Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary. Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Foreword to the First Edition

The aim of the editor and contributors to this volume is to establish an effective bridge between the surging progress in biomedical science and the clinical practice of pediatric endocrinology. Half a century ago the biochemical elucidation of the structure and subsequent synthesis of steroid hormones provided the basis for a revolution in the diagnosis and treatment of a number of endocrine and nonendocrine disorders; that era was soon followed by a succession of fundamental discoveries: structure of peptide hormones, identification of releasing hormones from the brain, rapid and precise assay methods, and synthesis of peptide hormones by molecular biological techniques, to name but a few.

In no field has laboratory science been more effectively translated into clinical progress than in pediatric endocrinology. A glance at the roster of contributors to this volume may well provide insight into why; many who are responsible for the dramatic advances in the laboratory also pursue active clinical careers.

This volume includes many new sections that were not presented in previous texts devoted to clinical pediatric endocrinology. It will serve as a valuable reference for family physicians, internists, pediatricians, and other health professionals, covering as it does the gamut of information from basic molecular biology to practical considerations in the diagnosis and treatment of pediatric endocrine disorders.

Solomon A. Kaplan, MD

Preface

The fourth edition of *Pediatric Endocrinology* aims to build on the models of excellence in basic and clinical research in endocrinology applied to newborns, infants, and children as they evolved in the first three editions. Now, close to 20 years since its inception, the current issue provides perspective on how much has been learned and applied for the benefit of those children referred to pediatric endocrinologists for evaluation and management. Each new edition has attempted to incorporate advances in the field that occurred in the preceding five years; the fourth edition is no exception. To achieve these aims, we involved those at the forefront of their field to share their expertise and to transmit new knowledge in the context of contemporary developments. This should be evident in the reorganization and increased number of contributors to this volume. In terms of organization, three sections are delineated. The first deals with principles and methods in pediatric endocrinology, beginning with an overview and historical evolution of the field, and its unique pediatric aspects. Three succeeding chapters review principles of molecular endocrinology and genetics, receptor signal transduction, and laboratory methods in pediatric endocrinology; together they form the nucleus of our discipline and provide a framework for the methods used to understand, investigate, and treat our patients. The second section contains five chapters dealing specifically with the most common endocrine-related disorders encountered in the newborn nursery and the NICU; ambiguous genitalia, hypoglycemia, disorders of the thyroid and abnormal thyroid function tests, disorders in calcium and phosphorous metabolism, and neonatal diabetes mellitus (NDM). Although rare, NDM has been disproportionately of value in understanding the role of the same defects, albeit to a milder degree, in the much larger problem of T2DM. The third section is organized on the traditional organ approach; here, several new authors have taken over a chapter or enlarged the list of contributors to an existing chapter, in each case bringing in new insights and perspectives in the process.

Dramatic changes have occurred in the past five years. Whole genome and exon sequencing is increasingly being applied as the cost of sequencing declines, yielding discovery of spectacular new findings. This might be best exemplified by the increasing complexity of the genes regulating puberty and reproduction, especially hypogonadotropic hypogonadism, and the recent description of a gene responsible for precocious puberty, *MKRN3*. In diabetes research, the discovery of betatrophin, a hormone that regulates β-cell mass and insulin secretion in response to insulin resistance; Irisin, which regulates fat metabolism and mediates improved glucose homeostasis in response to exercise; and the imminent application of closed-loop systems, as an "artificial pancreas", for treating children with T1DM requiring insulin treatment, portend exciting developments in the near future. Similar exciting discoveries are to be found in virtually every chapter. Altogether this edition covers a broad, but contemporary canvas of the field of pediatric endocrinology. We trust it is suitable to inform the serious student, and update the experienced practitioner or investigator in the field. We have introduced questions for each chapter and an online version supplemented by rich, in full color illustrations.

There undoubtedly will be errors and possibly omissions for which, as editor, I take responsibility and extend my apologies. I welcome any comments and advice on where and how to improve this book so as to make it a "must have" on the shelf of every NICU and every endocrinologist's office. I extend sincere and warm-hearted thanks to all contributors; each of your contributions is highly respected and highly valued.

As I look back on this and previous editions, I reflect on the enormous effort involved and yet consider it a labor of love and a great privilege.

Mark A. Sperling

Acknowledgments

An enterprise of this nature requires the contribution and support of numerous individuals. I gratefully acknowledge the contributions of each of the authors, whose friendship and collegiality were—and continue to be—indispensable to bring this work to publication. Constructive critique was provided by colleagues, post-doctoral trainees, residents, and visiting scholars to our departmental program in endocrinology. Ms. Anna Marie Rompala provided invaluable secretarial assistance. A special thanks to Ms. Jennifer Shreiner of Elsevier, whose experience, diligence, and patience enabled this project to move to timely conclusion. I am very grateful to Professor Michael Waters for permission to use his figure of the Growth Hormone Receptor as the cover image and to Elsevier for giving me the privilege of editing this book.

SECTION I

PRINCIPLES AND METHODS OF PEDIATRIC ENDOCRINOLOGY

CHAPTER 1

Overview and Principles of Pediatric Endocrinology

Mark A. Sperling, MD

CHAPTER OUTLINE

HISTORICAL BACKGROUND

Endocrinology is a discipline of science that seeks to understand how chemical signals secreted by cells regulate the function of distant (endocrine) or local (paracrine) tissues, or even their own function (autocrine), in order to integrate vital processes of life such as growth, reproduction, and metabolism (Figure 1-1). Classical endocrinology derived from careful clinical observation such as, for example, the gigantism associated with pituitary tumors or the characteristic bodily changes now known as Cushing disease which is also associated with pituitary tumors; histology indicated the former was likely the result of a product made by "acidophilic cells," whereas the latter was associated with the expansion of "basophilic cells." Unlike the chemical substances secreted into ducts leading to a target tissue ("exocrine"), the products of these acidophilic or basophilic cells had to traverse the bloodstream in order to reach their distant and often multiple targets. Hence, these were internal ("endocrine") secretions. Cushing disease was associated with hypertrophy of the adrenal cortex and certain tumors of these tissues mimicked the features of Cushing disease.[1] Hence, it was readily postulated that the pituitary secretes a substance that affects the adrenal glands and function; this substance was named adrenocorticotrophic hormone (ACTH) and it was deduced that the features of Cushing disease/syndrome were the result of a product or products from the adrenal gland. The destruction of adrenal tissue by tuberculosis or tumor was identified by Thomas Addison in 1855 and treatment of this entity with adrenal extracts, resulting in marked improvement, was first undertaken by William Osler in 1896.[2] However, the purification of these "internal secretions" began in earnest only at the turn of the 20th century with spectacular success as reviewed by Dr. Delbert Fisher.[2] In the first quarter of the 20th century, epinephrine, thyroxin, insulin, and parathyroid hormone (PTH) were purified, followed by the purification of the sex steroids from the ovary and testes as well as the pituitary and placental gonadotropins that stimulated the gonads to secrete these substances. These purifications required laborious chemical methods and the elucidation or measurement of their function required costly and cumbersome bioassays. For example, the assay of insulin potency, discovered in 1921, required the use of rabbits; the definition of 1 international unit (IU) of insulin was assigned to be the amount of insulin that lowers the blood glucose of a healthy 2-kg rabbit, fasted for 24 hours, to 45 mg/dL within 5 hours of injection. Clearly, such potency estimates reflected the relative crudeness of the purification; today's recombinant human insulin possesses approximately 29 IU/mg, whereas the potency of porcine insulin in the early 1980s was ~23 IU/mg and likely less at the dawn of insulin therapy for diabetes. Moreover, the lack of sensitivity in such assays prohibited the ability to measure this substance in normal blood or other biologic fluids; refinements such as measuring the incorporation of labeled glucose into the fat pad or diaphragm of a rat represented only an incremental improvement.[3] Growth hormone (GH), isolated in 1944, was assayed by its ability to increase the width of the tibia growth plate in rats after a defined period of injections and by comparing the unknown relative to a dose response of known concentrations administered in vivo.[4] Attempts to improve sensitivity and specificity led to the "sulfation

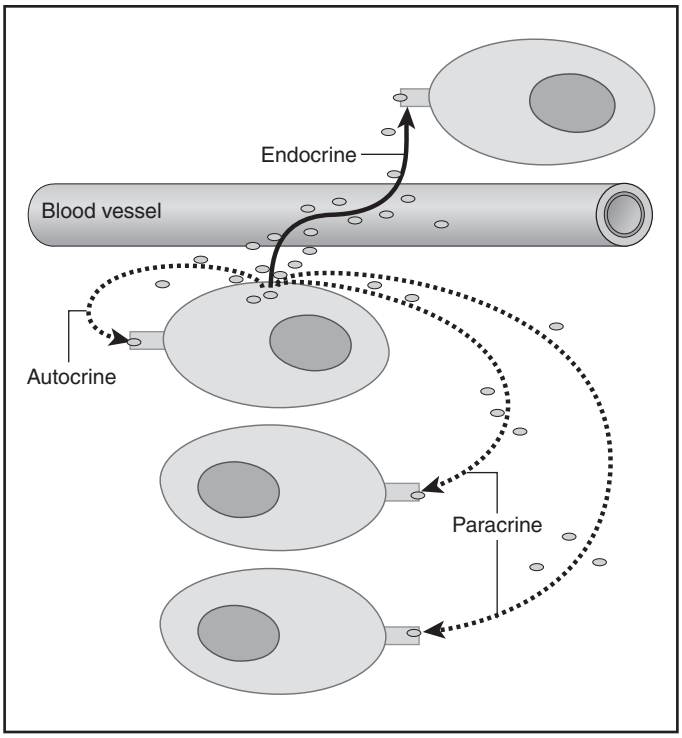

FIGURE 1-1 ■ Cellular signaling. Chemical signals synthesized and secreted by cells, may be released into the bloodstream to be distributed to target cells with specific capability to respond to the signal. These blood-borne chemicals constitute classical endocrine signals, also known as "internal secretions," to distinguish them from the chemicals secreted into a duct that leads directly to another organ (e.g., pancreatic enzymes destined for the duodenum via the pancreatic duct ["exocrine"]). However, the same cell may release the chemical that then affects nearby cells without traversing the bloodstream (these are known as paracrine effects) or act on a receptor on its own surface to modify the cells own functions (autocrine). (From King TC [2006]. *Elsevier's integrated pathology.* Philadelphia: Mosby, Figure 3-6.)

factor-somatomedin hypothesis" (Figure 1-2), in which it was postulated that GH leads to the generation of a second substance, derived from the liver, which mediates the growth-promoting (somatotropic) effects and hence was named "somatomedin."[4,5] Subsequent studies demonstrated that this substance was identical to a factor in serum, which had insulin-like properties in vitro, that was retained even after all insulin was "quenched" by an excess of antibodies specific for insulin. The convergence of these two pathways eventually led to the discovery of the factor now known as insulin-like growth factor (IGF)-I.[5] Despite these limitations, the scientific curiosity of these chemical substances that regulated functions as diverse as blood pressure (epinephrine, cortisol), water metabolism (arginine vasopressin [AVP], cortisol), growth (GH), glucose (insulin, cortisol), and reproduction (sex steroids, follicle-stimulating hormone [FSH], luteinizing hormone [LH]) spurred the formation of medical societies focused on endocrine diseases. As detailed in the article by Fisher from which the following historical aspects are quoted,[2] the Association for the Study of Internal Secretions was established in 1918 in the United States and renamed the Endocrine Society in 1952.

Pediatric endocrinology began as a subspecialty only in the 1940s with the establishment of endocrine clinics at the Massachusetts General Hospital and Johns Hopkins. These programs attracted postdoctoral trainees who then established their own pediatric endocrine units in the burgeoning growth of academic medical centers in the 1950s and 1960s. In the United States, the Pediatric Endocrine Society, first named the Lawson Wilkins Pediatric Endocrine Society (LWPES), was formed in 1972 and established as a subspecialty by the American Board of Pediatrics with its first certification examination in 1978; there are more than 1000 board-certified pediatric endocrinologists today in the United States. The European Society for Pediatric Endocrinology was formed in 1966, followed by the Japanese Society for Pediatric Endocrinology in 1967 and the British Pediatric Endocrine Group in 1972, all preceding the LWPES in the United States. Several other regional pediatric endocrine groups were formed, including the Australian Pediatric Endocrine Group, the Sociedad Latino Americana de Endocrinologia Pediatrica, and the Asia Pacific Pediatric Endocrine Society. All of these groups now meet jointly every 4 years at an International Pediatric Endocrine Congress.[2]

IMPACT OF HORMONAL ASSAYS AND MOLECULAR BIOLOGY

Two discoveries revolutionized the field of endocrinology and led to an explosion of basic, clinically relevant therapeutic knowledge in the second half of the 20th century. The first was the development of radioimmunoassay by Yalow and Berson, reported for insulin in 1960.[6] Here was a method for measuring the low concentrations of a hormone using as little as 10 to 50 μL of a biological fluid in an accurate, reproducible way with precision and sensitivity adequate for in vivo studies in humans or other species, as well as in vitro studies, such as the regulation of insulin secretion by nutrients, hormones, ions, and pharmaceutical agents in whole animals including humans, in vivo, or in isolated perfused pancreas, or in isolated islets. This was followed by the rapid development of assays for various hormones and an explosion of discovery, including the distinction between absolute and relative insulin deficiency as the difference between "juvenile" and "maturity onset" diabetes, the regulation of GH secretion in normal individuals at different ages and in clinical disorders of growth, the changes in thyroid function at birth and the possibility of screening for neonatal hypothyroidism, and the changes in gonadotropins and sex hormones during the process of normal and abnormal puberty. The discovery and purification of the hypothalamic releasing hormones for TSH, FSH/LH, GH, and ACTH were made possible by these precise assays using (rat) pituitary cells perfused by protein fractions derived from the hypothalami of animals.[7] The discovery that a hormone produced in a cell could affect the function of its neighboring cell(s), without traveling through the bloodstream (paracrine action) or even its own function (autocrine), was also enabled by the use of these sensitive and precise tools, expanding our concepts of a hormone

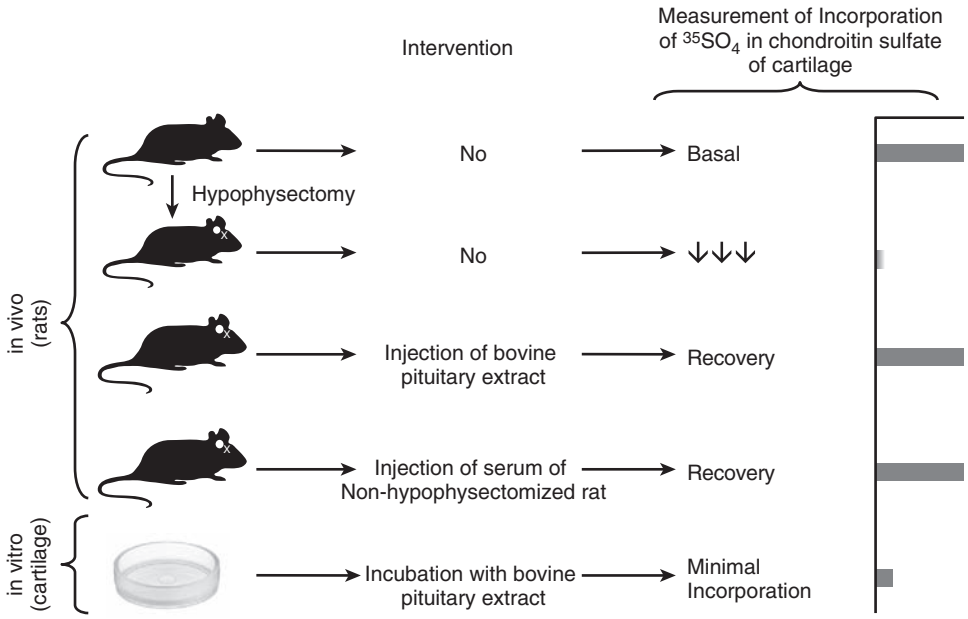

FIGURE 1-2 ■ "Sulfation factor" assay of growth hormone. The bioassay of growth hormone (GH) consisted of administering graded doses of bovine GH with potency approximately 1.25U/mg via daily subcutaneous (SC) injections for 4 days to young, growing, prepubertal rats (approximately 31 days) that had been hypophysectomized 10 days previously. Approximately 5 animals per group and about 5 doses (0 plus 4 graded increments) were used to construct the "dose-response curve" of the increase in the width of the tibia growth plate; the unknown was 2 to 3 mL of plasma also administered SC to approximately three to five animals per test dose. The sulfation assay was an attempt to refine the technique by examining the dose-response relationship between the incorporation of $^{35}SO_4$ into chondroitin sulfate in vivo, or in vitro into uniformly prepared cartilage rings obtained from young rats. As shown in the figure, the in vivo component examined basal activity of the animal's serum on the amount of radioactivity incorporated in vivo. Hypophysectomy almost completely abolished this ability to stimulate $^{35}SO_4$ incorporation, but injection of bovine pituitary extract or serum from a nonhypophysectomized animal restored this activity. However, in vitro incubation of cartilage rings with bovine pituitary extract resulted in only minimal incorporation. Thus, it was proposed that GH acted on an internal organ to produce the "sulfation factor." The sensitivity of these assays were, at best, in the 1 to 10 μg/mL range, and precision and reproducibility were poor (Tweed DC, McCullagh EP [1962]. Assay of growth hormone-like activity in blood plasma: a comparison of two methods. Clin Chem 8:141-150; also see references 4 and 5). Today's immunoassays permit measurement of plasma concentrations of GH with 1000-fold greater sensitivity than these early bioassays (ng/mL compared to μg/mL above) with high degrees of precision and reproducibility (Chapter 4). (The author is indebted to Oscar Escobar, MD, Associate Professor, Department of Pediatrics, University of Pittsburgh School of Medicine, Division of Pediatric Endocrinology, Children's Hospital of Pittsburgh, for creating this figure and granting permission for its use in this chapter.)

as a chemical messenger that influences, directs, and coordinates cellular functions throughout the body (see Figure 1-1). Similar principles enabled the identification of the receptor molecules at the cell surface or in its cytoplasm that permit the hormone signal to be transduced to a message for turning biological processes on, or off, in specific tissues.[8] Refinements using the principles of radioimmunoassay (RIA) but without radioactivity are the bases of modern laboratory methodologies for hormone measurement as well as for other chemical substances such as drugs; examples of modern application of these methods as well as the pitfalls are reviewed in Chapter 4. Signal transduction pathways and their relevance to pediatric endocrinology are discussed in Chapter 3. The notion that a hormone may not be capable of eliciting a response despite high concentrations was implicit in the entity labeled "pseudohypoparathyroidism" by Dr. Fuller Albright[9] but receptors and their signal transduction pathways were only systematically investigated beginning in the 1970s. These systematic studies, still ongoing,[8] continue to identify the pathways by which the hormone, after binding to its receptor, may elicit a response in one tissue but not in another. There may be other reasons why a hormone does not elicit an appropriate tissue response despite apparent high concentrations in the circulation. For example, an abnormal sequence in a hormone may prevent its full action at the receptor, and feedback control increases the hormone's secretion leading to high concentrations of partially functioning hormone with only minor or moderate impairment of function. Examples of such abnormalities include disorders of pro-insulin conversion to insulin.[10] Depending on the site of the abnormality in cleavage of pro-insulin, both the measurement of insulin and pro-insulin or its cleavage product C-peptide may demonstrate higher than normal values that could be interpreted as "insulin resistance." These studies also recognized that an activating mutation in a receptor will mimic the action(s) of a hormone, although the hormone concentration may be barely detectable, as exemplified by the precocious puberty in MCune-Albright syndrome (Chapter 3), whereas loss of function mutations result in the same clinical syndrome as hormone deficiency, even though the hormone

concentration is markedly increased compared to normal, as exemplified in Laron syndrome with poor growth and low IGF-I concentrations despite high circulating growth hormone concentrations (Chapter 10).Thus, the concentration of a hormone may not be directly related to its action. In summary, it is the ability to measure hormones at low concentrations (e.g., picomolar to nanomolar) in small volumes of biological fluids that enabled the rapid proliferation and understanding of endocrine regulation and function. It may be difficult for any reader who was not brought up in the era of bioassays to fully appreciate the impact of the application of the tool of RIA and its modifications to modern endocrine concepts and practice.

The second revolution built on the discovery of the double helix by Crick, Watson, and Wilkins, a discovery for which they received the Nobel Prize in 1962. This discovery and its offspring propelled the ability to identify the molecular basis of cell function, the genes that regulate these processes, and the genetic mutations that underlie congenital or acquired disorders, including those of the endocrine system. Pediatric medicine is a particular beneficiary of these techniques because congenital malformations of the endocrine glands, the abnormalities of hormone signaling as a result of defective hormone synthesis, and processing or receptor function to recognize and act on the hormonal signal are at the core of pediatric endocrinology, as reflected in this book. Chapter 2 provides an overview of the molecular and genetic methodologies applied in practice and research and also discusses the pitfalls in interpreting the results of genetic mutational analyses. This is a rapidly evolving field powered by the declining cost of gene sequencing and the ability to store and analyze huge data sets via computers. Whole genome sequencing of an individual is already being applied and likely will become part of established medical diagnostic practice in the near future. Therapeutic applications, such as, for example, choice of drug for maximum effectiveness while avoiding drug interactions or excluding drug sensitivity, are likely to follow.[11]

UNIQUE ASPECTS OF PEDIATRIC ENDOCRINOLOGY

Fetal Origins of Adult Disease

Pediatrics is all about growth and development of each aspect of human life—physical, emotional, cognitive, and sexual—from conception through birth, neonatal adaptation, infancy, childhood, puberty, and young adulthood. Changes in the mature organism continue, but the tempo is considerably slower than the rapid changes of early life. The endocrine system plays a central role in these adaptations and changes. It has long been known that environmental insults such as viral infections (rubella, herpes, human immunodeficiency virus [HIV], cytomegalovirus) or drugs (thalidomide, phenytoin), particularly in the first trimester, can result in distinct patterns of embryopathy. Only recently has it been appreciated that developmental plasticity is influenced by the intrauterine nutritional environment that may predispose to the later development of diseases such as type 2 diabetes. As a hypothesis, the "fetal origins of adult disease" is now well supported by epidemiologic and experimental data, including the epigenetic modification of gene expression via patterns of methylation or other modifications, some affecting the expression of genes regulating insulin secretion, cortisol, and other hormones.[12,13] These interactions are not restricted to early development—they may occur in the third trimester or beyond— but once "imprinted" they may be passed on to succeeding generations. Thus, the intrauterine environment may permanently modify the expression of genes, including those of the endocrine system.[14]

Acquisition of Patterns of Hormone Secretion and Action

At any given time, the plasma concentration of a hormone reflects its synthesis, secretion, and clearance, a concept that implies removal from the circulation in units of time. Indeed, the relationship between the production rate (PR) of a hormone (units/time), the serum or plasma concentration (C = units/mL), and its metabolic clearance rate (MCR) from the plasma (mL/time) is defined by the formula $PR = MCR \times C$, so knowing any two of these three variables permits one to solve the third. However, the concentration of a hormone may vary depending on such factors as time of day, stages of sleep, stage of puberty, renal or hepatic function, and the ingestion of other drugs. Hence, each of these aspects represents complex interactions. For example, the secretion of ACTH and the chief product of its action, cortisol, are related in phase, the former preceding the latter and being highest in the early morning and lowest toward midnight. ACTH synthesis may have a basal rate determined by the impulses from its hypothalamic releasing hormone, known as corticotropin releasing hormone (CRH), but both display a diurnal rhythm entrained by the light/dark cycle and relayed to the suprachiasmatic nucleus of the hypothalamus. As the fetus is not exposed to light/dark cycles and the newborn spends a majority of time asleep, it is important to know when the diurnal rhythm becomes established.[15,16] This has importance for undertaking measurements of cortisol in the newborn to determine if the hormone is deficient, as, for example, in evaluating newborn hypoglycemia. Also, stress results in a rapid increase in the CRH-ACTH-cortisol axis and the secretion of cortisol. Such rapid adaptation is essential for the appropriate adjustments to physiologic stress resulting in the "fight or flight response." It is known that the hypothalamic pituitary adrenal axis is established in utero and functional because inborn errors of metabolism such as those found in congenital adrenal hyperplasia as a result of defects in enzymes responsible for cortisol synthesis result in markedly elevated ACTH in utero, with hypertrophy of the adrenal cortex. However, after birth, there is a brief period during which adrenal secretion of cortisol is low as reflected in the plasma levels,[17] and it is not known how rapidly the newborn can adjust to a stressful situation by appropriate increments in the ACTH-cortisol secretion rates.[18] Some of the hormonal

cycles, such as GH secretion and FSH/LH secretion at the onset of puberty, are related to sleep rather than the light-dark cycle, as discussed in the relevant chapters of this book. But it is not known if these sleep-regulated patterns are operative in the newborn. Following birth, some inhibitory pathways of hormone secretion are not yet established, resulting in high hormone concentrations whose functional significance is not known. For example, inhibition of GH secretion by somatotropin release-inhibiting factor (SRIF) appears to develop only after birth, so that GH concentrations in serum are quite high in the newborn (averaging approximately 40 ng/ml), values that would be consistent with acromegaly in an adult. On the other hand, the expression of GH receptors on tissues and their linkage to postreceptor events is delayed and become fully operational only after several months, so that the effects of the high GH concentrations are muted.[19,20] The practical implications of these findings are that GH deficiency in a full-term newborn will not be characterized by discernible small size. Indeed, GH deficiency does not become manifest in a delayed growth velocity until after 3 to 6 months when the GH–growth hormone receptor (GHR) axis becomes established. Yet GH plays an important role in maintaining glucose homeostasis in the newborn, because GH deficiency may be associated with hypoglycemia, and this deficiency can be diagnosed without the need for stimulation tests if the GH concentration is lower than 10 ng/mL in the first week of life. Another hormone whose concentrations remain very high at birth and for several weeks thereafter is prolactin, presumably because the neurologic pathways responsible for dopamine secretion are not yet fully developed.[21] The physiologic implications of these adaptive processes in the secretion and action of prolactin in the newborn are not fully understood.

Adaptations in Endocrine Function at Birth

Separation of the newborn baby from its maternal blood supply after birth imposes a near-instantaneous need for adaptations in functions such as the requirements of oxygen, maintenance of body temperature, and sources of nutrients. The endocrine system plays a vital role in several of these adaptations; three are briefly described here and are explored in more detail in relevant chapters in this book.

Maintenance of Body Temperature

The hypothalamic-pituitary-thyroid axis is intimately involved in the adaptations of body temperature regulation. The fetus, bathed in amniotic fluid and supplied by maternal blood, maintains a temperature of 37° C in utero. Delivery into an ambient temperature of approximately 20° to 25° C in a modern delivery room represents a significant fall in ambient temperature that activates thyroid function. The concentration of TSH increases approximately 10-fold between birth and 15 to 30 minutes after cord cutting, to values of approximately 100 μU/mL. Simultaneously, type 2 deiodinase is activated, converting T_4 to T_3 rather than the fetal pattern of type 3 deiodinase that converts T_4 to reverse T_3. These rapid changes result in a surge of T_3 concentration, a decline in reverse T_3 concentration, and a somewhat later rise of T_4 concentration in the newborn's blood. Together, these coordinated changes in thyroid function enable T_3 to act on brown adipose tissue to activate nonshivering thermogenesis. Although TSH concentrations decline to values below 10 μU/mL by day 2 to day 3 of life, T_3 and T_4 values remain elevated for days to weeks at concentrations that would be consistent with thyrotoxicosis in older children and adults (see Chapter 7 for details). Hence, values of thyroid function reported for full-term or premature newborns must be reported as age specific and may often be labeled erroneously as "hyperthyroid" in laboratories that only list reference values suitable for adults.

Glucose Homeostasis

The fetus obtains all of its glucose via placental transfer from the mother, with little, if any, endogenous glucose production until delivery. Following cord cutting, epinephrine and glucagon each rise approximately three- to fivefold, growth hormone is high at approximately 40 ng per dl (as mentioned previously) as are cortisol values, which are highest at about 2 hours after birth and, on average, remain in the range of 2.7 to 7.6 μg/dL, mostly in the free form, in the first week of life.[17] The coordinated effects of these four classic "counterregulatory" hormones, together with a small fall in insulin, stem the initial decline in blood glucose concentration, activate glycogen breakdown and gluconeogenesis, and initiate lipolysis with later activation of ketone body production by day 2 to day 3 of life. Understanding these critical adaptations is essential for the appropriate management of hypoglycemia in a newborn, as detailed in Chapter 6.

Gonadotropins and Sex Hormones

In males, testosterone concentrations on day 1 of life are high, ranging from 75 to 400 ng/dL, values that are consistent with Tanner stages 3 to 4 of male puberty. These high concentrations decline rapidly within the first few days after delivery but remain elevated at 20 to 50 ng/dL in comparison to males aged 1 to 10 years in whom values are $<$ 10 ng/dL. A second rise in testosterone concentrations occurs between 1 week and 1 to 2 months, the mean values being approximately 200 ng/dl. Both FSH and LH also are relatively high in males at this age of life and decline to prepubertal levels only at about the end of the first year. In females, concentrations of estradiol are markedly elevated after birth and fall rapidly during the first week of life to prepubertal values, with a secondary rise occurring between 30 and 60 days followed by decline to prepubertal concentrations after 1 to 2 years. Values of FSH may range up to 14 mIU/mL in females and decline more slowly than in males, reaching prepubertal values only after 2 to 3 years. Likewise, LH values in females may be in the classical pubertal range in the first few months of life and decline to prepubertal values only after 1 to 2 years. This "minipuberty of infancy" is discussed

in greater detail in Chapters 5 and 15. A precise function for these perinatal changes in sex hormones and gonadotropins is unknown, but it has been proposed that they may have relevance to patterning of male or female neural function. In addition, clinical relevance is related to the common problem of thelarche in newborn-infant females, as discussed in Chapter 15.

In summary, knowledge of the endocrine adaptations following birth is essential for the appropriate evaluation of suspected abnormalities in endocrine function and the interpretation of age- and sex-specific values of circulating hormones.

