirm the results of the EMIT. GC/MS accuracy approaches 100% and is considered evidentiary in courts

of law. It is possible that a patient may test positive on urinalysis because he or she is taking a legitimately prescribed medication (e.g., meperidine [Demerol®]). These individuals should be considered false positives, and many urinalysis laboratories employ Medical Review Officers (MROs) to eliminate these cases.

Other Biological Screens

Procedures have been developed to test a patient's hair, breath, sweat, and saliva for the presence of alcohol, drugs, or their metabolites. The best known is probably the Breath-a-lyzer® test, which provides a highly accurate estimate of BAC. Instruments that look like a child's sucker change color when exposed to saliva containing traces of drugs. Finally, hair analysis can determine if an individual has used drugs any time in the weeks or months prior to testing. Obviously, the longer the individual's hair, the farther back in time detection will be possible.

ADVANTAGES AND DISADVANTAGES OF LABORATORY OR BIOLOGICAL SCREENS

Advantages

Biological and laboratory screens are most useful and most valid for those situations where evidence of substance use or impairment is required. Urinalysis, especially when combined with a GC/MS and an MRO, has an especially high sensitivity rate with almost no false positives. Because of the high sensitivity combined with a low false-positive rate, urinalysis is most often employed in situations where it is important to determine if an individual is drug-free. Examples of such situations include following an accident or injury in the workplace; compliance with drug-free workplace policies; fitness for work determinations; and compliance with the terms of abstinence-based treatment programs, probation, or parole.

Disadvantages

A number of limitations exist to using biological screens to determine who may or may not have a substance use disorder. The principle disadvantage is that individuals need only abstain for a few days to test negative on urinalysis. Conversely, some procedures such as hair analysis will yield positive results weeks or even months after use has stopped. Liver enzyme tests often have high false-negative rates for young, healthy, or early stage users who do not have a many-year history of heavy or abusive drinking. Laboratory procedures also can be expensive and time consuming. Finally, laboratory and biological screens cannot differentiate legitimate users from recreational or problem users. All a biological screen can tell the HCP is that the individual has recently used; biological screens cannot determine why the drug is present or the nature of the use. This led Fleming (1993) to recommend that laboratory testing be limited to assessing toxicity, while questionnaires and patient reports were more valid for differentiating problem from nonproblem users.

PSYCHOSOCIAL SCREENING INSTRUMENTS

Piazza, Martin, and Dildine (2000) noted that psychosocial screening instruments for detecting substance use disorders fall into one of two categories. The first category consists of so-called logically derived instruments. Logically derived screens typically have good content or face validity in that the items obviously measure substance use-related behaviors and problems. The greatest asset of logically derived screens is that a positive result is a strong indication that a problem is present. The greatest liability for logically derived screens is that the items are so obvious that anyone motivated to deny or conceal a problem can easily "fake good." In fact, it can be said that logically derived screens are best at detecting those individuals who wish to be identified. Despite this inherent weakness, however, O'Connor and Schottenfeld (1998) noted that self-reported information regarding substance use is "reliable and reproducible."

A second category described by Piazza et al. (2000) is comprised of what are known as empirically derived instruments. Empirically derived instruments use research and statistical analysis to identify items that can discriminate individuals with substance use disorders from individuals who are problem-free. Generally, the content of the item is unimportant. What is important is that the item correctly identifies who is a member of the criterion group (i.e., that group of individuals with a substance use disorder). Items on empirically derived screens often have poor content or face validity; however, they should have good to excellent predictive or criterion validity. Empirically derived screens appear to be best at identifying individuals who are motivated to deny or minimize a substance use disorder because item content appears unrelated to substance use. Unfortunately, because most empirically derived screens do not ask questions related to substance use, they frequently do not give any indication of the severity or extent of a drinking or other drug problem.

Michigan Alcoholism Screening Test (MAST)

The MAST was originally developed by Selzer (1971) and consists of 24 face valid items. Pokorny, Miller, and Kaplan (1972) and Selzer, Vinokur, and van Rooijen (1975) later developed abbreviated versions of the

questionnaire with 13 items each. The most discriminating items are

1. Have you ever attended a meeting of AA?
2. Have you ever sought help about your drinking?
3. Have you ever been in a hospital because of your drinking?

Items are scored 1, 2, or 5 points according to their diagnostic utility. The MAST is designed to assign respondents into one of three categories: no drinking problem (score of 0 to 3), possible problem (score of 4 to 6), and alcohol dependent (score of 7 or higher).

The MAST is one of the best known and most widely used logically derived screens. Its wide acceptance and use, however, are inconsistent with the problems associated with the instrument. Selzer (1971) acknowledged that because the items are so obvious, alcoholics wishing to avoid detection could easily do so. To correct for this, Selzer set the cutoff scores lower to improve sensitivity. This resulted in a false-positive rate of about 33% and lowered the overall accuracy rate to about 75% (Jacobson, 1983; Creager, 1989). Correlations between MAST results and counselor diagnoses reveal a concurrent validity of r = .65 (Mischke and Venneri, 1987). Finally, the MAST only assesses for alcoholism and cannot discriminate between alcohol abuse and problems with other drugs.

The MAST's applicability to women and minorities is also questionable. Jacobson (1983) reports that there is little information on female norms, and nothing in the literature addressing minority norms.

The high false-positive rate and low overall accuracy led Popkin, Kannenberg, Lacey, and Waller (1988) to conclude that the MAST "may be useful in detecting persons who acknowledge having an alcohol problem." Russell (1994, p. 58) described the MAST as lengthy, difficult to score, and "impractical for clinical use."

Self-Administered Michigan Alcoholism Screening Test (SAAST)

This is a modified version of the MAST that has been developed for self-administration. The SAAST is a 35-item questionnaire that correlates highly (r = .83) with the MAST. Davis, Hurt, Morse, and Brien (1987) reported that the SAAST correctly identified 92.1% of 520 alcoholic participants and only incorrectly classified 1.3% of 636 controls. It was not clear in the Davis, et al. study, however, whether the alcoholic group contained individuals who were attempting to deny a problem on the instrument. A 92.1% accuracy rate should not be surprising in a group of alcoholics who are being open and honest about their drinking experiences. A final concern is that like the MAST questions on the SAAST are specific to alcohol and do not address problems with other drugs.

CAGE, T-ACE, AND TWEAK

These three logically derived instruments were developed as brief screens that could be administered orally during a clinical interview. All three are very similar and share many of the same strengths and weaknesses. The CAGE was specifically developed for use by primary care physicians. Kitchens (1994) noted, however, that the CAGE had not been standardized for use with pregnant women. The T-ACE and the TWEAK are variations of the CAGE that were specifically developed to "ascertain drinking in pregnant women" (Nilssen & Cone, 1994).

The CAGE

Nilssen and Cone (1994) report that the CAGE is probably the "most widely used test in clinical practice." It consists of four items, answered with either yes or no:

1. Have you ever felt you should Cut down on your drinking?
2. Have people Annoyed you by criticizing your drinking?
3. Have you ever felt bad or Guilty about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (Eye opener)?

Two or more yes answers are interpreted as a positive screen, suggesting the need for further assessment. The principle advantages of the CAGE are that it is easy to remember, easy to administer during a clinical interview, and takes only about a minute to complete. The reported accuracy rates of the CAGE are quite variable, ranging anywhere from 40 to 95% (Sokol, Martier, & Ager, 1989). O'Connor and Schottenfeld (1998) reported that lifetime sensitivity for patients with an alcohol problem ranges from 60 to 95%.

Despite its advantages, a number of problems have been associated with using the CAGE. Nilssen and Cone (1994) noted that the CAGE is specific to alcoholism and does not assess for problems with drug use. They also note that the CAGE assesses lifetime use instead of focusing on current drinking history. Fleming (1993) reports that the CAGE's lifetime approach results in a false-positive rate of over 50%. Kitchens (1994) pointed out that while the CAGE is "reasonably accurate at identifying those individuals who are alcohol dependent or heavy drinkers," the CAGE is "not at all sensitive to detecting the lower levels of consumption that may be dangerous." In addition,

the items on the CAGE are very obvious and can be easily denied by someone motivated to do so.

The T-ACE

The T-ACE is similar to the CAGE, except that it drops the CAGE question on guilt and replaces it with a question on alcohol tolerance (Sokol, et al., 1989). Russell (1994) reported finding sensitivity and specificity rates for the T-ACE of about 79%. Russell stated that the T-ACE performed about the same as the MAST and slightly better than the CAGE with a sample of pregnant women. Despite the improvement in performance, the T-ACE still suffers from the same limitations as the CAGE, i.e., specificity to alcohol, lifetime focus, inability to detect early stage problems, and easy deniability. Another problem is that it has only been standardized on pregnant women and not on the general population.

The TWEAK

The TWEAK "combines questions from the MAST, CAGE, and T-ACE tests that have been found most effective" (see Table 66.1) (Russell, 1994). Russell reports that the TWEAK is superior to the CAGE or the MAST and equivalent to the T-ACE when used with pregnant women. Because the TWEAK is a derivative of the MAST, CAGE, and T-ACE, it shares the same liabilities as these instruments. In addition, the TWEAK is more complicated to score.

THE ALCOHOL USE DISORDERS IDENTIFICATION TEST (AUDIT)

The AUDIT was developed under the auspices of the World Health Organization (WHO) to serve as a multicultural screening instrument (Babor & Grant, 1989). The AUDIT "was specifically designed to be used in primary care settings to screen for alcohol problems at earlier stages" (Nilssen & Cone, 1994). The developers intended for the AUDIT to be used to identify harmful drinking rather than alcohol use disorders. However, Russell (1994) believes that the AUDIT "also can detect alcohol disorders with a high degree of accuracy."

The AUDIT is a logically derived, paper-and-pencil screen consisting of ten items. The items relate to three areas of harmful drinking: (a) amount and frequency of alcohol consumption, (b) dependency symptoms, and (c) harmful effects. Items are scored on a scale from 0 to 4, with a maximum possible score of 40. A score of 8 or higher is positive for harmful drinking. Russell (1994) claims the AUDIT has a sensitivity rate of 92% and a specificity rate of 93% for identifying harmful drinking. Isaacson, Butler, Zacharek, and Tzelepis (1994) reported sensitivity and specificity rates of 96% for patients in a general medical clinic. The AUDIT would appear to be a very strong instrument for identifying harmful or at-risk drinkers within a multicultural population.

Substance Abuse Life Circumstances Evaluation (SALCE)

The SALCE was developed to use with people arrested for driving under the influence (DUI). The intended use for the SALCE is to differentiate those individuals needing to alter their use of alcohol or other drugs from individuals who may have a more serious substance use disorder. Popkin, et al. (1988) report that the SALCE "was not designed to differentiate alcoholics from nonalcoholics." The SALCE is a logically derived screen consisting of an 85-item questionnaire that is to be used in conjunction with a 20-minute interview. Total screening time is estimated to be approximately 40 minutes.

Applicability of the SALCE is probably limited to use with DUI offenders as it has never been standardized on other populations. Internal consistency reliability for the SALCE is reported to be r = .93; no test–retest reliability

TABLE 66.1
Tweak

T	Tolerance: How many drinks can you hold?
W	Have close friends or relatives worried or complained about your drinking in the past year?
E	Eye-opener: Do you sometimes take a drink in the morning when you first get up?
A	Amnesia: Has a friend or family member ever told you about things you said or did while you were drinking that you could not remember?
K(C)	Do you sometimes feel the need to cut down on your drinking?

The TWEAK uses a 7-point scale. The Tolerance item scores 2 points if the respondent reports she can consume five or more drinks without falling asleep or becoming unconscious. A positive response to the Worry item scores 2 points. Positive responses to the remaining items are scored 1 point each. A total of 2 or more points indicates a positive screen. (Adapted by permission from Russell, M. (1994). Alcohol Health and Research World, 18, 55–61.)

was reported (Popkin, et al., 1988). Popkin, et al. (1988) report a 61% agreement rate between the SALCE and assessment based on professional interviews.

Popkin, et al. (1988) noted that the SALCE "appears to be reasonably well constructed, includes a measure of response bias (truthfulness), and has the automated capability for updating norms specific to DUI offenders." Popkin, et al. (1988) felt the SALCE had considerable potential for use in DUI programs. They did note, however, that no independently published evaluations of the SALCE exist and that the publishers consider their data to be proprietary and not available for independent evaluation.

The MacAndrew Scale

The MacAndrew Scale (MAC) and the MacAndrew Scale-Revised (MAC-R) consist of 49 true/false items embedded in the Minnesota Multiphasic Personality Inventory (MMPI) and the Minnesota Multiphasic Personality Inventory-2 (MMPI-2), respectively. Greene (1991) wrote that the MAC scale was originally developed to differentiate alcoholic outpatients from nonalcoholic psychiatric outpatients. The MAC and MAC-R are empirically derived scales designed to be indirect measures of alcoholism, because neither version of the scales contains any questions obviously related to actual alcohol consumption or alcohol-related problems.

Butcher, Dahlstrom, Graham, Tellegen, and Kaemmer (1989) stated that "raw scores of 28 or above strongly suggest substance abuse. Scores between 24 and 27 are somewhat suggestive of substance abuse, … [and] scores below 24 contraindicate a substance-abuse problem." Graham (1990) also noted that drug addicts and alcoholics obtained similar scores on the MAC.

Reliability and validity are problems for both the MAC and the MAC-R. Graham (1990) observed that "No internal consistency data were reported for the original MAC scale, but the MAC-R scale does not seem to have particularly good internal consistency." Butcher, et al. (1989) reported coefficient alphas of .56 for males and .45 for females. One week test–retest reliability coefficients for the MAC-R were .62 for males and .78 for females (Graham, 1990). Sensitivity rates for white males ranged around 80%, with false positive rates approximating 20% (Greene, 1991). Accuracy rates for the MAC and the MAC-R scales for adolescents, women, and minorities can be much poorer. Greene (1991) reported that true positive and false positive rates for African-American males were both nearly 60%, while true positive rates for white adolescents and women "ranged around 75%, with approximately 35% false positives."

Another validity problem common to both the MAC and the MAC-R is that the scales are not independent of other personality characteristics or psychopathology. Butcher, et al. (1989) noted that high scores on these scales "are suggestive of persons who are socially extroverted [sic], exhibitionistic, and willing to take risks." There is no mechanism for determining if a high score has been produced by a respondent's substance use or these confounding personality and behavioral variables.

Greene (1991), Butcher et al. (1989), and Graham (1990) all state that validity, reliability, and accuracy problems preclude using the MAC and the MAC-R to diagnose substance-related disorders. Graham (1990) stated that an elevated MAC-R score is only indicative of the "possibility of substance abuse," while Butcher, et al. (1989) believed that high scores are "associated with addiction-proneness rather than with alcoholic tendencies alone." Greene (1991) went so far as to suggest that professionals might want to "avoid using the MAC scale to predict whether a client will abuse substances, which has been the standard use of the MAC scale since it was first developed."

Substance Abuse Subtle Screening Inventory (SASSI)

The SASSI has gone through two revisions since its release in 1985 (Miller, 1985). The current version is referred to as the SASSI-3 (Miller, Roberts, Brooks, & Lazowski, 1997). The SASSI-3 actually consists of two separate screens: one logically derived, the other empirically derived. The logically derived portion is comprised of 26 face valid items formerly known as the Risk Prediction Scales (RPS). Items on the RPS are scored on a scale from 0 to 3. The second portion is made up of 67 true/false empirically derived items. The 93 items of the SASSI-3 are divided into five clinical subscales, two defensiveness subscales, one validity scale, and two supplementary scales. The SASSI-3 is written on a sixth-grade reading level and takes 15 to 20 minutes to complete. Hand scoring takes an additional 5 to 10 minutes.

The SASSI-3 is interpreted using decision rules for a configural analysis of the scores on the different subscales. The publisher claims a 93.8% correspondence rate between the SASSI-3 and a professional diagnosis, with a sensitivity rate of 94.1% and a specificity rate of 92.7% (F. Miller, personal communication, May, 1997). A separate study (Piazza, 1996) found that the adolescent version of the SASSI had similar accuracy rates. A plus for the SASSI-3 is that accuracy rates are about the same whether respondents are being honest about their substance use or are attempting to deny or conceal a problem. Additionally, the norm sample of 2800 individuals was comprised of about 30% African- and Native-Americans. This means that the SASSI-3 should be valid for these groups.

Reliability coefficients are equally impressive. Test–retest reliability coefficients for the clinical and defensiveness scales ranged from .92 to 1.00, while the

Cronbach alpha coefficient for the overall SASSI-3 was 0.94 (F. Miller, personal communication, May, 1997).

The SASSI-3 appears to be a compact and efficient marriage of the advantages to the two types of screens. Persons who are motivated to provide an honest report of their alcohol and drug use can reveal this on the Risk Prediction Scales. These data can be very useful in assessing the severity of a substance use disorder and for treatment planning. Persons who are in denial or who are deliberately being deceptive are typically identified through a configural analysis of the clinical and defensiveness scales. While information on the severity of the problem is lost, the SASSI can provide information on the degree of denial or defensiveness exhibited by the examinee.

DISCUSSION

Logically and empirically derived screens each have their own strengths and limitations. Choosing a screen involves trading off between ease of administration and accuracy. Selecting a screen should be based on the provider's needs, patient factors, and the circumstances under which the screen is to be used.

Logically derived screens seem to be best employed in situations where the motivation to provide an honest self-report is high. Typically, this means a situation where the patient is well known to the provider and a good working relationship exists. A positive relationship can lower defensiveness and denial, which should lead to a more honest self-appraisal. When these conditions are met, using an instrument like the CAGE, T-ACE, TWEAK, or AUDIT can be productive. All four of these screens are brief and easily administered, scored, and interpreted. It should be noted, however, that denial is a defining characteristic of alcohol and other drug use disorders. The motivation to deny or minimize a substance-related disorder may be strong even in the presence of a positive relationship.

Empirically derived screens should probably be employed in situations where the client is unknown to the provider, where there is a diverse client population, or where clients are likely to be motivated to conceal their problems. Generally, this would include situations such as intake, diagnostic, or evaluative interviews where clients may be motivated to present themselves in the most favorable light. It is probably best to use the SASSI 3, or a comparable instrument, in these circumstances. Using the SASSI-3 should yield valid and reliable results even if the examinee is trying to defeat the screen. The disadvantage to using any of the empirically derived screens, however, is they are more complicated to administer, score, and interpret. In fact, we would recommend completing the 3- to 4-hour training program before attempting to use the SASSI-3. The advantage of improved accuracy, however, would appear to make the cost of additional training well worth it.

Interactive Guided Imagery in Treating Chronic Pain

David E. Bresler, Ph.D., L.Ac. and Martin L. Rossman, M.D.

Chronic pain has become the Western world's most expensive, disabling, and common disorder. It is estimated that 8 to 10% of the population of most Western countries suffer from chronic headaches. Arthritis afflicts over 50 million Americans, of whom 20 million require medical care. Low back pain generates nearly 20 million doctor visits per year and has disabled 7 million Americans (National Center for Health Statistics). Add facial and dental pain, neuralgia, cancer pain, chronic neck and shoulder pain, fibromyalgia, and other common pain syndromes, and it's easy to understand why chronic pain is estimated to cost the nation's economy $60 billion dollars per year. The cost in human suffering is incalculable.

Our focus in this chapter is on the uses of a particular form of mental imagery, called Interactive Guided Imagery, to relieve chronic pain, increase pain tolerance, reduce the emotional toll and amplification of pain, and relieve suffering. In the past 30 years of treating patients with chronic pain and other chronic illnesses, we have found Interactive Guided Imagery to be unusually effective in relieving symptoms, enhancing tolerance, relieving feelings of hopelessness and helplessness, promoting healing, and increasing functional abilities in our patients.

WHAT IS INTERACTIVE GUIDED IMAGERY?

Mental images, formed long before we learn to understand and use words, lie at the core of who we think we are, what we believe the world is like, what we feel we deserve, and how motivated we are to take care of ourselves. They strongly influence our beliefs and attitudes about how we fall ill, what will help us get better, and whether or not any medical and/or psychological interventions will be effective.

Imagery has powerful physiological consequences that are directly related to the healing systems of the body. Research on the omnipresent placebo effect, the standard to which we compare all other modalities (and find relatively few more powerful), has provided some of the strongest evidence for the power of the imagination and positive expectant faith in healing. It is well documented that 30 to 55% of all patients given inactive placebos respond as well or better than those given active treatments or agents (Frank, 1974).

If people can derive not only symptomatic relief, but actual physiologic healing in response to treatments that primarily work through beliefs and attitudes about an imagined reality, then learning how to better mobilize and amplify this phenomenon in a purposeful, conscious way becomes an important, if not critical, area of investigation for modern medicine.

In addition to its potential for stimulating physical healing, imagery provides a powerful window of insight into unconscious processes, rapidly and graphically revealing underlying psychological dynamics that may support either health or illness. To the clinician, this "window" is invaluable for quickly identifying opportunities for positive change, manifestations of resistance to change, and ways to work effectively with both.

Guided imagery is a term variously used to describe a range of techniques from simple visualization and direct

0-8493-0926-3/02/$0.00+$1.50

imagery-based suggestion, through metaphor and story-telling. Guided imagery is used to help teach psychophysiologic relaxation, to relieve symptoms, to stimulate healing responses in the body, and to enhance tolerance to procedures and treatments.

Interactive Guided Imagery (IGI) is a service-marked term coined by the Academy for Guided Imagery to represent its highly interactive, nonjudgmental, content-free style of using guided imagery to evoke patient autonomy. This approach allows patients to draw upon their own inner resources to support healing, to choose the most appropriate adaptations to changes in health, and to find creative solutions to challenges that they previously thought were insoluble. IGI is particularly useful in our current healthcare climate, where cost-effective mind/body medicine, improved medical self-care, and briefer yet more empowering approaches to healthcare are becoming more highly valued by patients, providers, and insurers alike.

Before explaining the principles and practices of IGI, let's briefly examine some of the unique aspects of chronic pain that demonstrate why a sophisticated mind/body approach that utilizes techniques such as IGI is critical to long-term success.

CHRONIC PAIN DEMANDS DIFFERENT TREATMENT THAN ACUTE PAIN

Modern technology has created a huge variety of pharmaceutical products for pain relief, many of which are available over the counter. For acute or self-limiting pain, these agents are usually highly effective, for they provide temporary relief while the body heals itself. With the development of neural blockade and other modern anesthetic techniques, patients who undergo operative or other invasive procedures are generally spared all but the slightest degree of pre- or post-surgical discomfort.

Yet, the pharmacological approaches that have proven so successful in the management of acute pain are often ineffective or even counter-intentional for controlling chronic or long-term pain. Although acute pain usually gets better by itself as the body heals, chronic pain typically becomes worse with time. As a rough rule of thumb, chronic pain refers to any pain problem that lasts longer than 6 months. Victims are referred endlessly from doctor to doctor, for even if temporary relief can be obtained, the pain inevitably returns.

For example, when analgesic medications are used over a prolonged period of time, pharmacologic tolerance begins to develop and effectiveness is progressively reduced. As tolerance develops, patients typically increase their dosages with the idea that "a little is good, a lot will be even better." Unfortunately, higher dosages only produce greater amounts of side effects, for tolerance continues to develop. In addition, most of the more effective analgesic agents also carry a high risk of dependency.

As a result, it is common to find patients with chronic pain taking large amounts of ineffective medications that produce significant side effects, many of which even contribute to the pain experience. When patients or their doctors attempt to reduce these medications, withdrawal symptoms make pain even less tolerable, and they return in desperation to their former regimes.

When medications fail, patients are often told, "Nothing more can be done. You'll have to learn to live with it." But in our opinion, there is always hope for someone in pain. Until every therapeutic approach has been attempted, no one should ever be told, "Nothing more can be done."

This statement has two iatrogenic implications: First, it destroys the most significant healing asset that victims of chronic pain (or other chronic illnesses) possess, namely, hope or positive expectant faith. Second, it conveys the subtle message that if you "have to learn to live with it," the only time you won't have it is when you are no longer alive. This may add to the significant suicidal ideation already experienced by many people in chronic pain.

The way we communicate with patients in pain has important effects and implications. As we discuss below, such negative communications may actually retard the body's intrinsic healing abilities, while more positive, imagery-based suggestions may enable patients to unlock the door to the most potent and varied pharmacy yet discovered — the one in our own brain.

THE IMPORTANCE OF THE PAIN EXPERIENCE

One of the greatest challenges in researching and treating chronic pain is to resolve ambiguity in the terms and concepts we use to describe it. For example, it is helpful to distinguish between a pain *sensation* (mental awareness of an unpleasant stimulus) and the pain *experience* (the total subjective experience of pain). Furthermore, it is important to recognize that there is not necessarily any direct relationship between the sensation and experience of pain.

This is seen in a study reported by Beecher, who found that soldiers seriously wounded in battle reported only mild discomfort compared to civilians with similar injuries because they were elated to learn that the war was over for them and they were to be sent home. In contrast, patients with phantom limb pain often report agonizing discomfort even though the entire stump has been anesthetized.

Many individuals think of pain primarily as a tangible thing, much like a splinter is a thing, that is, an object or substance from outside that infiltrates the body. Thus, if you accidentally strike your thumb with a hammer, you

might say that you "feel pain in your thumb that is radiating to your hand".

Such a notion is totally inaccurate, for there is no pain "in" your thumb, any more than there is pleasure "in" your mouth when you eat something that tastes good. You probably wouldn't say, "Umm. My mouth is full of pleasure that is radiating to my stomach".

When you injure your thumb, you stimulate neural receptors that send a barrage of electrical and chemical messages up through the nerves in your hand and arm to your spinal cord and brain. Whether or not a given sensation becomes "painful" depends upon the way it is interpreted by the nervous system. If you've ever scratched an itch really hard, you know that sometimes it's hard to tell if something hurts or feels good. If, for all sorts of reasons, the nervous system decides that the messages from the thumb are urgent and require immediate action, it creates an experience of pain that is identified with the thumb so that you'll give it proper attention. However, it is important to note that the main pain receptor is between the ears, and that's where pain resides.

Like many perceptions, pain is well known to be influenced by learning and early developmental predispositions. For example, animals raised in a pain-free environment show insensitivity to noxious stimuli in later life. Social, cultural, and ethnic differences in the experience of pain also are well documented. A vivid example is the elective initiation rituals of many primitive tribes, which would be considered nothing short of torture if practiced by members of Western cultures.

Aristotle was the first to suggest that "pain is an emotion", as pervasive as anger, terror, or joy. The emotional component of pain is inexorably bound to other aspects of the pain experience, for anxiety and agitation are the natural consequences of a painful sensation that tells higher cognitive centers that something is wrong. If the "something" can be clearly identified and appropriate corrective action can be taken, the (acute) pain experience is terminated.

However, for most patients with chronic pain, the "something" is vague, and fear of continued pain in an unknown future produces even greater anxiety. On a physiologic level, sympathetic hyperactivity develops, as manifested by increased heart rate, blood pressure, respiration, palmar sweating, and muscle tension. In patients with musculoskeletal pain, this increased muscle tension often augments the sensation of pain, which further increases anxiety, which, in turn, produces even greater muscular tension and more pain. The amplifying relationship between pain and anxiety is well known to clinicians, for treatment of one frequently provides relief of the other as well.

Over time, exhaustion of sympathetic hyperactivity is inevitable, and more vegetative signs and symptoms soon emerge, such as feelings of helplessness, hopelessness, and despair, sleep and appetite disturbances, irritability, decreased interests and libido, erosion of personal relationships with family and friends, as well as increased somatization of complaints. Thus, acute pain and anxiety become chronic pain and depression.

It is well known that the most notable emotional change in patients with chronic pain is the development of depression. This may be overt or masked to both patient and health practitioner. In a sense, depression can be considered a type of emotional pain, and when it is effectively treated, the chronic pain experience is also often relieved.

It is important to emphasize the psychophysiological basis of chronic pain, for it is a complex subjective experience that involves physical, perceptual, cognitive, emotional, and spiritual factors. When a patient with low back pain complains that "my back hurts", his/her pain experience also may involve anxiety or depression (producing insomnia, loss of appetite, and decreased sexual desire), drug dependence or addiction, separation from work, family, and friends, loss of avocational interests and hobbies, numerous secondary gains, and a host of other problems. These may remain indelibly associated with the experience of back pain, even after the entire spine has been chemically anesthetized.

Thus, it is easy to see why no simple pill or shot can cure chronic pain. The most common error made by clinicians is to evaluate and treat only the physical aspect of the problem, for they assume that the objective of therapy is to treat pain in people. To us, however, the objective of therapy is to treat people in pain, which takes a much broader perspective. From this point of view, it is nonsensical to wonder if a patient has real vs. unreal pain, organic vs. psychologic pain, or legitimate vs. hysterical pain. Pain is an intensely subjective and personal experience, and even if no physical explanation for it can be found, pain is real and

PAIN VS. SUFFERING

In our culture, pain is usually considered an enemy to be fought and overcome, and our first approach is to search for a pain killer. This approach overlooks and ignores the survival value of pain, which can be a warning signal, a protector, a potential teacher, guide, motivator, or even an incentive for change. While some believe that chronic pain is a symptom that has lost its meaning, this is the result of our healthcare system's tendency to medicalize and externalize symptoms rather than to examine their meaning in a holistic context.

Whatever the cause, when one cannot tolerate or cope effectively with pain, he or she suffers, which is manifested as an inability to sleep, eat, work, or fully enjoy one's life. Life, in the most personal, meaningful sense, stops. As we discuss below, suffering is primarily an epiphenomenon of one's attitude and beliefs, and we are convinced that it is

possible to have pain, and yet not suffer, depending upon how we relate to the pain we experience.

In the more traditional psychological literature, a distinction is often made between pain sensitivity and pain tolerance. To illustrate the clinical importance of pain tolerance when teaching fellows and residents at UCLA, one of us (DB) found it helpful to compare X-ray films of two patients with knee pain.

The first patient was a professional football player who had undergone six prior knee surgeries. While reviewing his films, we wondered how this individual could walk, much less continue to play football. However, he reported little pain or discomfort, took no pain medications (they made him "feel less ferocious"), and only desired treatment that would increase stability and range of motion in his knees.

The second patient was injured on the job and had fi extensive workers' compensation litigation. Although his knee X-rays were completely normal, he suffered greatly and was unable to climb stairs, drive a car, or sleep for more than 2 to 3 hours at a time. He was totally disabled, despondent and depressed, and dependent on his family, four medical doctors, and seven different pain medications.

The first patient had significant pathology but high tolerance and barely complained of pain. The second had minimal if any pathology, but little tolerance to the pain he experienced.

In the clinical situation, we often confront limitations in our ability to reverse severe physical pathology (e.g., degeneration of cartilage in a joint). However, our ability to help patients enhance their tolerance of pain seems to have no upper limit. Thus, practitioners who help patients embrace a more positive belief or attitude about pain can be successful in helping to reduce suffering and enhance tolerance, even when nothing more (medically) can be done.

Increasing pain tolerance is, after all, the basis of effectiveness of our most potent pain medications. When a patient is given an injection of morphine (which mimics the effects of endorphins), he or she will often state. "It still hurts, but it doesn't bother me". This represents enhanced central tolerance, not reduced sensation, yet enables the patient to become more highly functional.

The extent to which a patient's suffering can be reduced through psychophysiological approaches such as IGI depends upon many complex variables including the patient's belief systems and attitudes, early life experiences, the degree of physical pathology, and perhaps most importantly, the meaning of pain in the context of the patient's life.

THE MEANING OF PAIN

Since the dawn of creation, pain has provided critically important information concerning our relationship to our inner and outer environments. Pain strongly conveys the message that something is wrong, and it encourages the body to take action to prevent further injury. From an evolutionary point of view, it is one of the most powerful ways to insure the survival of an organism in a dangerous world.

While most authorities acknowledge the positive aspects of acute pain, many believe that chronic pain is a biological mistake or obsolete symptom that serves no useful purpose. In order to correct this mistake, they recommend strong drugs or surgical procedures to obliterate the sensation of pain. It is interesting to note that the exact technique utilized will depend more upon the type of specialist consulted than upon the patient's unique needs.

For example, an internist may prescribe medication; a psychologist, psychotherapy; an acupuncturist, needles; a chiropractor, manipulation; and so forth. Abraham Maslow used to say, "When all you have is a hammer, you tend to look for nails".

In our opinion, the best long-term interests of the patient often are not served when the major goal of therapy is to artificially mask or suppress pain without attempting to understand its ultimate message. To do so is like responding to a ringing fire alarm by cutting its wires to stop the annoying clamor, rather than by leaving the burning building.

We invite patients to consider the notion that like the oil light in a car, their nervous systems are generating the experience of pain for a reason. We invite them to explore the possibility that chronic pain is usually not a disease or mistake but a symptom generated through the wisdom of the body.

We then teach them about the extraordinary self-balancing, regeneration, and repair systems of the body and remind them that symptoms are the way that the body tries to heal itself or prevent further injury. Like the oil light and the fire alarm, once their message is heard and appropriate action is taken, symptoms usually will disappear, for they are no longer needed.

Much of contemporary medicine is based on an symptomatic adjustment model of therapy designed to reduce or suppress symptoms. If a patient has high blood pressure, antihypertensives are prescribed to reduce it. If a patient is unable to sleep, medications are given for sedation at night. If a patient has excessive anxiety, tranquilizers are often utilized. But why does a given patient have hypertension, sleep disorders, or anxiety neurosis? What is the message that the symptoms are trying to convey? Exploring this question in a nonjudgmental way can be the key to relieving or modulating many symptoms, including chronic pain.

Pain is a message that alerts us to danger. Through the primitive, survival-oriented wisdom of the nervous system, it motivates us to correct the situation by changing and adapting to the shifting demands of the world in which we live. Through pain, we are warned about all of the dangers we face, and if we continue to ignore them, the

intensity of pain will increase in an attempt to get our attention and/or elicit some change.

Perhaps this is why many chronic pain patients receive only temporary relief after symptomatic treatment. Although the nervous system can be fooled for a short time by drugs or surgical treatment, if it believes that some subtle danger still remains, pain will attempt to break through and, over time, continue to return until the message is heard and properly responded to.

PRINCIPLES OF INTERACTIVE GUIDED IMAGERY (IGI)

Healing Benefits from Respectful Attention

Although no one really knows what consciousness is, we believe that it is critically related to the process of attention, for we only experience what we attend to. There is an old saying that "whatever you give your attention to grows," whether it be your garden, your children, your worries and fears, or your pain.

Over the years, most of us learn to give our attention to the conscious, verbal part of our mind that narrates a linear logical, rational, analytic monologue describing its perspective of the world and how we think about it. It's the little voice inside your head that talks all the time, the person most of us think we are.

However, who we really are is much more than just what we think. We are also the richness of our intuitions, emotions, feelings, memories, drives, fantasies, goals, appetites, aspirations, expectations, ambitions, values, passions, beliefs, perceptions, and sensations. Any or all of these aspects of self may require and even demand attention, finding ways to compete by intruding on everyday consciousness through physical, cognitive, emotional, or even behavioral symptoms, if need be.

Rather than suffer the results of neglecting these parts of ourselves, we can focus attention on them in a relaxed state of mind and invite images that represent them to come to mind. By properly dialoguing interactively with these images, we can reconnect with important and powerful inner resources that are deeply dedicated to protecting us and improving the quality of our lives.

Imagery is the Primary Encoding Language of the Body's Healing Systems

Imagery can be thought of as one of the brain's two higher-order information processing and encoding systems. The system we are most familiar with is that which uses sequential information processing, and it underlies linear, analytic, and conscious verbal thinking. Most health professionals are highly educated and highly rewarded for their abilities in using this mode of information processing.

Imagery serves as a simultaneous information processing system, which underlies the holistic, synthetic, pattern thinking of the unconscious mind, and can reveal to us how seemingly disparate areas of our lives are intimately related.

A brief clinical example from Dr. Bresler's practice serves to focus on the importance of this relational quality to life.

A 52-year-old cardiologist named John was suffering from excruciating low back pain following treatment for rectal cancer. Although surgery and radiation therapy apparently had eradicated the cancer, he described the pain that remained as unbearable. Because the area had been so heavily irradiated, neither repeated nerve blocks nor further surgery could be used to help relieve his terrible discomfort, and he had long ago developed tolerance to his pain medications.

When John first came in, he already had narrowed down his personal alternatives to three: (1) successful treatment, (2) voluntary commitment to a mental institution, or (3) suicide. John was convinced that under no circumstances could he continue to live with pain and, at the same time, maintain his sanity.

In reviewing his medical records, I noticed that during a psychiatric workup, John had described his pain as "a dog chewing on my spine." This image was so vivid that I suggested we make contact with the dog, using guided imagery. With his training in traditional medicine, he thought the idea was silly, but he was willing to give it a try.

In John's case, our initial goal was to have the dog stop chewing on his spine. Over the next few sessions, the dog began to reveal critically important information. According to the dog (named Skippy), John never had wanted to be a physician, his own career choice was architecture, but he had been pressured into medical school by his mother. Consequently, he felt resentment not only toward his mother, but also toward his patients and colleagues. Skippy suggested that this hostility had, in turn, contributed to the development of his cancer and to the subsequent pain problem as well.

During one session, Skippy told John, "You're a damn good doctor. It may not be the career you wanted, but it's time you recognized how good you are at what you do. When you stop being so resentful and start accepting yourself, I'll stop chewing on your spine." These insights were accompanied by an immediate alleviation of the pain, and in only a few weeks' time, John became a new person, and his pain progressively subsided.

This type of experience demonstrates how powerfully the imagery process can reveal meaning in a supposedly meaningless symptom, and show the way to healing. While imagery does not always lead so dramatically to relief, and disease remission from such dialogues does not always occur, they almost always lead to better self-understanding and enhanced coping skills for dealing with a chronic illness or condition.

Imagery Has Physiological Consequences

Numerous research studies have shown that imagery is able to affect almost all major physiologic control systems of the body, including respiration, heart rate, blood pressure, metabolic rates in cells, gastrointestinal mobility and secretion, sexual function, and even immune responsiveness (Sheikh & Kunzendorf, 1984).

Imagery is essentially a way of thinking that uses sensory attributes, and in the absence of competing sensory cues, the body tends to respond to imagery as it would to a genuine external experience. For example, imagine that you have a big, fresh, yellow, juicy lemon in your hand. Experience it in your mind's eye until you sense its heaviness and fresh tartness. Now, imagine taking a knife and slicing into the lemon. Carefully cut out a thick, juicy section. Now take a deep bite of the lemon slice and imagine tasting the sour lemon juice, saturating every taste bud of your tongue so fully that your lips pucker and your tongue begins to curl.

If you were able to imagine this vividly in your mind's eye, the image probably produced substantial salivation, for the autonomic nervous system easily understands and responds automatically to the language of imagery.

Here is the crux of the matter: If imagining a lemon makes you salivate, what happens when you imagine you're a hopeless, helpless victim of chronic pain? Doesn't it tell your nervous system to give up? Isn't it likely to create neural and biochemical signals that go along with being defeated rather than actively healing? And, in the other direction, might not resolving serious life problems, improving communications and relationships, and learning to modulate pain create a healthier and more functional physiology in the body?

Imagery is the Language of the Emotions

Imagery also is a powerful tool in the healing arts because of its close relationship to the emotions. Imagery is the expressive language of the arts — poetry, drama, painting, sculpture, music, and dance, and thus of the emotional self. Emotions show us what's personally important to us and they can be either potent motivators or barriers to changing lifestyle habits. As clinicians, we have concluded that, by and large, if an issue doesn't affect you emotionally, it probably won't make you sick nor is it likely to help you get well.

Emotions motivate us to action and they also produce characteristic physiologic changes in the body, including varying patterns of muscle tension, blood flow, respiration, metabolism, and neurologically and immunologically reactive peptide secretions. Modern research in psychoneuroimmunology points to the emotions as key modulators of neuroactive peptides secreted by the brain, gut, and immune systems (Pert & Chopra, 1997).

Patient Autonomy Is Most Supported by Using a Two-Way Interactive Guiding Style

One key to the extraordinary clinical effectiveness of Interactive Guided Imagery is the unique interactive communications component that it incorporates. By working interactively instead of simply reading an imagery script, the Interactive Imagery Guide ensures that the experience has personal meaning for the client, and that it proceeds at a pace determined by the client's actual needs and abilities rather than the guide's best guess estimate.

For example, an Interactive Imagery Guide might ask, "Of all the different problems, symptoms, and challenges now going on in your life, allow an image to form that represents the single most important and critical issue for us to work on now, and then describe it to me." The guide can then facilitate a dialogue between the client and the image to find out what the image wants, needs, and has to offer.

Because the content, direction, and pace are set by the client, not the guide, it is the client who actually (unconsciously) guides the process to the resources most needed to support healing, change, and positive therapeutic results.

Patient Autonomy Is Most Encouraged by Using Content-Free Language and Nonjudgmental Guiding

We often like to say that "the guide provides the setting, while the client provides the jewel." Whenever possible, the Interactive Imagery Guide uses nonjudgmental, content-free language, because it encourages clients to tap their own inner resources to find solutions for solving their own problems.

At a time when there is so much concern about false memory syndrome (Pope, 1996), this type of content-free guiding also insures that the client's experience is not unduly contaminated or influenced by the suggestions of the guide.

Patient Autonomy Is Encouraged by Specific Qualities and Skills Utilized by the Guide

There are important personal qualities that the Interactive Imagery Guide brings to the therapeutic experience, including a nonjudgmental attitude, patience, and trust in the client's own abilities. The consistent emphasis on resources and solutions, the repetitive inner focus as a source for solutions and strengths, and the modeling provided by the guide's belief that the clients have within them more resources than they had imagined, leads to minimal transference, greater opportunities for effective client self-care, an enhanced sense of self-efficacy, and the rapid development of patient autonomy.

PROVIDER–PATIENT/CLIENT INTERACTIONS

Patient Assessment Procedures

The Interactive Imagery Guide must first decide whether there are any contraindications to introducing imagery to the patient, such as a medical or surgical condition requiring emergency treatment, or mental illness precluding its use. Having decided that imagery may offer benefit, a history is taken regarding the client's prior experience with imagery, hypnosis, relaxation, meditation, or related approaches. This allows the guide to utilize prior positive experiences or to address relevant issues in the case of negative experiences.

If the client has no prior experience with relaxation or imagery, the guide usually invites the client to relax while being guided through a brief relaxation technique. The client is then invited to imagine him or herself in a beautiful, safe, and peaceful place and then to describe what he or she sees, heasr, smells, and feels there. The guide may suggest that this special place has other qualities that also might be uniquely helpful to the client. For example, a fearful client might be encouraged to imagine hi or herself in a powerful place, a sanctuary, or a place where you are completely safe and beyond harm. A client who feels he or she is too exhausted to deal with a situation might be encouraged to imagine a place of great energy and vitality, or a place of rest, renewal, and refreshment.

Imagining a quiet, safe place is one of the quickest ways to teach most people to relax and it powerfully illustrates the profound effects a simple imagery experience can have.

Occasionally, a client cannot imagine such a place, or gets more anxious as the eyes close and he or she begins to relax. If this anxiety doesn't respond to reassurance that the person is in control, and gentle encouragement to see what comes next, it may be a signal that the person has not experienced such a place or that relaxing may be psychologically dangerous to them. Relaxation-induced anxiety may also be a marker for early trauma, as is the experience of having an imaginary safe place suddenly turn dangerous or foreboding.

Alternatively, clients may be invited to turn their attention to specific symptoms, to allow images to form for them, and to invite healing imagery to come to mind. They may be invited to have an imaginary dialogue with an image of a symptom, or with a kind, wise "Inner Advisor" who can provide previously inaccessible information about their issues or illness.

In this relaxed state, we can invite images to form for almost anything we want to know more about, and systematically explore the images to expand awareness and identify new options that promote healing.

Typically, patients are initially seen one to three times to explore the potential benefits of working with IGI. After three sessions, clients may have solved the problem, may have found a successful way to work it out by themselves, may have identified an issue that will require additional work, or may have found that the method or practitioner is not suitable for them.

While imagery may bring psychological material to light that was not previously perceived to be part of the medical equation, it also can provide ways to work with this material that do not create unnecessary dependence on a therapist. Many medical or nursing professionals will work with patients if the situation appears it will yield to a brief course of teaching and counseling, while referring those with more complex issues to therapists who are more highly trained in the method.

Treatment Options

Because imagery is a natural way we think, and can almost always be helpful, there are virtually an unlimited number of situations where it can be used in healthcare settings. For simplicity, it may be helpful to consider three major categories of use:

1. Relaxation and stress reduction, which are easy to teach, easy to learn, and almost universally helpful.
2. Visualization, or directed imagery, where the client/patient is encouraged to imagine desired outcomes in a relaxed state of mind. This affords the patient a sense of participation and control in his or her own healing, which itself is of significant value. In addition, it also may relieve or reduce symptoms, stimulate healing responses in the body, and/or provide effective motivation for making positive lifestyle changes.
3. Receptive or insight-oriented imagery, where images are invited into awareness and explored to gather more information about a symptom, illness, mood, situation, or solution.

Another set of options to consider is whether the client will be able to use imagery most effectively as a self-care technique, in a group or class, or as part of an individual counseling or therapy relationship. Self-help books and tapes are another inexpensive option for many clients who are capable of utilizing these techniques on their own.

In practice, most patients and practitioners will explore all of the above options and utilize the ones that suit a given client the best, given the unique nature of the issue, patient coping responses and approach to life, and the amount of time, energy, and funds the patient is willing or able to invest in the process.

Description of Commonly Used Treatment Techniques

The list of techniques utilized in IGI is quite extensive, and this approach has been applied to problems ranging from severe depression and chronic pain, to post-traumatic stress, to relationship conflicts, to enhance creativity, to the search for life purpose. However, some of the more basic techniques include the following.

Conditioned Relaxation

This powerful, relaxation technique is based on Pavlovian classical conditioning techniques and utilizes imagery linked breathing and body awareness techniques to train the patient to relax automatically by taking a special "signal breath". Instead of tensing when pain starts to flare, patients become conditioned to relax and gently move the painful symptoms out of their bodies.

Symptom Suppression Techniques

Symptomatic imagery techniques reduce the physical symptoms of pain without concern for their causes. They are a useful alternative to analgesic medications, and are particularly helpful when discomfort is so intense that the patient cannot concentrate enough to use other guided-imagery approaches. They include a wide variety of scenarios and techniques, such as "glove anesthesia", a two-step imagery exercise in which patients first are taught to image developing feelings of numbness in the hand, as if it were being placed into an imaginary anesthetic glove. Next, they learn to transfer these feelings of numbness to any part of the body that hurts, simply by placing the "anesthetized" hand on it. Glove anesthesia often helps to take the edge off the pain sensation, thus permitting patients to explore other aspects of the pain experience more fully. In addition, glove anesthesia provides a dramatic illustration of the power of self-control. When patients realize that they can produce feelings of numbness in their hands at will, they recognize that they may be able to control their discomfort, too. This is profoundly therapeutic for pain sufferers who feel totally helpless and unable to affect their discomfort.

Symptom Substitution Techniques

Symptom substitution is another symptomatic technique that permits the nervous system to move the discomfort to a new area of the body where it will be less disruptive. For example, patients can learn to experience their headaches in, say, their little finger instead of their head. This technique does not ask the nervous system to stop the experience of pain (or to cover up the message it is trying to communicate). Rather, it moves the symptom to a less traumatized area so that patients can work more effectively to identify what is wrong.

Interactive Imagery Dialogue

This interactive technique can be used with an image that represents anything the client or therapist wants to know more about, and in many ways, it is the quintessential insight technique. We use it to explore an image of a symptom (whether physical, emotional, or behavioral), an image representing resistance that arises anywhere in the process, an image for an inner resource that can help the client deal with the current problem, or an image of the solution.

When using Interactive Imagery, the point is not to analyze the images, but to communicate with them as if they are alive (which of course, they are). This is not to say they have an existence apart from the client, but rather that the images represent complexes of thoughts, beliefs, attitudes, feelings, body sensations, expectations, and values that at times can function as relatively autonomous aspects of the personality. These constellations have been referred to as subpersonalities by Assagioli, or ego states by Watkins and Watkins.

The Inner Advisor

After relaxing in his or her own safe place, a client is invited to dialogue with an imaginary figure who is designed to be both wise and loving, or as characterized in analytic terms, an "Ego Ideal". We call this figure the "Inner Advisor", and it is often referred to as the "Inner Guide", "Inner Healer", "Inner Wisdom", "Inner Helper", "Inner Physician", "Higher Self", or any other term that is meaningful and comfortable for the client. As the client is invited to imagine a figure with these qualities, a dialogue with whatever figure arises is usually meaningful and helpful.

Evocative Imagery

This state-dependent technique helps clients shift moods and affective states at will, thus making new behaviors and insights more accessible to consciousness. Through the structured use of memory, fantasy, and sensory recruitment, the client is encouraged to identify a personal quality or qualities that would serve him or her especially well in the current situation. For instance, a client may need more calmness or peace of mind in order to deal more effectively with pain.

The guide then invites clients to relax and recall a time when peace of mind was actually experienced. Through the use of sensory recruitment and present tense recall, the clients are encouraged to imagine they are there again now, feeling that peace of mind. Once this peaceful feeling state has been well established and amplified, patients are invited to let the past images go, but to come back to the present, bringing the feelings of peace of mind. As they now become aware of their pain problems

while strongly in touch with this feeling, they are usually able to tolerate it far more effectively.

Evocative imagery was researched by Dr. Sheldon Cohen at Carnegie-Mellon University (personal communication) and found to be highly effective in shifting affective states. Research aimed at assessing the effects of those altered affective states on subsequent behavior, problem-solving, and self-efficacy remain to be done and offers a fertile field for future psychological and behavioral research.

Grounding: Moving from Insight to Action

This is the process by which the insights evoked by imagery are turned into actions, and increased awareness and motivation are focused into a specific plan for attitudinal, emotional, and/or behavioral change. This process of adding the will to the imagination involves clarification of insights, brainstorming, choosing the best options, affirmations, action planning, imagery rehearsal, and constant reformulation of the plan until it actually succeeds. It is often the missing link in insight-oriented therapies, for it connects the new awareness to a specific action plan. It's where the "rubber meets the road," and imagery can be used to enhance this process by providing creative options for action and by utilizing imagery rehearsal to troubleshoot and anticipate obstacles to success.

Treatment Evaluation

We refer to the time spent before entering into a formal guided imagery exploration as the "foresight" part of the process. Along with evaluating the appropriateness of using imagery with the client or patient, the guide works with the client to establish the desired goals and objectives for their work together.

As with any medical or psychological situation, goals can be defined in physical, emotional, or behavioral terms, and a reasonable trial period of exploration is agreed upon. We often ask patients to do three exploratory sessions and then decide whether this approach seems useful to them, whether they can best use it as self-care in a brief, time-limited period of work (10 to 15 sessions), or whether it looks like a longer-term piece of work will be needed.

Many physicians and nurses work for a defined period of time with patients in a psycho-educational or counseling model, with well-defined symptomatic or behavioral goals, and refer patients to mental health practitioners if their work becomes psychologically complex. At the same time, we urge that mental health practitioners take precautions to ascertain the medical status of any patient to make certain they are also aware of the medical options.

At the end of each session, and at the end the agreed-upon time period, the goals of the work are reviewed and progress assessed (we call this phase "hindsight"). After this evaluation, an agreement is made to terminate treatment, to continue for another period of time, to refer to another practitioner, or to define a period of time in which the client will do "ownwork" and then return to report progress.

Treatment Applications in Addition to Pain

Since imagery is a natural language of the unconscious and the human nervous system, its potential uses in the healing professions are protean. We think that imagery is essentially a way of working with the patient, rather than a way of treating particular disease entities. Thus, it is almost always useful as an adjunctive therapy, while it is rarely, if ever, utilized as a sole therapy.

Table 67.1 lists some of the major applications of imagery in the healing professions.

TABLE 67.1
Applications of Interactive Guided Imagery in the Health Professions

In Medicine

- Relaxation and stress reduction
- Pain reduction and symptom relief
- Increasing compliance with treatment regimens
- Tolerating difficult procedures
- Preparing patients for surgery
- Stimulating healing responses (immunity, blood flow)
- Insight and affect recognition
- Engaging patients in their own self-care
- Finding meaning in illness

In Psychotherapy

- Relaxation and stress reduction
- Systematic hyposensitization for phobias
- Conflict clarification and resolution
- Shift of locus and control and relief of powerlessness
- Positive suggestion, affirmation, and enhanced self-esteem
- Finding vision and meaning
- Action planning
- Values clarification
- Increased creativity and enhance problem-solving
- Modulation of mood and affect
- Insight and awareness development
- Grieving

In Nursing

- Relaxation and stress reduction
- Deepening rapport
- Enhancing compliance
- Tolerating procedures
- Pain and symptom relief
- Engaging patients in self-care
- Addressing emotional needs of patients

Contraindications and Precautions

1. Do not substitute imagery for necessary medical or surgical interventions.
   The primary danger in using imagery to augment healing in medical situations is when it is used in lieu of appropriate medical diagnosis and/or treatment. We emphasize the necessity of an accurate diagnosis prior to using any psychophysiologic approach so that the patient also is aware of the medical options for treatment. At times, patients may decide that they do not have acceptable medical options available and will then choose to use imagery and mind/body/spirit approaches as their first-line treatment. Although there are some situations in which this makes perfect sense, each situation must be evaluated individually to ascertain the patient's ability to judge for him or herself and to make such choices.
2. Do not use imagery inappropriately with patients with unstable or unmanaged psychopathology.
   There are several diagnostic categories of mental illness where the practitioner must use extreme care when utilizing exploratory receptive imagery techniques. In particular, patients who are psychotic or who are on the verge of psychotic breaks, patients with dissociative identity disorders, and patients with borderline personality disorders must be handled with care, and only by well-trained and experienced practitioners.
   While these diagnoses do not represent absolute contraindications for imagery work, they absolutely require treating health professionals to have appropriate training and expertise in these areas. While many clients with these diagnoses may benefit from certain uses of imagery (usually directed imagery scripts focusing on centering, calmness, self-control, safety, etc.), great caution should be taken when using potentially disorganizing receptive imagery techniques.
   In proper therapeutic hands, imagery techniques can be one of the most effective ways to work with clients who are survivors of traumatic abuse and who tend to pathologically dissociate. However, such treating practitioners must be well trained and experienced in working with both survivors of abuse and with exploratory IGI approaches.
3. Do not confuse responsibility with blame.
   The fact that an illness can be helped through mental processes does not necessarily suggest that it was caused by mental means. When using exploratory techniques such as imagery dialogue with symptoms, or working with an inner advisor, there is a tendency to confuse the ability to learn from illness with blame for causing the illness.
   This issue needs to be handled with skill and sensitivity, and while the practitioner may not be able to prevent certain clients from self-blaming (this may be an important issue to address with them), they can help most people realize that using positive images to stimulate healing does not necessarily mean that their negative images caused their illness.
4. Do not underestimate the holotropic principle and the innate resources of the patient.
   Imagery is a potent form of communication and suggestion. Whenever possible, we advocate using the patient's own imagery and an interactive guiding style because we are convinced that the client has within him- or herself a great deal of information, experience, knowledge and problem-solving resources that have not yet been used most effectively.
   While there are certainly places and situations where a guide needs to supply suggestions and images, these are relatively rare when utilizing IGI, and may even rob clients of the opportunity to learn an important way to help themselves. This creates or sustains a sense of dependency on the expertise of the guide, rather than attention to the inner abilities that have always been available to help them to help themselves.

SCOPE OF PRACTICE FOR INTERACTIVE GUIDED IMAGERY

This has been an important and problematic area for the Academy for Guided Imagery. As we considered the criteria for formal certification in IGI, we decided to exercise caution and restrict certification eligibility to professionals licensed to provide counseling services in their states of residence.

We soon found out that many states have no such licensing for therapists, and people of various levels of quality were providing counseling, psychotherapy, hypnosis, and guided imagery. As a result, we evaluate each candidate on an individual basis, assessing him or her for both competence and ethical standards as we observe them in clinical supervision as part of the Academy's training.

Health professionals must practice within the scope of their licensure, education, experience, and competence. Within these guidelines, certification in IGI can significantly help make professionals more effective at what they already do. Using guided imagery or IGI does not turn a physician into a psychotherapist, or a psychotherapist into a physician.

Instead, it gives each a greater range of skillfulness in working with issues that involve both mind and body, and with issues involving emotions and behavioral change.

Certified IGI practitioners must discriminate between psychotherapy and psychoeducation, and between enhancing healing responses and the practice of medicine. They must ethically practice each within their scope of licensure, training, experience, and competence.

Because our approach is holistic, there is more crossover in these areas than is immediately apparent. If we can effectively activate healing responses through essentially psychological means, how does this affect the scope of practice of mental health practitioners who are well-versed in IGI? Shouldn't they be critical members of every primary healthcare team? We believe so.

Training, Certification, and Issues of Competence

Many health professionals utilize guided imagery in their work, although they may have only learned to lead someone by reciting a noninteractive script. The quality of their training and competence with this approach is highly variable. Because the potential for doing harm always exists when these techniques are used inappropriately or without adequate skills, standards of practice and quality control are an issue of critical importance.

The Academy for Guided Imagery has established specific standards of competence and ethical behavior that must be met before Certification in Interactive Guided Imagery is awarded. Quality assurance is based largely upon direct observation of clinical work in small group and individual supervision sessions during the training program. Over 52 hours of supervision, four to six different faculty members carefully observe each candidate, and provide specific feedback to enhance his or her skills. We know of no other such standards of quality assurance established for imagery practitioners.

Reimbursement Status

Imagery practitioners usually bill and are reimbursed for their work in the same way as for other professional services they render. Sessions are usually billed as psychotherapy, counseling, stress reduction training, or medical hypnosis. When applied for medical purposes, medical practitioners may ethically bill for medical services, although insurance companies may challenge this if services are lengthy and repetitious. There are currently no separate billing codes for guided imagery or IGI.

PROSPECTS FOR THE FUTURE

When you look closely at almost every form of human therapeutic interaction and communication, imagery is usually centrally involved, primarily because it is a fundamental language of the body's healing systems. As this is better recognized, we are hopeful that health professionals will learn more about the best ways to utilize this potent form of thinking to support optimal health and healing.

Feedback from the thousands of health professionals who have taken IGI training confirms that it is a rapid route to insight, growth, and change. One constant piece of feedback we get is that learning to use imagery interactively has improved the listening, communicating, and therapeutic skills of our graduates, whether they are mental health professionals, physicians, or nurses.

We feel that competence in effectively yet respectfully guiding the imagery process should be a fundamental part of every health professional's education and training, and the Academy for Guided Imagery is working toward that goal by co-sponsoring many of its professional training programs with well-established schools of medicine, nursing, and psychology.

In addition to professional training and Certification in Interactive Guided Imagery, the Academy for Guided Imagery is a resource for self-help books and tapes and reliable information on imagery. The Academy also is participating in research studies exploring the uses of imagery in pain control, surgical preparation and recovery, and cancer chemotherapy, and it recently established the nonprofit Imagination Foundation to support further research in these and other areas. The Imagination Foundation is currently soliciting both funds and research proposals investigating imagery in healing.

Humans have always used their imaginations to solve problems that threatened their survival. Our times demand that we now learn to use this powerful information-processing and problem-solving mechanism even more effectively to help heal ourselves, our families, our communities, and our planet. A sustainable future depends in part on our ability to imagine it in both personal and global terms, and we are committed to supporting the healing potential of this much underutilized resource — the human imagination.

Behavioral Protocols for Burning and Cramping Phantom Limb Pain*

Richard A. Sherman, Ph.D.

CONCEPTUAL INTRODUCTION

Behaviorally oriented treatments for phantom limb pain have been in use at least since the late 1970s (e.g., Sherman, 1976). Use of behavioral interventions is predicated on the supposition that amputees can learn to recognize and then control incorrect levels of physiological functions related to their phantom pain.

This idea requires that (1) there are specific physiological parameters which are directly related to specific descriptors of phantom pain and (2) people can, indeed, learn to control them. Over the past several decades, data have accrued that strongly infer that the extent of near-surface blood flow in the residual limb is inversely correlated with intensity of burning/tingling descriptions of phantom limb pain and that many amputees can learn to control blood flow in the residual limb sufficiently to reduce or eliminate these sensations. Data also show that cramping/twisting descriptions of phantom limb pain are related to increased muscle tension and spikes/spasms of the major muscles in the residual limb and that amputees learning to eliminate these abnormalities also eliminate their cramping phantom pain. There are no known physiological correlates of shocking, shooting phantom pain and none of the behavioral interventions appears to be effective for this description of phantom pain.

RELATIONSHIPS BETWEEN PHANTOM LIMB PAIN AND MUSCLE TENSION

Ehrenholm (1951) quotes Amyot, Livingston, and others as having noted increased muscle tension and spasms in the stumps of amputees. He found that 51 of 99 amputees questioned about stump muscular activity reported spontaneous hyperactivity.

Onset and intensity of cramping and squeezing descriptions of phantom pain are related to muscle tension in the residual limb. A variety of studies have demonstrated that intensity of cramping phantom pain and amount of muscle tension in the residual limb change together from day to day (Sherman & Arena, 1992) and from moment to moment (Sherman, Griff Evans, & Arena, 1992).

Changes in surface electromyographic (sEMG) representations of muscle tension in the residual limb precede changes in cramping and squeezing phantom pain by up to several seconds. This relationship does not hold for any other descriptions of phantom pain. The critical point is that the amputee only shows changes in muscle tension in the painful residual limb. Surface EMG in the pain-free residual limb does not change significantly. If the change in EMG was simply a reaction to the change in pain, the change in EMG would have followed, rather than preceded, the change in pain and at least some change in

0-8493-0926-3/02/$0.00+$1.50

muscle tension in the pain-free limb should have been observed as would be expected from a generalized withdrawal reflex from pain.

Relationships between overall muscle tension in the residual limb and cramping phantom pain have also been shown to hold throughout the day in subjects' normal environments (Sherman, Evans, & Arena, 1993). The device used to establish the relationship was capable of recording surface EMG from the residual limb and button press representations of pain intensity (Sherman, Arena, Searle, & Ginther, 1991). The relationship between cramping phantom pain and muscle tension in the residual limb is supported by the consistent success of treatments resulting in reduction of residual limb muscle tension for cramping phantom pain but not for other descriptions (Sherman 1976; Sherman et al., 1991; Sherman et al., 1992).

Numerous amputees report that cramping phantom pain decreases with any activity that tends to decrease muscle contraction levels in the residual limb and increases with activities increasing overall levels of contraction. Thus, such activities as phantom exercises, which result in changes in muscle tension in the residual limb, can result in temporary changes in intensity of phantom pain. Gessler (1984) reported that when the muscles of the residual limb of 10 amputees with chronic cramping phantom pain were relaxed, the phantoms felt as though they were opening.

BURNING-TINGLING-THROBBING PHANTOM LIMB PAIN

Reduced near-surface blood flow to a limb has been implicated as a predictive physiological correlate (first cousin to a cause) in many pain conditions including causalgia and reflex sympathetic dystrophy (Karstetter & Sherman, 1991). Return of blood flow to normal patterns through any intervention, including time alone, usually results in either the complete cessation or significant decrease of the pain (Sherman et al., 1991). If phantom limb pain is a referred pain syndrome, anything affecting the nerve endings in the residual limb is likely to affect phantom pain as well. A number of excellent studies have demonstrated that (a) the ends of the nerves that used to serve the amputated limb are still sensitive to stimuli; (b) cooling the nerve ends causes increased firing rates; and (c) reducing blood flow to the extremity results in cooling it (Campbell, 1987; Harber, 1955; Janig, 1987; Koschorke, Meyer, & Campbell, 1987; Matzner & Devor, 1987; Sherman & Arena, 1992).

Chronholm (1951) quotes Pitres (1897) as having stated that the perceived temperature of the phantom is related to the temperature of the stump. Measurements of skin temperature in amputees have been made since at least 1952 (Berkeley Medical School, 1952). The study found that amputees' residual limbs were cooler at the distal end than paired points on the opposite extremity and that the cooler areas did not warm up when attempts were made in increase cutaneous blood flow through such mechanisms as giving the subjects whiskey to drink. Wahren (1990) reviewed the propensity of finger amputees to be very sensitive to the cold and for their pain to be aggravated by cold environments. They found that the residual areas of the fingers were cooler than corresponding areas on the intact hand and were more sensitive to pain in response to cooling. Kristen, et al. (1984) reported using videothermographic recordings of temperatures in the residual limbs of 50 amputees to detect phantom pain. They found that most amputees having phantom pain showed different patterns of temperature than those who had none.

Consistent, inverse relationships between intensity of phantom limb pain and temperature in the residual limb relative to that of the intact limb have been demonstrated for burning, throbbing, and tingling descriptions of phantom pain but not for any other descriptions (Sherman & Bruno, 1987).

It has also been established that (a) for these descriptors of phantom pain there is a day to day relationship between the relative amount of blood flow in the stump and pain intensity and that (b) there is an immediate change in pain when blood flow changes. However, this does not mean that the changes in blood flow cause the change in pain. It is possible that a change in pain intensity causes a physiological chain reaction which eventually causes a decrease in blood flow to the stump. This is improbable for several reasons. Although videothermographs normally record only near-surface blood flow patterns, hands are thin enough so that thermographs can record blood flow patterns throughout the hand. In four cases of burning or tingling phantom pain following a finger amputation, blood flow changed only in the area just proximal to the amputation site. The rest of the hand was essentially unchanged and there were no changes in the paired area of the intact hand. If blood flow was changing as a result of a reflex, we would have expected a bilateral change or, if unilateral, a change related to dermatomal distribution patterns in which an entire dermatome would have cooled off. This was not the case so we conclude that a reflex reaction is not likely. The subjects were taught to increase blood flow in the stump by using temperature feedback to relax, and thus dilate, the peripheral blood vessels. Increasing peripheral blood flow to the cool area of the stump resulted in a decrease in the pain intensity. If the decrease in blood flow was due to an increase in pain, blood flow would decrease for all descriptors of phantom pain, not just a consistent few (Sherman & Arena, 1992).

Numerous thermograms form the key evidence that the decreased blood flow associated with burning phantom

pain is not the subsequent result of a general sympathetic reaction because only the painful residual limb shows decreased blood flow—the other residual limb maintains its temperature. This tight, progressive relationship has been replicated numerous times (e.g., Sherman & Bruno, 1987) and indicates that there is more than a casual relationship between the two.

"The existence of a vascular related mechanism for burning phantom pain is also supported by the short term effectiveness of those invasive procedures, such as sympathetic blocks and sympathectomies, which increase blood flow to the limb and reduce the intensity of burning phantom and stump pain but not other descriptors (Sherman, 1980; Wall, 1981). It is indirectly supported by the virtual ineffectiveness of every surgical procedure involving severing nerves either in the spinal cord or running between the amputation site and the spinal cord (Sherman & Sherman, 1985; Wall 1981). Beta blockers such as propranolol cause dilation of peripheral blood vessels and have been reported to be successful in ameliorating phantom pain at least in the short term (Marsland, Weekes, Atkinson, & Leong, 1982)"(Sherman & Arena, 1992). Relationships between muscle tension and burning phantom limb pain (Sherman & Bruno, 1987) have been shown to be due largely to the change in near-surface blood flow that accompanies increased muscle tension (Laughlin & Armstrong 1985; Richardson, Schmitz, & Borchers, 1986).

RECOMMENDED PROCEDURE FOR BEHAVIORAL INTERVENTIONS TO PATIENTS WITH CHRONIC PHANTOM LIMB PAIN*

As early as 1979 it became apparent that different descriptions of phantom pain responded to different treatments (Sherman, Gall, & Gormly, 1979). Initial attempts to treat phantom limb pain with a combination of biofeedback and relaxation techniques showed excellent success up to 6-month to 3-year follow-ups with 14 of 16 successive phantom pain patients. The major difference between those patients who succeeded in learning to control their pain and those who did not was the ability to control their physiology in any measurable way. The two failures never (a) demonstrated the ability to relax or (b) reported subjective feelings which would be associated with learning to relax or to control their muscle tensions.

In an attempt to align behavioral and medical treatments of phantom pain with underlying physiological correlates, amputees who showed increased burning phantom limb pain in response to decreased blood flow in the residual limb were treated with peripheral vasodilators and temperature biofeedback. When increased muscle tension and spasms in the stump were related to episodes of cramping phantom pain, muscle relaxants and muscle tension biofeedback were used to control the pain (Sherman et al., 1997).

In the most recent cases, EMG biofeedback was effective for 13 of 14 trials for cramping phantom pain. EMG biofeedback had minimal success with 2 and no success with 10 of 12 trials for burning phantom pain. It had no success with 8 trials of shocking phantom pain. Temperature biofeedback was ineffective for 4 trials of cramping phantom pain, was effective for 6 of 7 trials with burning phantom pain, and had no success with 3 trials for shocking phantom pain. Nitroglycerine ointment (a topical vasodilator) was ineffective for 1 trial of cramping phantom pain and 1 trial of shocking phantom pain but successful for 2 trials of burning phantom pain. Trental (a blood viscosity enhancer) was ineffective for 2 trials of cramping phantom pain and 1 trial of shocking phantom pain. Nifedipine (a systemic vasodilator) was effective for 3 trials of burning phantom pain but ineffective for 1 trial of cramping and 2 trials of shocking phantom pain. Flexeril (a muscle relaxant) was effective for 2 trials of cramping phantom pain but ineffective for 1 trial of shocking phantom pain. Indocin (an anti-inflammatory agent) was ineffective for 2 trials of cramping phantom pain. These medications have potential side effects and cannot be used by patients with a variety of medical problems. Thus, the use of "self-control"-oriented strategies is encouraged to avoid these limitations.

It is clear that burning phantom pain responds to interventions that increase blood flow to the residual limb while cramping phantom pain responds to interventions that decrease tension and spasms in major muscles of the residual limb. Shocking-shooting phantom pain does not respond well or consistently to either type of intervention.

It is strongly recommended that biofeedback of appropriate parameters be used in conjunction with other self-control training strategies to treat cramping/squeezing and burning/tingling phantom limb pain. It is important for clinicians to recognize that biofeedback as utilized for control of phantom limb pain is not some kind of black box psycho-magic. Rather, it is simply the process of recording the physiological parameters (such as muscle tension in the residual limb) that precede changes in phantom pain, and showing the signals to patients. The patient uses the information to change the signal. The patient also learns to associate sensations related to onset of phantom pain with tension in the muscle, decreased blood flow, etc. and to use the learned ability to control the parameter to prevent the onset of or to stop it if it has already begun.

Unfortunately, the large, controlled studies with long-term follow-ups needed to clearly show that burning and cramping phantom pain are amenable to behavioral interventions have not been conducted.

* Modified from Sherman & Arena, 1992 and Sherman, et al., 1997.

SUMMARY

Cramping Phantom Pain

The existent data (e.g., Sherman, 1994) support the contention that nearly all amputees with cramping phantom limb pain, who can learn to recognize the relationship between their pain and spikes in the surface EMG of the residual limb and can learn to prevent the spikes from occurring, can prevent their phantom pain to the extent they can prevent the spikes. If the spikes continue, so will the cramping phantom pain. If the spikes can be voluntarily stopped once an episode of phantom pain begins, the episode can nearly always be almost entirely aborted. The small studies showed that the vast majority of people can learn to control nearly all of their cramping phantom pain. Again, no learning, no control. Follow-ups of 1 to several years showed that the results are sustained.

Burning Phantom Pain

The same premise holds true for burning as for cramping phantom pain. If patients can learn to increase blood flow to the residual limb, burning phantom pain will decrease to the extent that blood flow is normalized. The burning will remain away as long as blood flow remains normal. Unfortunately, about half of the patients have not been able to learn to raise the blood flow in their residual limbs to a significant extent.

Hypnotherapeutic Advances in Pain Management

Jan M. Burte, Ph.D., D.A.A.P.M.

There is little doubt that the induction of hypnoidal states utilizing chanting and breathing exercises dates back to earliest history. The earliest clinical records of hypnosis are attributed to John Elliotson (1792 to 1869), an English surgeon, who used hypnosis for pain management in his practice. James A. Esdaile (1808 to 1859) performed more than 300 operations using hypnosis as analgesia while practicing in India (Bassman & Wester, 1992). One such operation reportedly entailed the removal of a 103-pound tumor (Jackson, 1999). Hypnosis and trance represent an age-old treatment for a variety of conditions including pain; hypnosis has been embraced as a legitimate therapy consequent to continuing research only over the past 50 years (Hrezo, 1998).

Hypnosis as a form of pain management fell in and out of favor from the early 1940s until the 1960s when Milton H. Erickson demonstrated its utility with acute and chronic pain control (Erickson, 1986). The application of hypnosis within the medical and pain setting has continued to develop from the work of Hilgard and Hilgard (1975), Hilgard and LeBarron (1982), Barber and Adrian (1982), and Melzack and Wall (1965; 1983).

Zohaurek (1985) points out two historical misconceptions of pain that have affected the role of hypnosis in treating pain.

1. Pain was considered only to be a symptom of an underlying disease or trauma. Therefore, research and treatment focused on the etiological cause and ignored the pain, assuming it would disappear when the cause was addressed. Historically, pain reporting was by necessity heavily relied upon as part of the initial diagnostic procedure, where severity, location, and nature of the pain often assisted in proper diagnosis. Although pain reporting maintains a significant role in diagnosis, the advent of additional diagnostic procedures (i.e., CAT, MRI scans) goes beyond pain reports and reduces their unique significance. The reliance on pain reports was especially true in certain acute pain situations although not as much in chronic pain situations where a diagnosis had been reached (Bonica, 1990). It was postulated that hypnosis could mask the symptoms of pain and might interfere with obtaining a proper diagnosis and treatment (i.e., hypnosis utilized to mask pain associated with appendicitis could result in delaying care until the appendix had ruptured).
2. Pain was seen as evolving from either a physical or a psychological origin rather than from both. Pain was perceived to have either a “real/organic” basis or a “functional/imaginary” basis (Fordyce, 1976, Sternbach, 1978). Current thinking might view the impact of pain as an etiological factor that by its bidirectional psychoneuroimmunological role (on the psychological, endocrinological, and immunological systems) may contribute to the maintenance of illness (Burte, 2000) or enhance the progression or metastasis of certain illnesses (Paige and Ben-Eliyahu, 1997).

0-8493-0926-3/02/$0.00+$1.50

Since 1958, hypnosis has been recognized by the American Medical Association as a legitimate form of medical treatment when administered by an appropriately trained practitioner (Simon & James, 1999). Fortunately, with the resurgence of integrative, mind/body, psychoneuroimmunological approaches, current thought and research have begun to view hypnosis as a potentially significant modality in the treatment of pain and illness.

In this section, I focus on the hypnotherapeutic advances in pain management. In the next section, I discuss the applicability of hypnosis in the treatment of specific illnesses. Due in part to its historical misportrayal in the popular media, patients referred for hypnosis often ask, "But does it really work?" Contemporary popular media portray hypnosis as an effective means of pain control (Foderaro, 1996). Currently, sufficient experimental and clinical research exists to allow clinicians to respond affirmatively to the question. However, certain caveats, discussed later, still exist.

What then is medical or clinical hypnosis and what are the contemporary views of both practitioners and the public, especially within the realm of pain management? One recent survey indicates that most people have a positive view of the therapeutic benefits with a vast majority of respondents believing that it reduces the time that is usually required to uncover causes of a person's problems, and that hypnotized persons can undergo dental and medical procedures without pain" (Johnson and Hauck, 1999).

Retrospectively, it is important to recognize that "pain," until the 20th century, was considered an untreatable consequence of illness or injury. Indeed, Chaves and Dworkin (1997) astutely point out that hypnoanalgesia did not fully emerge until the 19th century, due largely in part to the societal belief that, at that time, did not include pain relief and reduced suffering as the primary goal in treatment. Prior to effective clinical techniques for pain management, pain was an accepted aspect of life. One might wonder whether the introduction of pharmacological forms of pain relief such as analgesia and anesthesia altered patients' perceptions and ultimately their thresholds for pain.

If pain can act as a mediator in trance production with pain patients, then did our progenitors and do perhaps third world cultures who had/have limited access to various forms of pain relief intuitively rely on hypnosis and self-hypnosis to alter their pain thresholds? For these individuals, pain, whether from childbirth, dental procedures, illness, or injury, was anticipated.

Today, the application of hypnotic analgesia in acute and chronic pain treatment has grown substantially. Both patients and clinicians are demonstrating increased knowledge and experience with hypnosis. In many cases, patients bring clinical experiences with hypnosis for related or unrelated issues to the treating physician (Lynch, 1999), thereby opening a door to increased complementary approaches to standard interventions.

Where this may be significantly prevalent is in the nonpharmacological strategies employed in managing cancer pain. As Zaza, Sellick, Willan, Reyno, and Browman (1999) point out, while pharmacological treatments are appropriately the central component of cancer pain management, the under-utilization of effective nonpharmacological strategies may contribute to the problem of pain and suffering among cancer patients. In a study of 214 health professionals, Zaza, et al. (1999) found that the healthcare professionals recommended "imagery" exercises 54% of the time and meditation 43% of the time. They expressed interest in learning more about hypnosis and other nonpharmacological strategies suggesting its under-utilization as a complementary or adjunctive treatment to standard care. In a critical review of the literature, Sellick and Zaza (1998) found that in randomized controlled studies of hypnosis in managing cancer pain, substantial evidence exists for its effectiveness when nonpharmacological pain management approaches are being sought.

This concept, then, of unifying both the confidence of the practitioner and the trust and belief of the patient, may represent the components necessary to obtain efficacious pain relief. Barber (1998) aptly delineates a two-component model as to why hypnosis may work for pain management. He suggests that in the first component the "clinician communicates specific ideas that strengthen the patient's ability to derive therapeutic support and to develop a sense of openness to the unexplored possibilities of pain relief within the security of a nurturing therapeutic relationship". In so doing, the patient is led to relax in the clinician's confidence in hypnosis. In the second component, "the clinician employs posthypnotic suggestions that capitalize on the patient's particular pain experiences which simultaneously ameliorate the pain experience and which, in small repetitive increments, tend to maintain persistent pain relief over increasing periods of time. This second component offers the patient a sense of voluntary learned control over his or her pain, thereby reducing anxiety and learned helplessness.

A somewhat more constructionistic view is offered by Chapman and Nakamura (1998) who suggest that hypnosis alters the learned pain experience (pain schemata) by interacting with feedback processes that prime the associations and memories tied to the pain, thereby shaping the formation of pain expectations and processes and ultimately reducing the experience of pain.

As mentioned previously, hypnosis has fallen in and out of favor over the years due in part to arguments concerning the lack of hard scientific data to support its efficacy or pathophysiology. With increasing frequency studies are demonstrating the impact of hypnosis on pain from the perspective of changes occurring in the brain itself. Rainville, et al. (1997) demonstrated that positron emission tomography revealed significant changes in pain-evoked activity within the anterior cingulate cortex

consistent with the encoding of perceived unpleasantness, thereby linking frontal lobe limbic activity with pain susceptible to hypnotic suggestion.

In an examination of exposure to noxious stimuli presented to subjects, Faymonville, Laureys, Degueldre, DelFiore, Luxen, Franck, Lamy, and Maguet (2000) found that hypnosis could reduce the intensity and unpleasantness of the exposure. By examining cerebral blood flow of subjects both with and without hypnotic intervention, they concluded that hypnotic modulation of pain appears to be mediated by the anterior cingulate cortex.

Rainville (1999a) in their examination of cerebral blood flow utilizing PET scans found that the hypnotic experience may result in increased occipital regional cerebral blood flow (RCBF) and delta activity (EEG) by altering the consciousness associated with decreased arousal via facilitation of visual imagery. Frontal increases in RCBF may be associated with verbal mediation of suggestions, working memory, and top-down processes involved in re-interpreting the perceptual experience of the noxious stimuli. They concluded that specific patterns of cerebral activation appear to be associated with the hypnotic state.

Other researchers have demonstrated the effectiveness of hypnotic analgesia on raising pain thresholds by examining the nociceptive flexion (RIII) reflex and EEG patterns (Danziger, et al., 1998).

However, the real question for clinicians is, "Can learning to develop hypnoanalgesia to noxious stimuli in a laboratory (an acute short-term artificial environment) be generalized to a patient's ability to control real nociceptive acute or chronic pain. Crawford (1998) found that chronic back pain patients could be trained to utilize hypnotic analgesia on a noxious stimulus and then generalize the hypnotic analgesia to their back pain. They concluded that "hypnotic analgesia is an active process that requires an inhibitory effort dissociated from conscious awareness, where the anterior frontal cortex participates in a topographically specific inhibitory feedback circuit that cooperates in the allocation of the thalamocortical activities." They further point out that the subjects could successfully transfer the experimental pain reduction to reduction of their own chronic pain and, in so doing, also experience increased well-being and increased sleep quality.

Utilizing a modulated form of pain, patients can learn the hypnotic skill of pain control or the raising of their pain thresholds. They can then be taught to generalize this skill to pain situations that are more a function of their illness or injuries.

Hypnotic analgesia has also been shown to reduce subjective pain perceptions and the nociceptive flexion reflex in high-hypnotizable subjects (Sandrini, Mianov, Malaguti, Nigrelli, Moglia, & Nappi, 2000). This raises yet another question. If pain can be unlearned via hypnoanalgesia, does it imply that at least to some degree it is a psychoneurologically learned behavior? The concept of the existence of a "neural signature of pain" that acts as a progenitor of subsequent pain experiences is offered by Melzack (1983). If this is so, we should teach patients how to communicate more positively when in acute pain stages before they develop chronic pain. Meta-analyses of 18 studies revealed a moderate-to-large hypnoanalgesia effect supporting the efficacy of hypnotic technique for pain management in both clinical and experimental pain settings (Montgomery, Dultamel, & Redd, 2000).

When we speak of pain patients and hypnosis, another important question is raised. Does hypnosis work equally well for all patients? The literature seems to suggest that numerous variables must be considered in drawing any conclusions. Issues of patients' hypnotic susceptibility, chronic vs. acute pain, and the origin and etiology of the pain are relevant factors.

In the realm of hypnosis, the question of the importance of hypnotic susceptibility and trance depth has long been debated (Frankel, Apfel, Kelly, et al., 1979; Hilgard & Hilgard 1979; Perry, Gelfand, & Marcovitch, 1979) especially with regard to pain (Hilgard and LeBaron 1982). Recent studies that have examined the importance of hypnotic susceptibility of pain patients (as opposed to non-pain patients) appear to indicate that when dealing with acute pain issues, hypnotic susceptibility is very important. Sandrini, et al. (2000) examined subjects rated as either high or low susceptibles on the Harvard Group Scale of Hypnotic Susceptibility (Shor & Orne, 1963) and the Stanford Hypnotic Susceptibility Scale (Weitzenhoffer & Hilgard, 1959). Utilizing a noxious stimulus, they concluded that, "the susceptibility of the subject is critical in hypnotically induced analgesia. Similarly, high hypnotic but not low hypnotic subjects demonstrated significant reductions in pain intensity and reduced nociceptive receptive reflexes during hypnotic analgesia (Zachariae, et al., 1998).

Increased hypnotizability was also found to positively affect sensory and pain thresholds during dissociated imagery and focused analgesia as measured by skin conductance responses, somatosensory event-related potentials, and pain perceptions (De Pascalis, Maguarano, & Belluschi, 1999). The ability to modulate pain was greater when subjects demonstrated higher hypnotic suggestibility (Rainville, 1999b). Controlled associative ability (Agargun, Tegeoglu, Kara, Adak, & Ercan, 1998) and the ability to utilize internal (guided imagery), and external distractors (word memory and pursuit of motor tasks) were also found to be effective only in high susceptibility subjects fulfilling analgesic suggestions (Farthing, Vonturino, Brown, & Lazar, 1997).

Is then the low suggestibility patient subjugated to not being able to utilize hypnosis or is suggestibility trainable? In a brief training experience Milling, Kirsh, and Burgess (1999), utilizing the Carlton Skill Training Program, found

that training failed to increase overall suggestibility scores or to enhance the effects of a suggestion for pain reduction. However, pain reduction was more highly correlated with post-traumatic levels of suggestibility than to pre-treatment suggestibility.

Many authors have thought that hypnotizability is a skill that is enhanced with practice but occurring at a rate set by the patient. It has been further suggested that "hypnosis may be best conceived as a set of skills to be deployed by the individual rather than as a state" (Alden and Heep, 1998). Others have suggested that hypnotic susceptibility may not be a factor in treatment. In a study of hypnotic susceptibility and the treatment of irritable bowel syndrome, hypnotic susceptibility to suggestion was not a factor in the positive effect found for hypnosis (Galovski and Blanchard, 1998). Utilizing the Hypnotic Induction Profile as part of the hypnotic experience, clinicians can within 5 to 10 minutes assess a patient's hypnotic response capabilities and provide the patient with an initial first-hand experience (skill acquisition trial) of what hypnosis is like (Spiegel and Spiegel, 1978/87). Any patient, but especially pain patients, may spontaneously shift to an altered state of awareness increasing their suggestibility merely as a function of their motivation to develop rapid rapport and trust in the clinician in an effort to escape the pain (Araoz, 1985).

A simple but effective means of incorporating the patient's willingness to accept suggestion is presented by Eimer (2000) who, at the end of an induction concludes, "As you go deeper and deeper into relaxation and hypnosis, the door way to your unconscious opens and, with your permission, I have the opportunity to talk directly to your unconscious and give it the information it needs to help you make the changes you want to make"(p. 20).

A review of the literature points to an increasingly broadening range of applications of hypnosis in treating medical conditions with associated pain. One area where hypnosis has been utilized for both acute pain and healing is with burn victims. Hypnosis has been shown to reduce pain even in situations where opioids fail to bring relief (Ohrbach, Patterson, Carroughen, & Gilbram, 1998). Treatment and dressing changes can be an extremely painful part of burn care. Wright and Drummond (2000) found that rapid induction analgesia (RIA) was effective in reducing pain and anxiety associated with dressing changes, and Ewin (1986) found that hypnosis positively reduced pain in adults during debridement. Similar findings were also found with pediatric patients (Foertsch, O'Hara, Stoddard, & Kealey, 1998). Indeed, burn victims may demonstrate enhanced receptivity to hypnotic suggestion secondary to issues of motivation, dissociation, and regression (Patterson, Adcock, & Bobardier, 1997), especially within the subset of burn patients who report high levels of baseline pain (Patterson and Ptacek, 1997).

Another area where hypnosis has been extensively utilized is in the arena of surgical intervention. Hypnoanesthesia, the use of hypnotic suggestion rather than general anesthesia to mediate pain during surgical intervention, has been successfully employed for endocrine cervical surgery (Defechereux, Meurisse, Hamoir, Gollogly, Joris, & Faymonville, 1999; Meurisse, Hamoir, Defechereaux, Gollogly, Derry, Postal, Joris, & Faymonville, 1999). Hypnosedation (hypnosis in combination with conscious IV sedation and local anesthesia) has been employed as an alternative to traditional anesthetic techniques (Faymonville, Meurisse, & Fissette, 1999; Meurisse, et al., 1999).

Hypnosis has also been shown to provide proprioceptive pain and anxiety relief, reduced Alfenta and Midazolam requirements and increased patient satisfaction and surgical conditions when compared to other surgical stress strategies in patient receiving conscious sedation (Faymonville, Mambourg, Joris, Vrijens, Fissette, Albert, & Lamy, 1997). Audiotaped hypnotic instructions produced reduced anxiety (Ghoneim, Block, Sarasin, Davis, & Marchman, 2000) while pre-operative hypnosis resulted in a reduction of consumption of analgesics (Engvist and Fischer, 1997) in third molar surgeries.

Self-hypnosis has been employed as an anesthesia for liposuction surgery (Botta, 1999) and for postoperative levels of pain control and relaxation in coronary artery bypass surgery (Ashton, Whitworth, Seldonridge, Shapiro, Weinberg, Michler, Smith, Rose, Fisher, & Oz, 1997) and arteriotomies (Austan, Polise, & Schultz, 1997). It is attributed to reduced reported pain and anxiety and improved hemodynamic stability during invasive medical interventions such as percutaneous vascular and renal procedures (Lang, Benotsch, Fick, Lutgendorf, Berbaum, Berbaum, Logan, & Spiegel, 2000). In particular, hand surgery that requires painful rapid remobilization of the hand is especially benefited by hypnosis. Hypnosis reduces perceived pain intensity allowing patients to be more compliant and able to withstand physical rehabilitative interventions (Mauer, Burnett, Ouelette, Ironson, & Dandes, 1999), as well as increased rates of anatomical and functional healing (Ginandes & Rosenthal, 1999).

Hypnosis also has demonstrated efficacy with children dealing with the pain and anxiety associated with invasive medical procedures (Hilgard & LeBaron, 1984), including bone marrow aspiration (Liossi & Hatira, 1999), resulting in lower levels of reported pain, reduced anxiety, and shorter hospital stays (Lambert, 1996; Smith & Barabasz, 1996). Distraction and imagery techniques have been shown to be highly effective in reducing pain in painful procedures (Broome, Lillis, McGahee, & Bates, 1992). Scripts and metaphors for children with painful conditions are readily available to the pediatric pain practitioner (Wester & O'Grady, 1991; Mills & Crowley, 1986).

Another significant area where hypnosis has continued to demonstrate its utility is cancer intervention. Numerous books and articles on the use of imagery and healing (Gaynor, 1994; Siegel, 1998) have discussed the psychoneuroimmunological benefits of hypnosis (see Chapter 64 on psychoneuroimmunology in this volume). For many years hypnosis has also been shown to provide significant relief and reduced suffering for cancer patients (Sacerdote, 1966; Hilgrad & Hilgard, 1975; Hilgard and Le Barron 1984) and more recently, by employing physical relaxation coupled with imagery that provides a substitute focus of attention for painful situations (Spiegel and Moore, 1997). Patients demonstrate an increased awareness of the willingness to employ hypnosis adjunctively to their standard medical care resulting in new programs that incorporate hypnosis into their treatment protocols (Lynch, 1999). As recently as 1996, the NIH Technology Assessment Panel presented its conclusion in *JAMA* that strong evidence exists for the use of hypnosis in alleviating pain associated with cancer.

Vidakovic-Vukic (1999) notes that irritable bowel syndrome (IBS) is a frequently observed painful disorder, but its etiology and pathogenesis are still unknown. However, it is clear that individual perceptions may play an important role in its pathogenesis. Vidakovic-Vukic points out that in recent years hypnotherapy has been shown to be successful in the treatment of IBS, resulting in either reduced or complete disappearance of pain and flatulence and a normalization of bowel habits. Similar results with a hypnotic treatment where the focus of intervention was "gut directed" and "symptom driven" found that abdominal pain, constipation, and flatulence improved, while anxiety scores decreased (Galovski & Blanchard, 1998).

McGrath (1999), based on the studies of P.J. Whorwell and those of O.S. Palsson, presents hypnosis as a significant component in the treatment of IBS with success rates approaching 80% reported in the literature. The focus of hypnosis for IBS should be on the gut-directed and associated symptomology. In a review article, Camilleri (1999) points out that in addition to various medicinal interventions and fiber intake, hypnosis may play an important role in relief of pain in IBS patients.

Hypnosis also has been shown to be effective in acute pain care settings such as emergency room settings with burn pain, pediatric procedures, psychiatric presentations, and obstetric situations (Peebles-Klieger, 2000; Zahourek, 1985). Iserson (1999) describes a simple method of hypnosis utilized in pediatric fracture reduction on four cases of angulated forearm fractures using distraction techniques when no other form of analgesia was available. Interestingly, fracture healing also may be enhanced utilizing hypnosis. Faster edge healing, improved ankle mobility, greater function mobility to descend stairs, lower use of analgesic, and trends toward lower self-reported pain were found in patients who received hypnotic intervention in addition to standard orthopedic emergency room care (Ginandes & Rosenthal, 1999).

Hypnotically induced glove anesthesia with transference to the pain site for acute pain relief is a commonly utilized technique. This is accomplished by using suggestions of creating a numbing sensation in the hand. Patients may be asked to imagine their hands in a bucket of anesthetic gel or a glove or other such images. This numbing or pleasant sensation is then transferred to the pain site with a pleasant increase in numbness. An excellent example of this technique is offered by Basserman and Wester (1984). Other techniques include distraction techniques and dissociative techniques (Burte, 1999; Eastwood, Gaskowski, & Bowers, 1998). In all cases, a trusting rapport with the clinician appears to be a critical factor in achieving the desired goals. In addition, as has been noted earlier, pain may act as a mediator toward an altered state of increased suggestibility to pain alleviation. Acute pain patients may willingly and rapidly transfer their pain to the hypnotherapist or anyone willing to accept the pain. Patients should be reassured that proper medical care is forthcoming and they can let go of their pain. As Schafer (1996) points out, perhaps as many as half the patients in an emergency room may be in spontaneous trance. An alternative approach is to focus on the imagery the patient spontaneously reports associated with the pain. Psychosemantics and somatopsychic queues are observed when utilizing the patient's perceptions, internal representations, and understandings of the pain to alter the cognitive, emotional, and sensory experience (Burte and Araoz, 1994).

Utilizing the New Hypnosis Model developed by Daniel Araoz (1985), patients are helped to achieve an altered state of internally directed experiencing of their symptomology. By focusing on the way they interpret and communicate their pain through any or all of their five senses, patients are led to a reinterpretation and understanding of their ability to modulate their pain. How patients integrate pain sensations will impact their pain thresholds. Positive suggestions to pain altered the amount of time that patients could keep their hands immersed in ice water (Staats, Hekmat, & Staats, 1998). For example, in the case of an individual with recently cracked ribs, he may be asked to experience or visualize the ribs as they appear to him. He is then asked to visualize ways to soothe, protect, or heal the ribs (i.e., an anesthetic band wrapped around the chest, relaxing, protecting, and healing the area of injury), while communicating calming, relaxing, and possibly "in control of the situation" thoughts. At times, visualizing being in a safe or pleasant situation helps induce a hypnoidal form of relaxation or mild dissociation. Though creating relaxation has often been seen as an important element-inducing trance for the pain patient, it may be a secondary goal with the imaging or individualized experience of the pain as the primary pathway to the hypnotic state.

Acute pediatric pain represents a somewhat different issue in that children often lack clinical insight regarding their condition, an understanding of the etiology, potential longevity, or plausible interventions available for amelioriating their pain, concepts that help adults cope with acute pain more effectively. Patients provided appropriate preoperative information demonstrate less acute pain (Stevensen, 1995). Hypnosis may represent a complementary treatment in conjunction with other forms of intervention such as pharmacological pain management (Russ & Weisman, 2000). By providing cognitive and behavioral schemata via modalities easily accessed by children (i.e., imagery, fantasy), the acute pediatric pain patient can be empowered similarly to the way adults utilize reason to empower coping ability with pain.

Hypnosis may be a means of reducing both pain and pain-related distress (Chen, Joseph, & Zeltzer, 2000). For example, Adam, a young cancer patient was treated utilizing hypnosis for pain. First he was taught glove anesthesia which he applied to areas where he was to have finger sticks, Broviac changes, and later bone marrow aspirations. He was taught to visualize himself as a cartoon super hero named He-Man. By lifting his crutch and later his finger into the air and reciting the words, "By the power of Grey Skull I am He-Man," Adam was magically (hypnotically) transformed into He-Man, the strongest man in the universe. At such times, he could withstand increased levels of pain and invasive procedures.

Recurrent pediatric headaches appear to show a positive response to hypnotic intervention when relaxation and/or thermal feedback techniques are employed (Holden, Deichman, & Levy, 1999). The use of autogenic training (hand warming) with imagery has also been useful in reducing or eliminating pediatric migraines when done early into the migraine episode at the first signs of visual aura or muscular discomfort.

Crawford, Knebel, Kaplan, Vendermia, Xie, Jamison, and Primbam (1998), in drawing attention to the transition of the acute pain to the chronic pain patient, note that by utilizing hypnosis, patients could alter acute pain experiences. They further suggest that learned hypnotic analgesia resulted in reported chronic pain reductions, increased psychological well-being, and increased sleep quality. The "neurosignature of pain" can influence subsequent pain experiences (Melzack, 1983). Specific pain reduction hypnotic skills may indeed be essential in developing lasting pain relief, especially in situations where chronic pain based on medical conditions (i.e., cancer tumors, herniated discs) is anticipated. In this context, hypnotic pain control may be conceived as a set of skills rather than a state (Alden & Heap, 1998).

Chronic pain patients clearly represent a different population than acute pain patients. The most common form of chronic pain, other than from illness, is chronic low back pain, accounting for $50 to $100 billion dollars a year in lost wages and medical care (Burte, Burte, & Araoz, 1994; Miller & Krauss, 1990). Unlike acute pain, chronic pain may result in significant changes in individuals, personalities, and clinical presentations as evidenced by performance on MMPI profiles (Strassberg, Tilley, Bristone, & Oei, 1992).

Chronic pain patients clinically demonstrate elevated levels of feelings of hopelessness, helplessness, and despair. They often report ongoing struggles with depression, somatic preoccupations, and obsessive concerns with fatal illness (Miller & Krauss, 1990). When chronic pain becomes a central issue in the individual's life, it may function as a coping mechanism altering the patient's capacities, both psychopathophysiologically and etiologically (Kuhn, 1984). In addition to its direct impact on pain alleviation, it is with the depression and hopelessness the chronic pain patient experiences that hypnosis can play a key role. Metaphors and hypnotic scripts can address both the pain and psychological distress (Havens & Walters, 1989). Individuals who are diagnosed with what would today be referred to as chronic pain syndrome (CPS) often are overwhelmed by the impact of their pain. For CPS patients the pain often takes on an all-encompassing life of its own, dictating the patient's quality of life both psychologically and physically. The CPS patient's pain alleviation is often complicated by issues of learned behaviors, conditioned avoidances, and conscious and unconscious secondary gains. Hypnotherapy represents a complementary component in a multidisciplinary approach that should first acknowledge that the CPS patient is not primarily a psychiatric patient but rather a composite of both psychological and physical distress. Melzack (1990) points out the advantages of a multidisciplinary approach inclusive of narcotics, for the purpose of rescuing people in chronic pain. As Hitchcock (1998) points out, there are significant myths and misconceptions about the chronic pain patient that the pain practitioner must address in formulating a treatment plan. She further points out that in many ways the patient is a valuable contributor to the understanding of his or her own condition. As such, hypnosis may assist patients in that understanding via uncovering techniques and experiential insights into various aspects of their pain.

In addition to low back pain, many other conditions can result in CPS. Patients experiencing temporomandibular disorders who underwent hypnotic intervention demonstrated significant decreases in pain severity and frequency which were maintained for at least 6 months after treatment (Simon and Lewis, 2000).

Self-hypnosis has been used adjunctively in dealing with pain associated with sickle-cell anemia (Dinges, Whitehouse, Onre, Bloom, Carlin, Bauer, Gillen, Shapiro, Ohene-Frempong, Dampier, & Orne, 1997). Hypnosis has helped adolescent teens and adults with cystic fibrosis (CF) develop improved attitudes about health and a sense of independence and decreased anxiety (Belsky & Kahanna,

1994; Olness & Kohen, 1996). Utilizing a technique introduced by Bressler (1990), Anbar (2000) taught CF patients to seek an inner advisor while in self-hypnosis to uncover information pertaining to their physical or psychological symptoms. In so doing, they achieved greater levels of physical comfort and reduced anxiety levels.

Hypnotic intervention resulted in improvement in symptoms resulting from multiple sclerosis (Sutcher, 1997); fibromyalgia syndrome, especially when utilized as part of a multidisciplinary treatment (Berman & Swyers, 1999); and phantom limb-pain (Sthalekar, 1993; Muraoka, Komjama, Hosoi, Mine, & Kubo, 1996). The list of illnesses, disease conditions, and injury-induced pain conditions for which hypnosis has historically been utilized and for which its application may apply is beyond the scope of one chapter. A review of the literature suggests that its clinical application is continually expanding.

Another arena where hypnosis may play a significant role in pain management and suffering is with patients experiencing psychogenic and psychosomatic pain. Through the use of the affect bridge (Watkins, 1971) and listening to the patient's somatopsychic language (Burte, Burtre, & Araoz, 1994) patients can gain insight into the range and variety of symptoms they are experiencing. The psychosemantics the patient utilizes in describing his or her life situations or pain offers insight into the nonorganic etiology of the conditions. Queues associated with past trauma may maintain the patient's symptoms, whereas re-associating those symptoms to positive images may result in symptom reduction or alleviation (Burte, 1993). With the psychosomatic patient with no known organic etiological basis for the pain the exploration of the negative self-hypnotic (NSH) statements associated with the condition will lend insight into the symptom output. This is especially relevant with patients experiencing sexual dysfunction associated with pain (Araoz, 1998; Burte & Araoz, 1994).

Techniques and case histories are presented in the above noted works, but the essence of the hypnotherapy is to have the patient, by experiencing these NSH statements in trance, identify the bridges between his or her psychic conflicts (semantic input) and the pain or dysfunctional symptoms (somatic output).

ACKNOWLEDGMENT

I thank Lea Racioppi for her assistance.

Drug Misuse and Detoxification

John Claude Krusz, M.D., Ph.D.

> … The use of drugs to alter consciousness is nothing new. It has been a feature of human life in all places on the earth and in all ages of history … the ubiquity of drug use is so striking that it must represent a basic human appetite…
>
> A. Weil (1972)

INTRODUCTION

The use of drugs that produce powerful effects on mood, affect, and thinking and alter levels and states of consciousness has been a part of our civilization since recorded history. This refers to both illicit substances (e.g., opium, cocaine, cannabis, synthetic psychoactive substances) as well as to licit and commonly available drugs (e.g., alcohol, tobacco, caffeine-containing beverages). Although the latter group of substances raises fewer emotionally heated societal concerns than the former, use and misuse of these substances are also discussed in this chapter.

CONFUSING TERMINOLOGIES

The term "drug abuse" has been used indiscriminately and is confusing and inaccurate. It commonly refers to repetitive usage of drugs that are productive of tolerance and physical dependence in a nonmedical or nontherapeutic context. The author prefers the term "drug misuse" rather than drug abuse for the following reason: On a pharmacologic level, one is not abusing the action of the drug itself. It is merely a molecule with a set of pharmacologic and biochemical activities relating to dosage and concentration, as well as route of administration, but as such no inherent ability exists to abuse what the drug does pharmacologically. The body that the drug is put into, however, is what is being abused, and in that sense, this author believes that the term drug abuse refers more to the abuse of the person, and when speaking about the drug itself, it is a case of misusing the drug. The other major point about drug misuse is that it tends to portray the idea that the drug involved is one that generally is a nonprescription medication or one upon which social sanctions have been placed. Therefore, the terms drug abuse or drug misuse are confusing and derived mostly from social definitions, as relating to people's behavior with pharmacologic substances. Different cultures consider various substances to be included in what is deemed drug misuse patterns at different times. For instance, although no one would question the drug misuse concept of a person's use of 2 liters of blended spirits per day and the consumption of 80 cigarettes in the same time on a chronic basis, one would hardly call the imbibing or consuming of the same substances for a shorter time drug misuse (e.g., New Year's Eve party, a Mardi Gras celebration). Jaffe (1990) uses the terminology "nonmedical drug use" as a substitute for the older and more confusing term drug abuse, and the author thoroughly agrees that changing the phraseology would be helpful. Terms like drug abuse tend to connote the usage of societally disapproved substances, whereas drug misuse or nonmedical drug use includes a whole spectrum of involvement and usage. This can include very casual or experimental use on a few occasions of even commonly available substances (e.g., nicotine, alcohol) to the use of certain substances for specific kinds of effects (e.g., consumption of large quantities of caffeine by students for the purposes of studying, the use of amphet-

0-8493-0926-3/02/$0.00+$1.50

amines and other central nervous system stimulants by truck drivers to circumvent occupational fatigue). The most extreme example of drug misuse, of course, would include chronic daily usage of large amounts of substances, licit or illicit, as originally conveyed in the more nonspecific term drug abuse.

DRUG ADDICTION

"Addiction" is another very confusing and, unfortunately, often misused term. Many substances are considered to be addicting, and the usual connotation of an addict is a person who is hopelessly and irreconcilably rooted in daily repetitive behaviors that are focused on obtaining and using large amounts of the same drug. In reality, the notion of addiction more properly should connote an extreme degree of drug dependence (see below). The degrees of drug dependence themselves form a large spectrum of usage from very casual to extremely habitual or addictive behaviors and are discussed in a succeeding section in this chapter. Once again, the term addiction has become distorted, and the social definition or notion of an addicted individual conveys a very severely impaired lifestyle with a daily search for, and use of, the substance to which the individual is addicted. The other confusing element for the term addiction relates to the mistaken notion that addiction is synonymous with physical dependence (see below). Physical dependence, as is discussed later, refers more to the occurrence of withdrawal symptoms upon sudden cessation of drug use, whereas addiction does not have the same inference, although, once again, in the minds of many people, the terms are often used interchangeably, and in that sense, imprecisely. It is particularly encouraging that major compendia on psychopharmacologic mechanisms of drugs do not even mention the word addiction once in their very extensive reviews of numerous categories of psychoactive substances (e.g., Psychopharmacology: Third Generation of Progress (Meltzer, 1987)).

DRUG DEPENDENCE

The term "drug dependence" is another confusing term with many different connotations. Unfortunately, it is also confused with physical dependence on drugs, and at the outset, drug dependence fits many of the characteristics of a behavioral syndrome. This implies that an individual who is using a particular psychoactive substance will devote a higher degree of effort to obtaining the substance and will presumably use the drug despite negative social and medical sanctions. The term drug dependence once again refers to a spectrum of usages, although generally it is taken to mean something more than strictly casual or intermittent use of a drug. The individual behavioral syndrome suggests that the drug is needed for social or personal well-being and that not using the drug has a greater cost to the individual's well-being and offers a poorer quality of life. Drug dependence typically includes activities designed to procure the drug upon which the patient is dependent, and the seeking and obtaining of the drug will be given a higher priority in the individual's life than other ongoing behaviors or activities. Once again, the continuum of drug dependence is very difficult to sharply demarcate from recurrent drug use on an intermittent basis, which does not have the characteristics of dependence or the behavioral syndrome of preoccupation with attainment, securing of a supply, and repeated, often daily use of the substance. In that sense, drug dependence has the connotations of compulsivity and is behaviorally similar to disorders that are chronic and relapsing in nature (Edwards, Arif, & Hodgson, 1981).

The range of drug-dependent behavior is as extreme as the concept of drug addiction (see above). On one end of the spectrum, it is as nontroubling in most people's minds as daily use of caffeine or tobacco, which certainly meet the criteria for a drug-dependent behavioral syndrome and yet do not have the social connotation of frank drug addiction. The other concept that creates a lot of confusion is the idea that the drug-dependent behavior in some way is disruptive, not only to the life of the person who engages in the drug-acquiring and drug-using behavior, but also that a societal cost exists as a result of that person's repeated search and usage of psychoactive substances.

TOLERANCE

The concept of tolerance to a drug's effect is strictly a pharmacologic issue and yet often also gets intermingled or exchanged with not only physical dependence, but also with drug dependence, as discussed above. Tolerance, in its broadest pharmacologic sense, refers to a smaller effect for any given dose of a medication or drug when given on a repeated basis. Therefore, in order to obtain the same pharmacologic effect, larger and larger doses of the medication or drug have to be administered. The classic example of tolerance to a psychoactive substance is the opiates. In this instance, tolerance includes shortened duration of effect, a decreased intensity of effect (particularly for analgesic, euphoriant, and sedating activities of the drug), as well as an increase in the dose which would be considered lethal.

Two types of acquired pharmacologic tolerance are generally discussed. One is dispositional tolerance, which has to do with increasing the rate of metabolism of the drug over time so that the same dose is more rapidly metabolized and, therefore, the effective concentration on receptors or end organs is reduced, resulting in a smaller effect. Many examples can be cited. Among the more common are the liver enzyme-inducing properties of alcohol,

anticonvulsants (e.g., carbamazepine acid, valproic acid), and barbiturates.

Pharmacodynamic tolerance refers to adaptive responses within biologic systems that are affected by the drug itself and result in a reduced response over time to the same dose of a drug. Because many of the effects are biobehavioral in nature, tolerance of the pharmacodynamic type is often noted to develop rapidly. The classic example is tolerance to the effects of opiates, particularly with regard to the euphoriant and sedating properties of the drug. Whereas tolerance to the respiratory depressant or miotic effects of opiates does not follow a similar pattern, a marked pharmacodynamic tolerance exists when the drug is given repeatedly, and this is most obvious with effects such as euphoria. Unfortunately, the escalation of a dose in a tolerant individual in order to produce a desired degree of euphoria or sedation often carries the risk of allowing toxic effects of the drug to occur (e.g., fatal respiratory depression), because tolerance to this effect of opiates does not increase nearly as much as the more behavioral effects of the drug. The underpinning of pharmacodynamic tolerance is always on the basis that the neuronal populations the drug affects become altered in their activity in the presence of continued administration of the drug.

Tolerance to a multitude of substances can occur in perhaps less dramatic ways, although the example of the barbiturates and other sedative drugs also involves pharmacodynamic tolerance. Additionally, dispositional tolerance plays a larger role in permitting the use of escalating doses of these drugs to obtain a desired degree of sedation or "high." Another factor in dispositional tolerance may lead to a decreased dosing interval based on the more rapid metabolism of the drug and excretion from the body. It certainly is conceivable that when a drug is metabolized more rapidly, a tendency to administer the drug more often exists, and in that sense the notion of the reinforcing ability of a drug comes into play. Drugs are notorious reinforcers, particularly if their effects are very profound and relatively short-lived or if their metabolism is increased at a fairly appreciable rate with continued use. The classic example of a powerfully reinforcing drug is cocaine and, to a lesser extent, amphetamines. The former substance has a marked ability to act as a reinforcer, particularly in maintaining drug misuse behaviors, simply because the half-life of cocaine is exquisitely short. Therefore, the behaviorally reinforcing repeated administration of the substance tends to promote a pattern of use which results in a rapid establishment of drug-dependent behavior. This is in the absence of any formal physical dependence on the substance, as might be encountered in the case of opiates, barbiturates, nicotine, or caffeine. This also introduces the topic of drugs as reinforcers of behavior, a powerful basic mechanism implicated in the generation of drug dependence as a behavioral syndrome (see the following section).

The phenomenon of tolerance also can transcend multiple categories of drugs. This is known as cross tolerance, and chronic exposure to one drug can frequently produce a tolerant state to other categories of drugs. Examples include cross tolerance of barbiturates to other sedative hypnotic compounds. In some cases, cross tolerance to amphetamines and cocaine and other stimulants is fairly easy to demonstrate, and perhaps more rapid enzymatic metabolism of the drugs in common may be a fundamental feature of the phenomenon of cross tolerance (Barrett, 1987).

DRUGS AS BEHAVIORAL REINFORCERS

This section attempts to outline the underpinnings of broader concepts already discussed, such as drug dependence, and some of the conditioning factors which may promote continued drug-seeking behavior. The reinforcing properties of drugs are well known, both in laboratory animals as well as in humans. Indeed, laboratory experiments have been designed to allow animals to perform repetitive tasks, such as lever- or bar-pressing, the running of mazes, and other behavioral tasks. These learned behaviors are reinforced by the reward, a dose of a drug that presumably produces a pleasurable effect and, therefore, promotes continued reinforcement and furthers behavior designed for obtaining more of the same drug. This is true for opioids, barbiturates, ethanol, and central nervous stimulants (e.g., cocaine, amphetamines, nicotine, caffeine). Many factors intervene in the effectiveness of a drug in promoting reinforced behavior, and most important are the properties of the drugs themselves, particularly if their actions are short and their euphoriant or stimulant properties are powerful in the central nervous system (CNS). The most dramatic example of reinforcement is with cocaine and amphetamines. Laboratory animals will continually bar-press, sometimes for thousands of repetitions, to obtain a single dose of the drug, even in the presence of toxic effects from the drug. Animals will literally die in their attempts to obtain more of the presumably pleasurable effects of cocaine. If placebo or saline is substituted for the drug, the furious activities will cease after a time; however, they will return with an even more rapid re-onset of behaviors if a single priming dose is given. A quite similar though less dramatic pattern is noted with morphine and other opioids. The timing and intensity of behaviors needed to raise the dose occurs at a slower rate than it does in the case of cocaine or amphetamines. A lessened pattern of reinforcement is noted in the case of barbiturates and other sedatives, and still less is seen with other drugs (e.g., nicotine), where the behavioral reinforcement is seen under a more restricted set of experimental conditions. Likewise, caffeine, despite being a

relatively powerful CNS stimulant in large doses, is a relatively weak reinforcer. A common substance like ethanol is one of the least reinforcing drugs in laboratory experimental situations. In the laboratory setting, many factors determine whether or not an animal will self-administer the drug (e.g., the CNS effects of the drug, the amount of work required to obtain a dose, the time allowed between the actual reinforcing behavior and the actual drug administration). It should be noted that these behaviors are strikingly not in the presence of any physical dependence on the part of the animals (Johanson & Schuster, 1991; Young & Herling, 1986).

The reinforcing properties may occur on both positive and negative bases. The former would be an example of behaviors that are reinforced because the drug induces pleasurable effects. The latter (negative reinforcement) would occur because the drug would terminate unpleasant or anxiety-provoking states, such as pain. Examples of negative reinforcement in a clinical setting occur with dependence on benzodiazepines and sedative hypnotics, as well as opiates, and many people continue to take the former two classes of drugs, not for their positive reinforcing effects, but rather to circumvent the onset of anxiety, panic, or other withdrawal symptoms (Busto, Sellers, Naranjo, Cappell, Sanchez-Craig, & Sykora, 1986; Wickler, 1980; Woods, Katz, & Winger, 1987).

The positive reinforcing effects of centrally acting drugs occur in spite of initially unpleasurable effects associated with initial usage of certain drugs. This is most clearly illustrated by morphine and other narcotic opiates. The initial effects associated with the use of these drugs can often produce severe nausea, vomiting, and other side effects that would appear to be not positively reinforcing. In light of this, the euphoriant and other properties of the drug are sufficiently strong, and as tolerance for the unpleasurable effects develops, the predominant reinforcer remains the euphoriant effect of the drug that promotes continued and escalating usage. Secondary reinforcers are often social factors, such as peer group or the perception that usage of the drug permits membership in an elite club or circle of friends. Indeed, peer approval is often a very strong secondary reinforcer, and this social reinforcement often will promote continued usage of a drug even though it initially causes unpleasurable effects. This is often seen in nicotine, marijuana, or alcohol usage, at least in the initial stages. One also has to consider that as physical dependence develops (see below), the onset of any unpleasurable effects associated with discontinuation of regular drug use will automatically promote or reinforce continued administration of the drug. This would then act more as a negative reinforcer, as outlined above in the case of benzodiazepines, although it is most dramatically encountered in the usage of morphine and other narcotics. Often, the cessation of repetitive usage of a drug will induce an anxiety-provoking aversive state, and this often is in the absence of any effects on the physical well-being of the individual. The perception of dysphoria and the threat of being left in a behaviorally anxious state often are powerful negative reinforcers for continued use of a drug. Even a drug such as nicotine, which does not produce a strong state of physical dependence, often will be extremely difficult to stop using because of very subtle perceived threats to one's well-being in the absence of the drug. This, therefore, promotes continued usage of the substance, presumably because there is an effect on psychological well-being with the nicotine present and a perception that all is not well if one does not continually administer the nicotine in the form of cigarettes or tobacco. Modern approaches to withdrawal from nicotine include use of chewing gum or patches of nicotine in a graded dosage to slowly taper away from the usual blood levels of nicotine, which are self-administered during the day when one smokes (see section on nicotine). These principles of positive and negative reinforcement are based on learning theory, and the issue of continued drug usage can be viewed as behavior which is maintained by the consequences of the drug action on the individual (Jaffe, 1989, 1990; Kaplan & Saddock, 1988).

PHYSICAL DEPENDENCE

The concept of physical dependence, mentioned previously, principally relates to repetitive use of a substance that establishes biochemical and pharmacodynamic tolerance factors in biologic systems (neuroadaptation), such that when drug use is stopped, a state of withdrawal occurs. This withdrawal state is the hallmark of physical dependence and is based strictly on alterations in the neuroadapted state of the organism consequent to repeated drug administration, usually of a drug that demonstrates principally pharmacodynamic tolerance but also may exhibit dispositional and other tolerances. By definition, a strongly positive reinforcement has already occurred, and the existence of a severe degree of drug dependence, together with behaviors that in the past may have been termed addiction, is accompanied by a severely modified neuroadaptive state secondary to the drug use. This neuro-adaptive state is a physiologically, biochemically, and pharmacodynamically changed system, which has been acted upon by the medication used, and these systems have been modified initially by the drug producing the physical dependence. The sine qua non of physical dependence is the expression of a state of withdrawal when the drug is abruptly terminated. It is implicit in the model of withdrawal that CNS functioning has been altered by continued administration of a drug. How rapidly the CNS returns to its baseline state after discontinuance of the drug is different for various medications or drugs, and withdrawal symptoms can be quite severe. Based on long-term usage of drugs like morphine or

opium, withdrawal symptoms can be even more profound and onset faster with pharmacologic antagonist medications (e.g., naloxone), and one can demonstrate withdrawal symptoms after a single dose of morphine by administering naloxone or nalorphine (Bickel, Stitzer, Bigelow, Liebson, Jasinski, & Johnson, 1988; Heishman, Stitzer, Bigelow, & Liebson, 1989).

Diagnostic criteria for opioid withdrawal have been developed and published in the DSM-III-R Diagnostic and Statistical Manual of Mental Disorders (American Psychiatric Association, 1987). Some of these criteria involve cessation of prolonged moderate or heavy use of an opioid (this is defined as several weeks or more) or, alternatively, reduction in the amount of opioid used, succeeded by at least three of the following: (1) craving for an opioid, (2) nausea and vomiting, (3) muscle aches, (4) lacrimation or rhinorrhea, (5) pupillary dilation, (6) piloerection or sweating, (7) diarrhea, (8) yawning, (9) fever, and (10) insomnia. These diagnostic criteria, although by no means complete, at least give a list of withdrawal effects that can be seen in the acute phase after discontinuance of chronic or even acute opiate use.

Abstinence syndromes create a spectrum of effects. The immediate syndrome of abstinence is as exemplified in the case above. Less dramatically, withdrawal from alcohol, cocaine, nicotine, or sedative/hypnotics, though productive of many symptoms, is a fairly benign event. The most life-threatening symptom for medical management is the occurrence of seizures. These are usually single in occurrence and rarely require medication. Similarly, even withdrawal from morphine rarely produces any life-threatening sequelae, although the person undergoing withdrawal may be extremely uncomfortable until the neuroadapted state returns to its biologic baseline.

DRUG MISUSE AS PRIMARY PSYCHIATRIC DISEASE

The misuse of psychoactive drugs raises some fundamental questions about whether or not such use can be considered principally a behavioral disorder or principally a psychiatric disorder. The author favors the former, and although a large body of data has been developed to categorize dependence and substance "abuse" (American Psychiatric Association, 1987), the author is by no means certain that the vast majority of tolerant and dependent states consequent to repeated drug use are indeed based on fundamentally psychiatric diseases.

While it is true that patterns of drug misuse can be quite profound and can coexist with well-recognized psychiatric entities like bipolar and manic depressive illness, schizophrenia, schizotypal, and the whole range of affective disorders, the author has noticed a strong pattern of drug misuse by patients who otherwise manifest evidence of organic brain dysfunction. For example, the author has observed that patients with neurobehavioral seizures (e.g., intermittent explosive disorder, temporal lobe syndromes, other behaviorally aberrant states) often give a history of self-administering psychoactive substances for the purpose of reducing internal anxiety and to produce a sense of calm and relative order insofar as their behavior and thought processes are concerned (unpublished observations). Furthermore, certain individuals will have documentable abnormalities on the electroencephalogram (EEG) and quantitative EEG (brain mapping). Some of these individuals, while they may require traditional psychiatric diagnoses as they are treated in the medical system, actually may have more of a fundamental organic derangement of their thought processes, emotions, and affect, as is often the case in temporal lobe disorders. Some of these patients exhibit features behaviorally compatible with an organic brain disorder, such as a partial complex seizure. This may manifest itself in purely behavioral terms and may be relieved or ameliorated by (self-medicated) psychoactive drug use. Often, patients will give a history of feeling calmer, thinking more clearly, and other positive aspects related to ongoing and repetitive use of amphetamines, cocaine, marijuana, or sedative hypnotics. From a neurologic and neurobehavioral standpoint, this type of history is not, in the author's opinion, fundamentally a psychiatric problem, but rather an organic state relievable by pharmacologic administration of psychoactive substances. This often predisposes an individual to many maladaptive patterns of behavior, and the issues of tolerance, physical dependence, and alteration of lifestyle based on sustained drug-seeking and drug-using behavior often become the primary focus of medical attention, whereas in reality one could postulate that these are secondary spin-offs of an organically aberrant neurologic state. Nevertheless, various psychiatric criteria have been developed for different kinds of drug misuse, and the history and evolution of psychiatric thinking in this area are well summarized by Jaffe (1989). A very nicely summarized and coherently presented chapter on these phenomena is to be found in Dr. Steve Stahl's book Essential Psychopharmacology.

The evolution and refinement of biologic and psychiatric criteria regarding psychoactive drug use are very much active processes and continue to progress. Indeed, it will be interesting to see what new revisions are proposed in upcoming DSM versions. One can certainly make a good case for the coexistence of primary psychiatric disorders and concurrent maladaptive drug use patterns as perhaps secondary biologic factors. Concurrent psychiatric treatment of both elements often comes under the rubric of dual diagnoses, wherein a primary psychiatric diagnosis is treated at the same time that one attempts to detoxify or eliminate psychoactive substance misuse patterns.

This portion of the chapter outlines major issues relating to usage of specific categories of psychoactive substances and includes a short synopsis of the scope of the problem. This was very well summarized by Mello and Griffiths (1987). The initial focus is on drugs with the largest societal impact (i.e., alcohol and tobacco), rather than focusing on the more traditional "hard core" items, such as narcotics and stimulants. From a psychiatric viewpoint, the overuse of alcohol and alcohol dependence ranks quite high in relationship to other psychiatric disorders. They outdistance other major psychiatric diseases, such as depressive disorders, phobias, schizophrenias, and phobic disorders, at least in terms of their lifetime prevalence rates. This translates into an enormous impact on public health issues, societal productivity, and the like. It has been estimated that in excess of $100 billion per year is lost in terms of productivity, actual and projected medical costs, and the effects of crime related to the pursuit of psychoactive drugs. This is probably a very conservative estimate, and the author suspects that the above figure, taken from a 1984 estimate, is probably a fifth of the actual cost to society. This is particularly true if one considers including overusage of legal intoxicants, such as alcohol and nicotine.

Major forces and trends have developed in the medical world, and a much greater societal awareness of the impact of repeated use of alcohol and nicotine currently exists. The overall usage of hard liquor has decreased somewhat, although this may be offset by continued and escalating nationwide usage of "softer" forms of alcohol, such as wine and beer. Generally, patterns of nicotine use have diminished somewhat, although this is still a very large problem in the adolescent or teenage population and continues to be a major problem in terms of lung cancer rates, particularly in women. A WHO report cites that 25 to 45% of women are smoking in wealthy nations worldwide. This is the first international study of women and tobacco use, and data suggest that female smokers will outnumber male smokers in the near future (American Medical News, 1982).

The 1980s saw an explosion in cocaine usage, both in its usual hydrochloride form as well as in free-base or crack cocaine form. The overall usage of cocaine seems to have decreased somewhat, with an increasing trend seen in the usage rate of addicting opiates, such as morphine and heroin. Indeed, designer-type drug use has been prominent as clandestine chemists seek to modify or improve existing opiate molecules. One unfortunate spin-off of such experimentation resulted in the appearance of a syndrome virtually indistinguishable from idiopathic Parkinson's disease based on the toxic effects of an impurity in the synthesis of illicit meperidine (Langston, Ballard, Tetrud, & Irwin, 1983). The neurotoxin identified destroyed the very same subnucleus in the substantia nigra which is etiologically and pathophysiologically involved in idiopathic Parkinson's disease. A small epidemic of young, opiate-misusing individuals surfaced in a fairly short time in California in the early 1980s. Obviously, this side effect was an unintended one, but is pharmacologically treatable with dopaminergic agents normally used to treat idiopathic Parkinson's disease.

Other "designer" opiates, such as alpha-methylfentanyl, also surface from time to time and speak to the creativity of individuals attempting to use opiate derivatives on a chronic basis. These designer drugs are usually structurally similar to the more regulated pharmaceuticals and represent an attempt to evade regulatory control and legal ramifications. Another so-called designer drug is MDMA ("Ecstasy," "hug drug") (Peroutka, 1987). This is only one representative of a whole family of phenyliso-propylamines, which share CNS stimulant and hallucinogenic properties. Recreational drug use of derivatized substances continued to be very prevalent in the 1990s. A number of items have been enjoyed, including gamma-hydroxybutyrate (GHB), flunitrazepam, and a host of amphetamine analogs, such as MDMA, MDEA, paramethylthioamphetamine, DOET, DMA, TMA, and some of their derivatives, and represent some 50 compounds with potential for widespread illicit use. As noted above, they also bridge pharmacologically distinct categories of psychoactive substances (Glennon, 1987). These designer substances are covered here in more detail.

MDMA (3,4-methylenedioxymethamphetamine) "Ecstasy," XTC, "Adam," "E"

This substance has probably enjoyed more use or, more properly, has been more widely enjoyed in the last decade than virtually all other designer drugs. MDMA was shown to consistently produce, in humans, increases in systolic and diastolic blood pressures, pupillary diameter, heart rate, and rises in plasma cortisol and prolactin (de la Torre et al., 2000). In rats, acute doses produced a hyperthermic response. One week after acute dosing, about 50% of 5HT and 5HIAA were lost in cortex and hippocampus, as were binding sites to SSRI drugs, thus indicating degeneration of 5HT neurons in the brain due to MDMA (Colado, Granados, O'Shea, Esteban, & Green, 1999). This remarkable toxicity to the serotonergic system has been consistently observed and is a peculiar feature of MDMA and related compounds like MDEA ("eve"). One hypothesis relates depletion of intraneuronal 5HT to activation of post-synaptic 5HT2a/c receptors located on GABA interneurons. This then leads to decreased GABA transmission and consequent increased dopamine synthesis and release that then is taken up by the formerly depleted 5HT containing neurons. The excessive dopamine in the 5HT nerve terminal is then deaminated by MAO-B, causing degeneration of 5HT nerve terminals (Sprague, Everman, & Nichols, 1998). Chronic users of MDMA showed

depressed serotonergic functions, including reduced prolactin and cortisol responses compared to controls, weeks after stopping the use of MDMA (Gerra, Zaimovic, Giucastro, Maestri, Monica, Sartori, Caccavari, and Delsignore, 1998). Cognitive problems have been documented in MDMA users. They had difficulties with sustained attention tasks and verbal and visual memory. Poorer memory performance was associated with lower CSF 5HIAA levels (Bolla, McCann, & Ricaurte, 1998). Parrott and Lasky (1998) described the effects of MDMA ("Ecstasy") on mood and cognition before, during, and after a Saturday night dance. Several days after ingestion of MDMA, users felt more depressed, abnormal, unsociable, and less well tempered than nonusers. They also performed more poorly on memory tasks. Criteria for dependence were met in several cases of chronic and heavy MDMA users (Jansen, 1999). Attempts have been made by PET scanning techniques to correlate the effects of MDMA on brain 5HT synthesis. In the dog, 5 hours after MDMA infusion, 5HT synthesis was about half of that at baseline and about one thirteenth of the synthesis seen 1 hour after infusion of MDMA, when a large increase was noted. A decrease in 5HT transporter binding was also seen in PET studies (Nishisawa, Mzengeza, & Diksic, 1999). Recently, MR spectroscopy studies (Chang, Ernst, Grob, & Poland, 1999) have shown that the brains of MDMA users have larger myoinositol fractions in parietal white matter, suggesting increased glial content and possibly inferring neuronal damage in these areas. Amphetamine analogs can cause seizures as one consequence of overuse. The characteristics of stimulant-induced seizures were studied by Hanson, Jensen, Johnson, & White (1990). Methamphetamine-related seizures were influenced only by diazepam and valproate whereas other anticonvulsants were ineffective.

MDEA (3,4-methylenedioxyethamphetamine) "Eve"

This is another of the many substituted amphetamine analogs; it is not as popular or available as MDMA. However, it, too, has been shown to produce serotonergic deficits and impair memory in rats (Barrionuevo, Aguirre, Del Rio, & Lasheras, 2000). MDEA also produces dose-related hyperthermia, and also affected 5HT transporter density in the frontal cortex and in the hippocampus. The pathology of fatal toxicity due to MDEA ingestion has been studied in seven males aged 20 to 25 (Milroy, Clark, & Forrest, 1996). Marked changes were identified in the liver with cell necrosis. Changes consistent with catecholamine-induced myocardial damage were seen in most of the cases. In the brain, perivascular hemorrhagic changes were noted in four cases. The changes were similar to those seen in heat stroke, although only two cases had documented hyperthermia. An additional report (Arimany, Medallo, Pujol, Vingut, Borondo, & Valverve, 1998) reported intentional overdose and death with MDEA.

2-CB (4-bromo-2,5-dimethoxyphenethylamine) also known as Synergy, Herox, Nexus, Venus

This psychoactive substance is a hallucinogen enjoyed as a designer drug. It is one of a number of psychedelic substances initially created by the libertarian pharmacologist, Dr. Alexander Shulgin. It has been described as an example of an empathogenic agent, as have MDMA, GHB, and other related substances (Velea, Hautefeuille, Vazeille, & Lantran-Davoux, 1999). These agents are overused at all-night parties called "raves," where obligatory prolonged social contact is part of the environment. 2-CB itself produces mild confusion, stupor, and a childlike interest in visual phenomena; a typical dose is 20 to 40 mg; the effects last up to 6 hours.

GHB (gamma-hydroxybutyrate) also known as "G"

This fatty acid derivative is structurally similar to GABA and has pharmacologic properties as an inhibitory chemical transmitter in the central nervous system. It has powerful CNS depressant effects and its actions may be mediated through specific receptors for this agent, or via activity on GABA-B receptors. Some of its actions also may involve alterations in dopaminergic transmission in the basal ganglia. It has been used clinically as a general anesthetic and to treat sleep disorders. It induces a state of euphoria, and has been enjoyed recreationally during the last few years (Tunnicliff, 1997). Although initially thought to be safe, recent reports (Reuters Health, 10-27-2000) confirmed 71 cases of death due to ingestion of GHB or its precursor, 1,4–butanediol (also called BD or "pro–G."). BD can be obtained on the Internet and is rapidly metabolized to GHB in the body. BD has been sold as a dietary and body-building supplement and as a sleep aid. It is also an industrial solvent. Fifteen of the deaths had no other intoxicants involved. Another case report (Harrington, Woodward, Hooton, & Horn, 1999) documented near-fatal or prolonged reactions to very small doses of MDMA or GHB in a patient who is HIV-positive and being treated with protease inhibitors. These drugs inhibit the cytochrome P-450 system in the liver and intestines and inhibit the metabolism of GHB and MDMA. GHB is also commonly used at all-night dance parties.

Of particular concern in the last decade is the escalating phenomenon of polydrug misuse. It is well known that alcoholics often abuse tobacco, tranquilizers, antidepressants, and caffeine. Similarly, physically dependent narcotic users often misuse other categories of drugs in an attempt to stave off withdrawal symptoms (see above). A common substance like marijuana is often used with alcohol and tobacco. Some of the history of legally prescribed

co-intoxicants dates back to the era of laudanum, which was a mixture of wine and opium. The emergence of polydrug use heightens the challenges for medical and other practitioners in terms of successfully reducing or eliminating simultaneous use of psychoactive substances. Also, the risk for medical complications consequent to multiple drug use escalates in parallel with the number of substances used. This poses many new kinds of problems, particularly where intravenous drug use is common. The widespread epidemic of AIDS, syphilis, bacterial endocarditis, and renal, hepatic, cardiac, and pulmonary complications of recurrent drug use add to the total cost to society (Jaffe, 1989, 1990; Mello & Griffiths, 1987).

Alcohol

The usage of ethanol is a worldwide phenomenon, somewhat more prevalent in so-called technologically advanced societies, such as North America and Europe. Alcohol is undoubtedly the single most widely used substance on the earth. It has been estimated that the total cost to society for alcohol-related medical issues accounts for 10 to 13% of the nation's total health expenditures. In 1975, the total cost in terms of accidents, crime, health-related problems, and productivity exceeded $45 billion. Obviously, accurate incidence and prevalence measures are extremely difficult to obtain, although population-based statistics show that males age 18 to 64 have the highest lifetime prevalence rate. In women, age 18 to 24, alcohol-related problems rank fourth in terms of prevalence among other psychiatric diseases (Myers, Weissman, Tischler, Holzer, & Leaf, et al., 1984; Robins, Helzer, Weissman, Orvaschel, & Gruenberg, et al., 1984).

Alcohol misuse has been separated in diagnostic criteria (American Psychiatric Association, 1987) from the older term "alcoholism." The latter term has been replaced by alcohol dependence, which implies prolonged excessive use of alcohol such that sudden cessation results in a withdrawal syndrome. The enigma of how alcohol produces its acute CNS depressant effects as well as the larger question of a specific locus of pharmacologic effect for the substance has been studied since the turn of the century. Meyer (1901) first proposed a membrane hypothesis for alcohol's intoxicating and sedating effects. He suggested that alcohol affected neuronal membrane lipids, and over the years many scientists have sought to confirm and extend his theory. Indeed, alcohol has been shown by several lines of experimental evidence to increase the fluidity of lipids in neuronal membranes. These experiments have been performed in vitro in membranes obtained from genetically sensitive mice that were predisposed to alcohol sensitivity or insensitivity. Gangliosides were found to be important in allowing alcohol's effects on membrane fluidity. Membrane-bound proteins are affected by their surrounding lipids when alcohol is present. Numerous receptor protein complexes have been shown to be affected by ethanol, including the GABA-benzodiazepine-barbiturate-chloride ion receptor, the adenylate cyclase system, including the guanine-nucleotide-dependent coupling protein (G protein), sigma opiate receptor, Na+K+-ATPase, as well as monoamine oxidase (Chen & Goldstein, 1976; Liljequist, Culp, & Tabakoff, 1986; Luthin & Tabakoff, 1984; Marks, Smolen, & Collins, 1984; Perlman & Goldstein, 1984; Tabakoff & Hoffman, 1983, 1987). Therefore, although no specific receptor has been found for alcohol, the interactions of the substance with multiple neuromodulating and neurotransmitter systems give additional depth, as well as confusion, to understanding of the basic pharmacology of alcohol.

Equally puzzling is the mechanism(s) that underlies the biochemical pharmacology of tolerance and physical dependence to alcohol. Once again, numerous lines of evidence point to serotoninergic and peptidergic mechanisms in the development of ethanol tolerance. For instance, genetically distinct rodents that self-administer alcohol have been shown to have reduced serotonin (5-HT) concentrations in the brain. Drugs that inhibit 5-HT reuptake into axonal terminals have been shown to decrease self-administration of alcohol by animal as well as human subjects. Turnover of norepinephrine in the CNS also is altered consistently during chronic alcohol ingestion by animals and humans. An association of arginine vasopressin (antidiuretic hormone) with maintenance of the tolerant state to alcohol also has been shown in numerous experiments. This naturally occurring brain peptide has multiple physiologic functions and is somehow involved in learning and memory. The reverse is also true in that antagonists to vasopressin can accentuate the loss of tolerance to alcohol. Genetically distinct rodents that lack this peptide were reported not to develop alcohol tolerance to prolonged administration of the substance (Bloom, 1989; Jaffe, 1990; Tabakoff & Hoffman, 1987).

The pharmacology of tolerance to alcohol includes pharmacodynamic tolerance, together with eventual development of a state of physical dependence when alcohol is maintained in the bloodstream at high concentrations for long periods of time. Withdrawal phenomena begin to occur within 10 to 96 hours after cessation of drinking, and so-called uncomplicated alcohol withdrawal may consist of mild tremors, anxiety, nausea, cramps, elevated blood pressure, hyperreflexia, disturbed sleep, and rebound of REM sleep, as well as hallucinations. Alcohol-offset seizures are also a relatively frequent complication of the withdrawal state and can occur even with alcohol present in the bloodstream. A reduction in blood level is sufficient trigger to onset of tonic-clonic seizures, which usually occur once or at most in brief flurries ("rum fits"). Cross tolerance demonstrated between ethanol and other sedative hypnotic drugs, including benzodiazepines, bar-

biturates, and chloral hydrate, although none exist between ethanol and opiate narcotics (Jaffe, 1990).

A more severe abstinence syndrome has been termed alcohol hallucinosis, with continued hallucinations, confusion, disorientation, weakness, and agitation. Hallucinations are often persecutory and have extremely vivid characteristics. This state may last for 3 to 4 days and has been termed delirium tremens or alcohol withdrawal delirium (Jaffe, 1990). Although most alcohol abstinence syndromes are self-limiting, delirium tremens is a medical emergency because of the instability of the cardiovascular system and also the potential for seizures. The larger long-term issue is that of a prolonged abstinent state, which can take many months or even years before normal biochemical equilibrium is established.

Biological risk for alcoholism has been shown to have genetic underpinnings, and multiple factors have been elucidated, including genetically determined differences and isoenzyme patterns for alcohol dehydrogenase, genetically distinct brain proteins, differences in brainwave EEG patterns, and in long-latency cognitive evoked potentials (P300). Two relatively distinct groups of alcoholics have been characterized, namely, type I alcoholics, who exhibit low novelty-seeking and high harm-avoidance behavior, and who drink to alleviate anxiety, and type II alcoholics, who show high novelty-seeking and low harm-avoidance behavior and who mainly drink to experience alcohol's euphoric properties (Cloninger, Dinwiddie, & Reich, 1989; Schuckit, 1987).

Although detoxification from alcohol is a complicated matter, it can be accomplished rapidly with pharmacologic and medical measures instituted to prevent seizures and acute cardiovascular collapse. Detoxification can be accomplished using lorazepam or, more traditionally, the older benzodiazepines (e.g., chlordiazepoxide) administered daily. These compounds reduce the anxiety, tremulousness, and noradrenergic overactivity associated with the acute withdrawal state. Curiously enough, conventional anticonvulsants, such as phenytoin, are ineffective in preventing alcohol-offset tonic-clonic seizures. Benzodiazepines and perhaps sodium valproate and carbamazepine may have a preferential ability to prevent alcohol withdrawal seizures. As noted above, even after the acute withdrawal state to alcohol is finished, extended abstinence features (the so-called prolonged alcohol abstinence syndrome) can occur for years, and persisting neuropsychological and electroencephalographic changes can be seen (Grant, 1987; Mendelson & Mello, 1979). Permanent impairments in brain function also are known to exist, particularly in Wernicke's disease and Korsakoff psychosis, characterized by structural changes in mammillothalamic tracts with profound disruption of memory, deranged thinking processes, and confusion, often on a permanent basis. Other long-term effects of alcohol have been seen in reproductive function, both in males and females, and human fetal alcohol syndrome has been well described in alcohol-exposed fetuses (Mello, 1987).

The treatment of alcoholism, both at the time of acute withdrawal as well as on a long-term basis, has taken many different approaches. Acute prevention of withdrawal symptoms can be accomplished readily via use of benzodiazepines, as mentioned above. On a long-term basis, if chronic anxiety is a predisposing factor to continued use of alcoholism, then it makes sense that long-term administration of benzodiazepines and other anxiety-reducing agents may prove useful. Newer agents, such as buspirone (BuSpar), which are serotonin agonists, also may play a role in the long-term treatment of alcohol-prone patients. Serotonin reuptake inhibitors, such as zemelidine and fluoxetine, have been shown to reduce alcohol consumption in alcohol-prone individuals (Jaffe, 1989; 1990).

More traditional pharmacologic approaches that have been used in the past to curb or eliminate alcohol consumption include medications like disulfiram and, to a lesser extent, carbamide. Both of these drugs inhibit the alcohol-metabolizing enzyme, aldehyde oxidoreductase (aldehyde dehydrogenase). This enzyme metabolizes a breakdown product of ethanol, namely, acetaldehyde, which is normally converted to acetic acid. Therefore, by inhibiting acetaldehyde's metabolism, levels of this intermediate build up and are associated with unpleasant side effects, such as tachycardia, flushing, vomiting, pounding in the chest, hypotension, sweating, and dizziness. These side effects are believed to act as deterrents and create a conditioned aversion to the usage of alcohol. Disulfiram was used for a long time, but its use currently has diminished because of lack of efficacy and because of ethical questions regarding its repeated administration. Other less widely used approaches from the past included the use of emetine and lithium, which produce protracted vomiting. It was felt that these agents could help induce conditioned aversion to alcohol. None of these techniques has been found to be useful routinely (Jaffe, 1989). Likewise, apomorphine, a dopaminergic agonist, also has been used as an aversive conditioning agent and is a treatment for the recurrent craving and anxiety surrounding the cessation of drinking. Clonidine has been used to reduce some of the increased central sympathetic tone in numerous drug cessation regimens, including alcohol, opiates, and CNS stimulants.

In large measure, the mainstay of rehabilitation efforts following the acute withdrawal of alcohol has centered on behavioral and cognitive therapies. The Alcoholics Anonymous 12-Step Program remains a useful tool, although the efficacy rate for successful rehabilitation from chronic alcohol use is quite low. Group and individual psychotherapeutic efforts are important concomitants in an overall approach to the rehabilitation from alcohol usage. In the last decade, it has been increasingly recognized that alcohol use is a problem not only from the standpoint of the effects of that molecule on the central and peripheral

nervous systems, but also as a worldwide problem with respect to polydrug use of multiple CNS-active agents simultaneously. Indeed, alcohol, nicotine, and marijuana are the top three drugs used in a nonmedical setting according to National Institute on Drug Abuse statistics (National Institute on Drug Abuse, 1983). Since alcohol is readily available, it is often used as a counter-drug to "smooth out" anxiety and dysphoria when other preferred centrally active agents are not immediately available. Heroin addicts in methadone programs and patients in other drug detoxification systems for cocaine and amphetamine abuse often use alcohol as a baseline tranquilizing agent. This underscores the need to search for better pharmacologic methods to treat underlying behavioral anxiety states. Perhaps newer central serotoninergic agents (e.g., selective reuptake blockers) and the buspirone category of medications may prove useful in the future. The author has observed that patients with an organically based predisposition to behavioral instability and consequent dependence on multiple centrally active agents often respond to anticonvulsant therapy in ameliorating or abating drug use (unpublished observations). More research is needed to define the rate and prevalence of CNS instabilities and usage of medications that stabilize organic brain dysfunction and their application in prevention of recurrent alcohol and other drug use (Kreek, 1987).

Nicotine and Tobacco

The practice of consuming nicotine in various forms is an example of a complex social behavior with multifactorial inputs. The initiation and maintenance of this behavior have their roots in social and cultural bases. The entire practice becomes a repeatedly reinforced, overlearned, and, in many cases, ex for automatic behavior, re-inforced by repeated conditioning. Nicotine in tobacco is a potent psychochemical, with central and peripheral nervous system effects as well as those on cardiovascular, gastrointestinal, skeletal, motor, and endocrine systems (Jaffe, 1990). Nicotine has been demonstrated to produce tolerance as well as physical dependence. Positive effects of nicotine have been demonstrated on various behavioral measures, such as facilitation of memory or attention, decrease in irritability, appetite suppression, and euphoria when administered intravenously. Animals can be taught to self-administer nicotine, although the reinforcing effects are less profound than cocaine or amphetamines. Nevertheless, the pharmacology of nicotine, together with the mode of administration wherein each puff of a cigarette can be considered a single dose of drug, make nicotine an almost ideal reinforcing agent, particularly with respect to its positive or pleasurable effects (as noted above), including behavioral alerting.

The pharmacologic mechanisms of nicotine affect the cholinergic systems of the central and peripheral nervous system with stimulation of nicotinic as well as muscarinic receptors. In addition, a large body of evidence imputes release of serotonin, dopamine, histamine, endorphins, and other neurotransmitters and neuromodulators as additional central effects of nicotine (Jones, 1987). A much more diverse pharmacology of some 4000 compounds has been identified in tobacco (when burned) and tremendously complicates the understanding of not only nicotine effects, but also effects of other potent substances contained in tobacco. Metallic ions, radioactive compounds, alkaloids, tars, cyclic aromatic hydrocarbons, and other substances have been recovered from tobacco that is burned. This makes tobacco the most complex of all misused substances and engenders great concern in terms of the epidemiology of cancers and other serious health complications, including cardiovascular diseases and peripheral vascular disease. Chronic obstructive lung disease, effects on myocardial ischemia, and acceleration of atherogenesis have also been demonstrated (Barry, Mead, Nabel, Rocco, Campbell, Fenton, Mudge, & Selwyn, 1989).

Despite the heightened national societal awareness of the ill effects of chronic tobacco use, increased usage has been reported in the female population in the last 2 decades. National rates of the incidence of lung cancer in women are approaching that in men and may well surpass it in the near future. In general, the nicotine content of individual cigarettes has been reduced, and the average amount of nicotine per cigarette has decreased from 2.3 to 1.2 mg, and the average yield of tars has similarly been reduced from 38 mg to around 10 mg per cigarette. Although the tars are much more associated with serious and even fatal medical complications, it is important to remember that so-called low-yield tar cigarettes do not contain less nicotine than the traditional high-tar preparations (Benowitz, Hall, Herning, Jacob, & Jones, et al., 1983; Jones, 1987). In addition, marked increases in national consumption of other tobacco preparations, such as snuff and chew, contribute to the problems on a national level.

Data accumulated from the literature show that the vast majority of people who have ceased using tobacco do so on their own without any formal help. Therefore, most of the persons studied in the setting of tobacco cessation really represent a minority of tobacco users. Comparatively, only a very small percentage of chronic smokers actually cease using tobacco each year, generally less than 5% (Fielding, 1985; Orleans, 1985). The abrupt cessation of nicotine use will reliably produce a withdrawal syndrome that varies in intensity from person to person. Continued craving is a chronic problem akin to the prolonged abstinence syndrome noted for alcohol and other centrally active drugs of misuse. Irritability, restlessness, difficulty in concentration, headache, and increased appetite,

together with insomnia, are frequent features of the nicotine withdrawal syndrome. Indeed, EEG changes have been documented for long periods of time after cessation of nicotine use, as are changes in physiologic parameters and performance on neuropsychological tests (Jaffe, 1990).

A host of treatment approaches have been tried, including behavioral counseling techniques and, more recently, the use of nicotine given in gradually reduced dosages, either as a gum (nicotine polacrilex and Nicorette) and most recently as a patch. Nicotine substitutes, such as lobeline, have been tried in the past, but are not very useful due to the much weaker CNS effect of this compound. Also, nicotine's inherent pharmacodynamic properties, together with the minute-by-minute regulation of dosage obtained via the practice of smoking, make oral forms of nicotine, such as gum, a poor substitute. The behavioral reinforcing effects of the act of smoking, with all of its psychosocial implications, are powerful conditioning stimuli which perpetuate the habit in the first place.

Patch forms of nicotine administration (e.g., Nicoderm™, Habitrol™) offer a continual release of nicotine into the system, such that dosage can be gradually reduced over a matter of 6 to 10 weeks and hopefully withdrawal from nicotine accomplished in a gradual manner so as not to induce negative behavioral phenomena associated with the nicotine withdrawal syndrome. Nicoderm and Habitrol patches offer only one approach to accomplish cessation of nicotine use. Many other behavioral approaches, including hypnosis and acupuncture, aversive conditioning, and other methods have met with partial success. Of prime importance is the degree of motivation on the part of the smoker to end continued usage of tobacco and nicotine. Generally, higher rates of cessation are noted in the setting of serious diseases. Physician advice often will go unheeded unless a concomitant motivator exists for stopping the use of tobacco. Clonidine also has been used in one study and was shown to be promising as an adjunct in reducing use of tobacco and other centrally acting substances.

Aversive conditioning techniques have also been tried, and one of the most effective methods is a so-called rapid smoking technique, wherein a skilled therapist works with the patient one on one. The patient inhales smoke from his or her own cigarette every 5 to 6 seconds, and this continues until the patient asks to stop administration of the nicotine. Presumably, the blood levels of nicotine create negative pharmacologic effects, such as nausea, and the author feels that this may be, in very skilled hands, an appropriate method to create an aversive environment surrounding the use of tobacco. Commercially available programs, which include many behavioral and aversive techniques, together with motivational techniques, have been available and in some ways are more effective, at least in the short term, to produce a higher cessation rate of tobacco use. Behavioral modification techniques can easily be incorporated, as can biofeedback and stress management techniques, to teach patients to substitute other behaviors for repeated use of tobacco and nicotine (Jaffe, 1989).

Caffeine

Although far less productive of dependence than many of the other substances discussed in this chapter, caffeine remains one of the most widely used substances in the world. It is a CNS stimulant and a modulator of smooth muscle contraction with pleasurable effects, both physically and psychologically. Caffeine has mood-elevating and antifatiguing properties. An average cup of coffee contains about 100 mg of caffeine, and cola-based soft drinks contain about half that amount. Tea, chocolate, and certain other plants consumed by human beings contain caffeine and other xanthine derivatives (e.g., theophylline, theobromine), which also produce CNS excitation at appropriate doses. It is not unusual to ingest 500 to 700 mg of caffeine per day, and it has been estimated that 25% of the American population does so (Jaffe, 1989).

The establishment of dependence on caffeine is an overlearned social phenomenon and is inextricably woven into many cultural practices (e.g., afternoon tea, morning coffee). From the standpoint of demonstrating withdrawal effects upon cessation of caffeine intake, one of the most prevalent neurologic symptoms is that of headache, together with increased fatigue. Headache, including vascular migraine syndromes, can be precipitated or exacerbated by removing caffeine from the diet. Rarely, headaches will increase and persist for weeks after curtailment of caffeine intake. Complaints of fatigability and decreased alertness also are common after stopping caffeine use. From a pharmacologic viewpoint, caffeine is a much weaker reinforcer of animal behavior in the laboratory than other CNS stimulants, such as cocaine and amphetamines. Chronic users of caffeine rarely report any euphoriant effects. After abstaining from the use of caffeine, reintroduction of the substance will institute pleasurable effects in former chronic caffeine users. Thus, a low level of neuroadaptation occurs with chronic caffeine use. Once again, its short half-life lends itself to repeated administration and thus chronic repetitive dosing, which tends to escalate the daily dose of caffeine. In most cases, caffeine can be withdrawn reasonably slowly without any adverse physiologic effects other than transient fatigue, irritability, and possibly headache. In fact, caffeine is found in many ergotamine preparations and has been used as an adjunctive medication for the treatment of migraine. Many patients with chronic headaches can keep the headache pattern at bay with caffeine dosed repeatedly throughout the day.

Extremely high doses of caffeine can theoretically produce sufficient excitation to allow seizures to occur, particularly in patients with lowered seizure thresholds.

Societally, caffeine overusage tends to be part of programmed behaviors, including concomitant use of nicotine. The DSM-III-R (American Psychiatric Association, 1987) diagnostic criteria for psychiatric disorders include that of caffeine intoxication, usually ingestion of more than 250 mg of caffeine. In special situations, it may contribute to behavioral instability and thus may warrant medical intervention to reduce unwanted side effects often seen with intake of large doses of caffeine.

Cannabis (Marijuana)

This CNS intoxicant has, from a world viewpoint, the highest rates of usage, and it has multiple pharmacologic properties, including euphoriant, mood-stimulating, behavioral, and potent cardiovascular effects. References to usage in Indian and Middle Eastern literature of the forms that are available reveal that cannabis and cannabis products go by many names, from the euphemistic "grass, weed, reefer, and pot" to ganja, bhang, dagga, hashish, and sinsemilla. All cannabis is derived from the flowering tops of hemp plants, and the plant is indigenous to many parts of the world. The plant contains over 400 chemicals, and about 50 of these are cannabinoids. The most abundant psychoactive cannabinoids include cannabinol, cannabidiol, and isomers of tetrahydrocannabinol (THC). The isomer responsible for most of the characteristic effects of ingested or smoked marijuana is D9-THC and it is responsible for many of the psychostimulant, euphoric, and, in higher dosages, hallucinogenic properties of the parent plant. Different cultures have extracted the active ingredients in various ways. In most cases, plants are harvested and dried, and dried leaves and flowering tops are usually smoked, ensuring a rapid onset of effect. Extraction of the cannabinoids into solvents also can produce potent pharmacologic effects. The THC content of cultivated marijuana has steadily increased. In the 1960s, average THC content was 1 to 2% in domestically grown marijuana, whereas today it is not uncommon for harvested material to contain 7 to 8% THC. Traditionally, more potent preparations, using only the flowering tops of the plant, often contain in excess of 10 to 15% of THC and are known as hashish or hashish oil.

The pharmacological effects of THC include sedation, decrease of aggressiveness, loss of ability to perform complex motor and psychologic tasks, perceptual and sensory distortions or enhancements and, in larger doses, ataxia, incoordination, stupor, as well as hallucinations. A great deal of energy has been extended in searching for marijuana receptors, and it is highly unlikely that the myriad effects of this substance will be explained by actions in a single particular kind of receptor in the CNS. Effects of chronic marijuana usage include diminished gonadotropin-releasing hormone, luteinizing hormone and follicle-stimulating hormone levels in both sexes. In women, diminished prolactin levels are seen after smoking marijuana. Numerous lines of evidence point to some interaction of cannabinoids with humeral and cell-mediated immune system components. Of great concern is the obligatory contamination of cannabis products with pesticides, herbicides, and organic and inorganic metals, which may add to the overall CNS toxicity (Jaffe, 1989, 1990; Mendelson, 1987). Persistent levels of cannabinoids and other extremely lipid-soluble substances have been demonstrated in tissues for months after cessation of marijuana use, which raises concerns of long-lasting effects of chronic marijuana use on behavior, cognition, and intellectual functioning.

Statistical surveys of the incidence of marijuana usage show that a declining fraction of adolescents and young adults regularly use the substance, although it remains one of the most commonly used psychoactive substances, and fully 50% of Americans have tried or used marijuana in their lives. Like all behaviorally reinforcing drugs, a small segment of users will have unpleasant behavioral and cardiovascular effects or exacerbation or production of psychiatric abnormalities and on this basis will probably not use the substance repetitively. Anxiety, panic reactions, and paranoid symptoms may be produced or aggravated in susceptible individuals, and many users do not rate these as pleasant effects. In comparison, the anti-anxiety and mild euphoriant properties of marijuana lend themselves to repeated usage as mild intoxicants and relaxants. There is seemingly no tolerance for the pleasurable effects of cannabis and, therefore, continued behavioral reinforcement would be expected to promote repetitive use of marijuana. However, there is tolerance to some of its effects on mood, and it is likely that this is responsible for the escalation of dosage needed to produce the same degree of "high" with repetitive use. Paradoxically, a "reverse tolerance" to the effects of cannabis has been described, in that smaller and smaller doses are needed over time to achieve certain desirable euphoriant effects. A well-described amotivational syndrome exists in cultures where daily usage of marijuana and hashish occurs. This has been described in the Caribbean (Jamaican) peoples, and there has been much debate as to whether or not marijuana directly affects motivation or whether these are indirect effects of the drug (Cohen, 1982). Social usage of marijuana is often impossible to study in its own right because of concomitant usage of tobacco, alcohol, and other commonly used substances, often ingested in close proximity to marijuana itself. This complicates research protocols and epidemiologic studies of marijuana use.

Attempts have been made to look for bona fide pharmacologic uses for marijuana. Trials of oral THC have been used successfully to reduce glaucoma in otherwise refractory patients (Jaffe, 1990). Similarly, a synthetic cannabinoid derivative, nabilone, has been used as an antiemetic. This

substance also produces many of the psychoactive effects of natural D9-THC (Jaffe, 1990; Mendelson, 1987).

Because of the production or exacerbation of psychiatric symptoms and behavioral aberrations associated with marijuana use, the DSM-III-R (American Psychiatric Association, 1987) has developed diagnostic criteria for a cannabis delusional order, as well as cannabis intoxication. These are generally utilized in conjunction with approaches to other chemical dependencies, and it is rare that prolonged psychotic or schizophreniform states will result from acute misusage of marijuana or its derivatives. The cannabis withdrawal syndrome has been described with impaired motor performance on discontinuation, associated with insomnia, anxiety, and other symptoms reminiscent of withdrawal from sedative hypnotics. Whether this represents a mere return to the patient's baseline state of behavior is uncertain but remains a possibility. Once again, utilizing the principle that the anxiolytic and psychostimulant properties of marijuana may help correct a baseline state of agitation or internal dysphoria, one might, therefore, search for more appropriate pharmacologic management of individuals who repeatedly use marijuana and its derivatives, thereby circumventing the potential for engagement in illegal and societally disapproved drug-seeking behaviors. Behavioral, affective, and cognitive therapies certainly play a strong role in the overall rehabilitation and management of individuals who have strong histories of chronic marijuana use.

Central Nervous System Stimulants (Cocaine and Amphetamines)

The most powerful reinforcers in licit or illicit usage are the CNS stimulants, particularly cocaine. Reference has been made (see above) to its powerful effects on reinforcement of self-stimulating behavior in animals and as clinically observed by usage in people. In the last 10 years, cocaine has emerged as the statistical drug of choice for recreational repeated self-administration. Although traditionally snorted or used intravenously as a soluble hydrochloride salt, free-base or crack cocaine has enjoyed widespread misuse throughout many cultures in the Western Hemisphere in the last decade. A similar phenomenon has been described for misuse of amphetamines, which historically dates back to World War II and to an epidemic of widespread amphetamine usage in post-war Japan in the 1950s. In the next 2 decades, amphetamine compounds were readily available pharmaceutically, and many adolescents and young adults used amphetamines, more so for their stimulant properties and less apparently so for purely recreational purposes (Abelson & Fishburne, 1976). In 1970, the Harrison Act was amended, and amphetamines were placed in Schedule II, with tight controls on distribution and dispensing of the substances. Large quantities of manufactured amphetamines were, nonetheless, illicitly diverted. By 1980, usage of amphetamines had declined rather dramatically, in contradistinction to the escalating use of cocaine in our population. Clearly, the inverse relationships are linked, at least in the authors' mind, based on the relative availability of cocaine and relative nonavailability of amphetamines. In the 1980s, reports of clandestine manufacturing operations for amphetamines and methamphetamines surfaced, and intranasal and intravenous use of "crank" continues alongside that of cocaine. The population at highest risk for use and abuse of these substances is the 18- to 25-year-old group. Cocaine is the only drug for which increasing risk of usage develops above this age group, although escalating usage of alcohol remains another major problem (Fischman, 1987; O'Malley, Johnston, & Bachman, 1985).

Pharmacological mechanisms subserving repeated self-administration of amphetamines and cocaine relate directly to the effect of these drugs on the dopamine system. In particular, their ability to block reuptake of dopamine and also to act as dopamine agonists produces CNS excitation, and this is coupled with repeated dosing, which becomes a powerful behavioral reinforcer. On a practical level, the effects of amphetamines are indistinguishable from the effects of cocaine, even to seasoned users, with the only major difference being the duration of the drug effect. The patterns of misuse for both substances tend to be similar, with a flurry of administration occurring in "runs" or binges, and that for cocaine generally lasting less than 1 or 2 days, whereas in the case of amphetamine usage, a typical binge may last for several days. Generally, the intense repeated usage of these substances ends when the availability of the drug is curtailed or when the user is exhausted, confused, or disorganized. Users will often inject larger and larger amounts of a drug to obtain the same degree of rush or flash, and the free-base form of cocaine is said to be more profound in this respect. The rush is often described in orgasmic connotations and becomes the principal focus for repeated use during the binge. Following such a binge, the user will often crash, with profound lethargy and often will sleep for up to 24 hours or longer to mitigate the severe CNS exhaustion attendant to prolonged stimulant use. The temporal pattern of binges consists of intense usage punctuated by short periods of abstinence. A phenomenon called sensitization (Fischman, 1987) exists which occurs with repeated psychostimulant usage. This has been demonstrated in both humans and animals and consists of an increased effect of a specific dose of a stimulant with repeated administration. Thus, the repetitive patterns are akin to the stereotypic behaviors elicited in animals with chronic administration of cocaine or amphetamines. Sensitization has been described for numerous variables, namely, local motor activity, stereotypic behaviors, increased seizures and startle responses, and other aspects of CNS stimulation. Post

(1977) compared the effects of repeated usage of psychostimulant drugs to animal models of "kindling" wherein repeated low-level stimulation of hippocampal and amygdala preparations resulted in prolonged after-discharges and seizure-like activity in brain preparations.

At the same time that the process of sensitization is occurring, the process of tolerance also occurs with regard to the rush or flash obtained with a single dose of cocaine. Cross tolerance and cross sensitization occur among CNS stimulants, and yet no tolerance occurs to the positive reinforcing effect of this group of substances on behavior. Thus, the ability of cocaine or amphetamines to act as reinforcers occurs consistently whether one has a short history of repeated cocaine use or an intermittent history spanning many years. The effect of sensitization seems to be consistently present, even with long periods of discontinuance of drug use (Post, 1977).

Treatment of dependence on cocaine and amphetamines is extremely difficult, as one can imagine, because of the extremely powerful behavioral and reinforcing effects of these drugs. Nevertheless, the list of severe and potentially fatal medical problems associated with unrestrained use of cocaine mandates very vigorous efforts at detoxification and rehabilitation of individuals who are severely dependent on these substances. In addition, a mixture of cocaine with heroin (so-called "speedballing") adds additional measures of medical risk, and certainly cocaine users are very well known to misuse multiple other substances, such as alcohol, sedative hypnotics, marijuana, and opiates. Long-term serious psychiatric complications of cocaine and amphetamine use include paranoid states and a syndrome virtually indistinguishable from paranoid schizophrenia with extreme hypervigilance. Persistent toxic psychoses, together with hallucinations, have been well described following prolonged amphetamine or cocaine use. More commonly, a briefer state of drug-induced delirium with suspiciousness, paranoia, and visual and tactile hallucinations (formication) occurs following binges or runs of stimulant use. Of great concern are more fatal medical complications (e.g., accelerated hypertension, cerebrovascular infarction, intracerebral hemorrhages, myocardial infarctions, coronary artery spasms, fatal cardiac arrhythmias, seizures, respiratory depression, gastrointestinal and peripheral vascular necrosis) from the prolonged vasoconstrictor effects of CNS stimulants.

Withdrawal from cocaine reliably produces a syndrome that is longer lasting and more pervasive than the typical crash following acute discontinuance of stimulant use. The entire abstinence syndrome occurs over a long period of time in stages. The first stage is rather brief, lasting 3 to 5 days, with anorexia and agitation being replaced by profound exhaustion, depression, hypersomnia, and hyperphagia. A second phase develops over the ensuing 6 to 12 weeks, with improved mood and a better normalization of sleep; however, cocaine craving returns, and the greatest likelihood of relapsing to former cocaine use occurs during this phase. Whether or not this stage mimics the natural cycle of binge use for amphetamines and cocaine is a point that has been debated (Jaffe, 1989). The third and most prolonged phase of cocaine withdrawal may take up to a year and resembles the prolonged alcohol abstinence syndrome, with establishment of successful conditioned avoidance responses and behaviors based on a combination of behavioral retraining and possibly medication.

Various medications have been utilized to curb cocaine craving, including clonidine and desipramine. Very fragmentary data with Tegretol (unpublished results) also indicate that this agent may be effective in curbing the intense craving for cocaine and amphetamines. In the acute phases of withdrawal, haloperidol or other dopamine blockers may very well be useful. In some cocaine users, particularly with underlying cyclothymic disorders, lithium has been reported to be helpful in reducing relapse to continued use of cocaine. It has been suggested that chronic blockade of dopamine receptors may alter craving for psychostimulants. However, the opposite effect has also been demonstrated, wherein neuroleptics given to recent cocaine users resulted in increased craving for the drug. Studies are in progress to determine which category of medicines may have long-term utility in curbing the nationwide epidemic of cocaine use. Similar treatments for amphetamine dependence have been developed, and tricyclic antidepressants are currently being used, along with dopaminergic blockers to block craving and some of the euphoriant actions of amphetamine. Alpha-methyl-paratyrosine (AMPT) was tried in older studies but is not clinically available. AMPT blocks the formation of dopamine and ultimately norepinephrine and had been found to block amphetamine-induced euphoria. However, it does not have any ability to block the effects of cocaine or methyl-phenidate (Ellinwood, 1979).

Rehabilitative treatment for chronic users of stimulants is rudimentary at this point. Numerous psychological approaches have been attempted, including behavioral, psychodynamic, and supportive psychotherapeutic techniques. In some cases, a contractual agreement by the person in treatment has been beneficial. In this type of arrangement, the person undergoing treatment agrees that the treating professional may inform his or her employer or professional societies if relapse into use of cocaine or amphetamine occurs within a certain time period. Within the boundaries of such an agreement, it has been shown that a significant portion of patients treated do abstain from a relapse into stimulant use. However, much higher relapse rates were noted after expiration of the contractual time period. Combining psychopharmacologic approaches with behavioral and psychotherapeutic techniques gives the best results, because chronic stimulant use is felt to create a relative

state of dopamine deficiency by downregulating postsynaptic receptors. This is by no means the only neurotransmitter system involved. Effects on the serotonergic system also have been described, and at this time tricyclic antidepressants still remain useful in helping to attenuate relapse rates. By blocking the uptake of dopamine, serotonin, and norepinephrine, it is felt that the antidepressant effects would help ameliorate the post-crash fatigue and lassitude that are parts of the second stage of cocaine withdrawal syndrome. At best, success rates are currently limited, and better psychopharmacologic agents have to be developed, although desipramine is now favored among the tricyclic anti-depressants.

Opioids

The history of opiate use dates back to the 1st century A.D. and most likely even earlier. The prototypical opiate, morphine, is found in the opium plant. The advent of pipe smoking ushered in the practice of ingestion by smoking, particularly in the Far East. Morphine and its synthetic derivative, heroin, remain very popular drugs of misuse and are among the most severe tolerance- and physical dependence-producing substances known in modern pharmacology. There seems to have been a return to more heroin misuse nationally in the last 5 years, and this, in part, reflects availability of natural materials and prevailing market and social forces that wax and wane regarding different drugs of misuse. During the height of the 1980s cocaine era, misuse of opiates had waned somewhat. However, there seems to be a return to the levels of usage seen in the 1970s.

The pharmacology of morphine and other opioids has been progressing steadily since the identification of multiple kinds of opiate receptors in the CNS. These developments in turn sprang forward from the identification of naturally occurring endorphins and enkephalins in the central and peripheral nervous system. The μ receptor subtype is the site of action of the classic opiates, namely, morphine, heroin, and codeine. These drugs are preferentially agonists at this receptor subtype. A second receptor is the site of action of numerous other clinically useful drugs, namely, butorphanol and nalbuphine. A Δ receptor has been identified and seems to be the binding site for endogenous met-enkephalin. A σ receptor also has been described, and stimulation of this receptor has hallucinogenic and excitatory effects with very little analgesia. Most of the analgesic effects of opiates are mediated through the μ receptor. The pharmacology of the tolerance and physical dependence to various effects of opiates is quite complicated, and some of the newer agents (e.g., pentazocine, cyclazocine) have agonist effects at one receptor subtype and antagonistic effects at other receptor subtypes. The pharmacology of these receptor subtypes is very well described (Jaffe, 1989; Woods & Winger, 1987).

The pharmacologic actions of opioids that have predominant effects at μ or κ receptors are subclassified into direct effects, dependence-producing effects, discriminative effects, and reinforcing effects. Many of these studies have been done in vitro and in animals and have less relevance to the pharmacology of these substances in humans. Much of the pharmacologic subcategorization has been done with agents that are antagonists to various kinds of receptors, such as nalorphine. This was the first substance noted to reverse the effects of morphine acutely, particularly analgesic and euphoriant effects. Although nalorphine antagonized morphine-induced euphoria and precipitated withdrawal symptoms, it, too, could produce analgesia in humans. Unlike the euphoriant-producing morphine, nalorphine generally produces dysphoria in humans. An even more selective opioid antagonist, naloxone, is currently in clinical use to acutely reverse some of the lethal effects of morphine or heroin, namely, those of respiratory depression and some of the effects on the cholinergic system peripherally. Naloxone (Narcan) can rapidly reverse agonist actions of morphine and heroin and can be dramatic in reversing acute life-threatening effects of overdoses in emergency room settings. A concerted effort has been made pharmacologically to elucidate and preserve analgesic properties of opioids with a minimum of euphoriant and physical dependence-producing properties. No ideal molecule exists, although some success with a combination of analgesic effects (by virtue of κ receptor stimulation) with a minimum of physical dependence-producing properties has been achieved with mixed agonist-antagonist molecules (e.g., nalbuphine, butorphanol, pentazocine) (Woods & Winger, 1987).

With respect to the withdrawal syndrome from opioids and the practical management of detoxification from this category of medication, volumes of literature have been written on opioid maintenance using methadone, and this drug enjoys a prime position in one of the major approaches to treatment of heroin and morphine use in the United States and other countries. The use of methadone was pioneered by Dole and Nyswander in the mid-1960s. Methadone is an opioid with relatively pure μ-receptor agonist properties and has a longer half-life than heroin or morphine. It has proved to be relatively safe in terms of daily use and to block the euphoriant effects of subsequent doses of heroin. Other opioid maintenance drugs have been investigated, although none is clinically available. One such medication, l-a-acetylmethadole (L-AAM), is under investigational use. It is similar to methadone in its action but has long-lived metabolites and can be given every other day. In any case, it is now more than 15 years since L-AAM was introduced, and it still remains a controversial and investigational drug. Another investigational drug, buprenorphine, blocks the subjective effects of parenterally administered morphine or heroin (Mello & Mendelson, 1980). Apparently, when given to patients

who are self-administering low doses of heroin, buprenorphine suppresses some of the withdrawal symptoms, whereas when given to patients using high doses of opiates, it seems to precipitate abstinence, more like traditional opioid antagonists.

The controversy surrounding use of methadone as a replacement for heroin or morphine has been debated for nearly 30 years. Proponents of methadone maintenance feel that a slowly tapered oral dosing of methadone can successfully achieve detoxification from heroin use. In addition, the methadone can block some of the euphoriant "rush" effects of injected heroin or morphine. Furthermore, one of the objectives of treatment is to prevent severe withdrawal which is associated with far higher relapse rates in return to use of injected opioids. Patients are often initially stabilized on 80 to 100 mg of oral methadone, and a tapering regimen which reduces the methadone dosage by 10% per week has often been employed. A more gradual taper (3% per week) is utilized when the methadone dose falls below 20 mg/day. Opponents of the methadone system cite widespread diversion of methadone itself and the sale of the substance by heroin addicts who are enrolled in oral methadone programs. Attempts have been made to institute oral naltrexone (Trexan) therapy when the methadone taper is nearly finished in order to have an oral opioid antagonist present in the former users' system on a daily basis. The aim of this therapy is hopefully to block euphoriant effects of any subsequently injected opiate should the person return to former usage patterns.

Because the acute opioid withdrawal syndrome is believed to be a state wherein the adrenergic nervous system is hyperactive, centrally acting α_2 agonists (e.g., clonidine) have been utilized to suppress some of the acute withdrawal reactions. Lacrimation, rhinorrhea, jitteriness, and sweating can be attenuated by the oral administration of clonidine. Clonidine is far less effective against other withdrawal phenomena, such as insomnia, craving, lethargy, and muscle aches, but has been utilized successfully in tapering off oral methadone dosage and institution of oral naltrexone, as discussed above. Blood pressure has to be monitored with clonidine, as it is a centrally acting antihypertensive agent. Sedation also can be a problem, although with regard to the restlessness involved in opioid withdrawal, this side effect may indeed be quite useful.

Other techniques utilized for accomplishing opioid withdrawal seem "hard-nosed" but take advantage of the unpleasant nature of withdrawal as an aversive conditioning technique. Abrupt withdrawal without any pharmacologic supports has been advocated by some as a reasonable way of accomplishing rapid detoxification from opioid dependence. Since clinical withdrawal is rarely life-threatening, it at least has the advantage of accomplishing what can be a lengthy detoxification program in a matter of days. Most oral methadone programs can continue for 3 to 6 months, and the cost of such programs is quite high. There is no evidence to suggest that rapid detoxification has any greater relapse rate than more traditional techniques (Jaffe, 1989). Furthermore, approximately 85% of heroin addicts meet criteria for at least one psychiatric diagnosis, and it is often the more psychiatrically impaired patients who have the lowest rates of success in formal detoxification programs.

Sedative-Hypnotics and Benzodiazepines

Among the most available substances in our society are benzodiazepine anxiolytics and sedatives, and use and misuse of this category of drugs have taken on dramatic proportions in the last 10 to 15 years. In past years, the same kind of problem occurred with use of older hypnotic/sedatives, such as barbiturates, which are much more tightly regulated since implementation of the Controlled Substances Act of 1970. Other nonbarbiturate sedatives, including glutethimide, methyprylon, chloral hydrate, and meprobamate, enjoyed widespread misuse in small segments of the population. An excellent overview of the scope of benzodiazepine usage in the United States is presented in a Task Force Report of the American Psychiatric Association (1990) on benzodiazepine dependence, toxicity, and abuse.

There has been an increasing awareness over the last decade that short half-life benzodiazepines can be problematic, in terms of potential for both dependence and misuse. Withdrawal from benzodiazepines is commonly believed to represent a return of the original anxiety symptoms for which the medication was prescribed (Ghist & Sannerud, 1987). Benzodiazepines and other sedative hypnotics are known to be fairly strong reinforcers, and much experimental data in humans have provided abundant evidence that a true physical dependence, as well as tolerance, can occur with virtually every benzodiazepine. Those benzodiazepines that are more lipid-soluble tend to be more problematic. Older benzodiazepines, such as diazepam (Valium), together with newer lipid-soluble short half-life preparations, such as alprazolam (Xanax) and triazolam (Halcion), are much more problematic in terms of tolerance- and dependence-producing properties with chronic usage. Withdrawal phenomena, including seizures, have been reported in patients who have misused high doses of benzodiazepines, barbiturates, and other nonbarbiturate sedative-hypnotics. Agitation and restlessness generally occur in a predictable fashion, and the length of time of the withdrawal process can range between several days to several weeks.

The magnitude of the problem of benzodiazepine misuse certainly far exceeds numerically that seen for opiates. It is estimated that 11 to 12% of the population has used benzodiazepines at least intermittently, whereas about 3 or 4% of the population uses benzodiazepines on a chronic

basis. Upward of a 100 million prescriptions per year have been written for these substances, and iatrogenic dependence is a very real issue on a national level.

Treatment modalities for benzodiazepine withdrawal have been devised using slow tapers and changes to long-acting, low-potency compounds. In general, avoidance of long half-life compounds for use as nighttime hypnotics, together with avoidance of ultrashort-acting compounds for the same purpose, would be a wise choice in preventing iatrogenic tolerance and dependence on benzodiazepines. Use of drug holidays is another technique that might favor a more rational use of this class of compounds.

Beta blockers (propanolol), clonidine, carbamazepine, and buspirone have been used in the treatment of withdrawal symptoms from benzodiazepines. Because withdrawal effects are related to the uncovering of inhibitory GABA receptor sites in the CNS, drugs such as carbamazepine may prove useful, not only to control benzodiazepine withdrawal seizures, but also to quiet the arousal state often seen in withdrawal (Klein, Uhde, & Post, 1986; Ries, Roy-Burne, & Ward, et al., 1989). Buspirone has been utilized in treating benzodiazepine withdrawal symptoms, and unfortunately does not prevent emergence of such symptoms although clinically it may be useful on its own merit to treat underlying anxiety while benzodiazepine dosage is tapered. Use of short-term phenobarbital also has been advocated in the treatment of benzodiazepine withdrawal symptoms. It is preferred to pentobarbital, which has its own spectrum of dependence-producing effects (Martin, Kapur, Whiteside, & Sellers, 1979).

Of equal concern in selected populations of drug-using individuals is the combined usage of benzodiazepines with alcohol or opiates. In both cases, additive and synergistic respiratory depression is a constant threat, and tolerance to respiratory depression does not develop for any of these substances (Jaffe, 1990). Recommendations from the American Psychiatric Association's Task Force Report (1990) on benzodiazepine prescribing include avoidance of short half-life preparations; discontinuance symptoms can appear even at ordinary therapeutic doses; the immediate discontinuance symptoms are felt to be a rebound presentation of the original anxiety symptoms with more severe withdrawal symptoms, including seizures, being manifestations of bona fide physical dependence; the onset of withdrawal symptoms occurs sooner and is more pronounced with short half-life preparations; tapering for high-potency short half-life preparations should be performed very gradually with additional use of other supportive medication as mentioned above. The task force guidelines also noted interaction of benzodiazepines with alcohol, particularly in terms of daily tasks, such as driving and effects on memory consolidation, and it was believed that benzodiazepines most strongly reinforced their use in patients who have a predisposition to misusing other categories of drugs such as alcohol, other sedative-hypnotics, and opiates. Thus, benzodiazepine misuse continues to be a national phenomenon, and iatrogenic factors clearly contribute to the problem.

A much more recent problem in the United States and in the world in the last few years is the use of flunitrazepam, commonly marketed as Rohypnol. Street names for this drug abound: Rophies, Ropies, Roofies, Ropes, Roches, Rochas, Rochas Dos, Rophs, Ropers, Ribs, R-25s, Roach-2s, Trip and Fall, Remember All, Mind Erasers, Forget Pills, and Date Rape Drug. This benzodiazepine has been implicated in sexual assault (date rape) cases especially when mixed with alcohol and is a cheap form of intoxicant (Saum and Inciardi, 1997). An estimated one in four women will be raped in their lifetimes and approximately 75% of these incidents will be acquaintance rapes. Flunitrazepam is odorless, colorless, and tasteless and produces drowsiness, impaired motor skills, and profound anterograde amnesia. Ultrasensitive techniques are available to detect this drug in urine and blood samples in suspected rape victims (Anglin, Spears, & Hutson, 1997). Flunitrazepam and GHB have become the drugs of choice for date rape situations, as they cause disinhibition and relaxation of voluntary muscles and cause lasting anterograde amnesia for events that occur under the influence of the drug. Alcohol potentiates these effects (Schwartz, Milteer, & LeBeau, 2000). One study in Sweden looked at male juvenile offenders who had used Rohypnol frequently and described its effects in producing feelings of increased power and self-esteem, in reducing fear and and insecurity, and in providing a sense that all was possible. It was also associated with loss of episodic memory and with impulsive violence, especially when used with alcohol (Daderman and Lidberg,1999a). The authors felt that the drug should be classified as a Schedule 1 drug in Sweden and they also pointed out in a second paper (Daderman and Lidberg,1999b) that flunitrazepam abusers became cold-bloded, ruthless, and violent and did not remember their violent actions. They discussed how flunitrazepam could exert profound effects on GABAergic systems and thus lower serotonin levels, a state where impulsive execution of violent crimes, including suicides have been well associated. A retrospective study in Prague of intoxicated poisonings over 4 years revealed that Rohypnol was the second most common intoxicant utilized, after alcohol (Rath and Vever, 1998). A survey (between 1995 and 1997) in Dade County, Florida, of benzodiazepines detected in biological samples from drivers arrested while driving under the influence (DUI) showed that 10% of the samples were flunitrazepam, but that these numbers fell dramatically after it became a Schedule 1 drug in 1997 (Raymon, Steele, & Walls, 1999).

Hallucinogens: LSD, Mescaline, Psilocybin, and Phencyclidine

Perhaps no other psychotropic substance has generated more research and theoretical interest into the mechanisms of mental dysfunction than lysergic acid diethylamide (LSD). This and other substances produce psychedelic effects with perceptual and sensory distortions as well as hallucinations. The discovery in 1943 of LSD's psychedelic effects by Hoffman stimulated a wave of excitement regarding potential use of LSD as a model for schizophrenia and other mental disorders. In the 1960s and early 1970s, the use of LSD-like substances, including psilocybin (extracted from mushrooms) and mescaline (found in the peyote cactus), escalated tremendously in U.S. society. The experimental use of these substances to heighten self-introspection and self-fulfilment created a strong scientific interest scientifically in unlocking the mechanisms for the effects of these drugs on CNS functioning. Resurgence of the pharmacologic mechanisms of these substances yielded abundant evidence that LSD and other psychedelic substances interact with serotonin (5-HT) receptors as well as other neurotransmitter systems in the brain. Actions of psychedelic substances were demonstrated in many brain areas, but in particular, the 5-HT2 receptor was felt to be a fundamental site of action of LSD. Other hallucinogens (e.g., mescaline) were found to have more profound effects on the locus ceruleus in the brainstem, and substances that block norepinephrine and serotonin receptors were found to be useful in preventing the psychedelic effects of hallucinogens (Jaffe, 1990).

Use of phencyclidine (PCP) and other similar substances has supplanted older hallucinogens. It and some of the newer designer drugs, such as MDMA, DOET, and the like (see above), have a plethora of pharmacologic actions in the CNS. Phencyclidine was first developed in the 1950s as an anesthetic for animals, and related substances, such as ketamine (Ketalar), are still used occasionally as anesthetics.

Originally, about 10% of patients anesthetized with phencyclidine would exhibit a state of delirium and aggressive behavior on emergence from the medication. Phencyclidine and some of its related substances have hallucinogenic, analgesic, CNS stimulant, and depressant actions simultaneously. They are bona fide intoxicants, producing slurred speech, nystagmus, and gait ataxia, together with numbness of extremities. Sweating, cataTonic postures, rigidity, and a blank stare are often responses to larger doses of the drug. Bizarre behavior, aggressive outbursts, and amnesia can occur. Distortion of sensory input to the CNS occurs, and evidence of CNS stimulation with sweating, fever, salivation, and muscle rigidity are seen. On the street, most of what is passed off as LSD is actually phencyclidine or similar derivatives, because these are easier to manufacture illicitly than LSD itself. PCP goes by a wide range of street names, including "angel dust", "crystal," or "hog." Pharmacologically, PCP affects multiple transmitter systems, but in particular, research has shown that it may antagonize CNS actions of N-methyl-d-aspartate (NMDA), and the receptor for PCP may actually be a part of an NMDA receptor complex controlling calcium and other ionic channels as well as sodium and potassium voltage-regulated channels. This is akin to the GABA-benzodiazepine-chloride ion channel receptor on which benzodiazepines and other drugs are thought to exert their effects (Jaffe, 1989).

One particularly relevant pharmacologic effect of phencyclidine is its agonist effect at the opiate receptor site. Why the actions of PCP at the σ receptor site overlap with its effects on NMDA receptors is uncertain. Multiple lines of data suggest the possibility that activation of the σ receptor and NMDA receptor has differential effects on sodium or potassium conductance, which may explain some of the excitatory effects of NMDA itself (Jaffe, 1989).

LSD and PCP are generally used in short runs or binges, with profound exhaustion and lethargy following multiple doses of these drugs. In the case of PCP, it is often smoked with marijuana or misused along with alcohol and other drugs. Toxic psychoses and flashbacks can occur with all hallucinogens, and "bad trips" have been seen in a small percentage of hallucinogen users. These can include states of paranoid ideation and can occur randomly despite repeated "good trips" in past usage of the drug. PCP, in particular, has been likened to a mild psychosis resembling schizophrenia, and although globally chronic misuse of hallucinogens and PCP was less prevalent in our society in the 1990s than it was in the 1960s and 1970s, there does remain a small percentage of people who prefer to misuse these substances on a repeated basis.

Acute treatment of hallucinogen and PCP toxic effects includes use of phenothiazines and dopamine- and norepinephrine-blocking drugs. Treatment with a dopamine blocker may be necessary for a week or longer, as protracted disorientation and toxic psychosis can occur, in particular, after phencyclidine. One unusual property of phencyclidine is its enterohepatic recycling, which can delay excretion of the compound. Urinary acidifiers have been used in the past to hasten renal excretion of the substance.

MDMA (ecstasy) has been mentioned already (see above) and remains a current hallucinogen used by a small fraction of mostly adolescent and college-age individuals. It has mixed pharmacologic actions with CNS stimulant and psychedelic and hallucinogenic properties. The continued wave of popularity of so-called designer hallucinogens continues unabated and will likely remain a problem in a small segment of the drug-misusing population.

Inhalants and Solvents

Drugs of misuse in this category involve a bewildering array of anesthetic gases and organic solvents, including xylene, toluene, benzene, kerosene, and gasoline, together with pressurized propellants like freon and other fluorocarbons. Hexane and some its derivatives are known to produce peripheral neuropathies as well as an agitated, disordered, encephalopathic state. Profound visual hallucinations, feelings of derealization, "spacin'" and distortions in the sense of time all occur. Chronic glue sniffing, in particular, is fraught with long-term effects, including an encephalopathy secondary to widespread brain damage from chronic administration of the volatile substance. Often, inhalant users are extremely young in age, generally come from low income populations, and do not have easy an access to other CNS-active agents. Sniffing of glue or a solvent from a closed container, such as a paper bag, or "huffing" of inhalants is performed generally as a group activity, and often other substances, such as alcohol, marijuana, and nicotine, are used concurrently. There is no specific treatment for acute CNS effects of these substances other than removal of the offending solvent. Typically, chronic users of inhalants tend to be dull in their affect, exhibiting some of the long-term sequelae of subtle, but widespread, encephalopathic process. Neuropsychological testing often confirms problems with memory and problems with motor speed performance on subcategories of neuropsychological testing.

A recent study (Young, Longstaffe, & Tenenbein, 1999) looked at the relationship of inhalant misuse to the use of other substances. This was a survey done in the setting of a juvenile detention facility with 209 children incarcerated over a 3-month period. The study obtained epidemiologic data about mean ages of substance misuse of a number of drugs, including inhalants. Mean age of initial experimentation for inhalants was 9.7 years, as compared to 11.9 years for marijuana, 12.0 years for alcohol inebriation, 11.2 years for cigarette use, and 13.2 to 14.7 years for the remaining substances (opiates, CNS stimulants, and psychedelics). Thus, the implication is made that inhalant misuse in early life may be associated with misuse of other substances.

Iatrogenic Dependence

One of the many tasks of physicians who routinely treat chronic pain patients is the detoxification and redirection of medication usage patterns for chronic pain or headache patients who have been allowed free access to opiate-containing preparations for relief of their symptoms. It is truly regrettable that more emphasis on proper pain management techniques is not offered during the routine medical school or house officer training phases of practitioners. In the author's opinion, too little emphasis is placed on proper pain control management techniques, and unfortunately, most pain is approached as if it were acute pain. Thus, practitioners prescribe opiates and other dependence-producing medications for conditions that are in themselves chronic and not likely to benefit from repeated administration of drugs. This problem is seen by every chronic pain practitioner, regardless of the population of patients he or she treats, and a great deal of effort, redirection, and patient retraining is mandatory in getting most chronic patients to undo the effects of iatrogenic dependence on opiates for chronic pain or headache problems. It is equally curious to the author that terminally ill patients who deserve pharmacologic support in relief of their pain often are, paradoxically, undertreated with pain-relieving medications, with the vain hope of sparing the terminally ill cancer-ridden patient the additional burden of addiction to an opiate. This seems trivial at best and further underscores the general lack of familiarity with proper use of highly addictive substances in the setting of pain control, particularly in terminal diseases.

Treatment approaches to detoxification of codeine, meperidine, and oxycodone preparations are generally accomplished fairly rapidly, and rarely is severe opioid withdrawal a protracted problem. Most detoxification measures utilize progressively smaller dosages of either the same or less addicting opiates, and therapy is often supplemented with anti-inflammatories, antianxiety agents, clonidine, and adequate attention to establishment of a structured sleeping regimen. Substitution of agents like carbamazepine for chronically painful syndromes that involve sharp and burning pain (e.g., reflex sympathetic dystrophy, sympathetically mediated pain syndromes, causalgias, and sharp components of peripheral and other neuropathies) often allows adequate pain management without resorting to dependence-producing medications. The greatest challenge for the pain practitioner is in reeducating the patient not to reach for the next dose of analgesic, and this particularly rings true in the treatment of chronic headache sufferers. Behavioral reorientation, training in biofeedbacking and stress management, and nonpharmacologic approaches to pain (e.g., cranial electrotherapy stimulation and transcutaneous electrical nerve stimulation therapy) offer the potential for adequate pain treatment for chronic conditions.

Ergotamine Dependence

One relatively rare, but nonetheless important, source of iatrogenic dependence occurs in the use of ergotamine to control recurrent headaches. Daily use of ergotamine in as low a dosage as 2 mg can lead to a cycle of dependence on the medication, and often escalating doses are needed to achieve the same headache-free state. In fact, Saper and Jones (1986) found that ergotamine used more than three times per week may also predispose patients to the phe-

nomenon of ergotamine dependency. The use of daily ergotamine can create a situation whereby headaches rebound if ergotamine is not continually administered. Over time, dosage of ergotamine increases, and any attempts to lower the daily dosage result in prompt exacerbation of the headache. After a time, only minimal or transient improvement in the headache pattern is noted, despite escalation of ergotamine dosage. In addition, treatment of the headache using other medication approaches often fails in the setting of ergotamine dependency. Fortunately, detoxification from ergotamine can be accomplished with the use of repetitive intravenous dihydroergotamine (DHE-45), together with intravenous opiates and sedative anxiolytics (e.g., lorazepam), and detoxification management of the ergotamine withdrawal headache will usually occur in 4 to 7 days (Raskin, 1988). After a successful withdrawal from ergotamine, headaches cease to be a problem for some time, but the patient is at risk for return of headaches and, therefore, effective pharmacologic measures must be instituted to prevent relapse into another cycle of ergotamine dependence.

CONCLUSION

This chapter has discussed basic pharmacologic principles, such as tolerance and physical dependence, provided an overview of the many different categories of misused drugs and their patterns of misusage, and outlined elements of detoxification of patients from these drugs. More likely than not, there always will exist personalities who will seek to misuse mind-altering substances, whether for purely recreational purposes or to attain internal states of peace or euphoria, or to counter, likewise, inner states of disquietude, anxiety, restlessness, and ennui. Whatever the specific reason for misusing a psychochemical, hopefully either substitution of licit medication or replacement of drug use by other self-activating behaviors would, in large measure, result in diminished misuse. A better understanding of basic pharmacologic mechanisms also would result hopefully in availability of medications with a minimal potential for production of tolerance and physical dependence. Exciting new prospects in the neurobiology and neuropharmacology of peptides in the CNS are emerging rapidly. Undoubtedly, mind-altering properties of neuropeptides, too, will come to light and be exploited by drug-using experimentalists, as has occurred with drugs discussed in this chapter. It may very well be part of human nature to want to change or alter one's sensorium, hopefully to a place that is more peaceful and less troubled, and thereby achieve a state of relative inner peace. That so many diverse chemicals producing so many different kinds of effects are all capable of achieving what is perceived as inner harmony speaks for the myriad underlying emotional needs of humankind.

In closing, the author would like to quote a passage from Aldous Huxley (1970):

> …That humanity at large will ever be able to dispense with Artificial Paradises seems very unlikely. Most men and women lead lives at the worst so painful, at the best so monotonous, poor, and limited that the urge to escape, the longing to transcend themselves if only for a few moments, is and has always been one of the principal appetites of the soul. And for private, for everyday use there have always been chemical intoxicants. All the vegetable sedatives and narcotics, all the euphorics that grow on trees, the hallucinogens that ripen in berries or can be squeezed from roots—all, without exception, have been known and systematically used by human beings from time immemorial. And to these natural modifiers of consciousness, modern science has added its quota of synthetics (p. 62).

A Multi-Systems Approach to Behavioral Health and Pain Management

Richard H. Cox, M.D., Ph.D., D.Min.

This chapter approaches behavioral health from a systems point of view rather than the more traditional behavioral medical designation, because it is important to identify with a larger body of information and practice than simply that of medicine. Further, the usual connotation of "multi-disciplinary" is not used because that labeling implies the utilization of skills of more than one professional discipline. Each discipline is more than a body of knowledge and an accumulation of skills. We live in a world of systems. Sociologists recognize at least six such systems: the social system, the political system, the economic system, the educational system, the religious system, and the domestic system. In addition and in permutations, other systems obviously exist as well.

A multi-systems approach to behavioral health allows the essence of many systems to impact the immediate situation. In this discussion we are concerned with the problem of pain management. Any one system offers partial answers; however, in many, perhaps most instances, even several systems offer less than complete answers. It is only in the understanding of multiple systems that we can even begin to understand the complex and vexing problems of pain. However, only the multi-system approach offers the patient and the practitioner a method for dealing with what will frequently be less than what either had hoped would eventuate. It is not only the involvement of several different disciplines working together on a healing team; it is the inherent philosophy, attitude, expectations, modeling, spiritual depth, and many more contributions of each participant. It is the value of whole systems within a holistic context that allows the team to transcend the skills of the individual's discipline and reach into the depths of who each is as a healing person and who the patient is who wishes to be healed.

The purpose of this chapter is not to be definitive in any area, but rather to further the holistic gestalt of the healing enterprise. Healing is both an art and a science, with no one discipline capable of claiming ownership to any larger part than any other discipline. In the most precise definition of healing, all disciplines and techniques are only adjunctive to the person who has the pain. Healing comes from within the organism, not from the technique or system providing the knowledge. All modalities, disciplines, and specialties assist in the process. More often than not, therapies speed the healing process, help the body's systems to sort out their own mechanisms for repair, and stop any further progress of inflammation, infection, and degeneration. Rarely, if ever, is it possible to designate the specific therapy that single-handedly produced the results.

When the outcome of a diagnosis and treatment is positive, all disciplines stand in line to accept the credit; when the outcome is less than desirable, it is difficult to find a discipline that will accept responsibility. The concept of "turf ownership" by professional disciplines has been a serious detriment to finding methods for the management of pain. Turf ownership has meant economic and power brokerage; hence, the needs of human suffering have been sacrificed because of the unwillingness of the healing disciplines to share their knowledge, admit that

0-8493-0926-3/02/$0.00+$1.50

they have a limited area of knowledge, and work with other professionals in a collegial fashion.

The concept of "systems" is crucial in that every healing philosophy builds upon a system that supports both the ideation and the practice of that particular approach. For instance, Western medicine works within a system that has become highly technical, political, and costly. As in all such healing-art systems, it is not possible to change only one part without disrupting the entire system. Sometimes it is easier and more effective to introduce a third player to integrate, sort out, and use parts of multiple systems as needed to arrive at a desired end. Alternative approaches to healthcare are the third party in human suffering at this time. The combination of many systems formerly not admitted into the healing-art circle have forced Western medicine to examine its system. Further, and probably more importantly, medical practice in the United States has been forced to listen to patients who are no longer willing to trust and pay for the one-system approach.

Eastern as well as Western, and all other healing systems, are steeped in cultural determinants that are not easily changed. Folk medicine systems are bound in a history all their own. The behavioral health system approach allows for picking and choosing from many systems rather than ascribing to any one system in its entirety. However, in order for this to happen, the team leader and all participants must allow themselves a professional degree of freedom and have a healthy enough personal ego to withstand the criticism that can be expected from their more system-bound colleagues.

There is no intent in this writing to deny or diminish the valuable contributions of all disciplines to the process of attaining and maintaining health. However, all health, both the attaining and retaining of such, is in the final analysis "behavioral". The patient who will not think positively, eat responsibly, exercise adequately, comply with health provider prescriptions, and at least to a minimal extent take charge of his/her own life, cannot hope to attain health. By the same token, disciplines that by overt or covert action limit patients to one practice of healing may be potentially harmful. Disciplines that do not recognize the behavioral aspects of health and healing sacrifice their patients' health to the ego of their profession. The simple fact that all disciplines rely upon their patients to be compliant demonstrates the foundation and essential nature of behavior as the primary basis for healing.

Western healing arts have been very slow to recognize the behavioral aspects of health and healing. Eastern systems recognized them and built behavioral components into their healing systems thousands of years ago. The difference lies within the focus of the art. Western healing has focused upon the techniques and abilities of the healer. The patient has been an object that was given pills, operated on, treated, etc. Eastern healing has always been philosophy*first* and techniques second. Western healing has emphasized techniques to the near dismissal of philosophy. Only several thousands of years later and in the light of increased technology and failed healing have Western healers (particularly allopathic physicians) been willing to incorporate the behavioral aspects of healing into their practices.

In truth, the majority of medical practitioners still do not incorporate the psychological, environmental, sociological, spiritual, and behavioral components of life into their practices. The name of the game in current Western medicine is "referral," thus further segmenting the body and the mind from the spirit. The patient is left to integrate what differing specialists have prescribed, but ostensibly none of them practices. It is not uncommon for a patient to be tangled in a web of many specialists and suffering from polypharmacy and tremendous confusion, as well as his or her basic illness. Although each specialist is highly trained, each operates within the same system; thus, the patient does not escape the single-system approach even when seeking a second opinion or changing physicians.

Many methods and disciplines that deal with pain exist but are not always administered within the medical system and do not necessarily follow the medical model. Behavioral medicine was originated by L. Birk in 1973 in relation to biofeedback. In 1977 the term was further canonized at the Yale Conference on Behavioral Medicine. The seminal work of Wilbert Fordyce (cf. Fordyce, 1976), utilizing operant conditioning and building on the historical work of Pavlov and Skinner, led the way for understanding the psychological underpinnings and emotional interactions of pain. Behavioral health is used in this discussion to emphasize an even larger concept, namely, that behavior is the key to any and all pain management programs. Understanding the interdisciplinary approach to pain means integrating all management around the firm acceptance that behavior is the major principle regardless of the technique or theoretical approach. Three major innovations sparked the beginning of modern pain theory: behavior modification, neuromodulation, and psychoneuroimmunology.

The Western world is now ready and requesting another innovation. Healing as practiced in this generation has proven that even with the remarkable advancements of medical technology and scientific interventions, the majority of the population cannot avail themselves of these benefits. Cost factors, bureaucracy, mismanaged care, and inattention to the inner person have made modern healing a vocational trade rather than a professional practice. Increasingly we have machines, laboratories, and technicians to do what professional practitioners formerly did. No one can say that medical science has not advanced. One can, and must say, that medical practice has become less face-to-face patient oriented. Thus, the behavioral component of practice has suffered tremendously. Patients no longer benefit from the wisdom of an experienced

practitioner, but are subjected to the statistical, actuarial, third-party pay organizations, whose basic interest is not in health but in profit.

The behavioral component of healing builds upon the concept that healing is much more extensive and deeper than solving the immediate problem of pain or dysfunction. Most ailments and complaints are not the health/illness issue itself but rather the results of that issue. Therefore, relieving symptoms doubtless decreases suffering but may not in truth bring about actual healing. In a multi-systems approach symptoms are seen as the results of dysfunction, not the dysfunction. Therefore, healing is much more than the alleviation of symptoms.

To unite the behavioral elements of healing would require a transformation of the Western mind, and a willingness to subrogate financial gain to the betterment of the individual. Social systems, philosophical ideation, teaching methods, curriculum renovations, administrative approaches, and far more than can be discussed in this short chapter will be needed to allow behavioral systems to bring together what they could and should do. The art and science of medicine in Western thought do not allow for the broadest holistic approach to healing. Larry Dossey, M.D. has helped us to see that healing at its deepest level is primarily behavioral and secondarily technique based (see Dossey, 1993).

We now await a marriage of the marvelous technology of healing to our knowledge of human persons as spiritual beings. Such a union could indeed bring the science and art of healing together. Actually, some small signs of this happening exist in isolated instances. In some places teams of healers are working together within a much more egalitarian system rather than in a pyramidal system with a physician at the top giving orders to the subordinates on the staff. Where systems exist with one profession "on the top", the obvious and practiced approach is that one part of the human is more important than others. It is true that in an emergency situation the hemorrhage must be stopped to save the patient's life; however, if the patient has no will to live, it may all be to no avail.

Relieving pain and building, maintaining, and restoring health belong to many different disciplines. Likewise, dealing with the pain that accompanies human existence is the bailiwick of many professions. Human pain can be classified as physical, emotional/behavioral, and spiritual/existential. This chapter primarily addresses only the emotional/behavioral and the spiritual/existential.

Some of the major professions that most directly assume care for these areas are

- Psychologists
- Psychiatrists
- Social workers
- Counselors
- Marriage/family therapists
- Clergy

Although there are many practitioners of varied sorts within these groups, and some that do not easily fit into any group, for the most part, the mainline professions dealing with human pain of a nonphysical sort are those listed.

Likewise, there are more kinds of intervention than could be listed in a reasonable chapter; however, most treatment modalities dealing with nonphysical pain (and often physical pain) are

- Pharmacology
- Psychotherapy/counseling
- Biofeedback
- Hypnosis/relaxation/guided imagery
- Desensitization
- Group process
- Psychodrama
- Psychoeducation
- Bibliotherapy
- Marriage/family therapy
- Pastoral care
- Social work interventions
- Alternative approaches (see the Encyclopedia of Alternative Medicine)

By far the most prevalent current method for controlling human behavior and any resultant pain (both physical and emotional) is medication. Although the profession best trained to manage psychopharmacology is psychiatry, the overwhelming preponderance of psychotropic medications are prescribed by nonpsychiatrist physicians. Clinical psychologists (trained in recent years) are very well equipped to manage psychotropic medication. However, even though the literature is replete regarding the superior efficacy of combined psychotherapy with psychopharmacology, few psychiatrists continue to practice psychotherapy today. In the not-too-distant past psychiatrists practiced both prescriptive medicine and psychotherapy. Psychologists, who are doubtless the broadest-trained professionals in the area of human emotions, and who do continue to practice psychotherapy, are as yet unable to prescribe. Doubtless this fact will change as public knowledge and demand reveal the benefits of the psychologist as a single behavioral practitioner, who can provide both psychotherapy and medication as well as have the skills to work within many healing systems. Now that psychiatry has moved into other areas, largely medicating the severely mentally ill, the masses of persons needing assistance with the emotional problems of normal living are left without a single service source.

This leaves the management of human emotional pain split among numerous professionals to deal with a single

emotional problem. Depression, probably the most prevalent of all mental illnesses, is illustrative of this point. The psychiatrist prescribes an antidepressant medication and may or may not refer for psychotherapy, and the psychologist provides psychotherapy and may or may not refer for medication.

Psychiatry is best described divided into three areas. Behavioral psychiatry attempts to deal with emotional pain by combining psychotherapy with medication, with the emphasis on psychotherapy and medication as an adjunctive support. Organic psychiatry manages primarily with psychotropic medications, usually without psychotherapy, while placing the emphasis upon neurochemistry. A third area of modern psychiatry, cosmetic psychiatry, actively attempts to modify the personality and the behaviors resultant therefrom entirely by psychoactive agents (see Hedaya, 1996).

A well-rounded, holistic, human-attentive discipline does not exist. The well-trained clinical psychologist is doubtless the closest to such a model. The clinical psychologist who has been trained in a practitioner-oriented model program is knowledgeable of social systems, learning systems, family systems, biological/physiological systems, psychopharmacological systems, a wide variety of diagnostic systems, and a broad spectrum of treatment systems. Such a well-trained professional still needs to be incorporated within the team rather than attempting to be "all things to all people".

We need to clarify the difference between health and healing. Behavioral approaches have value in attaining and maintaining health. They also have a valuable place in the role of healing. Most health professionals are, in truth, mostly practicing symptom relief, i.e., a part of the healing process. Behavioral practitioners, of course, at times also practice only small parts of the process. However, the literature shows that they are much more prone to refer their patients for the benefit of other disciplines than vice versa.

Although patients dealing with physical pain frequently expect to need the services of more than one health service provider, in the realm of emotional pain, relatively few patients expect that they will need the services of more than one provider. Further, relatively few patients receive the services they need in the treatment of mental illness. Physicians under-utilize psychologists for psychotherapy and psychologists under-utilize physicians for medical management. Recent changes in insurance-based medical practice have prohibited many of the referral benefits previously practiced and which practitioners of all kinds would like to continue to afford their patients.

The changing field of training and practice, combined with the evolving landscape of healthcare, is producing dramatic and traumatic changes. As has been noted, psychiatry has virtually abandoned psychotherapy. Psychologists are now trained in psychopharmacology and may soon have prescription privileges. The American Psychological Association at the 1996 Convention in Toronto, Canada endorsed moving toward prescription privileges for psychologists, and five states are currently entertaining potential legislation.

All healing professions are evolving and only the future will tell us which professions will practice certain specific methods. Most of the helping professions are branching out into areas previously practiced by other disciplines, and more and more there is doubt about the essential training needed for the practice of specific modalities. It seems that turf-building and turf-maintenance have been more important than the actual professional expertise required for the application of a specific modality.

For instance, social workers and counselors are including methods of treatment, such as hypnosis, and the use of psychological tests into their practices that were once believed to be the domain of psychology and psychiatry. Optometrists now prescribe medications, opticians are vying for the right to do refractions and, in some instances, are performing opthalmological functions not previously allowed. Nurses routinely prescribe pharmacologic agents with physician supervision that is sometimes very minimal. Pharmacists are moving toward prescription authority, opticians are gearing up for doing vision examinations, psychologists are now training for psychotropic prescriptive practice, and use of nurse midwives is no longer debated in many communities. In many settings, registered nurse practitioners are for all practical purposes today's family doctors. Physical therapists do spinal adjustments and joint manipulation, once the turf of the chiropractor. Most of these, and many more changes did not take place because of training, but rather grew out of need, economics, and political desires. In some instances, mainline medical practitioners were unwilling to provide services to underprivileged and rural populations.

In most instances, the practice began before the formalized education and training. Educational programs and certification followed the establishment of the practice. Such was the history of midwives. In a similar instance, patients were shown to benefit from manipulation; however, chiropractors were not allowed on hospital staffs. Physical therapists were already on the staff and respected practitioners in their field. Manipulation was a "natural" and with training (sometimes quite minimal) manipulative/adjustment techniques were introduced. Many more illustrations of how patient need has permitted and even mandated changes in the health service system exist. The purpose of noting these changes, and the many not mentioned, is that the pain management not only does not belong to one profession, but also nearly every profession is currently undergoing a tremendous metamorphosis in order to encompass more and more of the problem of human pain.

We must recognize that in the final analysis, it is behavior that counts in society. Humans have illnesses all of the time, but society is usually concerned only when behavior is impacted by pain and/or suffering. Different ages held forth different expectations for what was considered normal health. Furthermore, cultures, ethnicities, and even gender demand and allow differences in what is considered normal. Behavior is the key. It is the key to what is considered acceptable and when the patient changes geographic location, religious beliefs, or even jobs, what is acceptable may change. Although we as individuals may care how others feel, in truth, we as society really only care about how people act, and more specifically, how that action affects us as individuals.

In the final analysis, behavioral health is exactly that: behavioral health. Changing behavior can be done in a variety of ways. Sometimes behavioral changes come about due to internal thought process reorganizations. Other times the changes are due only to social demand and we behave in a given way to avoid the unpleasantness of society's reaction to us. At other times, changes in behavior come about due to physical and/or mental changes of a structural nature, e.g., the loss of a limb or the result of brain (or other) surgery. The most effective behavioral change occurs when the individual has reasoned through his/her actions and by cognitive choice has determined to act differently regardless of how he or she might feel or think.

Personality type and parameters of known past behavior are important indices to the adaptation, use/misuse, and eventual outcome of illness. Although the astute interviewing clinician may have excellent clues and insight into these factors, even with short- or long-term observation, psychological assessment utilizing validated psychological tests is the best single method to obtain documentation for diagnosis and intervention in the behavioral aspects of pain management. It was Hippocrates himself who said, "It is more important to know what sort of person has a disease than to know what sort of disease a person has" (quoted from *Alternative Medicine*, 1995).

Human behavior, including the management of pain, is best influenced by cognitive choices. The compliant, cooperative, consciously participating patient is certainly the best patient for helping find solutions. All professions have recognized the value of cognitive intervention in behavior.

Thus, one common thread prevails throughout almost all the professions, and that is counseling of some sort. The difference is whether the counseling is incidental (as in the case of most medical management) or primary (as in the case of psychotherapy).

In most instances, pain cannot be effectively managed apart from patient cooperation. As we do not have accurate methods to measure pain objectively, it is possible for the physical cause of the pain to be removed and for the patient to continue to report its presence. At differing times in our history, we have identified psychosomatic, somatopsychic, allodynic, histrionic, and other forms of pain that medical science could not diagnose by laboratory or physical examination. Finally, most practitioners now recognize that the single most valuable measurement of pain is that reported by the patient, regardless of what the tests may show. Thus, the labels ascribed to various pain experiences are not important. Behavior intervention is, because it starts with the patient's experience and ends with the patient's experience.

Behavioral health systems offer the most effective methods for "entering the patient's experience" and helping the patient to move out of it. Further, it is rarely possible to determine what aspect of treatment actually produced the result. Many practitioners have found that the techniques psychotherapists believe were helpful and what patients report were actually helpful are often very different. Although this type of dilemma makes statistically controlled research difficult, patient benefits are without doubt.

Behavioral health systems work best within a team setting. The reason they are spoken of as "systems" is that each professional entity recognizes that the combination of several disciplines is greater than the sum of the parts. Pain management when left to disciplines that practice in isolation leaves the patient as the coach of the team and often as the untrained captain of his or her pain. The patient is certainly primary and must be central to the planning and implementation of any pain management program; however, pain management given to a team practice combines the best of several disciplines, includes the patient, and equally important, provides a constant quality control check on the total treatment.

Whether the treatment method is problem-solving counseling, insight-producing psychotherapy, or psychoneuroimmunology, the behaviorally oriented practitioner will insist upon:

1. A thorough and complete history of the patient, including, but not limited to, the pain syndrome. This encompasses religious and spiritual aspects, developmental landmarks and difficulties, emotional problems, family concerns, social history, medical history, occupational history, family systems, and at times a genogram, as well as numerous other informational items that arise in the course of taking a complete history. (Few practitioners obtain a careful, complete history, particularly in the patient's own words rather only than from a preprinted form.)
2. The patient's pre-morbid and morbid personality. Frequently, psychological testing combined with the social history and a careful initial interview

provide these data. Psychological testing is the most cost-effective method for obtaining information of this nature. The Beck Depression Scale, The Hardiness Scale, the 16PF, The Minnesota Multiphasic Personality Inventory, The California Personality Inventory, the Edwards Personal Preference Schedule, and many more tests can be utilized to assess the personality. Those mentioned are considered "pencil and paper" type. Other specific tests are known as "projective techniques," such as the Rorschach Psychodiagnostic Test, the Thematic Apperception Test, Kinetic Drawing tests, and others. Tests in trained hands show how personality factors may be of value in understanding the etiology, process, and treatment of pain. Psychologists are helpful in understanding the meaning of pain, the secondary gains of pain, and the perceived purpose of the pain in a patient. The patient's perception is imperative. Pain, after all, is measured by the patient's perception. Without understanding how the patient perceives his or her world, the treatment of pain may only be a laboratory experiment. The reader is encouraged to review the discussion by Materson in this book.

3. The medical/physical/laboratory examination and diagnosis. Care needs to be given to other than routine blood, urine, and fecal tests. Routine tests frequently provide routine results. Physicians tend to be skeptical of some of the newer alternative-type diagnostic procedures. Further, an old axiom in medicine is still true: "We will not find it, if we don't remember to look for it." Persons with chronic pain usually have been through every routine test known and every common disease entity has been explored. The alternative practitioner often is successful when the traditional one is not because other avenues are being explored and tests considered by the general medical community as out-in-left-field are being pursued. A patient was recently referred to one practitioner who was two years post-CVA with residual hemiparesis and significant depression. Prozac and other SSRI mediations were part of her polypharmacological management by a variety of physicians of different specialties, but her condition was worsening. The use of her right arm and leg was only slightly better after two years of physical therapy, and her depression was severe and sometimes suicidal. Psychotherapy combined with auricular acupuncture produced dramatic results very quickly as two practitioners worked together. Medications were brought into reasonable control, and her mood was stabilized, with only minor episodic depressions. She is now opening doors with her previously paralyzed hand, utilizing prehensile grasp, and remarkably improved in overall social functioning. She, as well as her primary care physicians, were afraid of trying alternative approaches. Dr. Norman Shealy's book, Miracles Do Happen (1995), testifies to the effectiveness of alternative approaches to pain management.
4. Collaborative interviews and networking for diagnostic and treatment information and patient support. No individual practitioner can offer sufficient help in the limited time available. The family (and at times other networking persons) needs to be seen as a primary resource for support. This means family education, inclusion in the treatment plans, in the actual in-home treatment, and follow-up. Pawlicki discusses the role of the family elsewhere is this book. In primitive societies, the patient's family actually assisted the nursing, dietary, and housekeeping staff in hospitals. The emotional, hence healing, support given to the patient is clearly beneficial, to say nothing of the cost factor.
5. The willingness to experiment with different approaches. No one method of treatment suffices for all patients. Practitioners who are unwilling to entertain new ideas and new methods become disappointed in results. Patients who are unfortunately stuck with such practitioners suffer from stagnation and closed-minded thinking.
6. The emotional/existential aspects of human pain frequently require a deeply spiritual intervention. Although it does not require a clergyperson, frequently a clergyperson trusted by the patient can make early interventions very effectively. Rituals, symbols, and highly personal spiritual actions often produce healing. Further, every person has his or her own interpretation of the meaning of pain and why it is being endured. When a patient believes that pain is inflicted by God and must be endured for heavenly reward, it is very difficult to allow anyone to take away the pain and hence take away the reward for faithful endurance!
7. Last, but far from least, listen to the patient. Early labeling does not help. Considering a patient psychosomatic is of no value. Early correct diagnosis is obviously of major importance;

> however, we must not lose sight of the many times that the early diagnosis is wrong, but a plan of treatment is in place and not easily interrupted to look for another diagnosis. Because pain is perceived, and perception is reality to the patient, only the patient can tell the practitioner what hurts, what is wrong, and frequently what needs to be done to correct it.

This is particularly true in regard to emotional pain. The concept of behavioral health systems includes the concept of the person as part of a system which includes the family, neighborhood, school, church, club, community organizations, and all other aspects of occupation, society, and the world with which they are closely linked. One cannot overemphasize that to treat the person is to treat the system. To attempt to treat the patient without reference to the system is to assume an overly powerful role and to think that the influence of a few minutes in the practitioner's office can overcome the influence of the many hours during the week with family, friends, and the community.

Sometimes patients must be allowed to live with their pain until they are ready to give it up. The practitioner should not feel discouraged or that he or she has failed when patients do not overcome pain. The reward is real for both the patient and practitioner when pain is relieved; however, if the practitioner is successful in truly entering the patient's world, and if the patient establishes a healthy relationship with the practitioner, healing has begun.

The meaning of the relationship must be underscored. Patients learn to trust when there is genuine caring. Patients know if they are being treated as a person. Transference and counter-transference cannot be avoided; they can only be controlled and utilized productively. Positive transference is to be encouraged. The misuse of the transference phenomenon, which produces a transgression of boundaries, has unfortunately led to "throwing out the baby with the bath." The behavioral health system includes the practitioner as an integral part of the system. The practitioner who wishes to be a technician cannot extend his or her own healing qualities. The patient will respond to a relationship with trust and will respond to a technician as to any machine.

Some therapists take pride in avoiding relationships. To think that one does so is only a figment of the imagination. Whenever two persons meet, let alone work together on pain, an automatic, unavoidable relationship is established. The question does not have to do with whether there will be a relationship; the question only has to do with whether it will be a positive, healing one or a negative, damaging one. Many practitioners employ the healing tools of their trade only to cancel out those benefits with their poor interpersonal relationship ability.

The more one studies psychoneuroimmunology, the more one is forced to recognize the spiritual aspects of healing, including the value and art of touch, attitude, transfer of energy, prayer, meditation, and truly wishing another well. Such aspects of healing are not possible within negative relationships. Researchers who have studied healing in other cultures have documented both the positive and negative effects of psychoneuroimmology as well as the effects of cultural expectation. Voodoo, shamanism, and other psychic manifestations of culture, religion, and ethnicity are not unreal because they are psychic. They are all the more real because they emphasize the underlying behavioral systems that produce and alleviate human suffering.

When behavioral health systems are encouraged to work in harmony, the outcome is always greater. To argue whether the physical pain produces the emotional or vice versa, as is sometimes discussed, is immaterial. It is only when the practitioners of all parts of the human dilemma join the same team that answers to the problem of human pain are found. Behavioral health systems are crucial in understanding, not necessarily explaining, the causes of pain. As part of these systems, the behavioral health scientist utilizes a vast array of techniques and is often the best-equipped professional to be the team leader.

Suffering and pain are not synonymous. We may be better able to assist with suffering than with pain. Persons at peace with themselves and those around them clearly suffer less when in pain than those who are not. Pain is reduced or increased by one's perception of suffering. The narcotics used for pain control are linked to physiology. Pain and suffering may or may not be linked at the same time and/or in the same way to physiology. Suffering may not be reduced simply by the alleviation of pain. Why humans suffer is an age-old question epitomized in the biblical book of Job and doubtless discussed long before that time. We do not hope for understanding of the philosophical, theological, existential, and other esoteric aspects of pain. We do, however, believe that although we may not know why we suffer, we can learn to suffer less and assist others in relieving at least some of their suffering. Suffering, as distinguished from pain, is a learned response, as is the lack of suffering. Suffering occurs both in the presence and the absence of pain. Behavioral responses are not always explainable; however, they may be understandable. We do need to remember that pain is many times a friend, in that without pain we could die without knowing we were even ill. Suffering has its values. The lack of suffering for some, and in some cultures, is in and of itself painful. To relieve one of suffering does not guarantee the relief of pain, nor does the relief of pain guarantee the relief of suffering.

Pain must also be seen as a disease entity in and of itself not simply the result of injury or illness. It is possible

that at times pain is the illness. Pain disrupts, brings about dysfunction, produces further illness, and is far more than a combination of symptoms that could be classified as a syndrome. Pain, when diagnosed as a distinct illness, requires a full and complete behavioral and medical team to intervene. Frequently, until pain is seen as the illness rather than the results of an illness, permanent relief is not possible. When pain is recognized as the illness, behavioral approaches are mandatory in unraveling the mystery of pain and suffering.

Promoting Ethics and Objectivity in the Medicolegal Arena: Recommendations for Experts

Michael F. Martelli, Ph.D. and Nathan D. Zasler, M.D., F.A.A.P.M.&R., F.A.A.D.E.P., C.I.M.E., D.A.A.P.M.

INTRODUCTION

The skills required for conducting medicolegal evaluations too often exceed the expertise of the professional performing them. This certainly appears true in the personal injury arena, where promises of large financial settlements and higher forensic reimbursement rates have resulted in a proliferation of practitioners choosing this specialization. Too often, this occurs without having procured sufficient specific training in medicolegal evaluations and/or having demonstrated expertise in a clinical specialty independent of forensic practice. It is perhaps more so the case for chronic pain treatment providers who are frequently called into medicolegal proceedings as an incidental and sometimes undesirable consequence of routine clinical treatment.

Importantly, identifying and mitigating ethical conflicts that arise within the medicolegal arena present a formidable challenge for even the most skilled of forensic experts. Clinical training in medical and graduate schools has a customary and usually exclusive focus on training related to advocating for the patient's well-being. In independent examinations (IE) conducted within medicolegal contexts, the distinguishing feature is a requirement for objectivity that requires dissolution of the patient–doctor relationship in favor of a dispassionate examinee–examiner relationship. Collaborative rapport and expectancies of trust and assistance are eschewed. The resulting disparity produces many inherent ethical conflicts. Some are easily avoidable and tend to be associated with the unscrupulous practices of a few. Many others, however, relate directly to the medicolegal context itself, where the adversarial nature of the legal process conflicts with the scientific and therapeutic ethics of clinical treatment.

This chapter explicates the professional standards and ethical responsibilities of forensic experts who conduct medicolegal evaluations, with an emphasis on the role of the expert in facilitiating objective evaluations that assist the court in its decision-making process.

PROMOTING OBJECTIVITY AND GUARDING AGAINST BIAS

Without exception, the guiding principle in forensic ethics is the expectancy that the scope and content of an IE, subsequent reports, and testimony offered in depositions and court proceedings would be the same regardless of who retained the professional in question (American Academy of Physical Medicine and Rehabilitation, 1992; American Medical Association, 1997; Committee on Ethical Guidelines for Forensic Psychologists, 1991). However, frequent observations of significant disagreement among professionals, supported by preliminary survey data collected by the authors, indicate that lack of objectivity, or bias, is an all-too-frequent occurrence.

0-8493-0926-3/02/$0.00+$1.50

There are several common sources of bias, most of which can be addressed in terms of general professional ethics.

Communications in the Forensic Evaluation

Clear communications of ethical standards (e.g., informed consent) with both the attorney and examinee prior to commencement of the evaluation are prerequisites for establishing ethical interactions that facilitate objectivity. Examinations from treating clinician vs. the unique intent of the independent examiner, which produce wide discrepancies in terms of the type, scope, and time requirements of the evaluation, should be clarified with the examinee. Explaining that opinions regarding diagnoses, prognoses, and/or recommendations will not be shared directly should be included. The policy of asking the examinee to sign an informed consent form, with a witness present, is an increasingly adopted policy to be considered. Full appraisal of the retaining attorney should also define the scope and extent of the services rendered. These issues will be discussed in greater detail below.

The "Professional" Expert Witness

Experts who derive a large part of their income (i.e., 50%) from medicolegal evaluations may be at special risk for compromised objectivity. Medicolegal work incurs fees that are substantially higher than regular clinical fees, with generally much greater reimbursement. Significant pressures to maintain continued highly lucrative medicolegal referrals exert pressure to offer opinions consistent with the views of retaining attorneys, whose primary motivation is client advocacy.

Importantly, courts and attorneys usually prefer black/white opinions and eschew practitioners with less simplistic diagnostic and conceptual viewpoints. Practitioners can be subtly reinforced while garnering much higher reimbursements (vs. standard clinical fees) by employing a more dichotomous and simplistic (and easier) adversarial ethic vs. a scientific (more laborious) ethic in their opinions that are solicited (and paid for) by attorneys.

As is often the case, experts who are strongly invested in medicolegal practice will have an unequal weighting of referrals from defense or plaintiff attorneys, and in extreme cases experts may completely exclude one of these two groups. Further, professionals, like others, only have not biases, but also personal styles better suited for some settings than others.

Based on results of previous ethics surveys (Pope & Vetter, 1992; discussed below), observations of local practitioners, informal surveys and subsequent formal surveys conducted as part of an ethics review project, some preliminary inferences were offered by the first two authors (Martelli, Zasler, & LeFever, 2000a). Based on results of an anonymous survey of brain injury service providers from two southeastern cities, degrees of medicolegal involvement and degree and type of nonobjectivity among fellow professionals were estimated, along with requests for personality descriptors. Bias ratings showed strong positive association with the estimated degree of medicolegal involvement. Further, bias was fairly evenly distributed and discretely categorized into the three bias category options included on the survey: (a) plaintiff slant; (b) defense slant; and (c) retaining attorney slant. Further, there was some association between skeptical or suspicious behavioral traits and compulsive tendencies with practitioners perceived to have diagnostic biases more compatible with defense attorney interests/medicolegal involvements (i.e., defense expert). Histrionic or hypochondriacal and sympathetic personality traits were more associated with practitioners perceived to have diagnostic biases more favorable to plaintiffs (i.e., plaintiff expert). Descriptions relating social finesse and flexible morals, in contrast, were associated with practitioners perceived by reputation as attorney experts (i.e., agree with the retaining side, whether defense or plaintiff).

Importantly, a particular medicolegal specialization can be presumed to result in continued reinforcement of the same traits that served as a predisposition to the specializations, further reinforcing bias. Notably, the only protection against bias concerning pressures relating to high reimbursement rates and personal biases is the insistence on striving toward a local reputation for being fair and objective (i.e., a "straight shooter").

Bias also can be associated with exclusive attorney referral patterns. Many attorneys will avoid situations where there is consistent use of the same experts because of the appearance of bias. Nonetheless, the medicolegal community is not without examples of professionals who have been the sole forensic experts for the entire caseload of an attorney over the course of several years. Probitive questions during voir dire (i.e., questioning of an expert to establish the scope and depth of his or her expertise prior to being accepted as an expert) frequently address such questions, along with financial arrangements associated with forensic practice, etc.