EVALUATING ENDOCRINE DISORDERS IN INFANCY AND CHILDHOOD

A general principle of pediatric endocrinology is that the earlier the manifestation of either underactivity or excess hormone function, the more likely the cause is to be a genetic disorder with possible structural abnormalities. For example, the entity of septo-optic dysplasia with underactivity of anterior and posterior pituitary function may be associated with typical structural abnormalities of optic nerve hypoplasia, absence of the septum pellucidum or corpus callosum, a small anterior pituitary, interruption or absence of the pituitary stalk, and an ectopic or absent posterior pituitary bright spot on magnetic resonance imaging (MRI) of the brain.[22] Hypothyroidism found on newborn screening is most commonly associated with an ectopic thyroid gland; total absence or goitrous hypothyroidism should suggest a defect in the genes responsible for thyroid gland formation (TTF-1, TTF-2, PAX8) or an "inborn error of thyroid hormone synthesis" (Chapter 7). To be sure, perinatal events and maternal illness or medication must be considered. For example, perinatal asphyxia or a difficult delivery may be associated with later evidence of hypopituitarism. Maternal ingestion of antithyroid medications would result in their transfer across the placenta and may cause transient neonatal hypothyroidism, as these agents affect the fetal thyroid in the same was as they affect the maternal thyroid gland. Similarly, transfer of IgG antibodies that block or stimulate thyroid function will result in newborn hypothyroidism or hyperthyroidism that lasts for several weeks, until maternal antibodies are cleared from the circulation. A newborn with severe hyperthyroidism in the absence of any evidence of autoimmune disease in the mother almost certainly has an activating mutation of the TSH receptor (Chapter 7).

More subtle defects in endocrine function may appear later in childhood but still have a genetic basis (e.g., hypogonadotropic hypogonadism). This entity may not become manifest or discovered until delayed puberty is investigated. Macrosomia in an infant born to a mother with poorly controlled diabetes mellitus reflects secondary hyperinsulinism in the fetus, with hypoglycemia in the newborn when the maternal supply of glucose is curtailed. However, similar features in a baby born to a healthy young mother should immediately suggest the possibility of a genetic form of hyperinsulinism, most commonly the result of an inactivating mutation in the genes regulating the adenosine triphosphate (ATP)–regulated potassium channel (K_{ATP}) (Chapter 6).

Autoimmunity, trauma, and chemo/radiotherapy for a childhood malignancy are the most common causes of acquired endocrine disorders. Thus, as in all of medicine, a careful and thorough history, careful physical examination, and targeted investigation of hormonal measurements (taking into account age, time of day, and the value of obtaining a "free" hormone versus total hormone measurement) form the basis of the diagnostic approach. This may be followed by imaging of the suspected organ involved to diagnose the basis of the suspected endocrine dysfunction in the particular patient being investigated. Increasingly, molecular diagnostics is becoming an integral component of this evaluation, both to establish the cause of the entity and to provide guidance for prognosis, such as MEN2 (Chapter 14).

Definitive diagnosis may require stimulation tests (e.g., for growth hormone deficiency or with ACTH for suspected adrenal insufficiency) because a single random value is not sufficiently informative.

Finally, modern biology has provided pure synthetic compounds to replace what may be missing, such as thyroid hormone, cortisol, administration of pulsatile GnRH for Kallman syndrome, GnRH analogues for suppressing puberty, growth hormone, insulin, and ultra-long-acting somatostatin for childhood acromegaly as occurs in Carney complex or some patients with McCune-Albright syndrome. Hormone replacement must also take into consideration administration via the dermal rather than the oral route in order to avoid "first pass" considerations in bypassing the liver, as, for example, giving sex hormones such as estrogen.

CONCLUDING REMARKS

Endocrinology is the science of cellular communication that enables the biochemical integration of life's vital processes. Pediatric endocrinology is the linchpin for these processes during the developmental epoch from fetus to mature adult. Evolving developments in molecular biology, bioinformatics, pharmacogenetics, and bioimaging will ensure that this specialty remains at the forefront of pediatric research and practice. This chapter is intended as an introduction to this important field, with greater detail to be found in the chapters that follow. Much remains to be learned.

QUESTIONS

1. What key methodologies propelled progress in endocrinology in the 20th century?
   a. Radioactive tracers
   b. Radioimmunoassay
   c. Protein purification
   d. Molecular basis of hormone synthesis and action
   e. b and d
   f. All of the above

Answer: e

2. A unit of insulin is the amount of activity in which of the following?
   a. 1 μg of purified hormone
   b. The amount of insulin that will lower blood glucose in an average human adult by 100 mg/dl
   c. The amount of insulin that will lower blood glucose to 45 mg/dl in a 2-kg rabbit fasted for 24 hours
   d. The amount of insulin that can conveniently be packaged as 100 units/ml in 10-ml aliquots

Answer: c

3. Why is the "minipuberty of infancy" so named?
   a. Breast development or pubic hair is frequently observed in the first year of life
   b. Testosterone in males and E_2 in females are in the midpubertal range in the first few weeks of life
   c. LH responds briskly to a pulse of GnRH in infants at 3 months of age
   d. Maternal HCG from the placenta stimulates the development of testes and ovaries at term

Answer: b

4. The fetal origins of adult disease hypothesis postulates which of the following?
   a. All diseases in adults originate in the intrauterine environment.
   b. The intrauterine environment may induce heritable traits via epigenetic mechanisms.
   c. Diseases such as T2DM and metabolic syndrome could be avoided by appropriate nutrition for the mother during pregnancy.
   d. Post-zygotic mutations define the tendency for certain common diseases such as hypertension in adults.

Answer: b

CHAPTER 2

Molecular Endocrinology and Endocrine Genetics

Ram K. Menon, MD • Massimo Trucco, MD • Constantine A. Stratakis, MD, D(med)Sci

CHAPTER OUTLINE

INTRODUCTION

The study of the endocrine system has undergone a dramatic evolution since the 1990s, from the traditional physiologic studies that dominated the field for many years to the discoveries of molecular endocrinology and endocrine genetics.[1,2] At the present time the major impact of molecular medicine on the practice of pediatric endocrinology relates to diagnosis and genetic counseling for a variety of inherited endocrine disorders. In contrast, the direct therapeutic application of this new knowledge is still in its infancy, although recently the results of the first successful human gene therapy trials were reported (but not for endocrine diseases). In addition, the new information has led to a host of molecularly targeted therapies mainly in cancer; endocrine oncology has greatly benefited from the application of new drugs that were designed to battle specific mutations in, for example, thyroid cancer. This chapter is an introduction to the basic principles of molecular biology, common laboratory techniques, and some examples of the recent advances made in clinical pediatric endocrinologic disorders with an emphasis on endocrine genetics. Most new diagnostic testing, pharmacogenetics, and molecular therapies are discussed in the disease-specific chapters of this book, and only examples that highlight the principle/strategy under discussion are listed in this chapter.

BASIC MOLECULAR TOOLS

Isolation and Digestion of DNA and Southern Blotting

The human chromosome comprises a long double-stranded helical molecule of DNA associated with different nuclear proteins.[3,4] As DNA forms the starting point of the synthesis of all the protein molecules in the body, molecular techniques using DNA have proven to be crucial

in the development of diagnostic tools to analyze endocrine diseases. DNA can be isolated from any human tissue, including circulating white blood cells. About 200 μg of DNA can be obtained from 10 to 20 mL of whole blood with the efficiency of DNA extraction being dependent on the technique used and the method of anticoagulation employed. The extracted DNA can be stored almost indefinitely at an appropriate temperature. Furthermore, lymphocytes can be transformed with the Epstein-Barr virus (and other means) to propagate indefinitely in cell culture as "immortal" cell lines, thus providing a renewable source of DNA. For performing molecular genetic studies, lymphoid lines are routinely the tissue of choice, because a renewable source of DNA obviates the need to obtain further blood from the family. Fibroblast-derived cultures can also serve as a permanent source of DNA or RNA (once transformed), but they have to be derived from surgical specimens or a biopsy. It should be noted that, because the expression of many genes is tissue specific, immortalized lymphoid or fibroblastoid cell lines cannot be used to anlyze the abundance or composition of messenger RNA (mRNA) for a specific gene. Hence, studies involving mRNA necessitate the analysis of the tissue(s) expressing the gene as outlined in the section on "RNA Analysis" that begins on page 13.

DNA is present in extremely large molecules; the smallest chromosome (chromosome 22) has about 50 million base pairs and the entire haploid human genome is estimated to comprise 3 million to 4 billion base pairs. This extreme size precludes the analysis of DNA in its native form in routine molecular biology techniques. The techniques for identification and analysis of DNA became feasible and readily accessible with the discovery of enzymes termed *restriction endonucleases*. These enzymes, originally isolated from bacteria, cut DNA into smaller sizes on the basis of specific recognition sites that vary from two to eight base pairs in length.[5,6] The term *restriction* refers to the function of these enzymes in bacteria. A restriction endonuclease destroys foreign DNA (such as bacteriophage DNA) by cleaving the DNA at specific sites, thereby "restricting" the entry of foreign DNA in the bacterium. Several hundred restriction enzymes with different recognition sites are now commercially available. Because the recognition site for a given enzyme is fixed, the number and sizes of fragments generated for a particular DNA molecule remain consistent with the number of recognition sites and provide predictable patterns after separation by electrophoresis.

Analysis of the DNA fragments generated after digestion usually employs the technique of electrophoresis.[7] Electrophoresis exploits the property that the phosphate groups in the DNA molecule confer a negative charge to that molecule. Thus, when a mixture of DNA molecules of different sizes is electrophoresed through a sieve (routinely either agarose or acrylamide), the longer DNA molecules migrate more slowly relative to the shorter fragments. Following electrophoresis, the separated DNA molecules can be located by a variety of staining techniques, of which ethidium bromide staining is a commonly used method.

Although staining with ethidium bromide is a versatile technique, analysis of a few hundred base pairs of DNA in the region of interest is difficult when the DNA from all the human chromosomes are cut and separated on the same gel. These limitations are circumvented by the technique of Southern blotting (named after its originator, Edward Southern) and the use of labeled radioactive or more commonly nonradioactive probes. Southern blotting involves digestion of DNA and separation by electrophoresis through agarose.[8] After electrophoresis, the DNA is transferred to a solid support (such as nitrocellulose or nylon membranes), enabling the pattern of separated DNA fragments to be replicated onto the membrane (Figure 2-1). The DNA is then denatured (i.e., the two strands are physically separated), fixed to the membrane, and the dried membrane is mixed with a solution containing the DNA probe. A DNA probe is a fragment of DNA that contains a nucleotide sequence specific for the gene or chromosomal region of interest. For purposes of detection, the DNA probe is labeled with an identifiable tag, such as radioactive phosphorus (e.g., ^{32}P) or a chemiluminescent moiety; the latter has almost exclusively replaced radioactivity. The process of mixing the DNA probe with the denatured DNA fixed to the membrane is called hybridization, the principle being that there are only four nucleic acid bases in DNA—adenine (A), thymidine (T), guanine (G), and cytosine (C)—that always remain complementary on the two strands of DNA, A pairing with T, and G pairing with C. Following hybridization, the membrane is washed to remove the unbound probe and exposed to an x-ray film either in a process called autoradiography

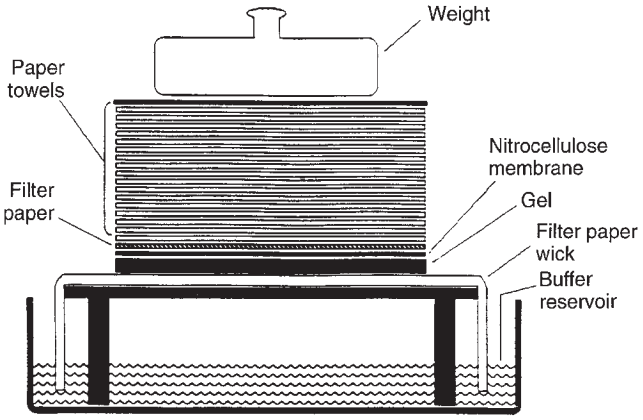

FIGURE 2-1 ■ Southern blot. Fragments of double-stranded DNA are separated by size by agarose gel electrophoresis. To render the DNA single stranded (denatured), the agarose gel is soaked in an acidic solution. After neutralization of the acid, the gel is placed onto filter paper, the ends of which rest in a reservoir of concentrated salt buffer solution. A sheet of nitrocellulose membrane is placed on top of the gel and absorbent paper is stacked on top of the nitrocellulose membrane. The salt solution is drawn up through the gel by the capillary action of the filter paper wick and the absorbent paper towels. As the salt solution moves through the gel, it carries along with it the DNA fragments. Because nitrocellulose binds single-stranded DNA, the DNA fragments are deposited onto the nitrocellulose in the same pattern that they were placed in the agarose gel. The DNA fragments bound to the nitrocellulose are fixed to the membrane by heat or UV irradiation. The nitrocellulose membrane with the bound DNA can then be used for procedures such as hybridization to a labeled DNA probe. Techniques to transfer DNA to other bonding matrices, such as nylon, are similar. (Adapted from Turco E, Fritsch R, Trucco M [1990]. Use of immunologic techniques in gene analysis. In Herberman RB, Mercer DW [eds.], *Immunodiagnosis of cancer*. New York: Marcel Dekker, 205.)

to detect radioactive phosphorus or in a process used to detect the chemiluminescent tag. Only those fragments that are complementary and have bound to the probe containing the DNA of interest will be evident on the x-ray film, enabling the analysis of the size and pattern of these fragments. As routinely performed, the technique of Southern analysis can detect a single copy gene in as little as 5 μg of DNA, the DNA content of about 10^6 cells.

Restriction Fragment Length Polymorphism and Other Polymorphic DNA Studies

The number and size of DNA fragments resulting from the digestion of any particular region of DNA form a recognizable pattern. Small variations in a sequence among unrelated individuals may cause a restriction enzyme recognition site to be present or absent; this results in a variation in the number and size pattern of the DNA fragments produced by digestion with that particular enzyme. Thus this region is said to be polymorphic for the particular enzyme tested—that is, a restriction fragment length polymorphism (RFLP) (Figure 2-2). The value of RFLP is that it can be used as a molecular tag for tracing the inheritance of the maternal and paternal alleles. Furthermore, the polymorphic region analyzed does not need to encode the genetic variation that is the cause of the disease being studied, but only to be located near the gene of interest. When a particular RFLP pattern can be shown to be associated with a disease, the likelihood of an offspring inheriting the disease can be determined by comparing the offspring's RFLP pattern with the RFLP pattern of the affected or carrier parents. The major limitation of the RFLP technique is that its applicability for the analysis of any particular gene is dependent on the prior knowledge of the presence of convenient ("informative") polymorphic restriction sites that flank the gene of interest by at most a few kilobases. Because these criteria may not be fulfilled in any given case, the applicability of RFLP cannot be guaranteed for the analysis of a given gene.

In the early years of the molecular endocrinology era, the RFLP technique was the mainstay of experimental strategies employed for investigating the genetic basis of endocrine diseases. For example, RFLP-based genomic studies were used to identify mutations in the rearranged during transfection (RET) oncogene as the etiology of the multiple endocrine neoplasia type-2 syndrome. However, at present for routine disease mapping, whole genome and even gene-specific association studies, the RFLP technique has been supplanted by more powerful and facile techniques such as microsatellite and single-nucleotide polymorphism studies (discussed later); at present RFLP analysis is only used within the context of a specific gene investigation and is increasingly being replaced by other means (genomic) of investigation.

Polymerase Chain Reaction

The polymerase chain reaction (PCR) is a technique that was developed in the late 1980s and has indeed revolutionized molecular biology (Figure 2-3). PCR allows the selective logarithmic amplification of a desired fragment of DNA from a complex mixture of DNA that theoretically contains at least a single copy of the target fragment. In the typical application of this technique, some knowledge of the DNA sequences in the region to be amplified is necessary, so that a pair of short (approximately 18 to 25 bases in length) specific oligonucleotides ("primers") can be synthesized. The primers are synthesized in such a manner that they define the limits of the region to be amplified. The DNA template containing the segment that is to be amplified is heat denatured such that the strands are separated and then cooled to allow the primers to anneal to the respective complementary regions. The enzyme Taq polymerase, a heat stable enzyme originally isolated from the bacterium *Thermophilus aquaticus*, is then used to initiate synthesis (extension) of DNA. The DNA is repeatedly *denatured*, *annealed*, and *extended* in successive cycles in a machine called the "thermocycler" that permits this process to be automated. In the usual assay, these repeated cycles of denaturing, annealing, and extension result in the synthesis of approximately 1 million copies of the target region in about 2 hours. To establish the veracity of the amplification process, the identity of the amplified DNA can be analyzed by electrophoresis, hybridization to RNA or DNA probes, digestion with informative restriction enzyme(s), or subjected to direct DNA sequencing. The relative simplicity combined with the power of this technique has resulted in widespread use of this procedure and has spawned a wide variety of variations and modifications that have been developed for specific applications.[9,10] From a practical point of view, the major drawback of PCR is the propensity to get cross-contamination of the target DNA. This drawback is the direct result of the extreme sensitivity of the method that permits amplification from one molecule of the starting DNA template. Thus, unintended transfer of amplified sequences to items used in the procedure will amplify DNA in samples that do not contain the target DNA sequence (i.e., a false positive result). Cross-contamination should be suspected when amplification occurs in negative controls that did not contain the target template. One of the most common modes of cross-contamination is via aerosolization of the amplified DNA during routine laboratory procedures such as vortexing, pipetting, and manipulation of microcentrifuge tubes. Meticulous care to experimental technique, proper organization of the PCR workplace, and inclusion of appropriate controls are essential for the successful prevention of cross-contamination during PCR experiments.

In general, PCR applications are either directed toward the identification of a specific DNA sequence in a tissue or body fluid sample or used for the production of relatively large amounts of DNA of a specific sequence, which then are used in further studies. Examples of the first type of application are common in many fields of medicine, such as in microbiology, wherein the PCR technique is used to detect the presence DNA sequences specific for viruses or bacteria in a biological sample. Prototypic examples of such an application in pediatric endocrinology include the use of PCR of the *SRY* gene for detecting Y chromosome

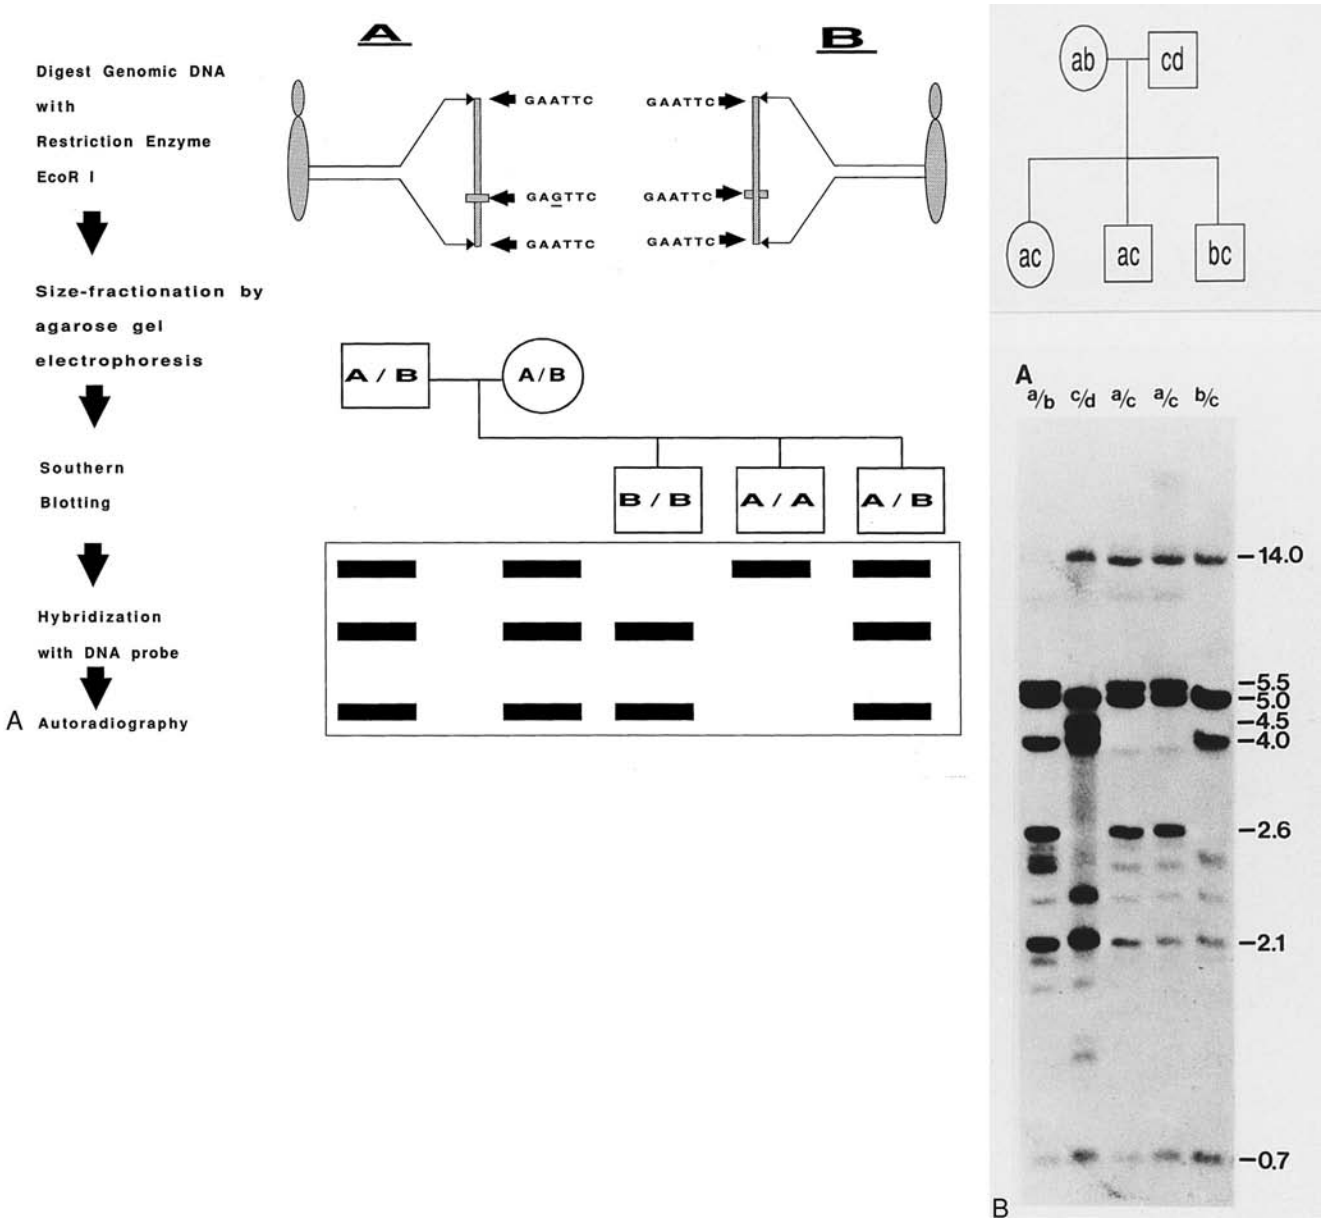

FIGURE 2-2 ■ Restriction fragment length polymorphism. **A,** Schematic illustration. A and B represent two alleles that display a polymorphic site for the restriction enzyme EcoR I. EcoR I will cut DNA with the sequence "GAATTC"; hence, allele B will be cut by EcoR I at three sites to generate two fragments of DNA, whereas allele A will be cut by EcoR I only twice and not at the site (indicated by horizontal bar) where nucleotide G (underlined) replaces the nucleotide A present in allele B. Following digestion, the DNA is size-fractionated by agarose gel electrophoresis and transferred to a membrane by Southern blot technique (see Figure 2-1 for details). The membrane is then hybridized with a labeled DNA probe, which contains the entire sequence spanned by the three EcoR I sites. Autoradiography of the membrane will detect the size of the DNA fragments generated by the restriction enzyme digestion. In this particular illustration, both parents are heterozygous and possess both A and B alleles. Matching the pattern of the DNA bands of the offspring with that of the parents will establish the inheritance pattern of the alleles. For example, if allele A represents the abnormal allele for an autosomal recessive disease, then examination of the Southern blot will establish that (from left to right) the first offspring (B/B) is homozygous for the normal allele, the second offspring (A/A) is homozygous for the abnormal allele, and the third offspring (A/B) is a carrier. **B,** RFLP analysis of the DQ-beta gene of the HLA locus. Genomic DNA from the members of the indicated pedigree was digested with restriction enzyme Pst I, size-fractionated by agarose gel electrophoresis, and transferred to nitrocellulose membrane by Southern blot technique. The membrane was then hybridized with a cDNA probe specific for the DQ-beta gene; the excess probe was removed by washing at appropriate stringency and was analyzed by autoradiography. The sizes of the DNA fragments (in kilobases, kb) are indicated on the right. The pedigree chart indicates the polymorphic alleles (a, b, c, d) and the bands on the Southern blot corresponding to these alleles (a [5.5 kb], b [5.0 kb], c [14.0 kb], d [4.5 kb]) indicate the inheritance pattern of these alleles. (Adapted from Turco E, Fritsch R, Trucco M [1998]. First domain encoding sequence mediates human class II beta-chain gene cross-hybridization. Immunogenetics 28:193.)

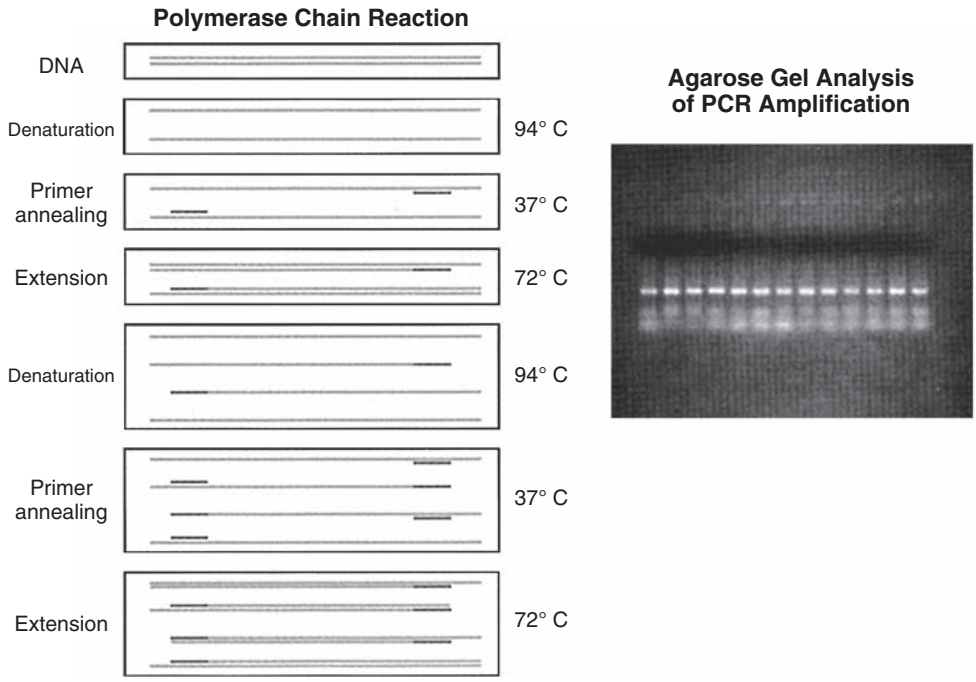

FIGURE 2-3 ■ Polymerase chain reaction (PCR). A pair of oligonucleotide primers (solid bars), complementary to sequences flanking a particular region of interest (shaded, stippled bars), are used to guide DNA synthesis in opposite and overlapping directions. Repeated cycles of DNA denaturation, primer annealing, and DNA synthesis (primer extension) by DNA polymerase enzyme result in an exponential increase in the target DNA (i.e., the DNA sequence located between the two primers) such that this DNA segment can be amplified 1 × 106-7 times after 30 such cycles. The use of a thermostable DNA polymerase (i.e., Taq polymerase) allows for this procedure to be automated. Inset: The amplified DNA can be used for subsequent analysis (i.e., size-fractionation by agarose gel electrophoresis). (Adapted from Trucco M [1992]. To be or not to be ASP 57, that is the question. Diabetes Care 15:705.)

material in patients with karyotypically defined Turner syndrome and the rapid identification of chromosomal gender in cases of fetal or neonatal sexual ambiguity[11] (Figure 2-4).

Most PCR applications, both as research tools and for clinical use, are directed toward the production of a target DNA or the complementary DNA of a target RNA sequence. The DNA that is made ("amplified") is then analyzed by other techniques such as RFLP analysis, allele-specific oligonucleotide hybridization, or DNA sequencing.

RNA Analysis

The majority (> 95%) of the chromosomal DNA represents noncoding sequences. These sequences harbor regulatory elements, serve as sites for alternate splicing, and are subject to methylation and other epigenetic changes that affect gene function. However, at present most disease-associated mutations in human gene have been identified in coding sequences. An alternate strategy to analyze mutations in a given gene is to study its messenger RNA (mRNA), which is the product (via transcription) of the remaining 5% of chromosomal DNA that encodes for proteins. In addition, because the mRNA repertoire is cell and tissue specific, the analyses of the mRNA sequences provide unique information about tissue-specific proteins produced in a particular organ/tissue.