ETHICS IN CONDUCTING MEDICOLEGAL EVALUATIONS

As a group, physicians pledge to uphold the Hippocratic oath, which directs that first and foremost, they do no harm. Licensed psychologists, although they take no oath, by virtue of privilege of license, adhere to professional ethics mandating that they promote the welfare of their patients, according to formal, professional, ethical guidelines published by the American Psychological Association (APA) and any regulatory state statutes (American

Psychological Association, 1995). The common thread implicit in all professional interactions is doing no harm to patients and others to whom the expert has responsibility. This ideal extends to professional work in the medicolegal community.

In a membership survey of the American Psychological Association (APA), randomly sampled psychologists were queried regarding ethical concerns in clinical psychological practice (Pope & Vetter, 1992). Forensic psychology ranked as fifth among the 23 categories of reported incidents of ethical dilemmas behind confidentiality, dual relationships, payment concerns, and teaching/training concerns. Major concerns included presentation of false testimony, the attorney's role in procuring desirable (potentially false) testimony, rendering of conclusions not grounded in objective data or scientific principles, and harm from reporting inaccurate data in forensic cases. Truly bitter language (e.g., "whore"), however, was reserved for descriptions of psychologists perceived as willing to present false testimony in court and/or who succumb to alleged attorney pressures or inducements for this kind of testimony.

A more recent membership of the National Academy of Neuropsychology (Brittain, Francis, McSweeney, Fisher, and Barth, 1997) revealed concerns from the majority of 456 respondents regarding examiner competence (64%), inappropriate use of tests (61%), and conflict between the law and ethics (55%). Further, 50% opined that the APA ethics code was insufficient to address ethical problems in neuropsychology, while 57% expressed dissatisfaction with the ability of ethics boards to enforce guidelines.

Clearly, such issues concern professionals practicing in the forensic and medicolegal arenas, the legal system, and those entities that make policy concerning training and certification for professional competency. Unfortunately, most physicians and psychologists acknowledge that they receive insufficient formal training or education with regard to ethics in medicolegal/forensic situations and that guidelines for ethical medicolegal practice have been lacking (Martelli, Zasler, & Grayson, 2000).

Problematic situations are inevitable when medical and psychological ethics are brought into the courtroom, where adversarial client advocacy is the rule. Appreciation and sensitivity to the potential disparities between conflicting interests and ethics seem the most logical approach to protecting the ethics and objectivity of medical and psychological examiners while affording the courts and its representatives benefit of their expertise. In the current chapter, relevant ethical issues are reviewed in order to illustrate ethical behaviors as they relate to many common aspects of medicolegal situations. Although some of the current dilemmas described are unique to the interaction of the American legal and healthcare systems, most have international relevance.

Expertise and Qualifications in Medicine and Psychology

It has been previously noted that formal guidelines describing the qualifications to serve as an expert witness are only recently being developed. General Principle A of the American Psychological Association Ethical Code for Psychologists (1995) implicitly addresses this issue:

> Psychologists strive to maintain high standards of competence in their work. They recognize the boundaries of their particular competencies and the limitations of their expertise. They provide only those services and use only those techniques for which they are qualified by education, training, or experience.

This principle is especially relevant to guidelines developed by Binder and Thompson (1995), which cover issues related to maintaining awareness of the relevant neuropsychological literature, seeking rigorous peer review to ensure competence, limiting practice to boundaries of competence, and seeking consultation as appropriate. Parallels certainly can be applied to physicians involved in the same process.

In 1996, the American Medical Association published its Code of Medical Ethics through its Council on Ethical and Judicial Affairs (AMA, 1997). Although this document is relatively general, it does stipulate that "medical experts should have recent and substantive experience in the area in which they testify and should limit testimony to their sphere of medical expertise." The code also notes that the "medical witness must not become an advocate or a partisan in the legal proceeding." Additionally, it encourages witnesses to inform attorneys of "…all favorable and unfavorable information developed by the physician's evaluation of the case."

There have been numerous other specialty organization publications dealing with recommendations for expert witness testimony. The American Academy of Physical Medicine and Rehabilitation's Board of Governors approved a "white paper" on expert witness testimony in April 1992. Central to these guidelines is the concept that the expert witness functions to educate the court as a whole, as opposed to "representing either of the parties involved, even though the expert witness may have been contacted primarily by one party." The guidelines note that the ultimate test for accuracy and impartiality is a willingness to prepare testimony that could be presented unchanged for use by either the plaintiff or defendant. Further review of this document reveals several recommendations which warrant attention: (1) the physician should identify opinions which are personal and not necessarily held by other physicians; (2) a distinction should be made between medical malpractice and medical maloccurrence when analyzing any case; and (3) there should

be a willingness to submit transcripts of depositions and/or courtroom testimony for peer review.

Especially relevant are guidelines that have been adopted by the American Academy of Neurology and developed by the American Board of Medical Specialties for the physician expert witness, which include the following two standards:

1. The physician expert witness should be fully trained in a specialty or a diplomate of a specialty board recognized by the American Board of Medical Specialties, and qualified by experience or demonstrated competence in the subject of the case. The specialty of that physician should be appropriate to the subject matter in the case.
2. The physician expert witness should be familiar with the clinical practice of the specialty or the subject matter of the case at the time of the occurrence, and should be actively involved in the clinical practice of the specialty or the subject matter of the case for three of the previous five years at the time of the testimony.

The preceding guidelines are frequently cited as a useful model for guiding expert witness qualification in clinical neuropsychology (Lees-Haley & Cohen, 1999). With regard to the first standard, however, it should be noted that standards of training in neurology are considerably easier to demonstrate than in neuropsychology. Standardized medical school curricula, standardized residencies approved by the American Board of Medical Specialties to insure common standard compliance, written examinations of basic medical information for individuals with degrees from foreign medical schools, and eligibility to sit for board specialty certification examinations all exist as clearly demonstrable criteria.

Clinical neuropsychology, as a profession, has been making greater efforts toward standardization of training, but given greater variability, has tended to rely even more strongly on board eligibility as an independent criterion with which to evaluate education, training, and experience. The APA Division 40 definition of a clinical neuropsychologist describes prerequisite training while suggesting that the attainment of the American Board of Professional Psychology (ABPP)/American Board of Clinical Neuropsychology (ABCN) diploma is the clearest evidence of competence as a Clinical Neuropsychologist (Division 40 Executive Committee (1989). More recently, training guidelines have been defined and accepted by professional organizations in neuropsychology (Hannay, Bieliauskas, Crosson, Hammeke, Hamsher, & Koff, 1998).

Based on these training guidelines and definitions, Loring (1995) proposed board eligibility as the training standard for expert witness consultations. This requirement would seem to promote standardized practice of neuropsychology while also providing a measure of quality control for those who conduct neuropsychological assessments for forensic cases.

The second standard regarding subject matter competency proscribes the offering of opinions outside areas of a professional's competence. In addition, it requires continuing active clinical practice in the area relevant to expert testimony, for 3 of the previous 5 years from the date of testimony. The failure to define level of "active clinical practice" might seem somewhat problematic, although by implication, greater vs. lesser levels of active practice would be more consistent with this principle. Consistent with APA Standard 1.05, which states that "psychologists … maintain a reasonable level of awareness of current scientific and professional information," Binder and Thompson (1995) offer that psychologists should remain aware of general trends in the relevant neuropsychological literature, use up-to-date neuropsychological tests and norms, rely on current knowledge, consider important demographic characteristics of individuals in making interpretations, and acknowledge limitations in current knowledge. An ability to discuss relevant research literature, accurately, and without notes, would be an obvious measure of this ability.

An additional issue with regard to identification of good expert witnesses in the area of evaluating persons with neurologic disability relates to credibility. Aside from the issues discussed above, it should be noted that many practitioners flaunt multiple certificates hanging on their walls. However, for many organizations, these certificates represent little more that "vanity" boards, where eligibility requirements are hardly stringent. The integrity of the individual should, in part, of course, be measured by the quality of the organizations they belong to, and the thoroughness of the inclusionary process for each organization. Relevant questions include whether the certifying organizations required the individual to take some type of oral and/or written test, what other inclusionary criteria were employed, whether attendance is required at a certain number of approved courses per year, whether the organization is the primary certifying organization, and so on. Inquiries about manner of receipt of board certifications and diplomates are important, given that certifying organizations and clinical specialty boards may have, in their earlier years, allowed "grandfathering" in of persons who were not required to meet current inclusion requirements.

Examination of the individual's publication record, as well as the types of publications should be assessed. Relevant questions would include whether the articles were published in peer-reviewed publications, and their recognized quality. In addition, lectures in one's claimed area of expertise should be reviewed, as should the organizations for whom they have lectured, with an emphasis on looking for those that are nationally or internationally

recognized. It is also important to critically examine an expert's qualifications based in part on clinical, scientific, academic, and administrative positions held, and the manner in which they gained appointment (e.g., the individual's historic performance, a voting process, or some less selective process).

Martelli, Zasler, and Grayson (1999) have attempted to summarize the relevant criteria by which professional expert competence can be evaluated. These have been adapted for psychologist and physician specialists in chronic pain assessment and treatment are included in Table 72.1. As can be seen, they are heavily borrowed from ethics in psychology. A qualifications checklist is included for the general knowledge/competency (again, borrowed primarily from psychology). In addition, a selected qualifications checklist is included for Chronic Pain Specialists. Finally, an Expert Opinion Competency/Credibility Weighting summary list is offered, which represents a preliminary framework for evaluating relative credibility of expert witnesses.

Dual/Multiple Relationship Considerations

Multiple relationships potentially constitute an ethical dilemma in the medicolegal context. For example, as indicated in APA Ethics Code, Section 1.17 (1995):

> Psychologists must always be sensitive to the potential harmful effects of other contacts on their work and on those persons with whom they deal. A psychologist refrains from entering into or promising another personal, scientific, professional, financial, or other relationship with such persons if it appears likely that such a relationship reasonably might impair the psychologist's objectivity or otherwise interfere with the psychologist effectively performing his or her functions as a psychologist, or might harm or exploit the other party.

There is a strong tradition in clinical psychological practice relating to proscription of both developing personal relationships with persons who are current or former clients, or providing psychotherapeutic services to persons with whom a prior personal relationship exists. Clearly, this prohibition is intended, in the former situation, to protect a patient from potential exploitation in a relationship predicated on equal status by someone who maintains, or previously maintained, a relationship based on higher power or skills and dependency. In the latter case, the purpose is guarding against problems stemming from the preexisting relationship obligations and biases conflicting with the prerequisite objectivity required by a psychologist for effective diagnosis and treatment.

The latter protection is most relevant in medicolegal work. Consistent deliberate opinion exists that a preexisting professional relationship would represent a potential conflict of interest that interferes with the objectivity required by an expert witnesses. As such, the presence of a preexisting relationship should usually eliminate consideration of serving as an expert witness in the case where any other expert is available. It should be noted that this mandate is often at odds with the conceptualization of experts in the legal community, where treating clinicians" are often considered to be more credible experts from the standpoint that they have more familiarity with the patient.

Perhaps the only exception might occur when no other expert is or can be made available, or where declining to serve as an expert witness might produce resultant harm to the patient from deprivation of needed service that outweighs threats to objectivity. In such cases, prudence would mandate documentation in the report of both the preexisting relationship and procedures and safeguards employed in order to facilitate the highest possible levels of objectivity. This should, of course, be balanced against potential compromise of the therapeutic relationship if the patient did not receive the desired expert testimony and/or opinions supportive of the patient's legal claim.

In an effort to elucidate ethical conflicts due to potential multiple relationships of medical professionals engaged in standard medicolegal practice, Blau (1984; 1992) differentiated the following professional roles: (1) "Treating Doctor", who has a special (usually empathic) bond with his/her patient, and whose role is to describe the everyday treatment procedures that were employed, and not offer opinions beyond those contained in their reports, or perform evaluations on the basis of anything other than medical necessity; (2) "Expert Witness", who without prior knowledge of the examinee obtains special and extraordinarily complete information and for whom, in order to promote objectivity, no bond with the examinee is permitted; (3) "Trial Consultant", whose function, consistent with the adversarial process, is to assist with critical scrutiny and impeachment of experts and opinions from the opposing side. As Blau notes, these roles represent different interests and obligations. Failure to set limits and avoid mixing of the conflicting interests inherent in these contrasting roles would undoubtedly reduce objectivity and compromise the opposing welfares of the different parties to whom obligations are maintained.

Unfortunately, in a frequently observed occurrence by the authors, treating clinicians accept invitations to serve as "expert" witnesses when other professionals are available. Although understandable, this practice is nonetheless problematic. This practice is appealing to attorneys for several reasons, including ease, as the professional is already involved; inherent time and/or cost savings to the patient and his or her legal representative; and the advantage of natural advocacy inherent in clinician-patient relationships. The problems include mixing of usually incompatible roles. The fact that this frequently occurs may be explained by

TABLE 72.1
Summary Guidelines for Evaluating Professional Expert Qualifications

Professional Expert Qualifications Checklist: General

- Knowledge Competence Base (derived from APA Ethics and P.M. &R. White Paper):
  - ❑ Remains aware of general trends in the relevant neuropsychological literature and incorporates current knowledge into regular p tactice
  - ❑ Uses up-to-date neuropsychological tests and norms and considers important demographic characteristics of individuals in making interpretations.
  - ❑ Appropriately acknowledges limitations in current knowledge.
  - ❑ Seeks rigorous peer review to ensure competence.
  - ❑ Can discuss relevant research literature accurately, without notes.
  - ❑ Limits practice to boundaries of competence, seeking consultation as appropriate.
  - ❑ Is fully trained in a specialty or has earned a diplomate of a specialty board in spacialty area (i.e., Pain Management), and is qualified by experience or demonstrated competence in the subject of the case.
  - ❑ Is familiar with the clinical practice of the specialty or the subject matter of the case at the time of the occurrence, and has been actively involved in the clinical practice of the specialty or the subject matter of the case for three of the previous five years at the time of testimony.

Professional Expert Qualifications Checklist: Chronic Pain

- **Professional Organizations:**
- (A) Current Memberships
- (B) Current Committee Memberships
  - ❑ American Academy of Pain Management
  - ❑ American Pain Society
  - ❑ American Academy of Pain Medicine
  - ❑ International Association for the Study of Pain
  - ❑ Canadian Pain Society
  - ❑ World Institute of Pain
  - ❑ State or regional chronic pain associations
  - ❑ Special national associations with significant pain management components (e.g., American Chiropractic Association, Assoc. for Applied Psychophysiology and Biofeedback)
  - ❑ Am. Psychological Assoc: Division 22 (1/2 point)
  - ❑ American Academy of Physical Medicine and Rehabilitiation (1/2 point)
- **Specialty Conference Attendances:**
- (A) # Attendances at Last Three Meetings of…?
- (B) # Presentations at Last Three Meetings of…?
  - ❑ American Academy of Pain Management
  - ❑ American Pain Society
  - ❑ American Academy of Pain Medicine
  - ❑ International Association for the Study of Pain
  - ❑ Canadian Pain Society
  - ❑ World Institute of Pain
  - ❑ State or regional dedicated Chronic Pain Conferences
  - ❑ Conferences of specialty national associations with significant pain management components (e.g., American Chiropractic Association, Assoc. for Applied Psychophysiology and Biofeedback)

the typically greater emphasis in professional ethical codes to proscription of conflicts between professional and non-professional roles and activities than between differing professional roles. Strasburger, Gutheil, and Brodsky (1997) argue that these conflicting professional roles should be avoided by offering the patient treatment record in lieu of testimony. That is, they recommend that treating doctors maintain strict role boundaries as fact witnesses and decline to perform the functions of an expert witness. In other words, treating clinicians ideally should provide testimony only as fact witnesses, and decline expert witness activities such as reviewing the reports or depositions of other witnesses. In situations where testifying as an expert witness cannot be avoided, they should acknowledge the inherent conflicts in both testimony and reports.

With regard to the relationships between attorneys and health practitioners, contrasting professional motivations and standards produce frequently conflicting interests. Financial incentives, which are well-recognized threats to objective patient reports, deserve equal consideration as a threat to to medical practitioners. Given the discrepancy between the adversarial client advocacy of attorneys, and the dispassionate, objective scientific ethics required of physicians and psychologists, concern must necessarily be raised when one considers that attorneys are the usual referral source, payers, and consumers of examination findings and reports from experts.

Moreover, medicolegal evaluations tend to be conducted by a limited number of professionals in the community, which fosters the development of social relationships between referring attorneys and medicolegal examiners. At a time when insurance reimbursement severely restricts payments, it would seem naive to think that attorney satisfaction with examiner findings is an irrelevant factor in the development of referral decisions, formal referral relationships, and/or social relationships. Subtle test-interpretation influences and adoption of adversarial and dualistic tendencies (e.g., either–or, black–white) in interpretation of findings may be operative both above and below the level of expert examiner or witness awareness. Such subtle threats to objectivity would seem especially likely in cases of greater ambiguity in either test results, behavioral observations, and/or responses on measures of motivation and response bias.

Importantly, the process of a consulting call to the examiner from the referring plaintiff or defense attorney to discuss initial findings and favorability to the case often represents an invitation to join the client–attorney team. Depending on favorability of findings, additional paid consultations may be scheduled with the expert regarding methods of presenting findings and invariably, juxtaposing the findings against opposing counsel arguments. This practice represents a subtle but incremental team invitation. This veiled invitation to join the client–attorney team seems much less subtle when the issues of validity of findings become equated with winning in court by a favorable jury or judge ruling.

Another important influence of an adversarial legal process is the reinforcement of dichotomous opinions. Uncertainties, shades of gray, and reservations are usually not conducive to an adversarial process and are often

eschewed in the legal process. Our experience confirms the expectancy that the initial selection of an expert is influenced by reputation and history with regard to the expert's tendencies to think in "black and white" vs. "shades of gray" and/or to find single causes vs. multiple determinants of behavior. Much less obvious are the tendencies for social reinforcement and subtle increases and decreases of interest or ego approval to potentially influence opinions in borderline situations.

For example, in the case of ambiguous clinical findings where an opinion of either malingered or valid test results is rendered in an attorney consultation, an initially tenuous endorsement could inappreciably become strengthened by confirmatory bias. That is, the tendency to selectively considered evidence in accordance with existing bias could be fueled by the clinician's underlying discomfort with expressing opinions that appear uncertain or displeasing to the retaining attorney.

With regard to the current healthcare environment, Martelli, Zasler, and Grayson (1999) noted that current managed healthcare organizations and practices leave many physicians, psychologists, and other healthcare professionals feeling diminished. Their expertise, opinions, and recommendations are questioned, while their services are constrained. Medical necessity has been redefined by bottom-line business accounting that pays greater attention to cost-effectiveness demands, increased accountability, and a low-leniency, cost-cutting atmosphere. At the same time, reduced insurance coverage and reimbursement create pressures to maintain accustomed standards of living by identifying new income sources for healthcare providers. Clearly, medicolegal work represents one of the last unregulated frontiers. The lucrative attorney referral-driven medicolegal arena clearly poses a real economic opportunity that not only offers financial incentives, but also ego expertise enhancements, which signify pressures for bias that ranges from subtle reinforcement of adversarial- and dualistic-oriented opinions to shaping of perspective. As such, the typical healthcare professional should assume that the maintenance of scientific objectivity will necessarily be difficult.

In a proposed remedy, Brodsky (1991) offers an interesting recommendation for protecting medical professionals from mixing the disparate responsibilities of science and adversarialism. Brodsky offers an objectivity quotient that equals the number of cases in which there is agreement with the referring attorney, divided by the total number of cases. He suggests that base rate and referral difference be acknowledged and offers a preliminary cut-off point of 0.8 or greater for suggesting preexisting bias. The present authors consider this a somewhat liberal cut off and suggest a maximum of 0.75.

Ethical Issues in Conducting and Independent Examination

Informed Consent

Within the context of the actual examination, full disclosure regarding the purpose of examination, as well as the tests and procedures being utilized, is required to optimize examinee compliance. Examiners must be careful about such disclosure in order to promote a balance between accurately representing the purpose of the testing to the examinee, without increasing distrust in a process that is, by its legal nature, adversarial.

As previously noted, many evaluations conducted from more traditional clinical referral sources and not originally performed as medicolegal evaluations become part of subsequent litigation proceedings. This is especially true in cases of injury and impairment. The medicolegal context clearly imposes special obligations and responsibilities for the medical professional. With regard to psychologists, relevant professional ethical principles have been elaborated.

Section 1.21 of the APA Principles (1995) states:

> When a psychologist agrees to provide services to a person or entity at the request of a third party, the psychologist clarifies to the extent feasible, at the outset of the service, the nature of the relationship with each party. This clarification includes the role of the psychologist (such as therapist, organizational consultant, diagnostician, or expert witness), the probable uses of the service provided or the information obtained, and the fact that there may be limits to confidentiality.

Informed consent guidelines have been provided by Johnson-Greene, Hardy-Morais, Adams, Hardy, and Bergloff (1997) for neuropsychological evaluations. They recommend that neuropsychologists explain fully to all patients in language that can be easily understood the purpose of the examination, the reason for referral, and any limitations of confidentiality. In medicolegal evaluations it is also important to indicate who will provide feedback about results, or explain that the circumstances of the independent evaluation dicate that no feedback is provided.

These ethical principles and related guidelines are probably more easily observed for evaluations conducted at the request of the plaintiff attorney, who functions as patient advocate and usually has communicated the purpose and potential benefit of the evaluation. In addition, the manner in which feedback will be provided is explained. Requests for independent evaluations from defense counsel, however, may be more challenging, given that the referral from the opposing attorney promotes greater distrust, especially when the examinee is informed

regarding the nature of the assessment, the examinee's relationship to the opposing attorney or insurance company, and information that feedback will not be provided directly to the examinee.

Third-Party Observers

It has been observed previously that court orders sometimes have permitted attorneys and/or legal representatives to sit in on independent evaluations. In such cases, the independent evaluation process is potentially corrupted as an additional and uncontrolled factor is added that may influence examinee behavior and performance. Less invasive, but possibly still disruptive, is videotaping of the independent examination. Probably least disruptive, although still possibly a threat to the integrity of the process, is the practice of audio taping of independent evaluations.

An additional ethical threat is posed when test material and examination procedures are revealed. Unprotected disclosure of assessment instruments and examination procedures potentially reduces the validity of such procedures in future assessment situations with other persons and, hence, potentially compromises the greater welfare of the public at large.

With regard to psychological and neuropsychological tests instruments and procedures, task force committees of the APA have issued reports with specific guidelines intended to limit the disclosure of tests, in order to protect the integrity and security of test materials, and to avoid misuse of assessment techniques and data (American Psychological Association, 1996). Notably, one of the tenets of the independent examination is that the examiner conveys only information that was garnered within the context of the exam, does not alter exam findings in any way, and does not document things that did not occur. At a less tangible level, the independent examiner's role is to make objective clinical interpretations and inferences based on dispassionate logic that is devoid of personal interest or interests of others. In contrast to the attorney, who explicitly advocates as an adversary for his or her client, the examiner should function only as an advocate for the truth. Too often, however, the adversarial nature of courts, legal proceedings, and attorneys "creeps" into the scientific arena and introduces a significant and powerful threat to objectivity that can produce bias in persons purportedly functioning as scientists. When creeping adversarialism (Martelli, Zasler, & Grayson, 2000b) infiltrates the examinations and opinions of scientists, distrust generated by systems adhering to adversarial principles only increases. Of course, the nature of these systems dictates that they must attempt to discredit even the most objective scientific procedures and findings. Demands to be present and observe independent examinations may be either reactive to fear of adversarial or biased procedures from the examiner, with or without reason, or attempts to collect as much information as possible to build stronger adversarial arguments to impeach opposite opinions.

Available Guidelines and Assessment Procedures

In the medicolegal examination, documentation regarding the evaluation and all procedures administered is usually closely scrutinized by opposing counsel and his/her team of experts. Consequently, tests and assessment procedures selected for medicolegal circumstances usually represent measures with a stronger research database, greater acceptance within the profession, and more established history of use in the courts. With regard to psychology, selection of such tests reflects, in part, anticipation of attacks on the scientific validity of psychological instruments. Section 2.07 of the APA Ethics Code (1995) states:

> (a) Psychologists do not base their assessment or intervention decisions or recommendations on data or test results that are dated for the current purpose, and
> (b) Similarly, psychologists do not base such decisions or recommendations on tests and measures that are obsolete and not useful for the current purpose.

Examiners are expected to use up-to-date tests and norms, rely on current knowledge, consider important demographic characteristics of individuals in making interpretations, and acknowledge limitations in current knowledge. Examiners are cautioned to interpret test results carefully if experimental procedures are utilized or tests are used with individuals for whom normative data are not available.

Report Content and Related Issues

Necessary and usual parts of a comprehensive assessment physician examiners should use for any examinee include the following: examinee demographic details; referral source and party responsible for payment; basis of report; documents requested and reviewed, including those not received; history of present illness; past medical history; family medical history; psychosocial history; educational history; vocational history; military history, if applicable; legal history, if applicable; review of systems; comprehensive exam findings, including pertinent negative findings; diagnostic impressions; opinions regarding maximal medical improvement (MMI); causality and apportionment opinions; recommendations and relevant appendices. Specific information relevant to opinions should ideally be delineated when reviewing documents that served as the basis of the report. This provides documentation that not only were the records reviewed, but

also demonstrates a more deliberate analysis of the information, temporal relationship of complaints to any injury in question, analysis of symptom profiles in correlation with the type of injury or impairment being claimed, consistency of reporting over time, findings suggestive of neurologic recovery pattern over time (or lack thereof), and clear delineation of inferential reasoning, among other purposes.

It should also be considered important to acknowledge potentially relevant information that was unavailable or not provided. For example, as is more often the case for defense-related evaluations, examiners may not be given an opportunity (or make an effort) to interview corroboratory witnesses; this can be frustrating to legitimate examiners trying to do a thorough and objective evaluation.

As part of the analysis of information and examination findings, an examiner's report should ideally include (a) an evaluation of the appropriateness of the diagnostic testing procedures and process; (b) an estimate of the reliability and validity of the findings that served as a basis for impairment claims; (c) an estimation of degree to which the measures used were specific and sensitive to the condition being examined; as well as (d) the degree of confidence in interpretations and opinions offered. Inherent in such testing should be evaluations, both from a physical, as well as mental standpoint, of response bias.

Notably, many examiners feel uncomfortable commenting on the testing procedures and/or conclusions of other clinicians. Objective assessment requires global analysis of opinions. This type of commentary is inherent in performing an adequate and comprehensive evaluation of any case. Meticulous evaluation of pre-injury problems, including prior treatment, medical, psychiatric, and otherwise, developmental difficulties (e.g., attention deficit disorder, or hyperactivity in school), psychoemotional problems during childhood, and learning disabilities, among other variables, must all be evaluated within the context of the clinical presentation. Prior injuries, surgeries, and past use of medication should be assessed, as should the frequency and severity, as well as functional significance, of any complaint that is being claimed post-injury that also was present pre-injury.

The individual's legal history, including police records, should be requested and reviewed, as this may have an impact on understanding current behavior. A history of certain types of legal problems may make an examiner more suspicious of some reported symptoms; nonetheless, ethical imperatives require that the examiner remain unbiased, complete an objective assessment, and not assume that individuals with certain types of background do not incur legitimate injuries.

Ethical Considerations when Submitting Reports

Ethical considerations clearly proscribe altering exam findings, or documenting things that did not occur. They also proscribe leaving out, or altering, potentially salient information from forensic or other reports. Further, the failure to address, and logically explain, inconsistent information or findings, reduces credibility and invites suspicion of bias.

The matter of issuing draft reports prior to the final reports poses an interesting dilemma that represents a potentially great danger to objectivity and ethical conduct. By introducing an opportunity for review and comment, attorneys or other interested parties may issue requests for changes. Requests issued from attorneys or referring parties for changes to reports, often for "legal purposes" (e.g., to clarify technical points for the court) or to clarify grammar, may represent a slippery slope that leads to nonobjective input and possible influence regarding other aspects of the examination findings and report. Recommendations that seem prudent include avoiding draft reports under all circumstances, and in order to avoid temptation or suspicion of impropriety, adopting a policy of refusal of any requested report changes, except for correction of notable grammar or information errors. In the case of true and significant errors occurring in the context of the report, or where important clarification of information is clearly relevant, three options can be advised: (1) attach an amended page to the report; (2) simply mark through (with a line) the incorrect portion of the report, without deleting or whiting out, and insert the correct information; (3) produce a corrected version and document that it is an updated version and the rationale for its production, while maintaining the original version with all other examinee records to produce upon request.

As previously noted, sharing examination results with the examinee are clearly proscribed by existing ethical guidelines and recommendations, as well as legal statues in most states. Signing of an informed consent, noting the potential dangers associated with sharing the information and/or report directly with the examinee, is increasingly recommended as standard procedure. It is also recommended that examiners have a disclaimer at the end of a report which generally reiterates the basis of the report and the opinions as germane to the expert's qualifications and training, and the fact that all opinions are given with "medical probability," unless otherwise stipulated. Finally, it is also advised that examiners include a statement that their conclusions are based, in part, on the assumption that the materials provided for review are true, correct, and complete, and that if more information becomes available at a later date, opinions may be subject to change.

CONCLUSION

Recommendations for Experts

Providers of medical information and testimony have ultimate responsibility for ethical conduct as it relates to this information. The authors offer the following recommendations for purposes of enhancing ethical relationships between expert clinicians and the courts.

- Avoid or resist attorney efforts at enticement to join the attorney–client team. Such compromises of scientific boundaries and ethical principles exist on a continuum ranging from standard attorney–client advocacy at the beginning of the expert consultation phase (e.g., promotional information when first retaining an expert, with either provision of selective or incomplete records or less than enthusiastic efforts to produce all records) and extending to completion of the evaluation, when requests for changes in reports and/or documentation might be made.
- Respect role boundaries and do not mix conflicting roles. Remember that the treating doctor possesses a bond with the patient, but does not as a rule obtain complete pre- and post-injury information in the context of assessing causality and apportionment. In contrast, the expert witness must conduct a thorough and multifaceted case analysis sans the physician–patient relationship in order to facilitate objectivity and allow optimum diagnostic formulations. Finally, the trial consultant's function in this adversarial process is to assist with critically scrutinizing and attacking positions of experts for the opposing side. These roles all represent inherently different interests, and mixing them can only reduce objectivity.
- Insist on adequate time for thorough record review, evaluation and report generation, and preparation for deposition and court appearances.
- Work at building a reputation for general objectivity and fairness, as well as reliance on multiple data sources, reaching opinions only after reviewing complete information from both sides and completing an unbiased evaluation.
- Spend a good part of your time actually treating the patient population being examined or about whom you are offering testimony. This treatment should be current, and with a comparable frequency to that of treating practitioner specialists. Maintain the ability to discuss relevant research and scientific methodology issues competently and without notes.
- Arrive at opinions only after reviewing all of the evidence from both sides of the adversarial fence, employing multiple data sources, completing an unbiased evaluation, and interpreting data within the full context of comprehensive historical, behavioral observation, and contextual information. Being otherwise favorable to the retaining attorney's interests suggests endorsement of "opinion prostitute," "scientific perjurer", or "hired gun" status (Martelli, Zasler, & Grayson, 2000b). The only way a practitioner can reduce the likelihood of facing an "opinion prostitute" on the opposing side in future cases is to insist on establishing and maintaining a reputation for scientific objectivity.
- Balance cases from plaintiff and defense attorneys. Predilection for one side or the other suggests bias and sets up predisposition to nonobjectivity. For example, a preponderance of plaintiff work suggests a bias toward overdiagnosis and/or uncritical sympathy, while a ratio that favors hiring by the defense suggests an underdiagnosis or skepticism bias. Perhaps Brodsky's (1991) suggested cutoff ratio of 0.80 for favorability findings (or our recommended ratio of 0.75) would represent an initial cutoff for defense vs. plaintiff ratio. That is, experts should do at least 25% of their work for the opposite side of the current case being represented. Further, it might be a reasonable expectation that data on these ratios be collected as an important method for considering the objectivity of opinions.
- Ensure against excessive favorability to the side of the retaining attorney or firm. Objectivity demands that scientific opinions not be influenced by the position of the legal advocate. Importantly, Brodsky (1991) recommends using a ratio of 0.8 as a cutoff for detecting excessive bias. That is, practitioners should possess prerequisite objectivity to disagree with the referring attorney at least 20% of the time. We suggest that a more useful cutoff would be 0.75, where experts are expected to generate findings that do not support the referring attorney's position at least 25% of the time (Martelli, et al., 2000b).
- Never arrive at opinions that are inconsistent with plaintiff records, exam data, test data, behavioral presentation, etc., especially when such opinions are favorable to the side of the retaining attorney firm. Instead, always:
  - Consider or mention, in reports and discussion, information not supportive of expressed opinions, including historical or behavioral obser-

vation information; exam and test findings; discrepancies between plaintiff's complaints and observed behavior and/or history; discrepancies between the severity of the injury and the severity of the reported symptoms; discrepancies between opinions and known occurrence rates (or base rates) in the general population; opinions and logical arguments of experts from the other side of the case, presented fully and in an objective manner.

Strive to demonstrate objectivity by disputing the opinion of other experts only through a complete and deliberate logical dispute of a full and complete representation of the other expert's findings, inferential reasoning, and conclusions.

Always assess response bias and make efforts to guard against motivational threats to valid assessment.

Avoid cutting corners, be thorough, and rely on standardized, validated, normed, and well-accepted procedures and tests.

Limit use of technicians and non-M.D.s or non-Ph.D.s for evaluation and testing.

Intensively assess the client being evaluated, use only appropriate normative data for comparisons (e.g., persons of similar education or age; comparisons to medical patients vs. psychiatric patients), take into account the symptoms' base rates (i.e., how frequently the symptoms occur in the general population and in the absence of the injury being evaluated), consider the many other explanatory factors for symptoms (e.g., medications, sleep disturbance, depression, etc.), and adjust the interpretations according to medical conditions (e.g., inherent somatic complaints of progressive disorders like M.S. and Parkinson's and chronic pain), relevant situational variables (e.g., attention and other deficits correlated with chronic pain conditions, fatigue, insomnia/sleep deprivation), cultural factors (e.g., rural impoverished backgrounds) etc.

Attempt to devise and employ a formalized quality assurance system that allows for monitoring and assessing (and improving) the validity and reliability of diagnostic and prognostic statements against real world findings. A formalized peer review system or similar mechanism that routinely allows for feedback from peers should be pursued.

Always prepare examinees by emphasizing the importance of accurate/honest performance with full effort on all interview questions, examination procedures, and tests (e.g., to produce valid and reliable profiles that permit comparison with known symptom patterns). Further emphasize the liabilities associated with exaggerating impairments (e.g., producing invalid profiles, lower the credibility, suspicion of malingering of all symptoms).

Recognize the limitations of medical and psychological data and opinions, and how, in science and medicine, few findings and symptoms are black and white, clean, or attributable to a single event (e.g., Occam's Razor).

Increase attention to issues relating to scientific methodology, objectivity, maintenance of scientific rigor.

Consider promoting increased awareness within the forensic professions of relevant issues relating to ethics and scientific objectivity. Promote utilization of objective data, such as Brodsky's (1991) ratio, in regular clinical practice, and recommend adoption of similar standards by local, state, and national professional organizations. Reinforce those who collate such data. Provide relevant information, including opinions and observations from known experts, as well as copies of relevant information such as this chapter, to colleagues. Promote issues relevant to legal use of medical and scientific evidence and testimony by encouraging courses in law school and programs offered by state bar associations and at annual trial lawyer and other association meetings.

Business Side of Pain Management

Devona Slater, C.M.C.P.

The clinical side of pain management is only half the battle. In today's environment being paid for the professional services you perform can be as complicated as treating your most complex pain patient. There is a wealth of information you must know that really should be classified as nonclinical but is just as important as the clinical information. Business expertise related to pain management is a necessity for every practice. You must recognize that if you do not run the business, the business will run you. This chapter is a place to start building your basic business skills.

PERSONNEL, STAFFING, AND MANAGEMENT STYLES

The first step in determining your staffing is to look realistically at the needs for your practice. A general rule of thumb for pain practitioners would be three or four staff per physician, depending on your mode of practice. The first two individuals would cover administrative duties including, but not limited to, scheduling, answering phones, booking appointments, medical records, billing, insurance collections, credentialing, personnel administration, and accounting functions. If billing, accounting, or payroll is outsourced, personnel will be reduced. You may need one clinical individual to start with, expanding to two or three as your practice grows. Clinical personnel should be an extension of you and used to handle back-office duties such as patient phone calls, prescription refills, lab reports, and initial charting for patient visits. A good pain nurse is worth his or her weight in gold, and will truly make or break the profitability of the clinic.

When trying to fill a position in the clinic it is best to define the position and set a salary scale before considering any one person for a position. Many practices make the mistake of knowing "Sally" is the perfect employee because she is a friend or used to work for a competitor. No one sits down and objectively looks at whether "Sally's" skills match what is needed to accomplish the job in the clinic. Choose staff wisely and avoid filling a position with "just a warm body." Finding the correct personnel will make your job easier down the line and patience is important in making the selection.

After finding that perfect employee it always amazes me how little training physicians give to staff on how they want the practice to run. Employees will generally live up to expectations set for them, but rarely succeed when no expectations are communicated. Orientation and training for each employee are very important steps to make the clinic operate smoothly. Personnel files are an essential element of any business and should be treated as confidential information. Documentation in employee files is as important as documentation in a patient's medical chart. The file should contain a current résumé, an emergency contact, specific tax forms (i.e., W-4 & I-9 and state employment), signature sheet from compliance and policy manuals, a current job description that lists expectations, performance evaluations, salary history, incident reports, and any other personal information gathered regarding the employee. Please be aware that incident reports and performance evaluations should be detailed and contain both positive and negative notes. Accurate documentation may be your only defense if you have to defend unemployment claims or wrongful termination suits.

TABLE 73.1
Sample Table of Contents

Administrative Manual	Clinical Manual
Office hours and schedule	Patient work-ups
Telephone management	Triage
Appointment scheduling	Charting
Medical records management	Patient education
Emergency procedures	Standing orders
Front desk check-out	Procedure set-ups
Patient billing and collections	Narcotics policy
Refund processing	Sterilization guidelines
Accounting and bookkeeping	Inventory control

OPERATIONS MANAGEMENT

Every practice needs a bible of how and why the clinic runs the way it does. In the office setting you will need several. First, you will want an employee manual, which will communicate what you expect from employees, outline benefits, and give some basic but essential information about your office. Some practices may choose to incorporate compliance information in this manual or segregate it into a separate manual. The goal of the manual is to set lines of authority, communicate basic business practices, and define the benefit structure offered. It is necessary that a written acknowledgment be retained in the personnel file of each employee stating that the manual was received, read, and understood by the employee.

The second sets of manuals you will want to complete are policy and procedure manuals. To accommodate personnel and for ease of understanding, I recommend breaking the policy and procedure manual into two separate manuals, one for administrative staff and one for clinical staff. It is even helpful to break them into sections that mirror the tasks assigned to employees. Remember, these manuals are to be very detailed concerning how you want tasks to be accomplished. Table 73.1 is a sample table of contents for each manual. Stop and jot down a brief note if you have strong feelings about how you want areas handled in your practice.

Many practices do not create a set of manuals until something goes wrong. This is a huge mistake. Communication and documentation in the medical office are as important as keeping medical records on patients. Writing things down with specific instructions is a good way for you to establish expectations and goals for your practice. Do not skip this step of creating a road map for the direction of your practice.

FINANCIAL MANAGEMENT

Many physicians make the mistake of believing that financial management is solely the process of recording how you spend the money brought in. In reality, financial management starts with when the patient is scheduled for the appointment. It is important for all of the staff to realize that this is the first step to a successful practice. Explaining financial policies on the phone when the appointment is made sets the tone of the entire process for the patient. The expectation is that the patient understands his or her responsibility for payment, what the office will and will not do regarding insurance, and this allows the patient to be prepared for that first visit. This is not something that should be viewed as greed but instead as a service to inform. The approach is to capitalize on every patient contact to communicate expectations. You inform them to bring in any prescriptions they are taking; why not remind them that you need a copy of the insurance card, precertification, or checkbook for the co-pay.

Registration or the "check-in" process is something that is neglected in many practices and has a huge impact on financial management. I cannot stress enough how important complete and accurate information is from this very point forward. If the registration process breaks down, the entire financial process is in jeopardy. With all the forms and tools in today's society, you would think this step would be easy, but it is the one that needs the most attention in physician offices. Remember how important selecting the right person is for the job. Invariably, I will go into a physician's office and find the least intelligent and lowest paid person in the front desk position. Not to belittle the point, but you get what you pay for and running the front desk is a critical process in the financial health of your practice.

It is recommended that you develop a form that captures not only the patient's information but also information of a close relative or friend. This might be the only way to locate a collection problem, so keep in mind what information is necessary in the process of skip tracing a patient. The registration form should include an assignment of benefits form as well as a financial policy statement. Do not accept registration forms that are not filled out completely. The patient is telling you something by not completing the information, i.e., "I don't care whether you get paid or not." Stop right there and do not allow that patient into your practice. There are no shortages of pain patients; you might as well only see the ones who are interested in paying for your services.

The financial policy for your practice should specifically instruct patients on what administrative procedures will be followed to help them obtain benefits for their healthcare. It should state clearly that patients are expected to pay for medical services regardless of insurance coverage. Payment arrangements or payment options such as credit cards or bank loans may be outlined in the policy. It also should inform the guarantor as to when an account will be referred to a professional collection agency. It is recommended that this be a two-part

carbon form signed by the patient. One copy is given to the patient and the other is retained in the chart or billing file for future reference.

Many practices also need to include an ABN, Advanced Beneficiary Notice. This is a form required by Medicare, which tells the patient that Medicare may not pay for the treatment they are requesting. In pain practices this is common, and communicating this message right at the beginning to the patient will help him or her understand what the financial responsibility might be when incurring this treatment option.

This process of registration, precertification, and benefit structure has become so complicated that many practices have hired what I would term as financial counselors. If your practice chooses to hire such a specialist, you must plan for this in your office layout. This individual will need a private place to speak with patients about confidential matters. Again, personnel selection is extremely important.

THE MEDICAL RECORD

The chart has become so important that a chapter should be devoted solely to its contents and organizational structure. I will summarize what should be a review for physicians regarding documentation. You must realize that documentation is not only a communication tool for your own office but also will help you in medical-legal issues as well as provide for a defense in billing. Each visit, yes, every encounter with the patient no matter how brief, should follow the charting guidelines in Table 73.2.

A well-organized chart is like gold, precious, and to be guarded. Do not underestimate the importance of organization. Simple tools will help keep everyone current on the status of the patient if the rules are followed. Pain charts should begin with the left side reflecting a medication and patient visit summary. Separate sections for visits/procedures, radiology findings, and previous medical records are suggested. The chart needs to work for you and be organized so that all clinical staff can quickly identify risk areas for the patient.

TABLE 73.2
Charting Guides

1. The medical record must be legible and complete.
2. Each visit should include the following:
   a. Date
   b. Reason for the visit
   c. Appropriate history and physical exam
   d. Review of ancillary data, lab or X-ray, as indicated
   e. Physician assessment
   f. Plan of care
3. Past and present diagnosis should be accessible to the treating and/or consulting physician.
4. Rationale for ordering and the results of diagnostic tests, X-ray or lab, should be documented in the medical record.
5. Patient health risk factors noted.
6. Patient's progress, including the response to treatment, change in treatment plan, revision of diagnosis, and patient noncompliance to the plan should be documented.
7. The plan of care should outline specific treatments and medications, specifying frequency and dosage, any referrals or consultations to outside specialists, education given to patient or family, and specific instructions for follow-up with physician.
8. Written support of the complexity of the visit and the physician's medical decision-making process to create the plan for treatment.
9. Medical documentation should not be limited to physician documentation; nursing and other non-physician staff should be dated and signed by the person making the chart entry.
10. CPT/ICD-9 codes reported on the HCFA 1500 form must be reflected in the documentation of the medical record.

CPT/ICD-9 CODING

The Center for Medicare and Medicaid Services (CMS) has adopted a single diagnostic coding system, the International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM). This coding system is used regardless of the setting in which the services are rendered in accordance with the coding guidelines and reporting requirements. Procedures/services are coded using the Health Care Financing Administration Common Procedure Coding System (HCPCS), of which the American Medical Association's Physicians' Current Procedural Terminology, Fourth Edition (CPT-4) system is a part.

The majority of third-party payors also subscribe to this methodology, making coding the industry billing standard. CPT-4 codes tell the payor what services were provided and billed, and ICD-9 CM codes provide the reason medical services were rendered. Documentation in the patient's medical record to substantiate codes listed on the HCFA-1500 insurance claim form may be reviewed by a payor, pre- or post-payment of benefits. Payors may deny payment or request a refund if documentation does not provide enough information to demonstrate that billed services were performed or that services were medically necessary.

A complete revision of current diagnosis coding systems is underway with a target implementation date of October 2001 in the United States. ICD-10-CM represents the most significant revision of ICD (International Classification of Disease) since its inception. There are thousands more diagnosis codes (more than 50%), with more characters; codes are alphanumeric and the organization has changed. The goal is granularity, i.e., to provide greater detail that will be useful in healthcare policy and outcomes research.

To code accurately, it is necessary to have a working knowledge of medical terminology and to understand the characteristics, terminology, and conventions of the ICD-9-CM. Transforming verbal descriptions of diseases,

injuries, conditions, and procedures into numerical designations (coding) is a complex activity and should not be undertaken without proper training.

Originally, coding was accomplished to provide access to medical records by diagnosis and operations through retrieval for medical research, education, and administration. Medical codes today are utilized to facilitate payment of health services, to evaluate utilization patterns, and to study the appropriateness of healthcare costs. Coding provides the basis for studies and research into the quality of healthcare.

Coding must be performed correctly and consistently to produce meaningful statistics to aid in the planning for the health needs of the nation. At the physician/patient encounter, the physician ascertains what is wrong with the patient through evaluation, diagnostic tests, and various forms of treatment. This information is then translated into the language of codes to send to the insurance carrier requesting reimbursement for services and procedures performed based on medical necessity and diagnosis involved.

The government's definition of medical necessity is a "service that is reasonable and necessary for the diagnosis or treatment of illness or injury, or to improve the functioning of a malformed body member" ("Medicare Carriers' Manual). In other words:

- Services must be consistent with the symptoms or diagnoses of the illness or injury under treatment;
- Necessary and consistent with generally accepted professional medical standards, i.e., not experimental or investigational;
- Not furnished primarily for the convenience of the patient, the attending physician, or another physician or supplier; and
- The service must be furnished at the most appropriate level, which can be provided safely and effectively to the patient.

Establishing medical necessity is the first step in third-party reimbursement. Justify the care provided by presenting the appropriate facts. These facts must be substantiated by the patient's medical record, which may be requested by the insurance carrier for pre- or post-payment review at any time.

The first diagnostic code referenced on the HCFA-1500 claim form describes the most important reason for the care provided. Often a single ICD-9-CM code adequately identifies the need for care. If additional facts are required to substantiate the care provided that day, list the ICD-9-CM codes in the order of their importance. Be careful to link your diagnosis codes to the proper CPT-4 code, especially when more than one procedure is provided during a single encounter or on a single date of service.

Physicians and coders often have a dilemma when attempting to code "pain" to the highest degree of specificity. Standard coding requirements are to code to the highest degree of specificity and code the "disease" not the symptom. In a pain management practice, it is often necessary to code the "pain symptom" until the physician is able to make a more specific diagnosis; this may take several visits and diagnostic tests.

Documentation should be reviewed and the patient's current pain diagnosis coded for each visit, independent of prior visits and treatment. Diagnoses change based on treatment outcomes and diagnostic tests; the physician should provide a diagnosis for every encounter and/or procedure performed.

Most Medicare carriers have implemented local medical review policies that list specific medical necessity coverage guidelines determined by the diagnosis code assigned. Policies vary from state to state so it is necessary for each practice to review its own carrier's local medical review policies. This can be done via the Internet. The Web site is www.lmrp.net.

If a remittance advice lists "not medically necessary" as a reason for nonpayment, the patient's medical record and the carrier policy should be carefully reviewed to determine if a different diagnosis would have been more appropriate. Billing personnel may need asistance from physicians to select a more appropriate code. A diagnosis should not be altered unless documentation in the patient's medical record substantiates the change.

Third-party payors differ on coverage and benefits as well as reporting requirements. For example, carriers exist that do not accept CPT-4 codes designated as "unlisted procedure", which makes it very difficult to bill a procedure that does not have a designated CPT-4 code. Carrier representatives should be queried for billing instructions in such instances.

Another approach for carriers that do not accept unlisted codes is to carefully choose a CPT-4 code that is very similar in description and objective and with a relative value unit (RVU) (from the Medicare schedule) that is also similar. Write to your major payors. Your letter should contain information about the procedure (attach a procedure report), what procedure code is thought to be appropriate, and additional explanation of the procedure. Explain that there is no CPT-4 code and that you will submit your changes under xxxxx procedure, and ask them to please notify your office if this is not acceptable or if the company would prefer that you use a different CPT-4 code or its own specifically assigned HCPCS code.

Included with procedure descriptions are common diagnosis codes. This listing of diagnoses is not intended to be exclusive of the indications for a specific procedure or treatment. Diagnoses are a composite of some of the

Medicare carrier policy statements and are intended as guidelines only.

Correct Coding Initiative

On December 19, 1989, the Omnibus Budget Reconciliation Act of 1989 (P.L. 101-239) was enacted. Section 6102 of P.L. 101-239 amended Title XVIII of the Social Security Act by adding a new Section 1848, Payment for Physicians' Services. This section of the Act provided for replacing the previous reasonable charge mechanism of actual, customary, and prevailing charges with a resource-based relative value scale (RBRVS) fee schedule, which began in 1992.

Accurate coding and reporting of services by physicians are major concerns of HCFA. Medicare carriers have included in their claims processing system various computerized edits to detect improper coding of procedures. Many of these edits are designed to detect fragmentation, or separate coding of the component parts of a procedure, instead of reporting a single code which includes the entire procedure.

The purpose of the National Correct Coding Council's (AdminiStar Federal) contract was to develop Correct Coding Methodologies for HCFA's Bureau of Program Operations. This manual, termed the Correct Coding Initiative (CCI), is used by all Medicare carrier intermediaries and some commercial payors as well. Commercial payors may have their own version of "CCI," sometimes referred to as "black box edits," that are not published.

Each CCI chapter consists of the Manual divided into two sections:

1. Mutually exclusive procedures are those which cannot be performed during the same operative or patient session;
2. Comprehensive and Compound procedure code combinations, which are divided into Column 1 and Column 2 procedures. The Component procedure (column 2) will not be reimbursed when the same provider renders the procedure on the same date; this is referred to as "unbundling".

Unbundling is essentially the billing of multiple procedure codes for a group of procedures that are covered by a single comprehensive code. Attempting to bill separately for these already bundled charges will constitute a claim for unbundled codes.

There are two types of unbundling: the first is unintentional and results from a misunderstanding of coding, and the second is intentional, when the technique is used by providers to manipulate coding in order to maximize payment. It is important to refer to a current copy of the CCI to avoid billing unbundled codes. This practice of billing unbundled codes is fraud and will be prosecuted as such by the U.S. Attorney General.

A copy of this quarterly publication can be obtained from: HCFA Correct Coding Initiative, AdminiStar Federal, P.O. Box 50469, Indianapolis, IN, 46250-0469.

Charge Tickets

Charge tickets should be designed as a communication tool for your billing staff. It should cover 90 to 95% of the services you perform. Each year the charge ticket should be updated for changes in CPT-4, procedure coding or ICD-9, diagnosis coding. It should always include all levels of evaluation and management services with some type of guideline to remind physicians of the appropriate medical situations that constitute each level.

Most physicians do not have a system for establishing prices for the services they perform. While it is true that many managed care fees are set, you must know your costs and individual statistics in order to evaluate whether you are being paid fairly for your services. It is good to start with some outside resources. Gather the Medicare RBRVS fee schedule, the ASA Relative Value Guide, and any other professional society recommendations regarding fees and put them into a worksheet that identifies the different schedules by CPT code. This will give you a side-by-side comparison so that you can begin to analyze and draft your own fee schedule.

The next critical step is to analyze your individual practice data. Evaluate the demand for pain services in your area and assess your competition. Gather some outside resources from your region's business journal or the Chamber of Commerce regarding the payors in your area and the number of lives that each represents. Finally, look at your utilization of the procedures you perform.

There are publications available for national averages per year on physician charges. The important thing to realize is that the information is on charges submitted, not on payments made. The information is available by region or by specific zip code. Normally, the information shows the average allowable reimbursement paid by commercial payors and 50 to 75% and 95% of what most physicians charge.

The most important element in setting fees is to identify how much it actually costs you to perform a procedure. This can be done in several ways. Activity-based costing looks at the cost of each activity needed while performing a procedure. Because most physician groups do not have accounting expertise to efficiently do this, I recommend estimating the direct costs by procedure, allocating a charge per procedure for overhead, and then adding an acceptable mark-up for profit.

Now go back to your spreadsheet and add the column of cost. You have all the information you need to decide how to set your fees. Profit cannot be realized if costs exceed income. Performing more services does not guarantee profit. You must constantly monitor your payors with regard to the fee schedule that they pay.

- Checks and balances must exist in your system to assure that you capture all charges into the billing system, that the insurance claims are generated, and that the money will come back to the practice within a reasonable time period. The first check and balance should be the schedule to the charge tickets. This should be done every day with no exceptions. Balancing controls by either dollar amount or hash totals of CPTs should be implemented to verify the charge tickets to the computer system. When insurance claims are generated, some verification system as well periodic monitoring of the accuracy of the claims should be done. Payment could come as soon as 14 days if filing electronically or take up to 45 days. If no payment is received by the 45th day, immediate collection follow-up should be started.
- Negotiate contracts that allow at least 90-day timely filing deadlines.
- File electronically.
- Keep track of internal turnaround time.
- Keep track of claims turnaround time.
- Work the mail to discover your problems.

The most important fact you must face is that you are not a bank. Accounts receivables on the books is not cash in the bank. Establishing and adhering to a financial policy will benefit everyone in your practice. You must establish a system to collect co-pays and small balances at the time services are rendered. Your best possible time for collection is when you see the patient for follow-up visits. Remind patients of their balances and that you will help them collect benefits that they have paid for from their insurance carrier. You are entitled to be paid for the services you have performed. Today is a plastic society; accept MasterCard and Visa in your practice.

Probably the best action for your practice is to make it everyone's responsibility to collect money. Knowing how to figure a bill, understanding co-pays and deductibles, and filing secondary insurance immediately all help reduce the practice's accounts receivable. When it comes to patient statements, put a due date on the statement. All individuals pay bills by the day they are due. Physicians make the mistake of not having due dates on statements, which sends the message that it is OK for the patient to pay whenever they can.

Many times office staff avoid collection calls. Collection calls are necessary to keep accounts receivable under control. Many times using a matter-of-fact attitude helps with making staff more comfortable in the process of collection calling. It is important to take the following approach:

- Call the person by proper name.
- Have your facts ready.
- Be pleasant but matter of fact.
- Most importantly, Follow-up… Follow-up…Follow-up.

Many times collections is nothing more than teaching patients about responsibility for their portion of the bill. Continually reminding patients of their payment promises and staying in contact with accounts that have slow payment are necessary for your financial health. Make sure your statements are easy to read and clearly tell the patient what you want them to do. Many times patients believe statements are only informational and have no call to action.

Being in private practice means accepting that a few patients never intend to pay. Identification and early placement of those accounts with a professional collection agency are in the best financial interest of your practice. Staff need to concentrate on those accounts under 90 days in order to have effective collections.

Finally, just a word to the wise: It is important for physicians to recognize and admit when they need help with business issues. Physicians are busy individuals and trusting by nature. They must develop business skills in order to survive. It is never wrong to ask for help or admit that something is not quite right, just do not wait too long before inquiring. Seek advice from well-qualified professionals who have the reputation of being brutally honest.

Pain Management: Medical and Legal Issues of Undertreatment

James S. Lapcevic, D.O., Ph.D., J.D., F.C.L.M.

The American physician is currently faced with a practice paradox (Parran, 1997), demanding a new balance in the prescribing of controlled medications for the treatment of pain. This newly developed clinical dilemma comprises underprescribing narcotic analgesics to a majority of pain patients, while, on the other hand, overprescribing to a minority of patients. To stay the course of quality clinical practice requires physicians to understand both the medical and legal strategies undergirding the forces forging a new paradigm of medical care. Several thematic key issues are considered in this structure.

Pain, an important and serious symptom, is one of the most common reasons for seeking medical care (Weiner, 1993). Nine of ten Americans age 18 years or older report suffering pain at least once a month, and 42% of adults report experiencing pain every day (Gallup, Inc., 1999). Chronic pain is experienced daily by an estimated 75 million people in the United States (Bostrom, Ramberg, Davis, & Fridlund (1997). In the last decade interest in pain management (Rorarius & Baer, 1994; Tittle & McMillan, 1994) has risen largely due to surveys revealing that inadequate pain control is a norm under traditional clinical management, with as many as 75% of postoperative patients unnecessarily suffering unrelieved pain (Shapiro, 1996). In recent years, we have gained a new awareness of pain, its effects on quality of life, and the evaluation and issues involved in its treatment. The increasing number of those experiencing pain and other chronic medical conditions urges physicians to stay abreast of the most current and effective options for pain assessment, evaluation, and management. Yet much pain remains underreported as well as undertreated (Anon., 1998; Dahlman, Dykes, & Elander, 1999). Varying patient populations have been found to receive less than quality treatment of their pain if indeed any treatment at all (Bernabei, Gambassi, Lapane, et al., 1998; Cleeland, Gonin, Baez, Loehrer, & Pandya, 1997; Foley, 1997).

In a survey of physicians, 82% responded that they had not been adequately educated in pain management (Lavies, Hart, Rounsefell, & Runciman, 1992); patient surveys found more than half wanted decision capacity on when more analgesia should be given them.

EDUCATIONAL INTERVENTIONS TARGET EFFECTIVE MANAGEMENT PAIN

Pain is defined as an unpleasant sensory or emotional experience associated with actual or potential tissue damage and described in terms of such damage (Merskey, 1986). Classification of pain is either acute or chronic (see Table 74.1), although acute pain can evolve into chronic pain if not treated fully, promptly, and adequately (Marcus, 2000) to avoid such conversion (Katz, 1996). Effective management requires multifactorial assessment of components that differ only in magnitude from one affected person to the next (Goldstein, 1999). Pain is a dynamic process with a clinical significance (Carr, Jacox, Chapman, et al., 1992) affecting sympathetic nervous system activity, neuroendocrine activity (Kehlet, 1989; Lutz & Lamer, 1990), and it has adverse effects on the immune

TABLE 74.1
Classification of Pain

	Acute Pain	Chronic Pain	
		Nonmalignant	Malignant
Duration	Hours to week	Months; years	Unpredictable
Pathophysiology	Identifiable	Not always identifiable	Identifiable
Prognosis	Predictable	Unpredictable	Multidisciplinary
Treatment	Analgesics	Multidisciplinary	

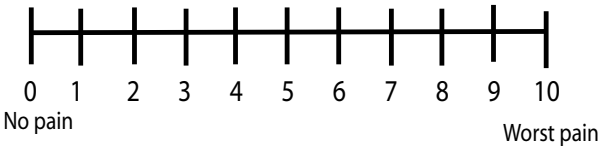

FIGURE 74.1 Visual analog scale for assessment of acute pain.

system (Terman & Liebeskind, 1991). The control of pain can influence clinical outcome (Whipple, Lewis, Quebbman, et al., 1995) while unrelieved pain can impair recovery (Brown & Carpenter, 1990; Carr, Jacox, Chapman, et al., 1992) as well as result in anxiety, depression, sleep deprivation, or any combination of these. Pain itself can be clinically assessed by subjective direct and indirect methods utilizing pain scales to chart the pain intensity. Common measures of pain intensity are

1. Categorical scale of pain intensity. A simple descriptive scale representing the oldest approach to pain assessment. Most often, this scale consists of four categories: 0 = no pain, 1 = slight or mild pain, 2 = moderate pain, and 3 = severe pain.
2. Visual analog scale (VAS) (Figure 74.1). The patient is asked to draw a mark somewhere along the line between no pain = 1 and worst pain = 10. Good agreement between descriptive and visual analog ratings has been found (Litman, Walker, & Schneier, 1985). To ensure proper management of pain, healthcare professionals should chart pain as formalized in a report prepared by the American Pain Society (APS) Quality Care Committee (American Pain Society, 1995) (see Table 74.2). Pain assessment should be charted as the "fifth" vital sign (Oncology Nursing Society, 1998) in patient evaluation. The Veterans Administration has made a decision to implement in all its facilities the process of charting pain as a fifth vital sign. Continued assessment of pain should involve evaluating and charting at several critical times in the pain management process (see Table 74.3) (Jacox, Carr, Payne, Berde, Biebart, Cain, et al., 1994). Distinguishing characteristics of acute and chronic pain (see Table 74.4) are summarized.

TABLE 74.2
Major Recommendations to Include in a Program Designed to Enhance Relief of Pain

- Make sure that a report of unrelieved pain will raise a red flag sufficient to attract the attention of clinicians.
- Make information about analgesics readily available, especially in the area where orders are written.
- Promise patients that they will recieve responsive analgesic care, and urge them to facilitate this process by communicating their pain.
- Define and implement policies (and safeguards) for use of advanced techniques for pain control (such as intraspinal patient-controlled opioid infusion).
- Assess on a continual basis both the process of pain control and procedures used to achieve this clinical outcome.

TABLE 74.3
Instances When Pain Should Be Evaluated and Charted

- Whenever there is a new report of pain
- At regular intervals after initiation of therapy
- At an interval commensurate with the therapy (such as 15 to 30 minutes after administration of parenteral drug therapy; 60 minutes after oral therapy)

Basic tenets (McCarberg, 2000) of pain management are

1. Do not assume a patient's pain is being adequately treated because the patient does not complain.
2. "Pain" should always be considered the fifth vital sign. Ask the patient about pain, prescribe what is needed to relieve that pain (including opioids, if necessary), and follow up with frequent evaluations of the efficacy of the treatment regimen.

TABLE 74.4
Distinguishing Characteristics of Acute and Chronic Pain

Acute Pain	Chronic Pain
A symptom of disease	Is itself the disease
Self-limiting	Persists beyond the usual course of acute disease
Provoked by	Provoked by
• Noxious stimulation	• Chronic pathologic process
• Tissue injury	• Dysfunction of PNS or CNS
• Abnormal function of somatice or visceral structures	• Psychological and learned (environmental) factors
Followed by emotional, psychological, and autonomic responses	May not be followed by autonomic and neuroendocrine responses; vegetative state may emerge
Has a biological function (alerting, warning, resting, healing)	Never has a biological function

3. Modify treatment according to patient response.
4. Make use of both pharmacologic and nonpharmacologic methods for pain relief.
5. Involve the patient as much as possible in pain control strategies, explain options available, and foster a positive attitude in the patient toward dealing with pain.
6. Ensure continuity of pain management once the patient leaves the hospital; pain can and should be controlled in the outpatient setting to the same extent as when the patient is hospitalized.

Over the past decade concerted efforts have been made to educate healthcare providers regarding the need to aggressively treat pain. Reliance on the primary care physician, who is quite capable of treating routine chronic pain conditions, continues due to the relatively small numbers of pain specialists. The American Academy of Pain Management, the American Academy of Pain Medicine, and the American Pain Society, professional organizations for the study of the scientific and clinical aspects of pain, have available membership directories that can help the primary care physician find help through a specialist in his or her area.

Pain is classified as acute or chronic. Acute pain is sometimes defined as pain that persists for less than 3 months and can be understood when associated with an acute injury as cause and effect. Chronic pain, on the other hand, is pain that persists for more than 3 months beyond the normal time of healing (e.g., pain related to chronic back problems or sickle-cell disease). Diseases such as AIDS can cause chronic noncancer pain and demand the same attention to pain relief as given to terminal cancer patients. Cancer pain is either resolved after the cancer is resolved or may continue indefinitely as a complication of otherwise curative therapy.

Pain may also be classified as neuropathic, or nociceptive and visceral. Nociceptive and visceral pain originates in muscle, bone, or visceral structures, whereas neuropathic pain originates in the nerves. Neuropathic pain can be defined as pain resulting from noninflammatory dysfunction of the peripheral or central nervous system without trauma or peripheral nociceptor stimulation, usually described by pain patients as "burning", "shooting", or "lancinating".

To make good pain management decisions, physiology, anatomy, and referred-pain pathways must be considered. There is no substitute for touching the patient. It has been said that the best cheap test for evaluating physiologic change and understanding the origin of a patient's pain is a good neurological physical examination (Saberski, 2000). The weak point in patient evaluation is the patient's complaint; the strong must be the physician's knowledge that pain is complex, and may not be what is expressed (Saberski, 2000).

While it is important to stay abreast of new technologies despite dramatic technological breakthroughs, there can be no replacement for a thorough and complete history and physical examination. Physicians may need assistance in identifying chronic pain patients who are not adequately coping with the experience of pain while making their quality of life independent of the perception of pain. By asking three questions, clinicians can identify patients who are in all probability not coping well and might benefit from psychological intervention that addresses self-efficacy.

The self-efficacy screen (Kores, Murphy, Rosenthal, Elias, & North, 1990) comprises three questions (see Table 74.5) with graded response. While this verbal screen is not sufficiently sensitive to identify all pain patients in need of psychological intervention, it will identify a subset for whom treatment can be expanded to address their psychological and physiological pain management needs. Patients with pain may have an exaggerated response if an underlying depression is also present. In patients using long-term opioids for treatment of chronic pain, some useful questions may be used to screen for signs of addiction (Ewing, 1984) (see Table 74.6). Portenoy (1996a) has classified aberrant drug-related behaviors into those probably more or probably less predictive of addiction (see Table 74.7).

TABLE 74.5
Self-Efficacy Screen

1. Do you feel that by taking care of yourself you can limit your pain?	Yes	No
2. Do you feel that doctors/therapists will control your pain?	Yes	No
3. Despite your best efforts, does your pain prevent you from getting a good night's sleep?	Yes	No

Note: A negative response to questions 1 and 2 and a positive response to question 3 indicate poor coping and need for psychological intervention. Note that question 2 is keyed paradoxically. While one might expect the pathologic answer to question 2 to be a positive response, it is a negative response that is actually interpreted as significant.

TABLE 74.6
CAGE Test

C	Have you ever felt you should cut down on your substance use?	Yes	No
A	Have people annoyed you by criticizing or complaining about your substance use?	Yes	No
G	Have you ever felt bad or guilty about your substance use?	Yes	No
E	Have you ever needed an eye opener in the morning to steady your nerves or get rid of a hangover?	Yes	No

Note: Any patient responding yes to two or more of the questions in this simple screening test should be subject to more intense scrutiny for the signs of addiction (Kores, Murphy, Rosenthal, Elias, & North, 1990).

TABLE 74.7
Representative Aberrant Drug-Related Behaviors*

Probably More Predictive
- Selling prescription drugs
- Forging prescription
- Stealing or "borrowing"
- Frequent prescription "loss"
- Injection oral/topical formulations
- Obtaining prescription drugs form nonmedical sources
- Concurrent abuse of related illicit drugs

Probably Less Predictive
- Aggressive demand for more drug
- Drug hoarding
- Unsanctioned dose escalation
- Unapproved use of the drug
- Unkempt appearance

* Empirically divided into those that are assumed to be relatively more predictive and those that are assumed to be relatively less predictive of addiction. (Adapted from Portenoy, R. K. Journal of Pain and Symptom Management, 11, 203–217, 1996.)

For pain of terminal disease, pain relief should be provided because easing pain and improving functions are the goals when treating acute and chronic pain patients whether or not there exists a history of addiction. By using questions geared to level of function and behavior, health care providers can adequately assess probability of drug abuse or addiction. Fear of addiction in the terminally ill patient is exaggerated as is the likelihood of inducing respiratory depression.

Pain at the end of life can be adequately managed with clearly defined management strategies. The World Health Organization has proposed a three-step analgesic ladder approach to pain management in which nonopioid, opioid, and adjuvant analgesics are used based on the type and intensity of pain (see Table 74.8). The steps are coupled to the Visual Analog Pain Scale assessment (see Figure 74.1). The categories of analgesics and dosages are succinctly noted (see Table 74.9), while comparison of opioids in oral and parenteral dosage conversion (see Table 74.10) shows clearly that dosage adjustments (Education for Physicians, 1999) are necessary when routes of administration or conversion from one opioid to another are considered. Opioids are the mainstays and clearly the agents of choice for treatment of moderate to severe pain. Through appropriate knowledge of opioid dosing intervals and titration of dose, severe pain even at end of life can be managed. Healthcare providers must remain diligent in management of end-of-life pain because unrelieved pain for the terminally ill patient is an ethical issue (Ferrel & Rhiner, 1994) as much as it is dehumanizing. The ethical principle of "double effect" allows for the administration of opioids to control pain even though the dying process may be hastened (Cavanaugh, 1996). Physicians can and should enhance the dying patient's quality of life by enabling the patient to avoid pain (Cavalieri, 1999).

TABLE 74.8
World Health Organization's Three-Step Ladder of Analgesics

Step 3: Severe pain
(7 through 10 on pain scale)
- Morphine
- Hydromorphone
- Methadone
- Oxycodone
- Transdermal fentanyl
- With or without nonopioid analgesics
- With or without adjuvant analgesics

Step 2: Moderate pain
(5 through 6 on pain scale)
- Codeine
- Hydrocodone
- Dihydrocodeine
- Oxycodone
- Tramadol
- With or without nonopioid analgesics
- With or without adjuvant analgesics

Step 1: Mild pain
(1 through 4 on pain scale)
- Aspirin
- Other nonsteroidal anti-inflammatory drugs
- Acetaminophen
- With or without adjuvant analgesics

TABLE 74.9
Categories of Analgesic Dosages Analgesics

Nonopioids	Opioids	Adjuvant Analgesics
Nonsteroidal Anti-Inflammatory	**Step 2 Opioids**	**Antidepressants**
• Aspirin (650 mg every 4 hours)	• Codeine (100 mg every 4 hours)	• Amitriptyline (25 to 150 mg at bedtime)
• Ibuprofen (400 to 600 mg every 6 hours)	• Dihydrocodeine (50 to 75 mg every 4 hours)	• Notriptyline (25 to 150 mg at bedtime)
• Diflunisal (500 mg every 12 hours)	• Hydrocodone (15 mg every 4 hours)	
• Sulindac (150 to 200 mg every 12 hours)	• Oxycodone (7.5 to 10 mg every 4 hours)	**Anticonvulsants**
• Naproxen (250 to 500 mg every 12 hours)	• Propoxyphene (180 mg every every 4 hours)	• Carbamazepine (100 mg to 200 mg twice or four times daily)
• Diclofenac (50 to 75 mg every 12 hours)		• Valproic acid (200 to 400 mg twice or four times daily)
• Salsalate (750 to 1500 mg every 12 hours)	**Step 3 Opioids**	• Gabapentin (300 to 1800 mg three times daily)
	• Morphine (15 mg every 4 hours)	
Acetaminophen (60 mg every 4 hours)	• Oxycodone (7.5 to 10 mg every 4 hours)	
	• Hydromorphone (50–150 mg every 4 hours)	
Tramadol (50 to 75 mg every 8 hours)	• Transdermal fentanyl (50 mg/hour)	**Local Anesthetics**
		• Lidocaine (1.5 mg/kg IV)
		• Mexiletine hydrochloride (400 to 600 mg/d)
		Capsaicin (topically three times daily)
		Steriods
		• Prednisone (20 mg/d to 80 mg/d)
		• Dexamethasone (4 mg/d to 16 mg/d)

[a] All dosages are oral unless specified otherwise.

GUIDELINE DEVELOPMENT

Many Americans are now over the age of 60. That segment of the population of the United States over 65 will double in the next 33 years, with the oldest of the old, those over age 85, the fastest growing segment of the entire population. The elderly represent 12.7% of the population or one in every eight Americans (James, 2000). By the year 2030, 20% of our population will be over 65. As the population ages, more conditions causing pain, from arthritis to malignancy, will emerge. A significant proportion of all pharmaceuticals will be analgesic agents (Hill, 1996).

In the past decade, societal and government needs have molded medical practice into a less variable and more standardized activity (Hill, 1996a). Guidelines for pain management have been issued by such diverse groups as the World Health Organization, the American Pain Society, the American Society of Anesthesiologists, the American Academy of Pediatrics, the International Association for the Study of Pain, and the United States Agency for Health Care Policy and Research (AHCPR) (Hill, 1995).

Federal oversight of controlled substances extends into community standards of care. According to the AHCPR guidelines (1992), opioids may be prescribed to treat acute and chronic pain, but the prescribing physician assumes the burden of proving that the prescription falls within normal clinical procedures for pain management. A physician prescriber of a controlled substance is obligated to demonstrate both the medical necessity and adherence to law of such a choice. Many healthcare practice acts do not provide for the interpretation of phrases such as "practicing medicine in a manner inconsistent with public health and welfare" (Hill, 1996b). It is often the legal process that later defines these concepts of "reasonably necessary" and "good faith" that are critical to the justification, and even legal defense, of controlled substance prescribing in an individual case. Allegations of prescribing too much, too little, or not prescribing a controlled substance that was needed according to the definition outlined in federal or state guidelines may be open to court interpretation through expert witnesses brought in by medical boards, plaintiffs, or the Drug Enforcement Agency (DEA). Claims that prescribing behavior was not in good faith or not reasonably necessary, requirements designed to establish medical necessity which may be redefined ad hoc, can make it difficult for physicians to justify their treatment decisions. To avoid unwittingly running a collision course with these complex issues, better training in proper pain management procedures is necessary for physicians (Carr, 1998). Generally, physicians who prescribe scheduled or nonscheduled analgesic medications believe their patients need them. Physicians must be aware of the immediate medicolegal ramification, including the burden of proof, that must be considered when analgesic medications are prescribed (Clark, 1998).

Ideally, treatment guidelines should be based on data from the medical literature, case law, and clinical experience, although the boards that administer and interpret healthcare practice acts are comprised of state government officials' appointees whose membership biases may be reflected in the guidelines (Hill, 1996b). While not all state medical boards hit the mark, many experts favor state medical policy, issuing from the medical boards rather than from elected officials, directly addressing physicians concerns through medical guidelines. In 1999, The Ohio State Medical Association, in cooperation with the state legislature, distributed a new clinical handbook titled *Pain: The Fifth Vital Sign*. Distributed to all physicians, but directed at primary care physicians, the booklet encouraged better pain management including a step-by-step guide to documentation requirement compliance.

In 40 states, a variety of efforts have been undertaken to improve pain management: lawmakers through specific legislation, regulators through new regulations, and state medical boards through revised or newly adopted guidelines and policy statements on pain treatment as state governments and medical boards focus on pain (see Table 74.11). Good documentation (the virtual flack jacket), despite its hassles, is one way to reduce the likelihood of a routine inquiry mushrooming into a full-blown investigation, although nothing—not the best documentation, the best guidelines, or the most enlightened regulatory attitudes—will reduce physician risk to zero, but that seems the inherent nature of the occupation. The kind of medical documentation adequate for most medical problems is often seen as inadequate in the treatment of pain (Hoover, 1996). The American Medical Association (AMA) and the American Hospital Association (AHA) have formulated criteria, in the development of an increasing number of

treatment guidelines, to guide policy makers in this area. Primary criteria include the potential to improve individual patient outcome, affect a large patient population, reduce cost either for the individual or in the aggregate, and reduce unexplained variations in medical practice (Carr, Jacox, Chapman, et al., 1995).

AHCPR guidelines for effective pain relief promise patients attentive and effective analgesic care as well as quantification in the medical chart of pain assessment and pain relief. AHCPR has issued recommendations regarding use of medications for management of pain in adults after extensive literature review and evaluation of data. The AHCPR guidelines establish basic principles with which analgesic drug treatment should comply (see Table 74.12) and integrate specialized technology and nonpharamacologic approaches. A systematic review of the literature is used to compile evidence for each mode of pain relief. Type I evidence comes from large trials; Type Ia evidence is derived from multiple, randomized, controlled trials that may be consolidated as meta-analysis. Type Ib data originate from at least one large, randomized, controlled study with statistically significant results. Type II studies involve well-designed but nonrandomized comparisons. Type III evidence is from descriptive studies. Type IV evidence is expert consensus, based on the opinions of prominent practitioners (Carr, Jacox, Chapman, et al., 1992). Balanced Analgesia combines an opioid and a nonopioid to reduce the opioid requirement and has now become standard practice (Joshi, 1994). Certain opioids should be avoided when possible. Meperidine hydrochloride is not recommended for long-term use because of the potential for accumulation of normeperidine, a toxic metabolite, that can cause confusion or seizures. Propoxyphene, for example, is an opiate with a 13-hour half-life. It is metabolized by a mechanism of n-demethylation through a saturable mechanism, forming the metabolite norpropoxyphene. In the elderly, susceptibility to the accumulation of this potential toxic metabolite exists. Additionally, partial and mixed opioid agonists such as buprenophine hydrochloride, pentazocine hydrochloride, butorphanol tartrate, and nalbuphine hydrochloride, because of their limited efficacy and possible toxicity, should be avoided (Cherny & Portenoy, 1994).

The newly found appreciation calling for aggressive action against acute pain resulted in the Federation of State Medical Boards of the United States, Inc. promulgating model guidelines in 1998 for pain management strategies and objectives (Model Guidelines, 1998). Clinicians will be held to those guidelines, and the quality of medical practice will be judged in part by the ability to meet those criteria. Some states have adopted even more stringent guidelines for pain treatment: at present, certain barriers to delivery of adequate analgesia and pain management exist. Members of the healthcare team, patients, and the healthcare system continue impeding the delivery of proper analgesia (see Table 74.13) (Jacox, Carr, Payne, et al., 1994).

TABLE 74.12
Pain Management Guidelines

Medications for Management of Pain in Adults

Medication	Evidence*	Comments	Precautions
Oral NSAIDs	Ib, IV	Effective for mild-to-moderate pain. Begin pre-operatively.	Relatively contraindicated in patients with renal disease and risk of or actual coagulopathy. May mask fever.
Oral NSAIDs in conjunction with opioids	Ia, IV	Potentiating effect resulting in opioid sparing. Begin pre-operatively.	As above.
Parenteral NSAIDs	Ib, IV	Effective for moderate-to severe pain. Expensive. Useful if opioids contraindicated, especially to avoid respiratory depression and sedation.	As above.
Oral opioids	IV	Route of choice. As effective as parenteral in appropriate doses. Use as oral medication tolerated.	
Intramuscular	Ib, IV	The standard parenteral route, but injections painful and absorption unreliable. Hence, avoid this route when possible.	
Subcutaneous	Ib, IV	Preferable to intramuscular route when low-volume continuous infusion is needed and intravenous access difficult to maintain. Injections painful and absorption unreliable.	Avoid this route for long-term repetitive treatment.
Intravenous	Ib, IV	Parenteral route of choice after major surgery. Suitable for titrated bolus or continuous administration but requires special monitoring.	Significant risk of respiratory depression with inappropriate dosing.
PCA (systemic)	Ia, IV	Intravenous or subcutaneous routes recommended. Good steady level of analgesia. Popular with patients but requires special infusion pumps and staff education.	Significant risk of respiratory depression with inappropriate dosing.
Epidural and intrathecal opioids	Ia, IV	When suitable, provides good analgesia. Use of infusion pumps requires additional equipment and staff education. Expensive if infusion pumps are used.	Significant risk of respiratory depression sometimes delayed in onset. Requires careful monitoring.

* Ia = evidence obtained from meta-analysis of randomized controlled trials.
Ib = evidence obtained from at least one randomized controlled trial.
IV = expert consensus based on the opinions and/or clinical experiences of respected authorities.
NSAID = nonsteroidal anti-inflammatory drug.
PCA = patient-controlled analgesia.

TABLE 74.13
Barriers to Delivery of Adequate Analgesia

Healthcare Professionals	Reasons for Patient Reluctance to Report Pain	Healthcare System

• Inadequate knowledge of pain management (especially clinical pharmacology)
• Poor assessment of pain
• Concern about:
  • Regulation of controlled substances
  • Side effects of pain medication
  • Development of tolerance
  • Fear of patient addiction
	• Fear that pain means progression of disease
	• Want to be a “good” patient
	• Do not want to distract physicians from treating underlying disease
	• Reluctant to take pain medication
	• Fear of addiction or of being classified as an addict
	• Concerned about adverse reactions and development of tolerance
		• Low priority given to pain management
		• Inadequate reimbursement
		• Limits availability of treatment
		• Limits access to treatment
		• Restrictive regulation of controlled substances

Modified from Jacox, A., et al. (March 1994). Management of Cancer Pain. Clinical Guideline. Rockville, MD: U.S. Department of Health and Human Services.

FOCUS ON PAIN

In 40 states (see Table 74.11), a variety of efforts have been made to improve pain management. Some of these have been undertaken by lawmakers through specific legislation, or by regulators through new regulations. Others are results of revised or newly adopted guidelines and policy statements on pain treatment from state medical boards. Aimed at making standards uniform across the nation and encouraging better pain management, physicians who prescribe a controlled substance "for a legitimate medical purpose" are reassured not to worry about board action or that of a state regulatory or enforcement agency. The Federation initiative was endorsed by the Drug Enforcement Administration and by advocates for better pain management. The medical use of controlled substances has gained a new legitimacy, but physician fears of regulatory scrutiny linger.

Historically, from the advent of the Victorian era until after World War I, doctors were held largely responsible for the heroin, morphine, opiate, and cocaine problem that swept the United States. The Harrison Narcotic Act of 1914 began the heavy-handed crackdown on narcotics that narrowed the scope of medical practice and interfered with their legitimate medical use, especially in pain management (Guglielmo, 2000). A short decade ago, conventional wisdom in the medical establishment was that physicians treating chronic pain with opioids were at substantial risk of being sanctioned by state medical regulatory boards for overprescribing (Hill, 1993; Joranson, 1992; Portenoy, 1996b). A review of state medical board actions from 1990 to 1996 reveals that the perception of regulatory risk far exceeds the reality (Martino, 1998). A California study (Morrison & Wickersham, 1998) concluded that most offenses of disciplined physicians involved some aspect of patient care (e.g., inappropriate prescribing) and in the face of increasing consumer complaints, medical regulatory boards may have increased dealings with physicians who commit disciplinary offenses. Regulatory risks associated with overprescribing are still perceived as real and far greater (Glanelli, 1999) than those associated with underprescribing despite regulatory relief efforts. The premise of the regulatory relief efforts was that the undertreatment of pain is a public health problem. Ann M. Martino, Ph.D., executive director of Iowa Board of Medical Examiners, recommends new laws be written to discipline physicians who prescribe too little pain medication. Ironically, she writes, the most immediate means [of achieving good pain management] may not be regulatory relief but more regulation (Martino, 1998).

It has been recommended that physician education is key to better pain management. Knowledge of the best drug and nondrug methods for controlling pain and of the federal and state laws that apply to medical practice is recommended at "should know" levels. State medical boards or medical societies are good resources. Caveat: A potent reminder finds that knowledge alone is insufficient to promote behavioral change (King, Bungard, McAlister, et al., 2000); in the absence of other actions such steps as disseminating a medical guideline or providing continuing medical education are unlikely to significantly, or even measurably, improve the effectiveness of an intervention (Goff, Canely, & Gu, 2000).

For decades, improving the quality of healthcare delivery relied on changing physician behavior. Experience has shown that quality improvement is better achieved through system solutions that support clinicians in providing quality care (Calonge, 2000). The imperative to measure, promote, and improve the quality of medical care continues to be an essential, if not daunting, endeavor. The quality of healthcare is, in the opinion of many, a serious problem (Chassin, & Galvin, 1998). Research demonstrates that physicians overuse healthcare services by ordering unnecessary interventions (Leape, 1992; Nyquist, Gonzales, Steiner, & Sande, 1998), underuse services by failing to provide a standard of care that would produce favorable outcomes (Chasin, 1997), and devise the wrong treatment plan or improperly execute the correct plan (Leape, 1994). Quality assurance in the healthcare system is an important public health objective (Lohr, 1990). The lessons of history confirm that the medical factors that have prompted medical malpractice litigation still continue but are in the public interest: scientific innovation, uniform standards, and liability insurance (Gostin, 2000). From a legal perspective, government directly and indirectly (the tort system) regulates the healthcare system.

Medical malpractice litigation ostensibly seeks higher quality care. Tort law, on the other hand, functions to deter substandard medical conduct, to avoid unnecessary injury, and as a fair method of compensation. Several reform methods are currently under public debate, the most prominent among these proposals being capitation on damages, which has been enacted in some states. Although this approach does not eliminate liability, it is proposed that such action would decrease fear of inordinate damage awards.

EMERGING STANDARD OF CARE IN PAIN MANAGEMENT AND LEGAL IMPLICATIONS

The rapidity of change in the clinical practice of medicine has brought frustration because of decreased autonomy, increased oversight, pressures on reimbursement, and allegations of fraud and abuse. Malpractice and legal complications of care have increased.

Despite the widespread promulgation of the benefits of opioid analgesics in all types of pain states—acute, chronic, and cancer—fear and trepidation remain on

TABLE 74.14
Key Points Included in the Controlled Substances Act

- Opioids are necessary to public health.
- A mechanism is devised for external medical input.
- Drug availability is guaranteed.
- The federal definition of an addict does not include the chronic pain patient.
- Regulations specifically recognize the treatment of intractable pain with opioids
- Prescription size is not restricted.
- Without a special license granted by the DEA, physicians may not provide methadone maintenance for patients with known addiction to controlled substances.

TABLE 74.15
Liability Issues in Pain Management

Liability to Patients
For cost-containment practices that affect pain management (Townsend, 1983)
For inappropriate pain management
Liability to Third Parties
For injury caused by patients treated for pain (Heller, 1992; Vainio, 1995; Wilchinsky, 1989)
Liability to Patients, Healthcare Providers, and Third Parties
For risks and side effects of drugs and pain management devices

the part of physicians prescribing opioids. The Uniform Controlled Substance Act of 1970 provides for the registration of those handling controlled substances, as well as for the labeling, order forms, record keeping, and reporting of substances or their use. Key points included in the Controlled Substances Act are listed in Table 74.14.

The issues of safety, efficacy, and compliance associated with the use of controlled substances invite problems of liability (see Table 74.15). States exercise parallel prohibition on the nonmedical use of controlled substances with most statutes based on the 1970 Model Uniform Controlled Substances Act. It is the intricacies and interrelationships between federal and state laws regulating the prescribing of opioid analgesics that have been repeatedly identified as one of the more significant barriers to the provision of effective pain management and palliative care (Rich, 2000). The barriers to pain management provide plausible reasons for so many patients to experience undertreated pain. Collectively, these barriers have either contributed to or caused an enduring epidemic of pain and suffering trailing in the wake of untreated pain (Rich, 2000). Patient-related barriers to good pain management also exist. The general public is ignorant and fearful of opioid analgesics, and reluctant to be viewed as too demanding of more in the way of care than has been proffered. Laypersons can hardly be more sophisticated and knowledgeable about an emerging aspect of clinical medical practice than healthcare professionals (Cleeland, 1992). In 1996, an international panel of distinguished healthcare professionals assembled by the Hastings Center (International Project, 1996) identified the goals of medicine as

> The prevention of disease and injury and promotion and maintenance of health;
> The relief of pain and suffering caused by maladies;
> The care and cure of those with a malady, and the care of those who cannot be cured; and
> The avoidance of premature death and the pursuit of a peaceful death.

The stated goals strike a remarkable balance between the curative and the palliative approaches to patient care, strongly suggesting that the hegemony of the curative model that is the hallmark of modern medical education and practice reflects a medical ethos inconsistent with the core values of medicine (Rich, 2000).

EMERGING LIABILITY ISSUES IN THE MANAGEMENT OF PAIN

It is argued that there are three essential duties of a healthcare professional (Edwards, 1984) regarding pain management:

1. The first duty is to minimize iatrogenic (physician-induced) pain; no further pain and suffering are to be inflicted upon a patient beyond the unavoidable consequence of a reasonable effort to effect a cure.
2. The second duty is to be a competent practition-er in pain management. Effective application of state-of-the-art pain relief techniques is required to relieve as much pain as possible without imposition of patient burden that exceeds benefit. This is a duty that can reasonably be placed on all physicians who care for pain patients and not one reserved for pain or palliative care specialists only. It is time for those physicians who are most likely to see chronically ill patients in the first line of duty (general practitioners, oncologists) to make pain control and palliative care a part of routine clinical practice (Stjernsward, et al., 1996).
3. The third duty is to adequately inform the patient of the risks and benefits of alternative pain management strategies, including that of

not pursuing pain relief (Emanuel, 1996). Physicians have a duty to continue their education throughout their professional lives to maintain their practices consistent with advances in science and technology.

The issue of whether physicians should be insulated from ethical or legal responsibility for undertreating pain due to deficiency in this area of medical education (American Medical Association, 1996) was in seemingly direct contradiction with the AMA's Principles of Medical Ethics and the current opinion of the AMA on Professional Rights and Responsibilities (1996).

There is a developing healthcare professional consensus that failure either to effectively manage pain that can be managed or to refer the patient to a professional who can bring state-of-the-art techniques to bear on the problem, constitutes a breach of professional ethics and a departure from an emerging standard of care (Oherney & Catane, 1995). The concept of the patient's legal right to effective pain management and the correlative duty on the part of physicians because of their virtual monopoly on the authority to prescribe narcotics to provide effective pain management to patients has begun to emerge in the last decade. One of the first serious discussions on poor pain management as an example of medical malpractice was conducted by Margaret Sommerville, a Canadian legal scholar and bioethicist (1986). With the prevailing standard of care, it is argued that because it is abundantly clear that physicians traditionally fail to alleviate pain, a patient would find it difficult to establish undertreatment of pain as a departure from the applicable standard of care. The failure of the medical profession to adopt and consistently apply readily available therapeutic modalities that would improve patient care presents precisely a situational scenario ripe for judicial standard setting. With deficiencies in prevailing custom and practice so clearly inconsistent with the traditionally attributable goal of the medical profession, courts appear likely to revert to a past irresistible impulse to find the entire profession negligent (Hooper, 1932).

A primary impetus for the promulgation of clinical practice guidelines for pain assessment and management has been the demonstration, through recent studies, that many healthcare professionals lack, or fail to apply, basic knowledge and skills in this area. A declaration that "not relieving pain brushes dangerously close to the act of willfully inflicting it" has become one of the strongest statements recorded from an objective, non-clinician perspective (Morris, 1991). The willful infliction of pain is torture, which is foreclosed to the government by the Eighth Amendment to the U.S. Constitution, as "cruel and unusual" even in punishment of convicted criminals.

TOWARD A NEWER MEDICAL MODEL

Inadequate pain control appears to be the spur for increased interest in physician-assisted suicide, but one reason for inadequate pain management is an unfounded concern of both patients and healthcare providers that pain control is a form of euthanasia. Euthanasia refers to the intentional act of painlessly putting to death persons with incurable and distressing disease as an act of mercy (Black's Law Dictionary, 1979). Appropriate pain management aims to reduce suffering, not cause death.

In January 1998, Kirk Robinson, president, and Kathryn Tucker, director of legal affairs, for the Oregon-based organization Compassion in Dying Federation (CIDF), sent a memorandum to every medical board in the United States arguing that dying patients have a right to adequate pain medications. Although the focus of the memorandum was end-of-life care, it outlined a series of steps for each state board to follow in addressing the perceived risks for overprescribing controlled substances and the absence of any risk real or imagined for underprescribing medications to any patient experiencing pain. The idea that state medical boards should take on the responsibility of scrutinizing licensees for inadequate pain care was urged, as well as the adoption of underprescribing as a ground for discipline. Additionally, the Compassion in Dying Federation (CIDF) put all boards on public notice that it was willing to assist chronic pain patients and their families in making complaints and/or in filing suits against practitioners who fail to provide adequate pain relief through underprescribing.

In July of 1994, the California Medical Board issued a formal statement on "Prescribing Controlled Substances for Pain Management." The Board stated that "principles of quality medical practice dictate that citizens of California who suffer from pain should be able to obtain the relief that is currently available" and that "pain management should be a high priority in California." Concomitantly, the Board issued "Guidelines for Prescribing Controlled Substances for Intractable Pain" (Webster's Third New International Dictionary 1993) which included the following admonition:

> The Board strongly urges physicians to view pain management as a priority in all patients… . Pain should be assessed and treated promptly, effectively and for as long as the pain persists. The medical management of pain should be based on up-to-date knowledge about pain, pain assessment and pain treatment (Medical Board of California, 1994).

The legal theory of negligence in medication error lawsuits can be applied to cases claiming inappropriate management of pain (Frank-Stromborg & Christiansen, 2000). In any allegation of inappropriate pain management, the patient (plaintiff) must prove:

1. that a duty of care was owed to the patient by the defendant (healthcare professional);
2. the duty owed was breached with conduct that violated a standard of care recognized in the profession;
3. that breach of the duty owed was the cause of injury or the suffering; and
4. the patient (plaintiff) suffered damages as a result (Keeton, Dobbs, Keeton, & Owen, 1984).

In cases involving pain control, the professional will be judged according to the expectation of what a reasonable practitioner would have done in similar circumstances (Willis, 1998). In general, the standard of medical care a physician may with reason and fairness be expected to possess is that commonly possessed or reasonably available to minimally competent physicians in the same specialty or general field of practice throughout the United States. A physician should have a realistic understanding of the limitations of his or her knowledge or competence and, in general, exercise minimally adequate medical judgment (Hall v. Hilbun, 1985). In litigation, the appropriate specialty is located to provide information through testimony about the standard of care and any deviation from such standard. In most cases involving questionable pain treatment, the standard of care usually is defined and represented by the AHCPR guidelines. A minority of jurisdictions take the position that adherence to customary practice should not insulate a physician from malpractice liability if the patient (plaintiff) can provide persuasive evidence that the physician failed or refused to apply readily available measures that would have prevented harm to the patient. The Wisconsin Supreme Court (Nowatske v. Osterloh, 1996) stated that should customary medical practice fail to keep pace with developments and advances in medical science, adherence to custom might constitute a failure to exercise reasonable care. Evidence that a defendant followed customary practice is not the sole test of professional malpractice (Toth v. Community Hospital, 1968). The notion that an entire medical specialty (Helling v. Carey, 1974), or at least all the members of a particular locale, would never be guilty of negligence by adhering to a substandard standard of care fell to a Louisiana appellate court statement:

> We are firm in the opinion that it is patently absurd, unreasonable, and arbitrary to hold that immunity from tort liability may be predicated upon a degree of care or procedure amounting to negligence not withstanding such procedure is generally followed by other members of the profession in good standing in the same community (Favalora v. Aetna, 1962).

Most lawsuits brought by patients against healthcare providers are for medical malpractice, which is defined as a breach of accepted medical practice resulting in injury and legally recognized damage to the patient. Courts are now willing to hold physicians liable for allowing a patient to suffer because of a failure to provide appropriate pain relief under the recognition of improper pain management as a breach of good and acceptable practice. A medical malpractice judgment exceeding $1 million against the Veterans Administration included an award of $125,000 for pain and suffering predicated largely upon the defendants' failure to provide sufficient pain medication in the final days of the patient's life (Gaddis v. United States, 1997). The primary claim and bulk of the total award for damages in a South Carolina case was based on a failure to timely and properly diagnose and treat the patient's throat cancer.

In California, William Bergman, a man in his early 80s, wrenched his back pulling a battery out of a car. Over the next few days he developed more and more back pain, which was originally thought to be a strain–sprain until the patient became immobilized due to the pain (Tucker, 2000). He was taken to the emergency room of a northern California hospital whereupon he was hospitalized for severe pain in his back with a diagnostic finding of metastatic lung cancer. The patient indicated he wished no treatment for his cancer but wished only to receive pain medication that would allow him to return to his home and functionality for what time he had left. Dr. Wing Chin became Mr. Bergman's assigned physician for his hospitalization. The patient was reported by nursing to have increasing Visual Analog Pain Scale (VAS) ratings despite receiving Demerol on a prn order for pain relief based on patient request. Bergman was subsequently discharged to his home with the oral pain medication Vicodin. Demerol is inadequate for cancer pain relief and is inappropriate for use in the aged due to nervous system toxicity that may develop as a side effect of metabolite formation. Morphine agents are appropriate for cancer pain relief. Oral Vicodin is indicated for moderate to moderately severe pain. Pain medications for cancer pain relief should be given at specific times, not on a prn basis. Dr. Chin was called regarding Mr. Bergman's pain and when asked about morphine agents for pain relief, the family was told that he (Dr. Chin) did not possess the required multiple prescription form pad to order these pharamaceuticals for patient use. After 2 days at home in what was described as "agonizing pain", a hospice nurse succeeded in contacting William Berman's regular physician, who immediately administered Roxanol achieving pain relief. Mr. Bergman died the next day.

Mr. Bergman's daughter (Beverly Bergman) was so disturbed by her father's suffering that she made formal complaint, supported by independent expert opinion, to the Medical Board of California (MBC), that the pain care provided to an elderly, terminally ill cancer patient was inadequate.

California is among the most progressive states in attempting to improve pain care. In 1994, the MBC adopted an official guideline on pain management, which specifically identifies failure to adequately manage pain as "inappropriate prescribing." The MBC expressly recognized that this is a form of professional misconduct, subject to the full range of sanctions.

The MBC agreed with Beverly Bergman that the physician had failed to provide adequate pain care but declined to take any action against the physician (Letter from MBC, 1998). It was not until after the MBC concluded that inadequate pain relief had been provided but declined to take any disciplinary action that a formal complaint was filed.

In February 1999 what appears to be the first malpractice suit against a physician (Bergman v. Chin, 1999) grounded primarily on failure to properly manage a patient's pain, was filed in Superior Court of California (Gaddis v. United States, 1997; Bergman v. Eden Medical Center, 1999). Cases of inadequate pain treatment may result in civil liability in tort cases with significant financial implications. The unusual aspect of the Bergman case is that a cause of action under the California Elder Abuse Statute is included, which provides heightened remedies to what would be available under a medical malpractice claim, including punitive damages, no cap on damages, and attorney's fees. The defendant physician and hospital agreed that the family was only entitled to the limited remedies available in a malpractice claim, repeatedly disputed the elder abuse claim, and petitioned for it to be dismissed. In January 2000 the court ruled against dismissal of the elder abuse claims, recognizing that inadequate pain care can constitute elder abuse. Kathryn Tucker, Esq., director of legal affairs for the Compassion in Dying Federation, explained that a successful trial means the Bergman family will be able to recover significant damages and as exposure for inadequate pain care becomes more significant, providers will be more motivated to attend and treat pain properly under exposure to significantly greater financial risk (Partners Against Pain, 2000). Dying patients clearly have the right to adequate pain medication; this was recently recognized by the Supreme Court (Vacco v. Quill, 1997; Washington v. Glucksberg, 1997; Burt, 1997).

Illustrative of the law's recognition that assurance of comfort and appropriate pain control are integral components of appropriate medical care (State v. McAfee, 1989) is, in this instance, a quadriplegic who was incapable of spontaneous respiration and sought court approval for discontinuation of his respirator. The Georgia Supreme Court affirmed the patient's right to refuse medical treatment and held that he was also entitled to have a sedative administered at the time:

> Mr. McAfee's right to be free from pain at the time the ventilator is disconnected is inseparable from his right to refuse medical treatment. The record shows that Mr. McAfee has attempted, in the past, to disconnect his ventilator, but has been unable to do so due to the severe pain he suffers when deprived of oxygen. His right to have a sedative (a medication that in no way causes or accelerates death) administered before the ventilator is disconnected is a part of his right to control his medical treatment.

The implication of this ruling is that providers may be held accountable for not providing such measures (Shapiro, 1996).

In a North Carolina negligence law suit, a healthcare provider was held liable for the first time for failure to treat serious pain appropriately (Estate of Henry James v. Hillhaven Corp., 1990).

Henry James, 74 years of age, a retired house painter, was diagnosed with cancer of the prostate for which he was subjected to removal of his testicles. The cancer, however, was metastatic in nature, having spread to his leg and spine. His pain was severe and excruciating. He was placed in a nursing home in February 1987. Almost at once, nursing began cutting his prescription pain medications by giving him on some days mild headache medicines, placebo substituted for morphine, or nothing at all. The nursing supervisor explained to the family he was in danger of becoming a drug addict and because James and his family were Medicare and Medicaid recipients she did not like her tax dollars supporting his drug habit. Eventually, Mr. James became irritable, withdrawn, and bedfast, where he lay sweating and moaning in pain dying 4 months later. His family eventually filed a complaint with a state regulatory agency and went to court. On November 20, 1990, trial began in North Carolina. After 3½ days of testimony, the jury took less than 1 hour to render the verdict that the nursing home had been negligent in failing to provide Mr. James adequate pain relief. At the trial, Catherine Faison, James's great niece, explained that as far as the nursing home was concerned, when he died, it was a closed issue; it was over. "It's not over for me," Faison told the jury. "I can't sleep at night when I think about the fact that he had to lay over there and suffer… I think about him laying there hurting, saying I want my medication, and not being able to get it. I don't want to suffer like that… I don't think anybody would. Somebody needs to say you can't do it."

Safe harbor provisions in intractable pain legislation enacted in many states grant immunity from discipline to physicians who treat intractable pain. These enactments clarify the position that physicians shall not be disciplined for treating intractable pain with large doses of medication, even if such prescriptions hasten the moment of the patient's death, as long as the intent is simply to alleviate pain. Such provisions are designed to clear the confusion that may occur because of the similarity with prescribing medications to end a patient's life.

In 1999, the Oregon Board of Medical Examiners disciplined a physician for the undertreatment of a patient's intractable pain. Dr. Paul Bilder, an Oregon pulmonary specialist, was disciplined for a pattern of failing to treat pain adequately (Goodman, 1999). The physician was reported to have undertreated patients as follows (Mascheri, 1999).

1. Tylenol (Loeb, 1996) was used for an elderly male cancer patient's musculoskeletal pain, denying requests for stronger medications when pain increased. He also denied a nurse's request for catheterization, citing a risk of infection. The patient died the next day.
2. He removed a catheter from an 84-year-old man against the patient's and family's request, directing that he instead use diapers. He further reduced a hospice nurse's requested dose of 5 to 20 mg of Roxanol every 4 hours to 0.25 cc and gave Tylenol (Loeb, 1996) to treat the patient's 102° temperature. The patient died that evening.
3. He refused a request for sedatives and pain control for a 35-year-old intubated, mechanically ventilated woman who became increasingly restless, had increased wheezing, and was fighting the ventilator. After the patient extubated herself, the doctor ordered a paralytic agent but no sedative following reintubation.
4. He used physical restraint to intubate a 33-year-old man without using anxiolytics or narcotics. The patient had been admitted with severe pneumonia associated with hypoxemia. The physician, it is claimed by the board, engaged in "unprofessional or dishonorable conduct" and "gross negligence or repeated negligence," according to a stipulated order released by the board. While the physician will not lose his license, this is the first time a state board has taken this type of actions.

Thus, in addition to potential liability to patients for inappropriate pain management, professional discipline of healthcare professionals also may ensue. As a result of development and growing acceptance of pain management guidelines, medical boards may be more inclined in the future to undertake disciplinary action for inadequate pain management.

Increased use of advanced directives resulting from passage of the federal Patient Self-Determination Act (effective December 1, 1991) also may increase physicians' exposure to professional discipline for inappropriate pain management. In the interests of sustaining protection, physicians are advised to honor appropriate pain management instructions set forth in patients' advanced directives. Where questions or concerns arise about complying with such pain management instruction, ethics committees should be consulted (Shapiro, 1994).

Appropriate pain management aims to reduce suffering, not cause death. When physicians deliberately administer lethal doses of medications — even for reasons of compassion — they risk prosecution for homicide, and when lethal doses of medications are prescribed, they risk prosecution for assisting suicide.

To avoid exposure to criminal prosecution, physicians should (a) prescribe medications in doses in accordance with what is necessary to manage pain with good medical judgment; (b) clearly communicate their rationale for pain medication prescriptions with patients, their families, and other caregivers; and (c) clearly document the intent behind and need for the medication prescribed.

Investigations of physicians for perceived excessive prescribing of pain medication reduces physician willingness to treat pain with strong pain medications. This is one factor contributing to the problem of undertreatment of pain. During the past few years, aggressive educational efforts have begun to correct the undertreatment of pain and other physical suffering in dying patients — a major failing in medical care (Noble, 1999).

A pending federal bill would have significant adverse impact on progress in this area. The Pain Relief Promotion Act of 1999 (PRPA, 2000), should Congress decide to enact it, would increase physician exposure to investigations for prescribing aggressive pain treatment at the end of life. It is the public fear of intolerable suffering that is a major reason for public support of assisted suicide (Blendon, Szalay, & Knox, 1992). In 1994, Oregon became the first state in the nation to pass a law permitting physician-assisted suicide. By November, 1997, all barriers (e.g., legal challenges and ballot measures to rescind the law leading to delays in implementation) were put aside and Oregon's Death with Dignity Act became fully operative.

The legal effect of PRPA is at odds with its appealing title because the act, introduced by Rep. Henry Hyde (R, IL) and Sen. Don Nickles (R, OK), is designed to override Oregon's physician-assisted suicide law (BNA Health Law Reporter, 1999). The primary goal of PRPA is to prevent physicians in Oregon from continuing to implement the Death with Dignity Act (Orentlicher & Caplan, 2000). Title I of the PRPA amends the Controlled Substances Act to nullify Oregon's physician-assisted suicide law. Section 101 of PRPA states opiates, drugs, and other controlled substances may not be intentionally used "for the purpose of causing death or assisting another person in causing death." While rejecting assisted suicide, Title I of PRPA makes a strong statement favoring palliative care as a part of a legitimate medical practice to use a controlled substance with the intent to alleviate patients' pain — "even if the use of such a substance may increase the risk of death" (PRPA, 1999 S102). Educational and

training programs for local, state, and federal law enforcement personnel on the legitimate use of controlled substances in pain management and palliative care (PRPA, 1999). In deciding what uses of controlled substances are consistent with the public interest, the U.S. Attorney General "shall give no force and effect to state law authorizing or permitting assisted suicide or euthanasia" (PRPA, 1999).

Title II of PRPA provides for "programs to provide education and training to healthcare professionals in palliative care". The PRPA would potentially expose to criminal prosecution physicians in every state who provide pain management drugs that they knew would or could increase the likelihood of a patient's death. Under Section 101 of PRPA, the line between acceptable palliative care and unacceptable assisted suicide is to be drawn solely by the physician's intents.

Section 401 of the Controlled Substances Act (CSA) contains a broad prohibition on the distribution and dispensing of federally controlled substances, and violation of Section 401 carries criminal penalties. Section 303, however, provides a so-called safe harbor from the broad prohibition (of Section 401) for the medical profession, allowing physicians to use such federally controlled substances, including the drugs necessary to ease the pain of patients, in the course of their practices. When Congress passed the Controlled Substances Act to address trafficking in illicit drugs, it employed language that incidentally covers physicians who use controlled substances to assist a patient in suicide or perform euthanasia. As currently drafted, PRPA adds to the end of that safe-harbor section (Section 803) two new elements of law that when read in the context of the CSA, radically affect the ability of physicians to practice medicine. The amendment first includes a deceptively physician friendly support for aggressive pain management that "may increase the risk of death" and next adds a provision removing from Section 823 the use of such federally controlled substances to intentionally cause or assist in the causing of a patient's death. Without this safe-harbor provision, physicians in Oregon who comply with their patients' wishes pursuant to that state's Death with Dignity Law will be subject to the CSA criminal sanctions. The notion of intent and the unclear manner in which it is used in S.1272 creates trouble for physicians in all states whether or not they plan to engage in physician-assisted suicide. Legally, intent is considered to be established where there is knowledge that the death is substantially certain to occur as a result of the conduct; however, intent also can be found where death should have been reasonably expected to occur as a result of the conduct. When intent is the critical issue, physicians must be concerned that law enforcement officers will see a criminal intent where none existed. The risk of prosecution is exacerbated by the fact that when high doses of medication are utilized in a terminally ill patient who dies of natural causes, the death may be mistakenly ascribed to the medication. The PRPA would mandate that those difficult, and subjective, questions be resolved by the criminal process, after the fact. Physicians are left exposed to the general criminal penalties associated with Section 841(a) if they potentially should have known that the dosage they prescribed would result in death, even if their subjective intent in fact was to provide palliative care. If the physician uses aggressive doses of opiate drugs to provide palliative care and is charged under the PRPA, a conviction would result in draconian consequences. The intent to cause death can be inferred from the drug or dose ordered, the potential therefore exists for physician incarceration if the local authorities view, in retrospect, the dosage received by the patient as excessive. A physician convicted under PRPA for using a Schedule II drug and causing a patient's death faces a minimum sentence of 20 years in prison and a maximum sentence of life in prison.

The Controlled Substances Act is an anti-drug abuse law enforcement statute administered by the Attorney General (Testimony before Senate, 1998). The Department of Justice was given the authority to prevent and prosecute illicit drug use, a power that has been exercised in large part by the DEA. Under the Pain Relief Promotion Act (PRPA) instead of looking to medical experts and the FDA for guidance on the appropriate use of opioids, barbiturates, and other palliative drugs in end-of-life care, physicians also would have to consider the views of DEA agents (Testimony before House, 1999).

By using a federal statue to override an Oregon healthcare law, PRPA contravenes the principle of federalism, a fundamental tenet of American law. The regulation of medical practice traditionally has been the province of states and their medical boards, not that of the federal government and its law enforcement agencies. The preamble to the Medicare law expressly prohibits any federal "supervision or control over the practice of medicine or the manner in which medical services are provided" (Iglehart, 1992).

In the past decade, physicians have become more likely to face civil lawsuits as well as criminal prosecutions when charged with substandard medical care. It is likely that the PRPA would induce physicians to avoid the threat of legal liability and again exacerbate the undertreatment of pain causing increased suffering in the patients with pain. Pressure on physicians to undertreat pain will increase under PRPA, yet the risk for so doing is an increasingly punitive reality — truly placing physicians between the rock and the hard place.

CONCLUSION

Pain is one of the most common reasons for seeking medical care, yet it is often inadequately treated. Untreated,

the pain accompanying illnesses slows recovery, severely impairs an individual's quality of life, and adds significantly to the healthcare system's financial burden. The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) standards (the new evidence-based pain management standards introduced by JCAHO) (Phillips, 2000) asserts that individuals seeking care at accredited hospitals, behavioral health facilities, and healthcare networks, have the right to appropriate assessment and management of pain. All patients are to be screened for the presence of pain. For those reporting pain, a complete assessment must be conducted to characterize a patient's pain by location, intensity, and cause, including a detailed history, physical examination, psychosocial assessment, and diagnostic evaluation.

The most reliable indicator of pain existence and intensity is the patient's self-report because it is more accurate than others' observations. These standards do not dictate specific pain management procedures nor advocate in any way the use of certain drugs (e.g., opioids).

A discussion of the emerging standards and guidelines (Jacox, Carr, & Payne, 1994) coupled with developing disciplinary and legal consequences to remold physician action and delivery of medical care utilizing the fulcrum of inadequate pain management as inappropriate medical care appears designed to move physicians into fungible units in need of surveillance to assure compliance with all controlling legal authority. The House version of the Pain Relief Promotions Act was passed in October of 1999, although a filibuster is expected when the bill is introduced in the Senate.

The New Mexico Supreme Court ruled that a physician could be held liable to a man who was injured by an automobile driven by his patient to whom he had administered drugs that caused drowsiness. It further held that a physician does have a legal duty to use reasonable care in treating patients, and that this duty extends to the driving public when the physician administers drugs known to cause drowsiness and impairment of judgment.

75

Provider Accountability for Inadequate Pain Management

Kathryn L. Tucker, J.D.

Patients in the United States are routinely undertreated for pain. This problem has been widely recognized and documented in the medical literature. In a seminal medical study of end-of-life care, researchers found that 50% of all patients who died during hospitalization "experienced moderate or severe pain at least half of the time during their last 3 days of life" (SUPPORT, 1995).

Elderly patients are particularly vulnerable to insufficient pain treatment. A recent study in the *Journal of the American Medical Association* found that up to 40% of cancer patients in nursing homes are not appropriately treated for pain. In addition, 26% of those experiencing pain did not receive any pain medication, and 16% were given over-the-counter pain relievers like aspirin or acetaminophen for their pain (Bernabei, et al., 1998). At the same time, it is well established that only perhaps 10% of dying patients have conditions in which alleviation of pain is truly difficult or impossible (Jacox, et al., 2000).

One repeatedly identified cause of this problem is physician concern that prescribing controlled substances will invite regulatory agency oversight (Breaking Down the Barriers, 1998). Other factors inhibiting adequate pain treatment described in the medical literature include the fear that strong pain treatment will hasten death (Schneiderman, 1997), and the concern that the patient will become addicted to the pain medication (Stavish, 1997).

Oversight is triggered in some states by laws that require duplicate or triplicate prescription forms, with copies going to reviewing authorities. These laws were intended to deter illegitimate drug use. Unfortunately, they have had an enormous impact on legitimate use, as well. It is not uncommon for physicians to be investigated for prescribing controlled substances in amounts that regulators perceive as excessive. Even if the physician's conduct meets relevant guidelines for pain management, such investigations may result in physician discipline, including suspension or revocation of prescribing authority, other limitations on medical practice, and other penalties (Hoover v. Agency for Health Care Administration, 1996). It has become widely recognized that the multiple copy prescription laws deter physicians from writing prescriptions for controlled substances, and thus, create barriers to access to adequate pain medication. In response, some states have, in recent years, eliminated traditional multiple copy laws (N.Y. Public Health Law, 2000). This is a step in the right direction; yet, it is unlikely to correct the serious problem of inadequate treatment of pain on its own.

The American Society of Law, Medicine, and Ethics (ASLME) recently undertook a reform effort, the Project on Legal Constraints on Access to Effective Pain Management. The Project developed a model Pain Relief Act that creates a "safe harbor" for physicians who prescribe pain medication as long as the physician substantially complied with accepted practice and care guidelines for pain management (The Pain Relief Act, 1996). This safe harbor shelters physicians from both disciplinary and criminal action if the physician can "demonstrate by reference to an accepted guideline that his or her practice substantially complied with that guideline." The physician also must have kept appropriate records, written no false prescriptions, obeyed the CSA, and not diverted medications to personal use (The Pain Relief Act, 1996).

0-8493-0926-3/02/$0.00+$1.50

The safe-harbor concept is also encompassed in state laws known as Intractable Pain Treatment Acts (IPTA). The existing state statutes generally provide shelter from disciplinary action, but make no mention of criminal exposure. The California IPTA, for example, provides that "no physician or surgeon shall be subject to disciplinary action by the board for prescribing or administering controlled substances in the course of treatment of a person for intractable pain" (California Business and Professional Code, § 2241.5(c)). To be immune from board discipline this IPTA requires that the patient not be known to have chemical dependency or to be using drugs for nontherapeutic purposes. The physician must prescribe medications for therapeutic purposes, keep appropriate records, not write false prescriptions, and prescribe in a manner consistent with the state and federal CSA (California Business and Professional Code, § 2241.5(c)).

Unfortunately, IPTAs have proven to be largely ineffectual (Rich, 2000). Reports continue to document that undertreatment of pain is pervasive (Rich, 2000). The situation in California exemplifies this failure.

California is among the most progressive states in attempting to improve pain care. The state legislature passed its IPTA in 1990 (Rich, 2000). In 1994 the Medical Board of California (MBC) provided all California physicians with a copy of the clinical guidelines for pain management issued by the U.S. Agency for Health Care Policy and Research (AHCPR), and adopted a policy statement in May 1994 encouraging aggressive pain care. Subsequently, the MBC (1994) adopted an official guideline regarding pain management, which specifically identifies failure to adequately manage pain as "inappropriate prescribing". In explicitly making undertreatment of pain a type of inappropriate prescribing, the MBC has expressly recognized that this is a form of professional misconduct and, thus, subject to the full range of sanctions.

In 1997, the California legislature passed the Pain Patient's Bill of Rights (California Health and Safety Code § 124960). This law provides, in pertinent part, that "a patient suffering from severe chronic intractable pain has the option to request or reject the use of any or all modalities to relieve his or her severe chronic intractable pain." (California Health and Safety Code § 12496(h).

This law explicitly confers a specific right on California citizens to request any and all modalities to relieve pain. Yet, notwithstanding California's official posture of a commitment to ensuring that patients receive adequate pain care, including specifically adequate access to opioid analgesics, we cannot assume that physicians are providing adequate pain care or being held accountable when they do not. A recent specific case demonstrates this.

In 1998, the MBC was presented with a formal complaint, supported by an independent expert opinion, that the pain care provided to an elderly, terminally ill cancer patient was inadequate. The MBC itself agreed that the physician had failed to provide adequate pain care (MBC Letter, 1998). Yet the MBC declined to take any action against the physician (MBC Letter, 1998). At least one other case of inadequate pain care presented to the MBC, also supported by an expert opinion that the pain care was inadequate, was also closed without any corrective action.

SIGNS OF CHANGE: ACCOUNTABILITY IN THE MEDICAL DISCIPLINARY AND TORT CONTEXTS EMERGE

There are signs, however, that the laissez-faire attitude regarding inadequate treatment of pain is beginning to change. In 1999, a state medical disciplinary board took corrective action against an Oregon physician who failed to treat his patients adequately for pain (Goodman, 1999).

Cases of inadequate pain treatment are beginning to result in civil liability in tort cases, with significant financial implications (Estate of Henry James v. Hillhaven Corp., 1990; Gaddis v. United States, 1997; Bergman v. Eden Med. Ctr., 2001). The recent emergence of guidelines and standards governing appropriate pain care permits establishing that, in a specific case, the pain care provided was inadequate and should result in professional discipline. Medical organizations establishing standards or guidelines for pain treatment include the World Health Organization (1986), the American Pain Society (1995), the American Medical Association (McGivney, et al., 1984), AHCPR (1992), the Federation of State Medical Boards (1998), and the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) (2000). These guidelines all indicate the importance of pain management as an essential element of medical treatment.

There are new requirements for mandatory assessment and routine charting of pain, imposed by the VA system, state law, and JCAHO accreditation provisions (California Health and Safety Code § 1254.7). These provisions will increase patient awareness of their right to good pain care, increasing the likelihood that patients will seek accountability for inadequate pain care, and will enable patients and their advocates to establish with a clear documentary record that the pain care provided in a particular case was inadequate and should result in professional discipline. The record developed by the new assessment and charting rules will for the same reasons also make civil liability on various theories, including professional negligence and elder abuse, easier to establish.

This is entirely appropriate and necessary because knowledge of how to treat pain is available. The problem is that without outside motivation, physicians fail to acquire and apply available knowledge. Physicians must be motivated to acquire and apply this available knowledge (Rich, 2000).

As these types of cases become more common, risk managers can be expected to undertake efforts to minimize risk, leading to more attentive and aggressive provision of pain care.

CHANGES IN LAW ON THE HORIZON

Laws such as Intractable Pain Treatment Acts and Pain Relief Acts, which currently provide a safe harbor for physicians who follow guidelines in prescribing medications to relieve pain, may be revised to explicitly create rough waters for physicians who fail to do so. Such revisions would require disciplinary action, or provide an explicit tort cause of action, when there is failure to adequately prescribe, order, administer, or dispense pain management therapies, including controlled substances such as opioid analgesics, for pain relief or modulation in accordance with prevailing clinical practice guidelines.

In the wake of the cases involving inadequate pain care presented to the Medical Board of California, discussed above, which resulted in no action by the Board, such legislation has been introduced in the California State Legislature. In its original form, the proposed California legislation would mandate the MBC to, at a minimum, compel physicians shown to have failed to treat pain adequately to receive continuing education in pain management (Assembly Bill 487, 2001). AB487 has been amended and is expected to pass in a form that requires all California physicians to obtain continued education in pain management.

By amending state law relating to pain in this way, essential steps in encouraging and motivating physicians to treat pain appropriately will be accomplished. Such amendments would create rough waters for physicians who fail to treat pain adequately. This is essential because a safe harbor is not enough; the seas outside must be rough. Physicians who presently fail to adequately treat pain are already in a safe harbor, in the sense that there is rarely professional accountability for such conduct. There must be a reason to seek the safe harbor. Until physicians are aware that professional consequences and accountability attach if they fail to treat pain adequately, necessary improvement in the provision of pain care will not occur.

Journal of Medical Licensure & Discipline, 84 (1998) ("[P]rinciples of quality medical practice dictate that ...people ...have access to appropriate and effective pain relief. The Board encourages physicians to view effective pain management as a part of quality medical practice for all patients with pain, acute or chronic, and it is especially important for patients who experience pain as a result of terminal illness.").

New York Public Law. (2000). Some states have phased out multiple copy prescription programs, substituting electronic data programs, e.g., N.Y. Pub. Health Law §§ 3332-3333 (Consol. 2000); 710 Ill. Comp. Stat. 570 (West 2000) (amended in 1999). It remains to be seen if this substitution will mitigate the problems caused by the multiple copy programs. Proponents assert that elimination of the need for a duplicate or triplicate pad will facilitate prescribing. Others are skeptical, asserting the concern that scrutiny would be applied to prescribing controlled substances is in no way mitigated by a program that enables electronic data sorting and review.

Law Enforcement and Regulatory View about Prescribing Controlled Substances for Pain

Dale A. Ferranto, M.S.

A BRIEF HISTORY OF DRUG ABUSE, ENFORCEMENT, AND REGULATION

In order to fully appreciate the law enforcement and regulatory view about prescribing controlled substances for pain, it is valuable to study the history of drug abuse and the resultant parallel development of governmental policy and control. This history is, in fact, the story of pharmaceuticals. Aldous Huxley, the famous British author, succinctly noted that "pharmacology antedated agriculture" (O'Brien & Cohen, 1984, p. IX). Drugs have been used and abused for centuries in medicinal, religious, and recreational settings. One of the earliest mentions of herbal medicines occurs in the Old Testament book The Song of Solomon. In Chapter 4, verses 13 and 14, Solomon sings of "spikenard" and "aloes". The early Chippewa Native Americans used spikenard as a cough medicine, and aloe is still used today as a disinfectant and burn remedy.

Various world events and scientific advances contributed to America's attitude toward drugs and the abuse of drugs through the centuries. The isolation of morphine from opium in 1804, coupled with opium's commercial value demonstrated by two intense Opium Wars between England and China, and the subsequent development of the hypodermic syringe in 1853 were medical breakthroughs of a double-edged nature. Most physicians believed that relieving pain with needle-administered morphine was harmless because the injected drug bypassed the digestive tract. The immediate post-Civil War era would thus find America with 400,000 morphine addicts (O'Brien & Cohen, 1984, p. XV).

Ignorance among medical professionals combined with popularization of hypodermic therapy (Weston, 1952) gave birth to an American drug dependence that has yet to be cured. At the time, opium was perceived as a vice but not a menace, so governmental regulation merely took the form of taxation.

Amidst the dark cloud of drug abuse naívete that soon engulfed America, two healing arts organizations were founded. The American Medical Association (A.M.A.) began in 1847, and the American Pharmaceutical Association (A.P.A.) was founded in 1852. Though weak and unsupported until 1900, each association would play vital roles in awakening the United States government and the people to the evils of drug abuse. Through legislative influence and sponsorship of model prescribing and pharmacy laws, the medical professionals assumed a major portion of the responsibility to detoxify the nation.

As the twentieth century began, attention toward another drug, alcohol, so consumed the early era prohibitionists that in 1881, to some people, opiate abuse was the favored alternative. The *Catholic World Magazine* of that year reported, "The gentleman who would not be seen in a barroom procures his supply of morphia and has it in his pocket ready for instantaneous use. It is odorless and occupies but little space" (O'Brien & Cohen, 1984, p. XV). Also, patent medications containing opiates and cocaine deluged America as cure-alls for "misery, general aches, pains, headaches, and that tired feeling" (Weston, 1952, p. 16).

0-8493-0926-3/02/$0.00+$1.50

Physicians, though now organized in a medical association, continued on courses of misguided treatments. Opiate abusers were medicated to keep them comfortable, not clean. Narcotic- and cocaine-based elixirs and cocktails enjoyed thriving "medicinal" markets. Drug abuse had a firm, yet unrecognized, foothold on America. But from all embryonic indicators of this terrible disease, government failed to react and develop policy to confront the problem early, particularly when the commercial production of heroin as diacetylmorphine (1898) emerged on the market.

The evolution of regulatory and enforcement activities started with mere taxation (1864) and research (1886) when Congress announced an act to "Provide for the study of the nature of alcoholic drinks and narcotics, and their effects upon the human system" (Weston, 1952, p. 17). Exercising national intervention in matters previously reserved for the individual states, the Federal Government embarked on a course of codification of narcotic laws (Johnson, 1988). And, while not entirely taboo, "recreational" drug use was coming under greater suspicion, and unless one obtained drugs by prescription, a great deal of negative stereotyping of addicts was attached to opiate consumption.

Americans, though, continued to cherish and readily seek physician prescribed drugs. This patent medicine craze of high opiate content medications and the delayed realization that "dangerously addicting substances were distributed with little worry for their effect" (Musto, 1973, p. 7) caused two major events. The first was a revival of an old form of professional criminality, drug diversion, and the second was a reaction by state and federal agencies to control the first.

The criminal physician and pharmacist seized the opportunity to cash in on the highly lucrative pharmaceutical drug business. Their enterprise, though, was nothing really new. In 1604, Miguel de Cervantes, *Man of Glass*, offered his view of the unscrupulous doctor, writing, "Physicians may and do kill without fear or running away and without unsheathing any other sword than that of a prescription" (Cervantes, p. 78). Additionally, Sir Arthur Conan Doyle, himself a physician, allowed Sherlock Holmes to conclude, "When a doctor goes wrong he is the first of criminals. He has nerve and he has knowledge" (Doyle, 1977). So doctors thus inclined and known as "croakers" or gentlemen of high rank who like their base and comfort without earning it (Keegan, 1987, p. 129) emerged as drug diverters and suppliers for drug abusers.

The government's reaction and policy response to the rising epidemic of pharmaceutical drug abuse quickened in the early 1900s. Prescription requirements increased for opiate substances, and curing addiction became a true legal and medical challenge. Federal laws, originally argued as unconstitutional, were then enacted, and they included the Pure Food and Drug Act (1906), The Harrison Narcotic Law (1914), the Drug Abuse Act (1970), and the Anti-Drug Abuse Act of 1988.

The nexus between drug abuse and prescriptions also led James H. Beal, an outspoken pharmacist/lawyer of the A.P.A., to propose a model state pharmacy law for habit-forming drugs. Though not enthusiastically embraced by his medical and pharmacist colleagues, Beal's model became a turning point in endorsing further narcotic-related healing arts legislation.

The diverse and heterogeneous growth of America during the new twentieth century fragmented our society resulting in more formal sanctions and controls by government on pharmaceutical substances of abuse (Richardson, 1974, p. 86). While the subject of drug abuse temporarily disappeared from government scrutiny during the World Wars, Great Depression, and Korean War, it reemerged with vengeance after the Vietnam conflict. America's appetite for drugs exploded and, simultaneously, drugs were being developed at a tremendous rate: approximately 75% of today's pharmaceuticals were formulated within the last 40 years. The supply–demand equation of this phenomenon has remained so unbalanced that full, complete, and effective enforcement of drug policies could now only be achieved in a police state.

The diversion of pharmaceutical controlled substances presented a unique regulatory and enforcement problem to authorities trying to prevent drug abuse. The Drug Abuse Warning Network (D.A.W.N.) reports that high-light hospital overdose admissions and coroner death reports in over 800 hospitals nationwide consistently indicated that pharmaceutical drugs were involved in approximately 50% of the deaths and, of the top 20 drugs of abuse, 15 were pharmaceuticals. Three sources of these drugs primarily appeared in criminal casework. The first was identified as "doctor shoppers" or patients who successfully scammed prescribers for medications. The second was prescribers themselves who had lost the ability or desire to practice medicine, and consequently decided to merely make a living by writing "scripts." The third source was prescription forgers.

Intermingled among the enforcement and regulatory thrusts to halt drug diversion by unscrupulous patients and prescribers was the increasing concern about pharmaceuticals and pain management. Because many of the drugs of choice being diverted and scammed were opioids, synthetics, and other acute and chronic pain medications, the legitimate medical practice prescribing of these drugs came under the same umbrella of enforcement and regulatory suspicion. Many states enacted multiple copy prescription programs hoping to monitor and control pharmaceutical drug diversion and abuse. In many cases, however, prescribers felt impeded in otherwise legitimate prescribing practices by the increased government oversight. The result was that many patients

who truly needed the opiate-strength medications did not receive them. More professionally palatable and patient-friendly prescription drug law and regulation options, particularly in the emerging medical discipline of pain management, would therefore be required as America entered the next millennium.

THE MISSION OF ENFORCEMENT AND REGULATION

There is a great deal of misinformation and misconception about the intended role of law enforcement and regulation in the prescribing, administering, and dispensing of pharmaceutical drugs. Some of the misunderstanding stems from weak investigative casework that resulted in poor administrative decisions and prosecutions. Horror stories are passed from prescriber to prescriber, and the facts are many times distorted. As a result, newly licensed and authorized prescribers begin their careers suspicious and somewhat paranoid about the role of government in the business of medicine.

The enforcement and regulatory mission is not intended to meddle in the practice of medicine. Overzealous and inexperienced investigators occasionally display an interfering, authoritative attitude that regrettably supports allegations of meddling but they are not encouraged by their employers to do so.

Similarly, enforcement and regulatory authorities have no desire to deny patient care and pain relief. However, initial complaints and information received by the investigators, medical consultants, and prosecutors often raise questions as to the type, quality, and quantity of medication treatment the patient is alleged to be receiving or being denied by the prescriber. This concern of authorities may erroneously translate into interfering with specific drug needs of the patient and prescribing actions of the prescriber.

The interest and obligation of enforcement and regulatory authorities, though, are to prevent the diversion of pharmaceutical drugs from legitimate medical practice to illegal uses. Pharmaceutical controlled substances, particularly pain medications, command a very high value on the "street." While the vast majority of prescribers never intentionally divert drugs to illegitimate use, hosts of interested "patients" and other nonlicentiates actively mingle and network in the pharmaceutical drug environment with the sole goal of separating the drugs from the prescriber and pharmacist.

It is also in the public and consumer safety interests for enforcement and regulatory personnel to ensure the highest medical standards of prescribing. Many states have specific guidelines issued by their licensing boards and bureaus to prescribers detailing the criteria used to evaluate prescribing practices. These standards are used as measures to comply with the state and federal prescribing laws, and they are the same foundation from which administrative disciplinary actions, criminal prosecutions, and civil litigations are launched.

Enforcement and regulatory agencies generally establish priorities for investigative case management. Attention toward prescribers has traditionally focused on the "Four Ds": dishonest, duped, dated, and disabled. Nonlicensed individuals (particularly medical clinic owners/operators) involved in pharmaceutical drug diversion and abuse usually manipulate prescribers to achieve illegal, profit-driven goals, and they may also be involved in prescription forgery, pharmaceutical drug smuggling, and billing fraud.

High on the food chain of enforcement and regulatory personnel is the "dishonest" prescriber. This licentiate may have lost the ability or desire to practice within accepted legitimate medical needs. Commonly driven by a get rich-quick greed, the dishonest prescriber makes a good living merely by "writing script" and sale of their signature. Both the public safety and the integrity of the medical profession demand immediate and intense efforts to stop the activities of the dishonest prescriber.

The "duped" prescriber is really a victim of a drug-seeking patient. In most states, a patient who "scams" a prescriber for a controlled substance has committed a crime. Specifically, the patient withholds material facts from the prescriber, i.e., the patient is receiving controlled substances from other prescribers. This obtaining by fraud and deceit is most pronounced by clever patients who are terrific actors, knowledgeable about prescribing practices and the *Physician's Desk Reference*, and present physical ailments that are difficult to confirm, and strike at the most opportune times and vulnerable targets such as weekend emergency departments (Burke, 2000), clinic lunch hours, and on-call medical group partners.

The third of the "Four Ds" is the dated prescriber. This prescriber has simply not kept abreast of current medical prescribing practices and, consequently, either prescribes incorrectly or refuses to prescribe as necessary or becomes an easy drug source to be duped. Continuing medical education is the key to salvaging this prescriber and maintaining contemporary standards of legitimate medical care.

The "disabled" prescriber is a person who has personal dependency problems that interfere with the professional practice of good healthcare for his or her patients. Drug abuse is one of the most common disabling causes for prescribers. Many regulatory boards and bureaus provide rehabilitation to disabled prescribers through impaired practice programs that limit the prescriber's authority while being paired with another prescriber who has legal oversight and reporting responsibility. Successful completion of the impaired practice program can lead to full restoration of prescribing privileges.

Enforcement and regulatory attention toward pain management prescribers could likely be generated by conduct of any one of the "Four Ds". It should be clear, though, that the dishonest prescriber, particularly in the specialty of pain management, would be a very high casework priority. At the same time, educating the police and the prescriber about legitimate and acceptable standards of prescribing for pain would help to better focus limited healthcare, enforcement, and regulatory resources where they will do the most good for the patient.

OPIA PHOBIA AND MULTIPLE COPY PRESCRIPTION PROGRAMS

While the mission of enforcement and regulatory authorities as previously described seems clear and well intentioned, prescribing paranoia, whether real or perceived, has emerged particularly among pain management prescribers. Described as a "chilling effect" or "opia phobia", a serious, sometimes overly cautious reluctance to treat pain patients with appropriately prescribed controlled substances exists throughout this community of prescribers. Affected prescribers maintain that excess governmental oversight and regulation coupled with multiple copy and electronic prescription systems for pharmaceutical drugs drives their inaction. Dr. Russel Portenoy may have described it best, "Laws and regulations intended to curtail illicit opioid use may be an unintended impediment to legitimate prescribing".

No empirical studies have demonstrated this theory of prescribing paranoia but it clearly ranks as an important element in the discussion of pain management. Possibly the closest measure of this chilling effect was observed when the state of New York placed benzodiazepines into its prescription monitoring system. The prescribing of benzodiazepines dramatically decreased. The disturbing effect of this response was quite possibly the undertreatment of conditions requiring sedative, tranquilizing, and hypnotic medications.

In the specialty of pain management, the relational cause and effect of opia phobia may manifest itself more dramatically and tragically. Dr. Brad Stuart, speaking from a hospice perspective, illustrates one such outcome stating, "Even though we know how to treat pain effectively, many physicians consistently undertreat it for a variety of reasons. No wonder sick people are looking for a way out" (Stuart, 1999). Managing legitimate pain by prescribing controlled substances in legitimate medical practice should be immune to any perception of enforcement and regulatory barriers.

Once again, understanding the problem and educating to the communities of regulators as well as the regulated about the solution are key steps in warming the chilling effect and overcoming an opia phobia. Both communities must communicate internally as well as together to discover the middle ground that will allow each to accomplish the prescriber, the police, and, most importantly, the patient's best interests. Dr. Daniel A. Dotson sums up this needed approach writing, "Exacerbating the fundamental misinformation and peer pressure (about prescribing for pain) is the effect of the regulation by various state and federal agencies which have been historically and, in some cases, still are unable to distinguish between the self-destructive drug-seeking lifestyle of the addict and the productive and responsible life of the legitimate pain patient consuming the same or greater doses of narcotics" (Dotosn, 2000).

Many states are now in the process of modifying or eliminating the real or perceived barriers to legitimate controlled substance prescribing for pain. In California, model legislation exists regarding the treatment of intractable pain, prescribing for the terminally ill, and a bill of rights for pain patients. Nationally, electronic and paper-form multiple copy prescription systems are being reviewed, revised, and in some cases, abandoned. Progress is slowly being made on the monitoring and medical fronts to affect better pain patient care.

LEGITIMATE PRESCRIBING IN GOOD MEDICAL PRACTICE

Through their enforcement and regulatory agencies and in concert with federal prescribing codes a variety of states have published guidelines for prescribers who treat patients for intractable pain. The Medical Board of California guidelines which follow are one example, and they are predicated upon the "position that the public is best served by a healthcare environment where physicians are free to exert their own best medical judgment consistent with accepted community standards of care" (Medical Board of California, 1996):

History/Physical Examination

A thorough medical history and physical examination must be accomplished. Prescribing controlled substances for intractable pain in California also requires evaluation by one or more specialists.

Treatment Plan/Objectives

The treatment plan should state objectives by which treatment success can be evaluated, such as pain relief and/or improved physical and psychosocial function, and indicate if any further diagnostic evaluations or other treatments are planned. Several treatment modalities or a rehabilitation program may be necessary.

Informed Consent

The physician should discuss the risks and benefits of the use of controlled substances with the patient or guardian.

Periodic Review

The physician should periodically review the course of opioid treatment of the patient and any new information about the etiology of the pain. Continuation or modification of opioid therapy depends on the physician's evaluation of progress toward treatment objectives.

Consultation

The physician should be willing to refer the patient as necessary for additional evaluation and treatment to achieve treatment objectives. Physicians should give special attention to those pain patients who are at risk for misusing their medications. The management of pain in patients with a history of substance abuse requires extra care, monitoring, documentation, and consultation with addiction specialists, and may entail the use of agreements between the provider and the patient to specify rules for medication use.

Records

The physician should keep accurate and complete records, including the medical history and physical examination, other evaluations and consultations, treatment plan objectives, informed consent, treatments, medications, agreements with the patient, and periodic reviews.

Compliance with Controlled Substances Laws and Regulations

To prescribe substances, the physician must be appropriately licensed in California and comply with federal and state regulations for issuing controlled substances prescriptions. Documented adherence to these guidelines will substantially establish the physician's responsible treatment of patients with intractable pain and will serve to defend that treatment practice in the face of complaints which may be brought.

The identification and acknowledgment of pain-prescribing issues by enforcement and regulatory agencies have been huge steps forward in improving patient care. Legislation and published prescribing guidelines for prescribing controlled substances to pain patients also have contributed to better understanding the responsibilities and limitations of the prescriber, the patient, and the police. Circling this structure of pain management healthcare and regulation, however, is an evolving body of criminal and civil litigation.

Historically, the concern of most enforcement agencies, regulatory boards, and prescribers has been overprescribing of pain medications to patients. The fear was based upon the addiction of patients and subsequent treatment of addicts that resulted in criminal prosecutions, administrative discipline, and lawsuits. Now the courts and administrative law judges are entertaining actions regarding the undertreatment of pain. In at least one such case, the alleged failure to treat pain has been charged as elder abuse (Lazarus & Stanton, 2000). The outcome of such cases may chart new approaches to pain management prescribing and should, therefore, be closely monitored by pain treatment specialists.

THE FIFTH VITAL SIGN: PRESCRIBING FOR PAIN

The medical discipline of pain management has been maturing for decades. Effective procedures and therapies to treat pain are growing in number every year. Pain is now considered a critical vital sign in the medical workup.

Yet, discussion and dilemma about the correct balance between treatment and regulation exist. Perhaps this needed balance can be achieved in an integrated approach by the prescribers, the police, and the public through education, expertise, and teamwork.

It is imperative that the medical community, the enforcement and regulatory authorities, and the patients have open dialog about their missions, responsibilities, and needs. The myths about prescribing practices held by the police and the myths about enforcement practices held by the prescribers need to be eliminated in order that patients can better understand and reap the benefits of their true treatment options and limitations. At the same time, all parties to the pain treatment issues need to stay informed and educated with contemporary knowledge about available care within regulatory boundaries and community standards. And, when such care and/or conditions become obsolete, the same interested parties should collectively see that they are legally discontinued or changed.

Prescribers as well as government regulators also should be experts in their respective fields. Pain management prescribers should be well versed in available treatments, controlled substances, alternative healing (Shannon, 2000) including nutrition (Fox, 2000), and multidisciplinary approaches to integrated therapies. Enforcement and regulatory personnel should understand the limits of legal and administrative standards, acknowledge and appreciate the complexities of pain management, and exercise their authority in fairness and under the spirit of the law to seek justice.

The shared education and expertise of each interest group (prescribers, police, and public) in a teamwork approach will enhance the likelihood of better communication and cooperation in solving pain management

issues. Achieving necessary compromises in draft legislation and proposed treatment regimens can speed up bureaucratic processes and advance patient care without undue delay. This common interest approach for improved treatment of the patient will also help to discourage the damaging us vs. them philosophy between prescriber and regulator.

As we begin the new millennium, healthcare providers are on the leading edge of patient driven treatment of pain. The patients' voice supported by new legislation is now an integral component of the decision-making treatment process. While the options available are multidisciplinary ranging from traditional medicine to transdermal magnets, one of the most basic courses of care, prescribing strong controlled substances, remains an action fraught with paranoia of government regulatory oversight and penalty coupled with a perceived addiction consequence for the patient. As a result, the patient suffers needlessly; and, studies have shown that pain can kill (Liebeskind, 1991).

Good prescribing is based upon the practice of good medicine. The prescriber who embraces established treatment guidelines during the initial and all subsequent adjustments to prescribing, dispensing, and administering controlled substances to pain patients will unlikely have any problems with enforcement and regulatory authorities. Legitimate medical indication is the guiding principle for the prescriber.

The laws and regulations that exist to curtail dishonest and dangerous prescribing practices of unscrupulous prescribers are not intended to deny the treatment of legitimate pain. They should not impede legitimate prescribing or allow government authorities to meddle in the practice of medicine. The enforcement and regulatory authorities, with support from the medical community, should be used to their full extent to protect the patient and the public healthcare trust.

Ethics of Care: Pain Management and Spirituality

Myrna C. Tashner, Ed.D.

For an effective discussion of the ethics of care and pain management and spirituality, we must reexamine how we view ourselves: body, mind, and spirit.

Since the time of René Descartes, humankind has gradually learned to focus on itself as body (matter) and mind (brain). In general, this is due to a "deal" worked out between Descartes and the Pope. In order to get permission to study the body, Descartes appealed to the Pope for permission to dissect a human corpse. In their agreement, Descartes agreed that he would have nothing to do with the spirit/soul, the mind, or the emotions if he should find them in the body. The soul, mind, and emotions were the exclusive jurisdiction of the church at that time. Descartes claimed the physical body as his realm of study, thus separating the body from the mind. This bargain set the tone and direction of science for the next 200 years. It divided the human into two distinct and separate spheres that could not overlap.

This agreement gave us the Cartesian era with its reductionist methodology, which attempts to understand life by examining the tiniest pieces of it and then extrapolates from those pieces to generalities about the whole.

Human development has been studied formally since the time of St. Augustine, but its beginnings date to the days of Jesus, and even back to the ancients. However, it has only been in the last 100 years or so that psychologists applied scientific methods to the examination of human development. Sigmund Freud was the first. He is credited with the beginning of psychoanalytic theory, a significant study of human development. Later, Jean Piaget contributed theories of cognitive and social development, including environment and relationships studies. But in the last 25 years, according to the American Psychological Association, society's concerns about adolescence, aging, and life span have become the focus of psychology. At the end of the 19th century, psychology was concerned with the study of mind and consciousness through introspection, thus describing experience. Now at the end of the 20th and beginning of the 21st, the focus of psychology has broadened to a science and practice concerned with human behavior, as well as the mental process that underlies experiences and behavior.

Maybe it is time to put us back together; after all, we are body, mind, and spirit/soul, a whole being. This chapter shows that when we manage our pain, and/or heal, we seem to do it as a whole being using our minds, emotions, and spirits within the body physical.

The establishment of the study of ethics may be considered the result of humankind's movement away from and/or forgetting of the natural laws, or the Laws of the Universe with the primary law: We are all one. Ethics is designed to protect and ensure that we do not harm those who choose to place themselves in our care. We must remember to do no harm to ourselves as well. In primitive cultures, moral principles of conduct and proper actions were part of the expected behavior of a member of the tribe. Only in particular situations, when the member chose to invalidate someone else's personal space, or neglected to respect the rights of his or her fellow tribe members, did the chief or medicine person get involved

0-8493-0926-3/02/$0.00+$1.50

to resolve the matter. For example, in the Mayan culture a tribesman would be expelled from the tribe and sent to live alone in the jungle for lying.

In our complex society, made up of members of many different cultures and backgrounds, we have evolved a specific professional discipline called ethics, or laws of professional conduct for our professional disciplines, such as medicine, psychology, ministry, and law. These are standards of expected behaviors to be considered a member of that group, or professional tribe.

The Dalai Lama, (1999) a respected religious leader, has written a book on the subject of ethics for our new millennium in which he describes ethics as a "universal responsibility" the individual needs to be a responsible person. Responsibility is a word derived from "respondere," the Latin word for the ability to answer. It is the ability to answer the urgings of our intuition and our heart, as well as respond with intelligence in the discipline we have chosen to practice. For example, we need to follow our awareness of what is needed to function as a healthy whole person, as well as how to maintain our body–mind–spirit's wellness.

Respect is also paramount. It is so important to respect what our bodies tell us, we need to look again at what our patients/clients are really telling us are their problems, and respect what they say. Although managed care does not like to reimburse for it, nor consider listening a part of care, or consider it appropriate to pay for it, the art of listening and questioning is important before diagnosing and prescribing treatment and medications.

To be a good listener, we need to begin by practicing on ourselves. How often do we listen to ourselves, seriously listen, and then respect what our intuition tells us about our body, mind, and spirit? This is an area of fertile ground for self-study, growth, and development, and possibly for forgiveness of self and/or others. Paying attention and appreciating what we learn about ourselves can only deepen our appreciation for and commitment to ourselves. Experience is a very good teacher.

Compassion is the word used to describe the feeling of empathy (including love, affection, kindness, gentleness, generosity of spirit, and warm-heartedness) toward others, while honoring our limitations to remove their problems or pain from them. Before we can have true compassion for others, we need to be compassionate toward ourselves. To have compassion means to undergo or suffer with a patient or loved one the painful experience in his or her life. Again this study begins with self, being with and going within ourselves, and then learning to live well and in harmony with self. It starts with responsibility for our needs and well-being through respecting what we learn about the self, and living in compassion and harmony with self.

We are involved in and dedicated to the science of medicine and pain management. Currently, it seeks to heal the body without necessarily recognizing the energy of the soul/spirit that lies behind illness and, therefore, cannot heal the body or the soul/spirit. To put it simply, how often do we not pay attention to our inner knowing and excuse it by saying something like, "Oh, well, I just missed it." Then we relieve our guilt and responsibility by telling ourselves that everything will work out okay. And that is true, everything will work out, with or without your cooperation. However, it can be more fun and fulfilling to learn about the beauty of breathing from meditation rather than from emphysema. Medicines aim to relieve the symptoms, but they may or may not heal the body, and medicine probably will not heal the pain of the soul/spirit. I have given up counting the number of patients who have told me, "If only I had stopped smoking or stopped being sexually promiscuous, this would not have happened." The fact is, if we are not responsible, respectful, and compassionate, and if we do not listen to our intuition, eventually we have a good chance of contributing to a body illness.

The science of psychology is in a situation similar to that of the science of medicine. Over time and under the influence of Cartesian philosophy of thought, psychology has come to mean the science of the study of the personality, emotions, and cognitions without recognizing the force and energy of the soul that lie behind the configurations and experiences of the personality. Therefore, psychology cannot heal the soul/spirit either, because the current science is focused on that which is visible to others.

FROM TREATING SYMPTOMS TO TREATING THE WHOLE PERSON FOR WELLNESS

Now we are experiencing a shift in attitude toward the treatment of illness from the Descartes reductionism to holism, considering the body, but also the mind, emotions, soul/spirit. In some medical practices (e.g., Dossey, Chopra, Sheely) healthcare professionals are working with the patient's body and spirit. Dossey's Reinventing Medicine (1999) describes the coming era of medicine as including a focus on and use of spiritual energy for healing intervention in hospitals.

There is scientific evidence to support the importance of emotions in pain management and healing. Research by Candice Pert (1997) on the molecular energy of emotions and how these emotions connect and influence the body is described in Molecules of Emotions. As a graduate student, Pert laid the foundations for the discovery of endorphins, the body's pain suppressors and ecstasy inducers. Her later discovery of the opiate receptors extended to every field of medicine and contributed to the synthesis of behavior, psychology, and biology. She went on to show that neurotransmitters secreted by the brain change physical activity, including behavior, mood, and

emotion. She described stress as information overload, a condition in which the body system is taxed with emotional unprocessed information to the degree that the body shuts down with what we call disease. Stress prevents the molecules of emotion from flowing freely. She discovered for herself the value of meditation practice and the power of visualization.

The scientist and philosopher, Gary Zukav, addressed the issues of the spirit and soul in his book *Seat of the Soul* (1989). He defined the soul as an energy system and described humans as multisensory beings, as opposed to five-sensory beings, capable of perceiving and appreciating beyond the human five-sensory personality. He stated that compassion, clarity, and boundless love are natural to the soul, and life is the opportunity of the soul to learn lessons about the laws of physics and the Universe. Life's experiences are for the purpose of soul growth, power, and energy. The soul has a reverence for all of life. To be reverent is to be spiritual. Reverence creates compassion, kindness, and patience.

In a sense we have come full circle, from the Pope and the Catholic Church maintaining their priority over the whole human, to medicine and science, which were able to study the body, to physicians like Freud and Jung who focus on the "untouchable" psyche or soul, to psychologists taking the soul and studying behavior and personality, to medicine now realizing it needs to consider the person as a whole vs. pieces or parts—body, mind and spirit— in holistic medicine.

RELIGION VS. SPIRITUALITY

For some time religions have focused on the practice of belief and ritual for the purpose of honoring the divine, or God, or Yahweh, or Allah. It can lead to and/or be a spiritual experience, but not necessarily. Religion is a set of doctrines, dogmas, beliefs held by a group of believers who may form a church. That brings to mind the image of people gathering in a building.

Spirituality is not religion. It conjures up a sense of the sacred and the soul. Our patients evolve into exploring what spirituality means for them. Deepak Chopra, M.D., in *How to Know God* (2000) describes spirituality as learning to cooperate with God, learning that there is one reality, the spiritual, that nothing lies outside the mind of God or awareness.

C. Myss, in *Why People Don't Heal and How They Can* (1997), describes spirituality as accepting divine direction, which is an ongoing process of self-discovery. It starts with a quiet, growing dissatisfaction with institutional religion, and an inner sense that there must be more to spirituality, the need to seek it out using meditation and a new path to inner power. It is a journey in self-discovery and an approach to God from a point of view that is not tied to a specific religion, but is more general. Myss suggests that illness possibly may be the means through which God leads us to discover more about ourselves. This could be true of the challenge of disease, or aging. In *Seat of the Soul* (1989), Zukav describes spirituality as the immortal process itself, that pertains to that which is immortal within you, the individual.

I like to think that spirituality gives power back to you as a person and makes you responsible for your life force. Spirituality empowers you as a person. Spirituality places the power where it belongs, in and with you. You are responsible as a person, but by listening to your "inner voice," you can learn much about yourself, your attitudes, and behaviors including your pain. This knowledge can lead to pain management and healing.

This self-awareness reframes you in the world. In the Cartesian concept of you as body, which has many systems that function for living, pain and illness are signs of malfunction in a system of the physical body. But if you consider yourself a spiritual being and the center of the dynamic of living, not your body, then your world looks like this: You are a spiritual being, living in a spiritual world, governed by spiritual laws, having a human experience. The effects and consequences of this change in the order of things are awesome, for each effect follows the Laws of the Universe, which are really simple. For example, as you intend, so it shall be. Or, as you think, so you are.

NATURE OF SPIRITUALITY

Spirituality can be a deep search for the meaning of life. Much of our knowledge of spirituality has come from Eastern traditions (Hindu, Buddhist, etc.), Jesus and Paul, Native Americans, mystics including Ralph Waldo Emerson and Henry David Thoreau, and contemporary ones, such as C. Myss, D. Chopra, N. Walsch, and the Dalai Lama.

Spirituality has an unseen dimension, beyond the five-sense component of energy. Healing of illness and pain has a historical involvement with spirituality. Some suggest that this is what the master teacher Jesus Christ was attuned with his many miracles. Humankind's fascination with this energy was evident in 18th-century Europe in medical societies that were challenged by some of their members to explain the healing process. In 1900 in Vienna the physician Franz Mesmer formulated a theory of healing using the energy of magnets and gravity. His ideas took hold in the United States, and influenced, among others, a New England watchmaker P.P. Quimby. Through his study of mesmerism Quimby produced changes in the mind by use of the mind. Quimby renamed the work "hypnosis," but later came to believe that a Higher Intelligence can work through us to correct thought errors that cooperated to create illness. Belief patterns of patients had to change. Quimby said he thought that was how Jesus

Christ healed and he proceeded to heal using this principle. Quimby attracted students and followers, including Mary Baker Eddy, who experienced her healing through his work, and who later founded Christian Science. She believed that prayer and the power of the mind could bring about healing. It is interesting to note that some insurance companies pay for the services of Christian Science practitioners.

Eddy's student and fellow mystic, Emma Curtis Hopkins, founded the Metaphysical School in Chicago. A New York physician, Dr. H. Emily Cady, and Charles and Myrtle Fillmore, co-founders of Unity School of Christianity, studied in Hopkins' school. Dr. Cady wrote a classic work for Unity School on the power of the mind entitled *Lessons in Truth* (1892), in which she detailed her understanding of the teachings of the master Jesus as practical and applicable for healing, as well as pain management. She explained a relationship with the Almighty One that was personal, practical, and the essential responsibility of the individual. She emphasized discipline of the mind and responsible management of thought. Remembered from these 19th-century metaphysicians are sayings based on the Law of Mind Action theme, i.e., change your thinking and change your life; or, thoughts held in mind produce after their kind.

SPIRITUALITY AND PAIN MANAGEMENT

When we talk about spirituality, pain management, and the power of the mind to heal, we are talking about concepts that have a historic base in our culture. Keep in mind that when we talk about spirituality and pain management, we are not necessarily talking about healing of the physical body, although that is what people in pain want.

Pain is a word that describes the experience of physical pain caused by cancer, surgery, burn; emotional/mental pain that can be situational or chronic; or spiritual pain as in a dark night of the soul or loss of the sense of self. We learn and grow, because pain can be a teacher. It can set up an addiction, not only to medications but also to the experience of pain for the benefits it can give us.

In the following true illustrations, we discuss four pain-filled experiences and the use of the mind and the inner spiritual power to manage the physical pain.

The author's experience with this concept was as a graduate student. I was working three part-time jobs to meet expenses. I also was studying for my licensing boards and doing my dissertation research. I also was very conscious of what I ate as I was just beginning my study of yoga, and learning to breathe correctly and to relax my body. One day I noticed small blisters on my right forearm, but I thought nothing of them and continued my schedule. I don't remember exactly how long it took, but within a few days, I was aware of a lot of pain in that arm which now had many more blisters. To make a long story short, I went to my physician who diagnosed shingles and prescribed medication for pain.

Of course, the prescribed medication was strong, and I experienced side effects. The pain didn't go away, but got worse. I had a choice: go into the hospital for a morphine drip, or just live with the side effects of the prescription drugs.

Instead, I chose to take aspirin and practice the relaxation technique I had learned in yoga. And I had the bright idea to add the image of white light flowing into my body going to the site of each hurting nerve ending and surrounding it, relieving it of the inflammation. I asked that it relieve me of the pain.

I knew about breathing and relaxation from yoga. My doctor had told me aspirin was the strongest non-prescription painkiller. But the image was something that came from within me. I quickly became aware that when I was in the relaxed state with that image, I was pain free. It was natural to be grateful and I giggled with delight.

The following story was told to the author by a Native American friend.

In the late 1960s, I developed severe pain in my left hand. The fingers were swollen with red speckles. I thought I had been bitten by something. Within days the pain and swelling had gone to my left knee, and my ankle and foot were painful and swollen. After 2 weeks of aspirin and Tylenol, ice and heat, I saw my family doctor. He examined me and ordered blood tests. Several days later I received his diagnosis: rheumatoid arthritis. He told me to expect continued pain and deterioration to the level of being wheelchair bound. I was devastated. I had three small children, a husband, a life. I couldn't be a cripple.

I called my mother in tears. She listened and told me she would study and pray about it. My mother was Native American, of the Choctaw nation. She was raised with both white and Native traditions. My grandfather was English. My sisters and I were raised with a mixture of both cultures. I refer to my mother as Native American, but never referred to myself as such. My father was very white Irish.

The pain continued. I called my mother again. She said she was praying. Nothing happened.

Several days later I went to my mother's house. My dad was out back in his garden. Mother met me at the door. She said she was expecting me. I limped

inside. She placed a kitchen chair in the middle of the room, pointed and said, "Sit." I sat.

Mother began by placing her hands on my shoulders, then my head. She began speaking with gut spouch. After a few minutes she began doing a slow native two-step dance around my chair. I had seen the dance many times in my lifetime and I accepted it as "right." I began to relax. My mother's tempo increased. Then she began speaking in another language. Her voice rose and fell. Her feet beat a tempo, and I felt my whole being slip into her chant; although I didn't understand the words, the tempo of her feet beat a chant into my heart. Time passed, maybe hours, I don't know. She finished by placing her hands to my head and shoulders and ordering the spirit of illness to leave my body, never to return. Was the pain gone at that time? No. But the next morning I awoke to less discomfort. By noon I could open and close my left hand. Within 3 days I was working—pain free. The medical community may say I went into spontaneous remission. I say I was healed.

Some 30 years later, I fell up the stairs at work. (Most people fall downstairs; I took a different route.) I hit my right knee on the stair's edge. That evening, it was very sore. Two days later I rose from the dining table but couldn't walk. The pain increased to the point that I couldn't ambulate without excruciating pain. Tears came to my eyes as I started up the stairs. I tried to ignore the pain and the symptoms. I tried to ignore the swelling. Finally, my uneven gait was noticed by my co-workers. I was sent to the doctor. He took X-rays. "Lucky," he said, "nothing is broken. All you have," he told me, "is degenerative arthritis. Bone on bone. It can only get worse."

I just looked at him, "How can that be, there wasn't any pain before I fell."

He offered pain medications and an anti-inflammatory, and told me to go home and live with it. "At your age you can only expect these problems to occur," he said.

And that's what pissed me off. I refused the steroids but took over-the-counter medications. Days, weeks passed, the pain continued. Finally, one day when I was alone, I screamed out to my mother, who had been gone for 10 years, "Why did you leave me! I need you!" I needed her to heal me. I want her to heal my pain. Couldn't she hear me crying? Couldn't she hear my heart begging for relief?

Nothing happened. Silence.

I wanted to feel her presence. I wanted to feel her touch. I asked the Great Spirit to help.

Once again silence. Or perhaps I just didn't hear.

We constantly hear that we make our own reality, so I started to try to direct healing toward myself. I asked others to pray. Nothing seemed to change.

And then one night I dreamed. I saw my mother as a young woman of 17 dancing in a field of wildflowers, laughing in a carefree manner. I tried to run to her, to stop her, just so she could touch me, and I touch her. I knew that if I could touch her I would be healed. She kept dancing just out of my reach.

When I woke up, I woke up to pain. Days passed. I constantly asked and prayed for help. I asked for the Great Spirit to intervene. And I asked that if my mother had any influence on her current plane of existence, to please help me. I dreamed of my mother again. As previously, she was just beyond my touch.

The next day while driving down the highway, I had to stop quickly, and tromped with my right leg on the brake. The pain ripped from my knee to my right hip. I had to pull over to the side of the road. I sat there for a few minutes. I said, "Great Spirit, Mother, help me!" In my head, or out of the air, I heard, "You don't need me. I taught you what you need to know".

The truths she had taught me began to enter my awareness: "No one can teach you the ways of the spirits/God. These things are only learned in your own silence. Look to your own spirituality." This is not what I wanted to hear. I wanted my mother to give me the magic formula that she had used 30 years ago. "What is my spirituality?" I asked.

Spirituality is a way of looking at and understanding this earth and yourself, a way of knowing what it is all about.

"I'm not looking for spirituality, Mother", I hollered out. "I'm looking for healing". Mother had always taught us that the spirit is everywhere: in the water, rocks, trees, birds. "How is this supposed to help now? I'm in a car. I can't go out into the woods, the forest". I sat there fighting with her voice in my head, because that's where it was. I finally was able to drive home.

I'm a nurse. But you cannot learn to work with Indian spirituality by going to medical school. An old holy person, a medicine person can teach you about herbs, and that everything must be in its proper place. They can teach you about using smoke, sweet grass, sage, and cedar for cleansing the environment and the air. They can teach you all of these things, but if the human spirit is not ready, the soul will not accept the teachings.

The native peoples believe that we were put on this earth with animals, plants, trees, and water. (I was taught this as a child, but I forgot this as an adult.) Native peoples believe that power comes from these things. Indian healers receive the power from spirit. Spirit is everywhere. You hear of animal helpers, but they don't give power; they are messengers that bring instructions from the spirit.

I continued to fight what Mother had said. How could my mother speak to me, a grown woman in a car going down the highway? And why did I keep calling to her? Because, deep in my heart, I knew that the spirituality my mother had taught me was still there.

After several days of fussing in my mind with how and why this was happening to me, I realized that I had to take control. I could almost sense my mother smirking in the corner: "So, finally you are going to do something about this. You have the qualities and abilities. You can heal yourself."

How could I take control? My body was controlling my every move, because of the pain. How could I take control? I couldn't even lean over to pick up a rock, smell the flowers. I could just see her saying, "You'll do it. You'll figure it out."

So I did. I began by taking an inventory of my being. I realized that I was overweight. My eating habits left a lot to be desired, and I always felt that exercise was self-abuse. So what could I do?

Once again I asked Great Spirit to help me. I realized that the task before me was more than I could handle alone. How could I change what had occurred over decades of life?

Then I had another dream. Mother always taught me that dreams are powerful things, almost like visions. In the dream I saw myself as I had seen my mother in a previous dream: not in a field of wildflowers, but as a young Indian girl running through the wooded hills of my childhood, barefoot, with the hair streaming down my back. In the dream the young girl turned and smiled at me, and I knew she was myself. What struck me most about my younger self was my smile and pain-free demeanor.

That weekend a dear friend came to visit. We stood back by the pond. I began telling her about the pain in my leg and my inability to walk and function. I told her about how I had been this way before, and how my mother had danced around my chair when I had received my healing 30 years earlier. Her face was puzzled, "How did she dance? Show me."

I began to do the two-step, slowly, as mother had done those years ago. I danced as she had danced the two-step to the spirit for my healing. My feet slipped naturally into the rhythm, my knees bent without pain, and I began the dance in the spirit of thanksgiving. My healing had begun. We went into the house and announced that I was able to dance without pain. I now knew without reservation that I was in charge of my healing.

My healing was and is spiritual. One must be ready to be healed. If our spirit is not ready, we will continue to live the role of sickness and pain. Sickness may be comforting to some. Many find their needs fulfilled in this way. I chose not to be sick or in pain. My spirit was willing to accept the healing. My spirit recognized that the time was right in a few traditional ritual dance steps. I know with the help of the Great Spirit, the loss of well over 50 pounds, the dietary changes to feed my soul, not just to satisfy my body, daily thanks to the Creator, and occasional thanks to my mother, I am now able to live as the spiritual being my mother taught and raised me to be with a much thinner body and lighter soul.

Bill's story.

"It happened so fast! Fire exploded out of the carburetor! My hands, head, chest, arms, my whole upper body was torched (50% of his body had third-degree burns) in the direct line of the flames, and I couldn't help but inhale the flames."

This began a life experience for Bill. Jeanne, his wife, was a nurse and rushed to his side with blankets to smother the flames that were frying her love. (She received second-degree burns on her hands and arms. Her hair was burned on the front of her head.)

The ambulance arrived and Bill was care-flown to the closest burn center, a 3-hour trip. The inhalation of the fire caused his throat to close, so he required intubation to survive the flight. Jeanne did not fly, but her nursing supervisor gave her a blanket and told her to go with Bill in the air ambulance, and sent her off to the plane.

Burns have to be the most painful experience, and third-degree burn, which is what Bill had experienced, the worst. If you have had the experience of burning your finger on a hot pan, you may remember what that feels like. Now multiply that feeling exponentially and begin to get a sense of what Bill was feeling. Two sets of skin grafts failed, due to infections and complications, and medical staff was concerned if the third graft would take.

Jeanne stayed by Bill's side. She is a woman of prayer and faith. Weeks passed, and with two failed skin grafts and concern that the third might not take, she prayed. That night when she had just gone to bed, she began to pray, "Oh God, I can't do this, I can't lose him, I can't face this. It is in your hands. I give up control." Almost immediately, the darkened room lit up with a bright blue light. The wall to her left opened up, and she could see into the burn unit. Bill was sitting in a recliner chair swathed in bandages: his arms, his chest, and his face. She saw a hand up to an elbow with thumb and index finger extended. The forefinger touched the fingers on Bill's right hand. Jeanne became frightened by what she saw. She

thought, "I can't be seeing this, I must be crazy, I must be having a dream, I can't be seeing this," and the vision faded. Jeanne fell into a deep sleep that night. Prior to the vision she had slept very poorly since the day of the accident.

The next morning Jeanne was at the burn center as early as they allowed visitors. As she walked through the door, Bill was sitting in the recliner as in her vision, swathed in bandages, but the tips of his right hand were pink, whereas the day before they were black. She told him of her vision. Bill looked at her and said he had had a dream, her vision. Did they share a vision, a dream? They didn't question it. Jeanne took Bill home 2 weeks later.

"Does he have scarring? Yes. Does he have residuals? Yes. Daily he lives with the scarring, the external perceptions. Do we see the scars? No. What we see is a whole person, able to function with all the human deformities, at a high level."

From that day forward, Bill felt he was healed. He even told his nurses he was going to get well. Bill had accepted his healing and his healing process had begun.

When I asked Bill what he did to cooperate with the healing, all he would answer was, "I don't know."

What Jeanne tells is that the nurses in the burn unit told him to breathe deeply like a woman in childbirth. Breathe deeply, relax, and don't focus on the pain. He went into an altered state of consciousness. Bill did say that he had to go within and not focus on anything. In his words, he had to "clean his mind." A psychologist would say that he disassociated and detached from the pain. Jeanne said that when she changed the bandages at home, she, too, would go into an altered state, and disassociate from her perception of pain.

After the experience with the bright blue light, Bill was able to function on less medication than expected. When Bill was released from the hospital, he went home on ibuprofen. To this day, he only takes ibuprofen for pain.

"We always thought there was a greater power; now we know", were the couple's final words on the experience.

Randy's story.

Randy was born with a deformity, mild spinal bifida. He had lived with it all of his life. But with age the deformity grew more pronounced and visible. For example, you could tell if Randy was tired or had a bad day, because he would walk through the hospital corridors leaning to the right, and that leaning became more pronounced with time. It also became more painful, to the degree that he needed a cane and couldn't climb stairs.

Surgery was his only alternative. In that surgery, they would fuse three vertebrae in his spine, making a paste of bone graft from his hip.

Randy was the head chaplain at the hospital, and always was there for anyone in need of prayer support. In his time of need and in preparation for his surgery, he asked the persons of prayer he trusted to pray with him for a successful outcome. In addition to Christians, his prayer team included those of Native American belief and Jewish, Buddhist, and Muslim traditions. This was his prayer team, and he related that he went into his surgery without fear. Even though this was a delicate surgery requiring the most skilled of surgeons, he had no fear.

Randy was no stranger to surgery. Previous post-surgical experiences of migraine and nausea could have presented a fear factor. He awoke out of the anesthesia with only a flash of nausea, which immediately dissipated.

Randy's wife, Joan, and one of his chaplain staff were waiting in his room as he was wheeled from recovery. He reported that he was so pain free and so hyped that he was unable to sleep until well past midnight. Nurses became concerned as he laid awake channel surfing and watching TV.

Surgery was on Tuesday. Wednesday morning Randy was standing, and that afternoon he walked with assistance. It did hurt and he did feel it, but there was no pain. He took an occasional pain shot the first couple of days.

Joan took Randy home on Saturday, and he walked up the stairs to the bedroom. He walked down those stairs Sunday and back up. He took hydrocodine every few hours for the first 10 days, as a prophylactic measure. But he just never had pain.

It was all pretty amazing. And Randy learned about the power of prayer over pain.

These four stories have four things in common. First, a power of the mind and heart existed to co-create the healing process. Second, each individual had medical involvement in his or her process. Third, each didn't hesitate to ask others to pray with and for his or her healing and highest good. These were persons who they knew could be objective and hold for the highest good without attachment to the outcome. And fourth, each was actively involved in his or her process. And unspoken, all learned to love themselves, forgive themselves for their parts in the health challenge (illness), accept that healing is possible, and trust the Universe for their learning and highest good.

What do these stories tell us as healthcare professionals committed to the healing arts and process? At some point, each patient makes a decision, consciously or unconsciously, what his or her healing process will be. As in the stories above, at some point the patients decided at the deep soul level that they wanted to experience healing. Each stated with feeling, he or she desired physical healing, and as that experience evolved, each healing meant alignment with the inner spirit. It was not instantaneous, although it could have been. Rather it was across time, possibly for the purpose of learning more about soul, spirit, and inner strength and power. Note, too, that the "illness-challenged" ones asked friends for prayer support. They chose persons who would be detached emotionally, and would hold for the highest good of the Universal plan.

While friends held for the highest good, the challenged person worked at what was his or her task for the healing. This included not only taking prescribed medications, but also practicing relaxation, losing weight, changing diet, using images to cooperate and facilitate with the process.

Also note that healing had to be accepted before it could occur. This brings up an interesting point: the challenged ones at some level came to terms, consciously or unconsciously, with what their contributions to the creation of the challenge was. They accepted responsibility and in that acceptance were able to take the next action step.

This brings us to the discussion of forgiveness. The author recalls asking the physician who diagnosed the shingles how this could have happened, as she was leading a wholesome lifestyle with good nutrition, exercise, etc. She had to come to terms with and forgive herself for not honoring the body's limitations before the pain could be managed. Until she could forgive herself for failing to recognize the body's needs and limitations, it would continue to give signals in the form of pain. Carolyn Myss' 1997 book on the power of forgiveness to heal indicates that forgiveness is the key to healing. Candice Pert's (1997) research suggests that the act and feeling of forgiveness send peptides along the neurotransmitters to the hurt part of the body, which helps create the healing. Forgiveness is a powerful energy experience, an act of self-love and self-responsibility with tremendous healing power.

WHAT IS THE HEALTHCARE PROFESSIONAL'S POSITION IN THIS PROCESS?

If we have done our own personal listening and learning, we will see more of these healing experiences in our practices. Awareness of our process helps us be more gentle and quiet, as well as better able to listen and hear what our patients are telling us. In the best way they can, patients tell us what they want for healing. Professionals who have had their own challenges may know what is being said. Not that I advocate experiencing pain, but the experience of pain is a powerful teaching experience, emotionally, mentally, spiritually, and physically. The experience of pain makes us conscious of how powerful the body/mind/spirit is when it is in pain. It signals us to wake up and pay attention. And with help, it makes us grow. It teaches us how important our healthcare skill is in pain management. But it also teaches us that what is done on the outside to us is not the whole story in pain management. An inner quality to pain management exists that is the responsibility of patients, and they hold the key to the effectiveness of pain management and healing in whatever form it takes. We are to perform our skill, then step back, be aware, and listen, refraining from other than supportive comments. It is well documented that patients give power to the words we say about their process, which can be more potent than the medicines dispensed, or adjustments and manipulations made. To illustrate, while writing this chapter, my friend Joan telephoned. She had asked me to pray with her during a foot surgery. It was not an unusual surgery, but she knew the power of prayer. On the day she phoned, it was 3 months post-surgery and I inquired as to how she was doing. She replied that she had been to the doctor for a check-up and he had commented that her foot was healing nicely. He told her that she was actually 3 weeks ahead of schedule, and he was surprised. She chuckled as she responded, "I'm not."

Pain management and healing are new as we noted at the beginning of the chapter. Descartes began the scientific study of the body, which paved the way for learning how the body physical works. Pert provided us with the molecular level of understanding energy in the body. From the spiritual perspective, Jesus and the ancients were able to do healings, and with the help of Mesmer and the metaphysicians we learned the power of words and prayer for healing. These insights help us humbly acknowledge our limitations as healthcare professionals, encourage our respect, and recognize our patients and their power, immanent and transcendent, for pain management and healing. It reminds us that the management of pain is a cooperative process between patient and all levels of caregiving. Each of us is reminded that we are powerful beings, not by might or muscle, but by the power of our word and thought. Forgiveness is a powerful tool of pain management, as are healing and love. Forgiveness creates wholeness, and nonforgiveness keeps us separated. When something is separated or broken from the whole, there is pain. Forgiveness brings healing because there is wholeness and oneness again.

Finally, pain is the tool for teaching each of us to function as a whole person, and eventually a whole people — body, mind, and spirit. In the process we learn about and discover our whole selves. We learn the power

of our thoughts and words to shape our life experiences. This is the ethics of care.

Documenting Pain

Barbara L. Kornblau, J.D., O.T.R./L., F.A.O.T.A., D.A.A.P.M.
and Lori T. Andersen, Ed.D., O.T.R./L.

INTRODUCTION

Documenting pain presents unique challenges for pain practitioners. Because one cannot actually see pain as one can see a broken leg or a rib on X-ray, for example, documentation of the signs and symptoms plays a critical role in effective treatments.

Many stereotypes about individuals suffering from pain exist in the world of payers, insurance adjusters, defense attorneys, workers' compensation administrators, family members, and others. For example, often, when the patient in pain enters the world of litigation, the individual faces a world of nonbelievers. Pain patients often are dismissed as having psychiatric problems rather than physical problems. For example, some still argue that conditions such as fibromyalgia are not physical syndromes at all. Sometimes patients face accusations of malingering by nonbelievers rather than the reality of suffering from pain syndromes.

Some think an absence of objective evidence makes it impossible to diagnose pain. Others claim medical and rehabilitation providers cannot measure pain to prove its existence. The mistaken belief that patients with chronic pain cannot progress gives payers an excuse to deny reimbursement to therapists. Further, some payers accept the erroneous notion that occupational and physical therapy intervention with patients suffering from chronic pain falls short of the necessary skilled care required for reimbursement.

In addition to these stressors faced by the pain practitioner, in the 21st century, pain practitioners face increasing threats of malpractice, and managed care. Case managers and panel membership often limit access to pain practitioners. Obtaining payment from insurance companies seems to take more work and for less money. Workers' compensation seems to constantly reduce services it will cover and the amount it will pay for those services. Payers want second opinions and pain practitioners face more and more regulations from numerous government programs.

Though documentation presents challenges to pain practitioners, it also records our successes and presents them to the world. If done carefully, it helps grease the reimbursement wheel. The medical record almost always constitutes the only evidence payers, case managers, and others see to justify pain management treatment and payment.

On the other hand, the pain practitioner's documentation also can tout failures and/or lend credence to the failures of others. For example, when something goes wrong with a patient, the medical record serves as the key evidence the jury or judge sees to prove that the clinician met the standard of care.

Accurate documentation of pain in medical records can make a significant difference in the lives of patients. Often the contents of the medical record play a significant role in determining whether or not a pain patient receives workers' compensation, social security disability, or other important benefits (Smollen v. Chater, 1996).

One can define medical record documentation as a serial and legal record of the patient's condition and the course of the medical or therapeutic intervention from admission to discharge (Aquaviva, 1998). This record describes how the patient functioned and the behaviors the patient displayed at the time of initial evaluation, during the course of treatment, and at discharge. Essentially,

0-8493-0926-3/02/$0.00+$1.50

the medical record should "tell the story" or "paint a picture" of the patient and the medical care provided.

REASONS FOR DOCUMENTATION

Documentation serves several purposes. First and foremost, accrediting bodies require it (Joint Commission on Accreditation of Healthcare Organizations, 2001a). To maintain accreditation status, hospitals, rehabilitation programs, outpatient programs, and others must maintain documentation according to the requirements of their accrediting bodies so they can maintain accreditation status. Accreditation is often required to qualify for reimbursement. Self-audits are performed as required by accreditation standards between surveys performed by the accreditation bodies themselves.

Documentation in the medical record provides a communication method for the members of the healthcare team. Healthcare clinicians may find themselves with little-to-no face-to-face contact. Other means of communication, such as telephone contact, provide difficult because of diverse schedules and the varied places where patients receive care. All healthcare clinicians have access to and should access the medical record. This access enables clinicians to read the documentation of other team members and thus keep apprised of the course of treatment, patient status, and progress from other viewpoints. This helps team members make appropriate decisions about patient course of treatment and facilitates coordination of patient care.

Looking ahead, documentation provides data for treatment innovations, research, and education. For example, a new type of pain treatment is administered to alleviate patients' pain. Documentation of the type of treatment rendered, the amount of treatment, the timing of treatment, and patient status and behaviors after treatment will demonstrate the efficacy and effectiveness of treatment. Data collected from all of those treated will provide researchers with outcomes data that clinicians also can use to justify the treatment to payers.

Outcomes data collected from documentation can be used for promoting or marketing one's program. For example, if an outpatient pain program has designed a specific program for returning injured workers to the workplace and the program succeeds in helping these injured workers return to work, the data available from the documentation will demonstrate the efficacy and effectiveness of the program. These data can be used to promote the program to case managers and others.

Documentation can be used for quality assurance and continuous quality improvement efforts to determine the effectiveness of specific treatment interventions or programs. The Joint Commission on Accreditation of Hospital Organizations (JCAHO), the Commission on Accreditation of Rehabilitation Facilities (CARF), and various other organizations all require monitoring of documentation to determine continuity of care and quality of services (Joint Commission on Accreditation of Healthcare Organizations, 2001a).

Documentation prevents clinicians and facilities from unsubstantiated claims of wrongdoing—in other words, "CYA." For this reason, hospitals usually include requirements for documentation in their policies and procedures. Physicians who fail to follow a hospital's documentation policy can lose their hospital privileges (Board of Trustees of Memorial Hospital of Sheridan County v. Pratt, 1953). Accurate documentation can protect clinicians from erroneous charges of malpractice, or criminal charges of improper use of narcotics. Proper documentation can protect clinicians from civil and criminal penalties resulting from charges of Medicare and Medicaid fraud and abuse or other civil or criminal charges (McKessy, 1998).

Fiscal reviewers, auditors, intermediaries, and payers often review documentation to determine if services billed were, in fact, provided. These reviewers and auditors may also review documentation to determine if services were medically necessary. The Medicare program requires that services must be reasonable and medically necessary in order for coverage and reimbursement for the care of the patient under the Medicare Guidelines. As the saying goes, "In God We Trust, All Others Must Document."

Private insurance companies have similar requirements. Triggers that may start an audit or claims denial include overprescription of controlled substances; providing the wrong medication; providing treatment without pre-authorization, referral, or prescription; absence of a treatment plan; lack of patient compliance; using too many modalities; and continuing treatment without improvement or results. Proper and complete documentation can protect the practitioner from potential problems.

Finally, most licensure laws require that healthcare professionals keep written medical records justifying the course of treatment. Failure to do so can result in disciplinary action against the licensee. (See Table 78.1.)

TABLE 78.1
Reasons for Documentation

1. To comply with accreditation requirements.
2. To communicate with other members of the healthcare team.
3. To provide data for treatment innovations, research, and education.
4. To collect outcomes data to market programs.
5. To provide data for quality assurance, continuous quality improvement and/or total quality management, peer review, and continued competency.
6. To prevent unsubstantiated claims of wrongdoing (CYA).
7. Payers review documentation to ensure treatment was performed as billed and medically necessary.
8. Most licensure laws require documentation.

MEDICAL RECORD AS A LEGAL DOCUMENT

The medical record serves as a legal document. State and federal laws and regulations establish minimum standards for record keeping. These record-keeping standards serve as prerequisites to state licensure, receipt of federal funding, and participation in federal programs such as Medicare. As a legal document, medical records document the nature of the care provided, including the quantity and quality of care, and protocols used for treatment. The medical record also documents the charges for the care given. Above all, the medical record carries the signature of the clinician.

State and federal laws prescribe the contents of the medical records, and the ownership, access, and confidentiality requirements of medical records. Various laws also control how long clinicians must keep medical records following discharge. The length of time often is based upon the statute of limitations for various administrative, civil, and criminal laws. For example, participation in Medicare requires providers to keep medical records for a length of time to enable the government to conduct investigations for fraud and other matters.

Medical records that play a role as a "legal document" often come under scrutiny in administrative, civil, and criminal actions. For example, attorneys involved in administrative and civil cases such as divorce/custody, insurance fraud, medical malpractice, personal injury, workers' compensation, disability benefits, and licensure board discipline may subpoena medical records to present as evidence.

As a recognized legal document, pain practitioners should never destroy or alter records after the fact to conceal a mistake or error. Chances overwhelmingly point to the reality that someone already has a copy of the original records as they appeared before the clinician altered them. Further, these types of alterations are illegal and subject clinicians to disciplinary action and, in some cases, criminal action. We call this conduct "spoliation."

Black's Law Dictionarydefines spoliation as "(t)he destruction of evidence" or "the destruction of, or the significant and meaningful alteration of a document or instrument" (Nolan, 1979). In Bondu v. Gurvich, the Florida Court of Appeals allowed a family member to proceed with an independent action for spoliation when the hospital was unable to produce the medical records needed as proof in a malpractice action. The patient died during the administration of anesthesia in a triple by-pass operation. Without the medical records as evidence, the malpractice action could not proceed (Bondu v. Gurvich, 1995). In another case involving spoliation, State Board of Medical Examiners v. McCroskey, the Court found that changing and backdating a note about a patient who bled to death cast doubt on the integrity of the medical record, violated the standard of care, and correctly subjected the physician to disciplinary action (State Board of Medical Examiners v. McCroskey, 1994).

In some jurisdictions, the jury can assume that missing evidence, if produced, would have been unfavorable to the spoiler. Other jurisdictions simply will exclude altered evidence while some courts will impose sanctions against the spoiler. Spoilers can also face criminal charges or dismissal of their case (Seigfreid, undated).

In addition to spoliation, clinicians must also watch out for falsification of documents. As a legal document, clinicians must never falsify anything in the medical record or face civil as well as criminal charges lest they do. In People vs. Smithtown General Hospital, a surgeon and a nurse falsified the medical record by omitting any reference to a prosthetic device salesman who assisted with hip replacement surgery. The surgeon and supervising nurse were criminally indicted for falsifying business records in the first degree, which was upheld by the court when the defended appealed to have the indictments dismissed (People v. Smithtown General Hospital, 1978).

CHARACTERISTICS OF GOOD DOCUMENTATION

Documentation must be clear, concise, objective, logically organized, legible, and contemporaneous. To communicate effectively, the documentation must be clear. To be clear, the healthcare professional must use terminology common to the people who will read the documentation. Know thy audience. Clinicians must assume someone else will read their records.

The pain practitioner's documentation often finds its way before the eyes of adjusters, attorneys, jurors, or others with little to no working knowledge of pain jargon. Medical records with pain jargon or other medical jargon lack clarity for a lay audience and lose much in translation. Clear, jargon-free, understandable documents can save clinicians a trip to court. In some jurisdictions, attorneys can subpoena medical records alone. If the attorney can understand the records, it ends there. If the records are not clear, the attorney may send a subpoena duces tecum, which requires the clinician to bring the documents to a deposition to read and explain them.

The use of abbreviations also renders medical records unclear. Facilities and agencies often develop an approved list of abbreviations for use in medical records. It is important that healthcare practitioners use the appropriate terminology or abbreviations, otherwise it will be like reading a foreign language for another healthcare practitioner. Even worse, miscommunication can occur with devastating results. The story of a physician who ordered ear drops for a patient is an example of miscommunication. The physician wrote in the medical record that the medication was to be administered t.i.d. in the patient's ear. As there

was no circle around the R, the recognized abbreviation for "right," the medication was administered elsewhere—not in the "ear".

Concise documentation presents the most important information about the patient without unnecessary distractors. It is much easier for one to read a concise record that gets to the point, as opposed to a lengthy note that one has to search for the relevant information. Most importantly, payers do not want to search for the information they need for payment. Those records will likely end up at the bottom of the payment pile in favor of another practitioner's concise records.

Avoid extraneous notes in the medical record that can confuse the reader or add unintended information. A notation in a chart referring to what another clinician reported with a handwritten "B.S." in the margin proved rather embarrassing for the clinician who, during her deposition was asked to explain the abbreviation.

Pain practitioners must use objective terms in their documentation. Pain behaviors and status should be described using measurable terms. Phrases such as "tolerated treatment well" or "patient doing well" provide no objective data. Payers and others in the medical record audience concern themselves with objective, functional changes the patient makes in response to treatment intervention. Clinicians should quantify pain measures and record objective changes in pain. Clinicians should describe the principles and methodologies used to reach their conclusions (Daubert v. Merrell Dow Pharmaceuticals, 1993). Objective records omit any pejorative comments about patients.

Clinicians must organize their records in a logical manner. No one wants to hunt through documentation to find specific information. Further, the time delay during the hunt may cause the patient harm. Categorizing information into sections and subsections easily identified by headings will assist readers in finding the information they seek. Clinicians should present data in an organized manner. In all cases, documentation should include a date and time of entry.

Clinicians should record their documentation contemporaneously and in a timely manner. Some clinicians find personal digital assistants (PDA) such as palm pilots helpful to write their documentation contemporaneously, while they examine their patients. By documenting when an event occurs, the clinician ensures a more accurate picture of what occurred. The more removed in time one writes the medical documentation, the more the medical record begins to look like a work of fiction. Furthermore, a late entry in the medical record attracts suspicion.

Finally, the documentation must be legible. Information written illegibly is considered to be undocumented or not written: "If I can't read it, you didn't write it." Illegible documentation will find its way to the bottom of the payer's payment pile in favor of easy-to-read documentation: "If I can't read it, I am not going to pay you." Like late entries, illegible documentation attracts suspicion: "What are they trying to hide?"

Illegible documentation does not provide protection (or CYA value) should the clinician face charges of malpractice, fraud, or disciplinary action. In fact, illegible documentation can lead to serious harm to the patient, and charges of malpractice, if other members of the healthcare team cannot read information. The classic problem arises when the pharmacist is unable to read the physician's illegible handwriting. In Texas, this problem led a jury to award almost a half million dollars to the family of a man who received the drug Plendil, used to treat high blood pressure, instead of the drug written on the prescription, Isordil, used to treat severe chest pain or angina (WebMD National News Center, 1999).

While the damage caused by illegible or sloppy documentation may not always lead to death of a patient, it can seriously damage one's reputation. Sloppy documentation can lead a jury, case manager, or insurance adjuster to believe the patient received sloppy care from the pain practitioner, which may lead to problems in the legal arena or a decrease in one's referral base.

The rules of documentation recognize that clinicians sometimes do make legitimate errors in writing their documentation. When clinicians make errors, they should draw a single line through the error, and write their initials and the date beside the error. Alternatively, clinicians may append the record with an explanation of the error. Erasures and correction fluid play no role in the medical record. Should clinicians not correct their errors, they live by the adage, "If it's in the chart, you did it."

TYPE AND FREQUENCY OF DOCUMENTATION

The type and frequency of documentation vary from facility to facility and are also affected by regulatory agencies such as JCAHO and CARF, state laws and regulations, and third-party payers. Agencies and facilities often have a procedure by which documentation forms are reviewed for possible inclusion in the medical record.

Clinicians perform the patient's initial evaluation upon the patient's admission to a service. Information documented in initial evaluations should include at a minimum medical history, current medications, allergies, drug sensitivities, presenting complaint, and assessment information. Initial evaluations may be written in longhand using a specific format, in a checklist format, dictated, written on a personal digital assistant (PDA), or some combination of methods. Oftentimes, regulations dictate the amount of time a healthcare practitioner has to complete and enter the initial evaluation into the medical record. In addition, in circumstances where a patient is transferred to another

service, regulations or policies may require that clinicians complete a new initial evaluation on the patient and document it in the medical record.

Progress notes for each visit, daily or weekly, also are often required as part of the medical record documentation. The provider of pain management services determines the overall style of progress notes. Progress notes may also be written longhand, or in checklist format, dictated or written on a PDA, or combination again, depending on the department, type of service, practice, etc.

Many clinicians use S.O.A.P. note format for their progress notes. One should use care when using S.O.A.P. notes so to avoid writing "soapy" S.O.A.P. notes. Soapy S.O.A.P. notes skimp on the information provided so the reader loses the picture quality of treatment. These soapy notes include phases such as "Patient doing well," "Continue treatment," "Tolerated treatment well," "No Complaints," and the symbol ∅, instead of descriptive, functional information about the patient.

Some healthcare professionals such as physicians document a separate entry for every contact they have with the patient. In contrast, other healthcare professionals such as occupational therapists and physical therapists may not document a separate entry for each contact. Rather, the frequency of documentation may be determined by the frequency of change of status of a patient and/or treatment provided. For example, an acute-care facility would probably require more frequent documentation than a skilled nursing facility because status of patient may change more frequently. In another example, a rehabilitation therapist who consistently provides the same treatment each visit might only summarize the type of treatment provided and progress in a note documented each week. A contact note may be entered in the medical record to document phone contacts with other healthcare practitioners, the patient, and the patient's family members.

Discharge notes or summaries state what treatment has been rendered, improvement made, instructions given to the patient and/or significant others, and recommendations for further or future care. Copies or records of all should be kept and/or placed in the medical record. Discharge documentation should include the condition of the patient at discharge, and the reason for discharge. Reasons for discharge may include goals met, no further progress anticipated, or patient's care transferred to another agency or healthcare practitioner.

CONTENT OF MEDICAL RECORDS

The medical record consists of items dealing with the overall care of the patient. It may include correspondence, phone call transcripts, copies of prescriptions, billing records, personal digital assistant (PDA) records, email records, results of lab tests, X-rays, and others. The contents of the medical record may be determined by hospital policy (for inpatient records), accreditation bodies, state licensing regulations, federal regulations for various programs such as Medicare, and professional standards of practice.

Because many pain patients are involved in the court system in some way, pain practitioners need to prepare themselves for encounters they and their documentation may have with the legal system. Regardless of what the applicable law or regulation states, in practice, if subpoenaed for a deposition, everything becomes part of the medical record. Attorneys will send requests listing every possible item that might relate to the patient. This could encompass, for example, all items on your computer hard drive pertaining to the patient, including, but not limited to, emails, draft reports, etc.; handwritten notes pertaining to the patient; copies of telephone messages; appointment book entries for all of the patient's scheduled appointments; and any other documents pertaining to the patient.

The pain practitioner should include certain items in the medical record that will obviate the need to rely on memory 2 years down the road when the patient's case comes up before a judge. By preparing in advance with proper documentation, the pain practitioner can look thorough and professional when questioned about treatment that occurred in the distant past. Time spent answering questions regarding the patient or former patient's work status, disability status, and impairment rating is reduced if documentation is complete. Table 78.2 lists and describes minimal content of the pain practitioner's medical record. Statutory requirements, conditions of participation in federal or state programs and accreditation bodies will probably require additional items.

DOCUMENTATION OF PAIN

In the 1980s and early to mid-1990s, as a result of fear of addiction, public policy steered physicians away from prescribing narcotics for patients suffering from chronic pain. Physicians were disciplined or threatened with disciplinary action for overprescribing narcotics especially to patients with chronic pain (Angarola, 1994). Comprehensive documentation of the need for pain medication provided one of the tools for defending oneself from charges of overprescribing narcotics. However, documentation of the prescription of narcotics, if against state laws and regulations, also could work squarely against the physician.

Thus, the looming threat of discipline and the fear of addiction led to underprescribing of narcotics by many physicians (Angarola, 1994). With studies showing as many as one half of all patients in pain not provided with appropriate pain medication, public policy shifted away from the fear-based, underprescribing of pain narcotics to a realistic approach based upon the needs of the patient (Oregon Board of Medical Examiners, 1999; U.S. Agency for Health Care Policy and Research, 1994).

TABLE 78.2
Minimal Content of Pain Practice Medical Record*

- Informed consent
- History and physical examination
  - Including history of drug substance abuse
- Drug sensitivities or allergies
- Document the pain with symptoms:
  - Location
  - Duration
  - Frequency
  - Intensity
  - Precipitating or aggravating factors
- Restrictions, limitations, and activity level
  - Correlate pain to function
  - How does the pain limit the ability to work or dress, etc.?
  - How does the pain affect mental status?
  - Is the patient depressed?
  - Can the patient drive safely?
- Evidence of impairment
  - Pain itself is not an impairment
- Subjective and objective measures of pain
- Copies of prescriptions legibly written
- Use of narcotics**
  - Record dose, amount, and number of refills
  - Document/contract, signed by the patient acknowledging
    - Use of controlled substances
    - Side effects and material risks
    - Method for dealing with
      - Exacerbations
      - Lost presciptions
      - Noncompliance with treatment
      - Misuse of medications
      - Substance abuse
- Referrals to other professionals
- Notation of reading consults and lab results
- Compliance with treatment
- Monitoring or other devices
- Follow-up required?
- Follow-up appointments scheduled and dated?
- Signature and date on every entry
- Discharge documentation
  - Reason for discharge
  - Referral upon discharge
  - Condition upon discharge
  - Conclusions
  - Instructions given
- Handouts given to patients copies in charts
- Time saving information (in case a request comes later)
  - What information will workers' compensation want from you as a provider?
  - What information will social security want from you as a provider?
  - Is the person working now? If not, why not?
  - What kind of impairment does the patient have?

* Check their state licensure laws to add state-mandated requirements and relevant accreditation bodies for their requirements. (From Joint Commission on Accreditation of Healthcare Organizations, Pain Standards for 2001, 2001a.)

** Recommended for physicians.

The acceptable contemporary approach to pain treatment emphasizes an assessment of the patient's pain, documentation of pain and management of the pain (Angarola, 1993; Oregon Board of Medical Examiners, 1999; U.S. Agency for Health Care Policy and Research, 1994). The key methodology to prove one's compliance with these basic elements lies in proactive comprehensive documentation using, at a minimum, the elements listed in Table 78.2.

Recognizing the controversy in prescribing pain medication that led to underprescribing of pain medications and the resulting unnecessary suffering of patients in pain, the JCAHO developed standards for pain management, enforceable through its accreditation process. These standards, effective for JCAHO surveys that occurred after January 1, 2001, state that all "patients have the right to appropriate assessment and management of pain" (Joint Commission on Accreditation of Healthcare Organizations, 2001b). Pursuant to the standards, the healthcare organization must take steps to ensure the pain of "all patients is recognized and addressed appropriately" (Joint Commission on Accreditation of Healthcare Organizations, 2001b). JCAHO standards require initial and regular reassessment of pain in patients. Proper documentation will demonstrate compliance with these standards.

According to the JCAHO standards, when documenting pain symptoms, the pain practitioner should include location, duration, frequency, intensity, quality, patterns, and precipitating, alleviating, or aggravating factors, and pain management history (Joint Commission on Accreditation of Healthcare Organizations, 2001b). However, the practitioner must realize that pain itself is not a disability. It is important to document how the pain restricts a patient's activity and his or her participation in life roles. The pain symptoms must be correlated to function. To document a pain patient's function, the pain practitioner may ask the following:

Is the patient depressed?
How has the pain affected his or her relationship with others?
How is the pain affecting his or her mental status?
Can the patient concentrate well enough to perform activities?
Does the patient comply with the treatment regime?
How does the pain limit the patient's ability to dress or care for him or herself? Can the patient drive safely?

The JCAHO standards delegate to each organization the responsibility to develop follow-up criteria for evaluation of patients in pain. The pain practitioner's documentation will be key to showing compliance with JCAHO's standards. Among the suggested criteria, the standards look at the need for information on the impact of pain on

daily life, function, sleep, appetite, relationships with others, concentration, and others emotions. JCAHO surveyors will rely on the clinicians' documentation to measure compliance with the standard. Therefore, documentation should reflect these areas. Clinicians who develop systems for documentation will assure they cover all of the bases.

THE SYSTEMS APPROACH TO DOCUMENTATION

Agency for Healthcare Research and Quality (AHRQ) (2001b) research shows that most medical errors are systems errors. For example, when a surgeon amputated Willie King's healthy leg, the system designed to track the proper body part through surgery failed (Institute of Medicine, 2000). Errors such as this are not the result of individual negligence or misconduct. The system failed and resulted in harm (Institute of Medicine, 2000).

Documentation plays a significant role in systems within healthcare. Peer reviewers and others can trace errors through documentation and documentation done properly can show an absence of errors, compliance with accreditation standards, or proof the system is properly working, resulting in error-free quality care.

The Institute of Medicine report (2000), "To Err is Human: Building a Safer System," suggests that the healthcare system look to ergonomic principles used in other industries but up to now ignored by the healthcare industry to improve efficiency and lower the error rate. Some of these methods that are successful in reducing errors in the medication process can be used to reduce errors and omission in documentation. These successful methods of prevention based on ergonomic principles include reducing reliance on memory which can be fallible and cause errors, simplifying of procedures, standardizing treatment processes, using standardized protocols and checklists, and decreasing reliance on multiple data entry (Institute of Medicine, 2000).

Pain practitioners can incorporate several of the ergonomic principles into their documentation systems to improve efficiency and decrease documentation errors, in other words, to streamline the process. To reduce reliance on memory, pain practitioners can use personal digital assistance (PDA) or handheld computers to write the documentation as the patient reports it to the clinician. This method also eliminates reliance on handwriting for ordering medication and other treatments, thereby eliminating potential errors (Agency for Healthcare Research and Quality, 2001a).

Standardizing and simplifying treatment policies and protocols and implementing checklists help the pain practitioner avoid confusion and reliance on memory. In essence, JCAHO's pain management standards spell out a standardized protocol for pain management, which gives practitioners a simplified process upon which to base treatment, policies, protocols, and checklists.

Avoiding the use of similar looking or sounding medications also lowers the likelihood of error. If physicians prefer to use certain specific medications on a regular basis, using preprinted prescription pads in a checklist format also can help eliminate errors.

Pain practitioners can eliminate other documentation errors by putting systems in place to document telephone calls with patients and consulting physicians. Systems for justifying and monitoring narcotics such as the contract listed in Table 78.2 provide one simplified method to document a potential problem on a consistent basis. Finally, pain practitioners should have systems to monitor the effectiveness of the systems they have put in place.

SUMMARY

Three rules of thumb to remember:

- If you charged for it, you did it.
- If the reader can't read it, you may not have done it.
- If you changed it after the case was filed in court or after you submitted a copy to the payer, you have a big problem.

Good medical record documentation can ensure quality care and protect the patient and practitioner.

Motor Vehicle Accidents

Christopher R. Brown, D.D.S., M.P.S

In the last 30 years, there have been more than 10 million "moderate to severe" injuries and over 1.5 million deaths in the United States from motor vehicle accidents (MVAs). The National Safety Council reported in 1996 that 11.2 million traffic collisions occurred. Of those, 9.6 million were a combination of property damage only and/or nondisabling injury collisions. The economic cost to the United States was estimated to be $176.1 billion — a staggering amount of money.

In terms of the dollar costs involved, Evans (1991) in Traffic Safety and the Driver indicates property damage to top the list at 37%, with medical costs in fifth place at 6% of the total. Data from the National Highway Traffic Safety Administration (1987) estimate the following:

	$ (Billions)	% (Total Expenses)
Property	27.0	37.0
Insurance	21.0	28.0
Productivity	16.0	22.0
Legal and court	4.0	6.0
Medical	4.0	6.0
Emergency (transportation, diagnosis, and support)	0.7	0.9
Miscellaneous	0.45	0.6

Understanding what happens to humans in MVAs takes more than statistics, graphs, and charts. It requires a combination of learning tools, investigative procedures, and a thorough understanding of human anatomy and physiology.

From an engineering perspective, we need to know certain factors about the automobile such as weight, speed, and its vector (direction of motion). Other factors that may contribute to overall force need to be understood as well to fully appreciate and estimate the resulting forces that may contribute to human injury potential.

LOW SPEED VS. HIGH SPEED

For practical purposes, the working definition of a low-speed impact is a collision in which the change in velocity of the vehicles (usually the one that contains an occupant claiming an injury) is less than 10 mph. It must be emphasized that this definition of low speed is subjective. Clearly, no general consensus among experts exists.

Although it is commonly accepted to describe impact severity and injury potential as functions of change in velocity, caution should be used when considering impacts of grossly dissimilar durations. Comparison of impacts based solely on their respective changes in velocity inherently assumes the impacts occurred over a similar duration, typically 90 to 140 msec for low speed impacts. For the majority of accidents this is a reasonable assumption. However, in some collisions, such as underride or sideswipe collisions, the impact duration may be in excess of 300 msec. Given an equal change in velocity, a vehicle that undergoes a longer duration impact will be exposed to lower peak forces. For this reason, underride and override collisions, although sometimes involving very high dollar amounts of property damage, can be less severe than a "damage" collision.

As an example of the effects of impact duration, consider skidding a vehicle to a stop. In theory, decelerating a vehicle from 30 mph to a stop by applying the brakes involves an impact between the tires and the roadway with a change in velocity of 30 mph, but with an impact duration of approximately 2.0 sec. The skidding vehicle is deceler-

0-8493-0926-3/02/$0.00+$1.50

ated at approximately 0.7 gs. Although braking a vehicle to a stop involves a 30-mph change in velocity, this is a quite different event than a 30-mph front-to-barrier impact. The barrier impact occurs over a much shorter duration and typically involves decelerations of 30 to 50 gs.

A factor to consider in low-speed rear-end motor vehicle accidents (LSREMVAs) is impact forces concentrated over very small areas. As an everyday event, this may occur while backing into a small diameter pole in a parking lot or contacting a corner or small area of a bumper. Vehicle structures typically deform in proportion to the amount of force applied. In impacts with narrow objects or to the corners of vehicles, the contact forces are distributed over a very small area producing large local stresses (force per unit area). These large local stresses can damage bumper and vehicle components at changes in velocity below the strength of that area. Testing by the Insurance Institute for Highway Safety indicates that the amount of damage and costs of repair will vary dramatically from car to car and will even vary greatly for the same vehicle depending upon the type and angle of low speed collision (Kaufman, et al., 1993). These factors have to be taken into consideration to determine forces transferred.

In reality, though, the definition changes situationally according to needs. Low speed infers that the occupants can't be hurt. High speed infers they can. As a rule of thumb, engineering studies will routinely define low speed as less than 10 mph closing speed.

Can you draw the same conclusions? Are the collision biomechanics the same? Are the injury mechanisms the same?

In professions that deal with MVAs and human injury, an erroneous assumption often exists that "one size fits all." In other words, there is a mechanism of injury that either happens or does not happen — people get hurt or they don't. In the dental profession regarding TMJ injuries, it was assumed that for TMJs to become injured in a rear-end motor vehicle accident (REMVA), the mandible had to go through a full range of motion. Videos of LSREMVAs clearly indicate that in low speed collisions it is often not the case. A few authors, therefore, erroneously assume that because this particular mechanism of injury is not present the TMJs cannot be injured. That, of course, is false logic. All parts of the body no matter what the location can receive injuries from many sources. Clinicians need to be aware of these mechanisms to clearly understand, diagnose, and treat the injuries they see. Understanding leads to a more definitive diagnosis and more effective treatment.

Statistics themselves are not particularly significant when trying to predict individual occurrences. Statistics may be used as an academic yardstick but can not be used to predict how an individual or small group of occupants will respond in any given situation. Predicting or judging anything based on a population smaller than what is statistically significant in the measured population is erroneous.

There is no such thing as a typical REMVA. Most REMVAs are offset collisions producing torsion, tension, compression, and shear forces to the human body as a whole and to the individual parts.

In reality, actual numbers regarding REMVAs are impossible to track (fatal vs. nonfatal).

REAR-END MOTOR VEHICLE ACCIDENTS

While statistics on fatalities are easy to track, the statistics on injuries are not. This especially holds true when it comes to REMVAs. Take, for instance, the port of statistical entry for comparing the two. With a fatality, police are involved, certificates are signed — a definite traceable system exists. A definite path which societies have determined also needs to be followed.

With injuries, however, this is not the case. Take into consideration the possible portal of entry into the medical system of the United States. A victim of a MVA may very well start out at the emergency room with a description of minor injuries that do not need immediate attention. At that point, there may or may not be any type of follow through. The victim may be referred back to a family physician if he or she has one, or the victim may be left to find his or her own way.

The choices people have for treatment of pain are varied. For instance, for the treatment of headaches following a REMVA, the person may choose to visit a physician, a chiropractor, a dentist, a massage therapist, an acupuncturist, an optometrist, an ophthalmologist, and so on.

Statistics, as a result, are not accurate and there is no predetermined course of action as in fatalities. In fact, even the accepted terminology varies from source to source on how to even describe injuries as a result of REMVAs. They may be described as STI (Soft Tissue Injuries), MIST (Minimal Impact Soft Tissue), CAD (cervical acceleration deceleration) all these descriptions are used to describe a pattern or type of injury as a result of "whiplash." Even with the difficulty of tracking these types of injuries, it has been estimated that 1 to 2 million CAD injuries occur per year from REMVAs (Evans, 1992). The 2 million per year estimates occur at rates roughly 5480/d, 1827/8 h, 228/h, 114/half h, and 4/min. Not only are REMVA injuries substantial in number, they also can produce long-term residual effects. In fact, the rate of recovery in whiplash injuries is poor; 20 to 40% of whiplash injuries have debilitating symptoms that persist for years (Carette, 1994). Patients destined to recover will do so in the first 3 to 4 months after initial injury (Barnsley, et al., 1994). The consequences are both long term and far reaching, resulting in extended sick leave

and increases in disability (Per-Olof, et al., 1998). Beyond that time period the probability of permanency increases.

While statistics vary greatly, it is safely assumed that up to 50% of all REMVAs will result in some type of neck injury. The risk of occupant disability is approximately 3 to 6%, a staggering number when one considers the number of motor vehicle accidents per year (Ono, et al., 1993). There is no truth to the assumption that injured people get better after some type of settlement or what is known as "green back poultice".

TESTING METHODS FOR PREDICTING HUMAN INJURY

Testing methods used to determine the kinds and types of injuries received in MVAs fall into five categories:

1. Humans (live)
2. Animals
3. Cadavers
4. Computer modeling
5. Anthropomorphic test dummies

The only totally accurate way to predict human response in REMVAs is to actually use living, breathing humans. Obviously, some restrictions apply for these types of situations.

First of all, humans get injured. A review of studies using live, human testing reveals that humans are brought to the bare minimum level of injuries and then no more. There are obviously good reasons for that! Therefore, the threshold of human injury is not totally statistically accurate.

Another drawback to the use of humans in crash tests is that although all test situations have very specific parameters small variables will cause a great change in human response to input forces. Variables such as occupant seating, anticipation of impact, the weight of apparatus strapped to the patient, helmet vs. no helmet, etc. greatly modify the parameters of human response, making each individual crash in truth anecdotal.

It also should be noted that crash tests are not designed to hurt human beings — they are designed to note human motion and/or response to energy input. All other testing sources, while providing great statistical information, provide no actual correlation to human injury. If one carefully reads published reports through the Society of Automobile Engineers (SAE), it will be obvious with a few biased exceptions that human motion studies do not predict injuries or lack thereof, but carefully note that they are individually dependent.

All other types of testing including cadavers are not accurate for the human response in low-impact REMVAs. In high speed crashes as the Delta V increases, the correlation between live human response and other factors increases. This is because all other testing measures purely mechanical response but no material response. Pain and dysfunction often result from the material response of viscoelastic human tissue. In other words, the quicker the impact, the higher the forces received, the more mechanical a human will respond and, therefore, mechanical/cadaver/computer modeling becomes more relevant. In low-impact REMVAs a few good studies with humans exist but virtually none with surrogates that correlate with human motion. As a result, while all crash test studies among living, nonliving, and nonhuman subjects yield good statistics for study and provide cost-effective ways to measure mechanical output, at best they provide unconfirmed approximate vague guidelines for human injury.

What crash and test studies will do will give subjective information such as:

1. Pain
2. Central Nervous System (CNS) information
3. Biological information
4. Physiologic information
5. Kinetic dysfunction following impacts
6. Latent reaction

All information gathered from crash test studies is statistical in nature and can never be applied to an individual in a given situation.

BIOMECHANICS

Biomechanics is a very inexact science when it comes to human beings. While mathematical predictions are accurate and easily obtainable, human reactions under different stresses are not. How can one explain when a person's parachute fails to open, and he or she beats the odds and survives a multi-thousand foot fall while another person will trip coming down some stairs, fall several feet and die? Examples of human response to energy input quickly lead one to the conclusion that the predictability of individual response is based strictly upon the individual's response; nothing more, nothing less. It is important, however, to understand generalities so that a practicing clinician can approach human injury with logical sense.

There are four basis response modes for a body subjected to external forces:

1. Elasticity. Elasticity is defined as deformation induced during forced application, which is completely recovered when the load is recovered. An example of this is the perfect spring. This type of reaction is rarely found in the human body.
2. Plasticity. Plasticity results from deformation of the initial geometry when the load is released.

In other words, the loading and unloading path are different. The absorbed energy is the product of force × motion in the direction of motion. Plastic deformation in essence equals the permanently stored (absorbed) energy. A good example of plastic deformation is the human earlobe's response to weighted earrings or inserts. When pressure is applied over time, the soft tissue of the ear will bend and be permanently changed.

3. Viscoelasticity. Viscoelasticity is body deformation under a load such that it recovers its geometry upon load release, but it does so by following a different loading path. The initial geometry is recovered but the body absorbs some of the applied energy. In a mechanical sense, shock absorbers and tires are good examples. Human soft tissue responds in a viscoelastic manner unless force is applied to the point of actual tissue rupture.
4. Brittleness. A brittle body ruptures with negligent plastic flow. Up to the point of rupture, however, response is purely elastic. The best example of this is glass. While each part of the human body under various conditions can exhibit some of these properties, in the true sense of the word, the human soft tissues respond in a viscoelastic manner.

INSTANTANEOUS CENTER OF ROTATION (ICR)

ICR of a joint is the mathematical determination of a theoretical point on which all motions rotate. The concept of ICR in a kinematic and biomechanical sense is an important one. It can be considered under healthy conditions to be the physiological center upon which human motions of a given joint will move. Various ICRs have been measured and determined for different body parts. However, in an REMVA, the ICR may change within microseconds, causing a great change in load distribution of the human body. In a landmark study by Kaneoka, et al. (1999), the ICR of the spinal column was measured and found to change in as little as a sub-4-mph Delta V resulting in a pathological motion.

The term ICR has been misapplied and misunderstood in some instances of human motion. This is especially true in the TMJs. First of all, the motions of TMJs are not purely rotational and do not move around the fixed axis of rotation. The axis rotation of TMJs will vary in anatomical planes. When subsequent motion of the head and neck apparatus exists, or compressed tissue in the retrodiscal area, the TMJs translate from the first moment. In this instance, virtually no pure rotation occurs. Under normal circumstances, the initial axis of rotation and resulting translation can very well be different from one TMJ to another within one person, resulting in axes of rotations that are not coupled symmetrically with one another.

The surface of the TMJs can be nongeometric for many reasons, including degenerative joint disease, remodeling, growth, angles of eminentia, scar tissue, etc. The condition and surface of the articulating surfaces and supporting structures and the resulting musculature function determine the potential motions of the TMJs resulting in a very complex motion system.

For the ICR of the TMJs to be accurately determined, they would have to be rotating cylinders that remain stationary throughout the motion, which of course they do not. The mandible changes its position as it moves throughout the range of motion. The result is not just a change of the head of the mandible, but the mandible itself. As it translates, rotates, moves in a 3-dimensional position, the ICR changes as well. Studies also indicate that the trajectory of the condylar heads along the surfaces can be affected by velocity (distance/time) and is a multiplane vector that can be affected by muscle soreness, speed of forced opening, rotational forces, compressive forces, and shear forces. The ICR of the TMJ will change dramatically in a very slight, fractional opening. When the ICRs of the TMJs are not perfectly matched, the articulating surfaces of the joints can be either distracted or compressed, depending upon which moment in time is measured. Rapid acceleration, such as that experienced in an REMVA, can affect the standardization of motion of the TMJs, creating nonhabitual moment arms resulting in excessive forces not physiologically compatible with the human anatomy involved. These changing patterns from moment to moment will result in gross motor dysfunction, which will produce differing articular motions. The result is that the ICR of the TMJs is a mathematical theory only and not an accurate representation of reality. TMJs and their supporting structures can become excessively damaged from indirect trauma such as that received by whiplash. The following is a list of potential TMJ injury mechanisms:

Mechanisms Contributing to TMJ Injuries without Direct Impact to the Mandible as a Result of LSREMVAs

1. Coefficient of friction— change in fluid viscosity— fluid is different, rough, yielding more drag.
2. Blunt trauma due to linear condyle distalization compared to skull bruising and tearing of soft tissues.
3. Slowness of muscles to react (seen in electromyographic studies) Muscles and joints do not have to go through full range of motion (ROM) for injury to occur.
4. Morphology of articulating surfaces may not be smooth, especially under compression.

Mechanisms Contributing to TMJ Injuries without Direct Impact to the Mandible as a Result of LSREMVAs (continued)

5. Cellular ability to repair is altered.
6. ICR is altered and changes through ROM.
7. Fast and slow wave motion from headrest and condylar distalization resulting in tearing of soft tissues at hard tissue junctions.
8. Hydraulic differential between upper, lower joint space, and disc apparatus.
9. Set up for repetitive strain syndrome—change in posture of neck and mandible/upper jaw/skull. Occlusion does not change.
10. Sympathetically maintained pain syndrome may contribute to degenerative joint disease over time.
11. Tearing of pre-existing adhesions, fibrotic tissue.
12. Bleeding in the TMJs (hemarthrosis).
13. Referred pain patterns from other peripheral injuries.
14. Most TMJ diagnoses are inaccurate and/or misdiagnosed in the first place.

Common Soft Tissue Acceleration/Deceleration (STAD) MIST Injuries of the Head and Neck Resulting from LSREMVAs

1. Temporal tendinitis
2. Myofascial trigger points (MFTP)
3. Ernest syndrome
4. Occipital neuralgia (GON, LON)
5. Cervical facet joint inflammation
6. TMJ posterior capsulitis
7. TMJ lateral capsulitis
8. Myalgia

Note: These clinical injuries can occur as a result of the previously mentioned mechanisms.

COLLISION DYNAMICS

There are three different types of collisions in every REMVA:

1. Automobile to automobile
2. Occupant to automobile interior
3. Occupant body part to body part

Automobile to Automobile

The easiest type of collision to understand is automobile to automobile. The motion is commonly divided into four different phases:

1. Contact
2. Vehicle at the peak of acceleration
3. Vehicle starting to slow down
4. Vehicle slowing to a stop

All such factors as bumper height, weight of the vehicle, angle of impact, and environmental factors may change the function of time and velocity resulting in an overlap of each phase.

Occupant to Automobile

The second collision, occupant to automobile interior, can also be generalized into four separate phases:

1. 0 to 100 msec. The initial phase occurs at 0 to 100 ms. When the vehicle moves forward out under the test subject, initial forward and vertical motion of the hips and low back occurs. Simultaneously, the upper part of the seat begins to flex rearward under the load of the torso which remains stationary during this time period.
2. 100 to 200 msec. During the first 100 msec, the seatback reaches maximum rearward movement. The subject moves upward and forward resulting in neck compression, cervical spine straightening, and movement upward and rearward. The head is in a chin-up type of position and begins to rotate rearward. By 160 msec, the vertical motion of the torso begins to pull the neck forward as the head continues into the extension. During this phase, significant shearing forces and ramping may start (vertical rotation).
3. 200 to 300 msec. At 200 msec, maximum vertical motion has taken place. At 250 msec, the head starts a forward motion. The seatback returns to its original position while the torso extends back down the seatback.
4. 300 to 400 msec. At 300 msec, the descent of the torso is now complete and is moving at the same velocity as the vehicle. At 400 msec, active deceleration of the neck occurs. At 400 msec, all impact-related motions are virtually completed and the human body is moving at the vehicle's velocity.

The total time for human movement in REMVAs is between 0.1 to 0.2 sec. Whether the impact results from low or high velocity, the time of energy exchanged is virtually the same. This is due to the biomechanical properties of the elements involved and may vary only by a few fractions of a second.

Occupant Body Part to Body Part

Human injury comes not from the first collision, but from the second and third collisions. Obviously, contact from the human being to parts of the automobile can produce great amounts of soft tissue injury. These can come from movement of the body into the seat, the headrest, a seatbelt, steering wheel, dashboard, automobile pillars, windshield, etc. All are potential injury mechanisms for human beings. However, the third col-

lision (body part to body part) has a great effect, especially in low impact situations. As the automobile goes through the motions, keeping in mind Newton's laws of motion, the occupants remain stationary relative to the automobile but seem to move toward the impact. The occupant lags behind the car, the torso lags behind the hips, the neck lags behind the torso, the head lags behind the neck, the vertebrae lag behind one another, the mandible lags behind the cranium, etc. As a result, the motion of the human during this time period is a non-physiological motion resulting in points of injury, which will almost always be at the connective tissue junctions between hard and soft tissues (as commonly seen in the TMJs and cervical vertebrae). The result is injuries to muscles, ligaments, and tendons. In an offset collision (which most are), a great amount of rotational forces will be placed on the body. The occupants will experience compression and shear forces, which cause great injury to the soft tissue. The differences in load variations to the human body during cycles of motion result in multiple stress and strain points. Each REMVA is unique and, accordingly, no such thing as pure forward and backward motion exists. Biomechanical forces applied in REMVAs are always multidimensional. As a result, there is no Delta V or closing speed under which a person cannot get hurt, nor is there a Delta V or closing speed over which all people will get hurt. The injuries are a result of individual response at a moment in time. These principles and conditions apply to soft tissue injuries and all body parts. The rate of acceleration of any given body part is of utmost importance (Newton's second law). The forces increase dramatically with an increase in acceleration. Soft tissue properties differ when applied with time variables.

Crushing of soft tissues can occur in blunt impact when body surface deforms and soft tissues get compressed between impact site and other hard tissues. Examples of these are

1. Tissues at the nuchal line and headrest (skull and headrest)
2. Tissues between spinal column and seatback
3. Tissues between vertebrae during ramping and submarining
4. Tissues between the condyles and skull (TMJ injuries)
5. Attachments of muscles (i.e., trapezius) during ramping and contact with friction of the seat, headrest, and body supports built into seats
6. Etc.

Because a moving body has inertia, when it collides a force is immediately produced on the impacted surface that starts to slow the body as a whole.

$$\frac{\text{Impacted Body Side}}{\text{Force Generated}} \rightarrow \frac{\text{Side Away from Impact}}{\text{Zero Force}}$$

The result is a net force that produces differential deceleration between body segments. The resulting biomechanical stresses (shear, compression, torque, etc.) acting simultaneously, and in opposite directions, often yield soft tissue damage.

WAVE MOTION

Stress waves travel at the speed of sound (square root of the ratio of the Young's modulus to the material density).

1. Travel through the body
2. Subject portions to local stresses and forces
3. Localized compressions
4. Localized tensions

Wave speeds for car material are approximately 9843 to 16,404 ft/sec (10 times the speed of sound). Time of energy transfer is 0.1 to 0.2 sec which means the energy travels the length of the car (15 ft) in 1.5 msec.

Elastic waves travel 67 times the car length (approximately 33 reverberations) in the energy transfer time of 0.1 to 0.2 sec.

Although viscoelastic for the most part at low forces, human soft tissue responds in an elastic manner. At high forces and as a function of time in which the force is applied, soft tissue may respond in a plastic manner resulting in permanent injury. Plastic waves travel much slower (slightly faster than the collapsing of impact surfaces) in automobiles and in human tissue as well. In MVAs, both waves are present due to crushed and uncrushed vehicle components. Not surprisingly, then, injuries often occur at locations remote from the impact site. The velocity (Newton's second law) of deformation is the predominant factor in determining the magnitude of wave created.

HIGH VELOCITY

Stress waves from impact site travel at the speed of sound in the surrounding tissues. Injuries occur at

1. Interfaces of unlike tissues (menenges, TMJs, muscle to bone attachments, facial linings, etc.).
2. Tissue/air interfaces (intestinal wall/gas, sinus cavities/linings).

A differentiation of tissue movement is contributed by the following mechanisms of injury:

1. Compression and expansion of the stressed tissues.

2. Production of pressure differential across a boundary.
3. "Spalling" energy is released as an energy wave attempts to go from a dense to less dense medium. (The wave is tensile, most human soft tissues can withstand more compression than tension.)

LOW VELOCITY (MOST COMMONLY EXPERIENCED IN MVAS)

Stress waves travel at less than 15 m/sec. Transverse waves of lower velocity and long duration (shear waves) are produced by displacements of body surfaces. The results are differentials created at

a. Sites of attachments
b. Sites of body part collisions

These forces will vary more when considering not only a difference in tissue viscosity but structural/architectural differences as well on both micro and macro levels.

HYDRAULIC PRESSURES

Tremendous amounts of pressure exerted within closed systems cause tearing at micro and macro levels. Fluid systems (i.e., shock absorbers) exhibit various mechanical characteristics under different rates of loading. Different types react in a dissimilar manner. The "containers" burst when loaded quickly. In other words, tissue reaction is time sensitive. The forces generated will be released through the path of least resistance. In humans, this path is often the point of connection between soft and hard tissues.

ENERGY INPUT AND FORCE × COMPRESSION: $F_{MAX} \times C_{MAX}$

This formula relates to how much energy is placed on a subject (or body part) during impact and how much is "lost" during the transfer. Tissues and organs can disrupt and dissipate energy transference. The larger the $F_{max} \times C_{max}$ the more energy loss will be experienced in the soft tissues and, therefore, more potential for destruction.

This relates back to Newton's first law (bodies at rest…). How much energy it takes to move tissues will determine injury potential. Tissues that slide over each other and don't resist won't absorb as much energy as those which cannot "get up and go" as fast as others. The lag time between body part motion due to differences in location, density, and reaction to forces plays a part in this phenomenon.

MUSCLE SPLINTING (PRE-TENSED)

Pre-tensing of the muscles can have an effect on injury in LSREMVAs in the following manners:

1. Increase injury potential
2. Decrease injury potential
3. Have no effect on injury potential

Contradictory? It is, but any or all of these can apply to each individual on any occasion or all at once and can apply to various body parts. For example:

1. Tighten neck
2. Lock knees anticipating impact
3. Pushing on the brake
4. Bracing with arms on the steering wheel anticipating impact

Any number of human responses can affect injury potential. The principles of movement are all the same.

All of the above can also relate directly or indirectly to cellular damage. Cell injury can occur when mechanical trauma damages the cell membrane, impairing its ability to act as a barrier to extra cellular calcium. Too much intra-cellular free calcium can overwhelm the mechanisms that normally maintain a relatively constant calcium concentration. The cell's inability to dispel the calcium can lead to an increase in osmotic pressure causing swelling, cell membrane damage, metabolic depletion, and cell death. This can occur in skeletal muscles, smooth muscles (blood vessel muscle lining), and nerve tissues. Mechanical cellular damage (from stretching) also can alter nerve tissue conduction. This cellular damage can result in muscle spasm, alteration of localized blood flow, hyperirritability, dysfunction, breakdown, and pain. All the aforementioned principles can apply to soft tissue injury on all levels simultaneously.

Common Soft Tissue Injuries Resulting from REMVAs

1. Cervical strain/sprain
2. Cervical facet joint inflammation
3. Occipital neuralgia
4. Myospasm
5. MFTPs
6. Temporal tendonitis
7. Stylomandibular ligament insertion tendinosis (Ernest Syndrome)
8. Injuries to the TMJs
   - Lateral capsulitis
   - Posterior capsulitis
   - Hemarthrosis
   - Disc displacement
     - Reducing
     - Nonreducing
   - Adhesions in the superior and inferior joint spaces

Principles Affecting Soft Tissue Injuries (How People Get Hurt): Thresholds for Soft Tissue Injuries

In The Real World (ITRW)

- There are no set thresholds for injuries to soft tissue.
- There are no set thresholds for injuries to hard tissues.
- Biomechanical trauma is unpredictable and anecdotal.
- Tissue strengths and tolerance will vary under different conditions.
- Body parts accelerate at different rates.
- Body parts move at rates different from the car and from one another.