There are many techniques for analyzing mRNA. Northern blotting (so named because it is based on the same principle as the Southern blot) is one of the original methods used for mRNA analysis. In Northern blotting, RNA is denatured by treating it with an agent such as formaldehyde to ensure that the RNA remains unfolded and in the linear form.[12,13] The denatured RNA is then electrophoresed and transferred onto a solid support (such as nitrocellulose membrane) in a manner similar to that described for the Southern blot.[8] The membrane with the RNA molecules separated by size is probed with the gene-specific DNA probe labeled with an identifiable tag that, as in the case of Southern blotting, is either a radioactive label (e.g., ^{32}P) or more commonly a chemiluminescent moiety. The nucleotide sequence of the DNA probe is complementary to the mRNA sequence of the gene and is hence called complementary DNA (cDNA). It is customary to use labeled cDNA (and not labeled mRNA) to probe Northern blots because DNA molecules are much more stable and easier to manipulate and propagate (usually in bacterial plasmids) than mRNA molecules. The Northern blot provides information regarding the amount (estimated by the intensity of the signal on autoradiography) and the size (estimated by the position of the signal on the gel in comparison to concurrently electrophoresed standards) of the specific mRNA. Although the Northern blot technique represents a versatile and straightforward method to analyze mRNA, it has major drawbacks. Northern analysis is a relatively

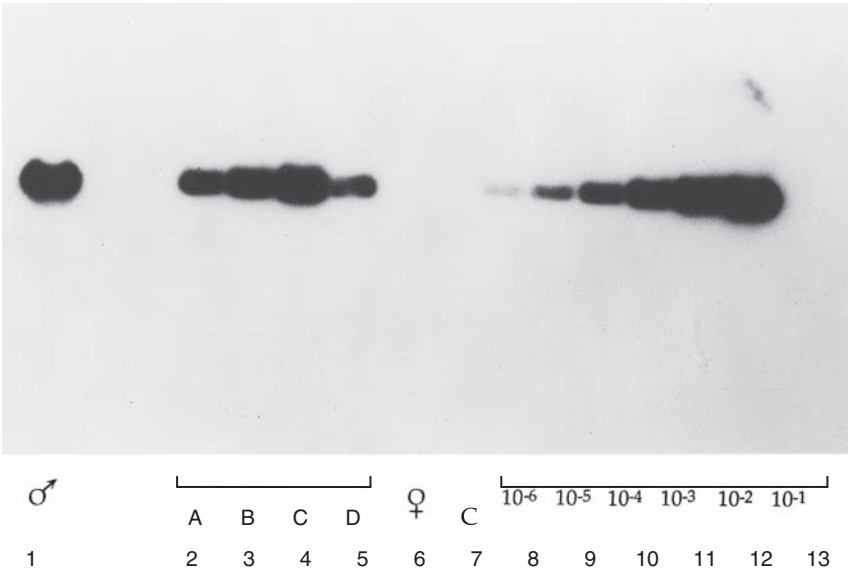

FIGURE 2-4 ■ Detection of *SRY* gene–specific sequence in Turner syndrome by polymerase chain reaction (PCR) amplification and Southern blot. *SRY*-specific primers were used in PCR to amplify DNA from patients with 45X karyotype. The amplified DNA was size-fractionated by agarose gel-electrophoresis and transferred to membrane by Southern blotting. The membrane was then hybridized to labeled *SRY*-specific DNA and autoradiographed. From left to right: amplified male DNA (lane 1); amplified DNA from patients with 45X karyotype (lanes 2-5); amplified female DNA (lane 6); negative control with no DNA (lane 7); serial dilution of male DNA (lanes 8-13). Lancet 342:140. © Copyright by the Lancet Ltd.)

insensitive technique, both in terms of the concentration of mRNA that can be detected and in terms of the fine structure. This technique cannot detect small changes in size, nucleotide composition, or the abundance of the mRNA being analyzed. At present, reverse transcriptase-PCR (RT-PCR) has become the technique of choice for the routine analysis of mRNA.

One of the most sensitive methods for the detection and quantitation of mRNA currently available is the technique of quantitative RT-PCR (qRT-PCR).[9] This technique combines the unique function of the enzyme reverse transcriptase with the power of PCR. qRT-PCR is exquisitely sensitive, permitting analysis of gene expression from very small amounts of RNA. Furthermore, this technique can be applied to a large number of samples or many genes (multiplex) in the same experiment. These two critical features endow this technique with a measure of flexibility unavailable in more traditional methods such as Northern blot or solution hybridization analysis. Whereas the detection of a specific mRNA by this technique is relatively straightforward, the precise quantitation of the mRNA in a given sample is more complicated. The first step in qRT-PCR analysis is the production of DNA complementary (cDNA) to the mRNA of interest. This is done by using the enzymes with RNA-dependent DNA polymerase activity that belong to the reverse transcriptase (RT) group of enzymes (e.g., Moloney murine leukemia virus [MMLV], avian myeloblastosis virus [AMV] reverse transcriptase, an RNA dependent DNA polymerase). The RT enzyme, in the presence of an appropriate primer, will synthesize DNA complementary to RNA. The second step in the qRT-PCR analysis is the amplification of the target DNA, in this case the cDNA synthesized by the reverse transcriptase enzyme. The specificity of the amplification is determined by the specificity of the primer pair used for the PCR amplification. To establish the veracity of the amplification process, the identity of the amplified DNA can be analyzed by electrophoresis, hybridization to RNA or DNA probes, digestion with informative restriction enzyme(s), or subjected to direct DNA sequencing

Whereas the detection of a specific mRNA by this technique is relatively straightforward, the precise quantitation of the mRNA in a given sample is more complicated. Because the production of DNA by PCR involves an exponential increase in the amount of DNA synthesized, relatively minor differences in any of the variables controlling the rate of amplification will cause a marked difference in the yield of the amplified DNA. In addition to the amount of template DNA, the variables that can affect the yield of the PCR include the concentration of the polymerase enzyme, magnesium, nucleotides (dNTPs), and primers. The specifics of the amplification procedure including cycle length, cycle number, annealing, extension and denaturing temperatures also affect the yield of DNA. Because of the multitude of variables involved, routine RT-PCR is unsuitable for performing a quantitative analysis of mRNA. To circumvent these pitfalls alternate strategies have been developed. One technique for determining the concentration of a particular mRNA in a biological sample is a modification of the basic PCR technique called competitive RT-PCR.[9,14,15] This method is based on the co-amplification of a mutant DNA that can be amplified with the same pair of primers being used for the target DNA. The mutant DNA is engineered in such a way that it can be distinguished from the DNA of interest by either size or the inclusion

of a restriction enzyme site unique to the mutant DNA. The addition of equivalent amounts of this mutant DNA to all the PCR reaction tubes serves as an internal control for the efficiency of the PCR process, and the yield of the mutant DNA in the various tubes can be used for the equalization of the yield of the DNA by PCR. It is important to ensure for accurate quantitation of the DNA of interest that the concentrations of the mutant and target template should be nearly equivalent. Because the use of mutated DNA for normalization does not account for the variability in the efficiency of the reverse transcriptase enzyme, a variation of the original method has been developed. In this modification, competitive mutated RNA transcribed from a suitably engineered RNA expression vector is substituted for the mutant DNA in the reaction prior to initiating the synthesis of the cDNA. Competitive RT-PCR can be used to detect changes of the order of two- to threefold of even very rare mRNA species. The major drawback of this method is the propensity to get inaccurate results because of the contamination of samples with the mRNA of interest. In theory, as the technique is based on PCR, contamination by even one molecule of mRNA of interest can invalidate the results. Hence, scrupulous attention to laboratory technique and set up is essential for the successful application of this technique.

In general, two types of methods are used for the detection and quantitation of PCR products: the traditional "end-point" measurements of products and the newer "real-time" techniques. End-point determinations (e.g., the competitive RT-PCR technique described earlier) analyze the reaction after it is completed, whereas real-time determinations are made during the progression of the amplification process. Overall the real-time approach is more accurate and is currently the preferred method. Advances in fluorescence detection technologies have made the use of real-time measurement possible for routine use in the laboratory. One of the popular techniques that takes advantage of real-time measurements is the TaqMan (fluorescent 5′ nuclease) assay (Figure 2-5).[16,17]

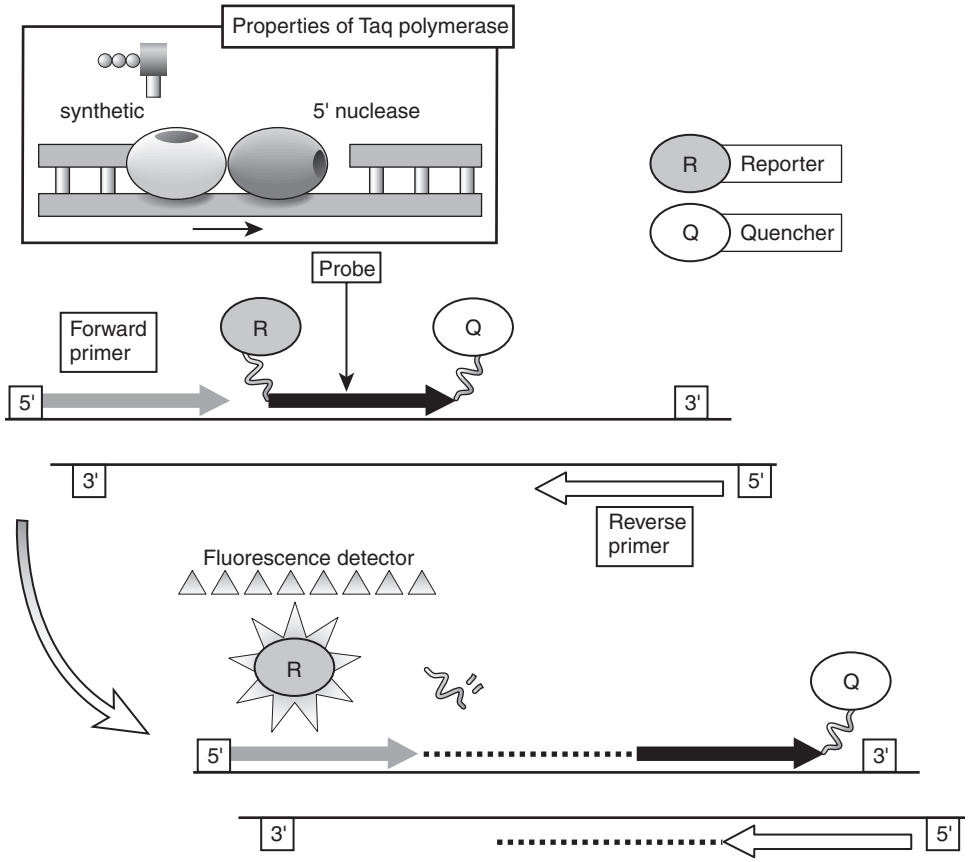

FIGURE 2-5 ■ Fluorescent 5′ nuclease (TaqMan) assay. Three synthetic oligonucleotides are utilized in a fluorescent 5′ nuclease assay. Two oligonucleotides function as "forward" and "reverse" primers in a conventional polymerase chain reaction (PCR) amplification protocol. The third oligonucleotide, termed the TaqMan probe, consists of an oligonucleotide synthesized with a 5′-reporter dye (e.g., FAM; 6-carboxy-fluorescein) and a downstream, 3′-quencher dye (e.g., TAMRA; 6-carboxy-tetramethyl-rhodamine). When the probe is intact, the proximity of the reporter dye to the quencher dye results in suppression of the reporter fluorescence, primarily by Forster-type energy transfer. During PCR, forward and reverse primers hybridize to a specific sequence of the target DNA. The TaqMan probe hybridizes to a target sequence within the PCR product. The Taq polymerase enzyme, because of its 5′-3′ exonuclease activity, subsequently cleaves the TaqMan probe. The reporter dye and the quencher dye are separated by cleavage, resulting in increased fluorescence of the reporter dye as a direct consequence of target amplification during PCR. Both primers and probe must hybridize to the target for amplification and cleavage to occur. Hence, the fluorescence signal is generated only if the target sequence for the probe is amplified during PCR. Fluorescent detection takes place through fiberoptic lines positioned above the caps of the reaction wells. Inset: The two distinct functions of the enzyme Taq polymerase: the 5′-3′ synthetic polymerase activity and the 5′-3′ polymerase-dependent exonuclease activity.

The unique design of TaqMan probes, combined with the 5′ nuclease activity of the PCR enzyme (Taq polymerase), allows direct detection of PCR product by the release of fluorescent reporter during the PCR amplification by using specially designed machines (ABI Prism 5700/7700). The TaqMan probe consists of an oligonucleotide synthesized with a 5′-reporter dye (e.g., FAM; 6-carboxy-fluorescein) and a downstream, 3′-quencher dye (e.g., TAMRA; 6-carboxy-tetramethyl-rhodamine). When the probe is intact, the proximity of the reporter dye to the quencher dye results in suppression of the reporter fluorescence, primarily by Forster-type energy transfer. During PCR, forward and reverse primers hybridize to a specific sequence of the target DNA. The TaqMan probe hybridizes to a target sequence within the PCR product. The Taq polymerase enzyme, because of its 5′-3′ nuclease activity, subsequently cleaves the TaqMan probe. The reporter dye and the quencher dye are separated by cleavage, resulting in increased laser-stimulated fluorescence of the reporter dye as a direct consequence of target amplification during PCR. This process occurs in every cycle and does not interfere with the exponential accumulation of product. Both primer and probe must hybridize to the target for amplification and cleavage to occur. The fluorescence signal is generated only if the target sequence for the probe is amplified during PCR. Because of these stringent requirements, nonspecific amplification is not detected. Fluorescent detection takes place through fiber optic lines positioned above optically nondistorting tube caps. Quantitative data are derived from a determination of the cycle at which the amplification product signal crosses a preset detection threshold. This cycle number is proportional to the amount of starting material, thus allowing for a measurement of the level of specific mRNA in the sample. An alternate machine (Light Cycler) also uses fluorogenic hydrolysis or fluorogenic hybridization probes for quantification in a manner similar to the ABI system.

MicroRNA

One of significant advances in the early 2000s in the field of RNA biology is the discovery of small (20 to 30 nucleotide) noncoding RNAs. In general there are two categories of small noncoding RNAs: microRNA (miRNA) and Small interfering RNA (siRNA). miRNAs are expressed products of an organism's own genome, whereas siRNAs are synthesized in the cells from foreign double-stranded RNA (e.g., from viruses or transposons or from synthetic DNA introduced into the cell to study the function of a particular gene/process). Additionally, there are differences in the biogenesis of these two classes of small nucleotide RNAs. These differences notwithstanding, the overall biological effect of these small nucleotide RNAs is translational repression or target degradation and gene silencing by binding to complementary sequences on the 3′ untranslated region of target messenger RNA; positive regulation of gene expression via such a mechanism is distinctly uncommon. The complexity of the phenomenon is increased by the fact that in a cell- or tissue-specific context a single miRNA can target multiple RNAs and more than one miRNA can recognize the same mRNA target to amplify and strengthen the translational repression of the target gene. It is estimated that this phenomenon is present in several cell types and the human genome codes for more than 1000 miRNAs that could target 60% to 70% of mammalian genes. miRNA-mediated events have been implicated in regulation of cell growth and differentiation, cell growth, apoptosis, and other cellular processes. To date, the major impact of the discovery of miRNA has been in the fields of developmental biology, organogenesis, and cancer. miRNA and miRNA-related events (e.g., proteins involved in miRNA processing) have been directly implicated in only a small number of nonneoplastic endocrine disorders (e.g., diGeorge syndrome and X-linked mental retardation). It is predicted that as we learn more about the basic biology of this process, small nucleotide noncoding RNAs will be implicated in the pathogenesis of a wider spectrum of endocrine diseases.

DETECTION OF MUTATIONS IN GENES

Changes in the structural organization of a gene that impact its function involve deletions, insertions, or transpositions of relatively large stretches of DNA, or more frequently single-base substitutions in functionally critical regions. Southern blotting and RFLP analysis can usually detect the deletion or insertion of large stretches of DNA. However, these analytic methods can be used for detecting point mutations only if the mutation involves the recognition site for a particular restriction enzyme, such that the absence of a normally present restriction site or the appearance of a novel site unmasks the presence of the point mutation. More commonly these techniques cannot be used for such an analysis, necessitating alternate procedures. High throughput or next-generation sequencing has revolutionized the identification of mutations in genes.[48]

Direct Methods

DNA sequencing is the current gold standard for obtaining unequivocal proof of a point mutation. However, DNA sequencing has its limitations and drawbacks. A clinically relevant problem is that current DNA sequencing methods do not reliably and consistently detect all mutations. For example, in many cases where the mutation affects only one allele (heterozygous), the heights of the peaks of the bases on the fluorescent readout corresponding to the wild-type and mutant allele are not always present in the predicted (1:1) ratio. This limits the discerning power of "base calling" computer protocols and results in inconsistent or erroneous assignment of DNA sequence to individual alleles.[18] Because of this limitation, clinical laboratories routinely determine the DNA sequence of both the alleles to provide independent confirmation of the absence/presence of a putative mutation. DNA sequencing can be labor intensive and expensive, although advances in pyrosequencing (discussed later), for example, have made it technically easier and cheaper.

Although the first DNA sequences were determined with a method that chemically cleaved the DNA at each

of the four nucleotides,[19] the enzymatic or dideoxy method developed by Sanger and colleagues in 1977 is the one most commonly used for routine purposes[20] (Figure 2-6). This method uses the enzyme DNA polymerase to synthesize a complementary copy of the single-stranded DNA ("template") whose sequence is being determined. Single-stranded DNA can be obtained directly from viral or plasmid vectors that support the generation of single-stranded DNA or by partial denaturing of double-stranded DNA by treatment with alkali or heat.[21] The enzyme DNA polymerase cannot initiate synthesis of a DNA chain de novo but can only extend a fragment of DNA. Hence, the second requirement for the dideoxy method of sequencing is the presence of a "primer." A primer is a synthetic oligonucleotide, 15 to 30 bases long, whose sequence is complementary to the sequence of the short corresponding segment of the single-stranded DNA template. The dideoxy method exploits the observation that DNA polymerase can use both 2′-deoxynucleoside triphosphate (dNTP) and 2′,3′-dideoxynucleoside triphosphates (ddNTPs) as substrates during elongation of the primer. Whereas DNA polymerase can use dNTP for continued synthesis of the complementary strand of DNA, the chain cannot elongate any further after addition of the first ddNTP because ddNTPs lack the crucial 3′-hydroxyl group. To identify the nucleotide at the end of the chain, four reactions are carried out for each sequence analysis, with only one of the four possible ddNTPs included in any one reaction. The ratio of the ddNTP and dNTP in each reaction is adjusted so that these chain terminations occur at each of the positions in the template where the nucleotide occurs. To enable detection by autoradiography, the newly synthesized DNA is labeled, usually by including in the reaction mixture radioactively labeled dATP (for the older manual methods) or, most commonly, currently fluorescent dye terminators in the reaction mixture (now in use in automated techniques). The separation of the newly synthesized DNA strands manually is done via high-resolution denaturing polyacrylamide electrophoresis or with capillary electrophoresis in automatic sequencers. Fluorescent detection methods have enabled automation and enhanced throughput. In capillary electrophoresis, DNA molecules are driven to migrate through a viscous polymer by a high electric field to be separated on the basis of charge and size. Though this technique is based on the same principle as that used in slab gel electrophoresis, the separation is done in

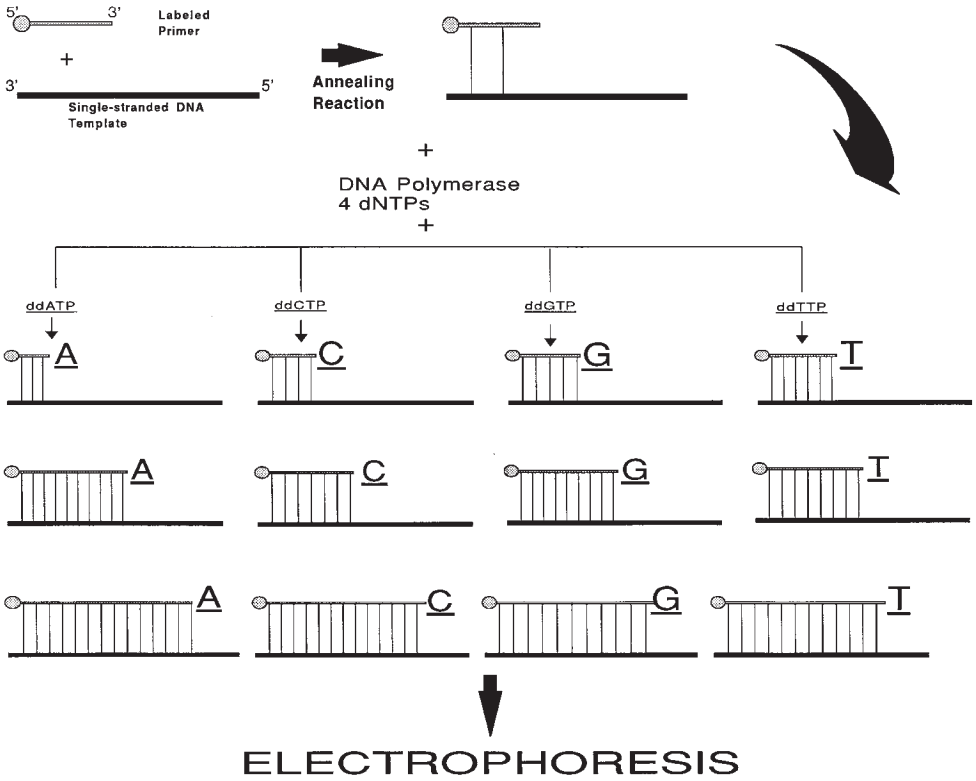

FIGURE 2-6 ■ DNA sequencing by the dideoxy (Sanger) method. A 5′-end-labeled oligonucleotide primer with sequence complementarity to the DNA that is to be sequenced (DNA template) is annealed to a single-strand of the template DNA. This primer is elongated by DNA synthesis initiated by the addition of the enzyme DNA polymerase in the presence of the four dNTPs (2′-deoxynucleoside triphosphates) and one of the ddNTPs (2′,3′-dideoxynucleoside triphosphates); four such reaction tubes are assembled to use all the four ddNTPs. The DNA polymerase enzyme will elongate the primer using the dNTPs and the individual ddNTP present in that particular tube. Because ddNTPs are devoid of 3′ hydroxyl group, no elongation of the chain is possible when such a residue is added to the chain. Thus, each reaction tube will contain prematurely terminated chains ending at the occurrence of the particular ddNTP present in the reaction tube. The concentrations of the dNTPs and the individual ddNTP present in the reaction tubes are adjusted so that the chain termination takes place at every occurrence of the ddNTP. Following the chain elongation-termination reaction, the DNA strands synthesized are size-separated by acrylamide gel electrophoresis and the bands visualized by autoradiography.

individual glass capillaries rather than gel slabs, facilitating loading of samples and other aspects of automation. Whereas manual methods allow the detection of about 300 nucleotide of sequence information with one set of sequencing reactions, automated methods using fluorescent dyes and laser technology can analyze 7500 or more bases per reaction. To sequence larger stretches of DNA it is necessary to divide the large piece of DNA into smaller fragments that can be individually sequenced. Alternatively, additional sequencing primers can be chosen near the end of the previous sequencing results, allowing the initiation point of new sequence data to be moved progressively along the larger DNA fragment.

One of the seminal technological advances has been the introduction of microarray-based methods for detection, and analysis of nucleic acids (discussed later). For purposes of detection of mutations, the oligonucleotides fixed to the slide/membrane are complementary to all possible base substitutions or a subset of small deletions and insertions. Fluorescent labeled PCR probes derived from the patient and representing the genes to be tested are then hybridized to the microarrays. Following appropriate washing protocols, the retention of particular probes on the slide will provide information regarding the presence/absence of a given mutation/deletion/insertion. There are limitations of microarray-based techniques; for example, similar to direct DNA sequencing methods, microarray-based methods also suffer from the disadvantage of not being able to reliably and consistently detect heterozygous mutations. Furthermore, microarrays cannot be used to detect insertions of multiple nucleotides without exponentially increasing the number of oligonucleotides that must be immobilized on the glass slides.

The most exciting new technique in mutation identification is pyrosequencing, which is based on an enzymatic real-time monitoring of DNA synthesis by bioluminescence; this read-as-you-go method uses nucleotide incorporation that leads to a detectable light signal from the pyrophosphate released when a nucleotide is introduced in the DNA strand.[22] The rapidity and reliability of this method far exceed other contemporary DNA sequencing techniques. However, the major limitation of this technique is that it can only be used to analyze short stretches of DNA sequence.

Pyrosequencing, introduced in the early 2000s, provided the background for the explosion of new techniques collectively known as high-throughput or next-generation sequencing (NGS). NGS provides longer read length and cheaper price per base of sequencing compared to Sanger sequencing. NGS is based on the uncoupling of the traditional nucleotide-identifying enzymatic reaction and the image capture and doing so in an ever-speedier way allows for essentially unlimited capacity. Currently, two systems are being used for NGS: the SOLiD (by Applied Biosystems, Inc.) and the Illumina (Solexa) systems. The first discoveries of gene mutations for endocrine diseases exploiting NGS were published in 2011.[21]

Semiconductor and nanotechnology-based systems are currently under use in massive sequencing efforts and promise an even cheaper and faster way of determining mutations and other abnormalities of the human genome; however, these technologies are currently not available for use in clinical pediatric endocrinology.

Indirect Methods

In the mid-1980s, the need for rapid, high-throughput, accurate, and economical mutation analysis systems led to the development of several technologies, as an alternative to analysis by direct sequencing, that allowed detection of single mutations in long stretches of DNA (200 to 600 bp). However, screening for mutations by indirect methods has fallen out of favor as NGS and Sanger sequencing have become faster and cheaper methods for identifying gene mutations. We only refer to them here briefly and for historical purposes, because some of these techniques are still in use sporadically, and understanding the literature published since the 1980s would be impossible without knowledge of the principles underlying these techniques.

Indirect methods of mutation identification included restriction endonuclease digestion of PCR products (PCR-RFLP), denaturing-gradient gel electrophoresis (DGGE), single-strand conformation polymorphism (SSCP), dideoxy fingerprinting (ddF), and heteroduplex mobility assay (HMA). Most of these methods utilized PCR to amplify a region of the DNA, a physical or chemical treatment of amplified DNA (e.g., by denaturation or restriction enzyme digestion), separation of the amplicons by gel electrophoresis (by denaturing or nondenaturing), and visualization of the separated sequence strands (by autoradiography or fluorescence-based detection). Most modifications in some of these techniques allowed simultaneous separation and detection of DNA fragments with the use of sophisticated equipment such HPLC and capillary electrophoresis.

Originally described in 1989, SSCP analysis had been a widely used method for the detection of mutations because of its simplicity and efficiency. In SSCP, DNA regions with potential mutations were first amplified by PCR in the presence of a radiolabeled dNTP (Figures 2-7 and 8). Single-stranded DNA fragments were then generated by denaturation of the PCR products and separated on a native polyacrylamide gel. As the denatured PCR product moved through the gel and away from the denaturant, it regained a secondary structure in a sequence-dependent manner. The electrophoretic migration of single stranded DNA is a function of its secondary structure. Therefore, PCR products that contained substitution differences, as well as insertions and deletions, had different mobility when compared with wild-type DNA. Overall, SSCP, depending on factors such as the specific sequence, amplicon size, and location of the mutation, was successful in 60% to 90% of instances in detecting previously identified sequence changes.

Dideoxy-fingerprinting (ddF) was essentially a hybrid of SSCP and dideoxy-sequencing in which primer extension products were generated in the presence of one dideoxynucleotide and subjected to chemical denaturation and electrophoresis on a non-denaturing polyacrylamide gel

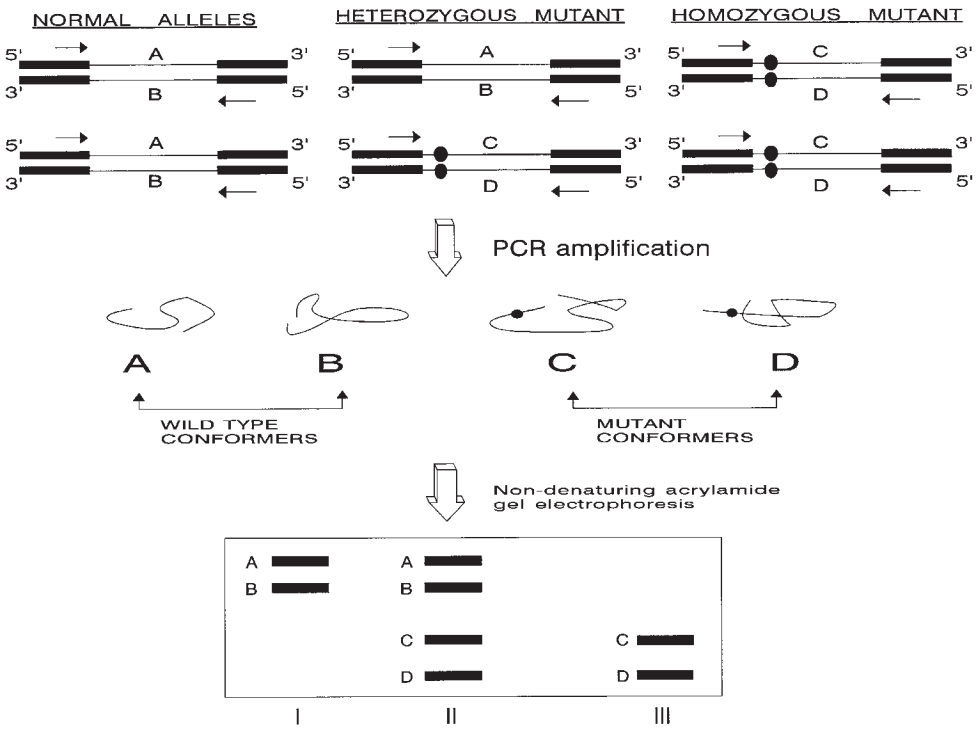

FIGURE 2-7 ■ Single-stranded conformational polymorphism (SSCP). Schematic representation of an experiment designed to use SSCP to detect the presence of heterozygous and homozygous single-base pair mutation (represented as a filled circle). The segment of DNA is amplified using PCR with flanking primers (represented by arrows). ^{32}P is incorporated into the newly synthesized DNA by either end-labeling the primers or by the addition of ^{32}P-dATP to the PCR reaction. Theoretically, four different types of conformers can be formed: A and B from the sense and antisense strand of the wild-type (normal) DNA, C, and D from the sense and antisense strands containing the single-base pair mutation. Following PCR the DNA is denatured and analyzed by nondenaturing gel electrophoresis: Lane I represents the wild-type conformers, Lane II represents the wild-type and mutant conformers from a heterozygous patient, and Lane III represents the presence of mutant conformers with the absence of wild-type conformers from a homozygous patient.

to exploit differences in secondary structure of single stranded conformers. The resulting electrophoretic pattern resembled sequencing gels in which the mobility of extension products was determined by both size and conformation. Modifications of the original procedure resulted in new and improved variants of ddF. Bi-directional ddF (Bi-ddF), in which the dideoxy termination reaction was performed simultaneously with two opposing primers, has allowed larger fragments (~ 600 bp) to be screened with almost 100% sensitivity. RNA ddF (R-ddF), in which RNA was used as starting material, enabled identification of mutations that resulted in splicing errors and allowed screening of genes with large intronic regions. Denaturing fingerprinting (DnF), a modification of Bi-ddF in which fingerprints were generated by performing denaturing gel electrophoresis on bidirectional "cycle-sequencing" reactions with each of two dideoxy terminators, allowed screening of DNA regions with high GC content avoiding the generation of "smearing" bands and, thus, increasing the sensitivity of the technique in identifying heterozygous mutations.