ABBREVIATED INJURY SCALE (AIS)

The AIS was developed in 1971 by the Association for the Advancement of Automobile Medicine and the Society of Automobile Engineers to statistically track injury categories. Injuries for each body region area are placed into seven levels (0 to 6). The AIS level is based on the level of injury revealed by an examination shortly after the crash by doctors trained in its application (Gennarelli, et al., 1998).

0 No injury.
1 Minor (may not require professional treatment).
2 Moderate (nearly always requires professional treatment, but is not ordinarily life threatening or permanently disabling).
3 Serious (potential for major hospitalization and long-term disability, but normally not life threatening).
4 Severe (life-threatening and often permanently disabling, but survival is probable).
5 Critical (usually requires intensive medical care, survival uncertain).
6 Maximum (untreatable, virtually unsurvivable).

As the AIS increases, the cost of medical support greatly increases. However, the purpose of the AIS is for statistics only.

No level is supposed to be used as a predictor of final outcome nor to estimate the cost of treatment. It is possible for injuries at any AIS level to subsequently prove fatal, although the threat to life potential of the injury increases steeply with increasing AIS level (Evans, 1992).

INDIVIDUAL TOLERANCES AND RISK OF INJURY

Occupant Position at the Time of Impact

Occupant position at the time of impact, one of the most important variables, is commonly overlooked and assumed in REMVAs. Occupant position will greatly reduce the Delta V required to surpass the soft tissue injury threshold. The Biomechanical Assessment Profile (BAP), a position assessment questionnaire developed by the author, allows the clinician and the occupant to help determine the true position at the time of impact. The slightest occupant position variation will greatly affect injury potential resulting in large increases of impact forces (SAE # 91294; SAE # 930211).

A normal position, such as that assumed by a crash test dummy, is not a normal position for most occupants (SAE # 700361). Being out of position is actually more normal for occupants than being in position, if normal is defined by the posture of crash test dummies at the time of impact. Positioning varies by occupant driving habits, anatomy, seat comfort, and anticipation of a collision.

There are three common actions of bullet vehicle drivers prior to impact:

1. Braking
2. Swerving
3. Spinning/yawing

These motions will change the following:

1. Impact angles of vehicles
2. Closing speed
3. Vehicle contact
4. Will potentially negate built-in safety systems
5. Will potentially affect vehicle damage

These factors also greatly affect the passenger position at the time of impact. Virtually all rear impact testing with dummy and cadaver subjects has been conducted with properly positioned occupants (erect, backs firmly placed against the seat back) (SAE # 912914). Being out of position can dramatically change the occupant's reactions to forces and resulting kinematics. Humans react quite differently than crash test dummies especially in low speed accidents. Variations in occupant positioning may contribute little to injury potential in high-speed crashes but can greatly increase or decrease injury potential in low-speed collisions.

Pre-Existing Conditions

"Pre-existing" is a term that is often misunderstood and abused. Susceptibility to injury does not negate the fact that damage can occur. In fact, a pre-existing condition can radically lower the amount of energy required to cause soft tissue damage. While there may be evidence of a condition radiographically, such as in localized bone breakdown of the cervical spine or the condylar head of the TMJs, the person may have been asymptomatic and remained so throughout his or her life if not for the large

amount of energy transferred in such a short period of time as in a motor vehicle accident.

In fact, pre-existing conditions can make a person more susceptible to injury when forced to move faster or more than is habitually required. These conditions may include, but are not limited to:

Arthritis
Cervical disc disease
Fibromyalgia
TMD of many varieties
Myofascial disorders
Emotional disorders
Drug use
Chronic subluxation
Poor spinal alignment
Cranial lesions
Reaction time. The time span of energy input is rapid; total time is 0.1 to 0.2 sec. In contrast, human response time is slow (even healthy people's muscular reactions don't begin until .08 to .14 sec). Total personal response time has been estimated at 2.5 sec but will vary according to each individual and the circumstance at the time of impact.

Can an acute problem be superimposed over a chronic condition? Of course, this possibility can and should be taken into consideration when arriving at a differential diagnosis. It is crucial that the clinician have a thorough understanding of the patient's condition. A thorough health history is essential and may include contacting previous treating clinicians. Good diagnostic equipment and excellent diagnostic skills are also necessary.

Gender (Women Compared to Men): Statistical Generalizations

Woman have:
- Approximately two times more minor soft tissue injuries than men
- Smaller neck diameters and longer necks
- Higher frequency of spinal stenosis
- Greater involvement in crashes/million miles driven (National Safety Council)
- Higher frequency of injury claims
- More severe injuries
- More treatment
- Higher healthcare bills
- Slower recovery
- Greater disability
- Worse prognosis
- More overall joint injuries (including TMJ)

Age (> 65 years):

Older drivers:
- Are more prone to injury
- Have decreased capacity for recovery
- Have poorer recovery

Occupant Size

In general:
- The larger the occupant's mass, the less likely an injury will occur.
- Taller occupants have been shown to be at risk for higher neck injury (tall and thin vs. short and fat).
- Size may correlate with age (child vs. adult; adult vs. old).
- Size of body parts can influence injury potential.

Direct vs. Indirect Trauma

What is the difference between direct and indirect trauma? Can you separate the two when it comes to MVAs? Can you tell the difference clinically and with diagnostic testing? Actually, under the examination of an MRI or clinician's diagnostic exam, tissue reaction and dysfunction are the same.

Examples of direct trauma

1. Penetrating — puncture
2. Penetrating — laceration
3. Crush mechanisms (Yes and No)

Examples of indirect trauma

1. Coup–contra-coup brain injury
2. Concussion (football helmet blow, boxer sustaining blow to the mandible)
3. Fracturing a bone – direct or indirect?
4. Spraining a knee, elbow, wrist by abnormal/repetitive movement (tennis elbow)
5. Repetitive strain syndromes of all types (carpal tunnel)
5. TMJ injuries

As previously mentioned injuries commonly occur at the interfaces between unlike tissues due to the

1. Differential of speed of body parts (lagging behind)
2. Differential of tissue makeup yielding variance of wave transfer
3. Differential of hydraulic pressure
4. Hard tissue rebounding

5. Crush mechanism of hard tissues approximating each other
6. Cellular damage

Each connective tissue junction has potential for suffering stress/strain. These types of mechanisms rarely, if ever, occur by themselves. Biomechanical forces in the real world occur in multiple directions and cutting in degrees simultaneously. The delineation between direct and indirect trauma is not one of physiological origin but rather medicolegal only. Human tissues are limited in their ability to respond and are governed by the same laws of physics as the rest of the universe. To say that, for instance, the soft tissues of the TMJs or their supporting structures cannot be injured unless the mandible is directly struck indicates a lack of understanding, education, truthfulness, or all three. In fact, most injuries to the human body except at the exact point of impact are indirect in nature.

AUTOMOBILE COMPONENTS THAT CONTRIBUTE TO HUMAN INJURY POTENTIAL

Headrests

Next to the position of the occupants at the precise time of impact, headrests are the most commonly overlooked contributors to head/neck injuries in REMVAs. They are often the silent contributors to occupant cervical injury. Federal law (FMVSS) requires that "head restraints must be at least 27.5 in. above the seating reference point in the highest position and not deflect more than 4 in. under a 120-lb load." Or, they must not allow the relative angle of the head and torso of a 95th percentile dummy to exceed 45° when exposed to an acceleration of 8 gs.

Vans and light trucks from 1991 have had to comply with standards. Studies show a 85-cm seatback height necessary to account for 95% of male occupants and 100% of female occupants. However, the generalization of headrest design does not allow for individual height differences and resulting cervical strain. The distance an occupant's head has to travel before impacting the headrest in a rear-end collision can greatly increase the forces applied to the head and neck (SAE # 670919). This distance can vary not only from structural design but also because of the occupant's build and seating preference. American consumers as a rule prefer adjustable headrests, but rarely have them adjusted to achieve maximum effectiveness. They are often set too low to protect the head/neck complex.

Transfer of energy (0.1 to 0.2 sec) and the slowness of human cervical muscles to respond (0.08 to 0.14 sec) result in almost no one being able to avoid direct contact with the headrest. Therefore, in almost every case involving a rear-end motor vehicle collision direct impact to the head, neck, and torso of the target vehicle occupants by the seatbacks/headrests occurs that can result in soft tissue injury.

Factors That Affect Headrest Protection of Occupants

1. Positioning
2. Ramping of the body
3. Flexion of the seatback
4. Head rides above and below
5. Distance the occupant's head travels to make initial contact (longer = more force)
6. Occupant positioning
7. Occupant's length of neck, arms, torso
8. Awareness of impact (bracing)
9. Virtually nonfunctional at best and detrimental at worse

Headrest design and position may contribute greatly to potential cervical/head injury. Due to occupant motion or pre-impact positioning, the headrest may even increase occupant injury.

Seat Construction

Federal Standard FMVSS 207 advocates strength requirements of 20 times the weight of the seatback. Most seats weigh about 40 lb. The resulting strength would be 800 lb — not enough in a significant impact. In fact, impacts may produce forces beyond the seat's designed ability to rebound, resulting in seatback collapse that greatly affects the amount and direction of force to the occupant (SAE # 670919).

Seat construction is not uniform from one car to the next. It varies in:

1. Angle
2. Stiffness
3. Elasticity
4. Materials
5. Coefficient of friction

Seat design helps determine relative impact of each body part:

1. Can lead to large differential between head, spine, shoulders, pelvis, and supporting soft tissues.
2. Change angle of force vectors.
3. Compression of the spine in association with bending forces of the rotating pelvis.
4. Relative flexibility of the seat can help determine relative flexibility of the spine.
5. Can greatly affect shear, and rotational forces on the occupant.

6. Occupant rebound motion after the input of energy is greatly influenced by the seat design, and can increase these forces. The seatback's rebound velocity at up to 150% of the initial velocity.
7. If the torso rebounds before the head has reached its rearmost position, the relative velocity between the head and torso will produce unequal rebound speeds (SAE # 930211).
8. In LSREMVAs, the rebound of the occupants in the front seat may be due more to the elasticity of the seat back than to vehicle deceleration.

Lack of seat uniformity makes LSREMVA cervical studies difficult to standardize. As previously stated, any given study cannot be used to generalize or apply to a given individual.

Ramping

The angle of the seat produces forces that may direct the occupant up the seatback. The target vehicle's rear may be deflected upward or downward depending upon the relative center of gravity between the target and bullet vehicles, resulting in the occupant traveling up the seat in a rearward position (relative to the car but stationary to the earth). The extent of ramping depends upon:

1. Angle of seatback deflection. Occupant ramping increases as seatback angle increases.
2. Slack of lap portion of the seatbelt. If rearward deflection of the seat causes slack in the seatbelt. Use of a belt or no belt may affect occupant motion.

Four Important Factors of Body Motion Leading to Occupant Injury Related to Seat Construction

1. Head displacement, translation, rotation
2. Differential motion of head, neck, torso
3. Occupant ramping up seatback
4. Occupant rebound

No fully instrumented rear impact tests are required by law for seat design. In high impacts seatbacks cushion the occupants from great accelerations. In low impacts the same qualities account for greater occupant acceleration in the rebound phase. The seatback design and resulting ramping may increase injury potential to the struck automobile occupants during low-speed collisions. There is a design trade- off between comfort and function/occupant protection.

AIRBAGS

Airbag Statistics

- Over 103 million (50.3%) of the more than 206 million cars and light trucks on U.S. roads have driver airbags. Over 77 million (37.5%) of these also have passenger airbags. Another 1 million new vehicles with airbags are being sold each month.
- Through September 2000, driver airbags have inflated in over 3.3 million vehicles in crashes. More than 560,000 passenger airbags inflated when a passenger was occupying the right front seat.
- The National Highway Traffic Safety Administration estimates that more than 5899 people are alive today because of airbags.
- Of the 62 drivers killed by airbags (48 females, 14 males), 40 are believed to have been unbelted, 21 are believed to have been using lap/shoulder belts (5 of these may have misused their belts; 2 of these were unconscious and slumped over their steering wheels so they were on top of their airbags; 2 used the shoulder belt only; 1 used the lap belt only). Belt use is unknown for the remaining driver.

By 1995, 100% of passenger cars have driver systems, and 87% have passenger systems. A total of 85% of trucks have driver systems, and 23% have passenger systems (SAE # 960665).

Airbags Are Designed to Save Lives

Overall, airbags have decreased belted fatalities overall by 12 and 27% of deaths in frontal crashes. It is estimated that 70% of frontal crash fatalities can be prevented by properly wearing safety belts and airbags (SAE # 922523).

Airbags save lives and decrease severity of injuries in exchange for increasing the number of minor injuries. There is an increase in abrasions, contusions, and lacerations. The body regions most frequently injured are the head and neck, upper extremities, trunk, and lower extremities. Of injuries received 90% are AIS I (SAE # 960658). Airbags actually increase the total number of injuries from vehicle collisions, especially in the Delta V of 16 to 32 km/hr (10 to 20 mph) (SAE # 960658).

Occupant groups at risk from airbag deployment include

1. Unrestrained
2. Elderly
3. Small stature
4. Disabled

5. Children
6. Out of position
7. Compromised health status of occupants

Significant factors that may influence injuries in MVAs with airbag inflation:

1. Severity of crash
2. Interior compartment intrusion
3. Age of restrained occupant
4. Health status including medications, drug, and alcohol use
5. Occupant height, weight, and proportions
6. Occupant position at time of impact/inflation
7. Safety belt wearing including proper positioning
8. Other occupants in the vehicle affecting the restrained driver
9. Loose objects in the vehicle
10. Pre-crash factors including pre-crash cardiac arrest, drowning, fire, and suicide

Airbag Systems

Airbag inflation is an explosion (200 mph) capable of killing a person in which the force is stopped in time by a nylon bag. It has four elements:

1. Crash sensors and controls
2. Inflator
3. Air bag itself
4. Diagnostic circuitry

Sensors

A ball in a tube or spring mass sensors are mounted in the front of the vehicle, and are designed to activate airbag deployment when a sudden deceleration occurs in the vehicle's forward motion of approximately 16 to 19 km/h (9 to 11 mph). Deployment starts 15 to 20 msec after initial impact.

Inflator

A pyrotechnic device inflates a gas generant (sodium azide) in 18 to 23 msec; 21 to 27 msec after impact the burning sodium azide produces nitrogen gas that expands the nylon airbag. The actual inflation takes 20 to 40 msec. The force exits and inflates the airbag at approximately 200 mph.

Nylon Airbag

Nylon provides a high strength/weight ratio, and is abrasion resistant with good elongation properties allowing for uniform stress distribution along seams with equally distributed forces. The driver's side is smaller and circularly shaped. It has less time and distance in which to inflate due to the steering wheel. Passenger-side airbags are rectangular, and three to five times larger than those on the driver's side.

Airbag tethers limit intrusion of the airbag into the driver's space and allow for more lateral expansion (untethered bags extend 250 to 300 mm toward the driver and untethered bags extend 380 to 510 mm). Airbags deflate in about 80 to 100 msec through vent holes in the back of the bag.

Diagnostic Circuitry

The circuitry has three main functions:

1. Entire system is evaluated every time the vehicle is turned on.
2. Continuous monitoring.
3. Operates a backup power source for inflation should there be system power failure.

Common Soft Tissue Injuries Resulting from Airbag Inflation

1. Abrasions, contusions to the head, neck and chest
2. Abrasions on the hands
3. Burns on the hands
4. Transient/permanent parasthesia of the chin
5. Injuries to the TMJs – external and internal
   a. Posterior capsulitis (damage to posterior lamina)
   b. Disc displacement
      1. Reducing
      2. Nonreducing
   c. Lateral capsulitis
   d. Adhesions in superior and inferior joint space
   e. Synovitis
   f. Hemarthrosis
6. Supporting structures
   a. Temporal tendons
   b. SM ligaments (Ernest syndrome)
   c. Teeth fractures and avulsions
7. Cervical strain/sprain
8. Cervical facet joint inflammation
9. Occipital neuralgia
10. Myospasm
11. MFTPs
12. Sphenopalatine ganglion neuralgia
13. Paresthesia at impact site
14. Compression neuropathies
15. Closed head injuries

Airbag Injuries Result from Both Direct and Indirect Trauma

"Smart" airbags that adjust their performance characteristics based upon the environment present at the time of the collision are in development. They are designed to "sense" the following:

1. Occupant seat position
2. Size of occupant
3. Child or infant
4. Severity of crash (closing speed)

There is a tremendous need for clinical case studies of injuries resulting from airbag deployment. Observations need to be documented and published by treating clinicians so engineers can have accurate information from the field.

SAFETY BELTS

Seatbelts are not perfect but nevertheless are among the most effective and simplest devices that help save lives. Although 49 states have seatbelt laws yet it is estimated that only 69% of U.S. citizens use seatbelts even when mandated. Seatbelts are designed to comfortably fit 80% of the U.S. population.

How Seatbelts Help Protect the Occupants

Seatbelts help in the following ways:

1. Controls ramping up the seat back.
2. May reduce the velocity of the occupant relative to the vehicle interior and thus reduce injuries resulting from occupant contacts.
3. Usage may minimize the potential of occupants to be out of position at the time of impact.
4. Allows the driver to be in position to remain in control of the vehicle after the impact.
5. May be effective in controlling forward rebound of the occupant.
6. Keeps occupant within the vehicle.
7. In frontal impacts, extends the time of "ride down," thus, effectively reducing the force on the occupant. This is accomplished by both structural design and stretching of the fabric.
8. Reduces the frequency and severity of occupant impact with the vehicle's interior (second collision). Occupants can still strike the vehicle's interior including dashboard, steering wheel, and windshield.

Most injuries from lap belts fall into the category of AIS I but can still cause permanent injury or death.

1. Increase in sternum fractures
2. Increase in neck sprains
3. Increase in thoracolumbar spine injuries
4. Increase in serious cervical spine injuries

All "increases" noted after mandatory seatbelt laws (Evans, 1992).

In addition, lap belts:

1. Can cause internal injuries upon frontal crashes or rebound from REMVA if the belt is positioned superior to the superior iliac crest of the pelvis.
2. Can cause severe strain on the lower back due to external forces.
3. Do not stop occupants from still striking the dashboard, steering wheel, or windshield with their heads.
4. Can cause "flailing" injuries of the lower extremities.
5. Can increase acceleration of the head/neck upon rebound in a REMVA.

A three-point shoulder harness (essential for airbag safety):

1. Can cause increased forces to the neck in a MVA even if properly positioned.
2. Can add rotational forces to the head/neck upon rebound (occupant rotates toward the door).
3. May actually increase likelihood of cervical injury in low speed collisions.
4. Reduce the incidence of serious injury by >57% (SAE # 912913).

Shoulder belts while very effective in saving lives can directly affect injury patterns and, in fact, cause injuries in low-speed accidents. Some common injuries include

1. Bruising and abrasions of shoulder, chest, neck, and abdomen
2. Cervical/head rotational and acceleration soft tissue damage

Even with seatbelts occupants can still directly contact the car's interior with their heads. This can vary according to the severity of the impact, location of the impact, and occupant body proportions.

VEHICLE DAMAGE AS A PREDICTION OF HUMAN INJURY

One of the most contentious areas of motor vehicle accident injuries is comparing the severity of injury to the cost of automobile repair. Although this argument at first

seems logical, upon further examination it is revealed to be fallacious.

Facts about MVAs and the resulting biomechanics and kinematics:

1. Biomechanics is an unpredictable science. Mathematically, scenarios can be predicted via computer modeling, etc. and information can be gathered following an accident by extensively monitored crash test dummies or other surrogates, but one little change in an almost endless supply of variables can result in dramatically different resulting forces and injury potential. In fact, measurements may differ between individual test subjects in the same carefully monitored crash test rendering predictions of outcome totally inaccurate. Applying the measured outcomes from crash test studies to predict an individual's chance of physical harm in a completely different accident is impossible. In fact, valid scientific papers are all quick to point out that the gathered data cannot and should not be used in this manner (SAE # 930211).
2. If there is truly a cost/injury ratio, then the higher the cost of repair, the more extensive the injuries to the occupants. In fact, often the opposite is true. Whenever a non-bumper impact to a vehicle occurs, large amounts of upper body damage occur to the vehicles involved. Vehicular panels are meant to crush, dispersing energy transfer over a longer period of time, and thus reducing the forces applied to the occupants. In today's vehicles with computerized components the cost of repair can be quite high with very little energy transfer to the vehicle itself. In fact, a recent crash test demonstrated the cost of repair to the same vehicle at the same impact speed varied by over $1000, depending on the angle of impact. In bumper impacts a great amount of force can be transferred to the occupants with little or no vehicular damage. As has been previously discussed, bumpers are not designed to reduce impact to the occupants – they are meant to reduce the costs of repair in a collision (Kaufman, et al., 1993).
3. In no instances do the amount of energy transfer and resulting injury involving humans directly correlate with the cost of repair to plastic, metal, etc. This is easily demonstrated by watching a football game. When a player gets hit in the head, do the managers look at the helmet and determine if an injury has truly occurred based on the amount of damage to the plastic helmet? On the other hand, when a person has an internal injury from a fall, is it correct to examine the floor upon which he or she landed and determine if an injury has occurred by the amount of damage to the floor? Of course not, yet this is attempted routinely in injuries resulting from MVAs.
4. Each accident must be analyzed as its own separate entity. The dollar amount to repair the involved automobiles cannot be correlated with injury potential.

When attempts are made to understand injuries that result from motor vehicle accidents many factors have to be included. The more the treating clinician understands about the forces involved, the more accurately treatment can be rendered. The cost of repair to the vehicles involved, however, is one factor that may be of interest for academic and epidemiological reasons but cannot be used as a yardstick for measuring the extent of injuries or the length of treatment time, or estimating the cost of service provided.

SUMMARY

Understanding the biomechanics and occupant kinematics in MVAs is essential for the clinician who treats soft tissue injuries. New car safety has dramatically decreased car accident fatalities in the United States. The result, however, is a new challenge to our healthcare system. People who would have died in the past are now living, but with extensive injuries. Soft tissue injuries are often dismissed as an annoyance or something that "you have to learn to live with." The truth is that they often can be debilitating and greatly affect the quality of life of victims and their families. "Learning to live with it" is not the answer. The answer lies in partnerships among victims, their families, treating clinicians, and third-party payers, partnerships based upon education and understanding. Too often a battleground is formed with experts representing vested interests lining up on each side. The result is a "double victim": one who was a victim of trauma from the automobile accident and also of the trauma of enduring medicolegal confrontations.

Treating clinicians can also become victims of sorts. It is commonly reported that carefully and thoroughly treating MVA victims is looked upon with distrust by third-party payers. Suggestions are being made that the practitioner cannot solely govern the formulation of a treatment plan (Farnham, 2001). Treating clinicians can become discouraged by the constant conflict of trying to help the patient heal and being castigated for trying to do so at the same time. As automobiles become more efficient in reducing deaths, the complexity of the injuries of the survivors will increase. Clinicians must strive continually

to increase their diagnostic and treatment skills, keeping the best interests of the patient first and foremost.

> It is one of the most beautiful compensations in life that no person can sincerely try to help another without helping themselves.

Achieving Insurance Independence in the Age of Managed Care

Christopher R. Brown, D.D.S., M.P.S.

INTRODUCTION

There has never been a better time to practice pain management in all of history!! How many of you reading this book feel this in your heart and mind? Unfortunately, probably very few. The statement is absolutely true, however, and this chapter will help you start finding your path toward success in pain management.

In the history of the most common affliction, pain, there has never been greater opportunity for successful healing. The technology and knowledge are there for predictable individual success. Opportunities that did not exist even a few short years ago are commonplace today.

Yet in the midst of these opportunities lies a dark specter hovering over every field in the healing arts: Managed Care. The very name brings depression into the hearts of many practitioners no matter what their degrees. It seems the powers that be in our different professions have already given up and handed the mantle of control of patient care over to accountants and actuaries.

The following concepts can be the first steps in dealing with your life, your success, and healing the pain of your career.

These guidelines are not for everyone. In fact, only about 5% of those reading this will actually grasp and accept the concepts presented. It has been said that about 5% of the U.S. population make the decisions that dictate the other 95% of the population's lifestyles. The same percentage probably holds true in the healing arts as well. To those 5%ers the future lies in two main avenues:

1. Individual decisions. You have to develop the courage to take control of your future. This means in body, soul, mind, concept, and most importantly, actions. Without that commitment, you are doomed to stand in the breadline of healthcare delivery waiting for the crumbs that are left, especially in the area of managed care.
2. Working together. Each of us desires to become successful. Contrary to popular myth, there is no such thing as a "self-made" person. Highly successful people are always striving to establish relationships with their peers. One of the buzzwords of modern times is "networking." Networking is an essential aspect of success to the healthcare practitioner. The days of a solitary person isolating him- or herself within the confines of a practice without other professional contact are gone. We have to literally join hands to help each other or our ability to provide individual care tailored to each patient's needs will be gone.

- How many of you who once loved to practice now wish you had not chosen your profession?
- How many of you have given up on the idea of success and are just hanging on?
- How many of you feel alone and vulnerable?
- How many of you are tired of being scared?

If this sounds like you and you want things to change, then perhaps you are one of the 5% who will become the

0-8493-0926-3/02/$0.00+$1.50

warriors of our professions. Our patients need our help. The rule of the day, however, is "physician heal thyself." In Micah 6:8, the author asks what God requires of His people. Is it the normal customs of the day? Is it rivers of oil or thousands of sheep? The answer, as is always the case, lies in simplicity: Seek justice, love kindness, walk humbly with your God.

All the techniques contained in this chapter are just means to help implement these ancient guidelines. Without these basic truths, all knowledge will be for nothing. These concepts are designed to lift those 5%ers to a level of practice few can imagine. The few who dare to take back their destiny. Success is a choice—so is failure. Which will you choose? There is no doubt in my mind that every person is a living, breathing, self-fulfilling prophecy. We become that upon which we dwell. In as much lie the attitude and fate of your practice.

Each day we redefine our life and create the environment in which we live. Each day holds the same potential as the next— no more, no less. Each day we choose to be happy, sad, mad, fulfilled, or empty. Each day has the potential of holding great achievement. We have the choice of processing the events of the day and deciding how to react. Events should not dictate our moods unless we make a choice to do so.

In II Timothy 2, Paul uses an illustration to demonstrate teamwork: In a house are many vessels: those of gold, silver, and pottery. All are different but all are used to enhance the household. Just like each vessel, each of us is different. We all feel, act, and react differently under any given circumstance. Also like each vessel, we are distinctly created and trained to serve a purpose. Each vessel uniquely made is designed to serve a purpose only it can fulfill; yet all work together for the common good. The purpose of this chapter is for each doctor and staff to find his or her unique position in the team to work for the common good of helping the patients whom we serve.

> When I've been successful, I've been in control.

> Katherine Hepburn

WHAT IS MANAGED CARE?

The concept of managed care has been around for quite some time. Historically, the industrial revolution is perhaps the best example of an actual "starting" point. Companies, along with the company store, had the company "doc" long before insurance was a concept in healthcare. If you were sick or injured, the company doctor took care of you. Costs were cheap and so were the results. In those limited days, that was the best that could be done. However, along the way, insurance companies decided they could make a large profit from illness, hence the concept of health insurance was born.

As a result of new technology, longer lives, new diseases, higher demand, etc., the costs and, more importantly, the risks involved dramatically changed the face of providing insurance coverage. As a result, the risk of predicting outgoing expenditures for the companies grew unpredictable. Insurance companies make money by accurate predictions balancing future risks with future income. That's the nature of the industry. Something in the formula had to change.

Make no mistake about it, capitalism is at the heart of our system. If insurance companies don't make large sums of money with limited risk, then there would be no insurance. The days of any of us thinking insurance companies are altruistic in nature have fallen by the wayside, and really that's OK.

For a while, the formula changed by dumping huge sums of money into the funnel and adding some restrictions such as demanding out-patient surgery instead of the traditional in-hospital. The result? On paper it looked good, but in the good old American tradition, the marketplace responded. Out-patient surgery clinics sprang up all over the place. The costs? — Of course, they escalated.

Now the real culprit became predicting the future. In other words, if the future risks could be controlled along with costs, then true savings and control could be realized. That, in essence, is managed care: risk control. Instead of the insurance companies taking on the risk, they are now sharing the risks with the providers and the patients.

Actually, a pretty smart and pretty fair deal, in a way; that is, in concept. The problem is that there are other entanglements as well. At first glance, it would seem that the hardest thing for us as private practitioners is an apparent drop in income. While obviously that doesn't make one jump for joy, it is not really the problem. The true problem is taking the decision process out of the hands of the practitioners and patients and placing it in the arena of a third party in some far-off land. It also robs doctors of their most precious assets: freedom of choice and the resulting happiness. Money comes and goes. Money not spent can be saved, invested, and ultimately multiplied. Happiness not spent today does not lead to happiness tomorrow. Happiness is a fleeting commodity with no shelf life. It is important for the doctors, their staff, and patients served that the provider and the whole personal delivery system be happy and customized.

Pain patients are unique and have to be approached that way. Many of these problems don't fit into actuary tables with the means now used. Currently one way of dealing with patients in a managed situation is to ignore them, shift cost to someone else, and hope they go away, or better yet, deny them treatment because a certain procedure or ailment does not fit into their coverage. This policy is expensive and absurd. It is costing everyone untold millions of dollars, and lives are being destroyed. These new plans have been carefully marketed as the

savior of our private system and for now, Congress and the American people for the most part are buying into it. Most practitioners are resigned to this story as their future, but if you want a different future, keep on reading. This is not the true story for our patients and us. A silver lining to this cloud exists and together we will find and live it. This chapter is not about insurance bashing, but rather taking control of our destiny.

What Does Managed Care Do for Patients?

Managed care provides a safety net of bottom line care for patients. It is, in essence, catastrophic coverage wrapped in the delusion of comprehensive care. It is the epitome of marketing. Promising something that cannot be delivered all the while convincing the recipients it's the best that can be done. If these principles were applied to you or me, it would be considered malpractice. Our society, however, has decided to grant special dispensation allowing for this misbehavior. The main drawback, to reiterate, is it leaves the patients out of the decision loop. Are people truly so stupid or misinformed that they should not be allowed to make their own healthcare decisions? In my opinion, the average individual is quite capable. I'm sure the people who devise these plans would whole-heartedly agree. In fact, they feel so strongly in that direction that they limit the patients' choices up front. As a result, the risk is reduced. If instead of three choices, the patient now only has two, then the risks are cut 33% right from the start. Now this is all well and good for someone with a runny nose or other predictable medical problems, but what about the pain patient who needs a multidisciplinary approach? It is hard to establish risk exposure so they are swept under the rug. Their choices are limited to the point of often not being able to get better within the system. This is where the 95%ers give up and throw in the towel. Guess what, though? Pain is one of the best motivators and people will continue to seek care from those who can heal them. Most patients who understand their problems and have hope are willing to own their health concerns and stop looking for a "big brother" to pay the bill. This is the area we will open your eyes to later. Don't give up — keep on reading; people will continue to seek care from those who can heal them.

What Does Managed Care Do for the Practitioner?

Managed care when you boil it down is nothing more than a marketing scheme to assure you of patients in the future, nothing more and nothing less. It is a system built on the premise of "if you don't join our plan, someone else will and you'll be left out in the cold with no patients." In fact, one of the early marketing fliers sent to my office was a picture of a dental chair with cobwebs on it saying, "this will be you in the near future." No joke, it really was that blunt. For a moment, please try to get rid of the emotion joined with this issue and take a cold hard look at the programs in which you are involved or have been tempted to join.

In the healing arts, the marketing truism is that a healthy practice needs to reinvest 5% of its gross back into the practice in the form of marketing to attract new patients. Five percent! Does anyone out there belong to any plans that only drop your fees 5%? If you do, then it is probably a plan that is cost effective, if there is an equal drop in marketing costs to offset the decrease in earnings. If your fees are dropped more than 5%, then how much more? Most of the managed care plans reduce fees about 35%!

Many practitioners have an overhead of around 60%. If an office only has an estimated profit margin of 5%, how can the practitioner make any money? By volume? Come on. It'll never happen. Let's play a game. A new marketing firm comes along and says, "Doctor, have I got a deal for you. I have a group of patients who may or may not come to you, but I'm willing to market them with no upfront costs for you at all. However, I'm going to ask you to pay me 35% of the gross charges (before overhead) for every patient who walks in the door!!!" How long will those marketing firms last? Oh, they'd do quite well. In fact, they've called managed care organizations (MCO) and they are flourishing. The main problem is not the patients, their employers, or even the fact that insurance companies want to make money, it is the fact that doctors are willing to fall back on their heels and pay exorbitant rates for marketing. Let go of your fear, docs. That's all MCOs do for you — nothing more and nothing less. Why do thousands of doctors work for reduced fees? Strictly out of fear and lack of self-respect and self-confidence. Those are the only reasons I can come up with. It isn't for the lack of income. Heck, I was losing money on every patient as it was, so financially I was gaining nothing.

There are all sorts of formulas on how to determine if you can afford to be involved in an MCO. The invasion of Normandy on D-Day could not have been as complicated as some people try to make it. All it takes to arrive at an answer for you personally is to do the following: Ask yourself, your wife/husband, and your staff this simple question: Are you willing to spend up to 35% of your gross income to market new patients into your practice? In real overhead terms, that means if all things remain the same, you could lose almost half your patients at an MCO reimbursement of 65%, keep the other half at full pay and remain relatively the same in terms of net income. Think about it! If the answer to the above question is "no," then you need to consider your role in managed care.

YOUR WORST ENEMY — CREATING AND ACCEPTING FAILURE

Quick, without thinking, who is your practice's worst enemy? Make a list:

1. MCOs
2. Your front-desk person
3. The IRS
4. The ADA/AMA/ACA, etc.
5. Your patients
6. Anyone else but you…

Wrong!

Without question, the worst enemy with whom you have to deal is you, and your attitude. The first step toward getting your practice life together is confronting the true enemy. To quote the wise sage Pogo: "I have met the enemy and he is us." We have blamed everyone but the one responsible for our failures. Managed care? It's not the fault of the insurance companies. They are out to make a profit and are doing so at record rates. They have paid the price of millions of advertising dollars and are reaping the rewards.

We have no one to blame for our circle of fear and failure but ourselves by allowing negative thinking and poor planning to enslave us. The first step in any type of recovery program is to admit there's a problem and own up to it. You have a choice for the kind of future you desire and deserve. You no longer have to fear the future. Success or Failure— Which Do You Choose? Life is a choice; success is a choice. The first thing you have to do is choose where you want to be. Are you happy with your life? Are you happy with your circumstances? Are you happy with your income, level of patient care, etc.? If the answers to these questions are "no" then you need to make a decision about change. Don't wait for the next MCO contact to come down the road and hope it doesn't take anything else away from you and your patients.

If you continue to practice the way you do now, then don't be amazed when you get the same results? Remember, "What you sow so shall you reap." Don't plant weeds and expect roses. Things will only get worse. If your practice is losing ground, then what are you doing about it? Sitting around and complaining, drinking too much alcohol, running away to the golf course and pretending the problems aren't there, blaming others, getting an ulcer, self-destructing…what?

There are answers to all the problems you have in your practice. Most are easy, some are hard. Up until now, outside forces were calling the shots. You need to make a decision to dispel the circle of fear surrounding your practice and control your own destiny. Do you want things to change? Not back to the way things used to be but rather better than they used to be.

The first step starts with a desire for some internal modifications. You're the captain and you need to start making changes in your life to ensure your success. Only when you understand the problems within and without can you develop a strategy for practice that will properly reward your efforts. It's been said that if you keep on doing what you've been doing, you'll keep on getting what you've been getting. In the past, that was a true statement. In this day and age of information overload and increasingly rapid changes, if you keep on doing what you've been doing, you'll get less and less. The "less" I'm referring to is not just money, but less of life including

- Less time with your family and friends
- Less time in meditation and worship
- Less peace in your heart and mind
- Less enjoyment of your profession

In other words, you lose your balance of life. You only have so much time and energy to give to all your projects. If one area of your life pulls away all your attention, then another aspect suffers. Energy can be neither created or destroyed — it can only be changed into other kinds of energy. Our lives are the same way. Every ounce of energy we use takes away from something else. Your time and energy are limited. It's always easier to talk about what we ought to do and harder to do it. The first step to achieving success is allowing yourself the right to succeed. This is a very important step that is often missed. Walter Bailey of Planned Marketing Associates refers to this as the "Permission Statement." Allowing yourself and your office to succeed above your previous expectations is an important psychological barrier that you must break.

Breaking the 4-minute mile was thought to be impossible and was not accomplished until Roger Bannister did in 1954. But did you realize that the impossible barrier was broken seven times that same year by other runners after Bannister succeeded? The impossible became commonplace.

Don't expect permission for success to come from anyone but you and those who care about you. Do you think other practitioners (your loving colleagues) who are unhappy want to see you succeed? If you discuss this with them, they will be glorious naysayers and try to keep you from changing. After all, one definition of someone else's success is "someone who is slightly less advanced than I am". Don't rely on your colleagues to applaud your desire to change. If you and your staff agree that it is OK to succeed, then you will have taken the first step to success. Most professional practices never get this far along the road to freedom. Modern doctors have been the victims of brilliant marketing. The doctor in our society, while still respected, used to be looked upon as the answer to our health problems. Through careful marketing and strategic positioning by third-party payers, the doctor

role has been perceptually altered to part of our healthcare system's problems. Healthcare deliverers charge too much, test too much, pad expenses," etc. So begin at the beginning and let it be OK within you to achieve success. You can't fool the person in the mirror. If you feel good enough about yourself to allow success, then success can follow. Before you achieve, you must believe. Deserving success, however, is more than a slogan. All the motivational posters and cliches won't do you any good if it isn't in your heart.

The best way for you to be successful is to deserve success. Those who are willing to pay the price of success in blood, sweat, and tears over a long period of time will be successful. Hard work, in other words, is the foremost key to success. On the other hand, aimless hard work will serve no purpose. You must work hard in the right direction. Success in any profession is not achieved by winning the lottery or luck, but rather by working incredibly hard over a long period of time. Allowing yourself to succeed means developing a work ethic that is second to none in your area of expertise. This means a no-compromise attitude toward working hard and doing the right things all the time. When your office affirms success, it also affirms a work ethic that will put others in second place. Managed care takes away the drive to succeed. Shedding that cloak and affirming your own destiny brings back the desire to work hard. Your practice once again becomes fun. Everybody wants to succeed but few people (5%ers) are willing to pay the price in terms of hard work. This step alone will help propel your office to the next level.

SELF-ESTEEM

Self-esteem is the value we place on the face in the mirror — ourselves. We all know people who would be willing to put in a job application as a speed bump and still feel inadequate. Feeling good about yourself is essential to your office's success. Constantly having a third party dictate your treatment of pain patients will wear you down over a period of time. The degradation of your clinical judgments by someone probably below your clinical skill level won't make him/her any smarter and will eventually bring you mentally down: the old "one bad apple…" scenario.

People who have low self-esteem are often unfocused, confused individuals who are easily frustrated. This is an almost fatal flaw in your position as a healthcare practice leader. People with low self-esteem create alibis for their failures. They also constantly blame others for their mistakes. People in this situation often think there is a "secret" out there somewhere that others know that they don't. It's difficult to work with these kinds of people in your office. It's even harder to deal with such a person over the phone dictating your clinical decision.

Individuals with great self-esteem will accomplish great things. Don't get this confused with the doctor who always argues with the speaker at meetings and always drives the most expensive car. Self-esteem allows for quiet control; one of the most self-destructive mechanisms is lack of control. Don't try to fool yourself. Self-esteem is something you must feel inside that you deserve. Developing a good work ethic and team effort will help fuel that inner engine that allows for success. Learning a self-esteem motto to be repeated over and over will not make success become a reality. If we keep telling ourselves we'll be successful, but not do the necessary mechanics, all we're doing is fantasizing. While positive verbal affirmations are important, unless they are linked with the mechanics necessary to bring success, we are only deceiving ourselves. Our words will be hollow and our self-esteem will never rise.

GOALS

Most successful people are dreamers: basically ordinary people who are not afraid to think big and dare to be different. Our dreams are our master plan, a direction in which we want to head. Yet dreams are often something so vague that they are nothing more than nebulous concepts with no definition. Goals, however, are our master plan, our step-by-step on how to live our dreams. Study any business success no matter what the field, and you'll find a common thread is having written, defined goals, and a plan on how to achieve them. What are your future dreams? Neither I nor anyone else can articulate them for you.

The first step is to have a clear vision of what you want: what you want to accomplish. For many people, this is the hardest step. Too many times our goals are built upon advice from others, what society thinks we should do, or plain old greed. None of the above will work for the long haul. At this point of your decision process, the details are not important. For those readers who love details, this concept will be difficult. The object is to determine where you want your life to go, not how to get there. It's often best at this point not to seek outside counsel unless your goals directly affect your family. Especially don't seek counsel from your professional peers. They often can be the worst naysayers in your life. Why would they want you to change? That may make them feel uncomfortable.

There's a line from an Amy Grant song "when the world around you sees you've changed, don't expect them to applaud…". Believe me, advice will come out of the woodwork at this stage and very little will be supportive. When the Wright brothers decided they wanted to make a flying machine, do you suppose the general consensus of their peers was supportive? I'm sure there would have been fellow bicycle makers lined up around the block with

advice about how their plan would never work, how foolish they were, and how the bicycle industry would not accept a flying machine. History is rife with countless examples of people who set goals who were laughed at, cursed at, and discouraged in every way. Leave your trusted colleagues out of the decision loop entirely until you know your desired direction. Even with your friends and spouse, the danger is the instinctive reaction of many people to start discouraging you, even with the best of intentions. This is a private matter: what you want, what you need. The time for sharing comes later in the process.

You need to think, articulate, and write down the goals. If you do this, you are ahead of 98% of all practitioners. As previously stated, this step can be very difficult for some. For others, it may take 30 seconds. Don't aim toward an illusion. A goal is often confused with a wish. To "qualify" as a goal the accomplishment must be measurable. Wishes are not. Examples of wishes that have been presented to me as goals are

1. Having peace and harmony in the office
2. Be the best I can be
3. Achieving financial independence

While these are fine thoughts, they are totally lacking in measurability. How will you know if and when they are achieved? For instance, "being the best that you can be" is a fine slogan for Army recruiters, but what does it mean? Can we all not be "better" every day of our lives? How about achieving financial independence? I recently read a survey asking people what that meant. For those with net worths less than 1 million dollars, financial independence meant hitting the million-dollar mark. For those with net worths greater than 1 million dollars, the figure jumped to 5 million. For those with net worths of 5 million, the definition jumped to 15 million!!! The moral of the story is, don't aim toward an illusion. Make sure the goals you set are yardsticks that can be held up to the light of scrutiny so you can see instantly whether or not you have hit your mark.

As a bonus, those around you will catch the passion as well and your team will remain focused. Will you fail occasionally? Of course you will. There will be days, even weeks, where you seem to be going in reverse. Some people who read motivational books get pumped up until the first adversity comes along and "pop" goes the balloon and they fall back to where they started. In fact, they may fall back even farther becoming bitter in the process. We all know those who live their lives in defeat. Success and goal achievement always progress in fits and starts. That's normal. The difference between winners and losers is that the losers quit when adversity strikes. That's why it's important to establish goals you care about enough that you are willing to overcome the rough spots and keep moving forward. If a goal is not worth working at, then it probably isn't really something your heart desires and your prophecy is true. It isn't worth your effort. So, in the process, be sure and match your goals to your gifts. That way each success builds toward the next. Disappointment in one area can actually motivate you to excel in another.

ESTABLISHING GOOD COMMUNICATION SKILLS

Communication is one of the toughest, most demanding, yet most rewarding skills you can acquire. Everyone needs to communicate better. The ability to communicate clearly is fundamental to success. Many people think good communicators are born, not made; that you either have it or you dont. Not true. Communication, both good and bad, is a habit that can be learned and mastered. Communication is interaction outside yourself with other people in a way that the right information is conveyed at the right time. It is, therefore, important not only to learn how to communicate, but when to do so. Content and time go hand in hand. Both aspects are essential. Communication involves much more than the practitioner lecturing to staff and patients. It also involves asking the right questions and patiently listening to the responses.

The first place to start with proper patient communication is where many practitioners make a fundamental error: asking patients what they expect as a result of seeking your care. In other words, what are their treatment goals? Sometimes you have to initially ignore your own preconceived notions of what the patient wants to achieve. Don't assume — don't guess…Ask!!

The object is not to cram your philosophy down patients' throats, but rather to make your goals and their goals the same. Asking, followed by listening, begins the building of a relationship with people that will overcome many barriers. By listening, you gain trust and make your patients more comfortable with you and your program. As a provider for an MCO, the relationship between you and your patient is initially based on the fact that you are willing to work more cheaply than the next guy. Patients are drawn to you because you are on a "preferred" list. Your communication with the patient is continually broken by the intervention of a third party. Communication is fundamentally flawed from the beginning.

If you fulfill patients' desires rather than dictate treatment, then everyone has the same agenda from the start. Too many times doctors try to dictate what pain patients should do rather than lead them in the direction that they already desire. This only propagates ingrained resistance from the word "go". It is a blueprint for failure.

One of the basic truths of any successful program is allowing the patient to "own" his or her problem. Until you and the patient are on the same side, how can you

expect success? Also, how can you define success with a patient until you know what he/she even wants?

We all know that some patients want 100% success all the time or they are not satisfied — unrealistical to be sure, but it is what they expect. That behavior needs to be determined up front. We've all had the bad experience of finding out after the fact that a patient's expectations were impossible to achieve in the first place. Unfortunately, this is often discovered after treatment has been initiated. It is much better to tell patients what can and can't be achieved based on their desires before therapy has begun. Most patients have a more realistic approach and have reasonable expectations. Knowing this up front greatly reduces the stress of practice and allows for true healing to occur. The point is, how will you know what the patient wants unless you ask the patient?

Fulfilling a patient's desires will allow him or her to be a partner in the healing process and assures you of clinical success as defined by the patient, not you. Gone are the days of the doctor/dictator. They are replaced by the doctor/partner. When you replace your dictator role with that of a partner, you will without question experience the following:

1. Increase in case acceptance
2. Increase in case success
3. Increase in your income
4. Increase in your practice satisfaction
5. Increase in your enjoyment of life
6. Increase in self-esteem
7. Decrease in your stress

PERSISTENCE

We are in a society built on drive-through windows, electronic access, and instant gratification. Persistence and hard work are not fashionable. They are, however, the fabric from which success is woven. This is the part that determines if your office will be successful in the age of managed care. Persistence will make your life great. Persistence allows you to fulfill your dreams.

It is easy to read any book on success, get all pumped up, and start the next day to achieve your dreams. It is something else, however, to do things right a month, a year, 5 years from now. Many people dream of the home-erun ball, winning the lottery, waiting for their ship to come, in, etc. You can compile all the get-rich-quick clichés you can think of, when, in actuality, financially successful people are the ones who make a plan and stick to it. That means, not only when it feels good, but also when there's major opposition. Persistence is what got us all through those long days of school. Dogged determination prevailed even when the days of practice seemed far away. We all remember waiting tables, driving cabs, or whatever helped make ends meet.

The fact that we successfully graduated and are in practice proves we all basically have what it takes to be successful, yet what has happened to our professions and us? For many, it has been a slow process of giving up a little of our practice at a time and persevering in the wrong areas, which have resulted in the erosion of private practice.

Many of us have just become sidetracked from all the distractions of modern practice life. Don't look to all of the excuses others use for their failures and for not achieving their dreams. Look within, forgetting excuses, and start looking instead for answers. Without dogged pursuit of your goals and dreams, you and your practice will never reach its full potential. How do you achieve a successful practice in the long run? How do you turn your practice around? How do you become the clinician you always dreamed you could be? You do the right things every day, day after day. Consistency and persistence will make all your plans fit together and reestablish your practice on your terms.

ESTABLISHING GOOD SYSTEMS

Without good systems, you will be like a car out of alignment. When you're going 15 mph, it seems to run pretty well, but when you're up to 80 mph the vehicle almost jumps off the road and you fight for control the whole time. With good systems come good habits. The old adage "practice makes perfect" is not true. Perfect practice makes perfect. Simply repeating the same mistakes over and over will not get you anywhere. Your systems need to be analyzed in light of your dreams and goals. Make your systems work for you and what you want to achieve, not vice versa. This is often a key to slavery in modern practices. Unless you have accomplished step one (asking permission to succeed with your staff), you will meet with major staff opposition. Don't let that happen or you will be taking a U-turn on the road to freedom. Watch out for a scary word — change.

Utilizing systems often conjures up thoughts of assembly-line healthcare delivery. In fact, however, developing good systems allows you to be more creative in your daily relationships with people. Good systems allow you more time to spend with your patients in an unhurried manner. Good systems allow you to utilize your time in a proper, effective manner, resulting in a more relaxed delivery of care. Your ability to properly serve your patients will increase while your stress will decrease.

Positioning Yourself for Success: The Road Not Taken

Positioning your practice for successful growth may go against conventional wisdom. It seems that nearly all the experts claim the future of healthcare delivery is a man-

aged care model. Whether this will be true for society or not, no one can answer. Whether it is true for your individual practice only you can answer. When you and your staff can develop the ability to make patients feel better about themselves when they visit you than they do anywhere else, then you will have practice success no matter what direction society takes. The healing and loyalty of pain patients are more often directed by how you treat them rather than by strict methodology.

We live in a consumer age. People, regardless of how much they complain about costs, still want quality and are generally willing to pay for it. Notice, I said "quality". You can't charge for what you can't deliver. So don't ever be tempted not to do what's right for your patients. Unscrupulous behavior will always negate success in the long run. The best practice position is to make co-decisions with your patients without outside interference from third parties.

Looking at the buying habits of people indicates an interesting trend. Often, price is not the main obstacle when it comes to purchases. The main concern is how to pay for it! Fitting a purchase of any kind into the monthly budget is usually the deciding factor when making buying decisions for something that a person wants. Planning your office's successful financial future must include accommodating your patients' financial obligations and creating avenues for payment.

There are two ends of the spectrum, both of which are disasters for practice growth when it comes to financial planning for patient payment. They are opposite in nature yet identical in results.

The first is denying all patients' personal financial obligations and relying solely on third parties for financial responsibilities. Without that personal commitment, there is no pressure to get well. We all have examples of that in our office; two categories are welfare and cap programs. Across the nation in all disciplines of healthcare, these are generally the two groups of patients who don't show for their appointments, don't do what you ask, and generally feel no responsibility for their actions. The result is financial and case failure. Financial commitment often begets healing. It is just human nature.

The other end of the spectrum is putting all the obligations on the patients upfront. In a utopian society, that would be wonderful. I have heard of practitioners — perhaps you're one of them — who always demand payment in full, upfront from everyone all the time. I wish it could be that way, but realistically if you want to build a solid volume, you must make some accommodations.

The most predictable strategy is to provide reasonable avenues for payment on your terms. Let me repeat, on your terms. You can't let patients say, "just bill me, doc, or your practice will be swallowed up. It's amazing how in one billing cycle you go from being the patient's savior to the villain. It builds resentment from you, your staff, and the patients. Everybody ends up stressed from the whole process. However, when established financial plans are in place and followed with persistence, the system will work and produce satisfied patients who are willing to pay for your services.

You can never provide healthcare for every person in your community. It physically can't be done. You have to make a choice. Which patient would you rather position your office to provide care for?

Most practitioners daily set themselves up to provide care for the patients with the least invested in their health — patients who tax you and your staff emotionally and financially. Why not choose to serve those who are willing to invest in their care and provide you with opportunities to provide treatment options that will give them a chance for true healing and a pain-free life? We as practitioners are faced with two basic choices:

1. Follow the crowd. Drop treatment goals so low that we give the cheapest form of care and fool our patients into thinking they are getting all our professional and personal skills can offer. The scenario will fill the model for managed care cost containment. The risk is placed on your shoulders and off those of third parties while letting someone else make your decisions for you and your patients. This is the road most healthcare practitioners are traveling. Is this what you want? Will this satisfy your life's dreams?
2. The road not taken. Develop high standards for your program, learn to properly communicate, carefully monitor its successes with outcome's measurement, skillfully market the type of patients you wish to treat, and provide reasonable avenues of payment for your patients. All decisions for your patient's treatment will be between you and your patient. Is this what you want? Will this satisfy your life's dreams?

Two roads diverged in the woods and,
I took the one less traveled by
And that has made all the difference.

Robert Frost

Most people (95%) will not take this road. That leaves endless opportunities for those of us who choose to place ourselves in the top 5% of our fields. There are lots of patients who want to get well and demand the best. In essence, there is very little competition when it comes to excellence. There is much competition for mediocrity. But how are patients to know the difference? Can we assume because we know ourselves that our patients should auto-

matically be aware of our skills? In reality, what if our clinical skills are just mediocre? What if we are just another office? Let's face it, if patients perceive all practitioners as being equal, then why not choose the cheapest? If you want a shirt and see the exact one you want in two places, why not choose the cheaper of the two?

To free your professional life, you must be able to make it obvious to patients that your office is different. Different is good. People like different. The first step in becoming a different and unique office is to do the things you love. You have to develop uniqueness about your practice — a position that allows your talents and those of your staff to stand out in the crowd.

USP

In the business world, this is known as a USP (Unique Service Position). In the healthcare sense of the term, it can be thought of as a type of speciality determined and defined by your talents, desires, and state practice laws. In other words, what makes you different from any other office so that people are willing to become your patients? Setting your goals also involves identifying your gifts. Make your job your love, your hobby. Ask yourself and your staff, "What does our office do better than any other office?" Sifting through all the different procedures can be difficult and you can expect some false starts. That's fine. It's part of the process. Don't become obsessed with your failures, but rather focus on your strengths. It may help to actually list the procedures that you consider more fun than work and determine which ones you do better than anyone else you know. When you find that area, then that can become your USP — the aspect of your office that makes you so unique that people are willing to bypass other clinicians to come to you; aspects of your practice that people are willing to gladly pay for even if their insurance companies fail to do so.

Some examples of USP in different disciplines are:

1. Dentistry: pain management, cosmetics, time spent with the individual
2. Medicine: work-related injuries, pain management, time spent with the individual
3. Chiropractic: myofascial therapy, corrective therapy, time spent with the individual
4. Massage: sports injuries, therapeutic touch, time spent with the individual
5. All disciplines: nutritional counseling, vitamin and botanical complementary care

As you may have noticed, one theme is listed consistently: time spent with the individual. Managed care is forcing clinicians to become more cost effective. One of the most obvious ways to do that is to spend less time with each patient. In this world of being a number, and computerized telephone screenings and statistics, people crave attention. It's sad to say but in today's world of practice, spending time with your patients is indeed a USP. It also touches one of the most basic of human needs: the need to be loved and paid attention to. Have you ever heard of patients complaining that a healthcare deliverer spent too much time with them? Of course not. But how many times have you heard just the opposite? No matter what your USP, the element of spending time with your patients is the most valued trait of all.

You must not only find your USP, but also develop it to the best of your ability. That will mean staff support in the growth process. It also will probably mean furthering your education. An important aspect of change and growth is making technology a strategic resource. Learning the importance of strategic technology is an important step because it affects every aspect of your practice. You need to ask the right questions and be sure you are getting the right answers.

It means your practice will become a work in progress. Make sure your USP aligns directly with your goals and that of your staff so your life will grow in the process. It will also help you achieve the all-important balance needed between your professional and personal life. Balance doesn't come easy. Most successful, happy people lead a well-rounded life. In the long run, this provides more reserves of energy, depth of character, and a stress-free perspective on life.

> It don't come easy.

PATIENT PROFILE

After you have determined your USP, you need to define what type of patient you want to serve and are able to serve best. This is the next logical step in your journey toward freedom of choice in today's healthcare environment. It is also one of the most important elements of a successful, happy career. You can't please everyone. You can't serve everyone. When first starting to practice, most clinicians try to be all things to everyone. It's impossible but it's also natural to try. After all, most people who go into healthcare fields sincerely want to help others.

That's the way it should be. However, those who are wise learn early in their careers that you can't be all things to everybody. Those who try end up exhausted, burned out, and bitter. Most providers learn this lesson slowly over a long period of time, eventually finding a niche from which to practice. Any healthcare provider by accident or by design will develop a patient profile. We are constantly reminded of situations that we often take for granted. Let's look at a few examples in the business world. Did you know that McDonald's target market is only 15%

of the entire population in the United States? In other words, around 85% of American citizens don't go to McDonald's. Rather than be discouraged about the numbers, McDonald's markets to the people who will go to McDonald's. When you enter under those golden arches, you know what you will get. It's all the same wherever you go. So what do you get at McDonald's? You get predictable food (not necessarily good), fast, at a cheap price. You know what you'll get, how fast you'll get it, and how much it'll cost in a clean, well-lit environment. Cloth napkins and candlelight? Forget it. A clown, maybe, and a toy in a Happy Meal™, but that's about it. Don't expect a sirloin steak or a private chef. You won't find them there. There are those people who want steaks and private chefs. There's nothing wrong with that. However, how much success would McDonald's achieve if they, along with their Big Mac™ and fries, offered filet mignon, baked Alaska, and a sushi bar? More than likely, it would spend a lot of money and actually lose hamburger sales in the process. Yet with focused marketing, McDonald's has consistently been one of the fastest growing companies in the world, all the while relinquishing 85% of the market. It can't please everyone but is determined to please the customer who wants its products.

Most healthcare providers carry the mental image that they have to serve everyone all the time. No matter how hard you try, you just can't do it. You have to define your population. If you choose to accept a managed care program, you are already defining your patient population based upon price. In fact, your target market is chosen for you. You may compete somewhat with others within the provider network, but the defining paradigm is price based. You have to decide if that is the arena in which you want to compete. If you've made the decision not to go the managed care road, then you and your staff need to define what type of patient you want to serve.

There are many ways to define your patient population. Many practitioners opt to define their patient population by procedure. If a person needs a certain procedure(s), then he or she fits the profile. There are other ways, though, that may help define your patient base. The possibilities include:

1. People without insurance who pay with cash, credit card, or check
2. People with only certain types of insurance.
3. People with indemnity insurance
4. People who pay cash upfront regardless of insurance coverage
5. Patients in a certain age bracket
6. Patients who can come in at certain times of the day
7. Patients who always show up on time
8. Patients who don't cancel their appointments at the last moment
9. Walk-ins
10. Emergency service

Defining a patient population is as diverse as the wants of the practitioners. It may take some creative thinking and time to find out just what type of patient fits your practice's needs. Discuss this with your staff. Their input is of the utmost importance and is crucial to your force of growth.

The 80/20 Principle

When beginning to define your patient population, keep in mind the 80/20 principle. In fact, this principle is a great yardstick with which to measure all procedures and activities. Train your office to think in terms of 80/20.

Thinking in terms of 80/20 allows you to compare relationships, time, and productivity. Because 80% of your income will come from 20% of your patient load, the first place to begin modifying your practice is to define who those patients are. Concentrating on those patients will bring the most effective results. What does concentrating mean? It can mean marketing, continuing education, or just scheduling extra time with them to help establish better relationships. As a result, if those same 20% give you 80% of your practice pleasure, then your personal satisfaction and that of your staff will increase as well. The line between work and pleasure will begin to blur and practicing will become fun again.

The second step is to do something about the weaker 80% of your practice that only accounts for 20% of your production and satisfaction. Eliminating your biggest source of irritation may be the best place to start. For instance, one of the biggest aggravations and revenue losses for many practices are last-minute cancellations and "no shows". The lost time literally adds days to your work schedule and can be the biggest overhead costs that you are forced to bear. Instead of the doctor storming up to the front desk and yelling at his receptionist, why not start a "no cancellation policy" for your patients? Might you lose some patients in the process? Yes, but guess what? They will now be messing up someone else's schedule and not yours. Not only will you drop the aggravation, but you will also become much more productive and regain control of your schedule. Now you guide the schedule. Before it was left up to the weakest part of the team, the patients who saw very little value in your services. In other words, utilizing this technique instead of being controlled, you are able to take control and guide your practice in the direction you choose. As a result, one of your patient profile attributes may be people who value your services enough to keep their appointments.

Some patients will really challenge your staff. After all, they have no control over their lives—so why should you? That's why it's important to have defined goals with

team members who back up one another. This especially includes the doctor. Nothing will break the morale of the staff more quickly than a doctor undercutting a staff member after he or she has gone through the trouble of enforcing a rule upon which you have all agreed. It takes courage at first to hold fast to the rules but it pays off rapidly. Your office collectively makes up its mind and collectively enforces it.

Unless you decide to change the direction of your office entirely, chances are 80% of your patients do not fit your desired profile and 20% cause you most (80%) of your aggravation. Changes must be made on purpose. Your office will not improve by accident. Your focus must develop an 80/20 mentality to grow and regain your practice freedom. You must constantly ask yourself, "What is the 20% that is leading to the 80% and which 80% is it leading to?" You must never assume that your office is on automatic pilot and your problems are solved. 80/20 thinking is not linear but rather part logical and part intuitive. Your practice situation cannot be analyzed strictly by the numbers. Allow your creativity to bloom. You will be amazed at how rapidly and effectively implementation of shared changes will positively affect the flow of. You will certainly get more from less. More personal time, more fun, more income, more satisfaction, and more happiness. The less? Less stress, fewer patients to see every day with better results, less conflict, and less frustration. There are really no boundaries to your success. As you grow, the boundaries grow as well.

The first reaction of many clinicians is that there is little chance of escaping from the low yield activities. They feel these time wasters are an essential part of their service to others. "I have to do XYZ," or put another way, "my patients would leave if I don't…" If you catch yourself thinking this way, think again. There is a great deal more leeway in your practice than you are accustomed to believing. The point of successful utilization of the 80/20 principle begins when you begin to think unconventionally. Following the crowd will get you just what the crowd gets. Don't expect anything more. But even if dropping low-value activities does require a radical change in your practice, you can deal with it. The other alternative is to watch your practice diminish a little at a time. Success and happiness will never be achieved.

Can you entirely eliminate problem areas? More than likely not unless you somehow decide to not treat or hire human beings. You can minimize those most troublesome areas, however, maximizing your happiness and productivity in the process. When you have identified the activities that take 20% of your time and yield 80% of the desired results, make plans to turn the 80/20 around. A short-term goal that is achievable is to nudge the 20% of the time spent on productive activities up to 40% within a year. This one change can have a profound effect on your practice.

Another wonderful by-product is being able to take more time off. Instead of having your time stolen one appointment at a time, those hours turn into days, which you and your staff can utilize for continuing education, community service, or just rest. The result is a happy, stable staff with sufficient time away from the office to remain excited and cultivate a positive mental attitude.

The 80/20 Principle by Richard Koch lists several ways to implement this rule into your every day life:

- Celebrate productivity rather than raise average efforts.
- Look for the short cut rather than run the full course.
- Exercise control over our lives with the least possible effort.
- Be selective, not exhaustive.
- Strive for excellence in a few things, rather than good performances in many things.
- Delegate as much as possible.
- Choose employees with extraordinary care.
- Only do the things we enjoy the most and do the best.
- Look beyond the obvious to uncover the ironies and oddities.
- In every circumstance work out where 20% of the effort can lead to 80% of the positive results.
- Calm down, work less. Rather than pursue every possible opportunity, target a limited number of very valuable goals where the 80/20 principle will work.
- Make the most of those few "lucky" streaks in life when we are at our creative peaks.

Remember the quote from Arnold Palmer, "Golf is a game of luck. The more I practice, the luckier I get."

The greatest part about utilizing the 80/20 principle in your life is that you do not need to wait for someone else to do it for you. You have the ability to turn your life into the one dreams are made of. You remember the dream for which you worked all those hours in school? The one that somehow got lost in the daily struggle to survive?

You have the ability within you to multiply all your highs and subtract all your lows. Your life can take on more and more relevance and shed the energy-draining time wasters. You can isolate all the great aspects that make you unique both personally and professionally and climb out of your daily rut. As an even greater plus, you can help your staff and patients achieve more than they had expected. People will appreciate you more because you appreciate them more. If you want to get the most from 80/20 thinking, you have to integrate it into your life. Will it take some effort? Of course it will! Let's face it — like it or not, changes are coming down the road for healthcare providers. The choice is not if your practice

will change but rather how it will change. The choice of how you will change and adapt for your benefit and those of your staff and patients is still up to you.

MASTERMIND ALLIANCES

A mastermind alliance is a relationship built when two or more minds work together toward common goals. The mastermind principle lets you utilize the full strength, experience, knowledge, and training of other people with similar desires. You can overcome any challenge or achieve any goal in your practice if you use the mastermind principle effectively. No one has ever achieved outstanding success in any field without applying the mastermind principle. All great minds are stimulated to creativity through contact with others of like desires. Without this contact, you will run out of creative energy and get off track. The steps of forming a mastermind group are

1. Determine your purpose. A group cannot determine a purpose if the individuals have not done so first. You must be sure the purpose of the group is the same as yours. This does not have to be down to the detail, but very close. Once you have decided what purpose a group will fulfill for you, then move on to step two.
2. Select members of your alliance who will help you attain your goals. Don't select members because you know and like them. Save those relationships for social settings, if desired. Make sure each member has the ability to work in harmony with others. A person who totally dominates meetings will adversely affect the group. Discord will destroy your alliance. There must be a complete meeting of the minds without hesitation from any member. In the mastermind setting, personal ambitions must be subordinate to the success of the goals and purposes of alliance. The harmony of your alliance is built upon mutual respect and honesty.
3. Determine your rewards for being involved with a mastermind group. They can be whatever you find is needed. These will vary according to each individual member's personal needs.
4. Set a time and place for regular meetings. Your alliance must be a priority or other commitments will get in the way.

Your professional mastermind alliance does not have to consist solely of others in the same profession. The beauty of these relationships is that most creative solutions to obstacles often come from outside your given area. Individual healthcare providers are often guilty of thinking they have the market cornered on problems, thinking others don't understand their problems "because they're not like me".

A problem that is unique to any given profession does not exist. The same challenges occur in chiropractic, dentistry, medicine, massage therapy, automobile repair, selling shoes, etc. As long as you are dealing with people and their money, the basic problems are all the same; only the individual circumstances and procedures change. Allow yourself the privilege of tapping into the minds of people with a common purpose but different perspectives. It is an exhilarating experience.

MARKETING

Once your USP and your 80/20 patient profile are defined, then the next step is to let others know about it, in other words, marketing. As you know, marketing carries many connotations, from sincere helper to used car salesman. Marketing should be a natural extension of your personal self. A multitude of excellent marketing courses, books, and tapes are available. The most important aspects of any marketing program for your USP are

1. It fits with your desires (goals/focus).
2. It's easy to implement.
3. It's cost effective.
4. It has measurable results (it works and you can prove it).

Note that one of the aspects not listed is "expensive." Some practitioners think if you throw a lot of money at a marketing program, it will be effective. Not so. Some of the most effective marketing programs are inexpensive. While it may be a good ego boost to see your smiling face plastered all over town, it may do nothing for your practice. Remember one true fact: people want to feel special. Despite all the problems in the modern healthcare delivery system, people still generally respect caregivers and want their personal attention. Which is better: working in five extra patients a day to pay for a super expensive marketing program so you can see even more patients or perhaps seeing five fewer patients and spending more time with each one individually so your overhead is less and your patients are happy with your care? Expensive and effective don't always go hand in hand.

When making paradigm shifts within your office, start with the simple marketing programs first before you get into expensive, extensive ones. Include your staff in marketing decisions. They will appreciate it and be able to provide creative ideas that can be tailored to your individual needs. Marketing should be fun and productive. If it is not, then your goals and desires are not in alignment. Our main obstacle is not managed care or third-party payers and other various programs, but rather our lack of self-esteem, lack of determination, and lack of desire to

succeed. Positioning yourself for success is a matter of doing the right things, at the right time, all the time, and developing a plan and sticking to it. There is no doubt about it. There has been no better time to practice in the history of mankind. Opportunities for greatness are all around you. The choice is yours.

FINAL THOUGHTS

One of the main problems as practitioners is that we feel we are facing the future alone. Make no mistake about it, private practice and clinicians being the decision-makers are under attack by well-financed organizations. Still, every crisis creates great opportunity. The fact that so many practitioners are willing to follow the winds that blow them in any direction leaves those who wish to develop happy productive lives almost unlimited opportunities. By nature of the trends, niche markets are being created for creative thinkers at a greater rate than ever before. The avenues for healthcare practitioners to be successful are virtually unlimited and growing more so every day.

Don't expect to do things the way you used to and get good results. It won't work. Don't expect our overseeing governing organizations to help us. Just as our patients fall into the cracks of the healthcare system, we, the creative thinking practitioners, fall in the cracks of our representative organizations. It's important to associate with people of like minds to recharge your batteries and allow the creative juices to flow. There's an old saying, "We grow too soon old and too late smart." If you wish to be successful, then make the choice to do so. Don't follow the crowd. It will take courage to take those first steps but the results as defined by your goals that lead to your dreams will be worth the effort. Proverbs 1 through 5 explain how to achieve happiness, the ultimate goal of everyone who is reading this book. The following are the essential keys to happiness:

1. Wisdom. The ability to know what is right, true, and enduring; good judgment; knowledge; to accept counsel, criticism, and instructions without anger; and to always keep learning.
2. Understanding. Being able to perceive with your senses. To be able to internalize your knowledge with total comprehension and apply that knowledge to your individual circumstances.
3. Discretion. The ability to break down information into specialized parts. To be able to digest information, categorize, and sort data so decisions can be made simpler in lieu of distinct circumstances and desired results.
4. Insight. Perception of the truth and hidden nature of things. Insight is developed as a result of the culmination of all achievements. It is the ultimate strength from which you may operate. Insight is the beginning and result of wisdom.

Surround all these gifts with vigilance. Be attentive. Always watch, work, and hone your skills. Be disciplined. Your practice life is like that of an athlete who must constantly work out to keep his/her physical attributes ready when opportunity for success presents itself. If you're attentive, then your insight will allow you to recognize opportunities and give you the skills to achieve them. It will take care of you far beyond measurable achievements. You will be successful even when logic says you can't. Like the old maxim, "Those who say it can't be done often get in the way of those doing it." Success doesn't happen by accident.

Developing wisdom, understanding, discretion, and insight takes hours, months, and years. Success is the point at which preparedness meets opportunity. If you wait for things to happen and only then get ready, you will meet with frustration and a sense of loss. Opportunity knocks all the time. The trick isn't being there to open the door at the precise moment but rather living in a state of preparedness with the ability to react. Success often comes disguised as a problem rather than being perceived at first as "golden." Surround yourself with people who are positive and believe in your mission. Apply these truths to your life and you will always be happy. Seek and develop these skills and, no matter what, your success will never be in question. You already have the tools to develop all the opportunities you will ever need. Your talents in conjunction with proven applied principles will assure your success. You have a choice for the kind of future you desire and deserve. You no longer have to fear the future. Success or failure— which do you choose?

81

A Practical Approach to Outcomes Measurement

Michael E. Clark, Ph.D. and Ronald J. Gironda, Ph.D.

INTRODUCTION

Outcomes assessment has become one of the "catchwords" of the 21st century among healthcare systems. With the advent of the Joint Commission for Accreditation of Healthcare Organizations (JCAHO) pain standards (2000), insurance company practice parameters, and state and/or federal practice guidelines (Agency for Health Care Policy Reform, 92-0032; 94-0592) outcomes assessment has become a necessary component of pain practice irrespective of practice setting. A multitude of pain outcomes instruments or outcomes systems exist, yet little guidance is offered as to how to choose an appropriate instrument or set of instruments. Indeed, a literature search on the topic of "pain treatment outcomes" yielded numerous articles reporting pain treatment results using a variety of outcome measures, but no articles focusing on how to select an appropriate outcomes method.

In the absence of specific selection criteria, practitioners' choices of outcomes methods may be determined more by happenstance than need. Often, instrument availability, economics, and marketing serve as the primary determinants of instrument selection rather than outcomes objectives or empirical findings. The end result may be the selection of an outcomes measurement system that has limited reliability or validity, fails to meet the needs of the practice setting, requires extensive financial or temporal investments, or, on occasion, overwhelms the practitioner with mountains of irrelevant or even inaccurate data.

This void in outcomes assessment guidance is remedied in the ensuing pages. We offer clinicians a practical means of selecting and using outcomes measures in an efficient and rational manner. In this regard, we first briefly review the recent history of healthcare outcomes assessment and the factors that contribute to its importance in today's pain practices. Next, we discuss issues that need to be considered in the selection of outcomes measures, and briefly review the most useful pain outcomes instruments. Finally, we outline a method for developing an appropriate outcomes methodology based on specific practice needs and outcomes interest. Note that our intent is not to promote any specific outcomes methodology or outcomes instrument. Instead, we hope to provide a method whereby any clinician can determine what available instruments best meet the needs of his or her practice and the limits of the setting.

Definition of Outcomes Measurement

Outcomes measurement refers to the systematic collection and analysis of information that is used to evaluate the efficacy of an intervention. Systematic collection requires that data are collected in a consistent, repetitive manner using the same outcomes measures or instruments. Analysis refers to the process of summarizing and reviewing the data to identify any meaningful trends. Often this second stage of outcomes measurement is underutilized. Data may be collected but are either filed away and not used,

0-8493-0926-3/02/$0.00+$1.50

or data summaries are prepared but never reviewed by the most appropriate individual or body.

Outcomes measures usually are collected prior to and following an intervention. In healthcare systems, usually we assume that the changes in health status we observe are the results of our intervention efforts. However, although outcomes measurement may involve very sophisticated procedures that are grounded strongly in science, in most cases it lacks the rigor of more formal research endeavors. Thus, it is important to remember that without additional data gathered in more controlled settings we cannot be certain that the observed changes result directly from our treatment efforts.

Historical Perspective

The first systematic use of outcomes measurement in healthcare dates to the early 1900s when Ernest Codman, a surgeon at Massachusetts General Hospital, introduced a method of monitoring surgical outcomes (Campassi & Lee, 1995; Tarlov, 1995). Subsequently, in 1950 healthcare outcomes were included as one of three medical quality management tiers (Tarlov, 1995; Iezzoni, 1997). However, not until the late 1980s and early 1990s did healthcare outcomes monitoring became commonplace. In 1988 Ellwood proposed that an outcomes management technology be implemented to monitor the quality of healthcare service delivery (Ellwood, 1988). With the proliferation of managed care organizations, the focus on enhanced service delivery quality inherent in the early outcomes management approaches has expanded to include cost containment, improved patient satisfaction, and increased quality of life as additional goals.

Rationale for Outcomes Measurement

There are numerous reasons why pain treatment outcomes monitoring has become an integral part of today's healthcare delivery systems. In some treatment settings outcomes management is mandated by regulatory bodies. For example, outcomes assessment is part of the State of Maine's Department of Public Health's standards for pain management (Dreyer, 1998). Similarly, major healthcare accreditation organizations now require that the components and results of pain treatment efforts of member facilities are monitored. The Rehabilitation Accreditation Commission (CARF) has been at the forefront of these efforts by developing elaborate outcomes standards for pain treatment programs (1999). JCAHO (2000) adopted standards for pain management in Acute Care and Behavioral Health settings that were implemented beginning January 2001. In addition, the American Academy of Pain Management (AAPM) pain treatment accreditation requirements mandate that an outcomes management system be in place (1997).

Other national and local bodies also have begun to recognize the necessity of monitoring the effects of pain treatment. Pain treatment guidelines, which include standards for pain outcomes monitoring, have been developed or adopted by the Agency for Health Care Policy and Research (1992, 1996) and the American Pain Society (1995). These guidelines incorporate recommendations for pain outcomes monitoring, as does the National Pain Management Strategy implemented by the Department of Veterans Affairs (2000).

With the increasing emphasis on medical care cost containment, healthcare insurers have become more interested in the cost effectiveness of pain treatment (Kulich & Lande, 1997). As a result, outcomes data may be required to justify charges for selected pain interventions. Marketing efforts also may benefit from developing an outcomes measurement system in that competition for the healthcare dollar is rampant and evidence of enhanced outcomes and treatment efficacy may increase patient referrals. Additionally, professional responsibilities and ethics may imply the necessity of monitoring outcomes. For example, many professions require that we not implement treatments that we know are harmful or ineffective. Yet, if we do not monitor outcomes we have no way to determine whether our efforts are effective. And finally, outcomes data, although they are not generally as reliable as data from laboratory studies, provide us with an empirical basis for treatment decisions where before we had only opinion based on anecdotal observations of the effectiveness of treatments.

Barriers to Pain Outcomes Monitoring

Although regulatory, accreditation, professional, consumer, and payor interest in pain outcomes has stimulated a rapid growth in the development of pain outcomes management systems, it is important to remember that the initial and primary purpose of outcomes management in general, and pain outcomes assessment specifically, is quality improvement. Unfortunately, numerous examples exist where pain outcomes data have been used in a punitive (e.g., denial of claims, denial of services) rather than a quality improvement fashion, particularly when cost containment is the ultimate goal. As a result, some providers are reluctant to adopt rigorous outcomes methodologies. Yet it is our opinion that implementation of an appropriate pain outcomes management system provides the best defense to the misuse of data cited above. For example, the data cited to deny claims or services typically originate from local, regional, or national practitioner databases. These data reflect considerable variability in treatment approach, practitioner experience, and effectiveness and rarely include pain-specific outcomes. In fact, they are not true outcomes data at all, but rather reflect patterns of professional practice. The collection of practice-based,

pain-specific outcomes data using reliable and validated instruments provides an excellent means of challenging denial practices, particularly if the outcomes information also demonstrates reductions in medical utilization (i.e., cost savings) following pain treatment.

Of course, numerous other barriers to adoption of a pain outcomes methodology exist (Rudy & Kubinski, 1999). Staff time to collect, summarize, and review data is necessary, and training in instrument administration and scoring may be required. Administrative approval and support must be obtained, along with funds to cover related external costs (e.g., instrument purchase, trainer or consultant's time). Patient and staff resistance and burden (e.g., time to complete the measures) should be anticipated and minimized prior to implementation.

FACTORS AFFECTING THE SELECTION OF OUTCOMES MEASURES

Several factors influence the selection of appropriate pain outcomes measures. They include the objectives of outcomes measurement, the type of pain treated, and the characteristics of the pain service setting.

Objectives of Outcomes Measurement

Pain outcomes methodologies differ in their objectives. Patient-focused outcomes approaches are concerned primarily with evaluating and improving patient treatment outcomes. Service delivery outcomes approaches focus on monitoring and enhancing pain service delivery systems. Professional association outcomes guidelines or standards (International Association for the Study of Pain, 1991) often address the former, while standards for service delivery outcomes tend to originate with accreditation organizations (e.g., JCAHO). It is important to note that these two approaches are not mutually exclusive. More elaborate outcomes systems may include aspects of each. Indeed, some pain accreditation bodies (AAPM and CARF) require that both types of pain-related outcomes be addressed.

Patient-Focused Outcomes

Outcomes methods that are patient focused primarily are concerned with treatment-related changes in patients' pain experience. These are the outcomes most familiar to pain practitioners. To assess treatment-related change, at least two administrations (pretreatment and posttreatment) of the relevant outcome measures are required. Often a series of measures collected at intervals during the individual's treatment provides the best picture of progress and may give more information regarding the efficacy of changes in treatment (e.g., altering the type or dosage of pain medications) occurring within the overall treatment episode.

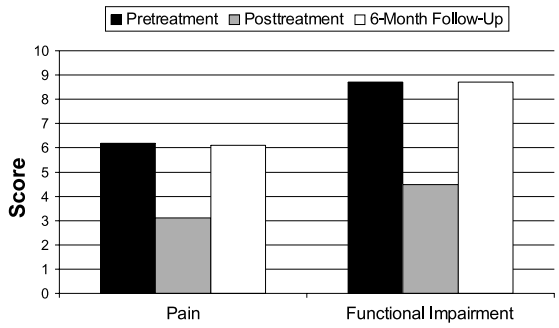

FIGURE 81.1 Effects of pain blockades.

Pain intensity is the most common patient-oriented measure, and typically is the outcome of greatest importance to the patient. Other key domains of patient functioning may include medication use, physical status (strength, flexibility), functional impairment, and emotional dysfunction, among others. Note, however, that the patients' primary interest will be pain relief. Numerous reliable and validated instruments are available to assess these other domains of pain outcomes (see "Pain Outcomes Instruments" for a limited review).

Patient-focused outcomes may be used in a number of ways. Information about average changes in pain measures following different treatment alternatives may assist the patient and the clinician in choosing which pain intervention best addresses the individual's pain problems and expectations. They also are a necessary component of program evaluation efforts that validate treatment effectiveness. The latter often are useful for marketing pain services or for increasing the likelihood of an insurer's payment for the services.

As an example, consider the hypothetical situation where providers at a university-based anesthesiology pain clinic decide to evaluate the effectiveness of their pain blockades. To accomplish this, they administer a multidimensional pain outcomes instrument to all patients with chronic nonmalignant pain undergoing the procedure prior to the first nerve block and again following the last nerve block. They also readminister the instrument 6 months after treatment to assess the short-term stability of any obtained changes. After 1 year of data collection (6 months of follow-up assessment) they graph their results, which are presented in Figure 81.1.

Based on these results, the providers conclude that the pain blockades appeared to provide some short-term pain relief and functional status improvement. However, they also conclude that the average benefits of the treatment were temporary, because after the 6 months following treatment the improvements had dissipated. As a result of these findings they decide to restrict their use of the procedure for the time being to individuals with severe acute pain or cancer pain, and to adopt other strategies for treating chronic nonmalignant pain.

Service Delivery-Focused Outcomes

Service delivery outcomes approaches are those that focus on the thoroughness and efficiency of the pain service delivery system rather than on patient outcomes per se. Service delivery outcomes measures are used to evaluate the performance of the service delivery system as it applies to the provision of pain treatment services. Performance measures may be compared to goals established by the service delivery organization, regulatory bodies, or to standards developed by accrediting bodies. Often this type of outcomes measurement approach is linked closely to quality improvement (QI) programs, where the ultimate goal is to improve the delivery of health services.

The recent dissemination of JCAHO pain standards has stimulated healthcare systems to develop measures to address service delivery outcomes. Unlike patient-oriented outcomes approaches where numerous reliable and validated outcomes instruments are available, data regarding service delivery outcomes generally are derived from compliance reviews of patient care documentation. Most often these reviews are conducted by randomly selecting and manually reviewing records to determine whether pain-related documentation is present, and if so, whether it meets the applicable standards. Standards may be those established by an external body (e.g., JCAHO) or those developed within the healthcare organization and adopted as policy.

Because the provision of pain services first requires the identification of individuals with a "pain problem," methods for differentiating between those with and without significant pain must be developed. Given that the JCAHO pain standards require that all patients be screened for pain (Joint Commission for the Accreditation of Healthcare Organizations, 2000), one way to identify those requiring further pain assessment and treatment is to define a pain intensity "trigger value." When a patient reports a pain intensity equaling or exceeding this value, the need for additional pain services is established. Service delivery outcomes measures then may be used to determine how well these pain services were delivered. Determining which specific outcomes measures to include depends on the objectives associated with the overall outcomes management program. Often selection of at least some of the measures will be determined by relevant outcomes standards or service delivery policies.

Consider the following example. A large tertiary care medical center that serves as a regional trauma center has identified reduction of debridement pain in its burn unit as a primary facility goal, motivated in part by concern over an upcoming JCAHO survey. An initial QI plan has been developed to monitor changes in debridement pain ratings as the first step in the process. Pain scores are collected every 15 minutes from all patients undergoing the procedure on each of four burn unit teams. Data are collected for 1 month. Results are presented in Figure 81.2.

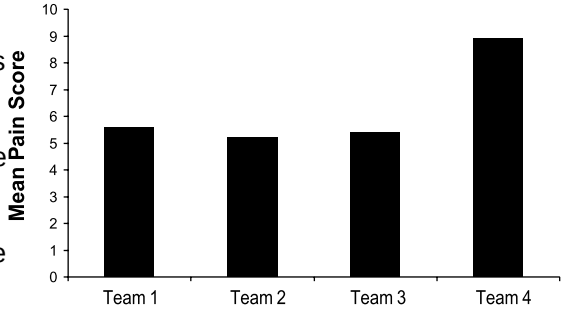

FIGURE 81.2 Mean pain ratings during burn debridement.

Based on these service delivery outcomes data, a QI plan is developed. Components of the plan include training staff to better assess and treat pain, educating patients regarding their pain treatment rights and the range of pain interventions that may be implemented, improving patient-controlled analgesia options, and reviewing Team 4's practices in detail to identify what factors (including chance effects) account for their lower levels of pain relief. During the QI process, pain ratings data will continue to be collected, and the interventions identified above will be implemented in steps to allow estimates of the relative impact of each.

Other examples of possible service delivery outcomes derived from the recent JCAHO standards include

- Percent of patients with significant pain who have a plan of pain care in their medical records.
- Percent of patients with significant pain where pain education was provided to the patient and family.
- Percent of patients with significant pain where evidence exists that pain interventions were provided.
- Patient satisfaction ratings of the service delivery system and service environment.

All of the above examples include a patient-focused pain measure (i.e., pain intensity) as the basis for identifying the patient population of interest. However, the primary intent of each is to evaluate the efficiency of the delivery of pain services rather than the effectiveness of pain treatments.

Type of Pain

Determining which patient outcomes domains to measure also depends on the type of pain typically treated in the setting of interest. For example, in a post-surgical unit, acute pain is likely to be the primary focus. Goals of pain treatment typically are limited to pain reduction. In this situation, pain intensity measures, collected over time (e.g., 1-hour periods), may be the only pain outcomes

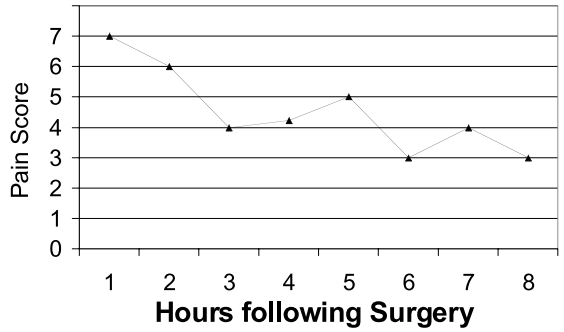

FIGURE 81.3 Pain scores over time on a postsurgical recovery unit.

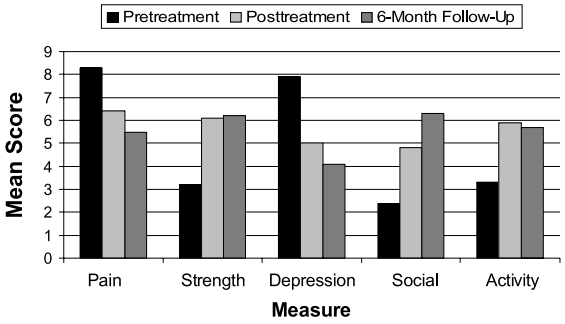

FIGURE 81.4 Changes in pain outcomes.

measure of importance. An example of the results of this type of outcomes evaluation is presented in Figure 81.3 and could be used to support the effectiveness of the pain treatment methods used in this setting.

Contrast this with a setting where chronic nonmalignant pain is the most frequent presenting problem. Chronic pain treatment goals generally encompass changes in many domains of function beyond pain reduction. Therefore, an appropriate outcomes measurement system should include multidimensional measures of pain-related functioning (International Association for the Study of Pain, 1991). Figure 81.4 illustrates some of the changes in these measures that might be expected following treatment. Note that the chronic pain outcomes include pretreatment, posttreatment, and follow-up measures of functioning. Changes in measures from pretreatment to posttreatment support the short-term efficacy of the interventions. However, the overarching goal of chronic pain treatment is to modify patients' long-term behaviors and adjustment. Therefore, readministration of the multidimensional measures at a point following treatment cessation is one way to assess the stability of treatment-related changes, and is required by some pain program accreditation bodies (American Academy of Pain Management, 1997; CARF, 1999). Table 81.1 summarizes suggested domains of outcomes relevant to specific types of pain.

TABLE 81.1
Recommended Outcomes Domains by Type of Pain

Acute Pain	Cancer Pain	Chronic Pain
Pain intensity	Pain intensity	Pain intensity
	Physical impairment	Physical impairment
	Interpersonal impairment	Interpersonal impairment
	Emotional dysfunction	Emotional dysfunction
	Activity level	Activity level
	Sleep difficulties	Pain-related fears
	Sexual impairment	Recreational impairment
		Sleep difficulties
		Vocational impairment
		Sexual impairment

Practice Setting

Practice setting refers to characteristics of the pain service delivery environment. Primary among these are the type and complexity of pain treatment services provided and the degree of administrative support.

Nature of Pain Services

Pain treatment encompasses a wide variety of interventions delivered in a multitude of settings. Some may involve minimal healthcare resources (medication management) while others may be highly technical (dorsal column stimulator implants) or lengthy (comprehensive multidisciplinary treatment). In general, the complexity of the outcomes system utilized should parallel that of the corresponding practice setting. That is, settings utilizing minimal treatment resources (total staff time and equipment) do not require, nor do they justify, elaborate outcomes measurement. In contrast, treatment settings with high resource demands (i.e., higher treatment costs) should utilize a broader spectrum of outcomes measures to detect change (or lack of change) in multiple outcomes domains.

A brief example may clarify this point. In an outpatient, single-provider pain clinic where the primary mode of pain treatment is pharmacological and resource demand is low, the associated patient-focused measures might be limited to pain intensity ratings and some brief measure of pain interference. A service delivery-focused measure, such as patient waiting times, also might be added. In contrast, an inpatient or outpatient pain surgical intervention practice, where resource demand is high, might be expected to monitor multiple patient-focused (pain intensity, functional impairment, changes in emotional status, return to work, etc.) and service delivery-focused (complication rates, surgical time, costs) over a longer timeframe.

Administrative Support

In the ideal practice setting, there would be no relationship between the type of outcomes system adopted and the degree of administrative support available. Unfortunately, in most cases, the degree of administrative support has a large impact on selection of an outcomes approach. Given the costs involved (i.e., supplies, contracts, and staff time), administrators may be reluctant to approve outlays for programs with no direct financial returns.

There are several steps a provider can take to maximize administrative support for pain outcomes measurement. First, identify all regulatory (state or federal), professional, and accreditation standards or guidelines that apply. Next, identify any local pain standards of practice that include pain outcomes requirements. Third, gather any available pain outcomes materials from local competing providers. Refer to these standards, regulations, and local outcomes data in the body of the pain outcomes proposal. It may be helpful to include some examples of consequences experienced by providers or settings that did not abide by the appropriate outcomes requirements as an additional means of persuasion. Last, meet with the administrative representative and present the basis and anticipated costs for the pain outcomes measurement program. Compromise may be necessary, but if the proposal is complete, well documented, and involves reasonable costs, the likelihood of approval will be maximized.

PAIN OUTCOMES INSTRUMENTS

Selection of appropriate instruments to use in a pain outcomes program requires some familiarity with basic measurement principals. Test reliability refers to the constancy of measurement; that is, the extent that the instrument yields similar results when administered under identical or very similar circumstances (Johnston, Keith, & Hinderer, 1992). If an instrument is unreliable, it is likely to generate inconsistent results that reflect the random effects of error rather than any systematic change attributable to treatment factors. Reliability is a necessary condition for validity, but adequate reliability does not ensure validity (Green, 1992). Validity generally refers to the degree to which the instrument measures what it was designed to measure (Johnston, Keither, & Hinderer, 1992). There are several types of validity which are assessed by different methods. In this review, we have chosen to emphasize concurrent validity or how well the instrument or measure compares to other established ("gold standard") measures of the construct or variable. Measures with good concurrent validity exhibit relatively high and clinically significant correlations with established measures of the pain domain under study. Measures adopted for use as part of a patient-focused outcomes system should exhibit adequate reliability and validity (CARF, 1999). If they are to be used in multidisciplinary settings, they also should conform to the Measurement Standards for Interdisciplinary Medical Rehabilitation established by the American Congress of Rehabilitation Medicine (Johnston, Keith, & Hinderer, 1992).

It is important to note that adequate test or measure validity and reliability do not ensure that a measure is appropriate for the outcomes context of interest. Although the determination of the appropriateness of a measure usually is a simple task (e.g., evaluating whether the education or knowledge requirements for completing the measure are consistent with the target population's abilities), occasions when the inappropriateness of a pain measure may not be immediately apparent do exist. For example, consider the situation where an outpatient, hospital-based pain treatment clinic wants to evaluate the effectiveness of its pain treatments. The clinic is in an urban area, with limited parking facilities, and caters mostly to elderly, inactive patients with multiple pain complaints. Clinic providers decide to use an 11-point (0 to 10) pain rating scale (a reliable and well-validated measure of pain intensity) as the primary effectiveness measure, administered prior to every visit. Patients are asked to report their current levels of pain using the 11-point scale. Data are collected and reported for a 6-month period. Results reveal no change in pain scores over time, and clinic staff members conclude that their efforts are not effective.

Are these conclusions justified? Probably not, as the question asked (current pain intensity) likely was not the best measure of pain intensity in this situation. Consider the difficulty this group of patients experiences in reporting for their appointments. They must prepare themselves for travel, arrange travel to the appointment, transport themselves to the clinic area, and sit in uncomfortable chairs waiting to be seen. As a result, their "current pain" rating may be closer to a "worst pain" rating, and may not accurately reflect the effectiveness of treatment. A better pain measure might instead be their "usual pain" which is less affected by the transient influences of the situation. Figure 81.5 presents hypothetical differences

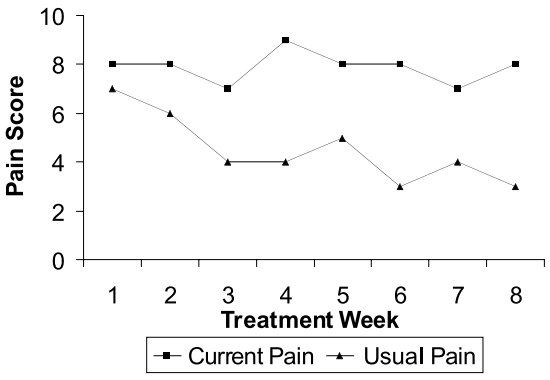

FIGURE 81.5 Pain scores over time.

between current and usual pain ratings gathered under these conditions, and clearly illustrates the desirability of carefully considering all aspects of a meas-ure when evaluating appropriateness.

There are several pain-specific self-report instruments that may be used to assess treatment outcome. The following review of selected pain treatment outcomes measures is limited to measures that have been validated with pain patient samples and were judged by the authors to have some utility for outcomes assessment. Absent from this review are several well-validated measures, such as the Coping Strategies Questionnaire (CSQ) (Rosenstiel & Keefe, 1983), which tap important aspects of the pain experience and have been widely used in pain research, but lack significant evidence of utility for general pain outcomes assessment. For the reader who is interested in a wider range of pain measures, more comprehensive reviews may be found elsewhere (Bradely, Haile, & Jaworski, 1992; Jensen & Karoly, 1992; Tait, et al., 1987).

Both unidimensional and multidimensional pain outcomes measures are reviewed in the following pages. Criteria for inclusion in this review were (1) evidence of acceptable reliability; (2) data supporting instrument validity (particularly concurrent validity); (3) prior use as a pain outcomes instrument; and (4) high utility for pain outcomes assessment, as judged by the authors.

Unidimensional Measures

In contrast to standards for acute pain treatment, current chronic pain treatment standards necessitate the assessment of outcomes across multiple dimensions of functioning (CARF, 1999). Although specific standards vary by type of pain, treatment modality, and practice standards, comprehensive pain treatment outcomes measurement generally includes the assessment of pain intensity, pain interference, emotional distress, vocational functioning, patient satisfaction, and medical resource utilization. The most common approach to assessing multiple outcomes domains is to assemble a battery of unidimensional instruments, each of which measures a single pain outcomes domain. In the following sections, we attempt to provide readers with several choices of acceptable unidimensional outcomes instruments within each outcomes domain. A summary of key unidimensional instrument characteristics is presented in Table 81.2.

Pain Intensity

Pain intensity measures form the basis of all pain treatment outcomes measurement approaches and are essential for most pain service delivery outcomes measures as well. Luckily, the measurement of pain intensity is perhaps the simplest component of outcomes assessment, and there are several easy-to-administer, psychometrically sound scales available. The three broad categories of commonly used pain intensity measures include the Visual Analog Scale (VAS), Numeric Rating Scale (NRS), and Verbal Rating Scale (VRS). The VAS and NRS typically consist of a single item requiring the patient to quantify the intensity of his or her "current," "usual," "least," or "worst" pain. Empirical evidence suggests that the combination of "least" and "usual" pain ratings provide the best estimate of actual pain intensity, while "least" may be the single most accurate predictor (Jensen, et al., 1996). However, for practical purposes clinicians can have confidence in the choice of a single VAS or NRS rating of "usual" pain, which appears to provide a reasonably valid estimate of actual pain. Interestingly, "current" and "worst" pain ratings were found to have a weaker relationship with actual pain intensity (Jensen, et al., 1996).

A reliable and well-validated form of the VAS is a 10-cm line anchored with the phrases "no pain" and "worst possible pain" or "excruciating pain." Patients are instructed to bisect the line at the point that best represents their level of pain, and the score is simply the length of the segment to that point. The VAS has been found to be valid and sensitive to changes in acute, cancer, and chronic pain (Breivik, Bjornsson, & Skovlund, 2000; DeConno, et al., 1994; Ogon, et al., 1996), and it yields ratio level data (Jensen, et al., 1992). Although comparisons of horizontal and vertical line orientations yield mixed results, using the VAS horizontally may provide slightly higher sensitivity (Ogon, et al., 1996; Jensen, et al., 1999).

The NRS consists of a numeric range from 0 to 10 or 100 with anchors similar to those of the VAS, and can be administered in oral or written form. Individuals are asked to quantify their pain levels by choosing a single number from the 11- or 101-point scale. The NRS has been found to have good psychometric characteristics (Jensen, et al., 1999) and to be sensitive to changes in acute, cancer, and chronic pain (DeConno, et al., 1994; Paice & Cohen, 1997). The data provided by the NRS can be treated as ratio level (Jensen & Karoly, 1992).

Verbal rating scales typically consist of a list or lists of pain descriptors that are rank ordered along a continuum of severity. Patients are asked to select the most appropriate descriptor or set of descriptors, and a score is assigned based on the rank(s) of the chosen word(s) (Jensen & Karoly, 1992). The McGill Pain Questionnaire (MPQ) (Melzack, 1975a) is a well-validated, widely used VRS that consists of 20 lists of descriptors of the sensory, affective, and evaluative dimensions of pain (Melzack, 1975b). Support for the tripartite structure of the MPQ is mixed, and factor analyses generally reveal significant overlap among factors (Donaldson, 1995; Holroyd, et al., 1992; Turk, Rudy, & Saolovey, 1985). The standard scoring procedure yields a Pain Rating Index (PRI) for each of the three subscales, although in practice these subscales are often summed to create a single PRI. The PRI has been shown to be sensitive to change and valid for use among acute, cancer, and chronic populations (Davis, 1989; Lowe, Walker, & MacCallum, 1991; Sist, et al., 1998). However, as is true of other verbal scales, it only yields ordinal level data because questions have been raised about the assumption of equidistance between ranked descriptors (Choiniere & Amsel, 1996).

Practical considerations suggest that the VAS or the NRS may be preferred to the MPQ or other verbal scales for the clinical assessment of pain intensity as they provide psychometrically superior data that are relatively easy to collect and score. When ease of administration and scoring are of greatest concern, the 11-point NRS may be the best choice. In contrast, when greater measurement precision is desirable, the advantage goes to the VAS or to the 101-point NRS.

Pain Interference

A central goal of pain intervention is to reduce the extent to which pain impairs physical activity, emotional functioning, and psychosocial role fulfillment. Several unidimensional measures of pain interference are available to assess the degree and nature of pain-related limitations in one or more domains of functioning. It should be noted that although some of these measures, such as the Sickness Impact Profile (SIP), tap pain interference across multiple domains of functioning, the primary construct assessed is the single dimension of pain-related impairment. These measures of pain interference should not be confused with instruments that simply quantify functional status and do not attempt to account for the role of pain in an individual's level of impairment. This difference is illustrated by the contrast between the SIP psychosocial scale, which measures the extent of emotional and social difficulties that are attributed to the pain condition, and the Beck Depression Inventory (BDI) (Beck, 1987), which assesses depressive symptomatology without concern for etiology.

The Pain Disability Index (PDI) (Pollard, 1984) is a seven-item measure of pain interference in physical and psychosocial role performance. The PDI has good internal consistency ($\alpha = 0.87$) (Tait, et al., 1987) and 1-week test–retest reliability (intraclass r = 0.91) (Gronblad, et al., 1993), and it has been shown to effectively discriminate groups of pain patients with varying levels of disability (Tait, Chibnall, & Krause, 1990). The measure appears to be sensitive to change (Strong, Ashton, & Large, 1994), and it is valid for use with chronic and post-operative pain patients (Pollard, 1984). Factor analysis supports the classification of the PDI as a unidimensional measure of pain interference (Tait, Chibnall, & Krause, 1990). The PDI has practical appeal as a brief, easy-to-use, and psychometrically sound measure of general pain interference when less comprehensive assessment of pain-related disability is adequate.

The SIP is a widely used, 136-item measure of perceived impairment (Brown, 1995; Williams, 1988) with high test–retest reliability (0.92) and internal consistency (0.94) (Bergner, et al., 1981). The SIP administration instructions were altered by Turner and Clancy (Turner & Clancy, 1988) to reflect pain-related impairment rather than general physical impairment. The 14 SIP subscales assess pain interference across a wide range of functioning, and they are combined to form the Physical, Psychosocial, and Total scales. The SIP scales have been found to possess good concurrent validity in chronic pain and cancer pain patients (Beckham, et al., 1997; Watson & Graydon, 1989), and they are sensitive to change resulting from multidisciplinary inpatient treatment for chronic pain (Jensen, et al., 1992). From a practical standpoint, the main weaknesses of the SIP are its length and the relative difficulty of scoring the inventory. In addition, individuals

with pain may find many SIP items to be less face valid and relevant to their conditions than those of measures developed specifically to tap pain-related disability. Nevertheless, the SIP remains the gold standard for detailed assessment of self-reported pain interference.

Emotional Distress

Although the measures of emotional distress presented here are not pain specific, they are widely used in pain intervention outcomes assessment. This reflects the considerable association between emotional distress and pain, the importance of treating concurrent depression and anxiety, and the recognition that psychological variables can have a significant impact on treatment outcome. The following emotional distress measures were selected based upon their brevity, convenience, and general acceptance among pain researchers for outcomes assessment.

The BDI is a 21-item measure of depressive symptomatology (Beck, 1987). This widely used instrument has been shown to have adequate psychometric properties (Beck, Steer, & Garbin, 1988), and it is sensitive to change resulting from multidisciplinary pain clinic treatment (Kleinke, 1991). The BDI discriminates well between chronic pain patients with and without depression (Geisser, Roth, & Robinson, 1997). However, researchers have raised questions about the appropriateness of using the BDI to detect depression among pain patients (de C. Williams & Richardson, 1993). Several BDI items contain somatic content (e.g., sleep disturbance, fatigability, and somatic preoccupation) that is confounded with commonly observed symptoms of chronic pain syndromes, and several studies have suggested that pain patients may produce higher scores on these items as a function of their pain-related physical symptomatology (Plumb & Holland, 1977; Wesley, et al., 1999). While this may limit total score comparisons with nonpain populations, removal of the somatic items has not been found to improve the accuracy of the measure for discriminating depressed from nondepressed chronic pain patients (Geisser, Roth, & Robinson, 1997). Consequently, clinicians may choose to use the BDI for treatment outcomes, although accurate classification of depressive symptomatology may require higher cutoffs.

An alternative measure of depression favored by some researchers for pain outcomes is the 20-item Center for Epidemiologic Studies-Depression Scale (CES-D) (Radloff, 1977). The CES-D has high internal reliability ($\alpha = 0.85$) in normal populations and good concurrent validity in chronic and cancer pain populations (Beckham, et al., 1997; Radloff, 1977). The CES-D may be somewhat more sensitive to change than the BDI (Turk & Okifuji, 1994). Normed on a normal population, the CES-D suffers from many of the same limitations as the BDI, potentially producing a high number of false positives among chronic and cancer pain patients. However, like the BDI, the CES-D has been shown to discriminate between chronic pain patients with and without depression, and removal of somatic items did not appreciably improve accuracy (Geisser, Roth, & Robinson, 1997; Turk & Okifuji, 1994). Nonetheless, higher cutoffs should be used in pain populations.

The impact of anxiety on pain treatment outcome has not been studied as extensively as that of depression. However, the existing evidence suggests a high concordance between pain and anxiety (Polantin, et al., 1993), and the need to address these symptoms in comprehensive pain intervention is well recognized. The State–Trait Anxiety Inventory (STAI) is a 40-item self-report inventory of state and trait anxiety that possesses adequate psychometric properties (Spielberger, et al., 1983), and is widely used for pain outcomes measurement. The STAI is sensitive to change (Mongini, Defippi, & Negro, 1997) and is an adequate choice for the clinician wishing to quantify levels of both acute anxiety and the more stable tendency to perceive one's environment as threatening.

Pain-Related Fear

Recently, researchers have begun to focus on the role of pain-specific emotional distress in the experience of pain. Emerging data indicate that pain-specific emotional distress, particularly pain-related fear, may play a more important role than general levels of affective disturbance in the development and maintenance of pain-related physical disability (McCracken, Faber, & Janeck, 1998). The construct of pain-related fear may be defined broadly as the fear of pain and the avoidance of behaviors that are anticipated to produce painful sensation or injury. Although no evidence currently exists linking levels of pain-related fear to treatment outcome, the available data suggest that pain-related fear may seriously compromise an individual's willingness to initiate and persist in the degree of physical reactivation and restoration that is essential to reversing the progression of pain-related disability. Accordingly, clinicians and researchers are beginning to pay more attention to the role of pain-related fear in pain treatment outcome.

Of the few available unidimensional measures of pain-related fear, the Pain Anxiety Symptoms Scale (PASS) (McCracken, Zayfert, & Gross, 1992) and the Tampa Scale (TS) (Kori, Miller, & Todd, 1990) are the most promising. The PASS is the longer of the two measures, with 40 items assessing cognitive and pain-related physiological anxiety symptoms, escape and avoidance responses, and fearful appraisal of pain (McCracken, Zayfert, & Gross, 1992). The four PASS subscales have good internal consistency (McCracken, Zayfert, & Gross, 1993), and the total score has good predictive validity and appears to be adequate for

TABLE 81.3
Domains of Outcome Assessed by Multidimensional Measures

Outcome Dimensions	BPI (32)	MPI (52)	NPDB–VA v.2 (74)
Pain intensity	Right now, average, least, worst	Pain severity subscale	Usual (0–10 NRS)
Pain interference	Pain interference in physical functioning	Pain interference in physical functioning; activity level	Pain interference in physical functioning; activity level
Emotional distress	Pain interference in mood and interpersonal relations	Emotional distress; support/response from others	Emotional distress; pain interference in interpersonal activities
Pain–related fear	—	—	Pain-related fear
Vocational functioning	—	—	Employment status; pain work interference
Medical resource utilization	—	—	Inpatient and outpatient visits; surgeries
Patient satisfaction	—	—	Satisfaction with various treatment components

Note: BPI = Brief Pain Inventory; MPI = Multidimensional Pain Inventory; NPDB-VA v.2 = National Pain Data Bank-VA Version 2, NRS, Numeric Rating Scale.

outcomes assessment (McCracken, Faber, & Janeck, 1998). Scores on the PASS have been found to predict self-reported pain severity, disability, pain behavior, and range of motion on straight leg raise (McCracken, et al., 1993; McCracken, et al., 1996). In addition, pain patients classified as "dysfunctional" by the Multidimensional Pain Inventory (MPI) (Kerns, Turk, & Rudy, 1985) were more likely to produce high scores on the PASS than those classified as "interpersonally distressed" or as "adaptive copers" (Asmundson, Norton, & Allerdings, 1997).

Perhaps a better measure of the pain-related anxiety is the TS, a 17-item instrument developed to assess kinesiophobia, or the fear of movement and activity due to concerns about injury or reinjury (Kori, Miller, & Todd, 1990). Although limited, recent evidence suggests that the TS may possess greater predictive validity than the PASS and other measures of pain-related fear. The TS has been found to be a superior predictor of a range of pain symptoms and behaviors, even after controlling for known confounding factors such as pain intensity and duration, gender, and negative emotionality. For example, the TS was an incrementally valid predictor of self-reported disability and behavioral performance during a lifting task after controlling for pain onset, lower extremity radicular pain, and pain intensity, while the PASS was not (Crombez, et al., 1999). In addition, the TS has been found to be a superior predictor of disability as compared to pain intensity, biomedical signs and symptoms, and negative emotionality (Crombez, et al., 1999; Vlaeyen, et al., 1999). Although no data on the ability of either the TS or the PASS to capture treatment-related change exist, either measure may be appropriate. However, given its superior predictive validity and shorter length, the TS appears to be the instrument of choice for assessing treatment-induced changes in pain-related fear.

Advantages and Disadvantages of Unidimensional Instruments

Unidimensional pain outcomes instruments generally are easily available, inexpensive, and necessitate minimal administration training time. Additionally, they are an efficient means of collecting data when only a single or a few selected outcomes domains are to be assessed. Unfortunately, using unidimensional measures to assess multidimensional pain treatment outcomes requires assembling a battery of individual instruments. The idiosyncratic nature of these batteries often restricts or prevents comparisons between local outcomes data and community benchmarked data. In addition, some of these instruments are quite lengthy and may include items that are not directly relevant to pain. Thus, while unidimensional measures may be the most efficient means of collecting pain data for one or two selected pain outcomes domains, the use of many unidimensional measures to cover all key chronic pain outcomes domains may decrease the utility of the obtained data while increasing staff and patient burden.

Multidimensional Measures

In response to the limitations associated with batteries of unidimensional instruments, a few multidimensional pain outcomes tools have been developed. Three of these are discussed below. Perhaps due to differences in the nature and extent of acute, cancer, and chronic pain conditions, two of these three instruments were developed to assess a specific type of pain. Validation of each of these three measures has been restricted largely to the types of pain for which the instrument was originally developed. Table 81.3 presents a comparison of the key features of these instruments, while Table 81.4 summarizes the strength of concurrent validity support for the instruments across acute, cancer, and chronic nonmalignant pain populations.

TABLE 81.4
Concurrent Validation Support for Multidimensional Measures

Measure	Acute	Cancer	Chronic Nonmalignant
BPI	Moderate	Strong	None
MPI	None	Weak	Strong
NPDB-VA	None	None	Moderate

Brief Pain Inventory

The Brief Pain Inventory (BPI) (Cleeland & Ryan, 1994) is a 32-item instrument developed to assess pain history, pain intensity, perceived recent response to medication/treatment, and pain interference. The BPI is well validated among cancer and chronic disease pain patients, and it has been translated into several languages. Factor analytic studies consistently have revealed the two factors of pain severity and interference across samples and language versions (Caraceni, et al., 1996; Radbruch, et al., 1999; Saxena, Mendoza, & Cleeland, 1999; Wang, et al., 1996). However, empirical data are limited mostly to cancer and chronic disease samples, and little is known about the sensitivity to change or psychometric properties of the instrument when used with chronic pain populations.

Multidimensional Pain Inventory

The MPI, formerly the West Haven–Yale Multidimensional Pain Inventory, is a popular pain measure that was developed to facilitate the comprehensive assessment of chronic pain patients (Kerns, Turk, & Rudy, 1985). Designed to be used in conjunction with behavioral and psychophysiological measures, the 52 items comprise 12 subscales that are dispersed across three sections: (1) pain intensity, pain interference, dissatisfaction with current functioning, appraisal of support from others, perceived life control, and affective distress; (2) punishing, solicitous, and distracting responses from significant others to displays of pain behaviors; and (3) frequency of the performance of household chores, outdoor work, activities away from home, and social activities (Kerns, Turk, & Rudy, 1985). The 12 subscales possess good internal consistency (α = 0.70 to 0.90) and acceptable 2-week test–retest reliability (r = 0.62 to 0.91). Adequate levels of unique variance and concurrent validity have been demonstrated for most scales (Kerns, Turk, & Rudy, 1985). The MPI appears to be sensitive to change, but the utility of specific subscales may vary across levels of adaptation and functioning (Strategier, et al., 1997).