DGGE is a method that was used to detect single-base pair substitutions (or small insertions or deletions) in genes.[23-25] Like SSCP, DGGE is also a PCR-based method and exploited the observation that when double stranded DNA migrates through a polyacrylamide gel incorporating a gradient of chemical denaturing agents, the mobility of the partially denatured ("melted") DNA molecule is extremely sensitive to its base composition. Thus, even single-base changes in the nucleotide composition of the DNA will result in altered mobility of the partially denatured DNA. G-C clamp is a modified DGGE procedure wherein the sensitivity of the procedure is enhanced by the incorporation of a G- and C-rich region at one end of the DNA.[24,26-28] This manipulation is most readily done by modifying one of the primers used for the PCR. The addition of the G-C rich region increases the melting point of the DNA fragment and makes it easier to detect changes in the nucleotide composition. Depending on the relative orientation of the chemical gradient and the electrical field during electrophoresis, DGGE could either be parallel or perpendicular. The relative sensitivity of these two protocols has to be determined empirically for each application of this method. Denaturing high-performance liquid chromatography (DHPLC) is a related technique that detects a variation in the DNA sequence but uses high-performance liquid chromatography (HPLC) instead of gel electrophoresis for separation of DNA fragments. The incorporation of HPLC allows for automation of this technique and significantly enhances improves throughput by this method.

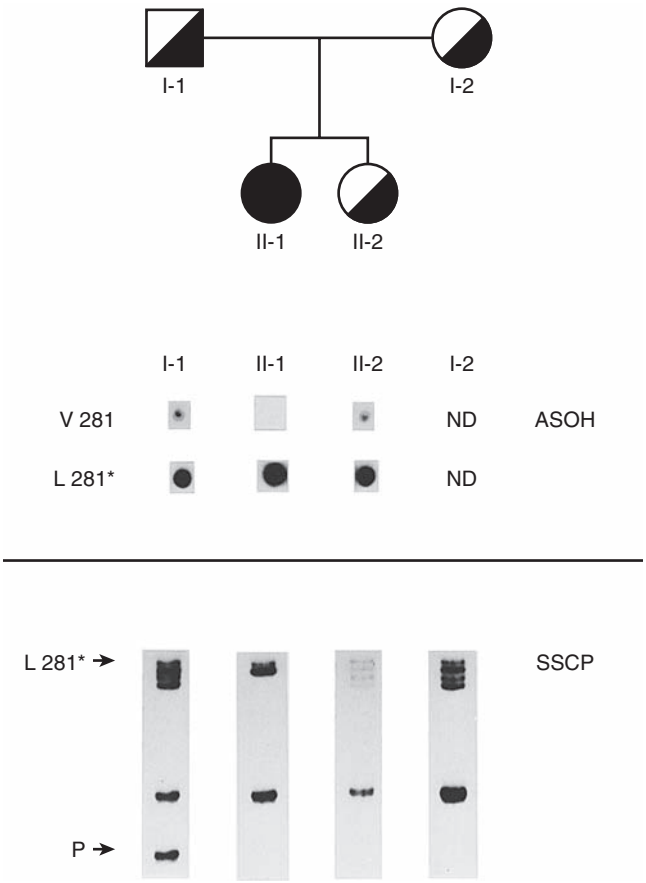

FIGURE 2-8 ■ Application of SSCP and ASOH to the analysis of the 21-hydroxylase gene in congenital adrenal hyperplasia. Detection of a mutation of codon 281 from valine to leucine (V281L). Upper panel: Pedigree of a family with proband II-1, who was referred for evaluation of hirsutism and secondary amenorrhea. Middle panel: ASOH results from both mutant and normal alleles at codon 281 shows both the father and sister of the proband to be carriers of the V281L mutation, while the patient is homozygous. ASOH was not performed on the mother. The asterisk indicated the mutant allele (L281). Lower panel: SSCP analysis revealed that the two additional conformers, representing the L281 conformer, were detected at the top of the gel in this patient and her family. The greater intensity of the conformers in the proband compared to her family members and the disappearance of the normal V281 conformer (adjacent to the L281 conformers) are consistent with her being homozygous for this mutation. L281 indicates the mutant conformer; P, normal polymorphism. (Adapted from Siegel SF, Hoffman EP, Trucco M [1994]. Molecular diagnosis of 21-hydroxylase deficiency: detection of four mutations on a single gel. Biochem Med Metab Biol 51:66.)

Heteroduplex analysis was a variation of the SSCP method and is used to detect single pair mismatches in double-stranded DNA.[29-31] Allele-specific oligonucleotide hybridization (ASOH) and reverse blot technique analyze DNA after amplification by PCR and detect sequence variations by the success or failure of hybridization of short oligonucleotide probes, which either exactly match or mismatch the sequence being tested (Figure 2-9). The amplified, target DNA was first denatured and applied to a nylon membrane in the form of a small dot. Once this target DNA was anchored to the membrane either by heating or by brief ultraviolet irradiation, the DNA was hybridized with a labeled (usually with ^{32}P) oligonucleotide, which encompasses the variable nucleotides of the DNA sequence of interest. The membrane is then washed with a salt solution where the salt concentration and the temperature control the specificity or "stringency" of the procedure. Following the wash, the probe remaining on the membrane was detected by autoradiography. When several nucleotide variations (i.e., alleles) are known to exist in the same target sequence, several identical membranes are prepared and each is hybridized with a different oligonucleotide probe that is complementary to one of the known sequence variations. The major disadvantage of this method was that it required prior knowledge of the base changes involved in the mutation and the precise stringency parameters for hybridization and washing of the membrane. A variation of the original method to perform ASOH is called the reverse blot technique[32] (see Figure 2-9). The difference when compared to ASOH is that the amplified target DNA is labeled and then hybridized to an anchored unlabeled probe. Because the length of the DNA molecules is an important factor that facilitates binding to the membrane, a key to the design of this method was the development of a relatively simple way to synthesize, using the PCR, a stretch of DNA that contained multiple copies (i.e., a polymer) of the relatively short allele-specific oligonucleotide probes.[33] In practice, the amplified DNA is nonradioactively labeled by previously tagging the PCR primers with either fluorescein or biotin. After hybridization of the denatured PCR product in the presence of a membrane containing all of the relevant polymeric probes, and washing as described earlier, the retained PCR products are revealed by detection via enzyme activity linked to either fluorescein antibodies or to streptavidin.

Certain classes of mutations are inherently difficult to detect using the traditional methods of detection outlined here,[18] and thus as NGS and other genomic methods become cheaper and more widely available they are expected to replace all of the preceding techniques. Mutations that are difficult to detect with any of the preceding methods include promoter region, 3′ untranslated region (UTR) or intronic region mutations affecting levels of transcript of mRNA as well as deletions of entire genes or of contiguous exons. Thus, if the genomic region examined is deleted from the mutant allele, PCR-based methods are unable to detect this mutation because the PCR product obtained from the genomic DNA will be exclusively derived from the wild-type allele and thus appear to be normal. Promoter regions, 3′ UTR, and intronic regions usually span genomic segments several orders larger than the coding exons and are thus not easily accessible for analysis with the methods outlined here. Different strategies need to be implemented for the analysis and detection of such mutations. Thus, deletions of one or more exons can be detected by quantitative hybridizations, quantitative PCR, Southern blotting, or fluorescence in situ hybridization with the combined use of such methods enhancing the sensitivity of the testing protocol. A technique termed "conversion" exploits the

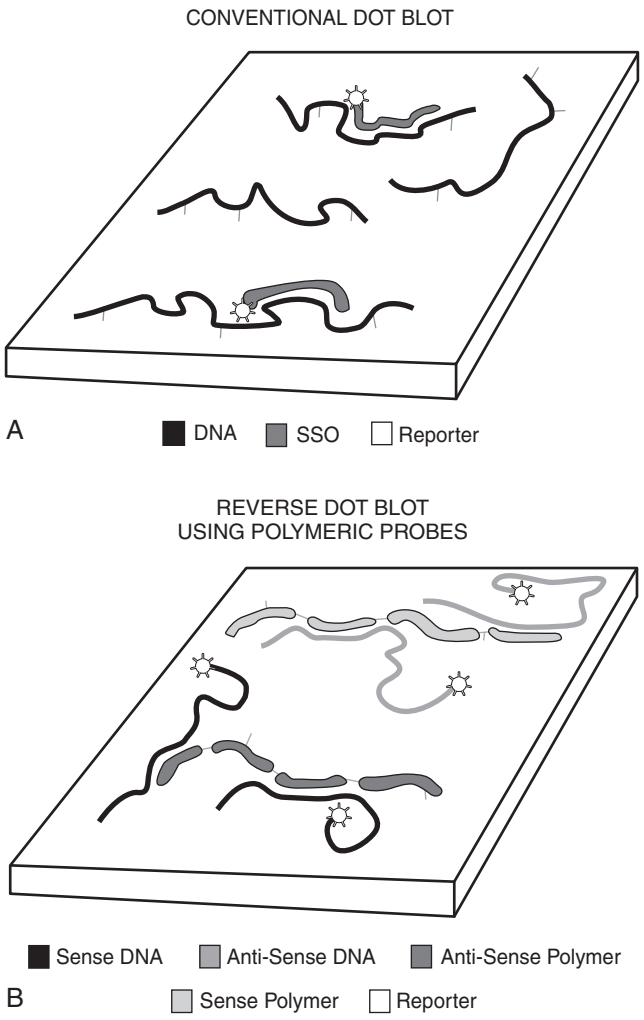

FIGURE 2-9 ■ **A,** Allele specific oligonucleotide hybridization (ASOH). The denatured (single-stranded) target DNA is anchored to a membrane, which is then treated (hybridized) with a solution of a short DNA segment of the gene of interest (sequence-specific oligonucleotide [SSO]). The SSO is tagged with a reporter molecule, such as ^{32}P. Unbound probe DNA is removed by washing with buffer solutions. Appropriate stringency conditions of hybridization and washes limit the hybridization of the probe specifically to its complementary segment in the target DNA molecule. Depending on the manner in which the DNA is spotted on to the membrane, this procedure is referred to as either a dot or a slot blot. **B,** Reverse dot blot. In this variation of the conventional ASOH procedure, the DNA probes (sense and antisense polymer) tagged with the reporter molecule are fixed to a membrane and the denatured target DNA (sense and antisense DNA) is then hybridized to the immobilized probe. Similar to the ASOH procedure, appropriate stringency conditions of hybridization and washes limit the hybridization of target DNA to those that contain the complementary segment to the immobilized probe. The advantages of this method include the increased sensitivity derived from the ability to fix multiple copies (polymer) of the probe to the membrane and that both complementary strands of the probe sequence are present on the membrane. (Adapted from Trucco M [1992]. To be or not to be ASP 57, that is the question. Diabetes Care 15:705.)

principle that the diploid state of the human genome is converted to a haploid state, which is then analyzed by one of the traditional methods.[34] The critical advantage of this manipulation is that heterozygous mutations are easier to detect in the haploid state because of the absence of the normal wild-type sequence.

POSITIONAL GENETICS IN ENDOCRINOLOGY

The Principles of Positional Genetics

For the purpose of disease gene identification, the candidate gene approach relies on partial knowledge of the genetic basis of the disease under investigation. This process was successful in identifying disease genes whose function was obvious. For example, the genetic defects of most of the hereditary enzymatic disorders, including congenital adrenal hyperplasia (CAH) syndromes, became known in the late 1980s, when the introduction of PCR made the tools of molecular biology widely available to the medical and genetic research community. However, at about the same time, research on diseases without any obvious candidate genes (e.g., the multiple endocrine neoplasia [MEN] syndromes) or diseases in which the screening of obvious candidate genes failed to reveal mutations was ongoing. It was in these diseases that the application of "reverse genetics," or more appropriately termed "positional cloning,"[35,36] yielded information regarding the genetic basis of these disease states. Positional cloning is complemented by the Human Genome Project (HGP) and the worldwide web in making available, in a fast and controlled manner, information that would otherwise be inaccessible.[37]

The process of positional genetics is outlined in Figure 2-10. The first step is the collection of clinical information from families with affected members, the determination of the mode of inheritance of the defect (autosomal dominant or recessive, X-linked, complex inheritance), and the phenotyping of subjects (or tissues) following well-established criteria for the diagnosis of the disorder. If inheritance is not known, formal segregation analysis needs to be performed to determine the autosomal, or X-linked, and the recessive or dominant nature of the inheritance.[38] Once this determination is made and the penetrance of the disorder is known, appropriate linkage software may be used.[39] For more information on currently available computer software packages, the reader may check http://darwin.case.edu and other related links.

Linkage is examined with polymorphic markers that span the entire human genome[36]; any marker that shows polymorphism and is known to lie close to or within a putative disease gene may be used. Genetic linkage can be defined as the tendency for alleles close together on the same chromosome to be transmitted together as an intact unit though meiosis. The strength of linkage can then be used as a unit of measurement to find out how close genetically different loci are to each other. This unit of map distance is an approximation of physical distance but is also highly dependent on other factors (for example, the frequency of recombination is not the same in both genders, differing along the length of chromosomes and through the various chromosomes). The likelihood (logarithm of odds [or LOD] score) method is widely used for linkage analysis.

Once a locus on a chromosome has been identified, the region (which is usually several thousands of base pairs in length) is narrowed by analyzing informative recombinations in the cohort of patients and families available for study. The disease region may harbor

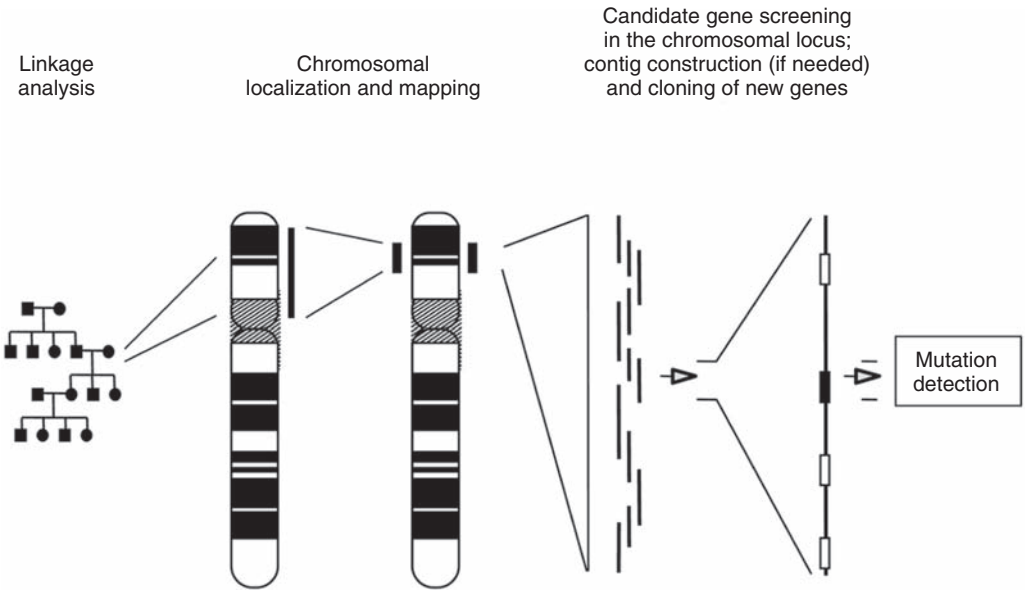

FIGURE 2-10 ■ The steps of positional cloning (see text).

already mapped genes. Online databases such as Gen Bank, ENSEMBL (www.ensembl.org), and others, and especially for clinicians the Online Mendelian Inheritance in Man (OMIM),[40] may provide all the necessary information. If a transcript is a reasonable candidate, mutation screening may identify the disease gene. If, however, these steps fail to identify the disease gene, screening new sequences from the area may be needed; today this is done typically by NGS followed by Sanger sequencing for confirmation. Chromosomal maps are linked by sequence-tagged sites (STSs) that are present in more than one genomic clone, thus providing critical information that allows for the proper aligning of DNA in a given locus. Polymorphic markers (including those that were used for the linkage part of the process) are the most useful STSs because they provide a direct link between the genetic and the physical mapping data. Individual clones can be sequenced; genes are identified in this process through their unique sequence features or through in vitro translation. In the past, expressed sequence tags (ESTs) provided information for what gene sequences are expressed from this area. Today, almost all the genes are fully sequenced; however, ESTs are still useful to look at especially when one is trying to identify a new gene for a given disease-linked locus. Each one of the newly identified genes may be screened for mutations, as long as the expression profile of the identified transcript matches the spectrum of the tissues affected by the disease under investigation. Although this is helpful for most diseases, for others the expression profile may even be misleading; thus, the presence of a transcript in an affected tissue is not always necessary. Complete segregation of the disease with an identified mutation, functional proof, or mutations in two or more families with the same disease are usually required as supportive evidence that the cloned sequence is the disease gene.[41]

Genomic Identification of "Endocrine" Genes

In the 1990s, positional cloning was used to identify a number of genes relevant to endocrinology; today this is being achieved by NGS and other genome-wide methods of identification of new disease genes. It is worth noting that endocrine tumor syndromes, despite their rarity and small overall impact on everyday clinical endocrine practice, are seminal examples of diseases whose molecular etiology was elucidated by positional cloning. Positional cloning played an essential role in unraveling the etiology of these syndromes because for most endocrine tumor syndromes there were no obvious candidate genes. Furthermore, positional cloning of genes responsible for familial tumor syndromes was greatly assisted by the use of neoplastic tissue for studies such as loss-of-heterozygosity (LOH), comparative genomic hybridization (CGH), and fluorescent in situ hybridization (FISH) applications. These techniques narrowed the genetically defined chromosomal regions and thus facilitated the identification of the responsible genes; LOH studies were critical in the identification of von Hippel–Lindau disease (VHL-elongin),[42] MEN 1 (menin),[43] Cowden disease (PTEN),[44] Peutz-Jeghers syndrome (STK11/LKB1),[45,46] and Carney complex (PRKAR1A)[47] genes.

NGS is used today to sequence the entire genome (whole-genome sequencing [WGS]) or only the expressed genes (whole exome sequencing [WES]) of a proband (or his family members) with the intention to identify the mutations responsible for a disease after the methods described here have positionally identified a locus of interest. In the absence of linkage or other positioning information (such as, for example, in the absence of family history, tumor material, or additional DNA samples) an individual's genomic DNA (or tissue derived from the individual) may be sequenced by WGS or WES.

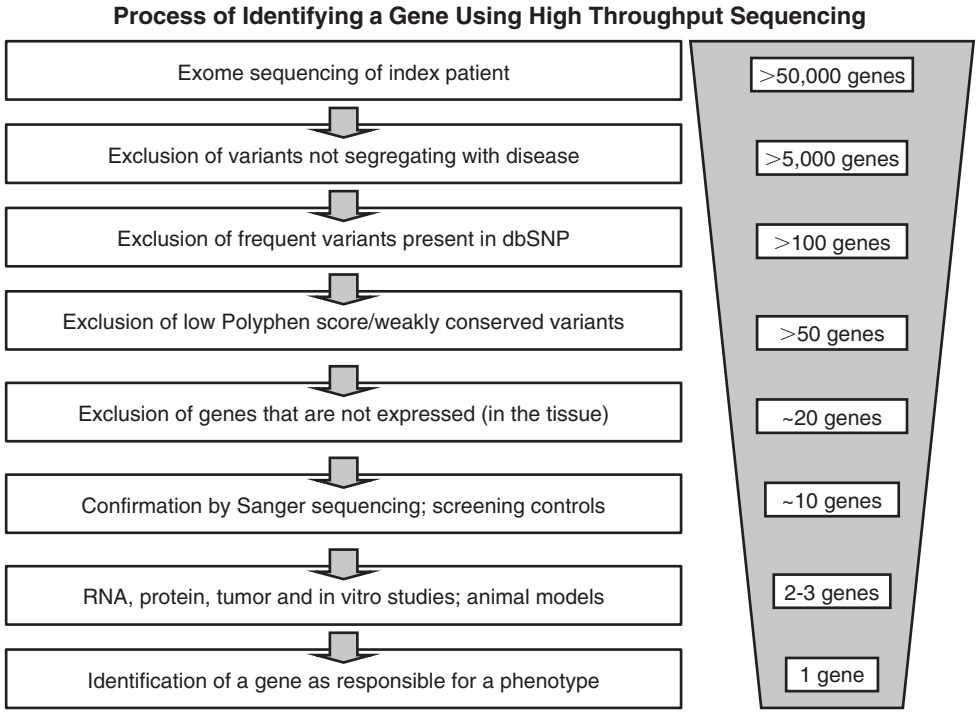

FIGURE 2-11 ■ Whole genome or exome sequencing is the currently preferred DNA sequencing technology for gene identification. However, even in the genome of phenotypically normal human subjects, these sequencing techniques yield a multitude of sequencing variants, including bona fide protein-truncating mutations, hence the need to use a systematic and careful filtering process to identify the causative gene(s). The steps in the analysis of gene mutations identified by high throughput sequencing techniques that culminate in the assignment of a gene to a specific phenotype are illustrated.

This, however, leads to the identification of many mutations and other variants that need to be excluded to identify the disease-specific gene(s). A typical flowchart for something like this is shown in Figure 2-11.

Impact of Modern Sequencing in Clinical Practice

Today genome-sequencing studies indicate that each human subject carries as many as 100 loss-of-function mutations with more than 20 genes being completely inactivated.[49] Many genetic variants are found to have previously unsuspected functional redundancies,[50,51] thus a patient may have many genetic variants within a singular signaling pathway leading to graded phenotypes.

An example of the application of the techniques of modern DNA sequencing in pediatric endocrinology that resulted in the elucidation of the disease mechanism is in the so-called white Addison disease (WAD) phenotype.[52,53] It has been recognized that patients presenting with primary adrenal insufficiency (pAI) are not always pigmented; this variant of pAI was called WAD. Increased pigmentation in pAI is attributed to the binding of high levels of adrenocorticotropin (ACTH) to the melanocortin (MC) 1 receptor (MC1R). MC1R, a molecule with high degree of sequence similarity to the MC2R, the ACTH receptor, binds to its regular ligand, α-melanocyte-stimulating hormone (α-MSH) and ACTH with an almost equal affinity.[54] α-MSH stimulates melanogenesis in cultured human melanocytes and acts specifically to increase the synthesis of eumelanin. Both α-MSH and ACTH are splice products of the same precursor pituitary protein, proopiomelanocortin (POMC), and play a role in determining pigmentation in humans, as homozygous or compound heterozygote mutations in the POMC gene are associated with hypopigmentation and red hair. In pAI that is not appropriately treated with glucocorticoids, POMC expression increases, and both α-MSH and ACTH increase. The important role of MC1R in the determination of human skin and hair pigmentation is beyond doubt: reduced function MC1R alleles lead to red hair, freckling, sun sensitivity, and an increased risk of cutaneous cancers, including melanoma.[54,55]

Familial glucocorticoid deficiency (FGD) due to ACTH resistance consists of at least three distinct genetic syndromes that are all inherited as autosomal recessive (AR) traits: inactivating mutations of the ACTH receptor (the MC2R gene) and its accessory protein (MRAP); isolated ACTH resistance (iACTHR) without MC2R, MRAP, or any other known mutation; and Allgrove syndrome (AS).[56,57] Turan and colleagues[52] described a patient with FGD without pigmentation: she was born with red hair, which gradually darkened during early childhood; despite repeated episodes of hypoglycemia, she was not diagnosed with pAI and was thus exposed to high ACTH levels until she was 6 years old. MC2R sequencing showed a homozygous T152K mutation that is known to affect trafficking of the receptor, like most ACTH receptor defects causing FGD. MC1R sequencing showed a homozygous R160W mutation that is

among the most common genetic variants of the receptor in red-haired individuals. In a fascinating confirmation of the roles of ACTH (and possibly other POMC-derived peptides) and MC1R in determining not only skin but also hair pigmentation, the patient's hair lightened and "reverted to a reddish color" following proper replacement with hydrocortisone and a decrease of serum ACTH levels.

This is the first demonstration of MC1R genetic variants affecting the phenotype in pAI. It is possible that MC1R, the major freckle gene, modifies the phenotype in Carney complex and other disorders associated with skin pigmentation and endocrine disease (e.g., McCune-Albright syndrome, neurofibromatosis syndromes, and others). Beyond the obvious diagnostic implications, MC1R variants also predispose to nevi and cancer. Could, for example, the nevi observed in Turner syndrome and their response to growth hormone (GH) depend on MC1R function? And how might variant MC1R signaling affect the function of other melanocortin receptors that to some extent interact and coordinate their cAMP responses? Would the clinical presentation of an MRAP defect causing FGD or an AAAS mutation causing AS be affected equally by MC1R variants?

With genetic variants responsible for even subtler effects (than, for example, red hair), DNA sequencing data challenge the practicing clinician to incorporate systems biology information in clinical practice. Clearly not all sequence defects identified by WGS or WES cause diseases; quite the opposite. The evidence is that there is redundancy and an exquisitely delicate and complex molecular balance in human biology. But clinicians have to incorporate genetics in their daily practice, and educators have to introduce molecular pathways and their genetic variability in classic physiology and pathophysiology lectures.[58]

EXPRESSION STUDIES (MICROARRAYS, SAGE)

Advances in biotechnology, instrumentation, robotics, computer sciences, and the completion of genome sequencing initiatives for several organisms, including the human, have resulted in the development of novel and powerful techniques. A seminal example of such a technique is the development of the microarray technology. Microarrays contain thousands of oligonucleotides deposited or synthesized in situ on a solid support, typically a coated glass slide or a membrane. In this technique, a robotic device is used to print DNA sequences onto the solid support. The DNA probes immobilized on the microarray slide as spots can either be cloned cDNA or gene fragments (ESTs, expressed sequence-tags), or oligonucleotides corresponding to known genes or putative open reading frames. The arrays are hybridized with fluorescent targets prepared from RNA extracted from tissue/cells of interest; the RNA is labeled with fluorescent tags such as Cy3 and Cy5. The prototypic microarray experimental paradigm consists of comparing mRNA abundance in two different samples. One fluorescent target is prepared from control mRNA and the second target with a different fluorescent label is prepared from mRNA isolated from the treated cells or tissue under investigation. Both targets are mixed and hybridized to the microarray slide, resulting in target gene sequences hybridizing to their complementary sequences on the microarray slide. The microarray is then excited by laser, and the fluorescent intensity of each spot is determined with the relative intensities of the two colored signals on individual spots being proportional to the amounts of specific mRNA transcripts in each sample (Figure 2-12). Analysis of the fluorescent intensity data yields an estimation of the

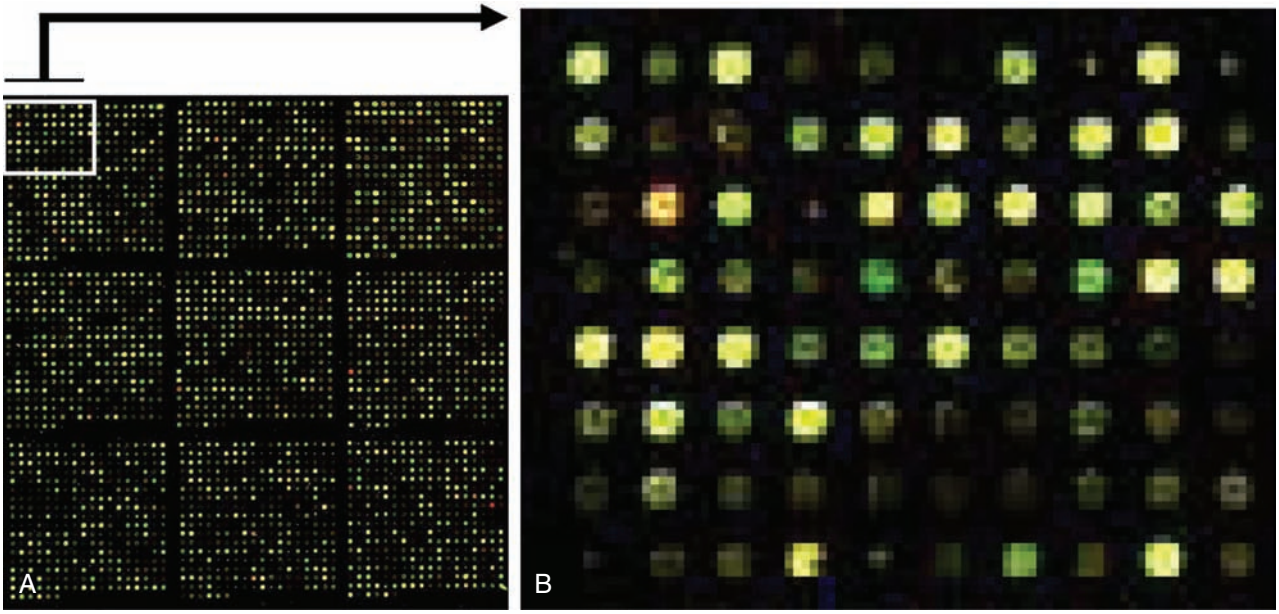

FIGURE 2-12 ■ **A,** cDNA microarray, fluorescent labeled cDNA targets, ACTH-independent bilateral macronodular adrenal hyperplasia (Cy3), and ACTH-dependent hyperplasia (Cy5) were hybridized to glass slides containing genes involved in oncogenesis. Following laser activation of the fluorescent tags, fluorescent signals from each of the DNA "spots" are captured and subjected to analysis. **B,** Magnified view of the microarray platform displaying the fluorescent signals; green (Cy3) and red (Cy5) with yellow representing overlap of these two colors. *(This image can be viewed in full color online at ExpertConsult.)*

relative expression levels of the genes in the sample and control sample. Microarrays enable individual investigators to perform large-scale analyses of model organisms and to customize arrays for special genome applications.