In addition to the measurement of treatment outcomes, the MPI has been used to classify chronic pain patients in order to identify major treatment needs. Cluster analyses have yielded a three-group typology of chronic pain patients consisting of dysfunctional, interpersonally distressed, and adaptive copers or minimizers categories (Turk & Rudy, 1990). Clinicians may find this typology useful for purposes such as planning pain treatment or testing the effectiveness of different interventions or intervention components across MPI groups of patients.

National Pain Data Bank

The National Pain Data Bank (NPDB) is a software-driven, outcomes package consisting of intake, posttreatment, and follow-up questionnaires. The NPDB was developed specifically to assess treatment outcomes, and it is the only measure that encompasses all of the domains of functioning typically considered to be essential to comprehensive outcomes measurement. The outcomes package allows the clinician to track changes in pain intensity, pain interference, emotional distress, pain-related fear, vocational functioning, patient satisfaction, perceived improvement, and medical resource utilization from intake through follow-up, obviating the need to use more than one measure. In addition, a large database of benchmark data is available to allow comparisons with the outcomes of similar modalities across the nation, a requirement of many pain treatment standards (e.g., CARF). Selected subsets of NPDB items have been found to have moderate (0.73) to high (0.94) internal reliability (American Academy of Pain Management, 1997). A preliminary investigation of the psychometric properties of the instrument among a chronic pain impatient sample revealed that the NPDB demonstrated good concurrent validity in relation to a number of widely accepted gold standard measures of pain-related impairment (Clark & Gironda, 2000). Analysis of the final data set has confirmed the preliminary findings, and investigations of test–retest reliability, concurrent validity, and sensitivity to change are currently being conducted.

Advantages and Disadvantages of Multidimensional Measures

Multidimensional pain outcomes measures have several advantages relative to unidimensional measures. Because these instruments were specifically designed for pain populations, they often contain fewer total items than combinations of corresponding unidimensional measures and tend to be better integrated. Additionally, as the instruments are uniform, results can be compared across treatment settings or geographic regions, which may assist in the eventual development of universal pain outcomes benchmarks. Disadvantages of the multidimensional measures are that they may be more difficult to obtain, require additional administration or scoring training as well as more data entry and management time, are more costly in some cases and, with the exception of the NPDB,

do not cover all of the key chronic pain outcomes domains. Nevertheless, when assessing multiple domains of outcomes in clinical settings, multidimensional measures generally are more practical.

A PRACTICAL APPROACH TO OUTCOMES MEASUREMENT

The process of designing a pain outcomes methodology consists of a series of discrete steps and requires that factors relevant to the outcomes system development process, such as those described above, be considered carefully. In the following pages we provide an outline of our suggested approach to this endeavor in the hope that it will assist the reader through this process.

Identify Outcomes Objectives

The first step in developing a pain outcomes measurement system consists of identifying goals, objectives, and scope of the outcomes program.

- Identify the basis for establishing the pain outcomes strategy. It may be a new hospital policy, legal opinion, or accreditation standard. Familiarity with the underlying rationale may make it easier to enlist administrative and staff support.
- Determine whether the outcomes objectives primarily focus on pain treatment issues or on the efficiency of pain service delivery. This distinction will have important implications for the eventual selection of outcomes measures.
- Define the scope of the outcomes plan. Are all available pain treatments to be included, or will only selected treatments be monitored? Does the plan cover every type of pain (acute, cancer, and chronic), or is it limited to only one or two?
- Choose which types of service settings will be included. Is it limited to outpatient areas, inpatient units, or specialty pain clinics? Are all providers working in the defined areas participating, or only some?
- Decide whether the outcomes data collection will be ongoing or limited to a preselected time interval.

Identify Administrative Supports and Limitations

Without sufficient administrative support, efforts to develop a pain outcomes system will fail. Staff will resent the added responsibilities in the absence of increased staff or concrete rewards. Presumably the basis for developing the pain outcomes system (JCAHO standards, insurer recommendations) will enhance administrative interest in the effort.

- Meet with the appropriate administrative representative to discuss anticipated costs and needed resources, citing any relevant local policies, local or national regulations, professional practice guidelines, or local competitors' outcomes practices and marketing data.
- Define the administrative limits (funds, positions) that are operative.
- Negotiate an agreement regarding support for the necessary resources.

Select the Relevant Outcomes Domains

Decisions regarding which pain outcomes domains to include often involve compromises between available resources and outcomes objectives. Yet outcomes efforts can be too ambitious as well. Collecting data for outcomes domains that are not central to the outcomes program objectives is a waste of staff resources and patient time.

- Select the relevant outcomes domains according to the focus of the outcomes program (treatment effects or service delivery), type of pain population involved (acute, cancer, or chronic), and setting.
- Avoid adding outcomes domains that are not directly relevant to the outcomes objectives. Additional domains may be added later if objectives change.
- Review any applicable guidelines, standards, or policies to ensure that all needed domains are included.

Select or Design the Needed Outcomes Measures

Selecting Patient Outcomes Measures

If the objectives of the outcomes program involve evaluating the effects of pain treatment, it is likely that suitable pain outcomes instruments will be available for use. This will avoid the difficulties associated with designing and validating a new instrument and will minimize delays in implementing the outcomes programs.

- Identify potential instruments that assess the outcomes domains of interest (Tables 81.2 and 81.3 may be helpful when matching outcomes instruments to outcomes domains).
- Investigate the reported reliabilities and review the validation data available for the identified instruments.
- Review any available data concerning reading-level requirements, and determine whether

those requirements are consistent with the target population's reading abilities.
- Attend to instrument length, administration and scoring requirements, and costs so as to maximize value and minimize resource demands.
- Determine whether the instruments are available in other languages if this is desirable given the characteristics of the target population.
- Choose the instrument or battery of instruments to use based on the above information.

Designing Service Delivery Outcomes Measures

As indicated previously, service delivery outcomes measures generally are not available in the form of validated outcomes instruments. In fact, with the exception of generic customer satisfaction measures, pain service delivery measures typically need to be designed locally. Fortunately, these measures are relatively simplistic. Usually, they involve tracking whether required pain documentation is present or whether designated pain services were provided in an efficient and timely fashion. Thus, designing appropriate service measures may involve no more than developing pain-specific chart review forms or simple customer feedback tools.

- Identify the specific service delivery outcomes questions of interest.
- Design the necessary outcomes tools (e.g., chart review forms, customer satisfaction surveys).
- If patient surveys or questionnaires are involved, evaluate item wording, specificity, and reading level to meet the target population's abilities.

Develop Procedures Needed for Implementation

Once the scope of the outcomes project has been defined and the outcomes measures have been selected, specific procedures for implementing the outcomes system must be developed.

- Determine how the pain patients targeted for study will be identified.
- Identify the roles, responsibilities, and training needs of all involved staff.
- Develop a timeframe for implementing all aspects of the outcomes system.
- Decide on a sampling strategy (i.e., randomly sample from among all possible data sources or attempt to collect data from every source during the data collection phase) depending on the sample size desired and the projected timeframe.

Design and Prepare the Outcomes Database

Preparation of the outcomes database prior to implementation of data collection requires reviewing every outcomes item or measure as well as all data entry and organization issues. Often this process yields valuable information that may streamline data collection and data management procedures.

- Decide what database and data analysis tools will be used.
- Design the necessary records storage and retrieval tools and conduct a "dry run" of data entry to identify any data collection problems.
- Make certain that the confidentiality of any patient information is maintained by discarding identifying information or by utilizing elaborate coding or encryption strategies.
- Develop a data analysis plan in advance of data collection efforts.

Collect the Outcomes

- Provide training in outcomes measure administration and data collection routines to relevant staff.
- Test the data collection procedures using only a few patients (treatment outcomes project) or records (service delivery project) prior to full-scale implementation.
- Arrange for backup coverage for the individuals collecting the data in the event of unexpected absences.
- Periodically review the workflow and data collection procedures to identify and troubleshoot any problem areas.

Analyze, Trend, and Report the Data

Unfortunately, it is common to find that elaborate outcomes data have been collected at significant expense but then are virtually ignored! Outcomes data analysis and trending are the cornerstones of an effective outcomes program. Analysis involves more than "eyeballing" the data. Although the level of statistical analysis will vary depending on the objectives of the outcomes plan and the psychometric sophistication of the staff involved, at the very least, it will be necessary to statistically summarize the data in a way that directly addresses the outcomes questions of interest. Ongoing review of the results by key personnel is critical and is mandated by some regulatory or accrediting bodies.

- For an ongoing outcomes program, establish a timeframe for systematically reviewing and

reporting on the obtained data (monthly, quarterly, semiannually, or annually).
- Develop a report template that provides summary data regarding the outcomes questions and use that same template for each reporting period in order to allow comparisons over time.
- If performance improvement actions are instituted prior to or during a data collection period, note the nature of the changes implemented, along with the date, in the database so that the effects of the changes can be evaluated.
- After each reporting period, review data from all prior periods in concert with the current results in order to identify trends of change in the data.
- Provide each staff person involved in the project with copies of the analysis report and schedule a meeting after each data collection period for review and discussion of the data and any identified trends.
- Design and complete a brief version of the analysis report for distribution to key administrators to help maintain their support for the project.
- Use the obtained data to explore any additional outcomes questions or to investigate observed trends in the data.
- Implement treatment protocol changes based on the identified trends. Changes should be introduced sequentially in order to allow the effects of each change to be evaluated separately.
- Review the outcomes data following each change in treatment protocol and decide whether to accept or reject the change.

SUMMARY

Interest in outcomes monitoring in healthcare systems will only increase in the immediate future. Within the field of pain treatment, we will see growing demands for data supporting the effectiveness of our interventions. Regulatory and accreditation bodies increasingly will emphasize the importance of pain outcomes programs for providers across all treatment settings. Indeed, the recent development of JCAHO pain standards and the growing national interest in pain issues already have had a profound effect on the pain management field. Given these trends, it is only prudent that we anticipate these changes and enter the 21st century prepared to incorporate outcomes measures as a standard part of pain treatment efforts.

Some practitioners might portray the ever-increasing demands for pain documentation and treatment outcome data as a punitive, nonproductive exercise. We see it as both a challenge and an opportunity. It is a challenge in that it will require us to evaluate more closely our clinical practice of pain treatment, and perhaps reconsider some of our treatment biases. It is an opportunity in that it provides us with the motivation and the means to empirically justify that which we do, and to improve what we do or how we do it in order to increase our treatment effectiveness and efficiency.

In the preceding pages we attempted to summarize and briefly explore some of the key issues related to pain outcomes measurement endeavors. We also presented a general framework for designing and implementing outcomes measurement in pain treatment settings. In recognition of the wide variety of pain practitioner settings and outcomes objectives, we tried to maintain a generalist' approach to the topic. In this regard, we may have sacrificed precision to enhance utility. It is our hope that the information we provided will be of value to clinicians seeking to better understand and improve the effectiveness of their pain treatment interventions.

Enhancing Adrenal Function

Arnold Sandlow, D.C. and Afshin Shargani, D.C.

INTRODUCTION

One of the most overlooked issues faced by the healthcare pain practitioner on a day-to-day basis is realizing and addressing the role of the adrenal gland and its dysfunction as related to the pain and nonpain patient alike. This chapter enables the practitioner to recognize, diagnose, and treat this common and underdiagnosed condition.

In our modern-day society we are barraged with various forms of stress on a daily basis. Some stressors are easy to adapt to, others can become seemingly insurmountable. Stress and stress-related disorders have been considered a significant cause of disease and may contribute to perhaps 75% of all illnesses. Pain subjects the patient to additional stress, which can potentially lead to stress-related disorders.

Thoughts about the adrenal gland automatically relate to thoughts of stress. They are inseparable. For the most part the lay public is familiar with the adrenal gland and its role in handling stress. From the perspective of the pain management practitioner the adrenal gland plays a major role, often unnoticed, and wholly underestimated. Understanding the relationship between the adrenal gland and the patient in pain can increase the ability of the practitioner to treat and manage the patient as a whole, addressing the underlying causes as well as the main causative factors.

Much of the healthcare in the United States is directed toward crisis care. Should we just wait until our patient has a full-blown organic dysfunction, or should we realize and be concerned with an adrenal gland that would allow us a higher level of health and well-being but is not functioning to meet the demands of the body? In the absence of gross pathology should any thought at all be placed on subtle, seemingly ubiquitous symptomatology?

"As the signs and symptoms of adrenal dysfunction are often relatively non-specific, adrenal disorders must be considered in the differential diagnosis of many common complaints" (Miller & Tyrell, 1996).

This chapter focuses on a continuum that exists somewhere between the likes of Addison's disease and Cushing's disease and is secondary to chronic maladaption. This chronic maladaption to stress leads to adrenal exhaustion and has been referred to by many different names. Dilman and Dean (1992) called it the Adrenal Maladaptation Syndrome, or hyperadaptosis. David Walther (1988), in Applied Kinesiology-Synopsis, calls it functional or relative hypoadrenia. Others call it adrenal insufficiency, exhaustion, or burnout (Table 82.1).

In contemporary society, long-term, never-ending emotional stress creates a tired or worn-out adrenal gland, principally because the adrenal gland does not have a chance to rebuild. Because stress is cumulative, stresses to which the body must react over time can cause mild to moderate adrenal insufficiency, the most common clinically observed entity. In this condition the individual can still react to stress; however, it will be done less efficiently and will take more time.

The goal of health is to maintain homeostasis. When the hypothalamic–pituitary–adrenal (HPAA) axis is disturbed, homeostasis is lost. A DHEA/cortisol balance (two hormones secreted by the adrenals) is considered to be a critical marker of overall hormonal health.

Also highlighted are diagnosis, laboratory testing, homeostasis, hormonal regulation, and feedback mechanisms, i.e., HPAA, and natural methods of controlling and

TABLE 82.1
Common Causes of Adrenal Stress

- Anger
- Fear
- Worry/anxiety
- Depression
- Guilt
- Physical or mental strain
- Excessive exercise
- Sleep deprivation
- Light-cycle disruption
- Going to sleep late
- Surgery
- Trauma/injury
- Chronic inflammation
- Chronic infection
- Chronic pain
- Temperature extremes
- Toxic exposure
- Malabsorption
- Maldigestion
- Chronic illness
- Chronic/severe allergies
- Hypoglycemia
- Nutritional deficiencies

enhancing the function of the glands and the important hormones they produce.

ADRENAL GLANDS AND THEIR HORMONES

The adrenal glands (or suprarenal glands) are the major organs that deal with life's minor and major ups and downs. They are pyramidal-shaped structures located on top of each kidney. The adrenal glands are made of two distinct sections: the outer cortex and the inner medulla. They are essentially two different endocrine organs. The adrenal cortex is made of three distinct layers or zones, which produce different types of hormones. The zona glomerulosa is the outermost layer, which produces the mineralocorticoids (aldosterone). The zona fasiculata is the middle layer, which produces glucocorticoids (cortisol), and the zona reticularis is the innermost layer involved in the production of sex hormones, mainly androgens.

Aldosterone

Aldosterone plays a vital role in the body, and its total absence, if untreated, can lead to death. Aldosterone stimulates the kidneys to excrete K and recapture Na, decreasing the blood K levels and increasing the Na levels. Increased levels of sodium, in turn, increase blood volume and pressure. Release of aldosterone is stimulated by increased blood K levels, decreased Na levels, loss of blood, and decreased blood pressure and volume. Control of blood pressure is in part achieved through the renin-angiotensin system with angiotensin II stimulating the release of aldosterone.

Cortisol

Cortisol is the main hormone produced by the adrenal glands in response to various short- or long-term physical, psychological, and physiological stressful stimuli in conjunction with catecholamines from the adrenal medulla, or independently. Cortisol's main action is catabolism of fats and amino acids from their stores in adipose tissue, muscle, lymphatics, and bone, making them available for producing energy and the synthesis of other compounds including glucose and proteins. Cortisol promotes gluconeogenesis and protein synthesis by the liver, enhances the effects of glucagon and growth hormone and decreases glucose uptake by the peripheral tissues. This results in increasing blood sugar levels for use by brain and heart tissues.

Cortisol is also a well-known and potent anti-inflammatory agent exerting its effects by decreasing the permeability of capillary endothelium, stabilizing the liposomal membrane, and promoting production of arachadonic acid, a precursor of prostoglandins.

Sex Hormones

Adrenal sex hormones are produced by the cells of the zona reticularis, the innermost layer of the adrenal cortex. The majority of these hormones are androgens, in the form of dehydroepiandrosterone (DHEA), which has one fifth of testosterone's potency. Other adrenal sex hormones, including estrogen and progesterone, are manufactured in very small amounts. Although they make up the main source of androgens in women, under normal conditions these hormones have a minor role in men mainly due to the presence of testosterone.

After the age of 25 a gradual decrease in DHT production is noted and at 75, it is 15 to 25% of its peak. DHEA levels have an indirect relationship with cortisol production. Therefore, a comparison of DHEA-S vs. cortisol levels can be used as an indicator of the patient's response to stress. DHEA also has been shown to act as a protective guard against stress in laboratory animals (Hornsby, 1997).

Epinephrine and Norepinephrine

The inner part of the adrenal gland, the medulla, is made of chromaffin cells and is essentially a part of the autonomic nervous system. It produces the catecholamines epinephrine (adrenaline) and norepinephrine (noradrenaline), as well as endorphins. These hormones play a major role in exciting the sympathetic nervous system for what is commonly known as the fight-and-flight response. The endorphins are natural painkillers and are secreted alongside epinephrine and norepinephrine.

HYPOTHALAMIC–PITUITARY–ADRENAL (HPA) AXIS AND BIOSYNTHESIS OF ADRENAL HORMONES

Stimulation and control of the hormonal production by the adrenal gland are orchestrated by a feedback mechanism

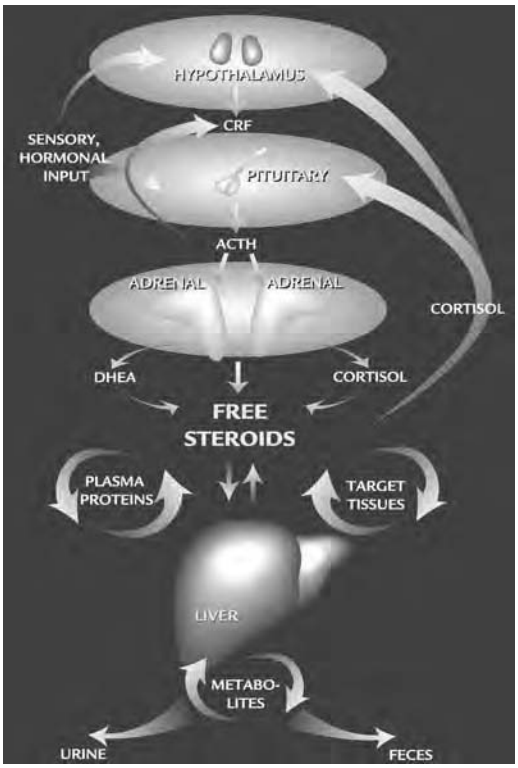

FIGURE 82.1 HPA axis and feedback loops. (Reprinted with permission of Great Smokies Diagnostic Laboratories.)

between the hypothalamus, pituitary, and adrenal glands. This is known as the HPA axis.

A healthy HPA axis (Figure 82.1) is one that involves an intricate interplay of positive and negative feedback loops that make up this marvelous homeostatic mechanism. The major players in this orchestra of hormones include cortisol, which is produced by the adrenal gland, adrenocorticotropic hormone (ACTH) produced by the pituitary, and the corticotropin-releasing factor (CRF) produced by the hypothalamus.

In addition to its regulation by the pituitary, ACTH is synchronized by counterregulation of CRF. A short-loop negative feedback on CRF by ACTH also emanates from the hypothalamic–pituitary region.

The process starts with the release of the CRF from the hypothalamus in response to physical, psychological, and physiologic stressors. CRF induces release of ACTH or corticotropin from the anterior pituitary directly into the blood. ACTH acts on the cells of the zona fasiculata, stimulating cortisol production and release.

Activation of the HPA axis due to a given stimulus leads to a stress response, which modulates the immune response. The interactions between the HPA and the immune system are characterized by a circuit, which includes activation of the HPA-axis and initiation of the stress response that, in turn, has immune-modulating properties, and a feedback mechanism derived from the immune system that regulates the HPA axis (Marx, Ehrhart-Bornstein, Scherbaum, & Bornstein, 1998).

The control of cortisol production is achieved by a negative feedback mechanism exerted by ACTH and cortisol. ACTH acts on the hypothalamus and decreases CRF production. Cortisol acts on both the hypothalamus and pituitary and decreases CRF and ACTH production. In the absence of stressful stimuli, cortisol production follows a normal circadian rhythm associated with sleep and wake cycles. Cortisol secretion is at its highest around 8 a.m. and gradually decreases, reaching its lowest point at midnight. Under prolonged stressful stimuli the brain overrides the normal negative feedback loop, constantly stimulating the adrenal cortex to produce cortisol. This disrupts the normal circadian rhythm of cortisol and results in a whole host of cortisol-related physiologic disorders, as well as hypertrophy of the adrenal glands. Increased cortisol levels are associated with accelerated aging, depression, schizophrenia, chronic fatigue syndrome, immune dysfunction, decreased REM sleep, obesity, hypertension, heart disease, and suppressed thyroid function.

Figure 82.2 shows the pathway of cortisol synthesis in the adrenal cortex. This synthesis begins with the conversion of cholesterol to pregnenolone, by the enzyme 20 α-hydroxylase, 22 hydroxylase, and 20,22 desmolase. In turn, pregnenolone (the mother of all hormones) may be converted into either sex hormones (androgens and estrogens) or mineral and glucocorticoids, more likely produced in the presence of chronic stress.

Pregnenolone's conversion to cortisol involves a series of enzymatic reactions, which are, in turn, controlled by ACTH and other stimulants of the adrenal gland as discussed earlier. A genetic deficiency of any of these enzymes can result in overproduction and underproduction of the dependent hormones.

ADRENAL GLAND DISORDERS

Adrenal gland disorders can be categorized into adrenocorticol hyper- or hypoactivity, resulting in severe excess or deficiency of adrenal cortex hormones, respectively. These conditions can be the result of pathological conditions within the gland itself, pituitary gland, supporting glands, or can be iatrogenic in nature.

Adrenocorticol Deficiency

Adrenocorticol deficiency is highlighted by a significant decrease in production of one or all adrenal hormones. This can be due to pathological conditions involving the adrenal gland itself or other causes. The patient's presentation varies, depending on the affected hormones.

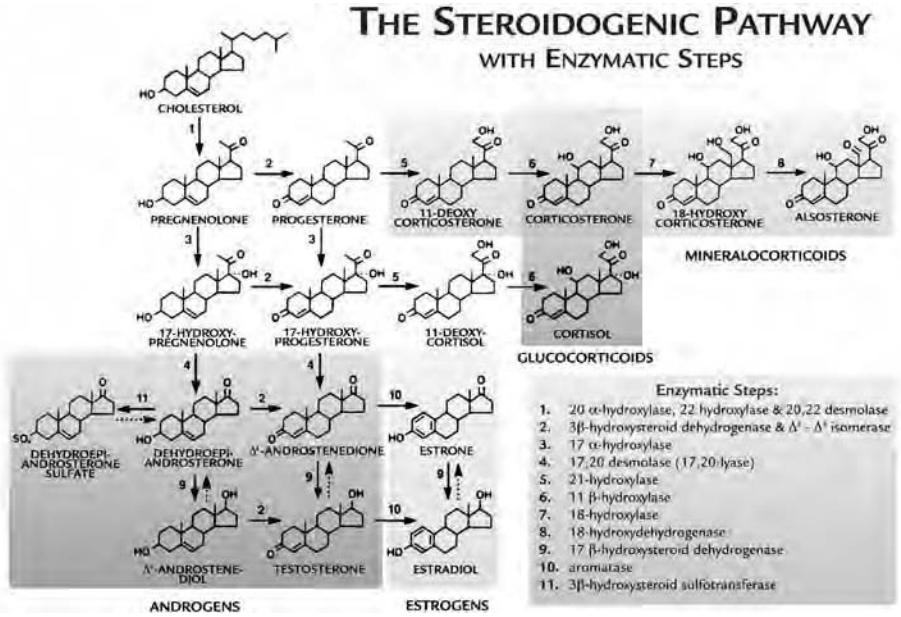

FIGURE 82.2 The steroidogenic pathway.

Addison's Disease

Primary adrenocorticol deficiency involves inherent disease of the adrenal cortex and is also known as Addison's disease. In Addison's disease all adrenal hormones are affected but most pronounced are the effects of decreased cortisol and aldosterone. Clinical findings include decreased weight, malaise, and gastrointestinal upset. Cortisol deficiency results in hypoglycemia and decreased ability to handle stress, while decreased aldosterone results in decreased blood pressure and electrolyte imbalance. Other findings include increased ACTH production by the pituitary; decreased blood levels of cortisol, aldosterone, and T4; and increased TSH. Increased pigmentation is another physical finding of adrenocorticol deficiency, which is due to increased production of ACTH and accompanying melatonin by the pituitary gland.

While Addison's disease is insidious, eventually it will result in severe deficiency of the adrenal hormones. This is known as Addisons' crisis, a serious life-threatening emergency requiring immediate medical intervention.

Autoimmune and iatrogenic factors are the leading causes of Addisons' disease in the Western countries, whereas tuberculosis is the leading causative factor worldwide. Other causes include metastases, adrenal hemorrhage, hemochromatosis, adrenomyeloneuropathy, and iatrogenic drug use.

Inherent Errors of Metabolism

Another cause of adrenocorticol deficiency is inherent errors of metabolism of the adrenal gland itself. It is also known as congenital adrenal hypertrophy. In this group of conditions the enzymes responsible for production of cortisol and aldosterone are deficient genetically, and depending on the severity of their deficiency can result in decreased production of cortisol and aldosterone that can be chronic or life threatening. The enzymatic deficiency also results in a buildup of aldosterone and cortisol precursors, which are converted to sex hormones, primarily androgens. This results in premature puberty in male children and virilism in female children. The decreased adrenal hormone production results in an overproduction of ACTH by the pituitary gland, which causes hypertrophy of the adrenal gland.

Secondary Adrenocorticol Deficiency

Secondary adrenocorticol deficiency is the group of disorders wherein the adrenal gland function is intact but does not receive appropriate stimulation for production and release of its hormones. The most common cause of this type of condition is decreased function of the pituitary gland due to various causes, which results in decreased production of ACTH and, in turn, cortisol, while aldosterone's production remains intact.

Disorders of the renin and angiotensin system due to kidney disease and other causes are another rare type of secondary adrenocorticol deficiency, which results in decreased production of aldosterone while cortisol production remains intact.

Drug-induced adrenocorticol deficiency can occur as a result of treatment with pharmaceuticals including Metyrapone, opDDD (Metiotane), Aminoglutethemide, Ketocoazole, and Etomidate.

Adrenocorticol Excess

This group of disorders is characterized by excess production of the adrenal hormones aldosterone and cortisol.

Cushing's Syndrome

Cushing's syndrome is characterized by excess cortisol in the circulation due to cortisol-producing adrenal tumors, ACTH-producing pituitary gland tumors, or iatrogenic causes. When the excess in cortisol production is due to adrenal tumors, excess androgens will also be present. When excess cortisol is due to ACTH-producing pituitary tumors the condition is known as Cushing's disease. Iatrogenic Cushing's is the most common type and is the result of treatment by glucocorticoids for their immunosuppressive or anti-inflammatory benefits.

Cushing's syndrome is characterized by a round or moon face, Buffalo hump, central obesity, thin arms and legs with muscle wasting, testicular atrophy and menstrual disturbances, high blood pressure, osteoporosis with increased risk of fractures, and immunosuppression resulting in increased susceptibility to infections. Mental changes may include depression, insecurity, uncertainty, and possible psychosis.

Conn's Syndrome

Conn's syndrome is characterized by elevated levels of aldosterone and is almost always the result of aldosterone-producing adrenal tumors, but on rare occasions it can also be due to renin-producing tumors. Elevated levels of aldosterone result in increased blood pressure and hypokalemia, which can lead to other clinical manifestations (Cotran, Jumar, & Robbins, 1989; Jeffcoate, 1993; Berkhow & Fletcher, 1987).

Pheochromocytoma

Pheochromocytoma is the only disease of the adrenal medulla that is caused by a tumor, which produces an excess of catecholamines. Symptoms of this disease include periodic high blood pressure, nausea, excessive sweats, pounding-type headache, anxiety, vomiting, and palpitations.

THE SCIENCE OF STRESS

A Canadian professor, Hans Selye, M.D., is responsible for pioneering the field of stress research. For this reason he was given the title "the father of stress." His writings on the subject date back to the 1930s, and he is credited with writing over 1700 papers and 39 books on the subject.

As the undisputed expert on the subject, he observed as early as 1925 that common symptoms are present in many diseases. He came to classify this as the syndrome of "just being sick". A triad was always present in this syndrome. After exposing rats to various types of stress they were sacrificed. Dissection revealed (1) adrenal cortex enlargement; (2) atrophy of the thymus, spleen, lymph nodes, and all other lymphatic structures; and (3) deep bleeding ulcers in the stomach and duodenum.

Selye classified the progression of stress on the body and its influence on the adrenal glands. The classification is called the "General Adaptation Syndrome" (GAS) (Selye, 1956). Three stages exist including alarm, resistance, and finally exhaustion.

Alarm Reaction: The alarm reaction is characterized by surprise and anxiety and is considered to be a general call to arms. The adrenal glands will secrete hormones, i.e., epinephrine, norepinephrine, and hydrocortisone. This phase is extremely rapid and the mechanism by which a seemingly petite mother lifts a car to get her child out from under it.

Resistance: With continuation of stress the body moves into this second phase, in which the body prepares to continue and adapt to the prolonged fight ahead. Adrenal hypertrophy and other factors of the stress triad are found in this stage. An individual can respond and meet the demands of the stress as long as this stage continues. If the adaptive stress is resolved, a rapid return to the resting state can be achieved.

Exhaustion: When the adrenal glands can no longer meet the demands placed on them due to prolonged stress, this stage is evident. This is then referred to as adrenal maladaptation, or hyperadaptosis, a term credited to Dilman and Dean (1992) (Dilman, you may recall, is responsible for the neuroendocrine theory of aging). Hyperadaptosis is considered by some to be a precursor to Cushing's syndrome. It is characterized by prolonged exposure to excess cortisol levels and is caused by the loss of hypothalamic sensitivity to the inhibitory effects of cortisol (Dilman, 1981). It is the chronically hyperactive HPA axis that causes these symptoms. These same high levels of stress have been shown by Selye (1976) to lead to many of the diseases of aging. Robert Sapolsky, the author of *Why Zebras Don't Get Ulcers* also recognizes the role of these hormones in disease (http://www-med.stanford.edu/school/Neurosciences/faculty/sapolsky.html, 2000; Sapolsky, et al., 1987). Additionally, chronic health problems, long-term nutritional deficiencies, and long-term emotional problems can all lead to the state of adrenal exhaustion.

Researchers have identified eight physical indicators of an individual's stress load (McGwen, 1998). Stressful life events such as divorce, job loss, family arguments, and even traffic jams, in addition to daily maladaptation, all add to stress. Among the stress indicators are

1. Increased blood pressure
2. Suppressed immunity to disease
3. Increased fat around the abdomen
4. Weak muscles
5. Bone loss
6. Increases in blood sugar
7. Increases in cholesterol levels
8. Increases in steroid hormones, i.e., cortisol

How our bodies react by manufacturing stress hormones is ostensibly even more significant than how we feel about the events. When an episode of acute stress is experienced, cortisol is secreted to protect us by activating, through a complex chain of events, the body's defenses. Acute stress (in the sense of "fight" or "flight" or major life events) and chronic stress (the cumulative load of minor day-to-day stresses) can both have long-term consequences.

One of Selye's first observations of the general adaptation syndrome was that animals under extended stress developed sexual derangements. Intense stress causes young animals to cease to grow and lactating females to produce no milk. Prolonged stress may be partially or totally responsible for amenorrhea in female athletes who are under intense training (Brooks-Gunn, Warren, & Hamilton, 1987). Recent research reports that wounds heal more slowly when patients are under psychological stress (Kiecolt-Glaser & Glaser, 2000). With constant sympathetic activation the immune system becomes depressed. Years of scrutiny have revealed that never-ending stressors unfavorably influence brain development.

Current research finds that those women who have higher levels of cortisol (the stress hormone) tend to have more abdominal fat. Dr. Elissa Epel (2000) of UCLA stated, "Psychological stress may increase abdominal fat in healthy people who have normal resting levels of cortisol and are of average weight."

NEUROENDOCRINE THEORY OF AGING

DHEA

Dehydroepiandrosterone (DHEA), a 17 keto-steroid and DHEA-S, its more powerful sulfate, are the major adrenal androgens. Secreted by the adrenal cortex in the innermost layer, the zona reticulosa, this steroid, which is largely produced from the precursor pregnenalone, has been implicated as a possible anti-aging hormone. Serum concentrations of DHEA-S are 20 times that of serum cortisol and the concentration of DHEA is 1/20th that of cortisol. DHEA and its sulfate have been shown to be interconvertable. Testosterone is purported to be five times more potent than androgens. DHEA-S is primarily produced from DHEA in the adrenal gland and liver. Several organs that are targets of androgenic and estrogenic sex hormones convert DHEAS back to DHEA.

The plasma half-life of DHEA is relatively short, at just under 30 minutes. It is for this reason that over 95% of circulating DHEA is in the form of sulfate (Berdanier, Parenta, & McIntosh, 1993; Rosenfeld, Rosenberg, Fukushima, & Hellman, 1975).

In females, androgens are the main source of male sex steroids. In sexually mature humans, ACTH stimulates the secretion of adrenal sex steroids.

DHEA-S is the major source of androgens for the fetus before birth. DHEA-S is detectable by age 7 and serum concentrations of both DHEA and its sulfate appear to be highest in the third decade of life (Bonney, et al., 1984). Levels then begin to gradually decrease and continue to drop. By the age of 70 or 80 years, values have plummeted to approximately 20% of peak values in men and 30% in woman (Bonney, et al., 1984; Rotter, Wong, Lifrak, & Parker, 1985).

DHEA has a very short half-life (less than 30 minutes); therefore, it is stored as its sulfated form, DHEA-S, which makes up to 95% of its circulating levels. DHEA-S can be readily converted to testosterone, estrione, and estradiol and plays a role in a variety of physiologic processes including protein synthesis and thyroid hormone function (Fitzgerald, 1992).

Adrenal insufficiency leads to a deficiency of DHEA. In a study published in the New England Journal of Medicine oral doses of 50 mg per day of DHEA or placebo were administered over a period of 4 months to women who were adrenal insufficient. They were evaluated for effects on well-being and sexuality, as well as on serum hormone and other biochemical values (Arlt, Callies, et al., 1999; Oelkers, 1999). When it came to scores of depression, anxiety, general well-being, and the physical and psychological aspects of sexuality, these adrenally deficient women were shown to have significant positive effects from DHEA supplementation (Oelkers, 1999). DHEA (12.5 to 50 mg/day taken in the a.m.) and pregnenolone (10 to 100 mg/day taken in the a.m.) have been recently propelled to the forefront by their over-the-counter availability and more is being published daily (Hornsby, 1997). DHEA has been touted as being effective for immune dysfunction, longevity, obesity, and depression. The verdict is not conclusive on all these possible usages, but they clearly are showing promise. The strongest evidence exists for its use with hormone replacement and for anti-aging. One marker of aging is a decrease in GnRH (gonadotrophin-releasing hormone) that may result in loss of reproductive function. This loss of function can

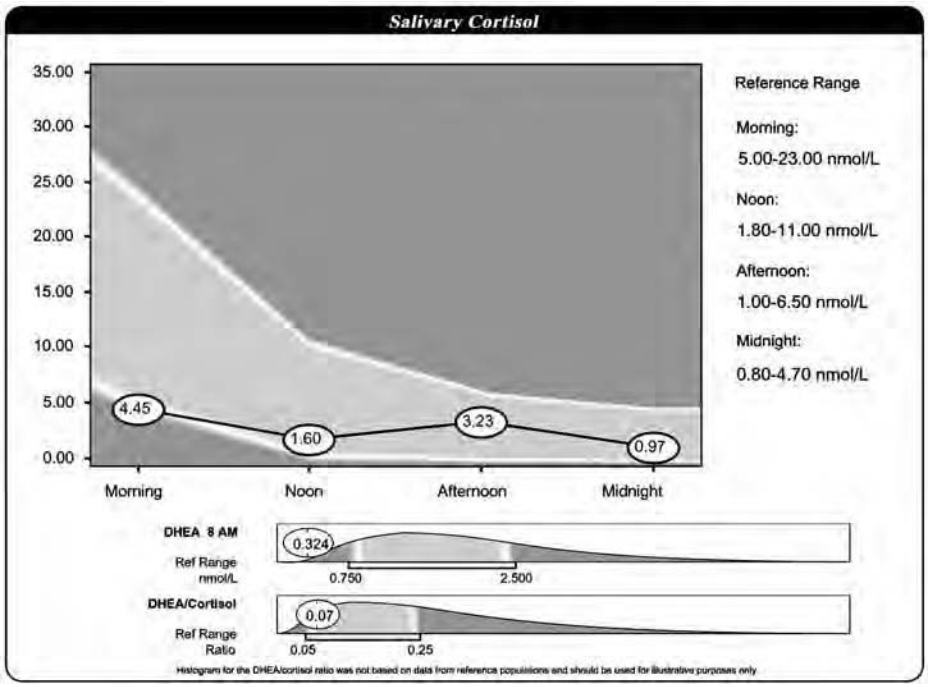

FIGURE 82.3 Lab report of salivary cortisol and DHEA. (Reprinted by permission of Great Smokies Diagnostic Laboratory.)

be reversed with a short administration of DHEA (Li, Givalois, & Pelletier, 1997).

DHEA is distinctive to primates. It is found in high levels only in humans, chimpanzees, and gorillas, and less so in monkeys.

Several articles talk about the anti-obesity effects of DHEA. "The anti-obesity function of DHEA is not simply one of inhibiting fat synthesis and deposition but is one of affecting a number of pathways that contribute to the maintenance of the isoenergetic state rather than the promotion of positive energy balance" (Berdanier, Parente, & McIntosh, 1993).

THE STRESS-IMMUNITY CONNECTION

It has long been proposed that the more stress on the body, irrespective of source, the more likely the immune system will be depressed. Elevated corticosteroids are known to have a significant effect in reducing immune defenses. In a recent study (Creuss, et al., 2000), 34 women with stage I and II breast cancer were divided into one of two randomized groups. One group received cognitive-behavioral stress management; the other group was placed on a waiting list. After 10 weeks of stress management, relaxation training, and cognitive therapy, patients from the treatment group noted significant changes that included a greater sense of purpose and meaning in their lives, better family relationships, and shifted priorities. Not surprisingly, their cortisol levels had dropped and were significantly lower ($p < 0.03$) when compared with the waiting-list patients who did not receive this care.

In a related study done by the National Cancer Institute (Sephton, Sapolsky, Kraemer, & Spiegel, 2000), salivary cortisol levels were checked four times daily in 104 patients with metastatic breast cancer for a period of 3 consecutive days. Patients with "flat" rhythms, an indication of a lack of normal variation, were found to have earlier mortality along with lower levels of natural killer (NK) cells and suppressed activity of those cells.

A nine-fold increased risk of recurrent breast cancer has been associated previously with extreme or severe stress (Ramirez, 1989).

LABORATORY TESTING

Salivary Testing

A simple test to determine hormonal deficiency and imbalance is gaining widespread popularity. Saliva testing is unique in that it measures the unbound hormone, which is that portion available to the cells of the body. About 1 to 10% of the steroids in the blood are in unbound, or free form. Because only unbound steroids can freely diffuse into various target tissues in the body, they are the only hormones considered biologically active. Because it is the most active part of the hormone, saliva testing is a good way to analyze how hormones affect your health.

One of its main advantages is in the ease of collection. It is noninvasive, easy, convenient, painless, and can be done at home by the patient in the privacy of his or her own home. When blood work is utilized to ascertain adrenal hormonal levels, those same levels could easily become

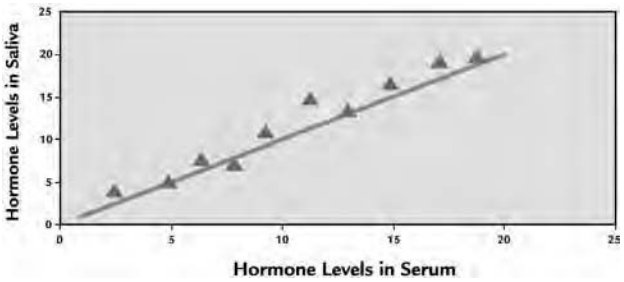

FIGURE 82.4 Linear correlation between salivary and serum hormones. (Reprinted with permission of Great Smokies Diagnostic Laboratory.)

elevated if the patient has any fear about injections, thus giving elevated and inaccurate information. Results retrieved in a stress-free environment will likely be the most sensitive. Figure 82.4 illustrates a comparison of hormone levels in saliva vs. serum, demonstrating a direct correlation.

When evaluating adrenal hormones, a 24-hour pattern of cortisol is examined at four different times, while DHEA is measured on two occasions in the same day.

Saliva samples are not just being utilized for DHEA and cortisol; they are being employed for measuring many hormones including estradiol, progesterone, testosterone and melatonin. Our hormones control many important psychological and physiological roles including our resistance, sleep patterns, and longevity. Thus, these tests provide physicians with accurate, dependable data that can be influential in prescribing hormones with confidence.

Mark Flinn, of the University of Missouri, has been studying the relationship that exists between health in children and stress. He maintains that the two best ways to measure stress are by measuring the adrenal hormone cortisol in saliva and by asking questions. This study has amassed data over the course of 13 years. In that time Flinn has collected more than 25,000 saliva samples from 287 children who live in the same rural Caribbean island village. An average of 96 separate samples were collected from each child. In addition, Flinn has tracked their growth, checked their health records, measured their levels of resistance, watched, listened, and asked questions in order to be very aware of what was happening in each of their lives.

He concludes that family matters more than anything else in a child's life. Stress hormones course through a child's system when a family has problems. "In the village, illness among children increases more than twofold following significant stress," says Flinn (Small, 2000).

Compilation of saliva subsequent to significant conflict within a group of children consistently failed to show high levels of cortisol, whereas one of those same children, returning home late from shopping a couple weeks later, had salivary cortisol levels that rose 60% above normal. This study gives scientific confirmation to the importance of how emotional stress contributes to physical illness.

During the Ceausescu regime in Romania thousands of children became orphaned as a by-product of his malevolence. Neglect that included being left alone in cribs or playpens, absent any stimulation and interaction, resulted in withdrawn, unpredictable children, who were prone to rocking in place and staring blankly at visitors. Harvard researchers have documented their later development, which included difficulty coping with normal human interaction and touch (Holden, 1996; DiPietro, 2000). Simply being touched and held throughout the first few years of infancy may well set up constructive stress-response patterns that last a lifetime.

OFFICE TESTING

RAGLAND'S SIGN

A simple test to help assess the status of the adrenal glands can be performed in an office-based setting as part of a thorough examination. Instead of simply taking a blood pressure reading while the patient is in the seated posture, begin by taking a reading while the patient is supine on the table. After recording the reading, immediately repeat the blood pressure in the standing position. Under normal circumstances, the systolic blood pressure should rise at least 8 mmHg. An abnormal drop in the systolic pressure is considered positive for adrenal hypofunction and this drop is referred to as postural hypotension.

NUTRITIONAL CONSIDERATIONS

In the context of this chapter it would be virtually impossible to enumerate and elucidate all the potentially beneficial supplements that aid in restoring a more properly functioning adrenal gland. We endeavor to discuss merely those that appear to be most advantageous and have the heaviest weight of published literature.

ADAPTOGENS

This group of substances helps the body adapt to stress, and has been shown to reduce the damage of the stress response, maintain homeostasis during chronic stress, reduce most evidence of the alarm stage, and delay the exhaustion phase. Royal Bee Jelly (one of the world's richest sources of pantothenic acid needed for the adrenal glands) is an adaptogen; however, the most widely researched are Siberian ginseng (*Eleutherococcus senticosus*) and licorice (*Glycyrrhiza*) (Ritchason, 1995).

Licorice

Licorice is a perennial herb native to the Mediterranean region, central to southern Russia, and Asia Minor to Iran, now cultivated throughout Europe, Asia, and the Middle

East (Bruneton, 1995; Karnick, 1994; Leung & Foster, 1996). It is one of the most widely used medicinal herbs and is found in numerous traditional formulas (Leung & Foster, 1996). Licorice is one of the most extensively researched medicinal and food plants. Licorice root has been used therapeutically for several thousand years in both Western and Eastern systems of medicine (Leung & Foster, 1996).

The Latin name for licorice is Glycyrrhiza glabra. Dioscorides, a 1st-century Greek physician is responsible for its genus name, Glycyrrhiza, which comes from glukos (sweet) and riza (root) (Foster & Tyler, 1999). The pharmacopeial name for licorice is Liquiritiae radix and it is known by other names including Liquorice, Gancao, sweet root, Yasti-madhu and Glycyrrhiza.

While the first recorded cultivation of the herb was in the 13th century by Piero de Cresenzi from Bologna, its use was first documented on Assyrian clay tablets ca. 2500 B.C.E for the treatment of coughs and relief of the unwelcome effects of laxatives. The Greeks used it ca. 372 to 287 B.C.E. for asthma, dry coughs, and all pectoral diseases. In China, first mention of the herb was in the Shen Nong Ben Cao Jing (ca. 25 C.E.). In addition to its advantageous properties as an expectorant and antitussive, the Chinese pharmacopeia notes its antispasmodic relief on gastrointestinal smooth muscle and its desoxycorticosterone-like action (Tu, 1992). Further to its other beneficial effects, the current ayurvedic pharmacopoeia reports it as an adrenal agent (Karnick, 1994). Licorice root and extracts as well as fluid and solid are in the U.S. National Formulary (1985). Studies have investigated and documented its favorable effects as an anxiolytic (Chen, Hsieh & Lai, 1985). The British Herbal Compendium reported its actions as an anti-inflammatory, expectorant, demulcent, and adrenocorticotropic (Bradley, 1992).

Harvesting comes from cultivation of roots that are 3 to 4 years old. The roots and stolons contain glycyrrhizin, also called glycyrrhizic or glycyrrhizinic acid (5 to 9% by weight), which is believed to be some 50 times sweeter than sucrose. That same sweet taste is lost or reduced when in an acidic medium (Leung & Foster, 1996).

Licorice is a natural way to supplement the body's endogenous cortisol production, giving the adrenals a well-needed rest. Dosage is 25 to 100 mg/day. Pharmacopeial-grade licorice root must contain no less than 4% glycyrrhizic acid, calculated in the dried root.

Chemically speaking, licorice root contains triterpenoid saponins (4 to 24%), mostly glycyrrhizin, along with a mixture of potassium and calcium salts, flavonoids (1%), amines (1 to 2%), asparagines, choline, and betaine; amino acids; 3 to 15% glucose and sucrose; starch (2 to 30%); polysaccharides; sterols; resin and volatile oils. Research done by Heikens, Fliers, Endert, Ackermans, and van Montfrans (1995) proposes that the hydrolytic metabolite of glycyrrhizic acid, glycyrrhetenic acid, is the major dynamic element causing inhibition of peripheral metabolism of cortisol that binds to mineralocorticoid receptors in like fashion to aldosterone.

Two hypotheses for licorice's mechanism of action have been suggested by research:

1. The binding of glycyrrhetinic acid to mineralocorticoids receptors, and/or
2. Blocking the action of 11-beta-hydroxysteroid dehydrogenase.

Recent publications advocate that both hypotheses may be implicated, particularly with the substantiation that the blocking of 11-beta-hydroxysteroid dehydrogenase is short term and that subsequent to its occurrence, the pseudoaldosteronism is directly linked to increased plasma concentration of licorice metabolites and their binding to mineralocorticoids receptors. 11-beta-hydroxysteroid dehydrogenase usually metabolizes glucocorticoids into inactive compounds rapidly, thereby controlling glucocorticoids' access to mineralocorticoids and glucocorticoids receptors. Increased glucocorticoid concentration in mineralocorticoid responsive tissue results from the licorice thwarting inactivation of hydrocortisone. This results in glucocorticoids occupying mineralocorticoid receptors and producing a mineralocorticoid response that is demonstrated by hypertension and increased sodium retention (Chandler, 1997).

Extreme quantities of licorice consumption (more than 20 g per day) have elevated concerns about the potential for glycyrrhizin in licorice producing pseudoaldosteronism (excess levels of aldosterone), which may cause symptoms of headache, hypertension, lethargy, potassium loss that upsets the balance of sodium and potassium and possible cardiac arrest. The pseudoaldosterone-like effects are generally attributed to the glycyrrhizic acid. Of note, within several weeks of cessation any symptoms of hyperaldosteronism disappear (Mantero, 1981). A deglycyrrhizinated licorice (DGL) preparation has been developed that provides most of the therapeutic benefits while reducing risk.

Usage should be limited to no more than 4 to 6 weeks at a time to prevent potentiation of glucocorticoids and mineralcorticoids. Prolonged use with high doses may result in water and Na retention and K loss. This may be accompanied by edema, hypertension, and hypokalemia. It is not recommended while pregnant and is contraindicated with liver cirrhosis, hypertonia, hypokalemia, severe kidney insufficiency, and cholestatic liver disorders.

Ginseng

The Latin name for ginseng is Panax ginseng. Its pharmacopeial name is Ginseng radix. Other names for it include Chinese ginseng, Korean ginseng, true ginseng

and Asian ginseng. The genus name *Panax* is derived from the Greek *pan* (all) and *akos* (cure), meaning cure-all. Like licorice, ginseng's therapeutic uses were recorded over 2000 years ago in the oldest comprehensive material medica, Shen Nong Ben Cao Jing.

Ginseng is a slow-growing perennial herb native to the northeastern mountain forests of China, Korea, and the far eastern portions of Russia. It is cultivated extensively in these same countries. Flowering of the plant begins in the fourth year and its roots take 4 to 6 years until the plant reaches full maturity. Many types and grades of the herb exist.

Pharmacopoeia grade ginseng from both China and Japan should be collected from the dried matured root in the autumn. The rootlets must be removed. Confirmation of botanical identity is confirmed by thin-layer chromatography (TLC) in addition to micro- and macroscopic examination.

Asian medicine uses dried ginseng as a tonic to revitalize and replenish vital energy (qi). Traditional uses include as a prophylactic aid to restore resistance, reduce vulnerability to sickness, and encourage health and longevity.

The origins of its activity are based on whole body effects rather than specific organs and systems, which provides support to the time-honored view that ginseng is a tonic that can invigorate the functioning of the organism as a whole. Ginseng is in the national pharmacopoeias of several European countries, Russia, and China. In the United States, it has been used as a stand-alone herb or as the main ingredient in a wide range of tonics, and energy and immunostimulant supplements. Over the course of the last half-century, numerous scientific studies of varying quality have been published on ginseng (Foster & Chongxi, 1992). Ten clinical trials have investigated the efficacy of ginseng on physical stress and psychomotor functions.

One such study by Caso Marasco et al. reported on its ability to improve quality-of-life in persons subjected to high stress (Caso Marasco, Vargas Ruiz, Salas Villagomex, & Begona Infante, 1996). This same study found that when ginseng was added to the base of a multivitamin it improved subjective parameters in a population exposed to high physical and mental stress. This suggests an adaptogenic effect to this combination.

The biologically active constituents in ginseng are made up of a fusion of triterpene saponins known as ginsenosides. Ginsenosides are found nowhere else in nature. The two main ginsenosides, Rb1 and Rg1, correspondingly suppress and stimulate the central nervous system. It is proposed that these contrasting actions may contribute to the adaptogenic portrayal of this herb and its ostensible capacity to balance corporal functions.

The Commission E monographs from Germany noted that the resistance of rodents was enhanced when various stress models such as coldness and immobilization tests were performed.

Siberian ginseng (*Eleutherococcus senticosus*) is in the same family but contains eleutheros instead of ginsenosides. It is also considered to be adaptogenic.

Use is contraindicated in hypertension. The *British Herbal Compendium* contraindicates use during pregnancy; however, the Commission E report fails to corroborate that. Ginseng is known to have estrogenic activity. It could negatively affect estrogen-dependent diseases in woman, i.e., endometriosis, fibrocystic breasts, or breast cancer.

Dosage for the root is between 1 and 2 g/day for as long as 3 months at a time. Tinctures, fluid extracts, standardized extracts, and decoctions are also available and dosage is dependent upon the source. Ginseng needs to be taken for at least 1 month before any positive effects are likely to be felt.

Ginseng along with another adaptogenic herb, ashwagandha, has been suggested to influence adrenal hormone activity by helping to support normal HPA function (Brown, 1996).

Other herbs shown to be of benefit to the adrenal glands include astragalas, bayberry, borage, burdock, kava, kelp, parsley, and rose hips (Leung & Foster, 1996).

Vitamins and Nutrients

Vitamin C reduces the effects of chronic stress by decreasing cortisol production (American Chemical Society, 1999; Nathan, van Droux, & Feiss, 1991). A high dietary intake of vitamin C may even help reduce the effects of chronic stress by inhibiting the release of stress hormones. Ascorbic acid when given orally (1 g twice daily) also buffered exogenous ACTH-induced increases in cortisol. An additional function of ascorbate in the adrenal glands is as a protective compound for cytochrome (Hornsby, Harris, & Aldern, 1985).

Evidence indicates adrenal cortex function is compromised in the event of a deficiency of vitamin B5 derivatives and metabolites (Gregory & Kelly, 1999). Alternatively, the administration of pantethine in several experimental animal models appears to enhance adrenal function (Kosaka, Okida, Kaneyuki, et al., 1973; Onuki & Hoshino, 1970).

Lipoic acid, known as the universal antioxidant, appears to prevent the accretion of catecholamines in cardiac tissue secondary to stress. It also augments the abolition of catecholamine degradation products (Fomichev & Pchelintsev, 1993).

Other nutrients that demonstrate possible effects include tyrosine, phosphotidylserine (PS), and plant sterols and sterolins.

TABLE 82.2
Associated Symptoms and Consequences of Impaired Adrenals

- Low body temperature
- Weakness
- Unexplained hair loss
- Nervousness
- Difficulty building muscle
- Irritability
- Mental depression
- Difficulty gaining weight
- Apprehension
- Hypoglycemia
- Inability to concentrate
- Excessive hunger
- Tendency toward inflammation
- Moments of confusion
- Indigestion
- Poor memory
- Feelings of frustration
- Alternating diarrhea and constipation
- Osteoporosis
- Auto-immune hepatitis
- Auto-immune diseases
- Lightheadedness
- Palpitations (heart fluttering)
- Dizziness that occurs upon standing
- Poor resistance to infections
- Low blood pressure
- Insomnia
- Food and/or inhalant allergies
- PMS
- Craving for sweets
- Dry and thin skin
- Headaches
- Scanty perspiration
- Alcohol intolerance

BIOFEEDBACK

Biofeedback utilizes audiovisual input to teach patients to control their own reactions to pain, stress, and similar noxious stimuli. Patients are able to visualize graphic representations of the effects of noxious stimuli on various physiologic responses such as blood pressure, heart rate, skin temperature, and sweating on computer monitors or auditory input. Then through trial and error subjects learn to control these physiological responses in order to decrease the negative effects of the noxious stimuli on their bodies.

Biofeedback has had particular success when utilized in the treatment of chronic pain and stress management (Kong, Lim, & Oon, 1989). Typically, a series of five to ten treatments are given.

IMPROVING ADRENAL HEALTH WITH LIFESTYLE

The most common reason why the adrenals are impaired is unresolved emotional stress. Attend to this first. Recognize concealed causes of stress. These could include toxins from solvents, pesticides, yeast, dysbiosis, parasites, structural misalignments, etc.

Optimize the diet. Also, get appropriate amounts of sleep. Because repair and rest occur between 11 p.m. and 1 a.m. these tools should be optimized. From an acupuncture point of view, the gallbladder releases toxins between these same 2 hours. If you are awake, they can back up into the liver.

In a recent study in the Journal of Behavioral Medicine, progressive relaxation was shown to be the most effective means of reducing the stress response when compared to music, attention control, and silence, which were found to be effective, but less so (Scheufele, 2000).

Sleep is an often overlooked piece of the health puzzle that has recently been shown to be of major significance. A new study in the Journal of the American Medical Association (JAMA) reports that sleep-related hormone imbalances often start to surface in the mid-1930s (Cauter, Leproult, & Plat, 2000) 149 healthy men between the ages of 16 and 83 were involved in this sleep study. By the time the men reached 36 to 50 years of age the amount of sleep spent in the most restful state (slow wave) had decreased by almost 80% from the late teens and early 20s. Sleep deprivation on any given night results in increased levels of cortisol and decreased growth hormone secretion the subsequent night. The relationship between sleep quality and hormone function may very well be a two-way street: lack of adequate sleep may interrupt hormonal equilibrium and at the same time hormonal imbalances can trigger sleep difficulties.

In a related editorial in the same JAMA issue, Blackman (2000) notes that early intervention (with hormonal testing) is the best method for screening.

When it comes to dealing with stress, humor plays a significant role that should be acknowledged and encouraged. Humor helps us make sense of, understand, and cope with reality and serves as nature's biofeedback, stress-control system (Woodhouse, 1993).

Massage, avoidance of food allergies and hypersensitivities, proper diet, and changed attitudes are just some of the positive tools that can be utilized in an effort to improve lifestyle. Learning stress management is a quintessential tool in reducing adrenal tension.

Exercise

The positive effect exercise plays in reducing daily stress cannot be overemphasized (Carmack, et al., 1999). Among working adults, physical activity performed during leisure time was found to decrease perceived stress (Aldana, Sutton, Jacobson, & Quirk, 1996).

Exercise is a great stimulator of positive mental and physical well-being. It increases oxygen uptake by red blood cells, lymphatic circulation, excretion of toxins, and has a profound positive effect on one's self-image. Exercise also increases endorphin production, which can indirectly reduce stress and pain throughout the body. Caution should always be exerted not to over exercise, which will overstress the body, thus reversing the beneficial effects.

Clinical experience strongly suggests that exercise is an effective way for stressed individuals to enhance their sense of self-control and coping self-worth (ACSM). The importance of regular aerobic activity as a means of dealing with stress is well documented. In addition to several positive effects already mentioned, it has been shown to reduce the cardiovascular impact of emotional stressors (Sotile, 1996).

Other forms of exercise that increase relaxation and mental focus include yoga and Tai Chi Chuan. The term "relaxation training" has been used to describe these types of intervention. Other relaxation training techniques are self-hypnosis, meditation, breathing exercises, and biofeedback.

Many believe that combining more than one type of relaxation training increases their effectiveness.

CONCLUSIONS

In the absence of serious disease, tumors, or other pathology, there exists a state of adrenal overuse that is brought on by difficulty dealing with the increasing stresses of life. Every human has a different adaptational capacity (i.e., tolerance to stress). Irrespective of the stressor, the response they elicit from the body is very similar, the most common being from emotional stimuli.

Recent advances in laboratory tests utilizing saliva that are both easy and convenient have been developed to help with diagnosis. Early testing, as promulgated by Blackman (Scheufele, 2000), is the first line of defense in maintaining a stronger endocrine system.

A healthy endocrine system starts essentially at the embryologic level. From the time of birth the simplest of things including cuddling, touching, and holding signal the beginnings of a healthy adrenal gland. Experiments with rat pups that had especially attentive mothers found they have more of a certain type of receptor on the surface of the hippocampus than in the relatively neglected group of rats. These specific receptors responded to a cortisol-like hormone. The fact that more of these corticosterone-receptors were present presages that the brain would be more sensitive and efficient in utilizing this hormone to terminate the stress response.

The conventional medical establishment has frowned upon natural approaches to managing adrenal function, generally because there has been no apparent relationship established between many illnesses and waning adrenal function. More often than not, adrenal decline is perceived as a side effect of the disease process instead of as the direct cause. It may be borne out that the decline of the adrenal gland is, in fact, both an indirect cause and a side effect of numerous persistent and acute infirmities.

The sum of all the stresses during the course of a lifetime can contribute to the aging process. The neuroendocrine theory of aging validates the paralleling decline of the endocrine glands and the aging process. It further bears out that restoring more youthful hormonal levels to these same organs can slow down, and in many instances reverse, some of the effects of that same aging process.

Profoundly potent herbs, along with certain vitamins including ascorbic acid, vitamins B1 and B6, the coenzyme forms of vitamin B5 (pantethine) and B12 (methylcobalamin), the amino acid tyrosine, and other nutrients such as lipoic acid, phosphotidylserine, and plant sterol/sterolin combinations (Kelly, 1999; Shelygina, Spivak, Zaretskii, et al., 1975). DHEA and pregnenalone supplementation, and a healthy lifestyle that includes regular exercise, proper rest, humor, de-stressing the nervous system and energy flows of the body through chiropractic and acupuncture, progressive relaxation, and biofeedback-make up the foundation of a prescription for a strong and vibrant adrenal gland.

Aromatherapy for Pain Relief

A.R. Hirsch, M.D.

In explaining the persuasive attraction of alternative medicine, Kaptchuk and Eisenberg (1998) note, "The fundamental premises are an advocacy of nature, vitalism, science, and spirituality." With this in mind, the science underpinning aromatherapy will be explored.

DEFINITIONS

One of the difficulties in understanding aromatherapy is that it means different things to different people. One part of its definition that is agreed upon is that aromatherapy uses odorous compounds to promote health and healing (Kaptchuck & Eisenberg, 1998). Beyond this, opinions differ. Aromachologists speak of using odors not to treat disease, but to promote wellness. Aromatologists believe in ingestion of the substance being used as well as its inhalation (Price & Price, 1995). Many aromatherapists believe in using massage coincident with inhalation (Tisserand, 1977). In this chapter, aromatherapy is defined as the use of odorants as inhalants to treat underlying medical or psychiatric conditions. This definition excludes any effects of ingestion or percutaneous absorption, although they may be significant depending upon the method of application (Weyers & Brodbeck, 1989). As defined, aromatherapy use is also independent of any effects of coincident, noninhalational therapy, such as massage, interpersonal interaction, or bathing.

This definition is consistent with the literature indicating that real aromatherapy involves the uptake of fragrant compounds only through inhalation, not by other methods (Buchbauer, 1993).

Many in the aromatherapy community believe that natural or essential oils are effective and that artificial synthesized compounds are not. However, in the treatment of neurologic and psychiatric diseases, literature does not differentiate between them (King, 1994). No distinction will be made herein between the use of synthesized as opposed to naturally occurring oils.

BACKGROUND

Why is the concept of aromatherapy under consideration today? One reason is its history. Throughout history, odorants have been used to treat various diseases. More than 5000 years ago the Egyptians treated disease using odors (Lindsay, Pitcaithly, & Geelen, 1997), and 3500 years ago the Babylonians used odors to exorcise demons of disease (Roebuck, 1988). The ancient Aztecs also used odors to treat disease. Aromatherapy has known no cultural or geographic boundaries. Virtually all cultures have fumigated the sick (Buchbauer, 1993).

ANATOMY OF OLFACTION

Neuroscience provides insight into the mechanisms by which odors may impact behavior and neurologic functioning.

There is an anatomic basis for the belief that odors can affect the brain and behavior (Brodal, 1969). Once an odor passes through the olfactory epithelium, it must stimulate the olfactory nerve, which consists of unmyelinated olfactory fila. The olfactory nerve has the slowest conduction rate of any nerve in the body. The olfactory fila pass through the cribiform plate of the ethmoid bone and enter the olfactory bulb. During trauma, much damage occurs

0-8493-0926-3/02/$0.00+$1.50

in this bulb (Hirsch & Wyse, 1993). Different odors localize in different areas of the olfactory bulb.

Inside the olfactory bulb is a conglomeration of neuropil called the glomeruli. Approximately 2000 glomeruli reside in the olfactory bulb. Four different cell types make up the glomeruli: processes of receptor cell axons, mitral cells, tufted cells, and second-order neurons that give off collaterals to the granule cells and to cells in the periglomerular and external plexiform layers. The mitral and tufted cells form the lateral olfactory tract and establish a reverberating circuit with the granule cells. The mitral cells stimulate firing of the granule cells, which, in turn, inhibit firing of the mitral cells.

A reciprocal inhibition exists between the mitral and tufted cells. This results in a sharpening of olfactory acuity. The olfactory bulb receives several efferent projections, including the primary olfactory fibers, the contralateral olfactory bulb and the anterior nucleus, the prepiriform cortex (inhibitory), the diagonal band of Broca (with neurotransmitters acetylcholine and GABA), the locus coeruleus, the dorsal raphe, and the tuberomamillary nucleus of the hypothalamus.

The olfactory bulb's efferent fibers project into the olfactory tract, which divides at the olfactory trigona into the medial and lateral olfactory stria. These project to the anterior olfactory nucleus; the olfactory tubercle; the amygdaloid nucleus (which, in turn, projects to the ventral medial nucleus of the hypothalamus, a feeding center); the cortex of the piriform lobe; the septal nuclei; and the hypothalamus, in particular the anterolateral regions of the hypothalamus, which are involved in reproduction. The neurotransmitters by which the olfactory bulb conducts its information include glutamate, aspartate, NAAG, CCK, and GABA.

The anterior olfactory nucleus receives afferent fibers from the olfactory tract and projects efferent fibers, which decussate in the anterior commissure and synapse in the contralateral olfactory bulb. Some of the efferent projections from the anterior olfactory nucleus remain ipsilateral, and synapse on internal granular cells of the ipsilateral olfactory bulb.

The olfactory tubercle receives afferent fibers from the olfactory bulb and the anterior olfactory nucleus. Efferent fibers from the olfactory tubercle project to the nucleus accumbens as well as the striatum. Neurotransmitters of the olfactory tubercle include acetylcholine and dopamine.

The area on the cortex where olfaction is localized, that is, the primary olfactory cortex, includes the prepiriform area, the periamygdaloid area, and the entorhinal area. Afferent projections to the primary olfactory cortex include the mitral cells, which enter the lateral olfactory tract and synapse in the prepiriform cortex (lateral olfactory gyrus) and the corticomedial part of the amygdala. Efferent projections from the primary olfactory cortex extend to the entorhinal cortex (area 28), the basal and lateral amygdaloid nuclei, the lateral preoptic area of the hypothalamus, the nucleus of the diagonal band of Broca, the medial forebrain bundle, the dorsal medial nucleus and submedial nucleus of the thalamus, and the nucleus accumbens.

It should be noted that the entorhinal cortex is both a primary and a secondary olfactory cortical area. Efferent fibers from the cortex project via the uncinate fasciculus to the hippocampus, the anterior insular cortex (next to the gustatory cortical area), and the frontal cortex. (This may explain why temporal lobe epilepsy that involves the uncinate often produces parageusias of burning rubber, known as uncinate fits (Acharya, Acharya, & Luders, 1996).

Some of the efferent projections of the mitral and tufted cells decussate in the anterior commissure and form the medial olfactory tract. They then synapse in the contralateral parolfactory area and contralateral subcallosal gyrus. The exact function of the medial olfactory stria and tract is not clear. The accessory olfactory bulb receives afferent fibers from the bed nucleus of the accessory olfactory tract and the medial and posterior corticoamygdaloid nuclei. Efferent fibers from the accessory olfactory bulb project through the accessory olfactory tract to the same afferent areas, for example, the bed nucleus of the accessory olfactory tract and the medial posterior corticoamygdaloid nuclei. It should be noted that the medial and posterior corticoamygdaloid nuclei project secondary fibers to the anterior and medial hypothalamus, the areas associated with reproduction. Therefore, the accessory olfactory bulb in humans may be the mediator for human pheromones (Hirsch, 1998a).

Some unique aspects of the anatomy of the olfactory system are worth mentioning. Smell is the only sensation to reach the cortex before reaching the thalamus. The only sensory system that is primary ipsilateral in its projection, olfaction does not depend upon the cortex, as has been demonstrated in decorticated cats.

Neurotransmitters of the olfactory cortex are multiple, including glutamate, asparatate cholcystekinin, LHRH, and somatastatin.

Furthermore, perception of odors causes modulation of olfactory neurotransmitters within the olfactory bulb and the limbic system. Virtually all known neurotransmitters are present in the olfactory bulb. Thus, odorant modulation of neurotransmitter levels in the olfactory bulb, tract, and limbic system intended for transmission of sensory information may have unintended secondary effects on a variety of different behaviors and disease states that are regulated by the same neurotransmitters. For instance, odorant modulation of dopamine in the olfactory bulb/limbic system may affect manifestations of Parkinson's disease. Mesolimbic override to many of the components of Parkinson's disease have been well documented, for example, motoric activation associated with emotional distress and fear of injury in a fire.

EMOTIONAL AND BEHAVIORAL EFFECTS OF ODORS

Odors can affect behavior by acting as alternative sensory stimuli. The phenomena of visual system mediation of the movements of Parkinsonian gait through the visual stimuli of lines placed on the floor (Dietz, Goetz, & Steddings, 1990) is an example of alternative stimuli. Other sensory input, including pain, has been shown to inhibit the Jacksonian march in epilepsy (Gowers, 1881 in Efron, 1957). Similarly, odors may act as competing sensory stimuli during an uncinate seizure (Efron, 1957). It seems possible that other sensory input, including odors, could modify Parkinson's disease as well as other neurologic conditions by acting as competing sensory stimuli.

Using another mechanism of action, odors can affect behavior and mood by producing secondary effects on the emotions of the individual. This is different from a direct neurophysiologic effect of the limbic system. Rather, the odor can change the mood of the individual, which then has secondary neurologic effects. For instance, mood or level of alertness can affect a variety of neurologic conditions, including the perception of pain. A soldier who is severely wounded in battle may continue to fight and not feel pain until the battle is over. Studies also suggest that persons in a positive state of mind are less bothered by pain (Fields, 1967).

Substantial evidence exists that odors can affect mood. As early as 1908, Freud stressed the importance of olfaction on emotion in his description of a patient with an obsessional neurosis.

> By his own account, when a child, he recognized everyone by their smell, like a dog, and even when he was grown up he was more susceptible to sensations of smell than other people … and I have come to recognize that a tendency towards osphresiolagnia which has become extinct since childhood may play a part in the genesis of neuroses.
>
> In a general way I should like to raise the question whether the inevitable shunting of the sense of smell as a result of man's turning away from the earth and the organic repression of smell pleasure produced by it does not largely share in his predisposition to nervous diseases. It would thus furnish an explanation for the fact that with the advance of civilization it is precisely the sexual life which must become the victim of repression. For we have long known what an intimate relation exists in the animal organization between the sexual impulse and the function of the olfactory organs.

Of all the sensations, olfaction is the one most intertwined with limbic system functioning (MacLean, 1973). The profuse anatomic and physiologic interconnections through the olfactory bulb, stria, and nuclei to the olfactory tubercle, and from there to the prepiriform cortex, the amygdala, and numerous other limbic system structures support this (Brodal, 1969).

Smells are described differently from other sensory modalities, adding credence to their connection to emotion. Other sensory modalities are first described cognitively; a picture, for instance, is identified as being of a ship, a woman, or a house and only secondarily is it described affectively: "I like it," or "I dislike it" (Ehrlichman & Halpern, 1988). But odors are first and foremost described affectively: "I like it," or "I dislike" it.

The olfactory/limbic/hippocampal connections help to explain olfactory-evoked nostalgia, the phenomena whereby an odor induces a vivid recall of a scene from the distant past (Hirsch, 1992). In 86% of 989 subjects queried, certain odors triggered vivid associations analogous to a flashbulb memory. Classically, an event must induce strong emotions for deposition of such memories to occur (Squire, 1987; Brown & Kulik, 1977). By directly stimulating the limbic system, odors likewise can act as the inducing agent. This phenomenon was vividly described by Proust (1934), who wrote that the aroma of madeleine dipped in tea evoked a flood of memories and nostalgic feelings. Olfactory-evoked recall is usually a positive experience, but it can be negative, as in the olfactory flashbacks of posttraumatic stress disorder (Kline & Rausch, 1985). Hence, it seems possible that olfactory-evoked nostalgia may affect behavior because approximately 90% of these memories are associated with strong affective tones (Laird, 1988).

The facts brings to the forefront the question of how odors impact behavior or mood. The answer can be represented by either of two constructs: the Lock and Key Theory or the General Affective Theory of Odors.

The Lock and Key Theory of Odors

The lock and key theory of odors (also called the systemic effect theory) (Buchbauer, 1993) suggests that odor acts very much like a specific neurotransmitter, a drug, or an enzyme. In this paradigm, an odorant has a specific effect on behavior or emotion — one odor for one emotion or one odor for, at most, a few emotions. Thus, an odor could be viewed like a medication in the pharmacopeia. For instance, in the world of neurology, propranolol is used for modulation of essential tremor, migraine headache, and anxiety. However, one would not use propranolol as a treatment for insomnia, dementia, or multiple sclerosis. The lock and key theory suggests that specific odors have specific effects. This theory has been proposed in virtually every book about aromatherapy in which specific odors are recommended for specific health effects (Damien & Damien, 1995; Cunningham, 1995; Feller, 1997; Price, 1991; Price & Price, 1995; Schnaubelt, 1995; Keville & Green, 1995).

An argument supporting the Lock and Key Theory is that odorants exert central nervous system (CNS) effects outside a subject's conscious awareness. In test animals, the more lipophilic an odor is, the greater its sedative effect. In addition, steric differences in odors create different effects despite similarities in perceived odor and volatility (Buchbauer, 1993; Buchbauer, et al., 1993).

According to the Lock and Key Theory, odors act as a drug (Buchbauer, 1993) with a potentially pharmacologic mechanism of action. The odorants are integrated in the membrane of the cells causing an increase in membrane volume due to disruption of the membrane lipids. This leads to electrical stabilization of the membrane, thus blocking the inflow of calcium ions and suppressing permeability for sodium ions. As a result, action potential production is inhibited, which induces narcosis or local anesthesia. At higher concentrations of odorant, the conductivity of potassium ions is reduced. It also is possible that the odorants act on protein kinase C, which could impact upon the spontaneous rhythm of nerve cells (Buchbauer, 1993).

This mechanism of action is further supported by established physiology for the action of an odor on the target organ, in this case, the brain. Inhalation of an odorant would have to produce measurable levels in the blood, sufficient to pass through the blood–brain barrier. Stimpfl et al. (1995) demonstrated that this does occur. One subject inhaled 1,8-cineol for 20 minutes, which produced a linear increase of 1,8-cineol in the blood, up to 275 ng/ml, a level high enough to allow penetration of the blood–brain barrier (Stimpfl, et al., 1995).

The General Affective Theory of Odors

An alternative theory, the General Affective Theory of Odors, also called the Reflectorial Effect Theory (Buchbauer, 1993), holds that an odor experienced as hedonically positive induces a positive, happy mood and when in a happy mood, an individual does almost everything better. For instance, when a person feels happy, it is easier to learn and to sleep, and headaches are less frequent. According to the General Affective Theory, a single odor could have a multitude of diverse effects, thus affecting virtually all behaviors.

The major premise that hedonically positive odors induce happier moods was demonstrated by Alaoui-Ismaili, et al. (1997); 44 subjects inhaled five odorants, namely, vanillin, menthol, eugenol, methyl methacrylate, and propionic acid. Six autonomic nervous system parameters were recorded: skin potential, skin resistance, skin temperature, skin blood flow, instantaneous respiratory frequency, and instantaneous heart rate. Evaluation of these parameters demonstrated a pattern consistent with known emotional states. Hedonically pleasant odors evoked mainly happiness and surprise, and unpleasant ones induced mainly disgust and anger (Alaoui-Ismaili, et al., 1997).

Milter, et al. (1994) also showed that exposure to odors could change emotions in the same direction as the hedonic valence of the odor. Using the startle reflex amplitude as a physiologic indicator of emotional valence, he found that the odor of hydrogen sulfide (H_2S) increased the startle reflex amplitude and the odor of vanillin reduced it.

Aromatherapists recognize the affective impact of odors as the mechanism of action. Buchbauer notes, "A pleasant odor has always been, and still is, an important factor for people to feel good, and feeling well is synonymous with good health. Therefore, we can conclude that all substances which are able to create a certain amount of well-being and well-feeling possess therapeutic properties and, therefore, can be called therapeutic agents" (Buchbauer, 1990). The General Affective Theory of Odors might be extended to include nonodorants in the pharmacologic arena such as valium. Valium may be useful for virtually all medical conditions because reducing anxiety makes conditions such as chronic pain, movement disorders, or insomnia less bothersome. Hence, an entire branch of medicine could be built around Valium: "Valiotherapy". If one ascribes aromatherapeutic results to the General Affective Theory as the mechanism of action, it follows that any odor that one likes induces a happier state and, hence, would have a positive effect on any disease. Again, the concept could be expanded beyond odors to any environmental stimuli, for example, a bird singing or a pretty landscape. A *Star Wars* movie might induce happiness in some observers and could be seen as inducing a positive mood state. The positive mood might lead to a reduction in pain, anxiety, and negative feelings. One could then categorize this as a form of alternative therapy: "Lucastherapy".

Reliance on the General Affective Theory of Odors implies that virtually any sensory stimulus could be used as a therapeutic tool. This largely trivializes the definition of therapy.

Another problem with the General Affective Theory of Odors is that the same odor, in different contexts, may induce opposite emotional tones (Sugawara, Hino, & Kawasaki, 1999). In *The Invalid's Story*, Mark Twain compares the disgust at the odor of a rotting corpse to the delight at the smell of cheese. The odors were the same but perceived to be from different sources. This suggests that an odor that is contextually appropriate in one situation might be considered totally inappropriate in another. If smelled in a positive context, it would be appreciated as hedonically positive and would enhance a positive affective state; smelled in a negative context, it would be perceived as hedonically negative and would, thus, induce a negative affective state. Therefore, the same odor could produce opposite mood states and opposite effects.

A variant of the General Affective Theory is that odors may induce a mood more congruent with the demands of the external environment. For instance, if the external environment requires that the individual be alert, the odor induces awareness of this; therefore, the individual responds by becoming more alert. Alternatively, if the external environment is such that it is more appropriate to be relaxed, the odor induces that awareness and the individual responds by becoming more relaxed. Evidence for the validity of this variant comes from studies of muguet odor. Where the external demand is for a greater degree of relaxation, individuals do become more relaxed, and in an environment where they are required to be more alert and vigilant, they become more alert. Warm, Dember, and Parasuraman (1991) demonstrated this effect of odorant-induced recognition of affective demands. A total of 40 subjects underwent vigilance tasks for 40 minutes during which they received periodic 30-second whiffs of air or one of two hedonically positive fragrances: muguet (independently judged as relaxing) or peppermint (independently judged as alerting). Those who received either the relaxing or alerting fragrance detected more signals during the vigilance task than the unscented air controls ($p < 0.05$).

This odorant-induced congruence of mood may also be applied to the pharmacologic agent, valium. Valium can induce opposite mood states in the same individual at different times. It can reduce anxiety to enhance concentration on a test, or it can reduce concentration to act as a soporific when the same individual is suffering with insomnia.

A corollary to the General Affective Theory is that hedonically negative odors or malodors have a negative effect on mood. If this is true, the simple elimination or masking of malodors with neutral or hedonically positive odors would induce positive effects.

Literature supports the negative effects of hedonically negative odors. Miner (1980) described some effects of exposure to the odor of livestock waste. They included annoyance, depression, nausea, vomiting, headache, shallow breathing, coughing, insomnia, and impaired appetite.

One of the malodorous pollutants that has been studied, trichloroethylene, a universally present air pollutant, can cause cephalgia (Hirsch & Rankin, 1993). Acute exposure to nitrogen tetroxide can cause cephalgia (Hirsch, 1995a) and chronic neurotoxicity (Hirsch, 1995b). Acute exposure to chlorine gas can cause neurotoxicity (Hirsch, 1995c). In 1991, Neutra, et al. (1991) reported that people living near hazardous waste sites suffer more physical symptoms during times when they can detect malodors than when they are unaware of them. Shusterman (1992) demonstrated that even at levels considered nontoxic, chemical effluviums can cause physical symptoms.

HEALTH EFFECTS OF MALODORS

Health effects of malodors can be divided into six categories: respiratory, chemosensory, cardiovascular, immune, neurologic, and psychologic.

Respiratory. Asthmatics are especially affected by malodors. Any strong odor may induce an attack in persons with unstable asthma and, even in nonasthmatics, malodors have been demonstrated to affect the cardiorespiratory system. Increased ambient oxidant levels correlate with slower cross-country running times in high school students (Wayne, Wehrle, & Carroll, 1967).

Chemosensory. Chronic exposure to malodors from pulp mills can cause permanent olfactory loss (Maruniak, 1995).

Cardiovascular. Certain malodors can induce an adrenocortic and adrenomedullary response leading to elevated blood pressure and a subsequent increase in stroke and heart disease (Evans, 1994).

Immune. Immune function may be compromised either directly, as a result of olfactory/neural projections to lymphoid tissue (Evans, 1994), or indirectly, as a result of malodor-induced depression or other negative mood states (Weisse, 1992).

Neurologic. Chronic exposure to intermittent malodors from a U.S. Navy dump site in Port Orchard, Washington induced cortical and subcortical dysfunction, which was manifested by encephalopathy: limbic encephalopathy and cephalgia (Hirsch, 1995d). Both ambient NO_2 and SO_2 impair visual adaptation to darkness and sensitivity to brightness, and increase alpha wave desynchronization on EEG (Izmerov, 1971).

Psychologic. Recognized for centuries and noted by Freud and others, psychologic effects of odors vary widely among individuals. Persons under major stress are particularly vulnerable to the psychologic effects of ambient malodors (Evans, 1994). Persons with a distorted or impaired olfactory sense may be annoyed by odors that other persons usually consider pleasant (Evans, 1994).

Certain bad odors irritate nasal passages. Resultant trigeminal stimulation releases adrenaline, leading to a tense and angry state. Thus, bad odors can trigger aggression that may then be covertly expressed. For example, in one experiment college men were instructed to apply electric shocks of varying intensity to their colleagues, supposedly for the

purpose of training them. When bad odors were present, the subjects chose to inflict greater degrees of pain upon their colleagues (Rotton, et al., 1979). Another example involves air pollution. On days when malodorous air pollution is high, the number of motor vehicle accidents increases, indicating that people drive more aggressively in a polluted environment (Ury, Perkins, & Goldsmith, 1972).

Various studies show how mood and well-being suffer in the presence of malodors. Residents exposed to the effluvium from nearby commercial swine operations reported that they suffered increased tension, fatigue, confusion, depression, and anger, and that their vigor decreased (Schiffman, et al., 1995). According to one study (Rotton, et al., 1978) ambient pollutants decreased personal attraction. In a German urban area, the moods of young adults fluctuated in synchrony with the daily fluctuations in quality of environmental air, a pattern especially marked among more emotionally unstable individuals (Brandstatter, Fuhrwirth, & Kitchler, 1988). Further, daily diary entries of women in Bavaria showed that variations in their psychologic well-being coincided with variations in ambient air quality. The correlation was particularly marked among women suffering from chronic diseases such as diabetes (Bullinger, 1989a; 1989b). In Israel, negative health effects were significantly associated with levels of urban pollution (Zeidner & Schecter, 1988).

The number of family disturbances and the number of 911 emergency psychiatric calls also were linked to malodors in the environment, as determined by ozone levels (Rotton & Frey, 1985). In several cities, the number of psychiatric admissions paralleled the quality of environmental air (Briere, Downes, & Spensley, 1983).

In a study of the malodorous emanations from a mulching site southeast of Chicago, it was found that on days when the miasma wafted from the site to the school across the street, children at the school demonstrated increased behavioral problems (Hirsch, 1998b).

Malodorous ambient SO_2 levels correlate with psychiatric admissions, child psychiatric emergencies (Valentine, et al., 1975), and behavioral difficulties with decreased cooperation (Cunningham, 1979). Ambient NO_2 levels covary with psychiatric emergency room visits (Strahilevitz, Strahilevitz, & Miller, 1979).

In nonsmokers, the odor of cigarette smoke has been demonstrated to exacerbate aggressive behavior (Jones & Bogat, 1978).

The fatigue and annoyance caused by ambient malodors undoubtedly reduce individuals' capacities to function normally. Their abilities to tolerate frustration, to learn, and to cope with other stressors are impaired. In one laboratory study, subjects exposed to unpleasant odors experienced increased feelings of helplessness (Rotton, 1983).

CONTRADICTORY THEORIES

If the General Affective Theory of Odors is true, a single odor can induce a positive mood in one person and a negative mood in another. This negates the Lock and Key Theory in which odors' effects are produced outside of conscious awareness. Robin, et al. (1999) demonstrated this using eugenol. Eugenol, which is often associated with the smell of dental cement, was rated pleasant by nonfearful dental subjects and unpleasant by fearful subjects ($p = 0.036$). Changes in subjects' autonomic nervous system measurements were consistent with their emotional states; (Robin, et al., 1998; 1999) 19 subjects were exposed to eugenol while recording six autonomic nervous system parameters, including two electrodermal, two thermovascular, and two cardiorespiratory. The results of seven subjects with high dental fear were compared with those of 12 without such fear. Those with dental fear had a stronger electrodermal response ($p = 0.006$), suggesting that eugenol triggered different emotional responses depending upon the unpleasantness of the subjects' past dental experiences. Thus, the same odor can have different effects depending upon the past experience of the individual (Robin, et al., 1998).

On the other hand, if the Lock and Key Theory is true, and an odor's behavioral effects are produced outside of awareness and independent of affective reaction, this negates the General Affective Theory of odors. Ludvigson and Rottman do just that, demonstrating that the scent of lavender enhances mood state while impairing arithmetic reasoning ($p = 0.01$) (Ludvigson & Rottman, 1989).

Given the previous information, several factors must be taken into account in reviewing the literature regarding efficacy of aromatherapy in the treatment of neurologic disease. Can odors elevate mood as the general affective theory maintains or do they act in lock and key fashion? Were the odors tested considered hedonically positive by each subject? This question is essential because what is hedonically positive for one person can be hedonically negative for another, and an odor that is hedonically positive at one concentration may be hedonically negative at another (Distel, et al., 1999). Was an associated change in mood independent of the desired effect? Was there a control group? Was it a single-blind or double-blind procedure? Was the subject size sufficient to obviate falsely positive test results? Did the subjects of the experiment have a normal or near-normal sense of smell?

Could suggestion have an effect? This is particularly relevant because various studies suggest that, as in traditional pharmacologic intervention (Flaten, Simonsen, & Olsen, 1999), odors have both placebo and nocebo effects as demonstrated by Knasko, Gilbert, and Sabini, (1990). Knasko subjected 90 people to water vapor sprayed in a room; 30 subjects were told that the water vapor odor was pleasant, 30 that it was unpleasant, and 30 that it was

neutral. Those who had been told that the odorant was pleasant reported being in a better mood than did the other two groups ($p = 0.05$). Subjects who had been told the odor was unpleasant reported having more health symptoms ($p < 0.0003$).

Were the experiments controlled not only for the effect of suggestion, but also for the effect of expectation of outcome? It seems possible that persons with a positive view of aromatherapy who believe that odors can have a positive effect will experience a positive effect because of their bias.

The effect of expectation has been demonstrated neurophysiologically by Lorig and Roberts (1990) who measured the contingent negative variation (CNV) of the EEG in 18 subjects presented with a mixed odor of lavender, jasmine, and galbanium. They found CNV amplitude for the mixed odors varied depending on what the subjects were told about it ($p = 0.05$).

Did the experimenter consider the effect of social desirability whereby subjects try to please the examiner by biasing their answers? (Visser, 1999)

In light of such questions, one must be circumspect regarding articles touting aromatherapeutic efficacy in the treatment of neurologic disease. Because the basic physiologic mechanism of aromatherapy intervention has not been fully established, skepticism seems all the more appropriate.

AROMATHERAPY FOR VARIOUS NEUROLOGIC DISEASES

As a general rule, neurologic diseases can be positively influenced by improving the patient's mood or allaying anxiety. Virtually all neurologic diseases are made worse with depression and/or high anxiety. If moods can be ameliorated by aromatherapy, it would suggest that aromatherapy could have a positive role in treating neurologic disease.

With this in mind, let us review the literature discussing the effects of aromatherapy in specific neurologic complaints and diseases.

Headache

Nontraditional therapies are frequently used in the management of headache, such as acupuncture, massage, and biofeedback.

Historically, odors have been recognized to have analgesic effects. When Roman soldiers returned from battle, they placed bay leaves in their baths to reduce their pains (Genders, 1972). In ancient Greece, the Corinthian physician, Philonides, recommended pressing cool, scented flowers against the temples to relieve headaches (Genders, 1972).

In contemporary lay literature, a multitude of unsupported claims are made for headache and pain reduction using specific odorants. These claims do not indicate whether the mechanism of action is primarily analgesic, soporific, or anxiolytic. Suggested odorants include cloves for dental pain (Price & Price, 1995); wintergreen for muscle pain (Price & Price, 1995; Gobel, et al., 1995); menthol, ginger, lemon grass, rosewood, clary sage (Damien & Damien, 1995), cajeput, tea tree, juniper, pepper, and rose (Walji, 1996), for headaches (Price & Price, 1995); lavender (Passant, 1986), *Lavandula angustifolia*, *Chamaemelum mobile*, *Ocimum basilicum*, *Origanum majorana*, *Rosmarinus officinalis* (Price & Price, 1995), eucalyptus (Damien & Damien, 1995), and true melissa (Price, 1991) for migraine; *Mentha* × *piperita* for "headache caused by digestive disorder" (Price & Price, 1995); peppermint and eucalyptus for tension headache (Saller, Hellstein, Hellenbrecht, 1988).

Experimental studies of odors for pain management are few. Hirsch and Kang (1998) studied 50 chronic sufferers whose headaches met International Headache Society criteria. Upon olfactory testing, only 31 demonstrated normal olfactory ability. Green apple odor was given in an aromatherapy inhaler. Only 15 subjects found the odor hedonically pleasant. In this open label, nonblinded study, subjects served as their own controls. The control condition consisted of resting in a dark, quiet room, and the experimental condition involved inhaling the green apple odor while resting in the same dark, quiet room. Results indicated that green apple odor produced no statistically significant improvement over simple resting in a dark, quiet room. However, in the subgroup of 15 subjects who liked the odor, there was a statistically significant reduction in the severity of the headache ($p < 0.03$). Therefore, the efficacy of the green apple odor was hedonically dependent. Subjects who liked the smell experienced a statistically significant reduction in the severity of the headaches, but patients who disliked the smell experienced no significant improvement.

The mechanism of the odor's action in reducing headaches in these 15 patients is subject to speculation. The odor may have induced a variety of psychologic effects. The therapeutic result may have been mediated through Pavlovian conditioning. For example, the respondents may have consciously or unconsciously associated (Kirk-Smith, Van Toller, & Dodd, 1983) the green apple odor with past anxiolytic or pain-alleviating experiences so that the association reproduced this same effect during the headache episodes. The odor also might have worked through olfactory-evoked recall, because olfactory-evoked recall is usually pleasant and associated with a positive mood state. The green apple scent, by inducing a positive mood state in the 15 patients, could thus have reduced perception of pain (Fields, 1967). This corresponds with the General Affective Theory of Odors described previously.

The lack of response in those who found the green apple scent unpleasant indicates that hedonics were more important than the particular odor used. This does not preclude the possibility of a neurophysiologic effect of the odor, including a change in serotonin, dopamine, acetylcholine, norepinephrine, GABA, gastrin, beta endorphin, or substance P, all of which are known to be modulators of headache, including migraine. Because these neurotransmitters exist within the olfactory bulb, they could, theoretically, be influenced by odors (Anselmi, et al., 1980; Appenzeller, Atkinson, & Standefer, 1981; Foote, Bloom, & Aston-Jones, 1983; Gall, et al., 1987; Haberly & Price, 1978; Halasz & Shepherd, 1983; Hardebo, et al., 1985; Igarashi, et al., 1987; Leston, et al., 1987; Macrides & Davis, 1983; Mair & Harrison, 1991; Moskowitz, 1984; Nattero, et al., 1985; Shipley, Halloran, & Torre, 1985; Sjaastad, 1986; Zaborsky, et al., 1985).

Green apple odor may have worked somewhat like pharmacologic agents used in the treatment of headache, for example, amitriptyline or propranolol, by modifying the neurotransmitters in the pain pathway. In patients who disliked the odor, a strong negative mood state may have been induced that overwhelmed the odor's neurophysiologic effect. Therefore, the pain was not alleviated.

Gobel also studied the effects of odors on headaches (Gobel, et al., 1995; Gobel, Schmidt, & Soyka, 1994). In that study, 32 healthy subjects underwent a double-blind, placebo-controlled, randomized crossover study of the effects of peppermint oil, eucalyptus, and ethanol. The odors were used in different combinations on various measures of headache pain, including the relaxation of peri-cranial muscles and contingent negative variation. In this study, three applications of odorant were placed on the skin of the forehead and temples at 15-minute intervals using a small sponge. After 45 minutes, parameters were assessed. To avoid factors of circadian rhythm, all testing took place between 3 and 6 p.m. To prevent subjects from recognizing the presence vs. the absence of odors and thereby breaking the double-blind nature of the study, "traces" of peppermint oil and eucalyptus oil were added to all applications.

Eucalyptus had no effect. Peppermint combined with eucalyptus and ethanol relaxed pericranial muscles ($p < 0.05$) as did a combination of peppermint and ethanol. The most reduction of pain sensitivity as measured by algesimetry was from a combination of peppermint oil and ethanol. Regulation of pericranial muscles was a postulated mechanism of action of the peppermint.

This study has several potential problems. Because the traces of peppermint and eucalyptus were sufficient to cause olfactory response, they also may have been sufficient to produce an effect, although they were described as inert. Hence, the authors may not have tested the particular odors they thought they tested. Furthermore, no parameter was measured to determine whether the effect was based on hedonics, to eliminate any influence of the general affective theory of odors. No assessment was made of subjects' olfactory abilities, nor was the anticipation effect (belief vs. nonbelief in aromatherapy) addressed.

The author postulated that the odors, through a peripheral mechanism in the gate control theory of pain, acted by segmental inhibition of the posterior horn (Gobel, et al., 1995). However, this same pathway could have been activated totally independently of the odors. The experimental procedure of applying the odors by rubbing cold oils on the skin may, in and of itself, have influenced the pain pathway. The cold stimuli could have induced firing of A deltafibers, which would have increased blood flow in the skin and created a counterstimulus to reduce the headache pain. Alternatively, the inhalation of odors may have affected central serotonergic systems leading to a change in mood state and, thus, a reduction in pain (General Affective Theory of Odors).

In another study, Gobel and colleagues found aromatherapy with peppermint oil was effective in treating tension headaches meeting IHS classification (Gobel, et al., 1996). Peppermint oil was applied locally in a randomized, placebo-controlled, double-blind, crossover fashion; 15 g of peppermint oil and 90% ethanol was used. The placebo was 90% ethanol solution to which traces of peppermint oil were added for blinding purposes. During their headache attacks, peppermint oil was applied across the foreheads and temples of 41 patients. The application was repeated after 15 and 30 minutes. Compared with the placebo, peppermint oil significantly reduced headache intensity after 15 minutes ($p < 0.01$). The analgesic effect equaled that of 1000 mg of acetaminophen. Very few studies that claim to have demonstrated efficacy of aromatherapy have been as carefully performed (Woolfson & Llewitt, 1992).

Another possible mechanism by which peppermint may relieve headache is by noncompetitive inhibition of serotonin and substance P (Saller, Hellstein, & Hellenbrecht, 1988). Odors may inhibit headaches by acting as calcium channel blockers. *Romarinus officinalis*, for example, has been demonstrated to relax tracheal smooth muscle by way of its calcium antagonistic property (Aqel, 1991).

Other Chronic Pain

Opinion regarding relief of nonheadache pain is mixed. In a blinded study by Dale & Cornwell (1994) of 635 postpartum women, use of lavender in the daily bath was compared with an aromatic placebo consisting of 2-methyl-3-isobutyl tyrosine diluted in distilled water. Of the women, 217 received lavender, 213 synthetic, and 205 control. This study demonstrated no statistically significant effect of using lavender in treating peroneal pain. In

a study that was not randomized, not double-blinded, and not age-controlled, Woolfson and Hewitt (1992) gave aromatherapy and massage in 20-minute sessions twice a week to 12 patients. Another 12 patients received massage only. The aromatherapy patients were massaged with lavender oil in an almond oil base. The other patients were massaged with almond oil only. Observations were recorded at the beginning and end of each 20-minute session and 30 minutes after treatment. All sessions were conducted in midafternoon. Approximately 50% of the patients were in the coronary care unit and the others were in intensive-care units; 50% of the patients were artificially ventilated. The authors state that 50% of the aromatherapy patients and 41% of massage-only patients reported a decrease in pain. This could be misleading, however. That six patients responded to aromatherapy and five patients responded to massage without aromatherapy is clearly not a statistically significant difference. If anything, these results indicate that aromatherapy was no better than massage alone. Given their selection of patients, however, one would not anticipate that aromatherapy would be effective, because the pathway for olfactory input was compromised by artificial ventilation.

In a study by Burns and Blamey (1994) of 585 women, no statistically significant effects were described, but analgesia was noted in four women who inhaled lavender, one who inhaled eucalyptus, three who inhaled clary sage, one who inhaled jasmine, two who inhaled chamomile, and one who inhaled lemon.

In 100 patients with pain of the periarticular system (Krall & Krause, 1993), treatment of from 10 to 20 days compared the efficacy of mint oil with that of hydroxyethylsalicylate gel. The mint oil was put into a gel and applied topically. Of the patients and physicians, 78% thought that mint therapy was highly effective and 50% of patients and 34% of physicians thought that hydroxyethylsalicylate gel was highly effective. None of the confounding parameters previously mentioned, such as olfactory ability, expectation, and hedonics, were addressed in this study.

COMMON SUSCEPTIBILITIES

Before using aromatherapy in neurologic conditions, consideration must be given to the potential risks of the treatment. Adverse reactions can occur among patients with diseases that predispose them to the development of side effects, and among the population as a whole as well.

Certain diseases make their sufferers particularly susceptible to adverse effects of aromatherapy. Approximately 40% of migraineurs report osmophobia, whereby an odorant induces a migraine headache (Blau & Solomon, 1985). A wide range of odorants can act as such triggers, depending on the individual. These triggers include perfume, cigarette smoke, and food odors (Hirsch & Kang, 1998).

Asthmatics, upon exposure to common odors, can suffer a worsening of their respiratory status independent of their olfactory ability. In a survey of 60 asthmatic patients, 57 (95%) described respiratory symptoms upon exposure to common odors including insecticide (85%), household cleaning agents (78%), perfume and cologne (72%), cigarette smoke (75%), fresh paint (73%), automobile exhaust or gas fumes (60%), and cooking aromas (37%). Room deodorant and mint candy also could cause respiratory distress (Shim & Williams, 1986). Four subjects who underwent an odor challenge with four squirts of a popular cologne all had an immediate decline in 1-second forced expiratory volume (18 to 58% reduction) (Shim & Williams, 1986).

Among persons who suffer complaints consistent with multiple chemical sensitivities, 24% of the men and 39% of the women note that odors precipitate their complaints (Miller, 1996). However, double-blind studies fail to demonstrate odorant-induced multiple chemical sensitivity symptoms (Ross, et al., 1999).

Inhalation of odorants can produce measurable levels in the blood (Stimpfl et al., 1995), and because many common fragrances contain naphthalene-related compounds (including menthol and camphor), persons with G6PD deficiency may be at risk from aromatherapeutic exposures (Olowe & Ransome-Kuti, 1980). In neonates, dermal application has demonstrated this, but in adults, it remains only a theoretic risk for inhalational aromatherapy.

A variety of essential oils are said to be able to precipitate seizures in epileptics. Whether these effects can occur by inhalation alone as opposed to ingestion or by percutaneous absorption is unclear. Proconvulsant odorants include rosemary (Betts, 1994; Tisserand, 1977), fennel, hyssop, sage, and wormwood (Tisserand, 1977).

Because aromatherapeutic inhalation of essential oils can produce detectable levels of the oils in the blood, these compounds, like any pharmacologic agents, could induce adverse drug–drug interactions in persons on medication. Such interactions could enhance metabolism of anticonvulsants or pain medications, for example, thus predisposing an epileptic to have a seizure or a chronic pain patient to withdraw from medication. Jori, Bianchetti, and Prestini (1969) demonstrated this potential. Inhalation of eucalyptol by rats increased microsomal enzyme systems, thus decreasing the effect of pentobarbital.

Odorants can produce harmful side effects not only among persons predisposed to disease, but among the healthy population as well. Airborne-induced allergic contact dermatitis is a recognized result of aromatherapeutic inhalation of tea tree oil (melaleuca oil) (DeGroot, 1996). Examples of common melaleuca oil allergens include d-limonene, aromadendrene, alpha-terpinene, 1,8-cineole

(eucalyptol), terpinen-4-ol, p-cymene, and alpha-phellandrene. Because of the highly volatile nature of essential oils, their common constituents and cross-sensitization, DeGroot postulated that the same airborne-induced contact dermatitis could occur with several other essential oils including lavender and a mixture of eucalyptus, pine, and peppermint (DeGroot, 1996). Bridges suggested that if odorants can sensitize the respiratory system as they do the skin, they might not only exacerbate asthma, but might actually precipitate asthma (Bridges, 1999).

CONCLUSION

With aromatherapy, just as with any therapeutic tool, practitioners must weigh the relative risk/benefit ratio in deciding upon its use in the treatment of pain.

Having spent the last decade and a half investigating the scientific basis of aromatherapy and having published more than 100 peer-reviewed articles in this area, the author does not believe that scientific literature supports, nor the risk/benefit ratio justifies, use of aromatherapy in pain management at present. This is a fluid position and as more studies are performed delineating the efficacy of aromatherapy, the author expects to endorse and use aromatherapy as part of the therapeutic armamentarium. Until such time, this form of alternative medicine in the treatment of pain cannot be recommended.

Objective Evaluation and Treatment Outcome Measurements in Soft Tissue Injury

Gabriel E. Sella, M.D., M.P.H., M.Sc, Ph.D. (Hon. C.), F.A.A.D.E.P., S.D.A.B.D.A., F.A.C.F.E., F.A.C.F.M., D.A.A.P.M.

Bones forget, muscles remember.

Old English Proverb

DEFINITION

Soft Tissue Injury

This type injury or traumatic pathological condition involves the soft tissues of the body as compared to the skeleton (Cailliet, 1988b). This chapter refers exclusively to injuries affecting muscles and fascia.

Skeletal muscle and overlying fascia form a continuum through the body (Busquet, 1998). The myofascial train comprises of fascial attachments and a continuum over bones, muscles, and connecting ligaments, capsules, tendons, and fascia covering individual muscular fasciculi and fibers (Cailliet, 1988a; 1993; Busquet, 1998). Thus, muscular or myofascial injuries have to be considered together both on an anatomic basis and on a functional basis (Anchor & Felicetti, 1999; Cailliet, 1988a; Sella & Donaldson, 1998).

Injuries may vary in etiology from an acute sharp or blunt form to acute hyperextension types (Cailliet, 1992a; 1991a; 1992b; 1991b; 1988b; 1994; Maigne, 1996; Pope, Anderson, Frymoyer, & Chaffin, 1991).

Any myofascial or muscular injury may affect the development of localized inflamation and consequent dysfunction (Maigne, 1996; Pope, Anderson, Frymoyer, & Chaffin, 1991; Travell & Simons, 1983).

Because muscles/fascia function in myotatic units, an injury affecting one muscle or the fascial envelope of one muscle is reflected to a relative dysfunction of the whole myotatic unit around the pertinent joint(s) movable by the affected muscle (Busquet, 1998; Sella, 2000a; 2000b). Consequently, homolateral myotatic units proximal or distal to the affected unit may become relatively dysfunctional (Busquet, 1998; Cailliet, 1988a; Travell & Simons, 1983). Because the contralateral myotatic unit may need to pick up at least part of the work of the affected unit, functional changes may occur in time in the contralateral unit as well (Busquet, 1998; Cailliet, 1988a; Travell & Simons, 1983).

It is very important for the investigator of soft tissue injury to realize that there is a complex myofascial relationship between the locus of injury and the rest of the myofascial envelope of the body (Busquet, 1998; Maigne, 1996; Pope Anderson, Frymoyer, & Chaffin, 1991). Whereas acute injuries may be followed by localized splinting, the chronic phase of such injuries is evidenced by protective guarding, which may be quite complex (Cailliet, 1988a; 1993). The investigator and/or treating clinician needs to be fully aware of the protective guarding pattern involving the case.

From this standpoint, it is far more complex to evaluate and treat soft tissue injuries than bony injuries such as fractures (Cailliet, 1988a).

0-8493-0926-3/02/$0.00+$1.50

The Objective Evaluation

In order to evaluate adequately soft tissue injury, one must understand the main parameters of symptoms/signs of such injury (Sella, 1995; 1998a; 1998b; 2000c; Sella & Donaldson, 1998). These parameters are usually a combination of any of the following:

Pain
Relative loss of strength
Relative loss of range of motion (ROM)
Relative loss of adequate function
Radiation of symptoms and dysfunction to the contralateral side of the injury site
Relative early or late development of myofascial pain syndrome exemplified by trigger points
Late development of muscular hypotrophy/atrophy and relative shortening

Whereas bone injuries can be evaluated with radiologic means such as X-rays, CT scans, or MRI, soft tissue injury involving skeletal muscles and fascia usually cannot be evaluated properly with any of these radiologic means (Cailliet, 1988a; 1993).

Therefore, the investigator and treating clinician have to rely not only on the clinical experience of evaluation/treatment of soft tissue injuries but also on other objective tools (Anchor & Felicetti, 1999; Galen, 1979; Sella & Donaldson, 1998;).

A prime concept regarding objective evaluation in the clinical sciences in general is that any methodology has to rely on epidemiologic and statistical criteria compatible with scientific and medicolegal requirements of today's society (Galen, 1979; Sella & Donaldson, 1998;). The primary parameter of such methodologies requires validity of clinical and objective measurement. Validity depends on a number of criteria, most particularly the following:

1. Internal consistency of any number of repetitions of the testing, with particular regard to any methodology used;
2. Test/re-test repeatability of any methodology utilized;
3. Reliability of results not only on clinical grounds but also in terms of measurements and/or comparisons against known databases or normative values;
4. Specificity, sensitivity, and predictive values of the clinical measurements according to the statistical requirements of epidemiologic tests;
5. Functional use of the results of the tests of different methodologies in clear clinical terms, especially involving the direction of the rehabilitation process (if the results of some tests have no clinical value in directing treatment, the results may be valid statistically but not in terms of clinical utilization);
6. Functional use of the results of different methodologies in terms of during, pre-, and post-evaluation of the treatment outcome.

Pain practitioners must become aware that the time-honored clinical opinion on diagnostic evaluation and treatment outcome has little value in the medicolegal eyes of the *Daubert* requirements for objective evaluation with new technologies (Sella, 2000c).

The pain practitioner dealing with soft tissue injury evaluation and treatment needs to utilize objective methodologies appropriate for each one of the major parameters of soft tissue injury symptoms/signs (Sella & Donaldson, 1998).

The discussion below details each methodology, including major strengths and limitations (Sella & Donaldson, 1998).

It may be relevant to note *a priori* that any such limitations of any given investigative modality may be countered by the strengths of another given modality. Thus, it is most usually advisable to utilize complementary investigative/treating modalities in order to obtain more robust results.

Objective Treatment Outcome Measurement

Each subject discussed below includes this section as it applies to it.

The clinician must use objective methods of rehabilitation to evaluate the resolution of symptoms and optimization of function. This may comprise questionnaires to be utilized during each visit, dynamometry or inclinometry utilized at regular intervals during the rehabilitation period, etc. As such, the outcome measure may contain not only the final quantitative values but also the chronology of symptom resolution and functional improvement.

SOFT TISSUE INJURY/DYSFUNCTION PARAMETERS

Pain

Acute soft tissue pain is most usually localized to the area of injury. It may involve direct or indirect trauma to the skin, subcutaneous tissue, blood vessels, nerves, fascia, and skeletal muscle as well as tendons, ligaments and bursae, periosteum, and bone (Cailliet, 1988a; 1993). As stated, only pain involving the muscles and fascia are discussed in this presentation (Anchor & Felicetti, 1999; Travell & Simons, 1983).

The acute pain is reflected by the body's reflex of splinting, part of the old survival complex of "fight or flight."

The injured part is "splinted," i.e., defended by the surrounding area of muscles, joints, and fascia as well as

the contralateral area and the appropriate myotatic units of either side.

If the acute pain is not resolved properly in terms of investigation and treatment, it may result in the development of myofascitis and protective guarding (Travell & Simons, 1983).

Pain assessment of soft tissue injury is difficult to perform using the statistical requirements described above. Nonetheless, it is the duty of the modern pain practitioner to do so (Sella & Donaldson, 1998). It is relevant to perform any test a number of times (i.e., at least five times) and measure the internal consistency of performance of the evaluee or patient (Sella, 2000a; 2000c). Any methodology or diversity of methodologies utilized should show a good measure of repeatability of pain assessment or reduction (Sella, 2000a; 2000c). When normative values or databases of objective measurements are known, the results of the pain investigation and/or treatment should be measured against those normative values for reliability (Sella, 2000a; 2000c). When the specificity, sensitivity, and predictive values of any pain investigative methodology are known, the clinical results may be comparable to such data (Sella, 2000a).

The functional utilization of any pain investigative methodology is only as good as the results obtained in relation to it. Therefore, the clinician may want to describe the validity of the application of the pain investigative tool in terms of the results obtained (Sella & Donaldson, 1998).

Because it is necessary to evaluate treatment results before, during, and post-treatment, any methodology for pain investigation/treatment needs to be objective and numerical in terms of the overall outcome measurement (AMA, 1993; Sella & Donaldson, 1998).

The following methodologies for soft tissue pain measurement are considered below.

Pain Questionnaires

There are a variety of soft tissue injury pain questionnaires. The McGill questionnaire is perhaps the best known and most commonly utilized (Melzack, 1975; 1987).

Any pain questionnaire utilization in soft tissue injury evaluation may have to be validated in terms of the statistical and functional criteria described above. Thus, the following may need to apply in order for the clinician or the investigator to be able to state that there is objective validity to the results of the pain questionnaire:

1. The questionnaire testing may be repeated at least five times within 1 month of testing or beginning treatment. The responses may be validated by showing internal consistency of coefficients of variation (CV < 10%) among the 5 or more repetitions for each question and response.
2. The test/re-test repeatability questionnaire tests can be evaluated in terms of the consistency of the response to the pain inquiry. The repeatability validation may be considered if the responses vary within 10%.
3. The reliability of the questionnaire results may need to be evaluated in comparison with known databases for the same kind of injury/response.
4. If available, the pain questionnaire may be considered in terms of specificity, sensitivity, and predictive values.
5. As the treatment is initiated, repeated pain questionnaire tests may show improvements in the overall symptoms/signs, especially with regard to the overall intensity/frequency of the soft tissue injury pain.

For the clinician who cannot afford the effort and luxury of repeated pain inquiry questionnaires in order to satisfy the objectivity criteria defined above, it is advisable to use such questionnaires no less than three times in the course of the clinical relationship. Thus, the patient/evaluee may have to respond to an original pain inquiry questionnaire during (1) the diagnostic evaluation, at the (2) beginning of the treatment period, and (3) at the end of the treatment period. Ideally, the responses should show a decrease or disappearance of the pain symptoms in time with treatment.

The Pain Visual Analogue

This is a visual format that allows the patient/evaluee to describe on a line or graph the intensity and/or frequency of the pain. It also may describe graphically the type of pain of soft tissue injury that one perceives.

The visual analogue is usually formatted on a "___/10" scale where 10/10 represents the highest degree of pain perceived in intensity/frequency and 0/10 represents a complete lack of pain in any region before or after treatment. The visual analogue is easy to perform and takes very little time to accomplish. The application of the visual analogue testing for soft tissue injury pain perception is rather similar to the pain questionnaire.

1. The pain visual analogue may be repeated at least 5 times within 1 month of testing or beginning of treatment. The responses may be validated by showing internal consistency of coefficients of variation (CV < 10%) among the 5 or more repetitions for each test.
2. The test/re-test repeatability pain visual analogues can be evaluated through the consistency of the response to the pain inquiry. The

repeatability validation may be considered if the responses vary within 10%. This holds true for the variables of pain intensity, frequency, or quality (e.g., burning, dull, etc.).
3. The reliability of the pain visual analogue results for adequacy of treatment may need to be evaluated in comparison with known databases for the same kind of injury/response.
4. If such results are available, the pain visual analogue may be considered in terms of specificity, sensitivity, and predictive values.
5. As the treatment is initiated, repeated pain visual analogue testing may show improvements in the overall numerical values representing the pain parameters.

For the clinician who cannot afford the effort and luxury of repeated pain inquiry visual analogues to satisfy the objectivity criteria defined above, it is advisable to use such pain visual analogues no less than three times in the course of the clinical relationship. Thus, the patient/evaluee may have to respond to an original pain inquiry pain visual analogue during (1) the diagnostic evaluation, at the (2) beginning of the treatment period, and (3) at the end of the treatment period. Ideally, the responses should show a decrease or disappearance of the pain symptoms in time with treatment.

The Pain Perception Threshold (P.P.T.)

The P.P.T. is a methodology whereby a pressure gauge is applied and pressed with a determined force on a trigger point or on a traumatized area until the evaluee/patient acknowledges the presence of pain rather than a perception of pressure (Fischer, 1977a, 1987a, 1990, 1994, 1997b; Sella & Donaldson, 1998). It can be used further (with the patient/evaluee's permission) to press until the evaluee states that the pain perception is that maximally tolerated. This tool objectively identifies the number of millimeters of pressure that differentiate the pressure perception from that of pain and/or that of pain recognition vs. maximal pain tolerance.

In forensic terms, it may be relevant to identify any degree of symptom magnification of pain perception/tolerance by applying the P.P.T. gauge on several areas homolateral and contralateral and identify pain perception in areas that have not suffered from soft tissue injury.

1. The P.P.T. may be repeated at least five times on the affected area and on the contralateral area within of 1 month of testing or the beginning of treatment. The responses may be validated by showing internal consistency of coefficients of variation (CV < 10%) among the five or more repetitions for each test.
2. The test/re-test repeatability of such repeated P.P.T. can be evaluated through the response consistency to the pressure gauge. The repeatability validation may be considered if the responses vary within 10%. This holds true for the variables of pain perception at given pressures and perception of maximal pain.
3. The reliability of the P.P.T. results may need to be evaluated for treatment adequacy in comparison with known databases for the same kind of injury/response.
4. If such results are available, the P.P.T. may be considered in terms of specificity, sensitivity, and predictive values.
5. As the treatment is initiated, repeated P.P.T. testing may show improvements in the overall numerical values of millimeters of pressure required to elicit the pain response.

For the clinician who cannot afford the effort and luxury of repeated P.P.T. to satisfy the objectivity criteria defined above, it is advisable to use P.P.T. no less than three times in the course of the clinical relationship. Thus, the patient/evaluee may have to be tested with P.P.T. during (1) the diagnostic evaluation, at the (2) beginning of the treatment period, and (3) at the end of the treatment period. Ideally, the responses should show a decrease or disappearance of the pain symptoms in time with treatment, i.e., an increase in the number of millimeters required to perceive pain or maximal pain. The eventual responses should be quite similar on the affected soft tissue injury site and on the contralateral site.

The Tissue Compliance Measurement (T.C.M.)

This methodology is particularly applicable to soft tissue injury where there is tissue edema and/or chronic myofascitis (Fischer, 1977a, 1977b, 1984, 1987b, 1987c; Sella & Donaldson, 1998). The same criteria that apply to the P.P.T. methodology apply to the T.C.M. methodology.

S-EMG

Surface electromyography is a valid methodology for the investigation and treatment of soft tissue injury pain where skeletal muscles are affected. S-EMG tests the degree of muscular electrical activity and effort during rest and dynamic action (Fischer & Chang, 1985; Sella, 2000a; 1995).

A number of S-EMG amplitude potentials (V RMS) parameters are particularly applicable to muscular dysfunction including (electrical) spasm, hypertonus, hypotonus, co-contraction, myokymia, fasciculations, elevated resting potential values, and abnormal laterality values differences between the affected sites and the nonaffected contralateral sites (Sella, 1995).

The S-EMG methodology has been described before in terms of specificity, sensitivity, predictive values, laterality, internal consistency, repeatability, and reliability by the author (Sella, 2000a). It involves dynamic protocols of bilateral myotatic units, at least one of which is affected by a soft tissue injury site (Sella, 1993).

1. The S-EMG dynamic protocol testing may be repeated at least five times for each segment of ROM on the affected area and on the contralateral area at any particular time. The responses may be validated by showing internal consistency of coefficients of variation (CV < 10%) among the five or more repetitions for each test. If the CV > 10% for the injured muscle but not for the unaffected muscles, the result is relevant for treatment follow-up.
2. The test/re-test repeatability of repeated S-EMG dynamic protocol testing can be evaluated if clinically necessary by at least three repetitions during at least 1 month of testing or treatment. The repeatability validation may be considered if the responses vary within 10%. This holds true for the S-EMG normal or pathological variables.
3. The reliability of the S-EMG dynamic protocol testing results may need to be evaluated for treatment adequacy in comparison with known databases for the same kind of injury/response.
4. Because such results are available for most skeletal muscles, the S-EMG dynamic protocol testing may be considered in terms of specificity, sensitivity, and predictive values.
5. As the treatment is initiated, repeated S-EMG dynamic protocol testing may show improvements in the overall pattern of change from pathological electric curves to normal curves during activity and rest.

For the clinician who cannot afford the effort and luxury of repeated S-EMG dynamic protocol testing to satisfy all the objectivity criteria defined above, it is advisable to use such S-EMG dynamic protocol testing no less than three times in the course of the clinical relationship. Thus, the patient/evaluee may have to be tested with S-EMG dynamic protocol testing during (1) the diagnostic evaluation, at the (2) beginning of the treatment period, and (3) at the end of the treatment period. Ideally, the responses should show a decrease or disappearance of the pathological curve variables described above. The eventual responses should be quite similar on the affected soft tissue injury site and on the contralateral site.

Current Perception Threshold (C.P.T.)

The C.P.T. is a valid methodologythat evaluates individual perception of pain via electrical stimulation of the peripheral pain fibers at the fingertip site (Sella & Donaldson, 1998). In addition to the perception of pain in A and C fibers, the C.P.T. also evaluates the perception of touch/pressure fibers of the A type.

Whereas such perception of any type of fiber, i.e., either touch/pressure or pain, may be considered subjective, repeated testing with the current on or off allows the investigator to distinguish quite easily between a patient with consistent responses vs. a symptom magnifier. Thus, even though the pain or touch perception may be an individual factor, testing may allow the investigator to address the issue of consistency vs. functional overlay. Individuals with soft tissue injury may or may not have nerve damage. When such nerve damage is of the sensory type and involves the A, Aδ, and Cδ fibers, the C.P.T. evaluation is an excellent tool for exclusion of nervous lesion vs. myofascial or other type of soft tissue pathology (Liu, Kopacz, & Carpenter, 1995; Masson & Boulton, 1991).

For the clinician who cannot afford the effort and luxury of repeated S-EMG dynamic protocol testing in order to satisfy all the objectivity criteria defined above, it is advisable to use such S-EMG dynamic protocol testing no less than three times in the course of the clinical relationship.

Thus, the patient/evaluee may have to be tested with S-EMG dynamic protocol testing during (1) the diagnostic evaluation, at the (2) beginning of the treatment period and (3) at the end of the treatment period.

Ideally, the responses should show a decrease or disappearance of the pathological curve variables described above. The eventual responses should be quite similar on the affected soft tissue injury site and on the contralateral site.

Objective Treatment Outcome Measurement

Objective treatment refers to numerical modalities involved in the pain rehabilitation process. Such modalities may be analgesics, in which case one would have to know the type of “pain killer” and the posology given in time. The objective outcome could be a linear follow-up of the pain level at the beginning of the treatment, at each visit, and at the end of the treatment period. For instance, the initial soft tissue injury pain level intensity may be 9/10; in time it may show a decrease pattern to 7/10, 5/10 and eventually reach 1/10 at the end of the treatment period. The example given above is pertinent to one pain treating modality or to a combination of modalities. The main object is to demonstrate a framework of pain level measurement that is consistent, numerical, and spans the beginning to the end of the treatment period.

Strengths and Limitations of Pain Investigation Methodologies

Every scientific methodology has inherent strengths and limitations. Therefore, it is incumbent upon the researcher, investigator or clinician to utilize multiple modalities or methodologies. The choice of combination(s) must be such that the strength of one modality can overcome the limitation of another modality. Furthermore, while theoretically any result derived from any individual modality may have artifact properties, results deriving from a battery of modalities cannot be considered technical artifacts.

In terms of pain investigation, pain questionnaires have the strength of consistency if they are given repeatedly. At the same time, responses are subjective because pain is a subjective phenomenon, thus the limitation of questionnaires. The same criteria apply to the pain picture or visual analogue.

The strength of the pain perception threshold methodology is that it helps to differentiate the perception of pressure from that of pain. Furthermore, it helps to assess individual perception of maximal tolerable pain threshold at the point of pressure. The limitation of the modality is that the subject could state, without any check for consistency, that he or she has pain or maximal pain. This inherent limitation was modified with the test of consistency (Sella & Donaldson, 1998) that modifies the original procedure which required testing of the injured or symptomatic site. The contralateral and other sites are tested at least three to five times for consistency of the numerical value of pain perception. If the responses are statistically consistent, especially with regard to pain perception of the symptomatic site, then the test can be considered valid.

The same considerations apply to the tissue compliance measurement (T.C.M.).

The strength of the S-EMG modality in the investigative mode is that it measures the consistency of effort of any muscular activity. If the amplitude of contraction pattern is abnormal related to pain or other dysfunction, it will remain so as an autonomous factor. The same applies to the parameter of spectral frequency. Specificity and sensitivity studies have shown that the likelihood of amplitude curve abnormality is high in myofascial pain, when tested with S-EMG (Sella, 2000a). The limitation of the S-EMG modality is that it cannot measure the intensity of the pain; to date no studies have been done on the subject so far.

S-EMG can be utilized concomitantly with other modalities. It can strengthen the reliability of the results of the pain questionnaire, pain visual analogue, P.P.T., and T.C.M. by the demonstration of internal consistency, because S-EMG has been shown to demonstrate internal consistency well (Sella, 2000c).

The current perception threshold modality investigates the perceptual threshold of electric stimulation of (close to the surface) nerve endings of peripheral nerves. Its strength may be that of the pain recognition at rather similar micro-electrical stimulation intensities, if the test is done repeatedly.

Its limitation is that recognition is a subjective perception and expression. However, repeated C.P.T. testing and statistical analysis of the results can demonstrate consistency or rule out inconsistency. Performance of this test as part of the battery described above can validate the pain symptom/perception, because the presence of pain should be paralleled by the consistent response pattern in all the tests.

Thus, one can investigate pain of soft tissue injury with several modalities and counter the limitations of one with the strength of another.

Relative Loss of Strength (L.O.S.)

Acute soft tissue injury is often followed by loss of strength of the injured muscle or myotatic unit (Anchor & Felicetti, 1999; Sella & Donaldson, 1998). The L.O.S. may involve direct or indirect trauma to the skin, subcutaneous tissue, blood vessels, nerves, fascia, and skeletal muscle as well as periosteum and bone. As stated, only L.O.S. involving the muscles and fascia is discussed in this presentation.

Acute L.O.S. is reflected by the body's reflex of splinting. The injured part is "splinted", i.e., defended by the surrounding area in terms of muscles, joints, and fascia as well as the contralateral area and the appropriate myotatic units of either side. The deconditioning maintained by pain and tissue inflamation results in relative L.O.S. If the acute L.O.S. is not resolved properly through investigation and treatment, it may result in the development of myofascitis and protective guarding L.O.S.

L.O.S. assessment of soft tissue injury is easy to perform in terms of the statistical requirements described above. Loss of strength can be measured objectively with dynamometry. A variety of dynamometers are on the market. They may refer to several areas of the body. For consistency, dynamometric testing must be performed at least through five repetitions and measure the internal consistency of strength performance of the evaluee or patient.

For repeatability, the dynamometry or other methodologies utilized to assess strength should show a good measure of repeatability for L.O.S. assessment and rehabilitation of strength. When normative values or databases of objective measurements are known, the results of the L.O.S. investigation and/or treatment should be measured against those normative values for reliability.

When the specificity, sensitivity and predictive values of any L.O.S. investigative methodology are known, the clinical results may be comparable to such data. The functional utilization of any L.O.S. investigative methodology is as good as the results obtained in relation to it. Therefore, the clinician may want to describe the validity of the

application of the L.O.S. investigative tool in terms of the results obtained from knowledge of the treatment.

Because it is necessary to evaluate the treatment results before, during, and post-treatment, any methodology for L.O.S. investigation/treatment needs to be objective and numerical for the overall outcome measurement.

Methodologies for soft tissue L.O.S. measurement are considered below.

L.O.S. Questionnaires

Questionnaires can be used to assess the event and presence of L.O.S. The evaluee/patient needs to be asked about the perception of L.O.S. before the injury as well as at the time of examination. L.O.S. questionnaires also may assess strength rehabilitation through the treatment period. Any L.O.S. questionnaire utilization in soft tissue injury evaluation may have to be validated through the statistical and functional criteria described above. Thus, the following may need to be applied in order for the clinician or investigator to be able to state that objective validity to the results of the L.O.S. questionnaire exists:

1. The questionnaire may be repeated at least five times within 1 month of testing or beginning of treatment. The responses may be validated by showing internal consistency of coefficients of variation (CV < 10%) among the five or more repetitions for each question and response.
2. The test/re-test repeatability of such repeated questionnaires can be evaluated for the response consistency to the L.O.S. inquiry. The repeatability validation may be considered if the responses vary within 10%.
3. The reliability of the questionnaire results may need to be evaluated in comparison with known databases for the same kind of injury/response.
4. If available, the L.O.S. questionnaire may be considered in terms of specificity, sensitivity, and predictive values.
5. As the treatment is initiated, repeated L.O.S. questionnaires may show improvements in the overall symptoms/signs, especially with regard to the overall intensity of the soft tissue injury L.O.S.

For the clinician who cannot afford the effort and luxury of repeated L.O.S. inquiry questionnaires to satisfy the objectivity criteria defined above, it is advisable to use such questionnaires no less than three times in the course of the clinical relationship. Thus, the patient/evaluee may have to respond to an original L.O.S. inquiry questionnaire during (1) the diagnostic evaluation, at the (2) beginning of the treatment period, and (3) at the end of the treatment period. Ideally, the responses should show in time a decrease or disappearance of L.O.S. symptoms with treatment.

The L.O.S. Visual Analogue

This is a visual format that allows the patient/evaluee to describe on a line or graph the intensity of the L.O.S. The visual analogue is usually formatted on a "___/5" scale where 0/5 represents the highest functional degree of L.O.S. perceived in intensity and 5/5 represents full strength.

The visual analogue is easy to perform and takes very little time to accomplish. In terms of the parameters described above for the L.O.S. questionnaire, the application is rather similar to the visual analogue testing for soft tissue injury L.O.S. perception.

1. The L.O.S. visual analogue may be repeated at least five times within 1 month of testing or beginning of treatment. The responses may be validated by showing internal consistency of coefficients of variation (CV < 10%) among the five or more repetitions for each test.
2. The test/re-test repeatability of L.O.S. visual analogues can be evaluated by the response consistency to the L.O.S. inquiry. The repeatability validation may be considered if the responses vary within 10%.
3. The reliability of L.O.S. visual analogue results for adequacy of treatment may need to be evaluated by comparison with known databases for the same kind of injury/response.
4. If such results are available, the L.O.S. visual analogue may be considered in terms of specificity, sensitivity, and predictive values.
5. As the treatment progresses, repeated L.O.S. visual analogue testing may show improvements in the overall numerical values representing the L.O.S. parameter.

For the clinician who cannot afford the effort and luxury of repeated L.O.S. visual analogues to satisfy the objectivity criteria defined above, it is advisable to use such L.O.S. visual analogues no less than three times in the course of the clinical relationship.

Thus, the patient/evaluee may have to respond to an original L.O.S. inquiry or L.O.S. visual analogue during (1) the diagnostic evaluation, at the (2) beginning of the treatment period, and (3) at the end of the treatment period. Ideally, over time the responses should show a decrease or disappearance of the L.O.S. symptoms with treatment.

Dynamometry

Dynamometry is the most useful methodology for measuring strength (Sella & Donaldson, 1998). It measures the sum total of myotatic unit strength rather than individual muscle. Therefore, soft tissue injury to one muscle and probable L.O.S. in that muscle are reflected by L.O.S. on the dynamometric testing. However, the testing involves several groups of muscles and it is likely that all the other muscles involved in the testing try to "protectively guard" the injured muscle and put out more effort than they would have done otherwise.

Dynamometry involves mechanical or electronic gauges. The numbers obtained for the various degrees of effort tested represent the overall strength of voluntary contractions of the muscular groups that are active in the testing.

In forensic terms, it may be relevant to identify any degree of symptom magnification of L.O.S. perception by applying the dynamometric instrument to several muscle groups (homolateral and contralateral) and identify L.O.S. perception in areas which have not suffered from soft tissue injury.

1. Dynamometry may be repeated at least five times on the affected and contralateral areas 1 month of testing or beginning of treatment. The responses may be validated by showing internal consistency of coefficients of variation (CV < 10%) among the five or more repetitions for each test.
2. The test/re-test repeatability of such dynamometry can be evaluated for response consistency. Repeatability validation may be considered if strength testing results vary within 10%.
3. The reliability of dynamometry results may need to be evaluated for adequacy of treatment through comparison with known databases for the same kind of injury/response.
4. If such results are available, the dynamometry may be considered in terms of specificity, sensitivity, and predictive values.
5. As the treatment is initiated, repeated dynamometric testing may show improvements (kilos or pounds) in the overall numerical values representing L.O.S. perception.

For the clinician who cannot afford the effort and luxury of repeated dynamometry to satisfy the objectivity criteria defined above, it is advisable to use dynamometry no less than three times in the course of the clinical relationship. Thus, the patient/evaluee may have to be tested with dynamometry during (1) the diagnostic evaluation, at the (2) beginning of the treatment period, and (3) at the end of the treatment period. Ideally, in time and with treatment the responses should show a decrease or disappearance of the L.O.S. symptoms i.e., an increase in the number of kilos or pounds.

S-EMG

Surface electromyography is a valid methodology for the investigation and treatment of soft tissue injury L.O.S. where skeletal muscles are affected (Sella, 1993, 1995, 1998a, 1998b). S-EMG reflects the degree of muscular electrical activity and effort during rest and dynamic action (Basmajian & DeLuca, 1985). The S-EMG methodology has been described in terms of specificity, sensitivity, and predictive values, laterality, internal consistency, repeatability, and reliability.

S-EMG involves dynamic protocols of bilateral myotatic units, at least one of which is affected by a soft tissue injury site. The S-EMG amplitude parameter is useful as an indicator of muscular effort and ability to proceed with a determined effort. The affected muscle will show a higher amplitude of activity potentials (V RMS) by comparison with the nonsymptomatic contralateral muscle (Sella, 1995, 2000a). This may be because it needs to use and elicit utilization of an increased number of contractile elements in order to obtain and achieve the same strength requirement end result.

However, injured muscle strength is usually lower than that of the asymptomatic muscle and at a certain point of effort requirement, it can no longer sustain the effort and increase the amplitude of contraction. Clinically, that occurs when the evaluee/patient gets rather severe muscular pain and states that he/she can no longer sustain the effort of contraction.

As compared to dynamometry, S-EMG does not reflect exactly strength but rather effort and ability to elicit effort (Kumar & Mital, 1996). On the other hand, it is specific to any given muscle in the myotatic unit, including the injured muscle. As stated above, dynamometry is not specific to a given muscle but to the whole myotatic unit or to the sum total of the myotatic units involved in the effort of strength testing (Sella & Donaldson, 1998).

1. The S-EMG dynamic protocol testing may be repeated at least five times for each ROM segment on the affected area and on the contralateral area at any particular time. The responses may be validated by showing internal consistency of coefficients of variation (CV < 10%) among the five or more repetitions for each test. If the CV > 10% for the injured muscle and its loss of strength but not for the unaffected muscles, such a result is relevant of treatment follow-up.
2. The test/re-test repeatability of such S-EMG dynamic protocol testing can be evaluated if

clinically necessary by at least three repetitions during at least 1 month of testing or treatment. The repeatability validation may be considered if the responses vary within 10%. This holds true for the S-EMG normal or pathological variables.

3. The reliability of S-EMG dynamic protocol testing results treatment adequacy may need to be evaluated in comparison with known databases for the same kind of injury/response.
4. Because results are available for most skeletal muscles, the S-EMG dynamic protocol testing may be considered in terms of specificity, sensitivity, and predictive values.
5. As the treatment is initiated, repeated S-EMG dynamic protocol testing of L.O.S. may show improvements in the overall pattern of change from pathological electric curves to normal curves during activity and rest.

For the clinician who cannot afford the effort and luxury of repeated S-EMG dynamic protocol testing in order to satisfy all the objectivity criteria defined above, it is advisable to use such S-EMG dynamic protocol testing no less than three times in the course of the clinical relationship.

Thus, the patient/evaluee may have to be tested with S-EMG dynamic protocol testing during (1) the diagnostic evaluation, at the (2) beginning of the treatment period, and (3) at the end of the treatment period. Ideally, the L.O.S. responses should show a normalization of the S-EMG amplitude curve described above.

The eventual responses should be quite similar on the affected soft tissue injury site and on the contralateral site. The S-EMG spectral analysis parameter mirrors the element of fatigue. Muscles which have been injured and suffer from L.O.S. are easily fatigable in clinical terms. Improvement of strength and stamina may be mirrored by the S-EMG spectral analysis results which show the decremental curve of the affected/treated muscle to parallel that of the asymptomatic muscle.

Objective Treatment Outcome Measurement

Objective treatment refers to numerical modalities involved in the L.O.S. rehabilitation process. Such modalities may include physical therapy aimed at muscle strengthening, agility, and increased endurance. The objective outcome could be a linear follow-up of the L.O.S. level at the beginning of the treatment, at each visit, and at the end of the treatment period. For instance, the initial soft tissue injury L.O.S. level may be 50% of the contralateral strength. With therapy, the strength may increase and normalize in time to 95% of the expected level in terms of the contralateral strength. This is pertinent to one L.O.S. treating modality or to a combination of modalities.

It is most relevant to demonstrate of measurement of strength regained through therapy which is consistent and numerical and spans from the beginning to the end of the treatment period.

Strengths and Limitations of Loss of Strength (L.O.S.) Investigation Methodologies

In terms of L.O.S. investigation, the L.O.S. questionnaires are consistent if they are given repeatedly. At the same time, the responses are subjective because L.O.S. is a subjective phenomenon, thus the limitation of questionnaires. The same criteria apply to the L.O.S. picture or visual analogue.

The strength of the S-EMG modality in the investigative mode is that it measures the consistency of effort for any muscular activity. If the amplitude of the contraction pattern is abnormal, it will remain so as an autonomous factor. As described above, in general, the amplitude of muscular contraction (at the minimal voluntary contraction level of effort) is higher in a muscle affected by loss of strength, probably because of the need to recruit more contractile elements for the activity (Sella, 1995).

The limitation of the S-EMG modality is that it cannot measure the intensity of the L.O.S. (Kumar & Mital, 1996).

S-EMG can be utilized concomitantly with dynamometry. Thus, it can demonstrate internal consistency in itself and also validate the statistical demonstration of the internal consistency of dynamometry (Sella & Donaldson, 1998; Sella, 2000c).

Thus, one can investigate L.O.S. of soft tissue injury with several modalities and counter the limitations of one with the strength of another.

Relative Loss of Range of Motion (L. ROM)

Acute soft tissue injury is often followed by L. ROM related to functional shortening of the injured muscle, myotatic unit or joint components (Anchor & Felicetti, 1999; Sella & Donaldson, 1998). The L. ROM may involve direct or indirect trauma to the skin, subcutaneous tissue, blood vessels, nerves, fascia and skeletal muscle, articular components, as well as periosteum and bone. As stated, only L. ROM involving the muscles and fascia are discussed in this chapter. Acute L. ROM is reflected by the body's reflex of splinting. The injured part is "splinted," i.e., defended, by the surrounding area in terms of muscles, joints, and fascia as well as the contralateral area and the appropriate myotatic units of either side. The loss of range of motion maintained by pain and tissue inflamation results in relative L. ROM. If the acute L. ROM is not resolved properly by investigation and treat-

ment, it may result in the development of myofascitis and protective guarding of L. ROM-related features.

L. ROM assessment of soft tissue injury is easy to perform using the statistical requirements described above. L. ROM can be measured with goniometry (inclinometry) objectively. A variety of goniometers and inclinometers are on the market (AMA, 1993; Gerhardt, 1992). They may be applicable to several areas of the body. It is very important to utilize the right instrument with the appropriate consistency of methodology (Gerhardt, 1992).

For consistency, goniometric testing should be performed at least through five repetitions measuring the internal consistency of joint motion performance of the evaluee or patient. For repeatability, the goniometry or other methodologies utilized to assess joint motion should show a good measure of repeatability for L. ROM assessment and rehabilitation of joint motion. For reliability, when normative values or databases of objective measurements are known, the results of the L. ROM investigation and/or treatment should be measured against those normative values in terms of reliability.

There are several consensus ROM speciality tables. However, the human joint ROM needs further studies in terms of normative data acquisition.

When the specificity, sensitivity and predictive values of any L. ROM investigative methodology are known, clinical results may be comparable to such data. The functional utilization of any L. ROM investigative methodology is only as good as the results obtained in relation to it. Therefore, the clinician may want to describe the validity of the application of the L. ROM investigative tool in comparison to the results obtained from knowledge of other treatment.

Because it is necessary to evaluate treatment results of joint motion rehabilitation before, during, and after treatment, any methodology for L. ROM investigation/treatment needs to be objective and numerical in terms of the overall outcome measurement.

The following methodologies for soft tissue L. ROM measurement are considered.

L. ROM Questionnaires

Questionnaires can be used to assess the cause and presence of loss of joint range of motion. The evaluee/patient needs to be asked about his or her perception of L. ROM before the injury as well as at the time of examination. L. ROM questionnaires also may assess joint motion rehabilitation through the period of treatment. Any L. ROM questionnaire utilization in soft tissue injury evaluation may have to be validated in terms of the statistical and functional criteria described above. Thus, the following may need to apply for the clinician or the investigator to be able to state that the L. ROM questionnaire results are objectively valid.

1. The questionnaire may be repeated at least five times within 1 month of testing or beginning of treatment. The responses may be validated as showing internal consistency in terms of coefficients of variation (CV < 10%) among the five or more repetitions for each question and response.
2. The test/re-test repeatability of such questionnaires can be evaluated for consistent response to the L. ROM inquiry. Repeatability validation may be considered if the responses vary within 10%.
3. The reliability of questionnaire results may need to be evaluated in comparison with known databases for the same kind of injury/response.
4. If available, the L. ROM questionnaire may be considered in terms of specificity, sensitivity, and predictive values.
5. As the treatment progresses, repeated L. ROM questionnaires may show improvements in joint ROM overall symptoms/signs, especially with regard to the overall intensity of the soft tissue injury.

For the clinician who cannot afford the effort and luxury of repeated L. ROM questionnaires to satisfy the objectivity criteria defined above, it is advisable to use such questionnaires no less than three times in the course of the clinical relationship. Thus, the patient/evaluee may have to respond to an original L. ROM questionnaire during (1) the diagnostic evaluation, at the (2) beginning of the treatment period, and (3) at the end of the treatment period. Ideally, with treatment and time the responses should show a decrease or disappearance of the L. ROM symptoms.

The L. ROM Visual Analogue

This is a visual format which allows the patient/evaluee to describe on a line or graph the extent of joint ROM loss. The visual analogue may be formatted on a ___/Xº scale where 0/0º represents the highest functional degree of L. ROM perceived (ankylosis) and Xº/Xº represents full joint motion.

The visual analogue is easy to perform and takes very little time to accomplish. In terms of the parameters described above for the L. ROM questionnaire, the application is rather similar to visual analogue testing for soft tissue injury L. ROM perception.

1. The L. ROM visual analogue may be repeated at least five times within 1 month of testing or the beginning of treatment. The responses may be validated by showing internal consistency using coefficients of variation (CV < 10%) among the five or more repetitions for each test.

2. The test/re-test repeatability of such L. ROM visual analogues can be evaluated for response consistency to the L. ROM inquiry. Repeatability validation may be considered if the responses vary within 10%.
3. Reliability of the L. ROM visual analogue results may need to be evaluated in comparison with known databases for adequacy of treatment for the same kind of injury/response.
4. If such results are available, the L. ROM visual analogue may be considered in terms of specificity, sensitivity, and predictive values.
5. As treatment is initiated, repeated L. ROM visual analogue testing may show improvements in the overall numerical values representing the L. ROM parameter.

For the clinician who cannot afford the effort and luxury of repeated inquiry using L. ROM visual analogue to satisfy the objectivity criteria defined above, it is advisable to use the methodology no less than three times in the course of the clinical relationship. Thus, the patient/evaluee may have to respond to an original L. ROM visual analogue during (1) the diagnostic evaluation, at the (2) beginning of the treatment period, and (3) at the end of the treatment period. Ideally, with time and treatment the responses should show a decrease or disappearance of the L. ROM symptoms.

Goniometry (Inclinometry)

Goniometry is the most useful methodology for measuring joint motion (Cailliet, 1994). It measures the sum total of myotatic unit and joint motion rather than individual muscles or joint components. Therefore, soft tissue injury to one muscle and probable L. ROM in that muscle are reflected by goniometric testing. However, the testing involves several groups of muscles and the joint. It is likely that the other muscles involved in the testing try to protectively guard the injured muscle and suffer from functional L. ROM as a consequence. Inflamation of the joint may reduce the ability to achieve full motion. Goniometry involves mechanical or electronic gauges. The numbers obtained with various degrees of tested effort represent the overall joint motion of the muscular groups that are active in the testing.

In forensic terms, it may be relevant to find any degree of symptom magnification of L. ROM perception by applying the goniometric instrument to several muscle groups and joints, homolateral and contralateral, and identify the L. ROM perception in areas that have not suffered from soft tissue injury.

1. Goniometry may be repeated at least five times on the affected area and on the contralateral area within 1 month of testing or the beginning of treatment. The responses may be validated by showing internal consistency with coefficients of variation (CV < 10%) among the five or more repetitions for each test.
2. The test/re-test repeatability of such goniometry can be evaluated through the consistency of the response. Repeatability validation may be considered if the joint motion testing results vary within 10%.
3. Reliability of the goniometry results may need to be evaluated in comparison with known adequacy of treatment databases for the same kind of injury/response.
4. If such results are available, the goniometry may be considered in terms of specificity, sensitivity and predictive values.
5. As the treatment is initiated, repeated goniometric testing may show improvements in the overall numerical values representing L. ROM perception of degrees of motion.

For the clinician who cannot afford the effort and luxury of repeated goniometry in order to satisfy the objectivity criteria defined above, it is advisable to use such goniometry no less than three times in the course of the clinical relationship. Thus, the patient/evaluee may have to be tested with goniometry during (1) the diagnostic evaluation, at the (2) beginning of the treatment period, and (3) at the end of the treatment period. Ideally, responses should show a decrease or disappearance of the L. ROM symptoms in time with treatment, i.e., normalization of the degrees of joint motion.

S-EMG

Surface electromyography is a valid methodology for the investigation and treatment of soft tissue injury L. ROM where skeletal muscles are affected. S-EMG reflects the degree of muscular electrical activity and effort during rest and dynamic action. The S-EMG amplitude curve of a joint motion may be different if that motion is partial or complete. In other words, the amplitude curve of the biceps during 50% of full elbow flexion will be different than that of 100% of full elbow flexion.

The S-EMG methodology has been described already in terms of specificity, sensitivity, predictive values, laterality, internal consistency, repeatability, and reliability. It involves dynamic protocols of bilateral myotatic units, at least one of which is affected by a soft tissue injury site.

The S-EMG amplitude parameter is useful as an indicator of muscular effort and the ability to proceed with a determined effort through full joint ROM. As compared to goniometry, S-EMG does not reflect exactly joint motion but rather effort and ability to elicit effort. On the

other hand, it is specific to any given muscle in the myotatic unit, including the injured muscle. As stated above, goniometry is not specific to a given muscle but to the whole myotatic unit or to the sum total of the myotatic units and joint(s) involved in the effort of joint motion testing.

1. S-EMG dynamic protocol testing may be repeated at least five times for each segment of ROM on the affected area and on the contralateral area at any particular time. The responses may be validated by showing internal consistency of coefficients of variation (CV < 10%) among the five or more repetitions for each test. If the CV > 10% for the injured muscle and its L. ROM but not for the unaffected muscles, such a result is relevant treatment follow-up.
2. The test/re-test repeatability of such S-EMG dynamic protocol testing can be evaluated if clinically necessary by at least three repetitions during at least 1 month of testing or treatment. Repeatability validation may be considered if the responses vary within 10%. This holds true for the S-EMG normal or pathological variables.
3. Reliability of the S-EMG dynamic protocol testing results may need to be evaluated in comparison with known databases for the same kind of injury/response for treatment adequacy of L. ROM.
4. Since such results are available for most skeletal muscles, the S-EMG dynamic protocol testing may be considered in terms of specificity, sensitivity, and predictive values.
5. After treatment is initiated, repeated S-EMG dynamic protocol testing of L. ROM may show improvements in the overall pattern of change from pathological electric curves to normal curves during activity and rest.

For the clinician who cannot afford the effort and luxury of repeated S-EMG dynamic protocol testing to satisfy all the objectivity criteria defined above, it is advisable to use such S-EMG dynamic protocol testing no less than three times in the course of the clinical relationship. Thus, the patient/evaluee may have to be tested with S-EMG dynamic protocol testing during (1) the diagnostic evaluation, at the (2) beginning of the treatment period, and (3) at the end of the treatment period. Ideally, the responses of L. ROM should show a normalization of the S-EMG amplitude curve described above. The eventual responses should be quite similar on the affected soft tissue injury site and on the contralateral site.

Objective Treatment Outcome Measurement

Objective treatment refers to numerical modalities involved in the L. ROM rehabilitation process. Such modalities may include physical therapy aimed at muscle stretching and lengthening as well as joint ROM. The objective outcome could be a linear follow-up of the L. ROM level at the beginning of the treatment, at each visit, and at the end of the treatment period. For instance, the initial soft tissue injury L. ROM level may be 50% of the contralateral joint motion. With therapy, the joint motion may increase and normalize in time to 95% of the expected level of contralateral joint motion.

The example given above is pertinent to one L. ROM treating modality or to a combination of modalities. It is relevant to demonstrate a framework of measurement of joint motion normalization through therapy which is consistent and numerical and spans the beginning to the end of the treatment period.

Strengths and Limitations of Loss of Range of Motion (L. ROM) Investigation Methodologies

For L. ROM investigation, L. ROM questionnaires have the strength of consistency if they are given repeatedly. At the same time, the responses are subjective because active L. ROM is a subjective phenomenon, thus the limitation of questionnaires. The same criteria apply to the L. ROM picture or visual analogue.

The strength of the S-EMG modality in the investigative mode is that it measures the consistency of effort of any muscular activity at any given point or curve of joint ROM. If the amplitude of the contraction pattern is abnormal related to L. ROM, it will remain so as an autonomous factor. The limitation of the S-EMG modality is that it cannot measure the extent of active L. ROM (Kumar & Mital, 1996; Sella, 2000b).

S-EMG can be utilized concomitantly with goniometry. Thus, it can demonstrate internal consistency and also validate the statistical demonstration of goniometry internal consistency (Sella, 2000c; Sella & Donaldson, 1998).

Thus, one can investigate L. ROM of soft tissue injury with several modalities and counter the limitations of one with the strength of another.

Relative Loss of Adequate Function (L.A.F.)

Acute soft tissue injury is often followed by loss of adequate function of the injured muscle or myotatic unit (Sella, 1995; 1998a; 1998b). The L.A.F. may involve direct or indirect trauma to the skin, subcutaneous tissue, blood vessels, nerves, fascia, and skeletal muscle as well as periosteum and bone. Only L.A.F. involving the muscles and fascia are discussed in this chapter.

Acute L.A.F. is reflected by the body's reflex of splinting. The injured part is splinted, i.e., defended by the surrounding area of muscles, joints, and fascia as well as the contralateral area and the appropriate myotatic units of either side. De-conditioning may be maintained by pain, tissue inflammation, and resulting relative loss of

strength and range of motion. If the acute L.A.F. is not resolved properly through investigation and treatment, it may result in the development of myofascitis and protective guarding.

L.A.F. assessment of soft tissue injury can be performed according to the components described above. However, because function is very variable in different individuals, there may be a need for further testing for pain, loss of range of motion, or loss of strength. Functional testing needs to follow the same procedural and statistical principles described above.

For consistency, it is important to perform any test as many times as possible and measure internal performance consistency of the evaluee or patient. Repeatability, any methodology or diversity of methodologies utilized should show a good measure of repeatability for L.A.F. assessment or reduction. Normative values or databases of objective measurements of loss of function related to soft tissue injury are not available because of the diversity of such losses. Nonetheless, the clinician needs to be on guard for consistency of performance or lack of performance of individual functional activities, e.g., typing on a computer.

When the specificity, sensitivity and predictive values of any L.A.F. investigative methodology are known, the clinical results may be comparable to such data. The functional utilization of any L.A.F. investigative methodology is only as good as the results obtained in relation to it. Therefore, the clinician may want to describe the validity of the application of the L.A.F. investigative tool in terms of the results obtained from knowledge of the treatment.

Because it is necessary to evaluate the treatment results before, during, and after treatment, any methodology for L.A.F. investigation/treatment needs to have objective and numerical overall outcome measurement.

The following methodologies for soft tissue L.A.F. measurement are considered.

L.A.F. Questionnaires

No soft tissue injury loss of function questionnaires exist. Therefore, the clinician needs to use models of questionnaires utilized for L. ROM and L.O.S., and modify them for each individual loss of function case. Any L.A.F. questionnaire utilization in soft tissue injury evaluation may have to be validated using the statistical and functional criteria described above. Thus, the following may need to apply for the clinician or the investigator to be able to state that there is objective validity to the results of the L.A.F. questionnaire:

1. The questionnaire may be repeated at least five times within 1 month of testing or beginning of treatment. The responses may be validated by showing internal consistency of coefficients of variation (CV < 10%) among the five or more repetitions for each question and response.
2. The test/re-test repeatability of such questionnaires can be evaluated for response consistency to the L.A.F. inquiry. The repeatability validation may be considered if the responses vary within 10%.
3. The reliability of the questionnaire results may need to be evaluated in comparison with known databases for the same kind of injury/response.
4. If available, the L.A.F. questionnaire may be considered in terms of specificity, sensitivity and predictive values.
5. The treatment progresses, repeated L.A.F. questionnaires may show improvements in the overall symptoms/signs, especially with regard to the overall intensity/frequency of the soft tissue injury L.A.F.

For the clinician who cannot afford the effort and luxury of repeated L.A.F. inquiry questionnaires to satisfy the objectivity criteria defined above, it is advisable to use such questionnaires no less than three times in the course of the clinical relationship. Thus, the patient/evaluee may have to respond to an original L.A.F. inquiry questionnaire during (1) the diagnostic evaluation, at the (2) beginning of the treatment period, and (3) at the end of the treatment period. Ideally, with time and treatment the responses should show a decrease or disappearance of the L.A.F. symptoms.

The L.A.F. Visual Analogue

This is a visual format which allows the patient/evaluee to describe on a line or graph the intensity and/or frequency of the L.A.F. It also may describe graphically the type of L.A.F. that one perceives. The visual analogue is usually formatted on a ___/10 scale where 10/10 represents the highest degree of L.A.F. perceived in intensity/frequency and 0/10 represents a complete lack of L.A.F. of any region before or after treatment.

The visual analogue is easy to perform and takes very little time to accomplish. In terms of the parameters described above for the L.A.F. questionnaire, the application is rather similar for the visual analogue testing of soft tissue injury L.A.F. perception.

1. The L.A.F. visual analogue may be repeated at least five times within 1 month of testing or the beginning of treatment. The responses may be validated by showing internal consistency of coefficients of variation (CV < 10%) among the five or more repetitions for each test.
2. The test/re-test repeatability of such L.A.F. visual analogues can be evaluated for response

consistency to the L.A.F. inquiry. The repeatability validation may be considered if the responses vary within 10%. This holds true for the variables of L.A.F. intensity, frequency, or quality.

3. The reliability of the L.A.F. visual analogue results may need to be evaluated in comparison with known databases of adequacy of for the same kind of injury/response treatment.
4. If such results are available, the L.A.F. visual analogue may be considered in terms of specificity, sensitivity and predictive values.
5. After treatment is initiated, repeated L.A.F. visual analogue testing may show improvements in the overall numerical values representing the L.A.F. parameters.

For the clinician who cannot afford the effort and luxury of repeated inquiry of L.A.F. visual analogue to satisfy the objectivity criteria defined above, it is advisable to use such L.A.F. visual analogues no less than three times in the course of the clinical relationship. Thus, the patient/evaluee may have to respond to an original L.A.F. visual analogue inquiry during (1) the diagnostic evaluation, at the (2) beginning of the treatment period, and (3) at the end of the treatment period. Ideally, with time with treatment the responses should show a decrease or disappearance of the L.A.F. symptoms.

Multiple Modalities

A number of objective tests such as dynamometry, goniometry etc. may be applicable on a case-by-case basis loss of functional activity. No example can be given since each loss of function may include different components.

S-EMG

This technology is probably the only soft tissue injury methodology applicable to most, if not all, losses of functional activity. The parameters of utilization during investigation and treatment have been described above.

Objective Treatment Outcome Measurement

Objective treatment refers to numerical modalities involved in the L.A.F. rehabilitation process. Such modalities are usually multiple. The objective outcome could be a linear follow-up of the L.A.F. level at the beginning of the treatment, at each visit, and at the end of the treatment period. For instance, the initial soft tissue injury L.A.F. intensity level may be 9/10, in time it may show a decrease pattern to 7/10, 5/10, and eventually reach 1/10 at the end of the treatment period. It is important to demonstrate measurement of the L.A.F. level which is consistent and numerical and spans the beginning to the end of the treatment period.

Strengths and Limitations of Loss of Adequate Function (L.A.F.) Investigation Methodologies

In terms of L.A.F. investigation, the L.A.F. questionnaires have the strength of consistency if they are given repeatedly. At the same time, the responses are subjective because L.A.F. is a subjective phenomenon, thus the limitation of questionnaires. The same criteria apply to the L.A.F. picture or visual analogue.

The strength of the S-EMG modality in the investigative mode is that it measures the consistency of effort of any muscular activity, be it normal or related to dysfunction. If the amplitude of the contraction pattern is abnormal related to L.A.F., it will remain so as an autonomous factor. The limitation of the S-EMG modality is that it cannot measure the L.A.F. level (Kumar & Mital, 1996). S-EMG can be utilized concomitantly with dynamometry, goniometry, or other modalities described above (Sella & Donaldson, 1998). Thus, one can investigate L.A.F. of soft tissue injury with several modalities and counter the limitations of one with the strength of another.

Radiation of Symptoms and Dysfunction to the Contralateral Side of the Injury Site

Acute soft tissue injury is often followed by loss of adequate function of the injured muscle or myotatic unit (Anchor & Felicetti, 1999). The contralateral and related sites are called into action. The general pattern and process as known as "protective guarding." It is important to note that the protective guarding has an immediate positive and beneficial effect of sparing the injured site.

A problem ensues if the injured site does not get immediate investigative and rehabilitative attention. In the latter case, protective guarding regresses from functional benefit to a dysfunctional process. Only symptoms and dysfunctions involving the contralateral side of the injury site muscles and fascia are discussed in this chapter.

The contralateral side is overworked, and muscular effort and imbalance are reflected shortly by the symptom of fatigue. Eventually, there may be functional loss of strength and even joint inflammation. The muscles and the fascia may develop primary or secondary myofascitis (Busquet, 1998; Cailliet, 1988a; 1992a; Travell & Simons, 1983).

If the initial dysfunction related to protective guarding and indirect radiation of symptoms is not resolved properly during investigation and treatment, it may result in the development of chronic pain and further dysfunction. It is likely that for muscular function, an engram change exists, with the engram of the contralateral side becoming

dysfunctional. Therefore, in addition to the investigation and treatment of the various symptoms such as described above, there is need for S-EMG biofeedback (neuromuscular reeducation) to redress the chronic functional disequilibrium.

The assessment of the symptom radiation to the contralateral side may be performed using the components described above. However, since function is very variable in different individuals, there may be an additional need for testing for pain, loss of range of motion, or loss of strength. Functional testing needs to follow the same procedural and statistical principles described above.

For consistency, it is important to perform any test as many times as possible and measure the internal consistency of the evaluee or patient's performance. For repeatability, any methodology or diversity of methodologies utilized should show a good measure of repeatability in terms of symptoms radiation assessment or reduction.

Normative values or databases of objective measurements of contralateral loss of function related to soft tissue injury are not available because of the diversity of such losses. Nonetheless, the clinician needs to be on guard for consistency of performance or lack of performance of individual functional activities, e.g., typing at a computer.

When the specificity, sensitivity and predictive values of any contralateral investigative methodology are known, the clinical results may be comparable to such data. The functional utilization of any contralateral investigative methodology is only as good as the results obtained in relation to it. Therefore, the clinician may want to describe the validity of the application of the contralateral investigative tool in terms of the results obtained from the knowledge of the treatment.

Because it is necessary to evaluate treatment results before, during, and after treatment, any methodology for contralateral radiation of symptoms/signs and investigation/treatment needs to be an objective and numerical overall outcome measurement.

The following methodologies for soft tissue contralateral radiation measurement are considered:

Questionnaires of Contralateral Symptom Radiation

No soft tissue injury symptoms radiation to the contralateral side questionnaires exists. Therefore, the clinician needs to use the model of questionnaires utilized for L-ROM and L.O.S., and modify such a model for each individual case of contralateral radiation/loss of function. Any such questionnaire utilization in soft tissue injury evaluation may have to be validated according to the statistical and functional criteria described above.

The Contralateral Symptoms Radiation Visual Analogue

This is a visual format which allows the patient/evaluee to describe on a line or graph the intensity and/or frequency of contralateral symptoms radiation. It also may describe graphically the type of symptoms of soft tissue injury perceived. The visual analogue may be formatted on a ___/10 scale where 10/10 represents the highest degree of contralateral dysfunction/radiation perceived in intensity/frequency and 0/10 represents a complete lack of such dysfunction before or after treatment. The visual analogue is easy to perform and takes very little time to accomplish. In terms of the parameters described above for other symptoms questionnaires, the application is rather similar for the visual analogue testing for soft tissue injury radiation to the contralateral side.

Objective Tests

A number of objective tests such as dynamometry, goniometry, etc. may be applicable from case to case of functional activity losses. No example can be given because each loss of function may include different components.

S-EMG

This technology is probably the only soft tissue injury methodology applicable to most, if not all, losses of functional activity related to symptom/signs radiation to the contralateral side. The parameters of utilization during investigation and treatment have been described above.

Objective Treatment Outcome Measurement

Objective treatment refers to numerical modalities involved in the rehabilitation process of radiation of symptoms to the contralateral side. Such modalities are usually multiple. The objective outcome could be a linear follow-up of the dysfunction level at the beginning of the treatment, at each visit, and at the end of the treatment period. For instance, the initial soft tissue injury contralateral dysfunction intensity level may be 9/10, in time it may show a decrease to 7/10, 5/10, and eventually reach 1/10 at the end of the treatment period. The main thing is to demonstrate a framework of measurement of the dysfunctional level which is consistent and numerical and spans the beginning to the end of the treatment period.

Relative Early or Late Development of Myofascial Pain Syndrome Exemplified by Trigger Points

Myofascitis, exemplified by the presence of trigger points and associated pain and dysfunction usually develops early in the chronology of soft tissue injury (Anchor &

Felicetti, 1999). The symptoms are usually a combination of the following:

1. The presence of exquisitely tender trigger points with or without radiation
2. The presence of tenderness on the involved muscle
3. The presence of loss of strength, time dependent on the same muscle
4. The eventual functional shortening of the affected muscle and possibly of the primary myotatic unit followed by loss of strength of the subtended joint(s)
5. The presence of pain that may become chronic and dysfunctional in itself
6. The radiation to the contralateral side with possible dysfunction in terms of secondary development of trigger points and myofascitis to that region
7. Development of symptoms in the radiation area

Radiation of myofascial dysfunction to the contralateral side is usually referred to as a late development in the chronology of myofascitis. It is important for the clinician to understand whether a muscle affected by trigger points is a primary muscle or a secondary muscle. In terms of treatment, a muscle which has secondary myofascial involvement needs treatment not only for itself, but also for the contralateral muscle/myotatic unit that was originally affected by the soft tissue injury.

The questionnaires and investigative modalities described above are valid within the framework of the symptoms/signs which develop and present themselves in primary or secondary myofascitis. The objective identification of a reduction of symptoms/signs needs to follow the same numerical pattern described above for each major soft tissue injury.

Late Development of Muscular Hypotrophy/Atrophy and Relative Shortening

Muscular hypotrophy has to be identified as resulting from structural or functional etiologies (AMA, 1993; Sella, 1995). The clinician needs to rule out neurological pathology from myofascial dysfunction. This presentation does not involve muscular or fascial diseases such as genetic, metabolic, endocrine or toxic myopathies, and related conditions.

The hypotrophy related to untreated myofascial conditions is a functional one, in the sense that the muscle may regain its normal size as the rehabilitative treatment progresses (Bousquet, 1998; Calilliet, 1992a). A finding of muscular hypotrophy and functional shortening is clinically a sign of lack of appropriate treatment for at least 2 months after the original injury event.

Muscular hypotrophy can be investigated with circumferential measurements (AMA, 1993). The limitation of this technique is that it measures the whole myotatic unit of the muscle, i.e., for biceps brachii hypotrophy, the circumferential measurement also assesses the other arm muscles such as the triceps, brachialis, and brachioradialis.

Nonetheless, this is an objective technique. As such it can be utilized within the statistical framework described above. Muscular shortening of functional origin may produce pain with motion and functional loss of joint ROM. These features can be investigated with the means discussed earlier.

S-EMG testing of the hypotrophic/shortened muscle can be done within the framework of the S-EMG ROM protocols. A hypotrophic muscle usually shows loss of strength and increased amplitude of contraction (μV RMS). Therefore, the S-EMG statistical techniques and the dynamometric statistical techniques are valid within this context.

In terms of treatment, physical therapy aimed at muscular agility, strengthening, and endurance in conjunction with S-EMG neuromuscular rehabilitation helps redress the hypotrophy/shortening of the dysfunctional muscles, even if applied late in the history of the pathologic event. The same statistical criteria for objectively follow-up of the treatment results described above apply within this context.

SOFT TISSUE INJURY: IMPAIRMENT MEASUREMENT

If there is a forensic or medicolegal issue with the etiology and post-treatment results of soft tissue injury, the clinician may be asked to perform an impairment evaluation. The clinician needs special training for this task. On the assumption that one can perform such an evaluation, the following parameters are paramount to the granting of any impairment-related percentage:

1. The affected part or system must have attained the state of “maximal medical improvement” (AMA, 1993; Sella & Donaldson, 1998). This means that the intensity/frequency/quality of any present symptom/sign must have a rather constant value within at least 6 months prior to the evaluation, and presumably stay within the same range for the foreseeable 24 months. This excludes, of course, terminal events such as amputations or other surgeries which preclude return to the *status quo ante* function without the help of prostheses, etc.
2. The impairment needs to be considered within medical technology knowledge to be permanent rather than temporary in nature (AMA, 1993). A temporary impairment cannot be granted the

status of permanency as with a given degree of permanent disability.

3. The examinee needs to use approved impairment percentages granted according to legal criteria, which may apply differently from state to state. The degree of impairment may be granted according to the consensus process and utilization of the AMA Guides or other criteria texts (AMA, 1993), as may be found in the Social Security, Workers' Compensation, or federal guidelines, legislative rules, etc.
4. All permanent percentages depend on an objective evaluation process with the statistical input described above.

SUMMARY

This chapter described criteria for the objective evaluation of parameters of dysfunction related to soft tissue injury and tissue response. The methodologies described may be utilized in a specific or focused manner as they pertain to specific dysfunctions. For instance, dynamometry may be appropriate in strength testing. Utilizing the strengths of different methodologies to counter the limitations of others is part of the arsenal of diagnostic investigation and follow-up through rehabilitation.

From Psychics of the Body to Clinical Outcome via Neurochemistry

Gary W. Jay, M.D., F.A.A.P.M., D.A.A.P.M.

The title of this chapter was given to me. At first I didn't like it: "Psychics of the body"? Then I realized that this is, more times than we'd like to think and far more frequently than we would like to admit, an accurate description of what may pass for medicine, particularly pain management.

Looking at the way we were trained, anatomically biased for the most part, we have become a group of physicians who think we know what is going on when seeing a patient purely on the basis of where the pain is located. The differential diagnosis then becomes a matter of which nerves connect to which nerves and the spinal cord, and then the brain, and how we can stop the pain from peripheral nervous system response to injury.

We have begun to develop a significant armamentarium in our treatment options. Almost always, it begins with analgesics. Good primary care physicians recognize that they need to ameliorate a patient's pain. That is what they were trained to do. So, unless there are reasons for doing any tests, the vast majority of which look at anatomy (plain X-rays, CAT scans, MRI scans), analgesic medications are utilized.

Then there are the pain management specialists who are trained to do blocks. They do them very well. Unfortunately, some are satisfied in knowing that a patient's pain is in his or her neck. Like any carpenter with a hammer, everything is a nail. The patient, therefore, will undergo a series of epidural blocks. If these don't stop the patient's pain, he or she is trundled off to another type of specialist, frequently a psychiatrist or psychologist.

When I began to practice pain management in 1980, interdisciplinary pain management programs were coming into their own. Patient outcomes were good. Over the last 2 decades, the business people controlling the application of medicine, good or bad, realized that while these types of patient treatment programs did work, they were expensive. So, getting reimbursed for applying inter- or transdisciplinary pain treatment was lost, because of monetary interests rather than patient care interests.

Anatomical, mechanistic algorithms were developed and placed into the practice setting. Physicians didn't need to be told what they could or couldn't do. They were just stymied by their inability to receive payment for services that the insurers didn't feel like reimbursing. Some insurers went even further, independent of medical realities, determining which disorders were, to them, real, and which ones were not. Those that insurers did not want to recognize as real were *a priori* not real and medical treatment for them did not justify reimbursement.

Today business people who are involved in running pain centers ask, "You tell me that psychological or psychiatric input is necessary in the treatment of chronic pain patients. Well, how come I can't find any multidisciplinary pain centers that have psychologists in them?"

Unfortunately, they are correct.

Some of these folk have looked at the nonmedical realities and determined that a real interdisciplinary pain center now consists of a physician and a physical therapist. Why? Both can receive reimbursement, however poor it may be.

0-8493-0926-3/02/$0.00+$1.50

A lot of psychologists are driving cabs, it seems.

So, where does that leave us? It seems to this author that it leaves us with four choices. First, pain management specialists should band together for the sake of their patients and fight this administrative determination of "appropriate care" of chronic pain patients. This needs to be done locally, regionally, and nationally, at the various levels of the insurance companies, the HMOs, the PPOs, and, of course, in Washington. However, until three physicians in a room can come to a single consensus, this probably won't happen. More importantly, if an insurance company doesn't want something to be done, it has the clout (read: Money) to not only assure that it does not get done, but also to destroy those physicians who care enough about their patients to persistently try to do it.

Second, we can meekly continue to do things the way they are now. Incredibly intelligent pain management physicians are losing their livelihoods as well as their self-respect because they can't band together effectively to enable the best patient care to be used. The national physician organizations appear to be too mired in their own internal politics to help.

Third, we can do our best to teach the patients, the folks who have lost their ability to receive the care they need and deserve, and enlist their help in trying to change the way things are. Unfortunately, if the layperson isn't sick, he or she seems to find no reason to fight for something not needed. At least not yet.

Finally, we, as physicians, can make the best of what we have left to use to help our pain patients. Anatomical, mechanistic treatments are going to have to take second place to a better understanding of neurochemistry: the physiology and the pathophysiology of the "software" of both the peripheral and the central nervous systems.

As the insurance companies, HMOs, and PPOs have determined, it costs only 1.2 cents for a generic acetaminophen and codeine tablet. Cheap enough to allow hundreds and thousands to be prescribed. This makes some sense to them, as an hour of hands-on physical therapy costs far more. In their minds, stopping the pain itself, and drugs, especially inexpensive ones, are good ways to do this.

As pain management physicians, we should be the most knowledgeable regarding the pathophysiology of neurotransmitter systems in the brain, and how to use this information for the betterment of our patients.

However, looking at the original premise of how we were taught, we tend to look at the anatomy first. Patient Jones is in a motor vehicle accident. His spleen is ruptured; this is verified by a CAT scan, so we surgically remove it. His arm is broken. Radiographic studies show us the break. Orthopedists are called in and the appropriate treatment is performed. Mr. Jones's headaches secondary to the acceleration/deceleration, or whiplash injury he received, are treated with NSAIDS. He is out of the hospital in a week. Medical rechecks with his orthopedist reveal that his broken arm is healing well. His general surgeon is happy with the way the abdominal wounds from surgery have healed. His primary care physician gives him more medication, "mild" opiates, for his continued complaints of headache.

Six months later, Mr. Jones is complaining about continued headache as well as pain in the abdomen around the scar tissue and continued pain in the arm.

Tests are done; CAT scans, MRI scans, blood work, all are normal. Mr. Jones is now a chronic pain patient, with no anatomical or mechanistic explanations of any of his pain complaints.

The initial injuries were clear, "exact" problems with ramifications directly to the periphery. Pain from Mr. Jones' injuries was transmitted via the peripheral nervous system to the spinal cord and then to the central nervous system via neuroanatomic pathways that are understood: Pain, via C- and A-delta fibers, comes into the spinal cord dorsal horns, some decussate and travel rostrally via the spinothalamic tract, among other pathways. The question, 6 months later, is simply put: Mr. Jones's arm is healed, he had no complications from surgery for his ruptured spleen, and no anatomical lesions exist in the cervical spine. Yet, he still has pain.

The peripheral nervous system has no reason to be ringing the pain bell, no reasons for nociception to be continuing.

Many physicians stop there in their analysis and begun to look for secondary gain issues or other motivations for Mr. Jones to have pain. Does he like his narcotics too much? Does he want to stay home and not return to work?

The obvious fact is that peripheral mechanisms of pain may affect central mechanisms. These central mechanisms may essentially take on a nociceptive life of their own. At this point, treating the peripheral end organ does not help the pain, as the pain is now central in nature, with continuous central nervous system input that is no longer a function of the first initiating peripheral mechanisms.

Most commonly, the surgeon looks at Mr. Jones briefly and can't find a reason for the pain. The orthopedist cannot find a reason for continued arm pain, which is now associated with edema, hyperesthesia, and even allodynia. The primary care physician cannot find a reason for Mr. Jones' headache, except possibly some minimal spasm in the cervical paravertebral muscles and the bilateral trapezius musculature.

In general, physicians tend to look for the primary anatomical reasons for pain, acute or chronic. When they are not found, the ability to give further aid is uncertain.

The pain is a pathophysiological problem that cannot be found on examination. Windup phenomena, whereby continuous C-fiber stimulation of the wide dynamic range neurons in the spinal cord, which turns these "on-off" cells on, full time, cannot be anatomically located via any standard testing. Pain derived from the sympathetic nervous

system secondary to such a physiological problem cannot be seen with any anatomical test currently used.

There are no blood tests for pain, nor are any other anatomic, mechanistic tests of chronic benign pain feasible at this time. Greater levels of information must be obtained and used by the pain management specialist. Before one can utilize a test for selective tissue conductance (sudomotor, or sweat testing), the physician must have determined a basis for looking.

Pathological changes of the central nervous system do exist in patients with chronic pain if it is of neuropathic or sympathetic origin. Neuroma formation, deafferentation, Wallerian degeneration do occur, with cell death in the periphery as well as the spinal cord. Gliosis following such neuronal cell death has been found on autopsy to occur in the spinal cord, as well as in the thalamus. However, there are no tests available to the clinician that show this.

When pain becomes centralized, techniques must be used to deal with aberrant, dysmodulated neurotransmitter systems. Anticonvulsant medications which function by increasing inhibitory neurotransmitter functions (such as gabapentin working to increase GABA, gamma aminobutyric acid, an inhibitory neurotransmitter; or clonazepam, which increases GABA in the internuncial neurons of the spinal cord) become very useful, despite the fact that no seizures are occurring.

However, one must know the pathophysiology of the problem on a neurochemical level to knowing what medications to use, and why.

Unfortunately, again, some clinicians treat by rote. They have read in a journal that gabapentin helped, anecdotally, several patients with reflex sympathetic dystrophy/complex regional pain syndrome-I and so they use it at the dosages that they read were used. I think this is bad only insofar as the clinicians are doing something that they have read about to help a patient without fully understanding the pathophysiological problem they are attempting to treat, or more importantly, why it may help.

Of course, with so much to read and so many specialties and subspecialties to read it for, I certainly would not expect all physicians who use gabapentin (again, only an example) to have such a deep understanding of its neuropharmacology. But, this is an area that the pain specialist should be accountable for learning; in reality, any and all pain specialists who are responsible for the diagnosis and treatment of chronic pain should be highly conversant with this information.

This is an area of extreme import, a place where we, as pain specialists, can and should excel.

Turning to Mr. Jonesheadaches, the applied treatment has been analgesics, starting with simple analgesics and then climbing the WHO (World Health Organization) ladder to narcotics. This is a simplistic, knee jerk response to the complaint of pain, in this case, chronic headache.

The pathophysiology of chronic (posttraumatic) tension-type headache has been described in detail in another chapter in this volume. To summarize: initial myofascial nociception secondary to the acceleration/deceleration injury will, if not treated appropriately in the first 2 to 6 weeks postinjury (via physical therapy, NSAIDS, and for some patients a muscle relaxant) will develop into a myofascial pain syndrome, with continuous nociceptive information going to the cervical aspects of the trigeminal nucleus and then rostrally. Continued nociception will induce changes in the serotonergic system via loss of metabolic ability to maintain homeostasis and the development of “empty neurons” as well as serotonergic receptor hypersensitivity. Affective disorders secondary to these same neurochemical changes of the serotonergic, noradrenergic, and endogenous opiate systems occur. The primary locus of pain from chronic tension-type headache then becomes central, secondary to dysmodulation of such neurotransmitter systems, while the initiating peripheral mechanisms become secondary.

At this point, physical therapy will be palliative, as the pain problem is central, not peripheral.

To treat this entity one must return the central neurotransmitter systems to a homeostatic norm. Treatment should thus be geared to this goal. The use of neuropharmacological entities that can do this is mandatory. Serotonergics and GABAnergic medications, possibly with others, are necessary. The use of other types of medications such as the alpha-II agonist tizanidine, which acts as a muscle relaxant and also works to diminish muscle pain via noradrenergic system manipulation, also may be effective, but only if used by physicians who recognize the problem for what it is and utilize neuropharmacological manipulations that can appropriately affect central neurotransmitter systems.

All that stated, the clinician must remember that while trying to return the dysmodulated central neurotransmitter systems to normal pharmacologically, the associated sleep disorder must be dealt with (again, serotonergically), along with physical therapy to stop any further continuation of peripheral nociception, and psychological care, to prevent the affective problems of depression and/or anxiety (both with a neurochemical basis) from persisting and, therefore, preventing the return of central neurotransmitter system(s) homeostasis.

Then there is the issue of chronic analgesic usage. This problem creates a separate headache entity, analgesic rebound headache. The continuous use of analgesics, narcotic or not, will further depress the innate, endogenous opiate system via a negative feedback loop. Until this headache form, which is purely neurochemical/neurophysiological in nature, is dealt with by stopping all exogenous analgesics in a safe, physiological manner, no other form of treatment for any of the headache problems Mr. Jones is enduring will be effective.

Finally, there is the continued abdominal pain that is bothering Mr. Jones. His pain is described as lancinating, with electrical-like jolts. These pain attributes speak for neuropathic pain, most commonly from the cutting of sensory nerves during the surgery. These nerves may develop neuromas, with ectopic electrogenesis inducing continuous nociceptive information. This continuous afferent nociceptive stimulation can induce central changes, at the level of the spinal cord, and later in the brain.

Once again, the clinician is forced to think about central neurochemical changes as well as, at least initially, peripheral changes. The use of tricyclic antidepressant (TCA) medications to help with the nerve-generated (neuropathic) pain may work both centrally as well as peripherally, with the TCAs also acting as local anesthetics at the site of nerve injury/ectopic electrogenesis and/or via the peripheral sodium pumps. Anticonvulsant medications also may work both centrally and possibly peripherally. Mexiletine Hcl, essentially an oral form of lidocaine, has been used for its ability to diminish abnormal nerve impulses. Again, the use of specific medications for their specific abilities to deal with the specific pathophysiological problems associated with a particular form of pain is appropriate and of extreme import.

The use of narcotics for central and neuropathic pain has been felt only recently to be useful. The logic, over the last several years, is that all pain must be eradicated. This is surely a worthy goal. I have found that narcotics are useful, but only in combination with other appropriate neuropharmacological treatments, specifically to maximize function.

The use of narcotics with N-methyl-D-aspartate (NMDA) receptor antagonists is an area of burgeoning research. To date, none are clinically helpful. Oral dosing of dextromethorphan creates significant side effects. Ketamine, in several forms, is being investigated. These medications are being tested to see if their use will decrease problems with narcotic tolerance as well as possibly allow a lesser dosage of narcotic to be utilized, again, very worthy goals.

Some clinicians are pushing the use of chronic narcotics for chronic benign headache. In my 2 decades of treating thousands of headache patients, I have never had to use this tactic to ameliorate or eradicate chronic headache. However, I was able to utilize an interdisciplinary treatment protocol to effectively treat headache patients. Now, with the inability to be reimbursed for appropriate interdisciplinary treatment of chronic headache patients, this may become the surrogate treatment of choice because fewer and fewer of the appropriate modalities are being reimbursed when used to treat these patients.

We appear to be at some sort of crossroad. Pain is now the "fifth vital sign" in the VA hospital system. JCAHO (Joint Commission on Accreditation of Hospital Organizations) has decided to come out with specific guidelines for the treatment of pain. CARF (Commission on Accreditation of Rehabilitation Facilities) has been doing this for years.

What is most confusing is that the CARF guidelines stress and demand an interdisciplinary treatment team. What I have seen of the JCAHO guidelines echoes this. Some states even tie reimbursement to being CARF accredited. I would certainly think this reasonable, if not for the fact that we clinicians who go the extra mile to achieve such accreditation lose money every time, as we must (and wish to) bring in psychological care, biofeedback for stress reduction, and more, as the guidelines indicate we must.

Yet, the vast majority of insurance companies, HMOs, and PPOs, along with Medicare and Medicaid, will not pay for (reimburse) these services—the same ones we must have to meet accreditation standards.

This all leaves us to do what we can, in spite of the moneyed forces arrayed against us.

We should be gathering information regarding the various treatment modalities, single or multiple, that are used effectively, or not so effectively, for specific pain problems. Clinical outcomes measurement is important and all pain specialists should focus more on this. Evidence-based medicine is important, and will hopefully become more important as time passes. Money saved by pain specialists who use proper treatments and who can document their outcomes, monetarily and from other aspects such as degree of pain relief, degree of functional return, and return to work data, is important information to document. The data may eventually have some impact on the insurers.

Nonfunding of treatment by insurers and employers appears to be bad judgment, as they do not save costs, just put them off into the future, where a patient may need several times the initial amount of capital for care than would have been necessary had it been done appropriately at the onset of the patient's pain problem.

What we as clinicians also can do is work to understand the pathophysiology of chronic pain in enough detail to use the tools, the medications we do have, in the best way possible. This may be, for now at least, the best we can do to help our chronic pain patients. We should be the best at doing it, and have the greatest understanding of the intrinsic reasons for using specific medications to deal with specific CNS neuropharmacological abnormalities. It is the least, or the most, we can do.

Musculoskeletal Ultrasound

John Porter, M.D. and Michael S. Jablon, M.S.T.

BRIEF HISTORY

According to leading radiologist Barry Goldberg, in an article published in the May 1998 issue of Diagnostic Imaging, "…in ten years ultrasound will account for more than half of all soft-tissue imaging studies." Ultrasound, which is the first study of choice in obstetrics and cardiology, will become the primary imaging study for all soft-tissue abnormalities, with CT, MR, nuclear medicine, and angiography relegated to a secondary position when, in rare instances, ultrasound cannot provide adequate diagnostic information.

The history of ultrasound dates back to 1912 when Lewis Fry Richardson in England patented two schemes for obstacle avoidance as a response to the sinking of the Titanic. The outbreak of World War I in 1914 and the menace of the submarine focused new attention on ultrasound as a way to detect objects underwater.

Since ultrasound's potential value in clinical medicine was first realized in the late 1940s and early 1950s, a slow but steady advance in its use has occurred. This process has been spurred by improvements in technology that have enabled ultrasound systems to obtain increasingly refined anatomical detail and to detect flow in increasingly smaller vessels.

The utilization of ultrasound has progressed to the point at which almost 25% of all imaging studies worldwide are ultrasound exams. The World Health Organization recommends the use of ultrasound after basic X-ray, and not CT or MR, due to wide availability of scanners.

The merits of ultrasonography as a diagnostic study are obvious. It is noninvasive and has no know risk. It can be done quickly, with little discomfort to the patient, and the capacity for bilateral imaging makes comparison with the asymptomatic, contralateral limb possible. In most centers, it is much less expensive than other imaging studies. Disadvantages, such as a learning curve, ease of interpretation, and variable image quality, seem to be diminishing as technology and experience increase.

Ultrasound is the ideal modality for the examination of soft tissue because of its multiplanar and real-time capabilities. Sonography yields anatomic information during active and passive mobilization that is unattainable with other modalities. In addition, synovial and cartilage thickness can be accurately quantitated, providing an objective means of following patients with inflammatory arthritides. Ultrasound examination of deep-seated joints such as the hip and shoulder is especially valuable. Joint effusions, loose bodies, tendonitis, and tendon and muscle ruptures can all be demonstrated sonographically. The noninvasive nature of the examination and lack of ionizing radiation make it very well accepted by patients, especially children.

ULTRASOUND — THE NEW GOLD STANDARD FOR SHOULDERS

In the April 2000 issue of the Journal of Bone and Joint Surgery Sharlene A. Teefey M.D., et al., in an article entitled "Ultrasonography of the Rotator Cuff," concluded that "Ultrasonography was highly accurate for detecting full-thickness rotator cuff tears, characterizing their extent, and visualizing dislocations of the biceps tendon". The article also revealed the results…"Ultrasonography correctly identified all sixty-five full thickness rotator cuff tears (a sensitivity of 100 percent). There were seventeen true-negative and three false-positive ultrasonograms (a specificity of 85 percent). The overall accuracy was 96 percent."

MUSCULOSKELETAL ULTRASOUND VS. MRI

Benefits of MRI

MRI use in medicine dates back to the early 1970s, and it has several advantages over diagnostic ultrasound. First, MR images, because of the similarity to actual anatomy, are familiar to both radiologists and referring physicians. Second, MR images can be acquired at distant sites 24 hours a day and interpreted in a timely and cost-efficient manner. Third, MR images provide a comprehensive evaluation of an extremity, including abnormalities of bone, cartilage, and soft tissues. Finally, standard MRI protocols have been systematized to the point that they are most operator independent.

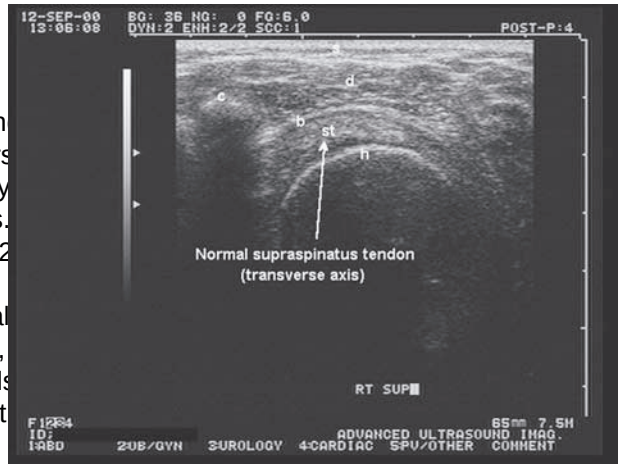

FIGURE 86.3 A normal supraspinatus tendon. (s) skin; (d) deltoid; (c) coracoid process; (b) bursa; (st) supraspinatus tendon; (h) humerus.

Benefits of Ultrasound

Sonography, which has been used in medicine for more than 30 years, has a different set of benefits. First, new and continuously improving high-frequency transducers allow detailed visualization of superficial structures. Second, sonography is portable, more available, and less expensive. Third, because sonography works in real time, procedures such as joint aspiration can be guided with sonography once an abnormality is detected. Fourth, because sonography measures motion, a dynamic examination may detect abnormalities that are present only with joint positioning and not obtainable with MRI.

Sonography should be the modality of choice when a tendon abnormality is clinically suspected. It is likely that because of the new high-resolution transducers differentiation between full-thickness and partial-thickness tendon tears can be identified with greater ease than with MRI. In addition, when evaluating the biceps brachii long head tendon for subluxation, the sonogram allows for evaluation in the neutral position and during external rotation. This view is important as transient medial subluxation of the long head of the biceps brachii tendon may occur only in this position. Because MRI is utilizing static pictures, if transient biceps brachii tendon dislocation is not present in the neutral position it will remain undetected (Jacobson, 1998) (Figures 86.1 and 86.2).

Another abnormality that may be identified better by sonography than by MRI is calcium hydroxyapatite crystal deposition or calcific tendonitis. Because calcifications, like tendons, appear as low signal on MRI images, their intratendonous presence may go unrecognized (Figures 86.3 and 86.4).

The Achilles tendon can be quickly and accurately evaluated. Sonography, like MRI, is useful in demon-

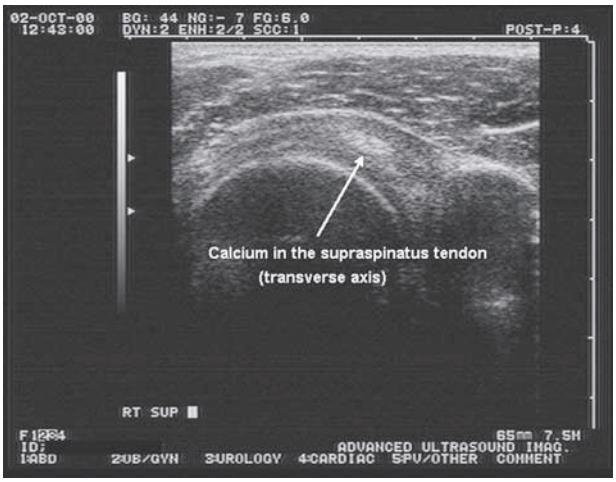

FIGURE 86.4 The area of increased echo signal within the interstitial fibers of the supraspinatus tendon is consistent with calcification (arrow).

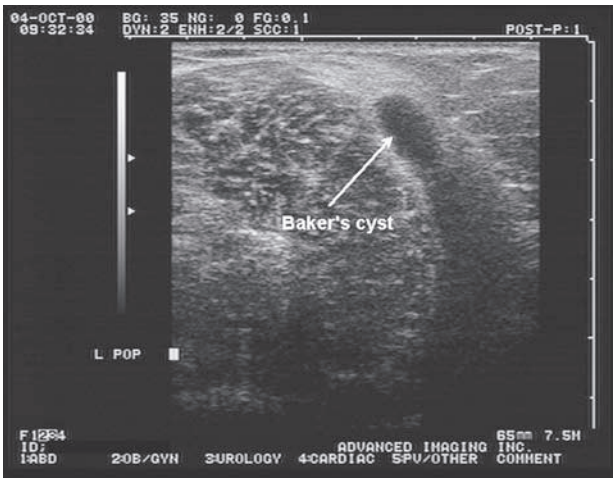

FIGURE 86.6 An enlarged gastrocnemius-semimembranosis bursa, consistent with a Baker cyst.

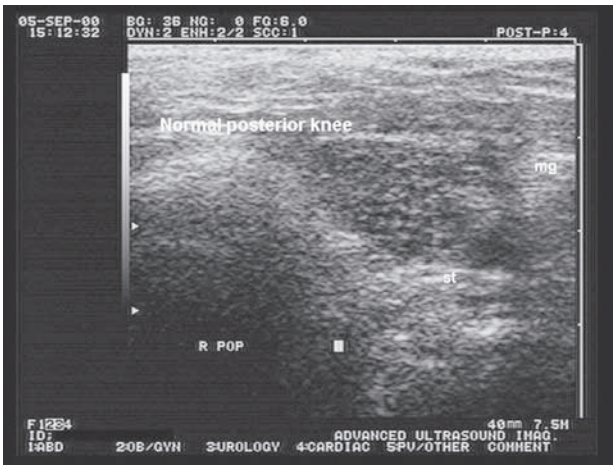

FIGURE 86.5 A normal posteriomedial aspect of the popliteal fossa. (mg) medial head of the gastrocnemius muscle; (st) semimembranosis tendon.

strating full-thickness tendon tear, partial-thickness tear, and tendonitis. High-resolution sonography allows detection of an intact plantaris tendon, a difficult at best to identify with MRI imaging. When a full-thickness Achilles tendon tear is identified by sonography, passive plantar flexion is used to determine if the torn tendon ends become approximated. Obtaining similar results with MRI imaging would require patient repositioning and generally is not done. Accurate sonographic information regarding the plantaris tendon and the torn Achilles tendon approximation can assist the surgeon in deciding between surgical and conservative treatment. Cost savings and patient convenience will become major considerations in the near future.

A palpable mass within the medial aspect of the posterior knee suggests the possibility of gastrocnemius-semimembraneous bursa, or Baker cyst. Sonography can confirm the presence of a cystic mass between the semimembraneous and the medial head of the gastrocnemius tendons. The diagnosis of Baker cyst, however, requires demonstration of a communicating neck between the posterior knee joint and the semimembraneous-medial gastrocnemius cyst. Other cystic masses can essentially be excluded once this communication is identified (Figures 86.5 and 86.6).

For patients with contraindications for MRI sonography is recommended as an alternative imaging method. Potential contraindications for MRI include the presence of certain metal implants or metal foreign bodies, cardiac pacemakers or other implanted electronic devices, pregnancy, and claustrophobia.

GENERAL APPLICATIONS OF SONOGRAPHY

Sonography of Muscle

Fifteen years before the development of MRI, ultrasound was the first real time imaging modality available for the evaluation of muscle pathology. Sonography can provide all of the information available with MRI and more with regard to muscle pathology. Its spatial resolution and definition of muscle structure are usually superior to that provided by MRI.

Numerous muscular pathologies can be readily detected with sonography. Small intramuscular lesions, localized inflammation and edema within the tissue (myositis), and detection of intramuscular lesions are readily detected with sonography. Sonography provides the functional capability of evaluating an area in motion; therefore, even the most obscure of intramuscular pathology can be detected. Overstretching (distraction) lesions, which most often occur in runners, ballet dancers, and gymnasts, are also routinely identified with sonography.

Sonography of Tendons

Prior to the application of ultrasound to the evaluation of the musculoskeletal system, clinicians relied on low-kilo voltage radiography and xeroradiography to aid in the diagnosis of tenomuscular injury (Bock, et al., 1981). These techniques provided little information beyond indicating the site of soft tissue swelling. Ultrasound provides detailed information about the involved anatomy and nature of the pathology.

Chronic tendonitis is easily diagnosed by an experienced musculoskeletal ultrasound sonographer. Frequently an increase in synovial fluid does not exist. The most common finding is thickening of the tendon itself (Middleton, et al., 1985; 1986). Ultrasonic comparisons with the asymptomatic side are essential to make the diagnosis of chronic tendonitis (Bruce et al., 1982; Crass et al., 1984, 1986; Demarais et al., 1984; Dillehay et al., 1984; Blei et al., 1986; Fornage, 1986).

Tendonitis is almost always attributable to chronic trauma and a high level of athletic activity (Roels & Martens, 1978; Feretti, Puddu, & Mariani, et al., 1985). The sonographic findings are identical in all locations. Focal thickening of the tendon and increased distance between the longitudinal collagen fibers are invariably present. Focal hypoechoic areas within the tendon are also present. The longitudinal tendon fibers are seen to be intact. In some patients, tendonitis continues for years with intermittent flare-ups. Calcification is most common at the distal tendon insertion.

Tendon Rupture

Rotator cuff tears are a frequent finding in the elderly and may be entirely asymptomatic. Autopsy studies of individuals more than 55 years old have discovered rotator cuff tears in 32% (Peterson & Gentz, 1983). However, a true traumatic tear is a rare finding. These lesions are most common in athletes, such as baseball pitchers, javelin throwers, and football quarterbacks.

The principal sonographic findings (Bretzke, Crass, Craig, 1985; Linnen et al., 1985) are fluid-filled defects in the supraspinatus tendon and increased fluid in the subacromial deltoid bursa. In some chronic cases of rotator cuff tear, the supraspinatus muscle layer may be completely absent (Mack, Matsen, Kolcoyne, et al., 1985). The diameter of the tear measured sonographically is always smaller than that observed with arthroscopy, plain film arthrography, or CT arthrography (Beltran, Gray, Bools, et al., 1986). In all of these invasive diagnostic modalities the joint is distended with fluid, air, or both. This leads to an exaggeration of the dimensions of the tear and the degree of muscle retraction (Ahovuo, Poavolaine, & Slatis, 1984).

Tendon tears can be isolated to the intrasubstance fibers. Often, they will not communicate with the capsule or subacromial deltoid bursa.

These intrasubstance tears cannot be repaired surgically. Sonography demonstrates the full extent of the lesion. This allows the surgeon to prepare most accurately in a pre-operative setting.

Three other disease processes are included in the differential diagnosis of soft tissue lesions of the shoulder. These are biceps tendonitis, biceps tendon dislocation, and edema of the rotator cuff (Jobe & Jobe, 1983).

Sonography of Ligaments

Traumatic injury of ligaments in the knee and ankle are very common, usually involving athletes participating in contact sports. Clinical examination is usually difficult to perform immediately following an injury. Chronic ligamentous injuries and cartilage defects associated with either acute or chronic trauma are difficult to evaluate clinically. Arthroscopy is an excellent tool to evaluate the cruciate ligaments and menisci, but extracapsular ligaments cannot be visualized. Computed tomography (CT) lacks appropriate contrast resolution to delineate ligamentous structures. Ultrasound and magnetic resonance imaging (MRI) are the best diagnostic modalities utilized today for the examination of ligaments. Both of these imaging techniques provide multiplanar capability and demonstrate ligamentous anatomy well (van Holsbeeck & Introcaso, 1991).

The advantages of ultrasound over MRI are ambulatory diagnostic capabilities, along with dynamic examination, cost, and patient compliance. The test also can be performed in the locker room, bedside, or in a physician's office. Often, rapid diagnosis allows for prompt therapy and rehabilitation, thus giving a better diagnosis.

Sonography of Bursae

The word bursa is derived from the Greek, meaning a wine skin. In modern usage, bursa refers to a variety of structures that have several features in common. They are all saclike structures with a lining similar to that found in diarthrodial joints. In addition, they are situated to facilitate movement of musculoskeletal structures (Canoso, 1981). Bursae are found in areas where a significant amount of motion can be expected, yet not necessarily isolated to synovial joints.

The analogy of a wine skin is quite appropriate; both have their greatest dimensions in length and width. This provides a large surface area that occupy little volume under normal circumstances (Codman, 1931). When positioned between two structures, this alignment allows mobility and gliding of one structure on the other.

Some anatomists (Gray, Piersol) believe that bursae are sacs filled with fluid. This is a misconception resulting from studies performed by injecting bursae with various materials.

Physicians who perform bursography and bursocopy often share this misconception because they distend the bursae with contrast material or irrigation fluid. In reality, bursae contain only a thin film of viscous fluid, which serves as a lubricant. The walls are separated by a diffusion film approximately 1 mm thick. Therefore, bursae are really potential spaces, only becoming fluid-filled sacs under pathological conditions (van Holsbeeck & Introcaso, 1989).

Bursae are divided into two groups, communicating and noncommunicating, depending on their relationship to a joint space. Noncommunicating bursae are more common in humans. Further categorization of bursae may be made based on their location: subcutaneous or deep (Canoso, 1981). Subcutaneous bursae are located between a bone and the overlying skin, such as the pre-patellar and olecranon bursae. Bursae are located in many places deep in the fascia. They separate the joint capsule, tendons, ligaments, and fascial planes (iliotibial tract).

Ultrasound provides the clinician with a noninvasive means of examining the bursae. In acute traumatic bursitis the primary value of sonography is to confirm that disease is limited to the bursa. Associated tendons, ligaments and joint space are easily examined to exclude bursitis secondary to pathology originating in these structures (Figures 86.7 and 86.8).

SONOGRAPHY OF THE SHOULDER

In the 1960s, clinicians called the shoulder the "forgotten joint" (Golding, 1962). There were no diagnostic modalities other than plain radiography for shoulder evaluation. Plain films are normal in more than 90% of patients with chronic shoulder pain. Tendon calcifications are present in some of these patients; others have ossified tendon insertions or cystic lesions around the anatomical neck. The significance of all these plain film findings is still debated in literature (Depalma, 1983; Refior, Krodel, & Melzer, 1987). There is, as yet, no proof of the relationship of these findings to certain types of shoulder disease, such as hydroxyapatite deposition disease, impingement, and rotator cuff disease. More recently, finding ossification in the coracoacromial ligament, acromioclavicular osteoarthritis, and narrowing of the subacromial space have been cited as signs of rotator cuff disease (Peterson and Gentz, 1983; Resnick & Niwayama, 1988; Gielen, van Holsbeeck, Hauglustaine, et al., 1990).

Both arthrography and arthroscopy of the shoulder were introduced during the 1970s. Arthroscopy of the shoulder is, without doubt, the most complete examination of the rotator cuff (Ogilvie Harris & Wiley, 1986). The orthopaedic surgeon examines the articular surface of the rotator cuff through the joint. Then a new incision is made to examine the bursal surface of the cuff through the subacromial deltoid bursa. Not only are rotator cuff tears seen, but tears of the labrum also are visualized. The orthopaedic surgeon has a clear view of the synovial cavity and can, therefore, diagnose synovial disease at an early stage. Arthroscopic surgery may be performed during the same session (Van Holsbeeck & Introcaso, 1989).

A disadvantage of arthroscopy is the invasive character of the procedure. Numerous complications such as neurovascular complications, damage to the labrum, considerable muscle injury, infection, and hemarthrosis have been described (Jeffries, Gainor, & Allen, et al., 1987; Lindenbaum, 1981). Chronic draining fistulas and leaking of synovial fluid are often cited as the most common complications (Henderson & Hoson, 1982).

Not all shoulder pathology is detectable with an arthroscope (Jobe & Jobe, 1983). Rotator cuff lesions communicating with the joint or subacromial-subdeltoid bursa are detected arthroscopically (Refior, Krodel, & Melzer, et al., 1987). Rotator cuff edema and fibrosis, generally regarded as the precursor of a rotator cuff tear, are not an arthroscopic

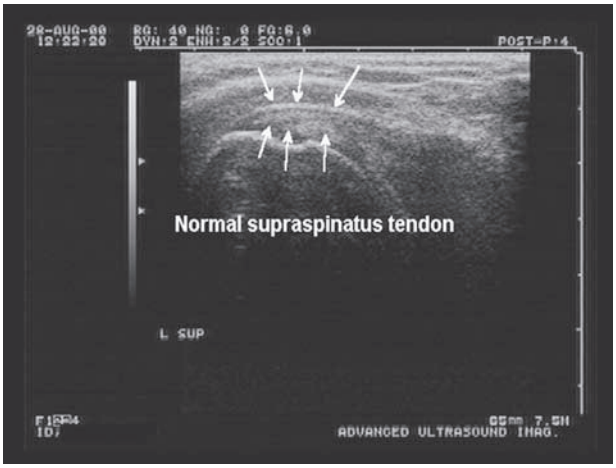

FIGURE 86.7 A normal supaspinatus tendon and overlying SA-SD bursa (arrows).

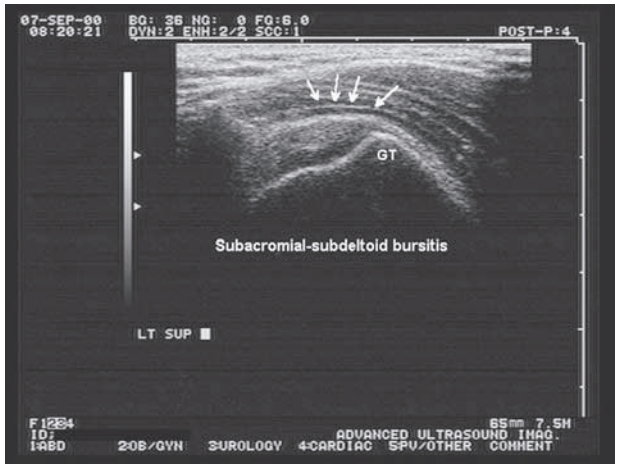

FIGURE 86.8 Inflammation and thickening in the bursa consistent with bursitis.

diagnosis (Neer, 1983). Orthopedic surgeons refer to these abnormalities as impingement syndrome.

Arthrography of the shoulder is less invasive than arthroscopy (Ahovuo, 1984). This procedure identifies full-thickness tears of the rotator cuff and tears involving the articular surface of the supraspinatus tendon. Detection of incomplete tears to the superior surface of the rotator cuff requires injection of the subacromial deltoid bursa (Neer, 1983). This type of tear is less common, and represents less than 5% of all rotator cuff tears. Most of the interventional radiologists, therefore, rarely perform an injection of the subacromial deltoid bursa. Arthrography has not been found to be effective in the evaluation of edema and interstitial defects of the rotator cuff. Like arthroscopy, arthrography is costly, invasive, and usually uncomfortable for the patient.

Impingement is the most common pathology causing chronic shoulder pain (Neer, 1983). It is caused by compression of the anterior cuff against the anterior acromial edge and coracoacromial ligament. The initial developments are edema and hemorrhage, which progress to tendonitis and fibrosis. Partial and full-thickness tears of the rotator cuff are the end stage of the disease spectrum referred to as "impingement syndrome." Unfortunately, no clinical tests exist that will differentiate impingement from rotator cuff disease. The persistence of symptoms may help the clinical diagnosis, depending on the patient's age and history. The majority of patients will experience 10 to 15 years of chronic shoulder pain before impingement progresses to rotator cuff tear.

Treatment for the early stages of impingement syndrome is often drastically different from the treatment for rotator cuff tears. Tendonitis of the rotator cuff is generally treated conservatively for as long as possible. This usually entails avoidance of painful elevation of the arm, anti-inflammatory medication, and injections of anti-inflammatory drugs into the subacromial space. Rotator cuff tears are treated differently. Surgery is usually recommended when large full-thickness tears exist. Early intervention is important before the tear becomes too large, grossly retracted and subsequently nonrepairable (Figures 86.9 to 86.12).

In a patient with impingement syndrome and rotator cuff tendonitis, a conservative, noninvasive approach is optimal.

The ideal technique should be readily available for screening a large population with chronic shoulder pain and be able to distinguish tears from edema of the cuff in the majority of cases. Ultrasound is the ideal technique. It is noninvasive and widely available for screening on a large scale (Crass, 1987; Mack et al., 1985). Reported sensitivity is more than 90% (Van Holsbeeck 1991).

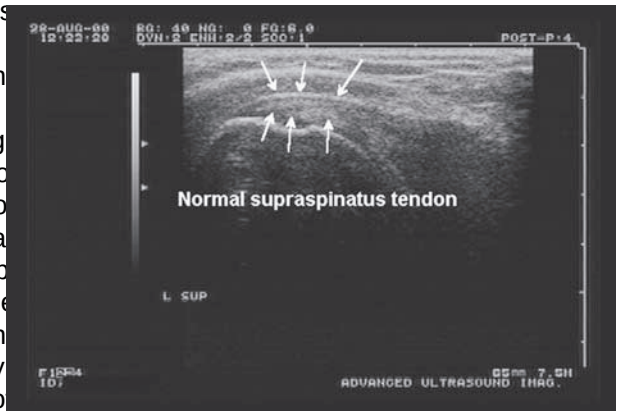

FIGURE 86.9 The normal distal supraspinatus tendon along the greater tuberosity.

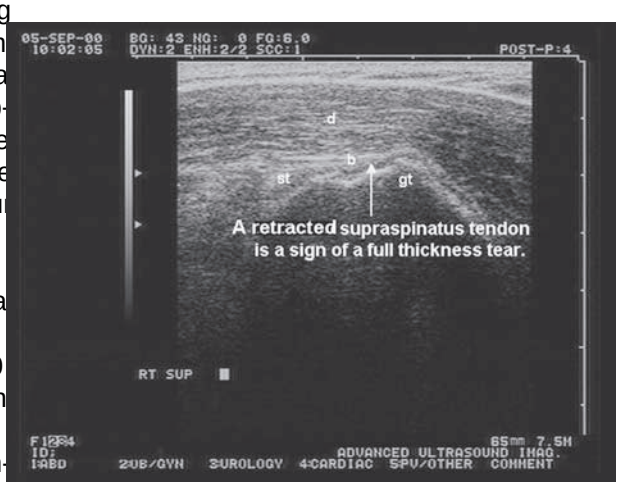

FIGURE 86.10 A grossly retracted supraspinatus tendon (st). A complete absence of the supraspinatus tendon is a reliable indicator of a full thickness tear. (d) = deltoid; (b) = bursa; (gt) = greater tuberosity.

Workup of Shoulder Disease

The estimated frequency of rotator cuff tears in people more than 60 years old is approximately 30% (Codman, 1985). With such a large potential group of patients, ultrasound is preferred to more invasive, expensive, and time-consuming techniques, such as arthrography, arthroscopy, and magnetic resonance imaging (MRI). The cost effectiveness of the technique and its noninvasive capability make ultrasound the first choice when evaluating soft tissue injuries.

Every examination of the shoulder should begin with a plain radiograph. The most detailed examination of the bony anatomy is still the conventional radiograph. Substantial narrowing of the subacromial space with an acromiohumeral distance equal to or less than 5 mm is due to large rotator cuff tears. In these cases, no further investigations are necessary (Cofield, 1985). Radiographs also can exclude referred pain to the shoulder due to a lesion in the adjacent structures or a neurovascular syndrome secondary to a Pancoast tumor (Batemen, 1983).

When chronic shoulder symptoms persist and normal plain films and positive clinical test results indicating cuff

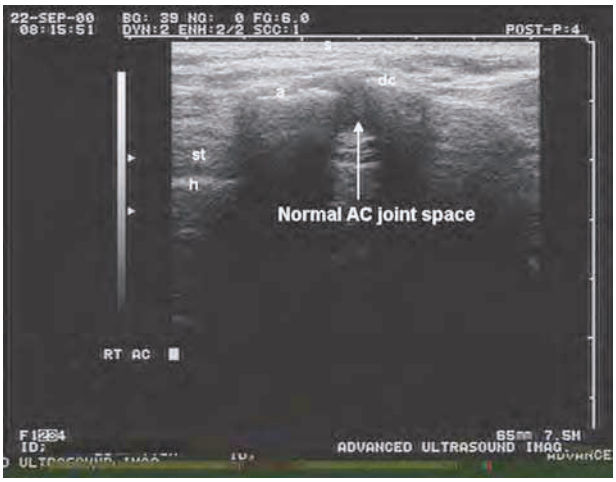

FIGURE 86.11 Coronal view of the AC joint. (a) = acromion; (dc) = distal clavicle; (st) = supraspinatus tendon; (h) = humerus; (s) = skin.

FIGURE 86.12 Degenerative changes involving the acromion process and distal clavicle (arrows) developing spur is identified (small arrowhead). Effusion is present within the joint (e).

disease exist, ultrasound is the tool of choice for establishing a diagnosis. Arthroscopy should be considered when patients present with normal radiograph and a normal sonogram of the shoulder, but with an unequivocal clinical examination (limited abduction).

SONOGRAPHY OF LARGE SYNOVIAL JOINTS

Large synovial joints are difficult to evaluate clinically; therefore, ultrasound examinations are often requested. Ultrasound is broadening our approach to the evaluation of joint disease. Even the smallest joints can be examined sonographically, i.e., interphalyngeal joints in the hands and feet. Arthroscopy is limited to the intra-articular structures. It allows the orthopaedic surgeon to evaluate the cartilage and perform corrective surgery in the same procedure. However, arthroscopy is an invasive technique with the possibility of risk to the patient.

The main advantage of ultrasound over arthroscopy is its ability to examine the extra-articular soft tissues. Many pain syndromes do not originate in bone or articular cartilage. Until now, these were strictly clinical diagnoses. Sonography can be used to diagnose disease of the extra-articular tissues with high sensitivity and specificity. Sonography can be tendonous, ligamentous, and muscular lesions. It can differentiate scar, granulation tissue, and complete and incomplete tears. In addition, ultrasound is completely non-invasive and requires no anesthesia or pre-medication.

Intra-articular pathology also can be accurately diagnosed utilizing sonography. It can routinely identify intra-articular effusion. In addition, ultrasound can locate synovial inflammation, hemarthrosis, and loose bodies within the joint. Cartilage and synovial thickness can be measured accurately, providing an excellent method to evaluate the effectiveness of treatment and the progression of disease (Aisen, McCune, McGuire et al., 1984).

In summary, sonography is a valuable diagnostic tool for both extra-articular and intra-articular pathologies. If the intra-articular examination is normal, no additional imaging studies are needed. Abnormal sonographic examination is an indication for evaluation with MRI, arthrography, or arthroscopy.

SONOGRAPHY OF THE ELBOW, WRIST, AND HAND

Clinical examination of the elbow, wrist, and hand is less complex than examination of the shoulder, knee, and hip. These joints are much more accessible due to their superficial nature. Ultrasound is valuable in the diagnosis of muscle, tendon, and ligament pathology, as well as cortical abnormalities, i.e., stress fractures, bone cysts, and arthritis. When radiographic examination is normal, ultrasound is indicated to evaluate persistent pain and swelling.

The Elbow

The most common soft tissue disorder of the elbow is epicondylitis. Tendonitis of the common extensor tendons (tennis elbow) and common flexor tendons (golfer's elbow) are often mistaken for intra-articular pathology, due to their close proximity.

Lateral epicondylitis is most frequent in elbow disorders. Biceps and triceps tendonitis also may be mistaken for joint pathology. These problems are best evaluated with ultrasound because calcifications are seen only in chronic disease. At the same time, the examiner also can evaluate for intra-articular loose bodies or cartilaginous defects. Joint effusion is a clear indicator of

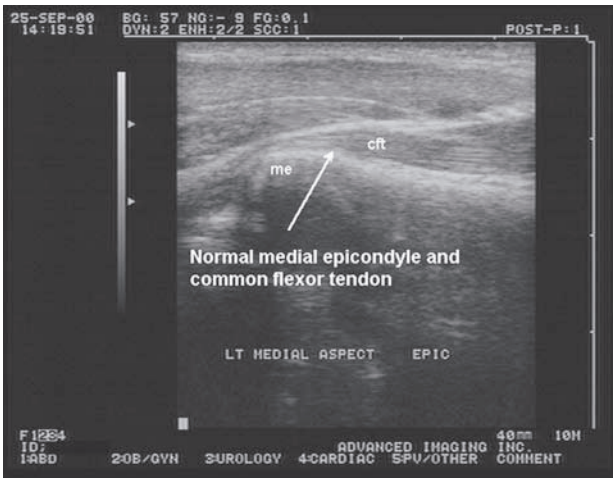

FIGURE 86.13 A normal common flexor tendon insertion (cft) along the medial epicondyle (me).

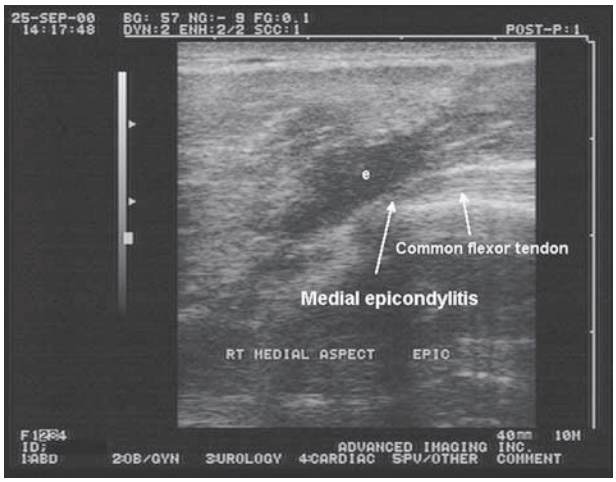

FIGURE 86.14 Inflammation of the common flexor tendon and adjacent soft tissues. Note the large effusion (e).

joint pathology. The most frequently observed joint pathology in the absence of radiographic findings is cartilaginous loose bodies. These loose bodies will be found in the anterior joint recess (Figures 86.13 and 86.14).

The Wrist and Hand

The initial indications for ultrasound examination of the wrist and hand are evaluation of tendon disorders and identification of the origin of swelling. Tendon ruptures are easily detected with ultrasound. A motion evaluation helps to identify tendon dislocations and entrapment. Tenosynovitis of the flexor tendons of the wrist and carpal tunnel syndrome are diagnosed easily with ultrasound. Identification of synovial cysts and specification of their origin are easily diagnosed with ultrasound. A cyst arising from a tendon sheath differs from that of a cyst originating from the joint. This can help in surgical management. Often these cysts feel solid during clinical assessment and may be mistaken for boney hypertrophy. The triangular fibrocartilage of the wrist also may be examined.

SONOGRAPHY OF THE KNEE, HIP, AND ANKLE

Knee

Sonographic examination of the knee is a commonly requested study of the lower extremity. The knee is a bicondylar joint stabilized by soft tissue structures: ligaments, tendons, menisci, and the joint capsule. These structures are all easily injured by trauma, particularly sports-related trauma. Ultrasound is the only readily available nonsurgical technique for the examination of soft tissue injuries at the time the patient presents for clinical evaluation. Normal plain film examination following injury is a definite indication for sonographic examination.

Intra-articular and extra-articular pathologies are equally common causes of knee pain. Pain and swelling of the knee accompanied by a normal radiographic examination are a clear indication for an ultrasound examination. Arthrography and arthroscopy are invasive techniques that evaluate only the intra-articular pathology. Sonography has the capability of demonstrating noninvasively both intra-articular and extra-articular pathologies. Ultrasound can provide information about a joint during a real-time examination. No other diagnostic imaging modality has this capability. In addition, the risk, discomfort, high cost, and delay that may be expected with other diagnostic procedures do not exist.

Tendonitis is a common cause of knee pain. Most frequently involved are the quadriceps, biceps, and patellar tendons. Increased edema and decreased acoustic signal within the involved tendon are visualized. Calcifications often are seen in cases with chronic tendonitis.

Bursitis also may be the cause of knee pain. Traumatic, septic, and hemorrhagic etiologies may cause bursitis. Rupture of Baker's cyst is almost always associated with pain and swelling of the knee, which may extend to involve the entire lower extremity. Ultrasound also is valuable in evaluating ligamentous injuries, synovial cysts, ganglia, muscle tears, aneurysms, and venous thrombosis.

Examination of intra-articular pathology can demonstrate synovial thickening, meniscal tears, articular cartilage defects, loose bodies, and cruciate ligament tears. Several limitations must be kept in mind. Tears of the posterior horn of the meniscus are diagnosed more easily than tears of the mid-body and anterior horn. The only absolute limitation of the intra-articular examination is that the cartilage surface of the patella and tibial plateau cannot be examined due to the lack of an acoustic window. Technical advances, such as new transducers and the further development of transmission ultrasound, will reduce

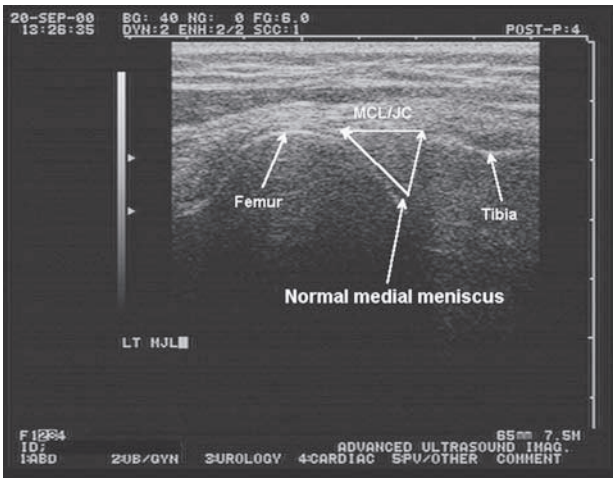

FIGURE 86.15 The normal triangular "wedge" representing the medial meniscus. Note the deep layer of the MCL and joint capsule appears intact (MCL/JC).

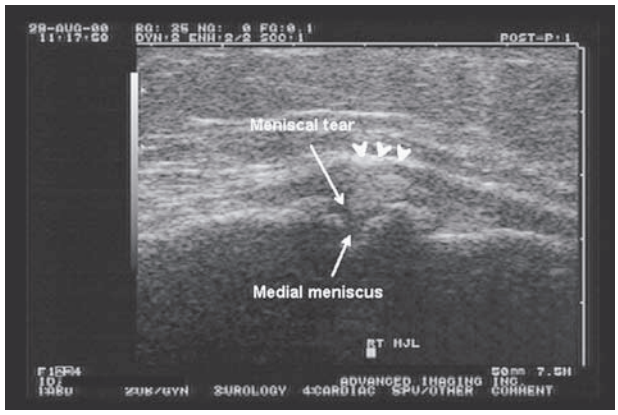

FIGURE 86.16 A torn meniscus with distention of the medial joint capsule along with herniation of the medial meniscus (arrowheads).

or eliminate these limitations. However, a normal sonographic examination demonstrating no effusion indicates that the source of pain lies outside of the joint (Figures 86.15 and 86.16).

Hip

Trauma to the hip results in bony injury almost exclusively. This is due to the protection and stabilization inherent in its ball-in-socket configuration. Often, the trauma is the result of a motor vehicle accident or sports-related injury. Plain radiograph and computed tomography (CT) are the best diagnostic modalities for evaluating these injuries. However, when radiographs and CT are normal, ultrasound examination is an excellent diagnostic tool to consider.

Ultrasound is highly sensitive in the identification of joint effusion. Joint effusions may be seen in infection, inflammatory arthritis, osteonecrosis, trauma, and tumoral diseases.

Ankle

The most common ankle injury is a sprain/strain. Most frequently, the lateral ligament complex is involved and the anterior talofibular ligament is damaged. The peroneal tendons and medial flexor tendons are beautifully imaged sonographically. These structures usually are completely exposed for sonographic examination. A motion evaluation is recommended to assess integrity and function. Cortical irregularities also can be detected in the ankle, i.e., stress fractures, bone chips, and osteochondral defects. In addition, joint effusions are easily identified. The plantar fascia can be viewed along the medial tubercle of the calcaneus. The normal measurement for this location is 3.5 mm thick. Any inflammatory change increasing the thickness of the fascia at this location may be indicative for plantar fasciitis.

HEMATOMA

Hematoma formation is a hallmark of muscle rupture. The degree of the hematoma is an excellent indicator of the extent of the underlying pathology. Intramuscular hematoma is characterized by blood dissecting within the fascial planes between muscles. More extensive injury will result in formation of intramuscular fluid collections easily identified on ultrasound images.

The evolution and resolution of intramuscular hematoma do not differ from hematoma anywhere in the body. Their initial sonographic appearance is that of a homogenous hypoechoic fluid collection.

Healing Muscle Rupture

Ultrasound is an excellent diagnostic tool for the evaluation of the various stages of muscle healing which often can take between 3 to 16 weeks to complete.

The role of sonography in the identification of muscle rupture healing lies in three areas. First is the identification of the extent of injury and measurement of the separation of wound margins. The larger the percentage of muscle tissue involved and the greater the distance of retraction, the larger proportion of scar tissue. This information will help the clinician in determining what steps are necessary, and if any are indicated. Ultrasound-guided aspiration of a hematoma may be desirable at the time of examination to reduce the distraction gap (van Holsbeeck & Intracosa, 1991).

The availability, ease of examination, no contraindications to its use, and low cost relative to MRI make follow-up of healing lesions practical. The majority of patients referred for evaluation of muscle lesions are athletes. Several studies have demonstrated that approxi-

mately 30% of all sports injuries are muscular in origin (Peterson & Renstrom, 1986). In these patients the decision of when to return to training or competition is extremely important. Recurrent injury resulting from early resumption of activity can be costly for both the individual athlete and the team. Repeated sonographic examinations can evaluate accurately the stage of healing, significantly decreasing the likelihood of recurrent damage.

Because of the low cost of ultrasound and no contraindications or patient discomfort, sonography can be used repeatedly to evaluate the various stages in muscle healing.

MYOSITIS/MYOSITIS OSSIFICANS

Myositis is a general term used to specify inflammation of muscle. Myositis ossificans, muscular contusion with intramuscular hematoma, may calcify and then ossify. These lesions are frequent findings in athletes involved in contact sports such as rugby or football.

The progression of myositis ossificans is easily followed with ultrasound. Maturation of these lesions takes approximately 5 to 6 months. Initially, within 3 weeks of injury, the lesion is identified as a soft tissue mass with disorganized inhomogeneous internal architecture. At this stage, the lesion is indistinguishable sonographically from a soft tissue neoplasm. Clinicians may refer to this lesion as gleosis, a palpable firm mass within muscle. This term comes from the Latin *gelare*, to freeze.

SONOGRAPHY OF RHEUMATOID DISEASES

Early diagnosis, assessment of inflammation, and detection of complications of rheumatoid disease are problems that can be addressed using ultrasound. The use of noninvasive techniques is especially important in patients with rheumatoid disease. Joint aspiration and arthrography are extremely painful when performed on an inflammed joint. In addition, these procedures are associated with significant risk of infection in this population due to immune suppression from chronic steroid therapy. Arthrography, arthroscopy, and joint aspiration must be kept to an absolute minimum in these patients (Moore, Sarti, & Lovie, et al., 1975).

Over the past 20 years, many noninvasive techniques have been proposed to evaluate cartilaginous involvement of rheumatoid disease. Most recently, magnetic resonance imaging (MRI) and sonography have come to the forefront in the noninvasive evaluation of rheumatoid disease. Given a perfect world scenario, both of these diagnostic studies are equally suitable for the diagnosis and follow-up of rheumatoid disease. Sonography has a major advantage over MRI in that the test can be conducted on the spot. Rheumatoid patients usually cannot tolerate lying motionless on a hard table for the 60 to 90 minutes required for an MRI examination. In addition, during sonographic examination the patient may move other extremities relatively freely, and it does not require sedation. Cost and availability factors also strongly favor ultrasound.

EVALUATION OF FOREIGN BODIES

One of the most frequent requests made of musculoskeletal radiologists in the emergency setting is the identification and localization of foreign bodies. The patient can give an indication of the likelihood of the presence of a foreign body, the material involved, and the general location. However, many of these patients may be children and difficult to evaluate clinically. Barefoot children possess a magnetic attraction to foreign bodies. All inquiries by the physician or parent about the accident are answered with screaming and tears. Another challenge is the evaluation for foreign bodies in patients involved in motor vehicle accidents. Commonly, they are under the influence of alcohol, received intravenous (IV) analgesics, lost consciousness during the accident, or have numerous injuries. Frequently, foreign bodies in these patients go unidentified. Unrecognized foreign bodies will result in chronic draining wounds, abscesses, and persistent pain. Surrounding infection can lead to devitalization of large amounts of tissue, joint destruction, and even limb loss (Gooding, Hardiman, & Sumers, et al., 1987).