The method of choice for global expression profiling depends on several factors including technical aspects, labor, price, time and effort involved, and, most important, the type of information that is sought. Technical advances in the development of expression arrays, their abundance and commercial availability, and the relative speed with which analysis can be done are all factors that make arrays more useful in routine applications. In addition, array content can now be readily customized to cover from gene clusters and pathways of interest to the entire genome: some studies examine series of tissue-specific transcripts or genes known to be involved in particular pathology; others directly use arrays covering the whole genome. Another factor that needs to be considered prior to embarking on any high-throughput approach is whether individual or pooled samples will be investigated. Series of pooled samples reduce the price, the time spent, and the number of the experiments down to the most affordable. Investigating individual samples, however, is important for identifying unique expression ratios in a given type of tissue or cell.

A requirement of all high-throughput screening approaches is confirmation of findings (expression level of a given gene/sequence) by other independent methods. A select group of genes are tested usually; these genes are picked from the series of sequences that were analyzed either because they were found to have significant changes or because of their particular interest with regard to their expression in the studied tissue or their previously identified relationship to pathology or developmental stage. The confirmation process attempts to support the findings on three different levels: (1) reliability of the high-throughput experiment (for this purpose the same samples examined by the microarrays are used); (2) trustfulness of the observations in general (to achieve that, larger number of samples are examined, assessment of which by high-throughput approaches is often unaffordable price- or labor-wise); and (3) verification of the expression changes at the protein level.[58] A commonly used confirmatory technique is quantitative real-time reverse transcription PCR (qRT-PCR). For verification at the protein level, immunohistochemistry (IHC) and Western blot are the two most commonly chosen techniques. IHC is not quantitative but has the advantage of allowing for the observation of the exact localization of a signal within a cell (cytoplasmic versus nuclear) and the tissue (identifying histologically the tissue that is stained). Modern Western blot methods require a smaller amount of protein lysate than older techniques and have the advantage of offering high-resolution quantitation of expression without the use of radioactivity.

CHROMOSOME ANALYSIS AND MOLECULAR CYTOGENETICS

Chromosomes represent the most condensed state in metamorphosis of the genome during a cell cycle. Condensation of the genetic material at metaphase stage is a crucial event that provides precise and equal segregation of chromosomes between the two daughter's newborn cells during the next step, anaphase. This is followed by relaxation of the genetic content after cell division. This ability of the genome to transform from a molecular level (DNA) to a materialistic submicroscopic stage (chromosome) provides a unique opportunity to visualize the genome of an individual cell of an organism. Different chromosomal abnormalities related to particular diseases or syndromes can be detected at this stage by karyotyping chromosomes.

Chromosomes can be individually recognized and classified by size, by shape (ratio of the short/long arm), and by using differential staining techniques. In the past, identification of chromosomes was restricted to chromosome groups only. The introduction of chromosome banding technique revolutionized cytogenetic analysis.[59] The banding patterns are named by the following abbreviations: G for Giemsa, R for reverse, Q for quinacrine, and DAPI for 4′6′-diamino-2-phenylindole; the last two give a pattern similar to G-banding. Further development of high-resolution banding techniques[60] enabled the study of chromosomes at earlier stages of mitosis, prophase, and prometaphase. Chromosomes are longer and have an enriched banding pattern at those stages, providing great details for the identification of chromosomal aberrations.

Outline of Methods

Preparation of good-quality chromosomes is an art. Many different methods for chromosome isolation have been developed in cytogenetics since the 1960s. The main principle behind all methods is to arrest cells at metaphase by disruption of the cell spindle. Metaphase spindle is a structure composed of tubular fibers formed in the cell to which the chromosomes are attached by kinetochores (centrosomes). The spindle separates the chromosomes into the two daughter cells. The agent commonly used for spindle disruption is Colcemid. The exposure time to Colcemid varies depending on the proliferative activity of cells. Cells with a high proliferative index need a shorter time of exposure to a high concentration of Colcemid, 0.1 to 0.07 μg/mL for 10 to 20 minutes. Slow-growing cells require longer exposure, 1 to 4 hours or overnight with a lower concentration, 0.01 to 0.05 μg/mL. Prolonged exposure to Colcemid or the use of high concentrations increases the proportion of chromosomes at late metaphase, resulting in shortening of the chromosomes. Conversely, a short exposure with a high concentration of Colcemid reduces the total yield of metaphases. The optimum strikes a balance of these parameters. There are some additional modifications that allow for the enrichment of long (prometaphase) chromosomes by using agents that prevent DNA condensation, such as actinomycin D, ethidium bromide, or BrDU. Cell synchronization techniques can also significantly increase the total yield of metaphase chromosomes.

Applications

Chromosomes are invaluable material for the evaluation of the genome integrity and its preservation at the microscopic chromosomal level. The areas of application

include prenatal diagnostics, genetic testing of multiple familial syndromes including cancer, positional cloning of the genes, and physical mapping (assignment of the genes on chromosomes and subchromosomal regions). The number and morphology of all 23 chromosome pairs in humans can be examined using G-banding differential staining of chromosomes obtained from a peripheral blood sample. Aberrations in the number of chromosomes or visible chromosomal alterations, such as translocations, deletions, and inversions involving extended regions, can be detected by this method. Advances such as spectral karyotyping (SKY) allow for better visualization of aneuploidy and translocations between different chromosomes.[61] Subtle rearrangements, such as submicroscopic deletions or cryptic translocations (an exchange of the small distal telomeric regions between the two nonhomologous chromosomes), can be visualized using specific probes in the FISH technique[62] (Figure 2-13).

Future Developments

Chromosome analysis will remain a powerful analytic tool in clinical and research fields for the foreseeable future. Possible strategies to improve existing methods include automatization and linearization of the genetic content by increasing resolution to visualize at the level of the chromosome, chromatin, DNA, and gene. Another possible direction of development is functional analysis of the genome using constitutional chromosomes and labeled expressed sequences from particular tissues mapped directly to their original positions on chromosomes.

MOLECULAR BASIS OF PEDIATRIC ENDOCRINOPATHIES

Since the 1990s, the application of recombinant DNA technology to the understanding of the pathogenesis of endocrinopathies has increased. Although this new approach to endocrinologic disorders has resulted in the delineation of new syndromes, its major impact has been in facilitating the diagnosis of these disorders. Genetic counseling including anticipatory surveillance, such as in multiple endocrine neoplasia (MEN) syndromes (Chapter 14), is also one of the areas of clinical pediatric endocrinology with major impact of this "new" knowledge. For example, it is becoming increasingly clear that phenotypically homogenous clinical syndromes may result from different genotypical abnormalities and that similar genetic abnormalities may have very different clinical manifestations. In contrast, therapeutic implications of such knowledge are still limited. Hence, the earlier hopes of spectacular gains from gene therapy have not been realized and significant problems need to be addressed before gene therapy becomes a reality in routine patient care. However, targeted pharmacotherapy exploiting knowledge gained regarding molecular mechanisms and pathogenesis has been successfully employed in the treatment of some diseases such as androgen insensitivity and thyroid cancer. This section demonstrates a couple of seminal examples of clinical endocrine disorders whose molecular basis has been elucidated. Details of the specific disorders are elaborated in the respective chapters of this book.

Defects in Peptide Hormones

Genomic Deletions Causing Human Endocrine Disease

One of the early discoveries regarding the molecular basis of endocrinopathies was the absence of the gene coding for a particular peptide hormone; the entire gene could be missing or only a part of the gene could be deleted. In either case, this resulted in the inability to synthesize a functional peptide so that the patient presents with clinical features indicative of deficiency of the hormone. A classical example of this type of endocrinopathy relevant to pediatric endocrinology is isolated growth hormone deficiency, type 1A (IGHD 1A).[63] In this syndrome the gene for human growth hormone-N (hGH-N) is deleted; disease results when both alleles of hGH-N are absent (indicative of an autosomal recessive inheritance). In the human there are two hGH genes (hGH-N and hGH-V) and both of them, along with the three placental lactogen (chorionic somatomammotropin) genes, are clustered along a 48-kilobase region of DNA. hGH-N is expressed in the pituitary gland and is the source of circulating GH in the human, whereas hGH-V is expressed only in the placenta and its biological function is not clear at this time. In autosomal recessive, type 1A isolated GH deficiency, although hGH-V is intact, the absence of the active gene, hGH-N, results in deficiency of circulating GH and the GH-deficient phenotype. In the original case description, the infants were of relatively normal size at birth but developed severe growth failure during the first year of life. A distinctive feature of these infants was the propensity to develop antibodies against GH in response to exogenously administered GH. This feature, although common, is not invariably present in patients with IGHD 1A. The state of the art method for screening for an hGH-N deletion is based on the PCR amplification of the highly homologous regions of DNA on the long arm of chromosome 17 that flank the *hGH-N* gene.[64,65] The presence of convenient restriction enzyme sites, such as SmaI, in the amplified DNA is exploited to ascertain the presence or absence of deletions in this region of the chromosome. Although this PCR-based approach is useful in most cases, it does not identify all cases with abnormalities in the *hGH-N* gene. In particular more rigorous methods are required for the identification of the less common causes of IGHD-1A such as point mutations. The study of the hGH-hPL gene cluster has also shed light on the function of prolactin, as several studies have identified subjects with hPL deletions. These deletions do not result in overt clinical abnormalities and specifically do not cause clinical effects in pregnant patients, suggesting that, despite high levels of hPL found during pregnancy, hPL serves no essential function in the human.[66]

Point Mutations

Peptide hormones act by binding to a specific receptor, which then results in the biological actions attributed to that particular hormone. The binding of the peptide hormone to its receptor, classically described as the lock and key mechanism, is a precise mechanism dependent on the complementary structures of the receptor and the site on the hormone that is involved in binding to the receptor. A change in the nucleotide sequence of the gene coding for a peptide hormone that results in altering an amino acid residue of the hormone can affect the function of the hormone if this change interferes with the hormone's ability to either bind or activate the receptor. Historically, point mutations resulting in aberrant protein production were well described with hemoglobin. This was possible because hemoglobin is present in abundant quantities in the blood, enabling purification and analysis of hemoglobin from patients suspected to have hemoglobinopathies. On the other hand, peptide hormones are present in infinitesimally lesser amounts in circulation, making their direct purification and analysis from blood a more daunting task. With the advent of recombinant DNA technology, it became feasible to clone and analyze the gene coding for the hormone directly, without having to resort to purification of the protein from blood or tissue. This approach has resulted in the identification of several clinical syndromes due to mutant hormones. One of the classical examples of this type of molecular pathology is noninsulin diabetes mellitus (NIDDM) due to mutant insulins.[67] A number of patients have been described with point mutations in the insulin gene. In general these patients present with hyperglycemia, hyperinsulinemia, and normal insulin sensitivity, a clinical picture that is attributed to the production of an abnormal insulin molecule with reduced biological activity. Thus, Insulin Chicago is characterized by a single nucleotide change, TTC to TTG, which results in the substitution of a leucine for phenylalanine residue at position 25 of the B chain (Phe-B25-Leu). Similarly, the other two well-characterized point mutations are characterized by the change of a single amino acid residue and result in the formation of Insulin Wakayama (Val-A3-Leu) and Insulin Los Angeles (Phe-B24-Ser). These mutations are located within the putative receptor-binding region of the insulin molecule, and the insulin molecules transcribed from these mutant genes are characterized by low binding potency ($< 5\%$ compared to normal) for the insulin receptor. A separate class of mutations in the insulin gene gives rise to the syndrome of hyperproinsulinemia with or without clinically significant carbohydrate intolerance. Thus, two mutations described involve substitution of a histidine for an arginine at position 65, and in the other case histidine at position 10 of the B chain is changed to aspartic acid. Although the original descriptions of these mutant insulins relied on the purification and analysis of the abnormal insulin molecule per se, the current availability of PCR-based methods to screen for these mutations has greatly simplified the laboratory diagnosis of this syndrome.

Another example of point mutations resulting in a phenotype that is especially relevant to pediatric endocrinologists is hypopituitarism secondary to abnormalities in transcription factors that orchestrate embryologic development of the anterior pituitary gland.[68,69] POU1F1 (also known as Pit1 or GHF-1) was the first transcription factor that was identified to play a specific role in

pituitary development. The *POU1F1/PIT-1* gene encodes a 291 amino acid POU homeodomain DNA binding nuclear protein that is present in somatotrophs, lactotrophs, and thyrotrophs. *POU1F1/PIT-1* is necessary for the normal development of these pituitary cell types. The first indication that abnormalities in *POU1F1/PIT-1* may result in a phenotypic change was derived from studies on strains of mice with genetic forms of dwarfism. The Snell and Jackson strains of dwarf mice are characterized by a deficiency of GH, prolactin, and thyroid-stimulating hormone (TSH). In 1990 Li and colleagues reported that Snell phenotype was caused by a missense mutation and that the Jackson phenotype was caused by a rearrangement in the *POU1F1/PIT-1* gene.[70] Since this landmark study, several recessive and dominant types of *POU1F1/PIT-1* abnormality have been recognized in sporadic cases and multiplex families with hypopituitarism.[71-73] *POU1F1/PIT-1* activates GH and prolactin gene expression, and can bind to and transactivate the TSH-B promoter. Accordingly, patients with *POU1F1/PIT-1* mutations demonstrate GH, prolactin, and variable TSH deficiencies.[71] It can be inherited in an autosomal dominant or recessive manner, but *POU1F1/PIT-1* mutations are not a common cause of combined pituitary hormone deficiencies.

HESX1 is a paired-like homeodomain transcription factor expressed in the developing pituitary gland. Mutations in this gene leading to decreased activity have been found in two siblings with panhypopituitarism, absent septum pellucidum, optic nerve hypoplasia, and agenesis of the corpus callosum, implicating a role for HESX1 in mediating forebrain development.[74,75] Another mutation in HESX1 was recently discovered in a patient with septo-optic dysplasia and isolated growth hormone deficiency.[76] Experimental evidence suggests that this particular mutation results in the production of an altered HESX1 protein with enhanced DNA binding activity that abrogates the transcriptional activity of PROP1, another transcription factor necessary for pituitary development.

PROP1 is thought to be involved in the differentiation of somatotropes, thyrotropes, lactotropes, and gonadotropes. Mutations in PROP1 leading to reduced DNA-binding and transcriptional activity have been identified in patients with combined pituitary hormone deficiency. These patients have a deficiency of TSH, GH, prolactin, luteinizing hormone (LH), and follicle-stimulating hormone (FSH).[77] Patients with a demonstrated gonadotropin deficiency may present with failure to enter puberty spontaneously, whereas other patients do enter puberty but have a subsequent loss of gonadotropin secretion. Although PROP1 is directly implicated in the differentiation of only four out of the five anterior pituitary cell types, some patients have also been described with ACTH deficiency. PROP1 mutations are believed to be relatively common (32% to 50%) genetic causes of combined pituitary hormone deficiency (PTH).[78]

Rathke's pouch initially forms but fails to grow in LHX3-knockout mice.[79] Humans have been found to have mutations in the *LHX3* gene, a LIM-type homeodomain protein, and demonstrate complete deficits of GH, prolactin (PRL), TSH, and gonadotropins in addition to a rigid cervical spine leading to limited head rotation. LHX4 is a related protein, which similar to LHX3 regulates proliferation and differentiation of pituitary lineages. A patient has been identified with a dominant mutation in this protein demonstrating deficiencies of GH, TSH, and ACTH, a small sella turcica, a hypoplastic anterior hypophysis, an ectopic posterior hypophysis, and a deformation of the cerebellar tonsil into a pointed configuration.[80]

Finally, Rieger syndrome is a condition with abnormal development of the anterior chamber of the eye, dental hypoplasia, and a protuberant umbilicus associated with growth hormone deficiency. All mutations in RIEG (Pitx2) found thus far have been heterozygous, with an autosomal dominant inheritance.[81]

Defects in Peptide Hormone Receptors

Molecular defects resulting in phenotypic abnormalities in humans have been described in a variety of peptide hormone receptors including GH, LH, FSH, TSH, ACTH, and insulin, and it is expected that this list will continue to expand in the future. Mutations in receptors for peptide hormone interfere in the actions of the hormone by altering the binding of the hormone, by altering the number of the receptors available for binding to the hormone, by interfering with the synthesis or intracellular processing of the receptor, or by disrupting the activation of the postreceptor signaling pathways. In general, mutations in the receptor result in decreased actions of the cognate hormone. However, mutations involving G-protein linked receptors are exceptions to this generalization and can result in a phenotype characterized by "overactivity" of the particular hormone system. Examples of these "gain of function" mutations include mutations in the LH receptor responsible for familial testotoxicosis[82] and mutations in the TSH receptor causing thyrotoxicosis[83] (refer to Chapter 7).

Insulin Receptor

Following the initial reports in 1988, a variety of mutations have been identified in the insulin receptor gene, with the majority of them being in patients with genetic syndromes associated with acanthosis nigricans and insulin resistance.[84] Patients with leprechaunism, a congenital syndrome characterized by extreme insulin resistance, fasting hypoglycemia, and intrauterine growth retardation, have two mutant alleles of the insulin receptor gene. Another syndrome associated with acanthosis nigricans and extreme insulin resistance, the Rabson-Mendenhall syndrome, has been linked to two different mutations within the insulin receptor gene existing in a compound heterozygous state. The syndrome of type A insulin resistance is a heterogeneous collection of conditions defined by the presence of insulin resistance, acanthosis nigricans, and hyperandrogenism in the absence of lipoatrophy or obesity. Molecular analysis of the insulin receptor gene has revealed that several of these patients have mutations in either one or both alleles of the insulin receptor gene. The initial expectation of mutations in the

insulin receptor providing the molecular basis for the common type of type 2 (NIDDM) diabetes mellitus has not been justified. Hence, no alterations in the insulin receptor gene were identified in a study of Pima Indians, an ethnic group with a greater than 50% incidence of type 2 diabetes mellitus. It is noteworthy, however, that studies have advanced the search for genetic variations that influence the propensity to develop type 2 diabetes mellitus.[85,86] Positional cloning-based analysis suggests that specific polymorphisms in the *CAPN10* gene are associated with type 2 diabetes mellitus in the Finnish and Mexican-American (Pima Indian) populations. Whether these genetic variations in the *CAPN10* gene, located on chromosome 2, which encodes a widely expressed calpain-like cysteine protease, are causal factors for type 2 diabetes mellitus or merely co-segregating markers remains to be established. However, current studies have not excluded the possibility that polymorphisms in the insulin receptor gene may confer a genetic predisposition for the precipitation of the development of NIDDM by obesity or hypertension.

GH Receptor

Genetic abnormalities in the GH receptor result in the primary form of the syndrome of GH insensitivity, also called Laron syndrome.[87] The human GH receptor gene, located on the proximal part of the short arm of chromosome 5, spans approximately 90 kilobases and includes nine exons, numbered 2 through 10, that encode the receptor protein, and additional exons in the 5′ untranslated region of the gene. The GH receptor protein contains an open reading frame of 638 amino acids, which predicts a 246 amino acid-long extracellular ligand-binding domain, a single membrane spanning domain and a cytoplasmic domain of 350 amino acids. In the human, the extracellular portion of the receptor exists in circulation as the GH-binding protein (GHBP). Exon 2 encodes a signal sequence, exons 3 through 7 the extracellular GH-binding domain, exon 8 the transmembrane domain, and exons 9 and 10 the cytoplasmic domain and the 3′ untranslated region. The mutations that have been described in the GH receptor gene include large deletions, nonsense mutations, splice mutations, and frameshift mutations.[88] The diagnosis of growth hormone insensitivity resulting from mutations in the growth hormone receptor gene is considered when patients demonstrate elevated GH levels and low IGF-1 levels. Because the growth hormone binding protein (GHBP) is the cleaved extracellular portion of the growth hormone receptor, patients with mutations in the growth hormone receptor that result in decreased synthesis of the receptor protein can demonstrate low GHBP levels in circulation. However, mutations in the growth hormone receptor gene that selectively involve the transmembrane or intracellular domains may demonstrate normal or even enhanced circulating levels of GHBP. For example, a patient with a mutation inhibiting dimerization of the receptor had normal GHBP levels because the receptor had a normal GH-binding site.[89] Another set of affected individuals had a mutation of the transmembrane domain of the receptor, leading to a truncated growth hormone receptor product that is postulated to be more easily released from the cell membrane and elevated GHBP levels were noted.[90]

PRINCIPLES OF INTERPRETATION OF GENETIC TESTS IN THE DIAGNOSIS AND MANAGEMENT OF PEDIATRIC ENDOCRINE DISEASES

In the past, genetic tests were usually carried out by research laboratories that had a specific interest in the disease/syndrome under investigation. Under this scenario the medical provider could generally rely on the expertise of the research laboratory to help with the identification of the appropriate test/test panel and interpretation of the results of the tests. However, with the increasing use of commercial laboratories for these tests, these responsibilities are being transferred to the medical providers. Hence, it is now essential for medical providers to become familiar with issues such as choosing of the appropriate test, the potential usefulness of the information provided by the test including false-positive and false-negative results, available preventive or treatment options, and social and behavioral issues related to genetic testing. The following are some of the points that should be taken into account when ordering or interpreting a genetic test for a pediatric endocrine disorder:

Limitations of commonly used PCR-based assays. In general routine PCR-based assays (whether they involve electrophoresis or DNA sequencing of the product) cannot reliably differentiate between the two alleles of an individual gene. Hence, in a given instance the detection of a mutation in an autosomal recessive disease could be either due to the mutation being present in only one of the alleles (and thus not likely to have clinical manifestation) or due to the mutation being present in a single allele with the other allele being absent (e.g., due to gene deletion) in which case the mutation in the one allele present would clinically manifest. In a similar manner the inability to amplify a loss-of-function mutant allele by PCR could either be due to the presence of two normal alleles (hence excluding the genetic defect) or because of the absence of both the alleles (due to gene deletion) in which case the genetic defect would be symptomatic. In many cases the latter scenario can be excluded by testing using alternative techniques such as Southern blotting.

Germline versus somatic mutation. Germline mutations are present in every cell descended from the zygote to which that mutant gamete (ova/sperm) contributed. In contrast, somatic mutations occur in a somatic cell (e.g., liver or bone marrow or skin) and hence are not present in other cell types in the body. Most common examples of inherited mutations are germline mutations. Examples of somatic mutations causing endocrine disorders are more rare—for example, in McCune-Albright syndrome the mutation in the GNAS gene may only be detectable in the skin (café au lait) or the bone (fibrous dysplasia) lesion.

Disorders of imprinting. In many instances, the genetic basis of the endocrine disorder is not due to a mutation but

rather is due to an abnormality in genomic imprinting. Genomic imprinting is the modification of gene expression dependent on whether the genetic material is inherited from the mother or the father. Classic examples are Prader-Willi syndrome (chromosome 15q12 deletion inherited from father) and Angelman syndrome (chromosome 15q12 deletion inherited from mother). Other examples of endocrine disorders in which imprinting is implicated are pseudohypoparathyroidism and Albright hereditary osteodystrophy, Russell-Silver syndrome, Beckwith-Wiedemann syndrome, the focal form of persistent hyperinsulinemic hypoglycemia of infancy (PHHI), and transient neonatal diabetes.

Penetrance and expressivity. Penetrance is defined as the percentage of people who have the gene and who develop the cognate phenotype. Expressivity is the extent to which a gene is expressed in one person. For example, when a gene has 50% expressivity, only half the features are present or the disease severity is only half of what can occur with full expression. The variable penetrance of many of the neoplastic components of the MEN syndrome is an example of this phenomenon.

One gene, multiple diseases. Examples of mutations in the same gene causing different disease (e.g., lamin A/C gene [LMNA] mutation causing Emery-Dreifuss muscular dystrophy, Hutchinson-Gilford Progeria, Charcot-Marie-Tooth type 2, familial partial lipodystrophy syndrome, and dilated cardiomyopathy). In many such instances, the variability can be attributed to specific mutation(s) for each of the different clinical manifestations or sets of mutations within different domains/regions of the gene. A similar example is mutations in the RET oncogene implicated in MEN2 syndromes, nonsyndromic paraganglioma, and in Hirschsprung disease.

One disease, multiple genes (phenocopy). Phenocopy refers to the development of disease manifestations that are usually associated with mutations of a particular gene but instead are due to another gene/etiology. Such a scenario could confound clinical diagnosis and management of a suspected hereditary endocrine disorder. For example, it has been reported that MEN1 syndrome which is usually caused by mutation in the *MEN1* gene can be mimicked by familial hypocalciuric hypercalcemia (FHH) due to an inactivating mutation in the calcium-sensing receptor, and the hyperparathyroidism-jaw tumor (HPT-JT) syndrome due to a mutation in the gene responsible for hyperparathyroidism type 2 (HRPT2).

RECOMBINANT DNA TECHNOLOGY AND THERAPY OF PEDIATRIC ENDOCRINE DISEASES

From a therapeutic point of view, recombinant DNA technology can be exploited to either tailor pharmacotherapy according to the genotype of a patient (i.e., targeted pharmacotherapy), manipulate genes within the human body (gene therapy), or engineer prokaryotic or eukaryotic cells to produce proteins such as hormones, which can then be administered for therapy or diagnosis. Whereas targeted pharmacotherapy and gene therapy are mostly restricted to the research arena, the use of hormones produced by recombinant DNA technology is well established in clinical endocrinology. Historically, insulin was the first hormone synthesized by recombinant DNA technology to be approved for clinical use.[91,92] At present, a variety of recombinant hormones including GH, LH, FSH, TSH, PTH, and erythropoietin are being used clinically or are in advanced stages of clinical trials.

On a theoretic basis it should be possible to synthesize any protein hormone whose gene has been cloned and DNA sequence determined. Thus, recombinant DNA technology makes it possible to insert the gene coding for a particular protein hormone into a host cell such that the protein is produced by the host cell's protein-synthesizing machinery. The synthesized protein is then separated from the rest of the host cell proteins to obtain the pure form of the hormone of interest. Both prokaryotic and eukaryotic cells can serve as the host cell for the production of proteins by this technology. Because post-translational modifications such as glycosylation may be essential for the optimal action of a protein hormone, the choice of the specific cell system utilized for the production of a particular protein hormone is critical. Prokaryotic cell systems such as *Escherichia coli* are suitable for the production of protein hormones that do not need posttranslational modifications, such as GH.[93] Eukaryotic cell systems such as Chinese hamster ovary (CHO) cells that are capable of post-translational modification of the protein are useful for the production of hormones such as TSH that require glycosylation for optimal bioefficacy.[94] In addition, eukaryotic cells are capable of synthesizing proteins that undergo the appropriate folding, a step that is not carried out by prokaryotic cells. The advantages of the use of recombinant DNA for the production of these proteins include the possibility of a limitless supply of a highly pure form of a protein and the absence of the risk of contamination with biological pathogens associated with the extraction of proteins from human or animal tissue. In addition, this technology permits the development of hormone analog and antagonists with much greater ease than conventional protein synthesis protocols.

The influence of genetic factors on the metabolism of various drugs is a well-established phenomenon with the effect of various iso-enzymes of cytochrome p450 on the circulating half-life of drugs such as anticonvulsants being a classic example of this interaction. Another example of the role of genotype on the choice of pharmacotherapy is the phenomenon of drug-induced hemolytic anemia in patients with G6PD deficiency. The genomic revolution has allowed for the exploitation of computational approaches to identify polymorphisms of known genes encoding proteins with different functional characteristics. These single nucleotide variations (also called single nucleotide polymorphisms, or SNPs) occur with varying frequencies in different ethnic populations and are the focus of intense scrutiny at this particular time. The promise that these SNPs hold out is that analysis of these SNPs for a given gene will allow the investigator to predict the response of the particular individual to a class of drugs/chemicals. This pharmacogenomic approach to

clinical therapeutics has already been successful in demonstrating an association between specific polymorphisms in the β-adrenergic receptor and response to β-agonists in patients with bronchial asthma, and polymorphisms in hydroxytryptamine receptors and response to neuroleptic drugs. The widespread application of the tools of molecular biology to unravel the molecular basis of action of hormones has also yielded benefits by allowing for customization of the pharmacotherapy of endocrine diseases and syndromes based on the specific individual genetic defect. One such example is the report of directed pharmacologic therapy of an infant with ambiguous genitalia resulting from a mutation in the androgen receptor.[95] In this infant with a M807T mutation in the androgen receptor, in vitro functional studies had indicated that the mutant receptor exhibited loss of binding capacity for testosterone with retention of binding for dihydrotestosterone. Furthermore, this differential binding was also reflected in the better preservation of the transactivation potential of dihydrotestosterone (DHT) compared to testosterone. These in vitro findings were exploited to treat the infant with DHT, resulting in restoration of male genital development. This case illustrates that in selected cases, in vitro functional assays can help identify subsets of patients with ambiguous genitalia and androgen insensitivity who would respond to targeted androgen therapy. It can be anticipated that in the coming years, more examples of such innovative therapeutic strategies and "customized" hormonal treatment protocols will become routine and implemented in the practice of clinical pediatric endocrinology.

CONCLUDING REMARKS

The application of recombinant DNA technology has resulted in a tremendous increase in our understanding of physiologic processes and pathologic conditions. Achievements such as the full sequence of the human genome in normal subjects[49] have resulted in a paradigm shift in the way that we think about genetic causes and predisposition to disease[58] and in the analysis of the function of hormones and related proteins.[96] In the traditional paradigm, investigators seeking to discover new genes or to analyze the function of known proteins needed to devote a significant part of their time to conducting "bench research" in "wet laboratories." The new approach in this "postgenomic" era takes advantage of the unprecedented power of computational biology to "mine" nucleotide, protein sequence, and other related databases. In the future, most researchers will deal with abstract models and data sets stored in computer databases. Hence, initial discoveries of novel genes or novel interactions between known proteins or intracellular signaling pathways could be made using the analytic power of computational software tools (functional genomics); these initial insights can then be verified and expanded upon by traditional laboratory bench methods. The advantages of this new paradigm are obvious with computational approaches taking a significantly shorter time, with less demand on manpower, and can easily expand the scope of the search to include multiple molecules and organisms (phylogenetic profiling). Several public-domain web-accessible databases are currently serving as the major repositories for this information. GenBank is the major repository for sequence information and is currently supported by the National Institutes of Health. One of the main sources of the physical location, clinical features, inheritance patterns, and other related information of specific gene defects is the Online Mendelian Inheritance in Man (OMIM) operated by Johns Hopkins University in Baltimore, Maryland. Johns Hopkins University also operates the online Genome Data Base (GDB), which allows scientists to identify polymorphisms and identify contacts for gene probes and other related research tools. The ever-expanding number of endocrine (and other) disorders that can be attributed to changes in the nucleotide sequence of specific genes has also increased the necessity for the availability of accurate, reliable, and timely genetic tests such as mutation detection. One source for such information is a collaborative website (www.genetests.org) that maintains an up-to-date catalog of commercially available and research-based tests for inherited disorders.