In looking for foreign bodies, radiographs alone are not adequate (Gooding, Hardiman, Sumers, et al., 1987; Anderson, Newmeyer, & Kilgore, 1982). A retrospective study of foreign bodies showed that the average time between injury and detection was 7 months; 38% of retained foreign bodies were overlooked on initial examination (Anderson, Newmeyer, & Kilgore, 1982). Nonradiopaque foreign bodies and patients with orthopedic implants pose the greatest challenge. These are the cases in which ultrasound is the most beneficial. In general, the use of ultrasound will increase the rate of success of identifying and localizing foreign bodies by at least 20%.

CONCLUSION

Sonography has demonstrated its cost-effective reliability in the evaluation of numerous musculoskeletal disorders. The techniques are difficult to perform; however, this can be minimized with proper training and standardized technique. The role of sonography in the evaluation of the musculoskeletal system is evolving. As technology continues to improve and experience with this imaging modality increases, sonography will establish itself as the gold standard for the diagnosis of musculoskeletal disorders (Jacobson, 1998).

ACKNOWLEDGMENTS

We would like to thank Marnix van Holsbeeck, M.D., Joseph H. Introcaso, and John Jacobson, M.D. of the

Henry Ford Hospital/University of Michigan Radiology Department, for their efforts in advancing the global availability of information on the topic of musculoskeletal ultrasound. We have made numerous references to their work and tried to make the appropriate references at all times. Minimally Invasive Endoscopic Surgery for the Treatment of Lumbar Discogenic Pain

Anthony T. Yeung, M.D. and John Porter, M.D.

INTRODUCTION

The history of low back pain and sciatica dates back to ancient times. Domenico Cotugno first described "sciatica" in its classic terminology in 1764 and believed that pain was generated by the nerve itself. The big three Vs — Valliex, Virchow, and Von Luschka — introduced the possibility of structure-referred pain (i.e., vertebral, body, disc, or nerve) in the 1800s. With the advent of X-rays 100 years ago, imaging of spinal anatomy allowed correlation of anatomic findings to conditions that explained the origin of low back pain.

The "Dynasty of Disc" began in the 1930s when Mixter and Barr demonstrated that radicular pain was associated with disc herniation (Farlan, 1973). Attempts were made later to minimize the paradoxical effects of invading the spinal canal by utilizing smaller incisions and image magnification. Although the overall result was not altered, minimal invasiveness did reduce the morbidity of traditional approaches.

Each change required a learning curve that initially was more difficult for the surgeon, but ultimately was embraced by surgeons because it was better for the patient. Endoscopic spine surgery continues this trend, but recent experience has revealed a much greater benefit that will ensure and secure the role of endoscopic spine surgery for the diagnosis and treatment of discogenic back pain.

This quantum leap from open decompression (lumbar laminectomy) to micro-decompression with endoscopic spinal surgery finally solved the problem of traumatizing spinal muscle and ligament, destabilizing the spine, and creating epidural and perineural scarring. This rapid advance was further aided by the parallel evolution of radiologic imaging such as CT and MRI.

ENDOSCOPIC SPINE SURGERY: WHAT IS ITS ROLE?

Few physicians question arthroscopic surgery's role in advancing our understanding of knee and shoulder pain and the treatment options arthroscopy affords. Endoscopic spinal surgery is poised to serve the same role (Kirkaldy). Introduced in the United States by Kambin, the procedure has evolved from a nucleotomy and targeted fragmentectomy to a surgical technique with the potential to offer a minimally invasive approach to spinal conditions currently without a viable surgical alternative.

The favorable efficacy of endoscopic lumbar discectomy compared to open discectomy, in a prospective randomized study, was published by Hermantin, Peters, Quartararo and Kambin in 1999. Endoscopic spine surgery, through the selective endoscopic discectomy technique, expands the endoscopic restrictions described in the article and does not exclude difficult cases at L5-S1 or extruded, migrated, recurrent, or sequestrated disc herniations. The technique also provides minimally invasive access to degenerative conditions of the lumbar spine.

0-8493-0926-3/02/$0.00+$1.50

ENDOSCOPIC SPINE SURGERY: THE POSTEROLATERAL APPROACH

The posterolateral approach allows access to spinal structures such as the superior articular process, the pedicle of the superior and inferior vertebra, the traversing and exiting nerve root, and the annulus in the area of the foramen.

A newly developed spinal endoscopy system by Richard Wolf Surgical Instrument Company, the Yeung Endoscopic Spine System (Y.E.S.S.), features a multichannel scope and special access cannulas that allow spinal probing in a conscious patient, diagnostic endoscopy, and "tube surgery" with very little surgical morbidity. This technique revolutionizes the old concept that all disc surgery is really decompressive nerve surgery. It brings in a new era that will allow true "disc surgery" and a more focused surgery at the tissue level such as contracting and sealing annular tears, annular reinforcement, and artificial discs.

The recent introduction of IDET (Intradiscal Electrothermal Annuloplasty) provides another tool for treating patients who suffer from back pain caused by annular tears, but IDET is another nonvisualized technique that will be noted for historical purposes as we now have the ability to do a "visualized IDET" under direct visual control. The history of minimally invasive spine surgery supports the view that a visualized endoscopic procedure will eventually advance a "blind" technique whose success is dependent on very strict inclusion criteria, and its eventual demise through overutilization by less experienced and lesser trained clinicans. The role of IDET may be defined further by data gathered from visual imaging of annular tears and correlating it with our current imaging studies.

TEAM APPROACH

Due to the complexity of back pain, it is important to treat the whole person. The medical team interfaces with the surgical team to obtain the best possible response and outcome for the patient (Yeung, 1999a). With the endoscopic spinal techniques described, the ability to identify the tissue pain generator is available through spinal probing. Furthermore, a multidimensional treatment algorithm can be devised that will lead to improved outcomes and better patient selection for surgery.

Patients not responding to standard conservative methods who may or may not be candidates for invasive surgery now have an opportunity for pain relief with endoscopic spine surgery. The endoscopic procedure, coupled with discography and spinal probing under local anesthesia, allows the patient to participate in his or her care (Kuslich, 1990; Yeung, 1999b).

CURRENT IMAGING METHODS

When compared with conditions diagnosed by spinal endoscopy, imaging studies are only about 70% accurate and specific (Yeung, 1999a; Kuslich, 1990). Conditions such as annular tears, rim tears with associated endplate separation, and various other discogenic pathologies are missed almost a third of the time. Tears that are in the ventral aspect of the disc are routinely missed by MRI studies. Small disc herniations that protrude beyond the outerfibers of the annulus may be missed. This is because the fragment may be flattened against the posterior longitudinal ligament or nerve, looking like a swollen or enlarged nerve. On the MRI, subligamentous herniations may appear as a thickened or bulged annulus. When the nerve is inflamed, the MRI may not be able to distinguish the enlarged nerve from a conjoined nerve, an anomalous branch, or a nerve with an adherent piece of disc.

Spinal endoscopy has allowed the endoscopic surgeon to identify the actual pathologic lesion, correlating it with the imaging study, and making the clinician more aware of the pitfalls of relying too much on imaging alone. It is imperative that the patient be examined with all these possibilities in mind to avoid labeling the patient a "head case".

CLINICAL PRESENTATIONS CORRELATED WITH ENDOSCOPIC FINDINGS

When the disc tissue is in direct contact with the nerve, chemical irritation occurs and an inflammatory membrane forms. Even a large epidural venous plexus that is inflamed can contribute to back pain and sciatica. When an inflammatory membrane is present ventral to the traversing and/or exiting nerve root, the clinical picture may not be clear.

Spinal endoscopy has confirmed nondermatomal pain in multiple patients with proximal thigh, buttock, and groin pain at levels distal to the root origin of the anatomic area. These also include patients who are considered to have spine pain by nonorganic physical signs.

Inclusion Criteria

All disc herniations are amenable to selective endoscopic discectomy in a skilled endoscopic surgeon's hands. Each surgeon will select his or her patient dependent on his level of skill. Discogenic pain from internal disc disruption and annular tears may benefit from thermal and chemical modulation of the disc.

Ideal Indication

Perhaps the ideal lesion for selective endoscopic discectomy is the far lateral, extra-foraminal disc herniation.

This type of herniation is the most difficult for the majority of spinal surgeons. A skilled spinal surgeon can access the lateral zone of the disc with a paramedian incision, but the posterior approach utilized by most traditional surgeons requires the removal of a significant amount of facet to actually reach the herniation. This approach also causes extensive tissue trauma due to the dissection, which is quite vascular.

Our experience suggests that it is easier to access the extraforaminal zone with the endoscope. Endoscopically it is also more difficult than a contained herniation, but the approach is much less traumatic for the patient. It is very important to remember that the success of any surgical procedure depends on proper patient selection, surgeon skill, the correct use of treatment modalities, as well as the combined diagnostic and surgical skills of the treatment team.

We have found that for the team diagnostic endoscopy confirms valuable information on predicted pain generators to actual sites. This approach also may alleviate the need for a surgical approach that is potentially destructive to muscle and adjacent soft tissue when a less invasive or conservative treatment is available.

Other validated indications include excisional biospy of spinal structures and tissue. A prime example is discitis. Currently treated with long-term antibiotics, discitis is much more effectively treated with endoscopic debridement and excisional biopsy of infected tissue. The initial clinical data results are promising, suggesting endoscopic excisional biopsy and debridement offer the optimal treatment option for this condition.

ALTERNATIVES TO FUSION

Fusion has traditionally been reserved for spinal instability and deformity. More recently with the development of fusion cages, patients have been offered fusion for discogenic back pain without leg pain. The pain generators have been discovered to arise primarily from the annulus, but also can involve the endplates and facet joints.

Patients with debilitating lumbar pain are currently being offered surgical fusion as a treatment option to stabilize the motion segment. Pain nociceptors from the annulus which are innervated by branches of the sinuvertebral nerve, have been shown to be deformed by heat at least 42°C. When the heat is increased to 65°C, type one collagen of the annulus contracts and thickens (Saal, Saal, and Ashley, 1997). Thermal therapy has been utilized to tighten stretched ligaments and unstable joints.

This approach is being applied to annular tears with favorable results. This type of lesion cannot always be imaged, even with the most sophisticated techniques; however, provocative discography has demonstrated its ability to diagnose such pathologies. Furthermore, when imaging studies identify these lesions as a high intensity zone (HIZ), there is a high incidence of positive confirmation by provocative discography.

Spinal endoscopy allows direct visualization of annular tears, identifying interpositional disc tissue as the single most common finding preventing annular tears from healing. This approach may provide a possible alternative to fusion as a first line of surgical treatment for discogenic pain with its origin from annular tears.

PROVOCATIVE DISCOGRAPHY

Our clinic utilizes discography as an integral part of the surgical workup. The literature supporting discography is currently considered controversial in some circles. The controversy presents because of the high inter-observer variability by discographers in reporting the patient's subjective pain. However, if the surgeon works closely on a team with an experienced discographer, and there is ongoing communication, we have found the two can help decrease the variability in the interpretation of the patient's response.

It is ideal for the surgeon to perform his or her own discography, as he or she is the one who must take the responsibility for deciding whether the patient will respond to endoscopic spine surgery. Furthermore, the surgeon always repeats the discogram at the time of surgery if the Selective Endoscopic Protocol that emphasizes vital dye staining of targeted tissue is used.

The discogram can be used to predict the presence of a collagenized disc fragment vs. a soft herniation, and the extrusion of a disc fragment as a noncontained herniation. In addition, discography can diagnose the presence of the type, grade, and location of painful vs. nonpainful annular tears (Yeung, 1995).

The senior author follows a classification for discograms based on Adams, et al. (1986), Osti (1992), and Sachs, et al. (1987). According to Adams, the basic pattern is grades I to V. The radial extensions are per Dallas where grade III is the extension to the inner annulus, grade IV up to the outer annulus, and grade V beyond the outer annulus. The extension of circumferential tears is described per Osti. When this classification is used, the number of quadrants of involvement can be determined by discography alone, and it is not necessary to do a post-discogram CT scan to get enough information to determine the efficacy of endoscopic surgery.

The Revised Discogram Classification

1. Cotton ball nucleus (normal cotton ball pattern).
2. Oval nucleus and painless extension of fragmentation beyond center.

3. Radial fissured extension to the inner annulus with no circumferential extension and no disc protrusion.
4. Radial extension to the outer annulus and circumferential component to 1 to 4 quadrants and disc protrusion.
5. Radial tear past outer annulus, circumferential 1 to 4 quadrants, most variable and definite disc protrusion with possible extruded fragment.

Clinically

- Grades 1 and 2 give no pain.
- Grade 3: Pain present at moderate pressure.
- Grade 4: Predominately back pain. Leg pain associated with central and far lateral protrusion, inflammatory membrane may be present.
- Grade 5: MRI can only detect in Zones I and II, the central and foraminal zones (may be associated with herniation). Possible prolonged healing time up to 9 months, depending on the size of the tear.

The Technique Incorporates Adjunctive Modalities

1. Flexible probes
2. Flexible mechanical instruments
3. Thermomodulation
   a. Radio frequency
   b. Laser

Since 1991 the senior author has treated over 1000 patients with a wide spectrum of disc herniations endoscopically. These include extruded and sequestered fragments. The success rate in the first 500 patients is an overall 86% good/excellent by MacNab Criteria. The success rate has continued to rise concurrent with diligence in the refinement of indications, techniques, and adjunctive therapy.

With the addition of a focused multidisciplinary team that enjoys working together, it is our hope that with a coordinated team approach we can easily reach the 90% plus good/excellent outcome and avoid the failed spine surgery syndrome so prevalent in today's surgical environment.

INTRADISCAL THERMAL THERAPY

As of July, 2000, only one published study on the treatment of back pain using Electrothermal Therapy (IDET) has been published. Electrothermal Annuloplasty (IDET) involves the insertion of an electrothermal catheter into a putatively painful disc under fluoroscopic guidance. Thermal energy delivered by the catheter results in a breakdown and restructuring of collagen fibers in the annulus. Proponents offer several explanations as to why this procedure might relieve pain attributed to the disc. It may be due to a stiffening of the disc itself, possibly alter the annular tears or, in fact, it may ablate nerve endings. Nevertheless, Saal, Saal, and Ashley (1997) report that 80% of the patients treated with IDET noted a significant decrease in their back pain of at least 2 points on a 10-point analog scale, improvement in sitting tolerance, and reduction in medication usage. An SF-36 Questionnaire revealed a positive change of at least 7 points.

Recent information from the International Society for the Study of the Lumbar Spine (ISSLS) was critical of IDET. They cited the lack of high-quality scientific evidence exists in favor of this treatment. Furthermore, no evidence in favor of IDET from randomized controlled trials, or from other published controlled studies about long-term safety, yet reports suggest over 20,000 patients have undergone this procedure. Caution is advised as with any procedure. These patients present with back pain without severe radiculopathy. Patients with severe radicular symptoms due to frank disc herniations are not candidates. If there is any amount of disc protrusion or herniation, selective endoscopic discectomy would be the treatment of choice.

VISUALIZED THERMAL ANNULOPLASTY

The author's choice of a visualized technique over the blind technique of a thermal resistive catheter is supported by his success in converting failed IDET procedures to successful ones using the selective discectomy and visualized thermal annuloplasty technique. In our experience one of the most common findings with failed IDET is the presence of a disc fragment or interpositional disc tissue fragment preventing shrinkage of the annular tear. On rare occasions one is able to find necrotic disc tissue (confirmed by pathology slides) in patients who have undergone IDET treatment.

We feel strongly that direct visualization overcomes both conditions when visual control of tissue reaction to thermal energy allows the surgeon to avoid carbonization of tissue and target the annular tear directly. In the Y.E.S.S. technique, inclusion of a side firing Ho:Yag laser also serves as the energy source that offers a tool that affects tissue shrinkage to the ablation of bone, just by controlling the laser setting.

Further advancement and application of these techniques will help expand the surgical capabilities of this procedure, allowing for treatment of conditions in a degenerative spine that are painful, but not responding to conservative treatment.

CHYMOPAPAIN

Low-dose chymopapain 500 units help "digest" the soft herniation and treat the collagenized fragment for ease of removal. The senior author uses chymopapain when disc fragments are found to be extruded and migrated behind the vertebral body. Other applications are when a recurrent herniation exists. Chymopapain is used to decrease the recurrence rate and dissolve the missed fragments. Chymopapain is injected and left in the nucleus pulposus for up to 5 minutes before endoscopic discectomy.

When chymopapain is used as adjunctive therapy, we have had no adverse effects or allergic reactions, even when the discogram identifies leakage beyond the annular fibers into the epidural space. If the discogram demonstrates uptake by the venous plexus, if it is absorbed as soon as it is injected, or if it communicates in any way with the thecal sac, demonstrating a communication with the disc space, we have not injected chymopapain. As a precaution against an allergic reaction, we routinely administer Benadryl™, 50 mg, and cimetidine, 300 mg IV, before injecting the chymopapain.

INTRAOPERATIVE STEROIDS

Whenever an inflammatory membrane was observed, stimulation of the nerve and surrounding tissue elicited pain. When there is no inflammatory membrane, the nerve and annulus can be manipulated without eliciting pain. When an inflammatory membrane is present, the patient's pain is often considered out of proportion to the imaged pathology. When there is significant inflammation noted, Depo-medrol® is placed intradiscally at the conclusion of the procedure.

RISKS AND COMPLICATIONS

Surgical risks and complications are real issues that need to be weighed before considering any invasive procedure. These include dural tear, nerve root damage, bleeding, or infection. The authors have seen variations of nerve anatomy and distribution on the annulus, including conjoined nerves not appreciated by imaging studies and accessory nerve branches that often connect the traversing with the exiting nerve. Removal of these branches usually do not affect the patients' clinical course.

The most common adverse effect of the use of electrothermal therapy is dysesthesia. Fortunately, most dysesthesia will resolve completely, as in a second-degree controlled burn. Occasionally, there will be severe sympathetic pain that will challenge post-operative pain management. A multidisciplinary team is extremely helpful in assisting the patient to cope with the pain. Usually good pain management with selective epidurals or nerve root block, the use of long-acting oral analgesics, and judicious use of gabapentin (Neurontin™) will mitigate this condition.

We have noted the presence of dysesthesia as a delayed response days and weeks after the procedure. Therefore, while we blame the use of laser and electrothermal therapy, the actual cause of this regional sympathetic condition is still unknown. The incidence of dysesthesia is about 5%. Complications of discitis, nerve injury, dural tear, and psoas hematoma total less than 1 to 2% overall.

Phytomedicinal Approaches to Pain Management

James Giordano, Ph.D.

Recent medical practice has seen a phenomenal increase in the utilization of alternative and complementary approaches by patients as well as physicians. One of the most dynamic and rapidly growing areas of complementary medical care involves herbal or phytomedicinal intervention. In the United States, herbs and phytomedicinals are commercially available in accordance with the Dietary Supplement and Health Education Act (DSHEA) of 1994. This act offers the proviso that herbs sold as supplements cannot be marketed for diagnostic, therapeutic, or preventive interventions for disease, and relegates them to the status of foods stuffs, additives, or (as the name would imply) nutritional supplements (or nutriceuticals). In this country, official governmental standards are not provided for the production of herbal products and, therefore, purity, potency, and viability can vary highly with regard to level of extract, contaminates, co-substances, and dose provided. Certainly this is not the case worldwide. Of particular note are the actions of Germany's "Commission E," a subgroup of the German Federal Health Agency. This organization has conducted an exhaustive study of over 350 common and medicinally used botanical preparations and has amassed basic scientific and clinical data that identify active constituents, chemical profiles, clinical applications, side effects, and contraindications for these herbs. Thus, the Commission E monographs stand alone as the most comprehensive and efficacious review of medicinal herbs currently available. Of equal importance is the current Physician's Desk Reference for Herbal Medicines. This volume provides a review of over 700 herbs assembled by PhytoPharm, U.S. Institute of Phytopharmaceuticals. The U.S. PDR for Herbal Medicines provides easy access for practitioners in an easy-to-read format for herbs that are commercially available, as well as enhanced research data on adverse effects, formulation, and safety. Taken together, these documents demonstrate that many herbs contain potent ingredients capable of exerting powerful biological effects. Also, active principal ingredients coupled with numerous constituent co-factors may set the stage for herb–drug interactions. Although consumers may view herbs as simple nutritional supplements, the potencies of these pharmacologic actions are medically important. When properly utilized, herbs can serve as adjunctive or perhaps primary agents in pain management. It is important for the practitioner to recognize that herbs often contain heterogeneous combinations of active principles. These can affect indication and use and may warrant pharmacologic contraindications. Although many herbs possess few or no notable side effects, a knowledge of the possible range of effects is critical. Similarly, a clinician must be aware that patients often maintain a "microwave mentality," in which the assumption is erroneously made that an herb is a "natural" product, therefore, "a little is good…more must be better." In accordance with the aforementioned information, it is exceedingly possible that overdosing even relatively benign herbs can have serious consequences. It is important for practitioners to be aware of not only active principles and constituents, but also to recognize viable dose ranges to maintain clinical effects. It should be noted, however, that both Commission

0-8493-0926-3/02/$0.00+$1.50

E and the U.S.P. DR for Herbal Medicines offer very well-defined caveats regarding the dosage of commercially available herbs. Clinicians and consumers must be cautious in their utilization of herbs, because these substances are not under direct governmental control for quality assurance, and doses of active and subconstituents can vary widely among preparations.

This being the case, clinicians who look to integrate herbal and phytomedicinal agents into their practice must be very specific when questioning patients about herbs (with precise inquiry regarding brand, dose, frequency, and combinations during initial assessments, follow-ups, and discharge planning). It may be useful, if considering integrating herbal preparations into practice, to procure the collaborative services of a compounding pharmacist to assist in the acquisition of superior quality, "pure herbs," that are as close to pharmaceutical grade extract as conceivably possible. For allopathic, osteopathic, and chiropractic practitioners, many medical associations offer ongoing continuing education in herbal treatments and nutriceuticals that provides information on effects, indications/contraindications, and use of herbs for specific disorders. Interactive recruitment of a naturopathic physician also may be of critical benefit if an expanded, integrative herbal practice is to be considered.

The herbs considered in this chapter fall into the category of "occidental" herbal preparations, and it is beyond the scope of this writing to address those herbs utilized in traditional Chinese, Indian, and various folk medicinal practices to treat pain. The U.S.P. DR for Herbal Medicines addresses compounds that fall within these categories, and the reader is referred to that document for appropriate review. Thus, while many herbs are capable of affecting some component of pain symptoms, the following group represents those with specific well-documented actions on specific processes that mediate pain. These are presented alphabetically for ease of access and readability.

BLACK COHOSH (*CIMICIFUGA RACEMOSA*)

A native plant of the North American continent, black cohosh is specifically cultivated as a medicinal herb in Europe. Alcohol-aqueous extract of icopropenolic extract of the plant yields the active constituents of several types of triterpenes including triterpene glycoside, 27-deoxiactein, and simifugoside. Active quinolizidine alkaloids include cytisines and methyl cytisine and the phenyl propane derivatives including isoferulic acid.

The active constituents of the plant appear to be the triterpene glycosides that affect the activity of central and peripheral estrogen receptors. Although equivocal evidence reports that LH levels are also affected by cohosh, studies demonstrate the major action is through either a direct effect on estrogen receptors or an indirect estrogenic activity of triterpene glycoside on smooth muscle of the female genital urinary tract. In this regard, black cohosh has been highly touted as an agent to relieve pain of premenstrual dysmenorrhea and perimenopausal discomfort.

In general, no overt side effects have been demonstrated or reported with use of black cohosh within the therapeutic dose range, although some initial dyspepsia may occur in sensitive individuals. Of particular note, however, is the activity of black cohosh in altering uterine smooth muscle motility; this agent is contraindicated during pregnancy due to a high potential for inducing uterine contractility and evoking spontaneous abortion. The actions of the tripertene glycosides can synergize the effect of antihypertensive medications through relaxant effects on peripheral vascular smooth muscle. Thus, the herb is contraindicated for use in individuals who are pharmacologically maintained on antihypertensive medication (due to the risk of profound hypotension). Overdose in excess of 5 to 10 g per day has been reported to result in dizziness, orthostatic hypotension, disorientation, headache, and vomiting, all apparently attributable to its vaso-relaxant mechanism and resultant central and peripheral hypotensive sequelae.

BLACK PEPPER (*PIPER NIGRUM*)

Black pepper is an indigenous plant to the Indian continent and is commercially cultivated in Asia and throughout the Caribbean. Berries of the pepper plant that have been liberated from the pericarp and berry-like fruit parts are utilized internally for stomach pain and are externally applied as a salve or ointment for neuralgia. Preparation yields a volatile oil whose chief constituents include sabineine, limonene, caryophyllene, α- and β-pinene and Δ-3 carene. Acidic amides include piperine, piperylin, piperolein A and B, and coumaperine. The plant also yields fatty oils and polysaccharides. The mechanism of action involves both volatile oils and acid amides, although certain glycosides (3,4-dyhydroxy phenyl ethanol glycoside, considered a substrate for enzymes responsible for producing the color of the plant) may have some activity as well. Taken internally, black pepper activates buccal high-intensity thermal receptors and increases salivation. Within the alimentary tract, pepper increases secretion of gastric mucosal cells. When topically applied, volatile oils and acid amides act at A-Δ and perhaps C-thermosponsive and polymodal afferents, either as a counterirritant or (indirect) secretogogue.

Adverse side effects and contraindications have not been reported for black pepper, nor have herb–drug interactions; black pepper appears to be safe and effective when used as an adjunctive agent in the treatment of dyspeptic gastric pain (including NSAID-induced dyspepsia due to decreased secretion of gastric mucosal cells) and as a topically applied agent for mild to moderate pain of neuropathic etiology.

BORAGE (*BORAGO OFFICINALIS*)

The borage plant is indigenous to Central and Eastern Europe where it is also cultivated commercially for culinary and medicinal purposes. Explants of borage are now grown throughout Europe and in the United States and Canada. The medicinal components of the plant consist of dried flowers, leaves, stems, and seeds. Borage oil is the fatty extract derived from the seeds. The chief constituent of the fatty oil is γ-linolenic acid, although linoleic acid is found in lesser quantities. The borage leaf yields several active constituents including numerous pyrrolizidine alkaloids (including supinin, lycopsamin, intermedin, amabiline, and thesinine), a variably water-soluble silicic acid, tannins, and mucilages. The oil is used in either liquid or capsular form for the treatment of neurodermatitis, its therapeutic effect due to the activity of alkaloids and tannins. The leaf is used as an external astringent, attributable to the tannins and mucilage.

Of note is that the borage leaf contains hepatotoxic alkaloids, which although present in nominal quantities, warrant against its internal use. An added caveat is that the borage leaf should be used as an external astringent for only brief periods of time, to lessen possible effects of the transdermal absorption of toxic alkaloids. Borage oil has not been shown to be contraindicated when used within the therapeutic dose ranges and duration, and no known herb–drug interactions have been reported for the oil preparation.

CAJUPUT (*MELALEUCA LEUCADENDRA*)

This large tree is originally from southeastern Asia and the Australian continent, and grown commercially elsewhere for medicinal purposes. The medicinal component is the oils of the fresh twigs and leaves, which are extracted, air dried, and steam distilled. This process yields active constituents of sineol, ± alpha terpineols, ± α-terpineols valerates, α-pinenes, and bicyclic sesquiterpenes. The oil is used externally as a salve or linament for sprains, myofascitis, tendonous and ligamentous overexertion injury, and may be applied topically over arthritic joints. Mechanism of action appears to involve direct activity of the terpineols with both anti-inflammatory and perhaps mild muscular relaxant effects. The high sineol content yields toxicity if the drug is taken internally or is allowed to contact mucus membranes of the lips, eyes, or nose. This latter effect is particularly viable in young children, in whom wherein facial application has been documented to induce glottal, bronchial, and diaphragmatic spasm. As well, the high sineol content may induce rapid overdose following internal consumption by adults. Profound hypotension, vascular and respiratory failure, myoclonus and spasm, and electrolyte disruption have all been reported. Other than contraindications against internal use or accidental contact with viable mucus membranes facilitating internal absorption, no direct contraindications for this substance exist. Health hazard and/or side effects for moderate external use of cajuput oil have not been reported, although some individuals report an initial irritative dermatitis that subsequently dissipates.

CAYENNE (*CAPSICUM VARIANTS*)

Capsicum is native to Mexico, Central America, and the southern United States and is grown in numerous locations for both medicinal and culinary purposes. The active ingredients are the capsacinoids (vanillyl amine amides), principally capsaicin and dihydrocapsaicin. Cayenne also contains carotinoids including violaxanthine, flavoniods (apiin and luteolin-7-0-glucoside), and steroid saponins. The principal utility of capsicum is as a topical analgesic. The active moiety capsaicin, when afforded transdermal access (characteristically via delivery in a pluronic lecithin organogel), binds to a vanilloid calcium-channel receptor on peripheral nociceptive C-fiber afferents. Capsicum binding to this site facilitates an inward flux of calcium leading to a rapid membrane depolarization and release of these fibers' primary neurotransmitter, substance-P (please refer to Chapter 89 on the neurobiology of pain). Thus, capsicum acts as a secretogogue at peripheral C-fiber afferents. Capsicum binding appears to be long lasting, thereby blocking the channel, depleting the C-fiber of substance-P, and producing a rightward shift in the stimulation-response curve of C-fiber afferents to thermal, mechanical, and chemical noxious input. Commission E has approved the use of capsicum for pain of muscular (myoscitis, myofascitis) and rheumatic origin.

Of note is that use should be limited to 2 days, with a 10- to 14-day interval between applications. Prolonged use of topical capsicum may cause festering dermatitis and ulceration. Capsicum should not be used on the periorbital skin, and should be discontinued should hypersensitivity, rhinoconjunctivitis, or dermatitis occur. It has been suggested that hypersensitivity to capsicum is due infrequently to direct sensitization, but rather is a result of a generalized pollen hypersensitivity with cross-reactivity to cayenne.

ENGLISH CHAMOMILE (*CHAMAEMELUM NOBILE*)

English chamomile, also known as Roman chamomile, grows naturally in southern Europe and northern Africa, and is cultivated throughout Europe and the American continent. The medicinal oil extracted from the fresh or dried flower heads contains volatile oils including the esters of angelic and tiglic acid. Sesquiterpine lactones, including nobilin, epinobilin and 4α hydroperoxy manolide. Flavoniods

include anfemoside, cosmosioside, and caffeic and ferulic acid esters. The mechanism of action is not well documented; however, the sesquiterpine lactones appear to act in the central nervous system, perhaps inducing the release of inhibitory neurotransmitters for central modulation of pain. English chamomile has been used for treatment of general headache, somatic distress, and premenstrual pain.

It has been suggested that use of English chamomile may result in sensitization reactions; however, no known side effects or herb interactions have been documented. In light of the sparse documentation of potential interactions and effects, the drug is not indicated for use during pregnancy.

GERMAN CHAMOMILE (*MATRICARIA RECUTITA*)

Growing naturally throughout western Europe and cultivated in North America, the flowers and entire herb are used as an infusion for inflammatory pain and pain-related anxiety. Active ingredients include the volatile oil consisting of (–) –α-bisabolor, chanazulene, and spathulenol. Bioactiveflavonoids include flavone glycosides, apigenin, luteolin, flavinol glycosides including quercetin, and methoxylizedflavoniods including chrysosplenetin. German chamomile also contains phytomedicinal hydroxycoumarins and mucilages. Analgesic effects are centrally mediated and are due to the activity of flavoniods: apigenin is an agonist at CNS benzodiazepine receptors, and may potentiate binding at the benzodiazepine–chloride ion channel complex. Apigenin also appears to exert activity as a monoamine oxidase inhibitor, with specific activity at monoamine oxidase A, and lesser activity at monoamine oxidase B. Thus, both norepinephrine and serotonin concentrations may be transiently elevated through the use of chamomile. These latter effects subserve spinal and supraspinal mechanisms of analgesia.

Patients who are hypersensitive to grass and mudwort pollen may exhibit cross-reactivity and sensitization to chamomile. Co-administration of CNS sedative agents including benzodiazepines, barbiturates, and ethanol should be avoided due to potentiation of central activity at benzodiazepine-binding sites and GABA potentiation. Concomitant use of monoamine oxidase inhibiting drugs should be avoided due to the potential for sympathomimetic and hypertensive effects.

GINSENG (AMERICAN AND KOREAN *PANAX* GINSENG)

A native plant of China, Korea, and Japan, it is also cultivated for nutriceutical purposes in the United States. The powdered preparation is used as either an infusion or in capsule form and is prepared from the dried root of the native plant. Active ingredients include the triterpene saponins; aglycone (20S)-protopanaxadiols including numerous ginsenosides (Ra1, Ra2, Ra3, Rb1, Rb2, and Rb3); aglycone (20S) propanax triols including ginsenosides Re, Rf, and Rg, aglycone oneanolic acids of ginsenosides Ro, saponin V, Rb1 and Rb2, the water-soluble polysaccharides panaxane (subtypes A-U) and several polyynes. The most active ingredients are the ginsenosides, which act as steroidal saponins. One reported mechanism of ginseng's analgesic effect is through the reduction in platelet-derived serotonin. The ginsenosides Ro, Rg1, and Rg2 inhibit platelet release reaction and thromboxane formation, thereby reducing platelet contribution to inflammatory and nocisponsive events. Saponin glycosides have been shown to stimulate corticotropin release, which may mediate, at least in part, a component of neuroendocrine analgesia. Although conflicting studies exist, data exist that illustrate the direct CNS activity of ginsenosides Rg2 and Rg3 at nicotinic ACh receptors. It is unclear whether this constituent functions as a partial agonist or mixed agonist-antagonist. By acting through central nicotinic ACh receptors, these ginsenosides appear to mediate a limbic component of pain processing, and thereby affect pain perception. Ginsenosides Rg2 and 3 may have activity at central GABA receptors, acting as partial agonists or mixed agonist-antagonists, to mediate a component of nociceptive modulation.

In general, care should be taken when considering use of ginseng in patients with cardiovascular disease (due to nicotinic stimulation) and/or diabetes (due to stimulation of insulin release and adrenergically mediated hypoglycemia). Thus, patients taking insulin or hypoglycemic agents should not employ ginseng as an adjunct analgesic. The use of nonsteroidal anti-inflammatory agents may be problematic due to the combined and potentiated anti-platelet and thrombolytic activity of NSAIDs and ginseng. The use of monoamine oxidase inhibitors with ginseng is contraindicated due to increased potential for sympathomimetic events (headache, tremor, hypertension).

SIBERIAN GINSENG (*ELEUTHEROCOCCUS SENTISOSUS*)

This plant is native to the Siberian regions of Russia, Northern China, Mongolia, and Korea. It is grown in Japan and North America. The dried roots and rhizomes are extracted for the production of the active compounds caffeic acid, hydroxycoumerins, several lignans including sasamine, eleutheroside-d phytosteroids including β-sitosterol-3-Oβ-D glucoside, rephinal acrylic acid eleutheroside B, several polysaccharides including eleutherane A-G, steroid glycosides, and triterpene saponins (eleutherosides I, K, L, and M). Siberian ginseng is used as an analgesic against kidney pain, rheumatoid pain (primarily

due to its immune modulating effect on T-lymphocytes induced by the eleutherane polysaccharides), and inflammatory pain. The latter effect is modulated by platelet-inhibiting actions mediated by hydroxycoumarins and triterpene saponins. The anti-platelet activity may reduce peripheral concentrations of platelet-derived serotonin that activate peripheral C-fibers in inflammatory pain.

Due to the stimulating effects of caffeic acid and the plant steroids, the herb is contraindicated for patients with hypertension. Possible interactions include a potentiated thrombolytic effect when used with nonsteroidals, salicylates, or anticoagulant agents. In addition, the hypoglycemic activity of the herb contraindicates its use for patients on hypoglycemic agents or insulin.

JAPANESE MINT (*MENTHA ARVENSIS PIPERASCENS*)

Indigenous to Europe, Asia, and commercially grown in North America, the mint oil is obtained through distillation of the flowering herb and removal of the active menthol ingredient. Chief components include menthol, menthone, limonene, neomenthol, and α and β pinene. It is used in Indian and Chinese medicine as a topical application of the essential oil for joint pain, headache, myalgia, and peripheral neuralgia.

Although Japanese mint, mint oil, and menthol can be used internally for the treatment of gastrointestinal pain, dyspepsia, and relief of respiratory congestion, the possibility of hepatic insult and hepatotoxicity contraindicates long-term internal use. As well, the cholagogic effect may precipitate and worsen cholestatic disease in patients with this comorbidity. Topically applied, precautions and contraindications are few; however, asthmatic patients may have exacerbation of airway or bronchiolar spasm upon initiation of menthol application. Facial, perioral, and perinasal use of menthol oil is contraindicated in pediatric patients because of increased risk of glottal and bronchial spasm. The anti-myospastic and neurotropic effects of topically applied menthol are due to the actions of menthol and menthone, perhaps as a counterirritant or through a direct mechanism not completely understood.

KAVA KAVA (*PIPER METHYSTICUM*)

A native plant of Polynesia and the South Sea Islands, kava kava is harvested for the dried rhisome and roots. Active ingredients are the kava lactones including (+)-kavain, yangonin, desmethoxy yangonin, kava pirones, and chalcones including flavokavain A and B. Used orally, kava lactones and pirones act at central GABA synapses to potentiate GABA release or facilitate GABA binding (primarily in brain). Kavain and dihydrokavain inhibit voltage-dependent sodium and calcium channels, thus exerting both a central and peripheral muscle relaxant and neural inhibitory effect. Desmethoxy yangonin, yangonin, and kavain reversibly antagonize monoamine oxidase B, resulting in increased availability of synaptic serotonin at spinal and supraspinal sites. This increase in serotonin subserves the analgesic effect via inhibition of nociceptive neurons in the spinal cord. Additional analgesic properties are attributed to kavain, which can inhibit cyclo-oxygenase 1 and perhaps cyclo-oxygenase 2 in peripheral tissues, as well as the CNS. By inhibiting formation of the principal initiating enzyme of the archidonic acid cascade, kavain thus attenuates the formation of prostaglandins and thromboxane which act as potent inflammatory and nociceptive mediators.

As a mild depressant, the drug is contraindicated for patients with a history or current presentation of depression. Initially, administration may lead to mild allergic hypersensitivity and dyspepsia; however, this appears to dissipate with repeated use. Some initial lethargy has also been reported but this side effect also decreases with repetitive use. Based upon mechanism of actions, kava should not be used with alcohol due to reciprocal potentiation of effect, with benzodiazepines because of potentiation of benzodiazepine activity at GABA receptors, or with CNS depressants (e.g., barbiturates) due to potentiated depressant effects. Patients taking SSRIs, tri- or heterocylic antidepressants should use kava with caution because of the potential for enhanced psychotropic effects. There are reports of dopaminergic antagonism occurring with kava; thus, use of kava in Parkinsonian patients is contraindicated. Similarly, cardiac patients should use kava with caution due to variable effects of kava on dopaminergic control of the heart. Although these contraindications and caveats are applicable to specific patient populations, a more general precaution is that patients should use care when operating heavy machinery or engaging in fine motor tasks, particularly during the initial phase of kava therapy because of decreased motor coordination, increased reaction time, and sedative effects. While these may be transient, the early phase of therapy produces the most salient side effects for which the greatest precautions are warranted.

MARIJUANA (*CANNABIS SATIVA*)

Originating as a hashish derivative in the Near and Middle East, cannabis is cultivated throughout Europe, Asia, and North and South America as a substrate for illicit recreational drug use. The active ingredients are the cannabinoids, mainly 9-tetrahydracanabinol and other bioactive cannabinoids. The flavoniods canniflavone-1 and -2 are also present. The analgesic actions of the cannabinoids appear to be due to binding at a discrete CNS receptor present in the thalamic, limbic, and cortical regions of the brain. Additionally, the effect of cannabinoids and

flavoniods on membrane lipid metabolism, specifically, the diversion of fatty acid metabolism against archidonic acid, appears to be a mechanism by which peripheral analgesic effects may be mediated. The legal implications of cannabis use are obvious. It warrants mention that this agent has seen licit use as an analgesic, and may have utility as a marketed compound (dronabinol) for the treatment of pain, AIDS-induced anorexia, and as an anti-emetic for use during chemotherapy. Characteristically, cannabis is smoked (in cigarette or water-pipe form), ingested (either directly or incorporated into sweets), or taken in capsular form. Multiple effects are attributed to cannabis including vacillation of mood, lethargy, altered concentration, increased reaction time, and alteration of sensations. Physiologically, cannabis induces bronchial dilation, mild to moderate immunosuppression, increased cardiac chronotropy, and mild hypothermia.

Although specific contraindications do not exist, the aforementioned side effects limit its utility and caveats against operating a motor vehicle or heavy equipment or engaging in complex tasks are afforded. Although regional interest in legalizing cannabis use for general purposes (both medicinal and recreational) exists, marijuana still remains an illegal substance with often dire penal consequences for possession and use. Thus, its use is limited to prescription dosing (dronabinol, marketed under the brand name Marinol™) for appetite stimulation, anti-emetic action, and as an analgesic adjuvant (generally employed in end-stage terminal disease pain).

SCOTCH PINE (*PINUS*)

Native species are found in Europe, Siberia, the near East, and Scotch pine is cultivated worldwide. Medicinal components include tar extracted from the trunk and branch, oil extracted from needles, and pine tips from dried shoots. Active compounds include a volatile oil containing bornyl acetate, cadinene, and thunnene, ascorbic acid and several resins. The pine needle oil contains Δ-3-carene and α- and β-pinenes. A subspecies of pine, pinus sylvesteris, contains camphene, limonene, and terpinolene yielded from the raw turpentine oil from the plant. Pine shoots are advocated by Commission E for the treatment of neuralgia and oral inflammation. Pine needle oil and turpentine oil are externally used in the treatment of neuralgia and rheumatoid pain. These effects are due to its enzymatic actions that inhibit prostaglandin formation in peripheral tissues.

No specific precautions are noted for external use of pine oils; however, patients with extensive skin injuries, acute burns, and open wounds should avoid application. Prolonged and extensive use of pine-based turpentine oils may have nephrotoxic and peripheral neurotoxic potentials.

SPRUCE (SPECIES OF *PICEA*)

Indigenous to north, central, and western Europe, spruce is grown worldwide. Medicinal oils are extracted from needles, branches, and shoots. These yield needle oil containing bornoachinate, limonene, camphene, and pinene. Spruce shoots yield a volatile oil containing primarily limonene, borniol, bornyl acetate, and ascorbic acid. Spruce needle oil and spruce shoots are sanctioned by Commission E for topical application in the treatment of neuralgia and rheumatic-type pain. Mechanism of action appears to be due to a secretolytic and tonic inhibitory effect on peripheral nociceptive afferents.

As with scotch pine oils, patients with skin trauma and injury should avoid use of spruce oil or use it cautiously. Pediatric use is not recommended due to the enhanced possibility of absorption and toxicity.

ST. JOHN'S WORT (*HYPERICUM PERFORATUM*)

Growing natively throughout Europe and North Africa, the plant has been introduced to Asia, the Australian continent, New Zealand, and is currently cultivated in North America. The specific medicinal utilization is of buds and flowers. These yield several active constituents; anthrosene derivatives include hypericin and pseudohypericin. Active flavoniods include hyperosides, quercitrin, rutin, and amentoflavone. Hypericum also contains zanthones, catechintannins, caffeic acid derivatives, and a volatile oil whose main constituents are aliphatic hydrocarbons and mono- and sesquiterpenes. The herb is Commission E approved for treatment of depression, anxiety, and may be used as an adjunct analgesic. These properties are related to the activity of the flavone and flavinol derivatives. Hypericin has been shown to inhibit reuptake of serotonin, norepinepherine, and dopamine and may evoke pineal release of melatonin. The reuptake blocking effects of hypericum increase the synaptic availability of serotonin and norepinepherine within the brain and spinal cord, mechanisms that facilitate supraspinal and centrifugal pain modulation.

Although no specific precautions are rendered against the use of St. John's Wort, numerous side effects warrant discussion. Some patients experience paradoxical restlessness (initially thought to be a hypomanic effect somewhat similar to that seen with SSRIs), while others experience fatigue and lethargy. Transient headache is also a reported side effect, although this occurs in less than 10% of patients. Initially, patients may experience dyspepsia or GI pain with St. John's Wort use; this effect is transient. Of note is that hypericum produces photosensitivity, particularly with higher doses, and patients should be cautioned regarding ultraviolet light exposure (i.e., sun tanning and/or tanning beds). The documented neurotropic

action of hypericum warrants precaution against several drug interactions. Certainly, SSRIs used concomitantly with St. John's Wort increase the potential for facilitated serotonergic availability and the occurrence of serotonin syndrome ("wet dog shakes," diaphoresis, tremor, agitation, flushing). Similarly, the use of monoamine oxidase inhibitors is contraindicated due to increased adrenergic neurotransmission and the possibility for hypertensive crisis and other sympathomimetic effects on the cardiovascular system. St. John's Wort induces hepatic cytochrome P450 enzyme activity; other drugs metabolized through this pathway may have significant disruption of hepatic transformation. Specifically, these include cyclosporine (decreased serum concentration of cyclosporine following concomitant use of St. John's Wort), indinavir (greater than 50% reduction in plasma concentration of indinavir with concomitant use of St. John's Wort), theophylline and digoxin (decreased area under-the-curve serum concentration digoxin with decreased digoxin efficacy and anticipation of rising digoxin levels approaching toxicity after discontinuation of St. John's Wort).

TURMERIC (*CURCUMA DOMESTICA*)

Native to India, turmeric is grown throughout south east Asia and privately cultivated in the southern United States. Medicinally, the rhizome is stewed and dried to yield the active volatile oils α- and β-tumerone, artumerone, α-, and γ-atlantone, zingiberene, and curcumol. The plant contains curcumoids including curcumin, demethoxycurcumin, and bidemethoxycurcumin. Turmeric is approved by Commission E for dyspepsia, loss of appetite, and abdominal pain. Prepared as a tea or in capsular form, it is taken internally after meals. Additionally, tincture of turmeric is used for anti-inflammatory effects and analgesia against inflammatory pain. It is believed that the tumerones, zingiberene and curcumin, are the active moities in reducing the inflammatory cascade through direct stabilization of membrane fatty acid content (thereby preventing biosynthesis of arachidonic acid and, subsequently, prostaglandins). This action may subserve analgesic effects as well.

Although frank precautions or adverse effects are not known for tumeric, the use of this agent has been found to potentiate cholecystic disease in patients with premorbid cholecystic pathology.

VALERIAN (*VALERIANA OFFICINALIS*)

Native to Europe and Asia, it is also cultivated in Japan and the United States for phytomedicinal purposes. The dried roots are utilized to yield the iridoids including the valepotriates, isovaltrate, and acevalterate. The volatile oil contains bornyl isovalerenate and valerenic acid. The plant yields the sesquiterpenes of valerenic acid, 2-hydroxyvalerenic acid, and 2-acetoxy-valerenic acid. Additionally, pyridine alkaloids including valerianine and d-methyl tyrrylketone are present. The valerenic acids inhibit the enzymatic degradation of GABA, thereby making this inhibitory neurotransmitter more viable at supraspinal and spinal postsynaptic binding sites. Nonselective GABA-A and GABA-B receptor effects are achieved through the use of valerian. Valerian also has a high content of glutamine, a metabolic precursor to the glial GABA shunt for the biosynthesis of GABA. This ultimately increases neuronal GABA content and potentiates post-synaptic GABA-ergic effects further. The anxiolytic, muscle relaxant, and sedative effects are similar to those seen with administration of other GABA receptor agonists (e.g., the benzodiazepines). However, unlike benzodiazepines, tolerance, dependence, and withdrawal are rarely seen when utilizing therapeutic doses of valerian.

The activity at central GABA receptors contraindicates the use of valerian with benzodiazepines or barbiturate agents that are also agonists at this multimolecular receptor site. As well, a caveat (particularly during the initial use of valerian) against the operation of complex machinery or complex motoric tasks due to the spinal motor inhibition, muscle relaxant, and CNS sedative effects should be noted.

WHITE FIR (*ABIES ALBA*)

Indigenous to the Balkans, it is cultivated throughout Europe and in the United States as a domestic plant and for phytomedicinal purposes. The timber yields an essential oil through extraction, with active compounds of limonene, α-pinene, champhene, bornyl acetate, and santene. These oils may act as mild counter irritants initially, and perhaps as secretogogues to nociceptive afferents. White fir oil is approved by Commission E for topical application in treatment of neuralgia and rheumatic pain.

Like other essential oils of pine and fir trees, over exposure to volatile oils may yield glottal and bronchial spasm. Thus, application to the face, periorbital, and perinasal regions and use in pediatric patients are contraindicated.

WHITE WILLOW (*SALIX*)

Native to central Europe, the plant also is cultivated in the North American continent where the bark yields the active glycosides and salicylic acid. Additionally, white willow contains tannins and flavoniods. White willow is approved by Commission E for general treatment of pain and inflammatory states. This is directly attributable to plant esters and glycosides that yield salicin, the metabolic precursor of salicylic acid. Salicylate is a potent inhibitor of cyclo-oxygenase (both 1, and to a lesser extent, 2), thereby disrupting the

TABLE 88.1
Suggested Dose, Utility and Precautions of Herbs with Pain-Modulating Activity

Herb	Dose	Utility/Precautions
Black cohosh	40–60 mg qd/bid or 60mg (2) bid	Not to exceed 1–3 g/d Possible abortifacient
Borage	500 mg qd/bid as a capsule	Short-term internal use (1 week) Possibly hepatotoxic
Cajuput	1 g/cc topical oil	Not for facial use Not for pediatric use Use sparingly
Cayenne	0.25%, 0.75% cream or topical transdermal gel (not to exceed 10 g/d)	Short-term (2–3 days) use only Avoid oral, occular contact Avoid genital contact
English chamomile	1.5 g bid/tid Infusion 50–200 ml	Not for use during pregnancy
Ginseng		
Korean	1–2 g/d as capsule (100–1250 mg available) or liquid (3 mg/ml)	Not to exceed 3 g/d Contraindicated in cardiovascular, hypertensive diabetic patients Not for use during pregnancy
Siberian	2–3 g/d root as extract (or capsule)	Not for use in hypertensive or diabetic patients
Japanese mint	2–3 drops extracted oil topically applied	Not to exceed 3 times daily Not for orofacial use Not for pediatric use
Kava kava	150–300 mg extract (capsular form) bid	Best taken with food Not to exceed 600 mg/d Not for use in excess of 3 months without supervision Not for use during pregnancy/nursing
Marijuana	2.5, 5.0, 10 mg capsules (Dronabinol: Marinol) 2.5–10 mg bid-qid	Legal ramifications Not for prolonged use Precaution in motoric tasks/coordination-dependent activity
Scotch pine	100 g alcohol extract bid; 20–50% topical cream, ointment, gel (1cc) tid	Not for orofacial use Not for pediatric use Not for use in asthmatic patients
Spruce	20–30% oil ointment (1cc) tid	Not for orofacial use Not for pediatric use Not for use in asthmatic patients
St. John's Wort	125–500 mg (0.3% hypericin) capsules; 200–300 mg tid	Initial 6-week trial recommendation Not for use with MAO-inhibitors, TCA, or SSRI/SNRI agents (potentiated effects) Photosensitizing: avoid UV exposure during use Induces hepatic microsomal P450 enzymes
Turmeric	1.5–3.0 g/d	Not for use in patients with premorbid or active cholecystic disease Not for use during pregnancy
Valerian	100–1000 mg capsules; 100–1000 mg qhs	Titrate dose to effect Not for use with alcohol, benzodiazepines, barbiturates May cause daytime drowsiness/lethargy Not for use during pregnancy or nursing

membrane arachidonic acid cascade that yields pro-inflammatory and pro-nocisponsive prostaglandins.

Although direct hazards and adverse side effects are not reported for therapeutic doses, patients who are hypersensitive to salicylates should not utilize white willow. As well, pediatric use of white willow should be cautious due to possible occurrence of Reyes syndrome. Long-term use and/or dose escalation may yield salicylate toxicity (typically characterized by tinnitus and metabolic acidosis). In light of the salicylate content of white willow, concomitant use of nonsteroidal anti-inflammatories or aspirin is contraindicated. This is to avoid possible adverse hepatic effects, concentration-induced toxic effects, and unwanted thrombolytic effects. There is equivocal evidence to suggest

the utility and contraindication of white willow bark in patients with premorbid gastritis and/or history of peptic ulcer disease. Certainly, the use of this compound should be cautious in patients with co- or pre-morbid ulcer due to the systemic action of salicylate on prostaglandin-induced mucus secretion in the stomach, thereby exacerbating ulcerative symptomology. However, studies suggest the direct action of white willow on the gastric mucosa may be considerably less than that of aspirin or other nonsteroidals. Regardless, it is best to be prudent in the use of this compound in patients with peptic or duodenal ulcerative disease.

SUMMARY

The information contained in this chapter is provided as an overview of those herbs identified to have viable, clinically researched evidence for treatment of pain. Their use as primary and/or adjunctive analgesics requires considerable expertise and caution on the part of practitioners. Unfortunately, precise pharmacokinetic parameters of each herbal preparation are not completely understood. A single herbal preparation may contain numerous active principles that are differentially yielded based upon type of preparation. Also, the actual concentration of the active principles may vary widely based upon preparation, quality of herb, season of herbal harvesting, as well as other factors. Accurate prediction of dose–response relationships, time course of effects, specific parameters for interaction and pharmacodynamic mechanisms and actions are somewhat difficult to assess given available information. For the clinician considering integrating phytomedicinals to clinical practice, a working maxim would be to "start low and go slow" utilizing the purest form of the herb commercially available, at the lowest viable dose, incrementally increasing that dose to effect, while observing for putative side effects and potential drug interactions.

To reiterate, recruiting the aid of a compounding pharmacist (to assist in obtaining the purest commercial form of herb), a naturopathic physician, and receiving specific (advanced) training in phytomedicinal practice are strongly advocated. Clinicians must be aware that simply because a substance is "natural" does not guarantee its safety. Although herbs often provide a reasonable alternative to commercially manufactured pharmaceutical products, a complete understanding of their chemistry, pharmacologic mechanisms and effects, and potential physiologic and pharmacologic side effects and interactions is mandatory.

ACKNOWLEDGMENT

The author wishes to thank Connie Parker for her assistance in preparation of all phases of this manuscript.

The Neurobiology of Pain

James Giordano, Ph.D.

Pain is a most beguiling clinical problem. With both subjective and objective components, pain becomes a unique experience for each individual. The neural substrates that are involved in processing noxious input contribute to both the sensation and perception of pain. By understanding the components of the pain transmitting and modulating systems we may gain insight toward the development of therapeutic strategies against chronic pain.

NOCICEPTORS

The first step in the nociceptive sensory pathway is the transduction of noxious stimuli to a relevant neural signal. In cutaneous, muscle, and visceral tissues, free nerve endings of nocisponsive primary afferents are responsible for this transduction step. It remains somewhat unclear whether the free nerve endings respond to the actual noxious stimulus or to evoked changes in the tissues which they innervate. In the latter case, noxious stimuli incur a cascade of cellular damage evoking the release of fatty acids and free ions from cell membranes. Among the fatty acids, arachidonic acid serves as the initiative substrate for induction of the enzymes cyclooxygenase 1 and 2 to catalyze the inflammatory cascade (subsequently mediated by prostaglandins and leukotrienes). Change in local tissue pH and the concentration of various ions, such as potassium (K^+), serves to directly affect membrane polarity of free nerve endings in the affected tissue as well as altering vascular permeability and mast cell degranulation. Degranulation of mast cells causes release of histamine and serotonin, which exacerbate vasodilatory and inflammatory effects. Serotonin may work directly upon the terminals of free nerve endings to initiate a sodium (Na^+) and/or calcium (Ca^{++}) current leading to heightened excitation.

The burning sensation that often accompanies high-intensity mechanical and thermal stimulation may be indicative of the sequential activation of discrete populations of differentially sensitive nociceptor nerve endings (and their associated primary afferents): first by the stimulus directly, followed by the resultant chemical changes in the affected tissue.

The free nerve endings subserving the transduction of noxious stimuli are responsive to high-intensity mechanical input (i.e., pinch, squeeze, intense pressure), high-intensity thermal input (e.g., noxious heat in excess of 45°C), mixed high-intensity mechanothermal input, and chemical stimulation (disturbance of the local chemical or ionic environment and presence of various pro-nociceptive substances). Transduction occurs as these stimuli evoke changes in the neural membrane integrity, producing a inward sodium and/or calcium current. The receptor potential for free nerve endings appears to be a graded response, with time- and intensity-dependence of the membrane polarity. Subsequent to transduction, the nociceptive signal is transmitted from free nerve endings in the periphery (or viscera) along what appears to be stimulus-specific, labeled lines of nociceptive primary afferent fibers. There are two type of primary nociceptive afferents, A-delta and C-fibers. These subtend distinct types of noxious input (e.g., thermal, mechanical, polymodal) and are responsible for differing subjective qualities of fast (i.e., "first") and slow (i.e., "second") pain, respectively.

0-8493-0926-3/02/$0.00+$1.50

PRIMARY AFFERENTS

A-Delta Fibers

These fibers are small, thinly myelinated neurons 1 to 5 µm in diameter, with conduction velocities in the range of 5 to 30 m/sec. The rapid rate of conduction is responsible for the initial sensation of pain (first pain) typically described as sharp, localized, and well defined. A-delta fibers have small receptive fields and are relatively modality specific. A-delta thermosponsive fibers respond to extremes of temperature. One population is activated by noxious heat, with an initial response threshold in the range of 40 to 45°C. Response function increases directly, although not necessarily linearly, as a consequence of temperature elevation, with maximal responses occurring at temperatures of 46 to 53°C. These responses subserve both the rapid, demonstrably painful response to an initial presentation of noxious heat and the ability to quickly discriminate the extent of thermal pain as a function of heat intensity. A second population, high-threshold cold afferents, respond to cold temperatures at or below a threshold of approximately 20°C.

A-delta mechanoreceptive afferents are activated by high-intensity mechanical stimulation (deep pressure, stab, pinch), although these fibers may be sensitized by and become secondarily responsive to noxious heat. Unlike A-delta thermal afferents, sensitized A-delta mechanoreceptive afferents respond to suprathreshold heat (usually in excess of 50 to 55°C) and/or repetitive presentation of noxious heat, rather than to a singular exposure to a heat stimulus at or above the nociceptive threshold. The sensitization of this second population to nociceptive A-delta afferents is thought to underlie clinical patterns of hyperalgesia (increased sensation of pain) seen following heat and burn injury.

C-Fibers

C-fibers are small, unmyelinated afferents. With fiber diameters ranging from 0.25 to 1.5 µm, the absence of myelin leads to slower conductance velocities that vary from 0.5 to 2 m/sec. This slower conductance subserves "second pain", a diffuse, poorly localized burning, throbbing, and/or gnawing sensation that follows, and is temporally and qualitatively distinct from the initial sensation of first pain. Numerically, C-fibers constitute the majority of primary nociceptive afferents found in cutaneous tissue. C-fibers are polymodal, and can be activated by thermal, mechanical, and chemical stimuli. In addition to responding to noxious (thermal, mechanical, and chemical) stimuli, C-fiber polymodal afferents may be activated by certain types of non-noxious, low-intensity stimulation. C-fiber thresholds to such non-noxious stimuli can be sensitized by high-intensity heat, pressure, or chemical disturbance. Similarly, C-fibers may be sensitized to lower thresholds for mechanical and chemical stimuli by noxious heat. However, unlike thermal sensitization of mechanosponsive A-delta fibers, C-fibers are sensitized by noxious heat of lower intensity (48 to 50°C). This may account for both the persistent second pain and hyperalgesia that occur following a milder burn injury. In this light, C-fibers may contribute to multiple sensations from a painful region. C-fibers also innervate muscle tissue, localized to the intrafibril matrix, tendons, and areas surrounding the vascular walls. C-fiber muscle afferents are polymodal, and are responsible for the nociceptive response to intense mechanical stimulation, numerous chemicals (including lactic acid), and heat. Although not directly activated by muscular contraction or the stretch reflex, intramuscular C-fibers can be sensitized (under ischemic conditions) to respond to even small myofibril contraction, and may respond vigorously to excessive stretch. This sensitization helps to explain the diffusely painful response to both passive and active movement of over-exerted, traumatized, or ischemic skeletal muscle.

Visceral Primary Nociceptive Afferents

Primary afferent innervation of the viscera is not completely understood. Conflicting evidence exists regarding the potential for nociceptive transmission from the viscera. Numerous stimuli are capable of producing visceral pain. Distention, compression, and chemical and tactile irritation of several visceral structures have all been shown to elicit distinct and quantifiable pain responses in humans that are often accompanied by reports of localized somatic and cutaneous pain. The diversity of responsiveness to various types of noxious stimuli suggests the presence of afferents with polymodal qualities. Taken with the diffuse, poorly localized quality that often accompanies visceral pain, such findings implicate the involvement of C-fiber-type innervation. C-fiber-type afferents innervate several visceral structures, although studies also have demonstrated the presence of A-delta fibers with polymodal sensitivity, particularly in the testes and structures surrounding the heart. As well, a small, unmyelinated J-fiber has been identified in the parenchyma of the lung. J-fibers have structural properties, receptive fields, and conductance velocities similar to C-fibers and respond to high-intensity mechanical changes in lung volume (i.e., distention and compression), inflammation, and exogenous chemical irritants (e.g., acidic and basic substances).

Nociceptive afferent innervation of visceral structures has several characteristics that are markedly distinct from those in cutaneous and muscle tissues. First, nociceptive afferent innervation of the viscera is relatively sparse, with considerable diffusion at projection sites at second-order neurons within the spinal dorsal horn. Thus, nociceptive input from the viscera may not evoke strong, well-localized volleys of excitation capable of spatially and/or temporally

summating at spinal relays. Second, the nature of visceral afferents is such that sensitization by chemical mediators and/or sympathetic activity (see below) appears to be required for their sustained firing. Given the sparse distribution of these fibers throughout the viscera and the diffuse connections with nociceptive units of the spinal cord, it appears that this sustained firing is responsible for the activation of second-order spinal afferents, and ultimately the transmission of visceral nociceptive signals. The perception of visceral nociception is vague, becoming more intense (and better localized) as increased painful activity in the innervated structure(s) sensitizes the involved afferents. Third, nociceptive afferent innervation of the viscera is often structurally co-localized with sympathetic afferent (and perhaps efferent) neurons. Noxious stimulation from the viscera can lead to concurrent excitation of both visceral nociceptive afferents and sympathetic innervation, capable of producing retrograde sympathetic outflow and sympathetically maintained regional hyperalgesia. Last, visceral nociceptive afferents are often integrated anatomically with somato-cutaneous nociceptive afferents within dorsal root ganglia or within the neuropil of second-order afferents of the spinal cord. Reciprocal sensitization within the dorsal root ganglion and the overlap of second-order receptive fields for visceral and somato-cutaneous input subserve the somatic referred component that is characteristic of much of visceral pain. In this regard it becomes clinically relevant to understand the convergence of visceral and somato-cutaneous afferents when attempting to predicting involvement of visceral structures in patterns of referred somatic pain.

Projections to the Spinal Dorsal Horn

Although a small number of nociceptive afferents synapse within the ventral spinal cord, the vast majority of somato-cutaneous and visceral nociceptive primary afferent fibers project to defined areas of the superficial dorsal horn. This area has been anatomically distinguished into discrete zones, known as the laminae of Rexed. The laminae, or layers, are numbered consecutively from dorsal to ventral regions. Both A-delta and C-fibers have been shown to terminate on specific populations of second-order spinal neurons in laminae I, II, IIa, and V, which are the origins of the ascending spinal pathways critical to pain transmission.

Neurochemistry of Primary Afferent Pain Transmission

The principal neurochemical mediator at the synaptic cleft between primary afferent nociceptors and dorsal horn cells appears to be glutamate. Post-synaptically, glutamate is capable of binding to two sets of discrete receptors. The AMPA (α-amino-3-hydroxy-5-methyl-isoxazole-4 propionic acid) receptor appears to be the initial site of molecular target for glutamate binding. Glutamate-induced AMPA receptor activation evokes a ligand-gated sodium current in post-synaptic second-order neurons of the dorsal horn that produces a rapid, depolarization. Glutamate is also capable of binding to a second site, the NMDA (N-methyl-D-aspartate) receptor. It appears that AMPA receptors either directly or indirectly modulate activation of NMDA receptors by glutamate through allosteric modulation of magnesium binding to a shared or cooperative domain of the NMDA receptors. With persistent AMPA receptor activation, the rise in intracellular sodium displaces a magnesium "gate" from the NMDA receptor, thereby increasing its sensitivity or releasing it from an inaccessible configuration to actively bind glutamate. It is hypothesized that this molecular change on the receptor level subserves a component of the altered neurological responses from acute to chronic pain. Glutamate binding at the NMDA receptor is responsible for mediating an inward calcium current that initiates a protein kinase-C to catalyze the induction of the enzyme nitric oxide (NO) synthase required for the intracellular production of NO.

Protein kinase-C is also capable of catalyzing other intracellular enzymatic reactions that stimulate protein synthesis in the second-order neuron. These glutamate-dependent protein kinase-C related reactions may be responsible for the production of new membrane-bound calcium channels and "new" NMDA receptors that may mediate or prolong sensitization of second-order afferents to input from nociceptors. It also has been posited that these molecular changes subserve, at least in part, second-order afferent sensitization to subthreshold primary afferent input, thereby producing hyperalgesic and perhaps allodynic responses. There is further evidence to suggest that prolonged activation of newly synthesized NMDA receptors may instigate protein kinase-C mediated nuclear reactions that may affect cell vitality and viable function (i.e., induction of apoptotic mechanisms of programmed cell degeneration and death).

Primary afferent nociceptors also release the undecapeptide substance-P. It is unclear whether substance-P is released directly following depolarization of primary afferents or as a consequence of feedback stimulation following glutamate release. Substance-P binds post-synaptically to neurokinin-1 (NK-1) receptors on second-order dorsal horn neurons. Prolonged activation of neurokinin receptors has been shown to result in the initiation and accumulation of a stimulatory proto-oncogene, *c-fos*, and its protein product, *c-fos* proto-oncogene appears to be responsible for mediating increased metabolic activity within the second-order neuron. Also, *c-fos* may interact on a molecular level to induce or increase the production of other proto-oncogenes, namely *ras* and perhaps *jun*. Together, these proto-oncogenes may be responsible for promoting nuclear mechanisms that code for novel (and perhaps aberrant) structural and functional proteins

involved in remodeling second-order neurons that are actively processing chronic pain.

In addition, sensitized primary afferents are capable of anti-dromic or retrograde release of neurochemical mediators of the inflammatory response. Prolonged activation of primary afferent A-delta, and particularly C-fibers, has been shown to evoke an anti-dromic release of substance-P. Substance-P provokes degranulation of mast cells in peripheral tissue leading to the release of several potent vasoactive and pro-inflammatory mediators including histamine and serotonin. Substance-P also may act directly as a vasodilator. In addition to anti-dromic release of substance-P, primary afferent nociceptors release calcitonin gene-related peptide (CGRP) from terminal branches to affect distal peripheral (and/or visceral) tissues. CGRP activates the enzyme NO synthase from the vascular endothelium leading to an increase production of nitric oxide and, ultimately, vasodilatation. Taken together, the effects of histamine, mast cell-derived serotonin, substance-P, and CGRP produce potent peripheral vasodilatory effects that lead to extravasation of chemical mediators that both propagate the inflammatory response and are directly pro-nocisponsive. These include vasoactive intestinal peptide (VIP), bradykinin, and platelet-derived serotonin. Of particular interest is the effect of rising concentrations of serotonin in extra-vascular tissue from mast cells and degranulated platelets. Our research has demonstrated that as peripheral serotonin concentrations rise, serotonin 5-HT_3 receptors on terminals of C-fiber primary afferents become directly stimulated, facilitating an increase in C-fiber depolarization and continuity of this cycle. These mechanisms help to explain how prolonged primary afferent activity can transform acute and subacute pain into a chronic condition with distinct neurologic and neurochemical properties.

SECOND-ORDER AFFERENTS

The dorsal horn of the spinal cord is a critical site for the convergence and neural processing of nociceptive information from peripheral primary afferent fibers. A-delta and C-fibers form synaptic connections upon distinct classes of wide dynamic range (WDR) and nociceptive-specific (NS) neurons within the spinal cord whose functional properties contribute to spatial and temporal transformations of the afferent input. These second-order neurons aggregate in the dorsal horn, project contralaterally, and ascend within the anterolateral quadrant(s) as the spinothalamic tract (STT) to sites within the brainstem, midbrain, and thalamus. The unique physiologic characteristics of WDR and NS neurons encode specific qualities of intensity, modality, and localization to the nociceptive signal that is transmitted to supraspinal targets.

Wide Dynamic Range Neurons

Wide dynamic range (WDR) neurons are localized with the highest concentrations in laminae I, II, V, and VI, with greatest numbers found in the latter levels. Although WDR neurons receive input from low-threshold cutaneous mechanoreceptor afferents (A-beta type), they are also a site of convergence for both A-delta and C-fiber nociceptive afferents. WDR neurons that are driven by nociceptive input are organized hierarchically within the dorsal horn, with the majority of primary A-delta and C-fiber afferent input occurring in laminae V. The size and responsivity of WDR neuron receptive fields increases progressively from laminae I to V: WDR units in laminae I and II have smaller receptive fields that are sensitive to gentle mechanical stimuli, those of laminae V have larger, overlapping receptive fields with graded sensitivities containing small, discrete regions excited by non-nociceptive input and broad regions that are maximally sensitive to high-threshold nociceptive stimulation.

WDR neurons are not individually sensitive to specific types of stimuli. Rather, individual WDR neurons, based upon response properties within their receptive fields, function to discriminate stimulus intensity. Increases in stimulus intensity activate coexistent areas of receptive fields of numerous WDR neurons. This pattern of engagement would involve slight differences in temporal activation, with individual WDR responses becoming phase-shifted. The activation of greater numbers of WDR neurons by high-intensity nociceptive stimuli would, therefore, result in spatial and temporal summation of these responses.

Nociceptive Specific (NS) Neurons

In contrast to the anatomical distribution of WDR neurons, nociceptive specific (NS) neurons are found in highest concentrations in laminae I and II, with lesser numbers in laminae V. NS neurons receive excitatory input from A-delta fibers and polymodal C-fiber afferents. Generally, NS neurons have small, non-overlapping receptive fields with a well-defined, center-surround organization. The central region is maximally excited by high intensity stimuli, while the outer region is differentially excited by frequency-based repetitive stimulation. This outer region may be inhibited by non-noxious input. The homogeneity of input from nocisponsive primary afferents and the small size and nociceptive selectivity of their receptive fields provide evidence that NS neurons appear to function in localization, and perhaps qualitative discrimination of particular types of noxious input (i.e., noxious pressure and/or heat).

Although painful sensations and responses can be evoked by WDR neuron excitation alone, WDR and NS activity appears to be necessary for the constellation of spatial and temporal qualities ascribed to pain. This

becomes apparent when the convergent inputs of A-delta and C-fibers upon WDR and NS neurons are considered.

The unique properties of the primary afferents and the second-order neurons essentially assemble the neurologic pain signal. For example, the sensation of first pain as punctate, well-localized, and temporally well-defined is a function of the response characteristics of both rapidly conducting A-delta primary afferents and their excitation of WDR and NS neurons. In contrast, second pain, a more diffuse, long-lasting nociceptive sensation that follows the initial stimulus is the result of the threshold, firing and conduction properties of C-fibers sustained by local tissue damage and/or chemical change, as well as patterns of temporal and spatial summation of C-fiber inputs by WDR and NS neurons. Both WDR and NS neurons are capable of after-responses that persist as a consequence of nociceptive afferent volley number and frequency; factors related to nociceptive stimulus intensity and continuity.

The anatomic and physiologic properties of second-order afferents also subserve the phenomenon of referred pain. As previously discussed, primary afferent innervation of visceral and deep muscular structures is organized so that these fibers converge upon WDR and NS neurons that also receive input from primary nociceptive (and non-nociceptive) afferents from specific somato-cutaneous regions. The convergence of visceral and cutaneous afferents from a given somatotome upon second-order WDR and NS neurons underlies patterns of clinical referred pain syndromes. Thus, sensory information from the viscera is often interpreted subjectively as afferent information from a cutaneous structure within the corresponding somatotome.

SPINOTHALAMIC TRACT(S)

The majority of WDR and NS neurons project contralaterally within the spinal cord and ascend within the anterolateral quadrant, forming the spinothalamic tract(s) (STT). A minority of fibers remain ipsilateral, and ascend outside of the STT within the ventrolateral white matter to supraspinal sites that correspond to the contralateral anterolateral quadrant projections. Anatomically, axons from second-order neurons in the superficial dorsal horn (laminae I and II) are segregated from those of deeper laminae (lamina V). This provides anatomical separation between the neospinothalamic (NSTT) and paleospinothalalmic (PSTT) tracts. While both the NSTT and PSTT may be considered “labeled-lines” for the transmission of pain signals, the differential localization of NS neurons to laminae I and II, in contrast to a greater abundance of WDR neurons in lamina V, subserves functional distinctions in the type of nociceptive information that is transmitted in these pathways.

The NSTT projects directly to the ventroposterior lateral (VPL) nuclei of the thalamus and is composed predominately of NS neurons from lamina I and II. WDR neurons are in smaller numbers within these laminae and they comprise only a minority of NSTT fibers. Recall that NS neurons receive almost completely homogeneous input from A-delta and high-threshold polymodal C-fiber afferents, and encode stimulus localization and modality. Therefore, the main role of the NSTT appears to involve transmission of these signal qualities to the thalamus.

The PSTT is composed of axons from second-order neurons arising in lamina V of the spinal cord. WDR neurons constitute the majority of cells from this lamina, with only a smaller number of NS neurons contributing to the axonal pool of the PSTT. Heterogeneous input to lamina V WDR neurons from both nocisponsive and non-nocisponsive primary afferents contributes to the transmission of some non-nociceptive signals along the PSTT. WDR neurons of lamina V also send axons ipsilaterally to ascend within the dorsal column medial lemniscal tract. This latter pathway is responsible for the transmission of light touch, vibration, and other low-threshold stimuli. Given the role of lamina V WDR neurons to encode noxious stimulus intensities, the co-localized transmission of nociceptive and non-nociceptive afferent information within the PSTT appears to serve a stimulus discriminatory function. This is further supported by the properties of PSTT WDR neurons to accumulate strong after-responses following nociceptive input. Such after-responses override weaker impulses evoked by non-nociceptive afferent stimuli, and produce temporally summated volleys within the PSTT. These events are correlated to, and appear to subserve the qualities and subjective characteristics of clinically relevant, second, and/or chronic pain.

Unlike the NSTT, the PSTT is not a direct thalamic pathway. PSTT fibers project to several supraspinal sites that are involved in (nociceptive) sensory processing and that may exert pain modulatory control. The PSTT may be divided into spinoreticular, spinotectal, and ultimately spinothalamic projections. Spinoreticular pathways project to areas of the brainstem reticular formation. These include the raphe nuclei of the rostroventral medulla and the nuclei reticularis gigantocellularis (NRGC) and paragigantocellularis (NRpG) of the caudal pons.

Spinotectal projections terminate within the tectum and periaqueductal grey (PAG) region of the midbrain. The spinoreticular and spinotectal circuits function in centrifugal pain control and ascending neurons from these sites serve as relays between spinal pathways and higher centers that mediate the perceptual and affective dimensions of pain. Of particular note are defined tracts from the reticular formation to several regions of the limbic forebrain, and a reciprocal neuraxis involving the PAG, the periventricular gray region (PVG), and hypothalamus. Thalamic projections of the PSTT differ from those of the NSTT; PSTT fibers project diffusely to the thalamus, with terminations at several intralaminar nuclei. (See Figure 89.1.)

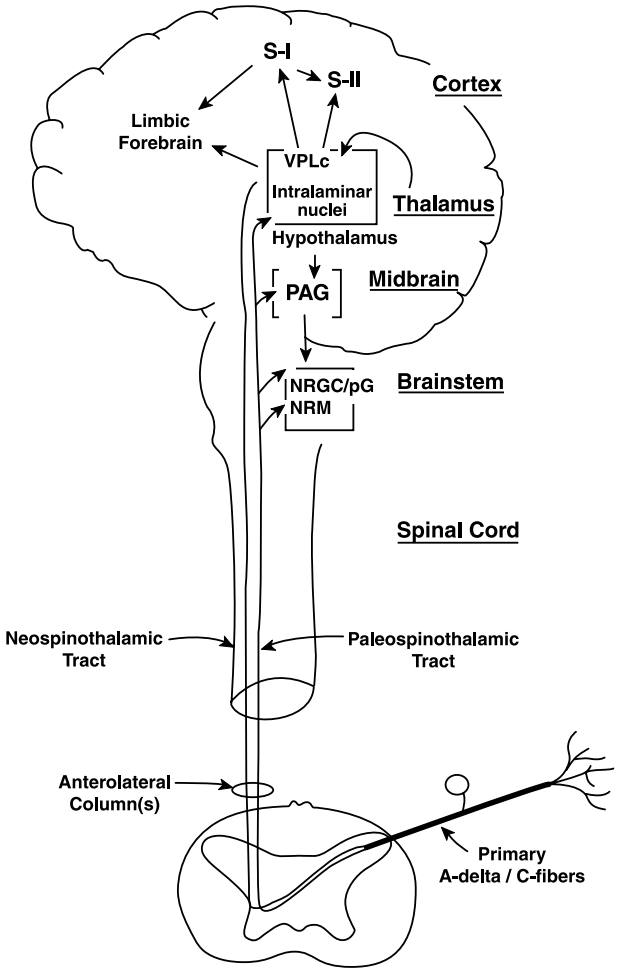

FIGURE 89.1 Cross-sectional schematic representation (not to scale) of spinothalamic tracts projecting to supraspinal loci involved in nociceptive processing.

BRAINSTEM NOCICEPTIVE NEURAXES

PSTT neurons differentially project to specific sites within the brainstem. Some stimulus specificity exists in PSTT activation of raphe and/or NRGC/NRpG neurons. Input from NS and/or WDR units excited by thermosponsive primary afferents appears to evoke greater excitation of raphe circuitry, while WDR and NS neurons driven by mechanosponsive input elicit somewhat greater activation of the NRGC/NRpG. Both circuits are apparently engaged by chemosponsive or polymodal C-fiber afferent activation of WDR or NS neurons. It has been suggested that such stimulus specificity is maintained at the midbrain level, and may be involved in the differential activation of PAG-raphe or PAG-NRGC centrifugal analgesic systems. The former system involves a release of opioids from the PAG that disinhibits serotonergic cells of the raphe nuclei, thereby causing an increased turnover and release of serotonin in pathways that descend in the dorsal lateral funiculi. These serotonergic fibers synapse heterogeneously in laminae I, II, and V, where serotonin may bind to serotonin 5-HT_{1b} receptors on processes of second-order nociceptive neurons. As well, serotonin may bind to 5-HT_{1b} receptors on an interneuron pool in several laminae of the dorsal horn to disinhibit the release of the inhibitory transmitter gamma-amino-butyric acid (GABA) and enkephalin to produce graded inhibition of second-order pain-transmitting afferents. PAG-NRGC connections involve a release of opioids from the periacqueductal grey that disinhibit noradrenergic neurons of the reticular formation (whose axons similarly descend in the dorsal lateral funiculi) to evoke a release of norepinephrine in laminae II and V. Norepinephrine binds to α_2 receptors on primary (and perhaps second-order afferents) to produce a graded hyperpolarizing inhibitory current, thereby toning down these neurons and producing an analgesic response. Whether these distinctions actually subserve modality specificity or reflect differential activation based upon stimulus intensity remains speculative. Although stimulus or intensity differences in the involvement of particular reticular nuclei exist, it is unlikely that any further discriminative processing of the nociceptive signal occurs at the reticular level. PSTT excitation of reticular neurons also activates neural systems involved in pain-related aversive and arousal responses.

MIDBRAIN NOCICEPTIVE MECHANISMS

Anatomical evidence demonstrates that PSTT fibers project to the midbrain PAG both directly and through interneuronal pathways from the reticular formation. Studies suggest that the PAG is somatotopically and perhaps stimulus-specifically organized. Somatotopic organization corresponds to the ascending hierarchy of PSTT afferents from progressively rostral somatotomes: the posterior PAG receives input from PSTT fibers of the caudal spinal cord while the anterior PAG receives PSTT projections from more rostral regions.

Stimulus-specific organization of the PAG seems to be a function of the population characteristics of PSTT WDR or NS neurons that are selectively excited by mechanical, thermal, or polymodal primary afferents. While it is difficult to determine whether absolute stimulus-specific organization exists, it is likely that regions of the PAG respond to somatotopic innervation of the periphery and would thus be maximally excited by input from a particular modality or intensity.

Although the function of the PAG in centrifugal pain control is clear, the role of the PAG in afferent processing of the nociceptive signal remains more enigmatic. Pathways exist between the PAG and hypothalamus and several structures of the forebrain. Stimulation of the PAG or fibers within this pathway elicit an array of arousal and behavioral activation responses that have distinct aversive or frightening emotional content. It is not completely understood whether the PAG mediates these responses

alone, or acts in concert with reticular structures, higher brain structures of the limbic system, or both.

THE THALAMUS

The NSTT and PSTT project to different nuclei within the thalamus. NSTT neurons project to a caudal area of the ventroposterior lateral nucleus (VPLc). Nociceptive inputs from the NSTT are arranged in columnar zones that are somatotopically organized. Thalamic neurons within these zones retain many response characteristics of WDR and NS units. Thalamic wide-range neurons have center-surround receptive fields with distinct, small areas sensitive to low-threshold excitation and a broad area that is excited by high-threshold nociceptive input. Thalamic NS neurons, like their spinothalamic counterparts, have smaller receptive fields that are excited by high-intensity mechanical or thermal input.

WDR and NS neurons of the VPLc summate responses as a function of stimulus frequency and intensity. Slow temporal and spatial summation is accompanied by a prolonged firing phase that exceeds the actual noxious stimulus and primary and secondary afferent discharges. This transformation parallels the time-course for the human experience of pain. It is probable that the temporal aspects of pain perception reflect serial processing of afferent information from the peripheral to the thalamic levels, with progressive extension of after-discharges along the pathway. It is tempting to speculate that such effects may "match" sensory, arousal, and environmental cues in establishing conditioned responses to circumstances surrounding painful stimuli.

The PSTT projects to several intralaminar thalamic nuclei, including the nucleus centralis lateralis and medialis dorsalis. Most of the neurons within these thalamic areas are of the wide-range type, sensitive to both nociceptive and non-nociceptive activation and with extensive overlapping input from cutaneous and visceral innervation. These units do not have the adaptive properties of neurons of the VPLc; intralaminar neurons summate responses, but response patterns do not reflect direct spatial or temporal transformation of increments in stimulus frequency or intensity. Unlike neurons of the VPLc, intralaminar neurons appear to be arranged in a "loser" somatotopic pattern and project diffusely to several regions of the cortex. The response patterns of individual intralaminar neurons, together with their anatomic distribution and cortical projections, suggest that thalamic connections of the PSTT act more as a relay to engage cortical systems involved in behavioral activation associated with nociception.

CORTICAL PROJECTIONS

Neurons from the NSTT project to the VPLc of the thalamus; thalamo-cortical fibers from this region terminate in S-I (and to a lesser extent S-II areas) of the somatosensory cortex. Thalamo-cortical fibers from the intralaminar nuclei, driven by the PSTT, project more diffusely, with only a small number terminating in S-I or S-II. The somatotopic organization of the thalamus is preserved in cortical projections, and nociceptive input contributes to distinct regions of somatosensory dominance within the cortex (i.e., the so-called sensory "homunculus", the spatial representation of bodily structures across the cortical sensory field). Somatosensory cortical regions are arranged in vertical dominance columns in which hierarchical processing of afferent input occurs. Only a small percentage of nociceptive input constitutes each given cortical column. Nociceptive thalamo-cortical input is distributed differentially within each column. Superficial cortical layers receive thalamic input from non-nociceptive pathways, while WDR- and NS-activated inputs are concentrated throughout the deeper cortical layers. Thus, for any given bodily region represented in a cortical column there is an array of non-noxious information (relayed through medial lemniscal tracts) and nociceptive information (relayed through the STTs) that creates the "depiction" of sensations that determines the subjective sensory experience. The integrity of the pain signal, and the unique qualities of its duration and intensity are a function of the additive transformation of afferent volleys from primary nociceptors through multiple processing ultimately terminating in cortical neurons. The slow adaptation, long after-discharges, and spatial summation of cortical S-I and S-II neurons represent the final and most direct contribution to the temporal and intensity dimensions of pain perception. Therefore, the experience of pain is not only individually variant, but may vary according to myriad combinations of exteroceptive circumstances for each individual.

The multiple intra-cortical projections from S-I/S-II to other parietal, frontal, and temporal regions most probably engage these brain areas in discriminatory, cognitive, and affective dimensions of pain.

PAIN MODULATING SYSTEMS

Cortical Inhibitory Processing

Neurons of the sensory cortex are capable of inhibitory control over the thalamo-cortical units of STT origin that project to them (although cortico-thalamic inhibition can also occur over neurons of the medial lemniscal tract that are non-nocisponsive). The extent of inhibition appears to vary with the frequency and intensity of thalamo-cortical input. For nociceptive input that is both rapidly temporally and spatially summating, a greater level of inhibition exists. Cortical inhibition involves "normalization" or "stabilization" of afferent volleys. This compensates for differences in response characteristics between thalamic

and cortical neurons and ultimately enhances the input-response function of thalamically driven nociceptive cortical inputs. In this way, a more direct transformation of the incoming signal is generated without over-summation. Cortical neurons also can excite thalamo-cortical fibers and STT units directly. This inhibition and excitation serve a modulatory role over afferent information that affects cortical circuitry. Cortical neurons can discriminately amplify or reduce the extent of nociceptive input. Such modifications strengthen the signal-to-noise ratio of particular afferent volleys and facilitate discrimination of sensory input. As well, this alternate excitation/inhibition may subserve changes in the nociceptive sensorium as a consequence of levels of cortical activity (e.g., sleep, hypnosis, biofeedback, etc.).

MIDBRAIN PAIN MODULATION

There is considerable evidence to show that the midbrain PAG is a principal site for endogenous pain control. Efferent projections from mesolimbic structures and the hypothalamus are capable of exciting PAG opioid neurons, as do inputs from the PSTT. The PAG exerts pain modulation by centrifugal inhibition of the PSTT and NSTT via disinhibition of bulbospinal projections from the raphe nuclei and NRGC/NRpG. Defined pathways from the PAG to the raphe nuclei and NRGC/NRpG are activated by high-threshold, high-frequency afferent volleys from the PSTT. Mechanical, thermal, or polymodal nocisponsive units of the PSTT appear to differentially stimulate discrete areas of the PAG to activate the raphe nuclei, NRGC/NRpG, or both. It is not fully understood whether selective PAG engagement of raphe-spinal or NRGC/NRpG-spinal neuraxes is dependent upon the modality, frequency, or intensity of the evoking afferent input.

The connections between the PAG and brainstem are polysynaptic, involving one or more pools of interneuronal relays. These multiple circuits function in levels of modulation that have the capacity for both serial and concomitant activation. This type of "volume control" is a function of the nature of the afferent nociceptive stimulus, the extent of PAG activation by PSTT (and perhaps hypothalamic and mesolimbic) neurons, and the excitation or inhibition of specific neural circuits to the brainstem. Thus, the PAG can discriminately recruit bulbospinal substrates whose net output determines the extent and properties of centrifugal pain modulation.

BULBOSPINAL PAIN MODULATION

Projections from the PAG synapse upon interneurons with terminations in the ventromedial pons and rostro-ventral medulla of the brainstem. These are the subcerulear nuclear group of the pons, consisting of the nucleus reticularis gigantocellularis (NRGC), nucleus reticularis paragigantocellularis (NRpG), and the nucleus paragigantocellularis lateralis (NpGL). These sites are often referred to as the reticular magnocellular nuclei (RMC). In the rostro-ventral medulla. PAG-originating interneurons synapse on neurons of the raphe nuclei, including the nuclei raphe alatus and raphe lateralis. These sites are combined when referring to the nucleus raphe magnus (NRM). The NRM and RMC directly receive efferent input from the PAG and afferent input from the PSTT. Both neuraxes are capable, either alone or in concert, of exciting NRM or RMC neurons to elicit centrifugal pain modulation. Inhibitory connections between these groups of brainstem nuclei exist as well. This inter-brainstem inhibition appears to determine the relative participation of NRM, RMC, or both groups in bulbospinal analgesia; moderate levels of activity within the RMC inhibit the NRM. In contrast, higher levels of RMC activity excite certain NRM neurons. Projections from the NRM and RMC descend in the dorsolateral funiculi (DLF) of the spinal cord and terminate in dense synaptic fields within laminae I, II, and V of the dorsal horn. Synaptic connections within these layers involve polysynaptic circuits of multiple spinal interneurons, as well as monosynaptic contacts with wide dynamic range, nociceptive-specific and primary afferent neurons.

Spinal interneurons receiving efferent projections from the brainstem synapse on WDR and NS second-order neurons as well as the terminals of primary afferent fibers. These interneurons are neurochemically heterogeneous, many release the inhibitory transmitter glycine, while others release the opioids enkephalin and/or dynorphin. These interneuronal contacts provide selective, multi-focal inhibition of specific groups of nociceptive afferents.

Synaptic connections between bulbospinal and WDR, NS, and perhaps primary afferent neurons exist in laminae I, II, and V. A single fiber from the brainstem may synapse on several second-order afferents within a given lamina. The differential projection of NRM or RMC terminals onto discrete populations of mechanosponsive, thermosponsive, or polymodally driven WDR and NS neurons in laminae I, II, and V further suggests that some stimulus- or modality-specificity may exist in the analgesic axis that originates from these brainstem nuclei. Figure 89.2 provides a schematic representation of this possible organization.

INTRASPINAL PAIN MODULATION

In addition to descending analgesic systems from the brainstem, pain modulation can occur through the activation of local circuits within the spinal dorsal horn. Interneurons that receive collateral projections from primary A-delta and C-fibers are found in laminae I, II,

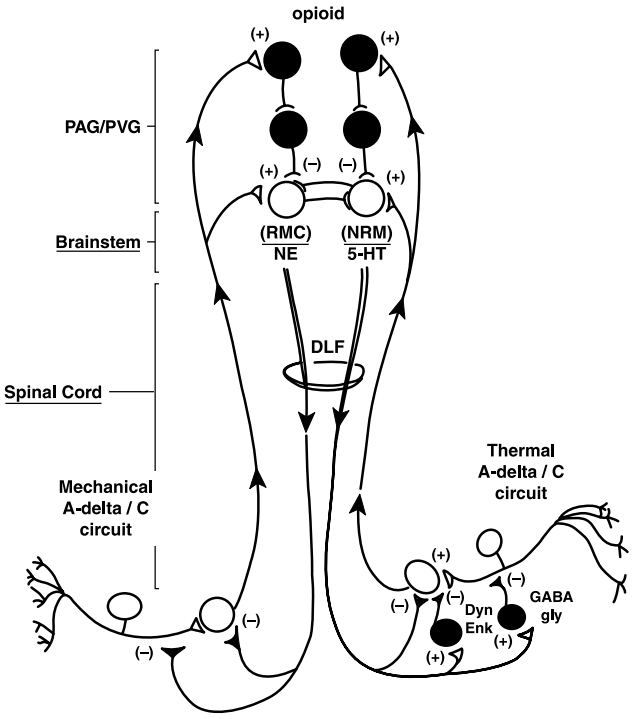

FIGURE 89.2 Schematic depiction of putative analgesic neuraxes modulating thermal and mechanical noxious input. Thermosponsive A-delta and C-fiber afferents may engage a descending serotonergic circuit (either directly or via activation of opioid neurons in the PAG/PVG that inhibit interneurons to disinhibit raphe-spinal mechanisms). 5-HT released from raphe-spinal neurons may (a) directly inhibit pain-transmitting afferents; (b) act at (excitatory) 5-HT_3 receptors on spinal opioid, GABA, and glycine interneurons to evoke release of the transmitters and modulate activity of primary or secondary nociceptive afferents. Mechanosponsive A-delta and C-fibers appear to engage a descending noradrenergic neuraxis (from the magnocellular reticular formation) either directly or indirectly via PAG/PVG activation. Norepinephrine released from reticulo-spinal neurons acts at α_2 receptors to modulate activity of primary and second-order nociceptive afferents. DLF = dorso-lateral funiculus; Dyn = dynorphin; Enk = leu/met-enkephalin; GABA = γ-amino butyric acid; gly = glycine; (+) = excitatory synapse(s); (–) = inhibitory synapse(s).

and V. These interneurons form reciprocal synapses upon primary afferent(s) and, in certain cases, second-order WDR and NS neurons. The majority of such interneuronal connections are found within a given horizontal section of the spinal cord, although some interneurons have terminal fields that are trans-segmental. Pharmacologic and electrophysiologic evidence has demonstrated that these interneurons are inhibitory. Many produce and release the inhibitory transmitter glycine, as well as the opioid peptide dynorphin. The pharmacology of this latter compound has been extensively studied. Dynorphin binds post-synaptically with κ-opioid receptors. There is some heterogeneity in κ-receptor populations; however, most found in the spinal cord are negatively coupled to N-type calcium ionic channels. Dynorphin binding at these sites on primary or second-order afferents closes the calcium channel thereby producing a hyperpolarizing inhibitory current, essentially "tuning down" or "shutting off" the transmission of nociceptive information along this neuraxis. This local circuit inhibition modulates firing of primary A-delta and C-fibers afferents; a particular pattern of primary afferent firing may excite populations of local interneurons to exert recurrent inhibition. Similarly, primary afferent activity may evoke local spinal inhibition of certain populations of WDR and NS neurons.

Low-threshold mechanosponsive dorsal column afferents, driven by a $A\beta$ mechanoreceptors, also exert modulatory influence over WDR and NS neurons that comprise the STT. Interneurons in laminae IIa, III, and IV with synaptic fields linking the dorsal columns and STT evoke brief inhibitory post-synaptic potentials (IPSPs) in STT cells following dorsal column excitation by low-intensity mechanical stimuli. These IPSPs persist after termination of the low intensity stimulus, and cause a brief, rightward shift in both the time- and threshold-based stimulus response function of the affected WDR and NS cells within the STT. In other words, low-level mechanical stimulation of the dorsal column tract is capable of overriding or de-sensitizing WDR and NS activity within the STT. This phenomenon subserves the clinical efficacy of low-frequency transcutaneous electrical nerve stimulation (TENS), and helps to explain the somewhat beneficial effect of rubbing a painful area.

SUMMARY

The anatomical and physiologic systems that subserve pain and analgesia are complex. Heterogeneous populations of neurons from the periphery, through the spinal cord, brainstem, thalamus, and ultimately the cortex with discrete neurochemical and physiological properties, all contribute to the amalgam of sensations that compromise the constellation of features known as pain. By understanding the structure and function of this system, we may develop enhanced therapeutic approaches to acute and chronic pain that target these substrates more effectively and selectively, thereby reducing deleterious side effects while facilitating an enhanced quality of life.

ACKNOWLEDGMENTS

The author wishes to acknowledge the untiring assistance of Connie Parker in the preparation of this manuscript.

TABLE 89.1
Physiologic and Pharmacologic Properties of Primary Afferent Nociceptors

Type	Stimulus	Anatomy	Diameter	Conduction/Properties	Chemistry
A-delta	High threshold	Free endings	1–5 µm	10–30 m/sec	Glutamate
	Mechanical	Myelinated		Fast; first pain;	Subs-P
	Thermal	Punctate fields		well localized	CGRP (?)
	(>45°C)				VIP
	(<20°C)				Post-synaptic activation of AMPA receptors
	Mixed-sensitized				Short-term NK-1 receptor activation
C-fiber	High threshold	Free endings	0.5–1.5 µm	0.5–2 m/sec	Glutamate
	Polymodal	Unmyelinated		Slow; second pain; chronic;	Subs-P
	Thermal			poorly localized	CGRP
	Mechanical	Diffuse receptive			CGRP (?)
	Chemical	fields			CCK (?)
	Sensitized				Post-synaptic activation of NMDA receptors
					Potentiated NK-1 receptor activation
					May induce neural plasticity (?)

TABLE 89.2
Physiologic and Pharmacologic Properties of Selected Pain Modulating Systems

System	Anatomy	Chemistry	Physiology/Properties
Intraspinal	Interneurons, laminae II, V	Opioid	
Segmental	Synaptic contact with recurrent processes of A-delta fibers	Dynorphin	Acts upon κ-receptors
		Leu/met-enkephalin	Acts upon δ (and perhaps µ) receptors
		GABA	Acts upon $GABA_B$ receptors: potentiates chloride flux hyperpolarization
		Glycine	Stabilization of membrane fatty acid metabolism
			Glycine binding site modulation
Bulbospinal	Descending fibers from NRM of medulla	5-HT	Acts upon post-synaptic $5\text{-}HT_{1D}$ receptors on (pre-synaptic) primary afferents and (post-synaptic) second-order neurons
NRM	Fibers descend via DLF		
	Mono- and polysynaptic contacts with primary and second-order units of dorsal horn		Hyperploarizing; inhibitory
	Synapse upon interneurons		Acts upon post-synaptic $5\text{-}HT_3$ receptors on GABA, glycine, and opioid spinal interneurons; excitatory; evokes release of inhibitory modulators
RMC	Descending fibers from NRGC/NRpG of pons	NE	Acts upon post-synaptic α_2-receptors on (pre-synpatic) primary afferents and second-order afferents
	Fibers descend via DLF		
	Mono- and polysynaptic contacts with primary and second-order afferents of dorsal horn		Graded hyperpolarization, inhibitory
Midbrain	Multilevel connections: inputs from	Opioid	
PAG	hypothalamus, limbic system, cortex	Leu/met-enkephalin	Acts upon µ and δ sites
PVG	Activated by STT	endorphin	Acts upon µ-receptor subtypes (perhaps μ_3 receptors)
	Polysynaptic contact with brainstem to disinhibit centrifugal modulatory systems		Some direct opioid release into CSF
			Graded slow hyperpolarization; inhibitory

APPENDIX A

Code of Ethics

PREAMBLE

The American Academy of Pain Management recognizes the many facets and problems that pain patients experience. For this reason, the American Academy of Pain Management endorses and reaffirms the benefit of the interdisciplinary and multidisciplinary commitment which professionals from a variety of disciplines can make to the field of pain management.

The conduct of the individuals credentialed by the American Academy of Pain Management shall be consistent with all applicable local, state, and federal regulations and with codes of conduct as established by the credentialed individual's primary discipline. Individuals who are credentialed by the American Academy of Pain Management are committed to increasing their knowledge of the mechanisms of pain, and its respondent behavior. Every effort will be made to safeguard the health and welfare of patients who seek the services of individuals credentialed by the American Academy of Pain Management.

PROFESSIONAL CONDUCT BY SPECIALTY

The credentialed individuals are obligated to maintain their skill competency such that it conforms to the standards of conduct to the individual's community, practice, and discipline. The treatment of pain, and the implementation of a patient's plan is a multidisciplinary/interdisciplinary effort. Credentialed individuals will conduct their professional behavior so that it facilitates the services of all team members for maximum benefit to the patient.

RESPONSIBILITY

The credentialed individuals shall be responsible for determining that standards are applied evenly and fairly to all individuals who receive services. Individuals who are employed by an institution, agency, or clinic have responsibility to be alert for institutional pressure which may be counter to the best interest of the patient, and shall make every effort to improve those conditions.

Credentialed individuals provide thorough documentation and timely feedback to members of the team, employers, carriers, and other interested parties in order to assure coordinated, managed care. All reports will be objective and based upon an independent professional opinion, within the credentialed individual's expertise. Credentialed individuals will provide only those services for which the individual is competent and qualified to perform. Credentialed individuals will refrain from providing services which are counter to the ethical standards of their discipline, or which would be a violation of standards established by applicable regulatory boards governing service to pain patients.

CONFIDENTIALITY

Credentialed providers are obligated to safeguard information obtained in the course of their involvement with a patient. Information may be released with a patient's permission; in circumstances where there is a clear and imminent danger to the patient, or others; and, where required by court or subpoena. Individuals who seek the services of a credentialed provider shall also be advised, that in some jurisdictions, insurance companies and regulatory boards may also have access to collected information, test results, and opinions. Patients have the privilege to the extent that is feasible and practical, and in those cases where there would be no legal or clinical contraindications, to see their chart when this can be arranged at a mutually convenient time.

EDUCATION, TRAINING, AND COMPETENCE

Credentialed providers shall maintain high standards of professional competence. They shall recognize the limits of their skills and license. They shall offer services consistent with the standards of their profession.

Credentialed individuals have an obligation to accurately represent and disclose their training, education, and experience to the public. Credentialed providers shall engage in continuing education. This will minimally include 100 hours of relevant education in pain management every 4 years. Credentialed providers recognize that the field of pain management is rapidly developing and shall be open to evaluate and consider new procedures and approaches to pain management. Credentialed providers should refrain from any activity which may result in harm to a patient without first considering alternatives to such an approach, seeking services which may achieve the same benefit without the associated risk, obtain consultations from other providers, and inform the patient of any risks inherent to any procedure or approach.

BUSINESS PROCEDURES

Credentialed providers will abide by all prevailing community standards. They will adhere to all federal, state, and local laws regulating business practice. Competitive advertising must be honest, factual, and accurate. Such advertising shall avoid exaggerated claims. Credentialed providers will not enter into any arrangement where fees are exchanged that would be likely to create conflict of interest or influence their opinion about services rendered.

Credentialed providers shall engage in behavior which conforms to high standards of moral, ethical, and legal behavior. Credentialed providers will not engaged in sexual contact with patients.

RESEARCH

Credentialed providers may engage in research about the management of pain. In doing so, they shall have the safety of their subjects as a priority. Investigation shall be consistent with the traditions and practices of the credentialed individual's discipline. Credit is given to all individuals who participate in a study.

APPENDIX B

Patient's Bill of Rights

The American Academy of Pain Management endorses a Patient's Bill of Rights. It is an expectation that compliance with patient's rights can contribute to an effective patient care program. A modification of the American Hospital Association's statement on a Patient's Bill of Rights has been incorporated as part of the framework of the American Academy of Pain Management's Bill of Rights. The modifications consist of the following:

1. The patient has the right to considerate and respectful care.
2. The patient has the right to obtain from his or her credentialed provider, complete current information concerning their diagnosis, treatment, and prognosis in terms the patient can reasonably be expected to understand. When it is not advisable to give such information to the patient, the information should be made available to an appropriate person on his/her behalf.
3. The patient has the right to receive from his/her credentialed provider, information to make informed consent prior to the start of any procedure and/or treatment. This shall include such information as the medically significant risks involved with any procedure and probable duration of incapacitation. Where medically appropriate, alternatives for care or treatment should be explained to the patient.
4. The patient has the right to refuse any and all treatment, to the extent permitted by law, and to be informed of any of the medical consequence of his/her action.
5. The patient has a right to every consideration of privacy concerning his/her own medical care program, limited only by state statues, rules, regulations, or imminent danger to the individual or others.
6. The patient has the right to be advised if the clinician, hospital, clinic, etc. proposes to engage in or perform human experimentation affecting his/her care or treatment. The patient has the right to refuse to participate in such research projects.
7. The patients has the privilege to examine and receive an explanation of the bill.

All activities of pain management are to be conducted with an overriding concern for the patient and above all, the recognition of their dignity as a human being.

APPENDIX C

American Academy of Pain Management Credentialing

The American Academy of Pain Management is a nonprofit organization whose members are committed to increasing their knowledge of mechanisms of pain and its respondent behavior. The Academy is the largest organized association of multidisciplinary pain practitioners in any country. The Academy serves as the official Board for Credentialed Practitioners.

Problems associated with pain and attempts to control pain have historically been the principal reasons individuals seek healthcare. In recent years, the medical community has made great strides in its ability to treat pain patients.

Along with this progress has come a considerable change in pain management. Multidisciplinary pain facilities have demonstrated a new service delivery approach to pain management. Added to this phenomenal growth are a number and variety of inpatient and outpatient pain clinics.

With increasing frequency, the topic of pain management is on the agenda of discussion at clinical conferences. Insurance carriers and employment/governmental bodies have begun to focus great attention of this topic. Credentialed practitioners listed in the Academy's Registry have found increased referrals and have provided expert testimony about pain.

The Academy offers a credentialing process for individuals who treat pain patients. The Academy was founded and organized by individuals with years of relevant experience in treating acute, recurrent acute, cancer, and chronic pain sufferers. All respective disciplines are interested in furthering the knowledge and management of pain.

Pain management is not best delivered by any one profession or specialty, and for this reason the Academy represents a comprehensive, interdisciplinary membership. Credentialing is offered to professionals from a wide variety of disciplines who meet high standards for the practice of pain management. The Academy has developed a Model Code of Ethical Practice and continues to develop the standard of care in pain management. To the extent that standards are rigorously adhered to, it will be the intent of the Academy to include various disciplines.

When applying for credentialing, applicants must submit three professional letters of reference, copies of their license, official academic transcripts, application form, and curriculum vitae. The Credential Review Committee evaluates this material. The Academy has a written evaluation for new applicants.

Individuals who are credentialed receive a registered certificate, listing in the National Registry of Multidisciplinary Pain Practitioners, notice of conferences with reduced fees, and periodic educational publication.

The Academy presently publishes quarterly, The Pain Practitioner, containing hands-on information regarding pain management. The association also publishes a peer review journal, American Journal of Pain Management. Members will have an opportunity to serve on committees that will help shape the discipline. The American Academy of Pain Management is the only multidisciplinary pain management credentialing body.

COMMONLY ASKED QUESTIONS

Q: What is the American Academy of Pain Management?

A: The Academy is a nonprofit organization established to provide credentialing for individuals who treat patients suffering from chronic pain.

Q: Who is the Academy's Board of Advisors?
A: The board of the Academy is national in scope and blends both academicians and practitioners for the purpose of establishing rigorous standards for the treatment of pain patients.

Q: How does one become a member of the American Academy of Pain Management?
A: Healthcare providers may apply for membership. Credentialing is dependent upon the level of education and work experience in fields related to pain management.

Q: What are the benefits of membership with the Academy?
A: There are many, including a certificate registered by the Academy noting your status; listing in, and copy of the National Registry of Multidisciplinary Pain Practitioners; notices of conferences with reduced fees; periodic publications; and continuing education opportunities.

Q: What education and training are available?
A: An annual clinical meeting provides pain practitioners with the latest state-of-the-art treatment methods.

Q: How does one apply for membership to the American Academy of Pain Management?
A: An application packet, which includes the Statement of the Purpose of the Academy, the Code of Ethics, The Patient's Bill of Rights, a listing of the Board of Directors, and the biographical application dossier are available by contacting:

American Academy of Pain Management
13947 Mono Way #A
Sonora, CA 95370
(209) 533-9744

APPENDIX D

Overview of Academy Services and Products

It is the goal of the Academy to bring together the many clinicians who work with individuals in pain and to assist in the creation of quality services for those individuals. The intent of the Academy is to be inclusionary, and not restrictive to any specialty. The Academy has developed many services and products which can help clinicians reduce pain and improve quality of life for their patients. Please take your time and learn more about the American Academy of Pain Management. Visit our website at www.aapainmanage.org, ask questions, make suggestions and invite your friends and colleagues to visit as well.

Membership

Membership is available to clinicians, individuals, and students for a $150 annual fee. As a benefit of membership you are listed in the *Directory of Pain Practitioners* on the Academy web site and you may link your web page to this Directory. You will also receive a membership card, the quarterly journal and newsletter, as well as discounts on Academy services and products.

Credentialing

The purpose of credentialing is to establish a professional Code of Ethics and Patient's Bill of Rights; to promote professional accountability and visibility; to identify those pain practitioners who have met specific professional standards; to advance cooperation among the various specialties that treat individuals suffering pain; and to encourage continued professional growth and development of pain practitioners and the field of pain management. The Academy offers three levels of credentialing to clinicians: Diplomate, Fellow, and Clinical Associate.

Publications

The Academy publishes a peer-reviewed, quarterly journal, *The American Journal of Pain Management*, which provides valuable clinical research information in a multidisciplinary format. The Academy also publishes a quarterly newsletter, *The Pain Practitioner*, which features useful clinical topics, monitors trends, and reports important Academy news.

The Academy also has a best-selling multidisciplinary textbook titled *Pain Management: A Practical Guide for Clinicians*. This textbook is a very comprehensive overview of multidisciplinary pain management.

Internet

The award winning Academy web site provides diverse and meaningful information. Browse through informational pages, search Citeline for medical topics, join the on-line pain management community in the Open Forum, read the latest newsletters, access current research on outcome measurement in pain management, read the Patient's Bill of Rights and much, much more.

Annual Clinical Meeting

In September of each year, the Academy holds a clinical meeting which has over 100 nationally known faculty and offers CME/CEU credit in many disciplines. This meeting is designed for clinicians who are interested in providing state-of-the-art multidisciplinary pain management, and who are looking for information, answers, and solutions to the issues and dilemmas confronting clinicians in pain management.

Continuing Education

The Academy is approved by ACCME to provide category 1 MD credit. The Academy is also approved to provide continuing education by The American Psychological Association (APA), The American Dental Association (ADA), The American Association of Oriental Medicine (AAOM), The National Board for Certified Counselors (NBCC), American Association of Nurse Anesthetists (AANA), and the American Podiatric Medical Association (CPME). The Academy also provides continuing education to nurses and pharmacists in cooperation with the University of the Pacific School of Pharmacy and Health Services and to chiropractors in association with Cleveland Chiropractic College.

Pain Program Accreditation

Pain Program Accreditation is a voluntary process that gives pain management programs an opportunity to demonstrate compliance with peer-reviewed quality treatment standards established by pain practitioners. The Academy has a long history of accrediting pain programs based on published standards and onsite review. A broad cross-section of pain programs is eligible for accreditation.

National Pain Data Bank

The purpose of the National Pain Data Bank is to collect information about patient demographics, history, pain profile, functional status, quality of life and daily living, return to work, treatment satisfaction, and cost of care. A quarterly report of the data is sent to all participating programs. Participating programs have found this data useful in determining treatment outcomes, in creating more cost-effective treatment protocols, in creating marketing strategies, and in working with third-party payers.

The National Pain Data Bank has been featured twice at the American Medical Association (AMA) Practice Parameter Forum as a demonstration of how to conduct and analyze outcome measurement in pain management.

Second Opinion Utilization Review

The purpose of Second Opinion Utilization Review is to create unbiased reports for clinicians that would be available for use in record review, institutional privileges, arbitration, medicolegal matters, reimbursement disputes, malpractice, and licensing disputes. Experts are available for depositions and trials. Contact the Academy at (209) 533-9744 if you are interested in learning more about this program.

University of Integrated Studies

The University of Integrated Studies offers Master of Arts and Doctor of Philosophy degrees in Integrated Studies, with disciplines in Pain Studies, Anti-Aging, and Mind/Body/Spirit, through a distance learning format. Visit the University web site at www.univintegratedstudies.edu to learn more about this exciting offering. The Academy was given initial temporary approval to operate a degree-granting university on July 2, 2000 by the State of California.

WORKING TOGETHER

As a leader in pain management with a vast infrastructure we can assist you with creative pain management solutions, conflict resolution, continuing education, life-long graduate university learning, accreditation, and measuring outcomes in pain management. Join the Academy dynamic pain management team!

APPENDIX

E

Definition of Pain Management

PAIN MANAGEMENT

- The systematic study of clinical and basic science and its application for the reduction of pain and suffering.
- The blending of tools, techniques, and principles taken from discrete healing art disciplines and reformulated as a holistic application for the reduction of pain and suffering.
- A newly emerging discipline emphasizing an interdisciplinary approach with a goal of the reduction of pain and suffering.

Richard S. Weiner, Ph.D.
Executive Director
American Academy of Pain Management

Kathryn A. Weiner, Ph.D.
Associate Director