With the ubiquitous use of these powerful tools in laboratories around the world, genes are being cloned and genetic diseases are being mapped at a rapid pace. In all of these exciting developments, one still needs to keep in mind that whereas this "new" science has allowed for hitherto inaccessible areas of human biology to be probed and studied, a lot remains to be understood with respect to individual disease processes. Hence, at the present time, we have only a rudimentary understanding of the correlations between phenotype and genotype in many of the common genetic diseases such as congenital adrenal hyperplasia. These lacunae in our knowledge dictate that clinicians should be cautious about basing therapeutic decisions solely on the basis of molecular and genetic studies. This is especially true in the area of prenatal diagnosis and recommendation for termination of pregnancy based on genetic analysis. As we improve our understanding of the molecular and genetic basis of disease and translate this knowledge into gains at the bedside, it behooves us, both as individuals and as a society, to be cognizant of critical issues relating to the privacy of health data and to remain vigilant against misuse by inappropriate disclosure of this powerful knowledge.

QUESTIONS

1. Which of the following is the correct statement with regard to miRNA?
   a. A single miRNA can target only one RNA.
   b. A single mRNA target can be recognized by only one miRNA.
   c. miRNAs act by binding to complementary sequences on the 5′ untranslated region of target mRNAs.
   d. One of the mechanisms by which miRNAs exert biological effect is by enhancing degradation of the target mRNA.
   e. Positive regulation of gene expression is the most common biological effect of miRNAs.

Correct answer: d

2. You are evaluating an infant who is suspected of having isolated growth hormone deficiency, type 1A (IGHD 1A). Which of the following statements is correct with regard to IGHD 1A?
   a. The gene that is deleted is the hGH-V gene expressed in the pituitary gland and is the source of circulating GH in the human.
   b. The classical inheritance pattern of this condition is autosomal dominant.
   c. These infants are usually small at birth.
   d. These infants have a propensity to develop antibodies against GH in response to exogenously administered GH.
   e. Measurement of random GH levels is not useful to make a diagnosis of GH deficiency in the newborn period.

Correct answer: d

3. Which of the following statements is correct with regard to commonly used PCR-based assays?
   a. In general, PCR-based assays can routinely differentiate between the two alleles of an individual gene.
   b. The inability to amplify a loss-of-function mutant allele by PCR is diagnostic of a gene deletion.
   c. DNA contamination is not a significant concern with PCR-based assays.
   d. The PCR technique can be used to directly amplify products of protein degradation.
   e. PCR-based assays use the enzyme Taq polymerase, a heat-stable enzyme originally isolated from the bacterium *Thermophilus aquaticus*.

Correct answer: e

4. Prader-Willi syndrome is an example of a disorder of imprinting. Which of the following statements is true about genomic imprinting?
   a. Genomic imprinting is caused by a mutation in genomic DNA.
   b. Genomic imprinting is more relevant for diseases inherited from the mother.
   c. Genomic imprinting is more likely to occur in the firstborn child.
   d. Genomic imprinting is almost always caused by endocrine disruptors.
   e. The focal form of persistent hyperinsulinemic hypoglycemia of infancy (PHHI) is an example of a disorder of imprinting.

Correct answer: e

5. Positional cloning (or "reverse" genetics) resulted in the identification of the genetic basis of several endocrine disorders. Which of the following statements is true about positional cloning?
   a. The positional cloning strategy requires at least a partial knowledge of the genetic basis of the disease under investigation.
   b. The positional cloning strategy is useful for identifying the genetic basis of diseases without any obvious candidate gene(s).
   c. Positional cloning can only be applied to diseases with an autosomal dominant inheritance pattern.
   d. Informative recombination interferes with positional cloning.
   e. The Human Genome Project (HGP) did not facilitate the strategy of positional cloning.

Correct answer: b

CHAPTER 3

Receptor Transduction Pathways Mediating Hormone Action

Bassil Kublaoui, MD, PhD • Michael A. Levine, MD

CHAPTER OUTLINE

INTRODUCTION

Hormones exert their actions by binding to specific receptor proteins, a process that induces conformational changes or compartmental redistribution of these proteins. The activated receptor is now capable of inducing positive (or negative) intracellular effects that ultimately are recognized as a physiologic response. The specificity of hormone action is determined by the affinity of hormones for different receptors, the cell-specific expression

TABLE 3-1 **Major Types of Hormone Receptors**

Receptor Class	Hormone Receptors
G protein–coupled receptors	ACTH and other melanocortins, V2 vasopressin, LH, FSH, TSH, GnRH, TRH, GHRH, corticotropin releasing factor, somatostatin, glucagon, oxytocin, gastric inhibitory peptide, type 1 PTH, free fatty acid, GPR54, orexin, ghrelin, melanin-concentrating, calcitonin, glucagon-like peptide-1, and calcium-sensing receptors
Type 1 cytokine receptors	Growth hormone, prolactin, and leptin receptors
Receptor tyrosine kinases	Insulin, IGF-1, and fibroblast growth factor receptors
Nuclear receptors	Thyroid hormone, vitamin D_3, PPARγ, HNF-4α, glucocorticoid, androgen, estrogen, mineralocorticoid, and DAX1 receptors

of the receptor, and the unique responses induced by ligand occupancy.

Since the early 2000s, our understanding of hormone action has advanced rapidly with the success of genomics and advanced molecular biologic techniques. This combined approach has led to the discovery and classification of an unexpectedly large number of receptors, some quite novel and others even unanticipated, that are members of large families of genetically conserved proteins. Moreover, our understanding of receptor action has been clarified by the identification and detailed characterization of post-receptor signaling proteins and signaling mechanisms. Four major receptor superfamilies have been identified that are distinguished by protein structure, cellular localization, and effector systems. These families include the G protein–coupled receptors (GPCRs), cytokine receptors, tyrosine kinase receptors (RTKs), and nuclear receptors (Table 3-1). This chapter reviews major features of these important receptor families. Mutations influencing receptor function leading to endocrine disorders are also highlighted.

G PROTEIN–COUPLED RECEPTORS

More than 1% of the genome of vertebrates encodes a large protein family of receptors that sense molecules outside the cell and activate inside signal transduction pathways and, ultimately, cellular responses. These receptor proteins are embedded in the plasma membrane and are coupled to intracellular signal generating systems by heterotrimeric G proteins (i.e., G protein coupled receptors [GPCRs]).[1] GPCRs are also known as seven-transmembrane domain receptors, 7TM receptors, heptahelical receptors, and serpentine receptors. They are called transmembrane receptors because they pass through the cell membrane, and they are called seven-transmembrane receptors because they pass through the cell membrane seven times. The human genome encodes roughly 950 G protein–coupled receptors, which detect photons (light), hormones, growth factors, drugs, and other endogenous ligands. Approximately 150 of the GPCRs found in the human genome have unknown functions. Most GPCRs are odorant and pheromone receptors.[1] Also important to note is that most hormones bind to GPCRs, and hence G protein–dependent signal transduction represents the most common mechanism for hormone action (Table 3-2).

G protein–coupled receptors are involved in many diseases and are also the target of approximately 40% of all modern medicinal drugs.[2] G proteins were discovered when Alfred G. Gilman and Martin Rodbell investigated stimulation of cells by adrenaline. These investigators discovered that when adrenaline binds to a receptor, the receptor does not stimulate enzymes directly. Instead, the receptor stimulates a GTP binding protein, which stimulates an enzyme. An example is adenylate cyclase (AC), which produces the second messenger cyclic AMP. For this discovery, they won the 1994 Nobel Prize in physiology or medicine. The 2012 Nobel Prize in chemistry was awarded to Brian Kobilka and Robert Lefkowitz for their work that was "crucial for understanding how G protein–coupled receptors function."

The GPCR superfamily is divided into eight major classes.[1,3] These receptors contain an N-terminal extracellular domain that is frequently called the ectodomain or exodomain.[4] These receptors also contain seven putative transmembrane spanning alpha helices (TM-I to TM-VII). The alpha helices are connected by three intracellular (i1 through i3) and three extracellular (e1 through e3) loops that are often collectively called the *serpentine region* (Figure 3-1).[4,5] The C-terminal intracellular region is usually referred to as the *endodomain*.[4]

GPCRs are activated by a wide variety of signals, including proteins, nucleotides, amino acid residues, Ca^{2+}, light photons, and odorants (see Figure 3-1).[1] It is postulated that ligand binding alters the conformation of transmembrane domains and intracellular loops, increasing the affinity of the receptor for specific heterotrimeric guanosine nucleotide binding proteins (G proteins) (see Figure 3-1).[6,7] G proteins share a common heterotrimeric structure consisting of an α subunit and a tightly coupled βγ dimer. The α subunit interacts with detector and effector molecules, binds guanosine 5′-triphosphate (GTP), and possesses intrinsic GTPase activity. There are 16 genes in mammals that encode some 20 different α chains. The Gα subunits are categorized in four classes and include Gsα (G stimulatory), Giα (G inhibitory) and Goα (G other), Gq/11α, and G12/13α. They behave differently in the recognition of the effector but share similar structures and mechanism of activation. The Gα subunits consist of two domains: a GTP-binding domain and a helical insertion domain. The GTP-binding domain is homologous to Ras-like small GTPases and includes switch regions I and II, which change conformation during activation. The switch regions are loops of

TABLE 3-2 **G Protein–Coupled Receptors and Clinical Conditions Associated with Receptor Mutations**

Receptor	Germline Mutation	Endocrine Disorder
ACTH/melanocortin-2 receptor	Inactivating mutations (homozygous, compound heterozygous)	Familial glucocorticoid deficiency type 1
Melanocortin-4 receptor	Inactivating mutations (most heterozygous, some homozygous)	Obesity
V2 vasopressin receptor	Inactivating mutations (most X-linked recessive, rarely X-linked dominant)	X-linked nephrogenic diabetes insipidus
LH receptor	Inactivating mutations (homozygous, compound heterozygous) Activating mutations (heterozygous)	Males: types I and II Leydig cell hypoplasia Females: asymptomatic or hypergonadotropic hypogonadism with primary amenorrhea Males: male limited precocious puberty
FSH receptor	Inactivating mutations (homozygous, compound heterozygous)	Females: autosomal recessive hypergonadotropic ovarian dysgenesis or milder hypergonadotropic hypogonadism Males: variable impairment of spermatogenesis
TSH receptor	Inactivating mutations (most homozygous or compound heterozygous, rarely heterozygous) Activating mutations (heterozygous)	Resistance to TSH Autosomal-dominant inherited non-autoimmune hyperthyroidism/toxic adenomas
GnRH receptor	Inactivating mutations (homozygous or compound heterozygous)	Isolated hypogonadotropic hypogonadism
TRH receptor	Inactivating mutations (compound heterozygous)	Central hypothyroidism
GPR54	Inactivating mutations (homozygous, compound heterozygous)	Normosmic isolated hypogonadotropic hypogonadism
Ghrelin	Inactivating mutations (homozygous, possible heterozygous)	Short stature due to decreased growth hormone secretion
GHRH receptor	Inactivating mutations (homozygous/compound heterozygous)	Isolated growth hormone deficiency
Type 1 PTH receptor	Inactivating mutations (homozygous, heterozygous) Activating mutations (heterozygous)	Blomstrand's chondrodysplasia if homozygous and rarely if heterozygous; enchondromatosis if heterozygous Jansen's metaphyseal chondrodysplasia
Calcium-sensing receptor	Inactivating mutations (heterozygous, homozygous) Activating mutations (heterozygous)	Familial benign hypocalciuric hypercalcemia typical if heterozygous, neonatal severe hyperparathyroidism rarely if heterozygous, typical if homozygous Autosomal-dominant hypocalcemic hypocalciuria, Bartter syndrome type V

alpha helices with conformations sensitive to guanine nucleotides. The helical insertion domain is inserted into the GTP-binding domain before switch region I and is unique to heterotrimeric G proteins. This helical insertion domain sequesters the guanine nucleotide at the interface with the GTP-binding domain and must be displaced to enable nucleotide dissociation.

The α subunits associate with a smaller group of β(5) and γ(12) subunits.[8] Combinatorial specificity in the associations between various G protein subunits provides the potential for enormous diversity and may allow distinct heterotrimers to interact selectively with only a limited number of G protein–coupled receptors and effector proteins.[6,7,9]

There are two principal signal transduction pathways involving the G protein–coupled receptors: the cyclic AMP signal pathway and the phosphatidylinositol signal pathway. G protein–induced signal generation is regulated by a "molecular timer" that is determined by the rate of GTP exchange and hydrolysis. In the inactive state, G proteins exist in the heterotrimeric form with guanosine 5′-diphosphate (GDP) bound to the α chain. Interaction of a ligand-bound receptor with a G protein leads to release of GDP, with subsequent binding of GTP to the α chain. The binding of GTP to the α chain leads to dissociation of the α chain from the βγ dimer, allowing the now free α-GTP chain to interact with target enzymes and ion channels. The βγ dimers also participate in downstream signaling events through interaction with an ever-widening array of targets, including certain forms of AC and phospholipase C, potassium channels, and G protein–coupled receptor kinases.

G protein signaling is terminated by the hydrolysis of α-GTP to α-GDP by an intrinsic GTPase. A group of proteins, called regulator of G protein signaling (RGSs), acts as GTPase-activating proteins (GAPs), specific for Gα subunits. These proteins accelerate hydrolysis of GTP to GDP and terminate the transduced signal. In some cases, the effector itself may possess intrinsic GAP activity, which helps deactivate the pathway. This is true in the case of phospholipase C β, which possesses GAP activity within its C-terminal region. This is an alternate

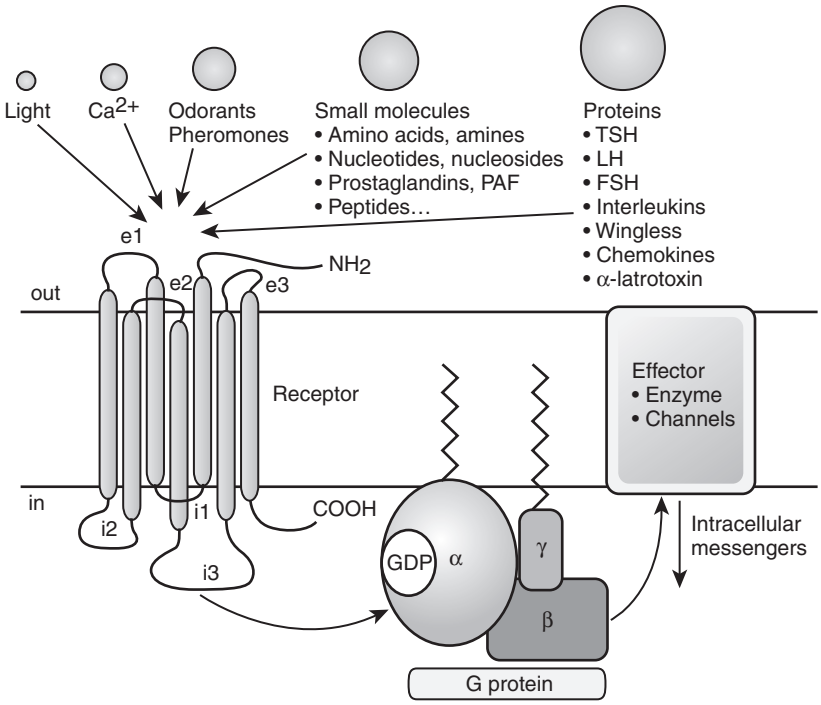

FIGURE 3-1 ■ GPCR structure and function. GPCRs have an N-terminal extracellular domain, seven putative transmembrane domains separated by three extracellular loops (e1-e3) and three intracellular loops (i1-i3), and a C-terminal intracellular domain. Ligand binding results in the exchange of GTP for GDP, which induces dissociation of the G protein into a GTPα subunit and a βγ subunit. Then these subunits alter the activity of intracellular effector enzymes and transmembrane channels, resulting in the alteration of intracellular levels of second messengers that can include cAMP and calcium. (Adapted with permission from Bockaert, J., & Pin, J. P. (1999). Molecular tinkering of G-protein–coupled receptors: an evolutionary success. *EMBO J, 18,* 1724.)

form of regulation for the Gα subunit. However, it should be noted that the GAPs do not have catalytic residues to activate the Gα protein. Rather, GAPs reduce the required activation energy for the reaction to take place. After hydrolysis of GTP, the Gα-GDP chain reassociates with the βγ dimer; the reassociated heterotrimeric G protein is now capable of participating in another cycle of receptor-activated signaling.[1,6,7,9]

Specificity in ligand binding is conferred by variations in the primary structures of the extracellular and intracellular domains.[1] Specificity of effector responses is conferred by the variations in the primary structure of intracellular domains and isoforms of the Gα subunits of G proteins.[10,11] Some GPCRs couple predominantly with $G\alpha_i$ /$G\alpha_o$ subunits that act primarily to decrease adenylyl cyclase activity.[11-14] Other GPCRs couple predominantly with $G\alpha_s$ subunits that increase adenylyl cyclase activity or $G\alpha_q$/Gα[13,16-18] subunits that increase phospholipase C activity.[11,15,16]

Interestingly, data show that cytoskeletal proteins may modulate receptor–G protein coupling. For example, the erythrocyte membrane cytoskeletal protein 4.1G can interfere with A1 adenosine receptor signal transduction.[17] 4.1G also influences metabotropic glutamate receptor 1α-mediated cAMP accumulation, increases the ligand-binding ability of metabotropic glutamate receptor 1α, and alters its cellular distribution.[18] 4.1G may also play a role in receptor-receptor dimerization.

Receptor agonist-independent and agonist-induced homo- and heterodimerization have increasingly been recognized as important determinants of GPCR function.[19] For example, the GPCR somatostatin receptor 5 (SSTR5) primarily exist as monomers in the absence of an agonist. However, they form homodimers in the presence of an agonist.[20] Furthermore, it has been shown that SSTR5 can form heterodimers with type 2 dopamine receptors (DRD2)—another GPCR—in the presence of hsst2 agonist or dopamine.[21] Agonist-induced activation of SSTR5-DRD2 heterodimers in Chinese hamster ovary (CHO) cells expressing SSTR5 and DRD2 is increased when compared to agonist-induced activation of monomers and homodimers in CHO cells expressing only SSTR5 or DRD2.[21] Heterodimerization of receptors may also lead to inactivation of one of the receptors in the complex. For example, heterodimerization of somatostatin receptor 2A (sst2A) with somatostatin receptor 3 (SSTR3) appears to lead to inactivation of the heterodimerized SSTR3 without inactivating the heterodimerized SSTR2.[22]

GPCRs can form heterodimers with nonreceptor transmembrane proteins. Both the calcitonin receptor (CALCR) and the calcitonin receptor-like protein (CALCRL) can form heterodimers with three different accessory proteins that are termed "receptor-activity–modifying proteins (RAMPs)": RAMP1, RAMP2, and RAMP3.[23-25] Whereas CALCRs can be activated by ligand in the absence of heterodimerization with a RAMP, CALCRLs are only activated by ligand if heterodimerized with a RAMP.[23,24] RAMPs alter the ligand specificity of the heterodimerized receptor.

CALCRs that are not in heterodimers with RAMPS are activated by calcitonin and thus constitute the classic

CALCR.[23,24] However, CALCRs heterodimerized with RAMP1, RAMP2, and RAMP3 bind amylin and constitute amylin1, amylin2, and amylin3 receptors, respectively.[23,24] CALCRLs dimerized with RAMP1 bind calcitonin gene–related peptide and constitute the calcitonin gene–related peptide receptor.[23,24] CALCRLs dimerized with RAMP2 and RAMP3 bind adrenomedullin and constitute adrenomedullin1 and adrenomedullin2 receptors, respectively.[23,24] RAMPS alter function of other GPCRs that transduce hormone action. The distribution and function of parathyroid hormone 1 and 2 receptors are altered by binding to RAMP2 and RAMP3, respectively.[26] The distribution and function of the glucagon receptor is altered by binding to RAMP2.[26] Dimerization/heterodimerization may occur in the endoplasmic reticulum (ER) shortly after protein synthesis occurs.[27] The ER plays a role in determining whether or not a protein will be expressed elsewhere in the cell, thus protecting the cell from misfolded and (likely) mutant proteins.[27] The non-heterodimerized CALCRL is an orphan receptor because the CALCRLs cannot leave the ER for the cell membrane unless heterodimerized with RAMPs.[28]

The melanocortin receptors also utilize accessory proteins. Circulating ACTH binds to five different forms of the melanocortin receptor (types 1-5), but only the melanocortin 2 receptor (MC2R) in the adrenal cortex leads to release of adrenal steroids. MC2R interacts with Gs, which leads to activation of adenylyl cyclase and formation of cAMP. The MC2R is the smallest G protein–coupled receptor known to date and belongs to a family of melanocortin receptors (types 1 to 5) that bind to various derivatives of proopiomelanocortin, especially α-MSH. The accessory protein melanocortin 2 receptor-associated protein (MRAP) is required for MC2R function, as it is critical for the translocation of the receptor from the endoplasmatic reticulum to the cell surface.[29] Moreover, MRAP facilitates signaling of the MC2R.[30] Loss of function of MRAP thus prevents membrane expression of MC2R and completely prevents ACTH signaling. Interestingly, MRAP forms a unique antiparallel homodimer in close proximity to the MC2R.[31] The MRAP accessory protein can also interact with other melanocortin receptors, particularly MC5R, but exerts negative effects on their signaling. Expression of MRAP was shown to be predominantly present in the zona fasciculata in the rat adrenal gland, consistent with its facilitating role in glucocorticoid production. Hence, mutations in MC2R[32] or MRAP[29] can lead to familial glucocorticoid deficiency secondary to ACTH resistance. By contrast, MRAP2, a protein with 39% amino acid homology to MRAP, shares the MC2R-trafficking function of MRAP but does not appear to play a major supportive role in adrenocortical ACTH signaling. On the contrary, in vitro studies have shown that overexpression of MRAP2 can suppress MC2R activation.

Failure of the endoplasmic reticulum to export mutant GPCR homodimers and mutant GPCR wild-type GPCR heterodimers to the cell membrane has been found to be the cause of dominant negative endocrine conditions. A dominant negative mutation is a heterozygous mutation that results in a phenotype that would only be expected in the presence of a homozygous mutation. Some heterozygous MC4R mutations cause dominantly inherited obesity due interaction of wild-type MC4R with the mutant receptor, and this specific effect of protein-protein interaction results in a dominant-negative effect.[33,34] In addition, some V2 vasopressin receptor gene mutations that are known to cause nephrogenic diabetes insipidus encode mutant V2 vasopressin receptors that form dimers in the ER that cannot be exported to the cell membrane.[35]

These mutant receptors also interfere with cell surface expression of wild-type receptors by forming heterodimers with the wild-type receptors that cannot be exported from the ER to the cell membrane.[36] This finding explains why females heterozygous for these V2 vasopressin receptor gene mutations do not concentrate their urine with even high doses of desmopressin, a synthetic V2 vasopressin receptor agonist, in spite of being able to produce wild-type V2 vasopressin receptors.[37] A similar phenomenon explains dominant transmission of partial TSH receptor resistance in patients heterozygous for some inactivating TSH receptor mutations.[38] In these patients, mutant TSH receptors form oligomers with wild-type receptors and prevent export of wild-type receptors from the endoplasmic reticulum to the cell membrane.[38]

Similarly, misfolding and misrouting of some mutant gonadotropin-releasing hormone (GnRH) receptors in the endoplasmic reticulum (as well as oligomerization of these mutant GnRH receptors with wild-type GnRH receptors) decrease cell membrane expression of wild-type GnRH receptors.[39-41] This phenomenon, however, has not been found to have clinical implications in relatives of probands homozygous or compound heterozygous for mutations that cause isolated hypogonadotropic hypogonadism (IHH) because individuals heterozygous for these mutations demonstrate an intact GnRH-gonadotropin axis and do not have clinical signs of IHH. Thus, in these individuals enough wild-type GnRH receptors do not oligomerize with mutant GnRH receptors and are transported to the cell membrane to maintain sufficiently normal GnRH-GnRH receptor interactions to avoid development of IHH.[40]

GPCRs activate G proteins at very low levels in the absence of ligand binding, but in some cases genetic mutations that lead to substitution of a single amino acid can greatly increase the interaction rate of the unliganded receptor for its G protein. Hence, GPCRs that are specific for luteinizing hormone, thyroid-stimulating hormone, thyrotropin-releasing hormone, glucagon-like peptide-1, melanocortin, and cannabinoid receptors can activate G proteins in the absence of ligand binding,[42,43] demonstrating constitutive activity that increases linearly with increased cell surface expression of the receptors.[44] It has also been recognized that there are ligands (often called inverse agonists) that decrease the activity of these receptors.[45] Receptor ligands that neither increase nor decrease the activity of receptors are now frequently referred to as neutral antagonists.[43]

The term *antagonists* is applied to these ligands because they block activation and inactivation of receptors by agonists and inverse agonists, respectively.[43] The term

agonist only refers to receptor ligands that increase receptor activity.[43] A scale has been formulated to express the continuity in receptor ligand function—from −1 (representing a full inverse agonist), to 0 (representing a neutral antagonist), to +1 (representing a full agonist).[43,45] It is possible that inverse agonists play a role in treating medical conditions caused by GPCR mutations that lead to increased constitutional activation of the receptor.[43]

Receptor desensitization and resensitization play a role in GPCR activity. Since the early 2000s, mechanisms of GPCR desensitization and resensitization have been elucidated. Three processes for receptor desensitization have been described.[46,47] The first receptor desensitization process is rapid uncoupling of the G protein from GPCRs.[47] This process occurs within seconds to minutes after initiation of the process and occurs as a result of phosphorylation of GPCRs.[47] G protein receptor kinases (GRKs) have been increasingly recognized as playing a major role when this process involves homologous desensitization.[46]

Homologous or agonist-dependent desensitization occurs after agonist activation of the receptor that is desensitized.[47] GRK-mediated phosphorylation of serine and threonine residues in the third intracellular loop, or the C-terminal intracellular domain leads to activation of β-arrestins, which in turn inactivate adenylyl cyclase (Figure 3-2).[46-49] Second-messenger–dependent protein kinases also contribute to receptor desensitization when this process involves homologous desensitization, but they also participate in receptor desensitization when desensitization involves heterologous desensitization. Heterologous or agonist-independent desensitization occurs as a result of activation of a different receptor from the one that is desensitized.[47]

The second receptor desensitization process is internalization/sequestration of GPCRs. This process is slower than receptor phosphorylation-induced uncoupling of the G protein from GPCRs and occurs within minutes to hours after initiation of the process. This process is reversible because the receptors can be recycled to the cell surface (see Figure 3-2).[47] GRKs and β-arrestins play a role in initiating internalization/sequestration of β2-adrenergic, LH, FSH, TSH, TRH, vasopressin V2, angiotensin II type 1A, and other G protein–coupled receptors in clathrin-coated vesicles (see Figure 3-2).[46,50-57] Dephosphorylation of the sequestered receptor followed by disassociation of the receptor from β-arrestin is necessary for the receptor to be recycled to the cell membrane and resensitized (see Figure 3-2).[16]

The third receptor desensitization process is down-regulation. With down-regulation, the number of intracellular GPCRs decreases due to increased lysosomal degradation and decreased synthesis of the receptors due to alteration of transcriptional and posttranscriptional regulatory mechanisms (see Figure 3-2).[58,59] Down-regulation is a slow process that occurs within several hours to days after initiation of the processes that lead to its development.[60]

One of the ways the Arg137His V2 vasopressin receptor mutation interferes with mutant receptor function and causes X-linked nephrogenic diabetes insipidus is by

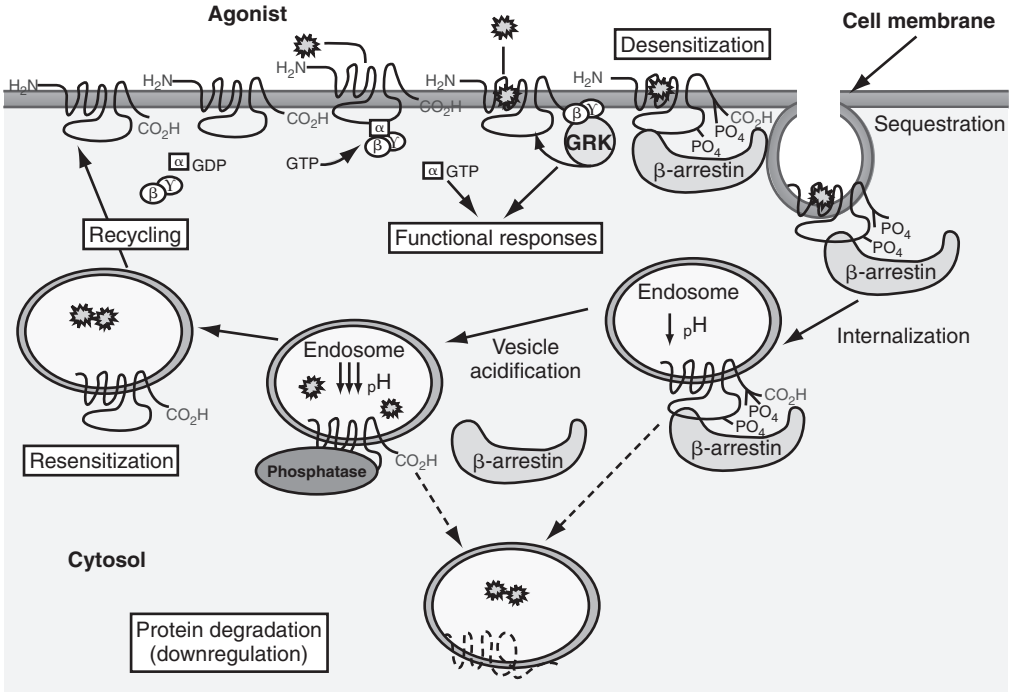

FIGURE 3-2 ■ Desensitization and recycling of GPCRs. Shortly after an agonist binds a GPCR, G-protein–receptor kinases phosphorylation of serine and threonine residues in the third intracellular loop or the C-terminal intracellular domain leads to activation of β-arrestin. Activation of β-arrestin inactivates adenylyl cyclase and initiates sequestration of the GPCR in clathrin-coated vesicles. Dephosphorylation of the sequestered receptor and subsequent disassociation of the receptor from β-arrestin is followed by recycling of the GPCR to the cell membrane. Alternatively, once sequestered the GPCR can be destroyed in lysosomes. (Adapted with permission from Saunders, C., & Limbird, L. E. (1999). Localization and trafficking of α2-adrenergic subtypes in cells and tissues. *Pharmacol Ther, 84,* 200.)

altering desensitization and recycling of the mutant receptor.[61] In vitro studies have revealed that the mutant receptor is constitutively phosphorylated. Thus, even in the absence of ligand binding the mutant receptor is bound by β-arrestin—which in turn leads to sequestration of the mutant receptor within clathrin-coated vesicles. Recycling of the mutant receptor back to the cell membrane requires the mutant receptor to be dephosphorylated and disassociated from β-arrestin. However, the mutant receptor remains constitutively phosphorylated while sequestered and thus cannot be disassociated from β-arrestin and recycled to the cell membrane—thereby reducing cell membrane expression of the mutant receptor.

Some investigators suggest that most GPCR-inactivating mutations can be classified by the effects of the mutations into one of five classes.[62] Class I inactivating mutations interfere with receptor biosynthesis. Class II inactivating mutations interfere with receptor trafficking to the cell surface. Class III inactivating mutations interfere with ligand binding. Class IV inactivating mutations impede receptor activation. Class V inactivating mutations do not cause discernible defects in receptor biosynthesis, trafficking, ligand binding, or activation but may cause medical disorders. There are also inactivating mutations that interfere with receptor function via multiple mechanisms and thus cannot be placed into one class.

Of the eight classes of GPCRs, only classes A, B, and C contain receptors for mammalian hormones (Figure 3-3).[3] Class A receptors contain the rhodopsin-like receptors and are divided into at least 15 groups.[3,63] Four of these groups contain receptors activated by hormones. These are the peptide receptor, hormone protein receptor, GnRH receptor, and the thyrotropin-releasing hormone (TRH) and secretagogue receptor groups.[3]

The peptide receptor group includes the angiotensin, adrenocorticotropin hormone (ACTH)/melanocortin, oxytocin, somatostatin, and vasopressin receptors.[3] The hormone protein receptor group includes the receptors for glycoprotein hormones, including follicle-stimulating hormone (FSH), luteinizing hormone (LH), and thyrotropin (TSH) receptors.[3] These receptors have large extracellular N-terminal domains and ligand-binding sites that include the first and third extracellular loops (see Figure 3-3).[1,3] There is also much similarity in amino acid sequence among these receptors (see Figure 3-3).[1] The GnRH receptor group only contains the GnRH receptor.[2] The TRH and secretagogue receptor group includes the TRH receptor and the growth hormone secretagogue receptor.[3]

Class B GPCRs are structurally similar to members of the hormone protein receptor group (see Figure 3-3).[1] However, unlike the glycoprotein hormone receptors, class B GPCRs do not share similar amino acid sequences.[1] This family contains receptors for high-molecular-weight hormones, including calcitonin, glucagon, gastric inhibitory peptide, parathyroid hormone (PTH), and corticotrophin-releasing factor (CRF).[1,3,64]

Class C receptors have a large extracellular domain with two lobes separated by a hinge region that closes on

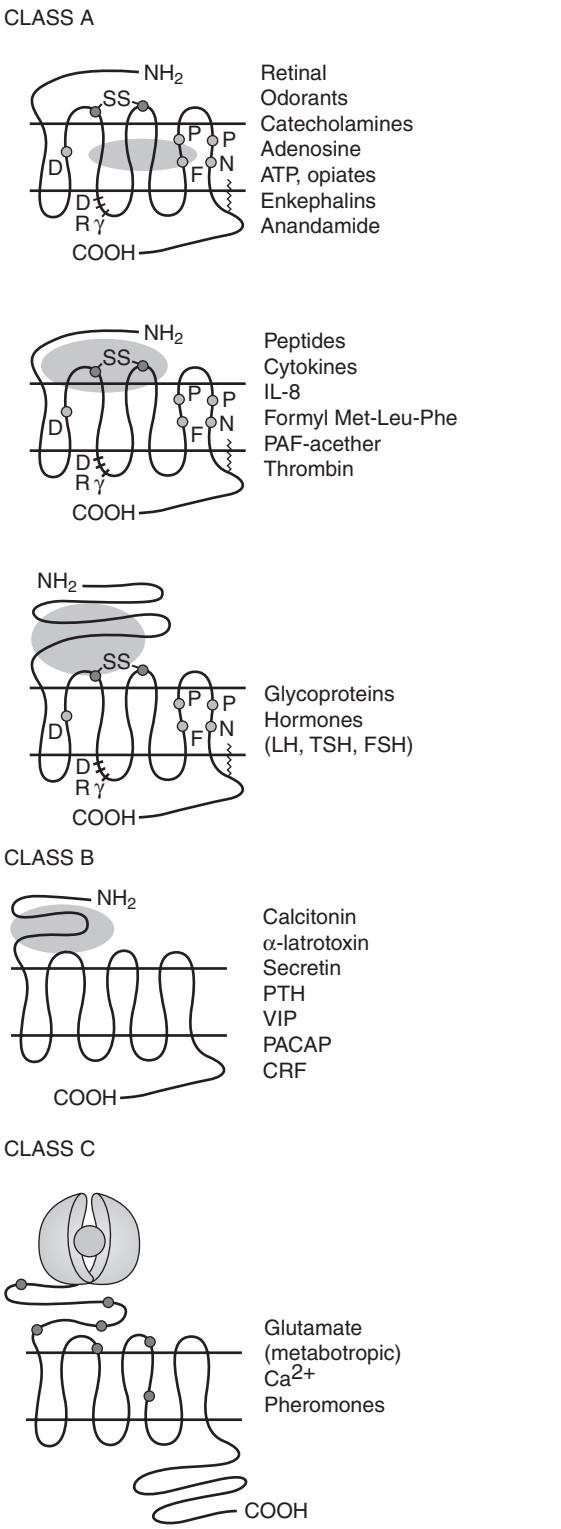

FIGURE 3-3 ■ Examples of class A, B, and C GPCRs. The oval represents the ligand. These receptors can differ in amino acid sequence, in length of the N-terminal extracellular and C-terminal cytoplasmic domains, and in the receptor regions involved with ligand-receptor interactions. (Adapted with permission from Bockaert, J., & Pin, J. P. (1999). Molecular tinkering of G protein-coupled receptors: an evolutionary success. *Embo J, 18*, 1725.)

the ligand (see Figure 3-3).[65] This region has also been called the *Venus flytrap* domain or module due to the trapping mechanism of the hinge region.[66] This family includes the calcium-sensing receptor (CASR).[1,2]

CLASS A RECEPTORS THAT TRANSDUCE HORMONE ACTION

The Peptide Receptor Group

Adrenocorticotropin and Melanocortin-2 Receptors

It is important to note that a newly accepted name for the ACTH receptor is *melanocortin-2 receptor* (MC2R) because the ACTH receptor is one of five members of the melanocortin receptor family of GPCRs.[62] For the purpose of clarity, when discussing interactions between ACTH and its receptor, the older name will be used for the remainder of this chapter. The ACTH receptor gene is located on the short arm of chromosome 18.[67] The ACTH receptor has a small extracellular and intracytoplasmic domain. Adrenocorticotropin-induced activation of the ACTH receptor in the *zona fasciculata* and *zona reticularis* of the adrenal cortex stimulates $G\alpha_s$, resulting in increased intracellular cAMP levels that stimulate steroidogenesis by activating cAMP-dependent kinases.[68-70]

Hereditary isolated glucocorticoid deficiency, resistance to ACTH, and familial glucocorticoid deficiency (FGD) are the same names for an autosomal recessive syndrome that consists of glucocorticoid deficiency accompanied by normal mineralocorticoid secretion. FGD has been classified further as FGD types 1 and 2 and the triple A syndrome.[71] Patients with FGD type 1 are homozygous or compound heterozygous for point mutations, resulting in ACTH receptors with abnormal function and account for 25% of FGD cases.[71-77] In contrast, patients with FGD type 2 have ACTH resistance due to mutations in melanocotin-2 receptor accessory protein (MRAP).[78] Triple A (Allgrove syndrome) is an autosomal recessive syndrome characterized by ACTH-resistant adrenal insufficiency, achalasia, and alacrima—which is caused by mutations in the achalasia-adrenocortical insufficiency-alacrima syndrome (AAAS) gene[79] thought to regulate nuclear pore complexes and nucleocytoplasmic transport.[80]

Patients with FGD type 1 usually present during infancy or early childhood with hypoglycemia.[74,82-86] Less commonly, patients may present with a severe infection, frequent minor infections, or childhood asthma that resolves with treatment with physiologic doses of glucocorticoids.[71,74,82] Hyperpigmentation thought to be due to increased ACTH levels acting on the MC1R may be seen as early as the first month of life, but usually becomes apparent after the fourth month of life.[72-74,82-84,87] There is one reported case of FGD type 1 without hyperpigmentation despite elevated ACTH levels in a patient with homozygous mutations in both the MC2R and the MC1R.[88] The assumption that hyperpigmentation is caused by increased ACTH levels acting on the MC1R (both in FGD type 1 and Addison's disease) was substantiated in this patient whose MC1R mutation had previously been implicated in red hair and pale skin phenotypes. Neonates with FGD type 1 may also suffer from jaundice.[74,84,86,89] Tall stature accompanied by an advanced or dissociated bone age, in spite of normal age of onset of puberty, appears to be common in children with FGD type 1.[71,74,77,82,83,87] Patients with FGD type 2 have normal heights[71,90] and present earlier than patients with FGD type 1. The pathophysiology of tall stature in FGD type 1 is unknown. Both forms of FGD exhibit absent adrenarche confirming the importance of ACTH in the induction and maintenance of adrenarche.[78]

At presentation, plasma cortisol, androstenedione, and dihydroepiandrosterone levels are low or low normal—and plasma ACTH levels are elevated.[71,74,82-86] When supine, patients with FGD type 1 have renin and aldosterone levels that are near normal.[71,83,85,86] Histologically, the *zona fasciculata* and *zona reticularis* are atrophied with FGD.[82] However, demonstrating the lack of an essential role for ACTH in the embryologic development and maintenance of the *zona glomerulosa*, adrenal cortices in patients with all types of FGD contain *zona glomerulosa* cells.[71,81-83,87,91]

Abnormalities in ACTH receptor expression may be seen in other conditions. Evidence suggests that the ACTH receptor-$G\alpha_s$-adenylyl cyclase-cAMP cascade maintains differentiation of adrenocortical cells and that impairment of this cascade leads to dedifferentiation and increased proliferation of adrenocortical cells.[92,93] Adrenocortical carcinomas from some patients have been found to have a loss of heterozygosity (LOH) for the ACTH receptor gene, resulting in markedly decreased ACTH receptor mRNA expression.[93] Growth of the tumors with LOH for the ACTH receptor gene also may be more aggressive than the other tumors. An activating mutation of G_{i2} that constitutively suppresses adenylyl cyclase activity has also been found in adrenocortical tumors.[92] Thus, decreased ACTH receptor activity may be associated with tumorigenesis.

Interestingly, many patients with ACTH-independent macronodular adrenal hyperplasia (AIMAH)—a cause of ACTH-independent Cushing syndrome—exhibit increased glucocorticoid levels in response to noncorticotropin hormones that do not normally induce glucocorticoid release.[94-99] These hormones include gastric inhibitory peptide, exogenous arginine and lysine vasopressin, luteinizing hormone, human chorionic gonadotropin, angiotensin II, catecholamines, leptin, and serotonin receptor agonists.[94-99] Increased expression of the receptors for these ligands in the abnormal adrenal glands has been implicated as a possible explanation for the abnormal induction of glucocorticoid release by these noncorticotropin ligands.[99] However, receptors for some of these ligands are expressed in normal adrenal glands.[99] Thus, the mechanism for this phenomenon remains to be fully elucidated.

Other Melanocortin Receptors

Murine studies reveal that melanocortin-3 receptor (MC3R), another of the five members of the melanocortin receptor family, regulates fat deposition as MC3R

deficient mice have normal body weight with increased fat mass.[62] The role of the MC3R in humans is less clear. More than 24 human MC3R mutations have been identified without evidence of obesity.[100,101] However, patients with these mutations were not phenotyped for fat mass to assess whether they phenocopy the mouse model, which exhibits normal body weight with altered partitioning leading to increased fat mass and reduced lean mass.[101-103] Homozygosity for a pair of single-nucleotide polymorphisms of the MC3R gene that result in production of partially inactive MC3Rs was found to be associated with pediatric-onset obesity in Caucasian American and African American children.[104]

The melanocortin-4 receptor (MC4R) is another member of the melanocortin receptor family and plays a role in controlling appetite and weight.[105] The MC4R has baseline constitutive (i.e., ligand-independent) activity that can be inhibited by the inverse agonist agouti-related peptide (AgRP).[105,106] Activation of the MC4R by its natural agonist α-melanocyte stimulating hormone (α-MSH) produces anorexigenic effects.[105,107,108] More than 150 naturally occurring MC4R mutations have been identified, causing hyperphagic obesity, increased lean body mass, increased bone density, and increased linear growth.[109-114] Patients with homozygous mutations appear to have more severe obesity than their heterozygous relatives, consistent with codominant inheritance.[7,115]

MC4R mutations are thought to be the most common monogenic cause of human obesity. The prevalence of pathogenic MC4R mutations in obese populations varies widely ranging from 0.5% to 5.8% depending on the screening criteria and population.[116-119] AgRP gene polymorphisms appear to be associated with anorexia nervosa.[112,113]

Little is known about melanocortin-5 receptors (MC5Rs) in animals and humans. There is only weak evidence from a single linkage and association study of families in Quebec that suggests that MC5Rs may also play a role in regulating body weight and fat mass.[114]

Another member of the melanocortin receptor family, the melanocortin-1 receptor (MC1R), controls skin and hair pigmentation. Activation of MC1Rs in skin and hair follicle melanocytes by the pro-opiomelanocortin (POMC)-derived peptides α-MSH and ACTH stimulates the synthesis of eumelanin, a brown-black pigment.[120,121] Inhibition of MC1R baseline constitutive activity by agouti protein, or specific mutations, leads to release of pheomelanin, a red-yellow pigment, from the melanocytes.[121]

Inactivating homozygous mutations of the POMC gene cause hypoadrenalism, red hair, fair skin, and early-onset obesity. Hypoadrenalism is characterized by glucocorticoid deficiency due to lack of ACTH production from the POMC precursor. Fair skin and red hair are due to a lack of ACTH and α-MSH-induced melanocyte release of eumelanin that results from activation of MC1Rs. Of note, non-white patients with homozygous POMC mutations do not appear to have the fair skin and red hair phenotype.[118,122] In white individuals eumelanin synthesis appears to be dependent on POMC-derived peptides, whereas in darker individuals other genes may control eumelanin synthesis.[123] Obesity is due to lack of α-MSH–induced anorectic effects, which normally result when α-MSH activates MC4Rs.[124] Heterozygosity for POMC gene mutations has been associated with hyperphagia, early-onset obesity, and increased linear growth.[124-126] Both homozygous[127,128] and heterozygous[129] mutations of prohormone convertase 1 cause obesity in humans. Prohormone convertase 1 acts on POMC, proinsulin, and proglucagon. Patients with prohormone convertase 1 deficiency also have neonatal enteropathy and postprandial hypoglycemia. The cause of enteropathy is unknown but hypothesized to be related to the processing of GLP-2 by prohormone convertase 1. GLP-2 is known to stimulate proliferation and repair of intestinal epithelium.[130]

Vasopressin Receptors

Nephrogenic diabetes insipidus (NDI) results from decreased responsiveness of the renal tubule to arginine vasopressin (AVP), with resulting excessive loss of free water. NDI is characterized by polydipsia and polyuria that is not responsive to vasopressin and vasopressin analogs.[131] Vasopressin binds to the V2 vasopressin receptor (AVPR2), a Gs-coupled receptor, in the basolateral membrane of collecting duct principal cells in the kidney and activates translocation of aquaporin-2 (AQP2) water channels to the apical membrane, thereby inducing water permeability. X-linked NDI is caused by inactivating mutations of the V2 vasopressin receptor (AVPR2) gene located at Xq28 and accounts for about 90% of genetically determined NDI.[132-135] More than 200 AVPR2 mutations have been described including missense, nonsense, insertions, deletions, and complex rearrangements.[136] Mutations have been categorized into five classes based on mechanism, including abnormal transcription, mRNA processing, translation, aberrant folding and intracellular retention, loss of the G protein binding site, loss of the AVP binding site, and defects in intracellular trafficking.[131,137,140] Some patients with X-linked NDI are responsive to high doses of desmopressin. Autosomal recessive NDI (ARNDI) is caused by loss-of-function mutations in the gene for the aquaporin-2 water channel and accounts for about 10% of genetic forms of NDI.[137,139] More than 40 known mutations cause ARNDI. Autosomal dominant forms of NDI are also caused by mutations in AQP2 that are functional but fail to be transported to the apical membrane. They account for $< 1\%$ of genetic forms of NDI and generally have a milder phenotype than ARNDI or X-linked NDI.

Gain-of-function mutations in the V2 vasopressin receptor have also been reported.[141] DNA sequencing of two patients' V2R gene identified heterozygous missense mutations in both, with resultant changes in codon 137 from arginine to cysteine (R137C) or leucine (R137L). These mutations resulted in constitutive activation of the receptor and clinical features of inappropriate antidiuretic hormone secretion (SIADH), which was termed *nephrogenic syndrome of inappropriate antidiuresis (NSIAD)*.[141] The patient with the R137L mutation demonstrated the expected decrease in AVP levels with a water-loading test but urine aquaporin 2 levels remained inappropriately elevated.[142]

The Glycoprotein Hormone Receptor Group

The glycoprotein hormones include TSH, FSH, LH, and HCG. These hormones share common α subunits that dimerize with hormone-specific β subunits. TSH, FSH, and LH bind to the extracellular N-terminal domain of the TSH, FSH, and LH receptors, respectively.[1,3,143,144] The effects of HCG are mediated by the LH receptor, which is also known as the luteinizing hormone/choriogonadotropin receptor (LHCGR).[145]

Glycoprotein hormone receptors have a large (350 to 400 residues) extracellular N-terminal domain, also known as the ectodomain, that participates in ligand binding (see Figure 3-3).[4,145] The ectodomain includes leucine-rich repeats that are highly conserved among the glycoprotein hormone receptors.[4,145] There is 39% to 46% similarity of the ectodomain and 68% to 72% similarity of the transmembrane or serpentine domain among the three glycoprotein hormone receptors.[4]

The glycoprotein hormone receptors are coupled to G_s, and hormone binding stimulates adenylyl cyclase, leading to increased intracellular cAMP levels and protein kinase A (PKA) activation.[145] Mutations leading to endocrine dysfunction have been reported for each of the glycoprotein hormone receptors.

LHCGR Receptors

Both inactivating and activating mutations of the LH receptor have been found in humans.[145] The LH receptor gene is located in chromosome 2 p21 and consists of 11 exons.[146,147] Exon 1 encodes a peptide that directs the LH receptor to the plasma membrane.[145] Exons 2 through 10 encode the ectodomain.[145] The last exon encodes the transmembrane domains that are also known as the serpentine regions.[4,145,146] Single nonsense mutations, amino acid changes, and partial gene deletions have been described that generate LH receptors with decreased activity.[145] Single–amino-acid changes have also been found that lead to activation of G_s in the absence of ligand binding.[145]

Development of LH resistance requires biallelic mutations that inactivate the LH receptor gene, as one normal receptor allele is capable of producing adequate receptor protein to ensure physiologic signaling.[145] In contrast, activating mutations of the LH receptor gene cause endocrine disorders in the heterozygous state.[145]

In the fetus, LH receptors are primarily activated by HCG.[145] Leydig cells begin to express LH receptors shortly after testicular differentiation at 8 weeks of gestation.[145] Thereafter, androgen production due to activation of these receptors by HCG plays an important role in the development of male genitalia and testicular descent.[145] Thus, male infants with inactivating mutations of the LH receptor may present with abnormally developed genitalia—including micropenis, cryptorchidism, and an XY disorder of sexual differentiation.[145]

Males with mutations that completely inactivate the LH receptor exhibit failure of fetal testicular Leydig cell differentiation. This phenotype, which is known as type 1 Leydig cell hypoplasia, includes female external genitalia with a blind-ending vagina, absence of Müllerian derivatives, and inguinal testes with absent or immature Leydig cells.[148-155] In addition, patients have elevated serum LH levels, normal serum FSH levels, and decreased serum testosterone levels that do not increase in response to HCG administration.[148-155] Mutations that lead to this phenotype include a nonsense mutation (Arg545Stop) that results in a receptor that is missing TM4-7, an Ala593Pro change, and a TM7 deletion (ΔLeu608, Val609) that decreases cell surface expression of the LH receptor.[153,154,156] These mutant receptors are unable to couple to G_s.[153,154,156]

Males with mutations that do not completely inactivate the LH receptor present with type 2 Leydig cell hypoplasia, which is characterized by a small phallus and decreased virilization.[152] A mutation that leads to this phenotype includes the insertion of a charged lysine at position 625 of TM7 in place of hydrophobic isoleucine that disrupts signal transduction.[157] Another mutation (Ser616Tyr, found in patients with mild Leydig cell hypoplasia) is associated with decreased cell surface expression of the LH receptor.[154,157] Other deletion and nonsense mutations have also been found to cause mild Leydig cell hypoplasia.[145]

Males with inactivating mutations of the LH receptor may also present with a phenotype intermediate in severity between type 1 and type 2 Leydig cell hypoplasia. A compound heterozygote patient with Ser616Tyr on one allele and an inactivating deletion (Δexon 8) on the other allele presented with Leydig cell hypoplasia, micropenis, and hypospadias.[158] The Cys131Arg mutation has also been found in patients with Leydig cell hypoplasia, small phallus, and hypospadias.[159] This mutation is located in the leucine-rich repeat segment of the LH receptor extracellular domain and interferes with high-affinity ligand binding.[159]

Deletion of exon 10 of the LH receptor gene leads to an LH receptor that binds LH and HCG normally.[160] Interestingly, whereas HCG binding can elicit normal transmembrane signaling, LH binding fails to activate the receptor.[160] Because HCG is the principal in utero LH receptor-activating hormone, and second-messenger response of the mutant receptors to HCG is not impaired, it is not surprising that a male patient found to be homozygous for the mutation was born with normal male genitalia.[62,160] Pubertal progression and later gonadal function, however, are dependent on LH activation of the LH receptor.[62,160]

Because deletion of exon 10 of the LH receptor gene results in a mutant LH receptor with diminished intracellular signaling in response to LH, it is also not surprising that the patient homozygous for this mutation was found to have delayed pubertal development, small testes, and hypergonadotropic hypogonadism when evaluated at the age of 18 years.[160] Prolonged HCG therapy resulted in normalization of testicular testosterone production, increased testicular size, and the appearance of spermatozoa in semen.[160] Similarly, inactivating mutations of the LH β subunit cause abnormal pubertal development, severe testosterone deficiency and azoospermia but normal external genitalia in males. In females inactivating mutations of the LH β subunit are

associated with normal pubertal development and menarche followed by oligomenorrhea, enlarged multicystic ovaries and infertility.[161]

Mutations that constitutively activate LH receptors cause male-limited precocious puberty (MLPP), also known as testotoxicosis—which may be familial or sporadic.[155,162,163] Boys with this condition present with GnRH-independent precocious puberty before the age of 4 years when the Asp578Gly is present and as early as the first year of life when the Asp578Tyr mutation is present.[145,164-166] Patients with this condition may also have an enlarged phallus at birth.[164]

During the first 5 years of life, patients with MLPP have very low LH and FSH levels but have testosterone levels in pubertal range.[167] During adolescence and adult life, testosterone levels do not increase above age-appropriate concentrations and gonadotropin levels normalize.[145,167-169] Thus, adolescents and adults with MLPP do not usually manifest signs of androgen excess (such as hirsutism or severe acne).[145,167] Most mutations that cause MLPP are located in the TM6 and i3, regions that participate in receptor-Gs protein coupling.[145] A milder phenotype was reported in a patient with a heterozygous activating mutation (C617Y) in TM7.[170] This mutation was inherited from the patient's mother who was apparently unaffected. Somatic activating mutations cause sporadic Leydig cell adenomas.[105,171]

Activating mutations of the LH receptor do not appear to have a phenotype in females. In prepubertal girls, this may be due to low or absent LH receptor expression or due to insufficient aromatase expression in prepubertal granulosa cells. During puberty, activation of LH receptors on ovarian theca cells leads to the production of androgens that are converted to estrogens by aromatase in granulosa cells.[145] LH, along with FSH, also plays a role in inducing the differentiation of follicles into Graafian follicles and triggers ovulation and release of the oocyte.[145] Detailed phenotyping of the carrier mother of a MLPP male with the Asp578Gly activating mutation of the LH receptor failed to reveal any abnormalities in her menstrual cycles or fertility. LH dynamics, androgen, and FSH levels as well as response to GnRH agonists were normal.[173]

Females with inactivating mutations of the LH receptor may be asymptomatic or present with primary amenorrhea.[145] Females with complete inactivating LH receptor mutations may present with primary amenorrhea, inability to ovulate, and decreased estrogen and progesterone levels accompanied by elevated LH and FSH levels.[154,174] Affected individuals may have signs of low estrogen levels, including a hypoplastic uterus, a thin-walled vagina, decreased vaginal secretions, and decreased bone mass.[154,174] A homozygous LH receptor mutation (N400S) has been associated with empty follicle syndrome.

FSH Receptors

Inactivating and activating FSH receptor mutations have also been described,[175] but they are far less common than LH receptor mutations.[175] The FSH receptor gene is located in chromosome 2 at p21 and contains 10 exons.[176] The last exon of the FSH receptor gene encodes the transmembrane and intracellular domains.[177]

FSH is required in females for normal follicle maturation and the regulation of estrogen production by ovarian granulosa cells.[175,178,179] FSH is required in pubertal males for Sertoli cell proliferation, testicular growth, and the maintenance of spermatogenesis.[175,180]

The first inactivating mutation of the FSH receptor was found in Finnish females with autosomal recessive inherited hypergonadotropic ovarian dysgenesis (ODG). ODG is characterized by primary amenorrhea, infertility, and streak or hypoplastic ovaries in the presence of a 46XX karyotype and elevated gonadotropin levels.[181] Twenty-two out of 75 Finnish patients with ODG were found to be homozygous for a C566T point mutation in exon 7 of the FSH receptor gene.[182] This mutation leads to the production of an FSH receptor with an Ala189Val substitution in an area of the extracellular ligand- binding domain that is thought to play a role in turnover of the receptor or in directing the receptor to the plasma membrane.[182] The mutated receptor demonstrates normal ligand-binding affinity but has decreased binding capacity and impaired signal transduction when studied in transfected mouse Sertoli cells.[182] Males homozygous for this mutation have variable impairment of spermatogenesis and low to low-normal testicular volume but are not azoospermic and can be fertile.[183] The C556T point mutation is uncommon outside Finland, where the carrier frequency is 0.96%.[184] Other mutations that alter signal transduction but not receptor expression or binding include Ala189Val, Asn191Ile, Ala419Thr, and Phe591Ser. The Ala189Val mutation causes primary hypergonadotropic amenorrhea in women and no spermatogenesis in men in the homozygous state and secondary amenorrhea in the heterozygous state.[185,186] The nearby Asn191Ile mutation also causes hypergonadotropic amenorrhea in the homozygous state but no clinical phenotype in the heterozygous state.[187] The Ala419Thr mutation was identified in a heterozygous woman with primary amenorrhea.[188] The Phe591Ser mutation causes primary amenorrhea and premature ovarian failure (POF) in the homozygous state and a predisposition to sex cord ovarian tumors in the heterozygous state.[189] Primary amenorrhea and POF have been described in women with homozygous mutations that totally impaired receptor binding to FSH[190] or that resulted in reduced expression of the FSH receptor on the cell surface.[191]

Compound heterozygosity for mutations that cause partial loss of FSH receptor function may cause endocrine dysfunction in women.[192,193] Women may present with infertility, secondary amenorrhea, osteoporosis, and a history of delayed onset of puberty accompanied by elevated LH and FSH, low-normal plasma estradiol, low plasma inhibin B levels, slightly enlarged ovaries with immature follicles, and a small uterus.[192] This may be caused by FSH receptor gene mutations that result in an Ile160Thr mutation in the extracellular domain that impairs cell surface expression and an Arg573Cys mutation in e3 that interferes with signal transduction.[192] Other women present with primary amenorrhea and very elevated gonadotropin, low plasma estradiol and inhibin B levels, normal-size ovaries with immature follicles, and a

normal-size uterus.[193] This condition is associated with an Asp224Val substitution in the extracellular domain leading to impaired cell-surface expression and a Leu601Val substitution in e3 impairing signal transduction.[193]

Activating mutations of the FSH receptor have also been described. Surprisingly, a hypophysectomized male was found to be fertile and to have serum testosterone levels above 4.9 nmol/L and normal testis volume in spite of undetectable gonadotropin levels.[194] This patient was found to be heterozygote for an A1700G mutation in exon 10 of the FSH receptor gene that resulted in an Asp567Gly substitution in an area of the third intracytoplasmatic loop that is highly conserved among FSH, LH, and TSH receptors.[194-196] The same substitution in corresponding areas of the LH and TSH receptors also results in constitutively active receptors and is found in MLPP and thyroid adenomas, respectively.[194-196] Other activating mutations have been identified to cause spontaneous ovarian hyperstimulation syndrome (OHSS). Ovarian hyperstimulation syndrome is a common complication of treatment protocols used to induce ova for in vitro fertilization and is characterized by multiple follicular cysts lined by luteinized cells, which can result in abdominal discomfort and distention as well as ovarian enlargement and fluid sequestration. One such mutation is the Asp567Asn, which was found in a woman with recurrent spontaneous OHSS.[197] The Thr449Ile and Thr449Ala mutations cause a conformational change that leads to loss of specificity for FSH leading to sensitivity to HCG[198] and TSH[199] causing spontaneous OHSS during pregnancy or with hypothyroidism. The Ile-545Thr mutation caused spontaneous OHSS in a woman during the first trimester of pregnancy despite a normal HCG level.[200] This mutant receptor displayed detectable constitutive activity as well as promiscuous activation by HCG and TSH.

TSH Receptors

The TSH receptor gene is located on chromosome 14 and contains 10 exons, with the first nine exons encoding the large extracellular domain and the tenth exon coding the remainder of the receptor.[201-204] At low extracellular TSH concentrations, TSH receptor activation leads to stimulation of $G\alpha_s$—which activates adenylyl cyclase, resulting in increased intracellular cAMP levels.[205,206] At higher extracellular TSH concentrations, activation of the TSH receptor also stimulates the G_q and G_{11} proteins—activating phospholipase C and resulting in the production of diacylglycerol and inositol phosphate.[206]

TSH receptors differ from the other glycoprotein hormone receptors in that they exist in two equally active forms.[207,208] These are the single-chain and two-subunit forms of the TSH receptor (Figure 3-4). The single-chain form of the TSH receptor is made up of three contiguous subunits: the A subunit, C peptide, and B subunit.[208-210] The A subunit begins at the N terminal of the extracellular domain and contains most of the extracellular domain.[208-210] The C peptide is connected to the C terminal of the A subunit and continues the extracellular domain.[208-210] The C peptide contains a 50-amino-acid sequence that is only found in TSH receptors.[208-210] The B subunit is connected to the C terminal of the C peptide and contains the TMs and the C-terminal cytoplasmic portion of the receptor.[208-210] The two-subunit form of the receptor is missing the C peptide, which is cleaved from the protein during intracellular processing and consists of the A and B subunits attached by disulfide

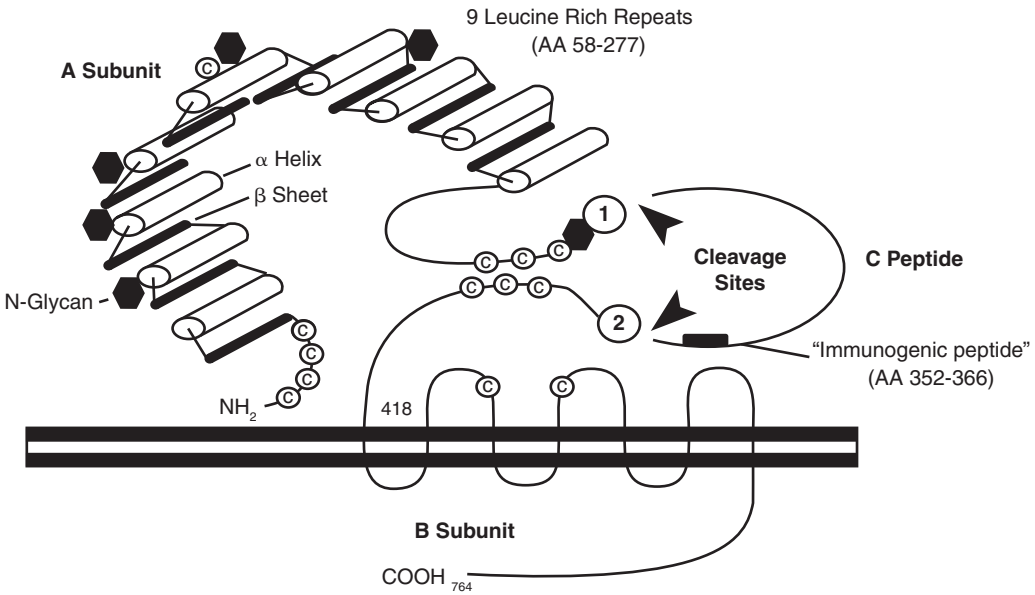

FIGURE 3-4 ■ The TSH receptor. There are two forms of TSH receptors. The single-chain form is made up of an A subunit, C peptide, and B subunit. Posttranslational cleavage of the C peptide from the single chain form results in the two-subunit form. This form consists of the A subunit joined to the B subunit by disulfide bonds between the C-terminal cysteine residues of the A subunit and the N-terminal cysteine residues of the B subunit. (Reproduced with permission from Rapoport, B., Chazenbalk, G. D., Jaume, J. C., & McLachlan, S. M. (1998). The thyrotropin [TSH] receptor: interaction with TSH and autoantibodies. *Endocr Rev, 19*, 676. Copyright 1998, The Endocrine Society.)

bonds.[211-214] It is surprising that both receptor forms are activated equally by TSH because the C peptide and nearby regions of the A and B subunits participate in signal transduction.[207-209,215,216]

Spontaneous single-allele mutations of the TSH receptor gene leading to replacement of Ser-281 (near the C terminal of the A subunit, with Ile, Thr, or Asn) result in a constitutively active TSH receptor that may cause intrauterine or congenital hyperthyroidism, or toxic adenomas.[210,217-219] Activating somatic mutations that cause toxic adenomas have also been found in different transmembrane domains of the TSH receptor.[220-227] More specifically, clusters of mutations are located in the i3 and TM6 regions—found to be involved with signal transduction in all glycoprotein hormone receptors.[220-222,224-226] The prevalence of activating mutations of the TSH receptor in toxic adenomas has been estimated to range from 2.5% in Japan to 86% in Brazil.[223,224,226,228-231]

Activating somatic mutations of the TSH receptor have also been found in multinodular goiters.[232] Interestingly, different activating mutations have been found in separate nodules in the same individual.[232] Some well-differentiated thyroid carcinomas have activating mutations of the TSH receptor.[233-235] Somatic activating mutations of the *GNAS* gene encoding $G\alpha_s$ have also been found in some toxic adenomas and differentiated thyroid carcinomas.[92,236,237] Activating germline mutations of the TSH receptor can cause sporadic or autosomal dominant inherited non-autoimmune hyperthyroidism that presents in utero, during infancy, during childhood, and in some cases in adulthood.[219,238-247] These mutations have been found in the N-terminal extracellular and transmembrane domains.[219,239-248]

Patients with heterozygous mutations that lead to constitutively active TSH receptors typically develop hyperthyroidism.[208] In contrast, biallelic loss of function mutations in the TSH receptor genes is required to cause hypothyroidism.[208] Most known loss-of-function TSH receptor mutations are located in the N-terminal extracellular domain.[249] A spontaneous Asp410Asn substitution, near the carboxy terminus of the C peptide, results in a TSH receptor with normal ligand binding affinity and impaired $G\alpha_s$-mediated signal transduction.[250] Patients homozygous for this type of mutation present with compensated hypothyroidism.[250]

Patients homozygous or compound heterozygous for loss-of-function mutations of the TSH receptor present with the syndrome of resistance to TSH (RTSH). Loss-of-function mutations of the TSH receptor that cause RTSH have been identified in the N-terminal extracellular domain, TM4, TM6,[251] i2, e1, and e3.[252] Clinical severity of RTSH may range from a euthyroid state accompanied by elevated TSH levels (fully compensated RTSH), to mild hypothyroidism unaccompanied by a goiter (partially compensated hypothyroidism), to congenital thyroid hypoplasia accompanied by profound hypothyroidism (uncompensated RTSH).[70,250,253-257] In patients with uncompensated RTSH, a small bilobar thyroid gland is located at the normal site.[70] Loss-of-function mutations of the TSH receptor are a rare cause congenital hypothyroidism[258,259] more common in Japan and Taiwan (up to 7% of children)[260,261] where R450H is particularly frequent. Because the sodium-iodide symporter is TSH dependent,[162] iodine and (99m) pertechnetate uptakes are diminished or absent in patients with RTSH.[70,262] In rare cases, iodine uptake is high-normal.[263] These compound heterozygous mutations of the TSH receptor had some $G\alpha_s$ activity and no G_q activity suggesting that iodine uptake is solely controlled by $G\alpha_s$ activity and not G_q activity. Some families have been found to have an autosomal-dominant form of RTSH that is not caused by a mutation of the TSH receptor.[264,265]

HCG and TSH Receptors during Pregnancy

Due to its structural similarity with TSH, at high concentrations HCG can activate the TSH receptor.[266] During pregnancy, HCG activation of TSH receptors leads to elevation in thyroid hormones seen after the ninth week of gestation—and decreases in TSH levels between the ninth and twelfth weeks of gestation.[267] This phenomenon does not usually result in maternal hyperthyroidism (gestational thyrotoxicosis).[267,268] However, when HCG levels are abnormally elevated due to gestational trophoblastic disease due to a molar pregnancy or choriocarcinoma, hyperthyroidism may occur.[269-273] The prevalence of thyrotoxicosis in gestational trophoblastic disease correlates with HCG levels. In one study of 196 patients treated with chemotherapy for gestational trophoblastic neoplasia, the prevalence of thyrotoxicosis was 7%.[274] Biochemical thyrotoxicosis only occurred in patients with HCG levels $> 10^5$ and clinical thyrotoxicosis only occurred in patients with HCG levels $>10^6$. Serum TSH is consistently suppressed when HCG levels are above 4×10^5.[275]

A mother and daughter were identified with recurrent gestational hyperthyroidism and normal serum HCG levels.[276] These individuals were found to be heterozygous for a point mutation in the TSH receptor gene, resulting in a Lys183Arg substitution in the extracellular domain of the receptor. It is believed that this substitution increases activation of the receptor by HCG, causing gestational hyperthyroidism.

The Gonadotropin-Releasing Hormone Receptor Group

Gonadotropin-Releasing Hormone Receptors

The GnRH receptor gene is located on 4q13 and includes three exons.[280,281] Unlike glycoprotein hormone receptors, GnRH receptors lack an intracellular C-terminal domain.[282,283] By contrast to most GPCRs, the GnRH receptor is coupled to G_q/G_{11} and hence ligand-binding leads to stimulation of phospholipase C and not adenylyl cyclase.[284] Phospholipase C cleaves phosphatidylinositol-4,5-diphosphate (PIP2) to inositol 1,4,5-triphosphate (IP3) and diacylglycerol, leading to increased protein kinase C (PKC) activity.[285,286]

Some patients with idiopathic hypogonadotropic hypogonadism (IHH) are homozygous or compound heterozygous for loss-of-function mutations in the GnRH receptor gene.[287-289] Unlike patients with Kallmann syndrome, they have a normal sense of smell.[287-289] GnRH

receptor mutations that cause IHH result in decreased binding of GnRH or impaired GnRH receptor signal transduction, or decreased GnRH receptor cell membrane expression due to misrouting of GnRH receptor oligomers from the endoplasmic reticulum.[40,41,287-289] Some mutations, including E90K, L266R and S168R, that cause misfolding and retention within the endoplasmic reticulum exhibit a dominant negative effect due to retention of wild-type receptors.[290]

Female patients with mutations that partially compromise GnRH receptor function may present with primary amenorrhea and infertility associated with a normal or small uterus and small ovaries with immature follicles.[287,291] Males with the same mutations may present with incomplete hypogonadotropic hypogonadism (characterized by a delayed and incomplete puberty) or with complete hypogonadotropic hypogonadism (characterized by absent puberty).[287,291]

Some patients with IHH due to mutated GnRH receptors have partial or normal gonadotropin responses to exogenous GnRH.[287,291] However, decreased amplitude in the pulsatile LH secretion can be observed in these patients.[287] Females with a partial or normal gonadotropin response to exogenous GnRH are more likely than nonresponders to become fertile in response to pulsatile exogenous GnRH. [287,292]

Activating mutations of the GnRH receptor have not been described in the germline or in pituitary adenomas.[293]

The Thyrotropin-Releasing Hormone and Secretagogue Receptor Group

Thyrotropin-Releasing Hormone Receptors

Like the GnRH receptor, TRH receptor activation leads to increased phospholipase C activity.[294] To date, only inactivating mutations that cause endocrine dysfunction have been reported for the TRH receptor. One patient was identified with central hypothyroidism due to mutated TRH receptors.[295] He presented during the ninth year of life with short stature (−2.6 SD) accompanied by a delayed bone age (−4.1 SD), a low plasma thyroxine level, and a normal plasma TSH level. Exogenous TRH did not induce an increase in plasma TSH and prolactin levels. He was found to be compound heterozygous for TRH receptor gene mutations, resulting in receptors that failed to bind TRH or induce IP3 production. Another family was identified with complete resistance to TRH due to a nonsense mutation in the TRHR (p.R17X) producing a TRH receptor that lacked the entire transmembrane domain.[296] The proband was homozygous and presented with short stature, growth failure, and fatigue at age 11. He had a low free T4 with a low-normal TSH. TRH stimulation testing failed to stimulate TSH or prolactin. Surprisingly his 33 year-old sister who was also homozygous had escaped detection despite two normal pregnancies brought to term. She had no signs or symptoms of hypothyroidism but exhibited thyroid function tests similar to the proband. She breastfed normally. Both the proband and his sister had normal cognitive function. This report suggested that the TRH receptor is not essential for normal cognitive function or female fertility and lactation. The mouse model corroborates these findings.[297]

Other Class A Receptors That Transduce Hormone Action

Free Fatty Acid Receptor 1

At the time a new GPCR is discovered, the ligand for the newly discovered receptor is often unknown. Thus, until a specific ligand is discovered, these GPCRs are known as orphan receptors. According to the Human Genome Organization (HUGO) Gene Nomenclature Committee, these G protein–coupled orphan receptors should be named alphanumerically GPR followed by a number until their ligand is known. Once a specific ligand is identified, a more specific name is given the receptor.

The ligands for GPR40 were unknown when the receptor was first discovered. The HUGO Gene Nomenclature Committee changed the name of the receptor to free fatty acid receptor 1 (FFAR1) when the ligands were identified as medium- and long-chain fatty acids. With rare exceptions that are clearly identified, this chapter follows HUGO Gene Nomenclature Committee recommendations (see www.gene.ucl.ac.uk/nomenclature/index.html for more information on receptor nomenclature).

FFAR1 is one of several GRCRs for lipid mediators. Lipid mediators are intercellular lipid messengers that include sphingosine 1-phosphate, sphingosylphosphorylcholine, dioleoyl phosphatidic acid, lysophosphatidic acid, eicosatetraenoic acid, bile acids, and free fatty acids.[63] FFAR1 is activated by medium- and long-chain fatty acids, whereas FFAR2 (formerly known as GPR43) and FFAR3 (formerly known as GPR 41) are activated by shorter-chain fatty acids.[63] There is now evidence that FFAR1 activation by medium- and long-chain fatty acids has endocrine implications. FFAR1 is expressed in human pancreatic β-islet cells.[298] FFAR1 is involved in cholecystokinin secretion from I cells in response to fatty acids.[299] It has also been implicated in fatty acid stimulated GLP-1 and GIP secretion from L and K cells.[300] GPR120 is expressed in enteroendocrine cells and has a physiologic role in GLP-1 secretion.[301] FFAR2 and FFAR3 are expressed in adipose tissue and FFAR3 has been implicated in leptin production.[301]

Fatty acid–induced stimulation of FFAR1 in β-islet cells leads to activation of the $G\alpha_q$-phospholipase C second-messenger pathway, which in turn leads to release of calcium from the endoplasmic reticulum that augments insulin-mediated increases in intracellular calcium concentrations due to glucose-induced activation of voltage-gated calcium channels.[302-305] Because an increased intracellular calcium concentration induces insulin release, FFAR1- mediated augmentation of glucose-mediated increases in the intracellular calcium concentration leads to amplification of glucose-stimulated insulin release. [302-305]

An identified variant in FFAR1 (Gly180Ser), found in a Sicilian population, resulted in obesity, impaired glucose, and lipid stimulated insulin secretion.[306] Two other variants, Arg211His and Asp175Asn, are not associated

with alterations in insulin release.[306,307] TAK-875, an FFAR1 agonist, was shown to reduce hemoglobin A1c in patients with type 2 diabetes in a phase 2 clinical trial.[308] Wild-type mice placed on an 8-week high-fat diet develop glucose intolerance, insulin resistance, hypertriglyceridemia, and hepatic steatosis—whereas FFAR1 knockout mice on the same diet do not develop these conditions.[309] The clinical relevance for patients is not yet clear. However, an Arg211His polymorphism in the FFAR1 gene may explain some of the variation in insulin secretory capacity found in Japanese men: Arg/Arg homozygotes had lower serum insulin levels, homeostasis model of insulin resistance, and homeostasis model of beta-cell function than His/His homozygotes.[310]

KISS1 Receptor/GPR54

Homozygous inactivating mutations in the gene encoding the KISS1 receptor (GPR54) were initially described in French and Saudi Arabian patients with IHH; in both cases the affected subjects came from consanguineous families.[311-314] The Saudi patients carried a Leu148Ser mutation, whereas the French patients carried a 155bp deletion. Leu148 is highly conserved among class A GPCRs.[315] The mutation does not affect expression, ligand binding, or association with G_s but impairs ligand-induced catalytic activation of G_s.[315] At the same time, an African American patient with IHH was described who was compound heterozygous for inactivating GPR54 mutations.[313] Since publication of these initial reports, additional patients have been described. A boy with a Jamaican father and a Turkish-Cypriot mother, and with cryptorchidism and micropenis at birth and undetectable LH and FSH levels at 2 months of age, was found to have compound heterozygous GPR54 mutations.[316] Another missense mutation (Leu102Pro) that exhibits complete inactivation of GPR54 signaling has been identified.[317] Surprisingly, patients with this mutation exhibited spontaneous pulsatile LH and FSH secretion with normal frequency and a blunted amplitude and family members had partial pubertal development.[317]

Unlike patients with Kallmann syndrome, patients with GPR54 mutations have an intact sense of smell. Furthermore, in contrast to patients with IHH due to GnRH mutations, patients with GPR54 mutations increase serum gonadotropin levels in response to exogenous GnRH. Thus, biallelic loss of function mutations in GPR54 are a rare cause of normosmic IHH.[314,316]

Ligands for GPR54 derive from a single precursor protein, kisspeptin-1.[318,319] The longest derivative protein that acts as a ligand for GPR54 is metastin, so called because it is a metastasis suppressor gene in melanoma cells.[318] Metastin consists of kisspeptin-1 69-121.[318,319] However, shorter C-terminal peptides derived from kisspeptin-1 bind and activate GPR54.[318] Administration of metastin to adult male volunteers increases LH, FSH, and testosterone levels.[320] Studies in animal models suggests that Kiss1 expressing neurons in the hypothalamus modulate GnRH expressing neurons to initiate puberty and modulate sex steroid feedback on GnRH release.[314,321,]

An activating mutation in GPR54 was identified in a patient with central precocious puberty.[322] The adopted girl was found to have an Arg386Pro mutation, which led to prolonged activation of signaling in response to Kisspeptin.

Orexin Receptors

Orexins act on orexin receptors, located predominantly in the hypothalamus, to control food intake and play a role in the regulation of sleep/wakefulness.[323-325] There are two types of orexin receptors: the orexin-1 and the orexin-2 receptors.[325] There are also two types of orexins, orexin A and orexin B, formed from the precursor peptide preproorexin.[325] Orexins are also known as hypocretins, and orexin A is synonymous with hypocretin-1 and orexin B with hypocretin-2.[324,325] Orexin A acts on orexin-1 and orexin-2 receptors, whereas orexin B only acts on orexin-2 receptors.[323,326,327]

Like most class A GPCRs, orexin receptors couple with $G_{q/11}$ and G_i/G_o to activate phospholipase C and inhibit adenylyl cyclase, respectively.[325,328-330] Surprisingly, evidence suggests that orexin receptors also couple with G_s—which increases adenylyl cyclase activity.[330] Orexins increase food intake and duration of wakefulness.[323,324,331] Orexin A and activation of the orexin-1 receptor have greater orexigenic effects than orexin B and activation of the orexin-2 receptor.[332] The orexin-2 receptor mediates the arousal effect of orexins.[332] Most patients with narcolepsy with cataplexy have diminished levels of orexin A concentrations in cerebral spinal fluid and lack orexin-containing neurons.[324,333-336] This is thought to be due to postnatal cell death of orexin neurons in the hypothalamus.[337] HLA DQB1*0602 is associated with narcolepsy with cataplexy and an autoimmune process has been suggested but no autoantibodies have been identified. Thus far, no mutations in orexin receptors have been found in humans. A mutation in the orexin-2 receptor causes narcolepsy in dogs.[338] There is one described mutation (leu16ARG) in the HCRT gene in a child with early onset narcolepsy with cataplexy.[339] This mutation was shown to impair processing and trafficking of the mutant orexin leading to undetectable orexin A concentrations in the CSF.

Ghrelin Receptors

Another class A receptor that transduces hormone action is the ghrelin receptor. The receptor is also known as the growth hormone secretagogue receptor type 1a because the receptor is also activated by a family of synthetic growth hormone secretagogues.[105,332] Ghrelin is a product of posttranslational modification of the ghrelin gene product proghrelin.[340] Ghrelin is mainly produced in the stomach.[341,342] Activation of ghrelin receptors located in the hypothalamus and pituitary somatotrophs enhances growth hormone secretion.[343] The ghrelin receptor also has an orexigenic role.

Plasma ghrelin levels are elevated just prior to eating and decrease rapidly after eating.[344,345] In addition, intravenous administration of ghrelin to humans increases appetite and food intake.[346] Plasma ghrelin levels are

elevated in individuals with Prader Willi syndrome.[347] Thus, hyperphagia in patients with Prader Willi syndrome may be due at least in part to overactivation of ghrelin receptors by ghrelin. Screening of 184 extremely obese children and adolescents for mutations of the ghrelin receptor gene failed to identify a single mutation likely to cause obesity.[348]

Short individuals in two unrelated Moroccan kindreds were found to have a C to A transversion at position 611 in the first exon of the ghrelin receptor gene.[349] This transversion results in replacement of the apolar and neutral amino acid alanine at position 204 of the receptor by the polar and charged amino acid glutamate. This mutation interferes with normal constitutive activity of the receptor and decreases cell membrane expression of the receptor. Receptor activation by ghrelin, however, is preserved. Two thirds of individuals in the kindreds heterozygous for the mutation had height greater than or equal to 2 standard deviations below the mean. One heterozygous individual's height was 3.7 standard deviations below the mean. Prior to onset of growth hormone therapy, the only individual in the kindreds homozygous for the mutation had a height 3.7 standard deviations below the mean. Surprisingly, the patient homozygous for the mutation became overweight during puberty. The weight of the patients heterozygous for the mutation varied from underweight to overweight. Another patient who presented with severe short stature (−3 SD), vomiting, ketosis, hypoglycemia, and low BMI was identified to be a compound heterozygote for a W2X and an R237W mutation in the ghrelin receptor.[350] His IGF1 was low at 44 ng/mL and he failed GH stimulation testing and had a normal IGF1 generation test, and he had improvement in his height velocity and hypoglycemia in response to growth hormone treatment. Four more ghrelin receptor mutations were identified in a Japanese cohort with short stature (△Q36, P108L, C173R, and D246A).[351] △Q36 showed a minor reduction in activity. C173R led to intracellular retention. D246 caused impaired signaling and P108L led to reduced binding affinity to ghrelin. Two other mutations were identified in a cohort of patients with constitutional delay of growth and puberty in Brazil (Ser84Ile and Val182Ala).[352] Both resulted in decreased basal activity. The patients were short at presentation (−2.4 and −2.3 SD) but reached a normal adult height without treatment.

Another product of posttranslational modification of proghrelin, obestatin, appears to play a role in controlling appetite and weight.[340] Activation of the obestatin receptor, previously known as GPR39, in rats results in decreased food intake and weight.

Melanin-Concentrating Hormone Receptors

Formerly known as SLC-1 or GPR24, the type 1 melanin-concentrating hormone (MCH) receptor (MCHR1)—and the more recently discovered type 2 MCH receptor (MCHR2), formerly known as SLT or GPR145—may play a role in regulating feeding and energy metabolism in humans.[353-356] When activated, MCHR1 couples with $G_{q/11}$ and $G_{i/o}$ to increase phospholipase C activity and inhibit adenylyl cyclase activity, respectively.[353,354,357] MCHR2 couples with $G_{q/11}$, and MCH binding leads to increased phospholipase C activity.[355,356]

Studies in rodents reveal that MCH is an orexigenic hormone, and treatment of rodents with MCHR1 antagonists decreases food intake, weight, and body fat.[353,358,359,360,361] MCHR2 is not expressed in rodents.[360] Two loss-of-function mutations were identified in MCHR1 in humans (R210H and P377S).[362] Cells transfected with either mutant receptor failed to respond to MCH despite normal cell surface expression of the receptor, suggesting a receptor activation defect. These mutations were identified in two markedly underweight individuals and were not found in an obese cohort.[362,363] Analysis of the MCHR1 gene in more than 4000 obese German, Danish, French, and American children and adolescents revealed several single-nucleotide polymorphisms and gene variations in the German children and adolescents that may be associated with obesity.[364] Another study of 106 American subjects with early-onset obesity failed to definitively identify MCHR1 and MCHR2 mutations as a cause of obesity.[365]

CLASS B RECEPTORS THAT TRANSDUCE HORMONE ACTION

Growth Hormone–Releasing Hormone Receptor

The growth hormone–releasing (GHRH) receptor gene is located at 7p14.[366] GHRH receptors interact with G_s to stimulate adenylyl cyclase, resulting in increased intracellular cAMP levels that lead to somatotroph proliferation and growth hormone secretion.[367] Thus, it is not surprising that activating mutations in $G\alpha_s$ leading to constitutive activation of adenylyl cyclase have been found in some growth hormone–secreting pituitary adenomas in humans.[368]

Many mutations in the GHRH receptor that cause isolated growth hormone deficiency have been identified. These include 6 splice site mutations, 2 microdeletions, 2 nonsense mutations, 1 frameshift mutation, 10 missense mutations, and 1 mutation in the promoter.[369-372] The first naturally occurring mutation in the GHRH receptor (D60G) was found in the *little* mouse, which has a dwarf phenotype.[373,374] This mutation in a conserved amino acid in the extracellular domain impairs the ability to bind GHRH.[375] The first human mutation in the GHRH receptor (E72X) was identified in a consanguineous Indian family.[367] The same mutation was found in three apparently unrelated consanguineous kindreds from India, Pakistan, and Sri Lanka.[366,376,377] A different mutation (5′ splice site mutation in intron 1) was identified in a large Brazilian kindred of more than 100 individuals.[367] Both mutations result in the production of markedly truncated proteins with no receptor activity.[367,377] A frameshift mutation was identified in a patient with severe short stature and was the first documented case of early onset anterior pituitary hypoplasia.[371] In another family, two siblings with isolated growth hormone deficiency were found to be compound heterozygous for inactivating GHRH receptor gene mutations.[378]

Three more novel mutations were identified in families with severe short stature in the United Kingdom (W273S, R94L, and R162W).[369] The only mutation found in the promoter region of GHRH affects one of the Pit-1 binding sites.[379]

Studies of subjects in these large kindreds who are homozygous or compound heterozygous for inactivating GHRH receptor gene mutations have shown that affected children experience severe postnatal growth failure with proportionate short stature.[366,367,377,378] Males have high-pitched voices and moderately delayed puberty.[366,367,377] Unlike infants with complete growth hormone deficiency, they do not have frontal bossing, microphallus, or hypoglycemia.[366,377,378] Bone age is delayed with respect to chronologic age but advanced with respect to height age.[377] Some patients have been found to have pituitary hypoplasia.[366,377] Growth velocity increased with exogenous growth hormone therapy.[366,367,377,378] Remarkably, growth hormone treatment of two siblings from Turkey with the E72X mutation allowed them to reach a normal adult height despite pretreatment heights of −6.7 and –8.6 SD and initiation of growth hormone around age 14.[380]

Further studies in the Brazilian cohort revealed that homozygotes had increased abdominal obesity, a higher low-density lipoprotein (LDL), and total cholesterol but normal carotid wall thickness and no evidence of premature atherosclerosis.[381] Treatment of these patients with GH for 6 months improved body composition, reduced LDL and total cholesterol, and increased high-density lipoprotein (HDL). Surprisingly this was associated with increased carotid intima-media thickness and atherosclerotic plaques.[382] Reevaluation 5 years after the discontinuation of growth hormone showed a return to baseline for these measures.[383] Heterozygotes for the null mutation had normal adult heights and IGF1 SD scores but exhibited reduced body weight, body mass index (BMI), lean mass, fat mass, and increased insulin sensitivity.[384]

SNPs in the GHRH receptor have been shown to contribute to height-SDS variation,[385,386] but mutations remain a rare cause of isolated growth hormone deficiency.[387]

Gastric Inhibitory Polypeptide Receptors

The gastric inhibitory peptide receptor (GIPR) gene is located on the long arm of chromosome 19.[388] Two functional isoforms exist in humans due to alternate splicing.[389] GIPR activation induces $G\alpha_s$ activation of adenylyl cyclase.[389-391] Gastric inhibitory polypeptide (GIP) is also known as glucose-dependent insulinotropic polypeptide and is released by K cells in the small intestine in response to food. GIP has numerous physiologic actions, including stimulation of glucagon, somatostatin, and insulin release by pancreatic islet cells.[392,393] Human mutations in the GIP receptor have not been identified to date. One study identified a SNP in the GIPR that is associated with insulin resistance in obese German children.[394] Another study identified an SNP in the GIPR that is associated with reduced fasting and induced C-peptide levels.[395]

The GIPR is implicated in food-dependent Cushing syndrome. Circulating cortisol levels in patients with food-dependent or GIP-dependent Cushing syndrome rise abnormally in response to food intake.[94,95] GIP does not normally induce cortisol release from adrenocortical cells.[396,397] These patients may have adrenal adenomas or nodular bilateral adrenal hyperplasia that overexpresses GIPRs that abnormally stimulate cortisol secretion when activated.[396,398] Thus, in these patients postprandial GIP release leads to activation of these abnormally expressed and functioning adrenal GIPRs, resulting in excessive adrenal cortisol secretion.[396,397]

Parathyroid Hormone and Parathyroid Hormone–Related Peptide Receptors

Two types of parathyroid hormone (PTH) receptors have been identified. The type 1 PTH receptor (PTHR1) is activated by PTH and parathyroid hormone–related peptide (PTHrP) and mediates PTH effects in bone and kidney.[399] In spite of 51% homology to the PTHR1, the type 2 PTH receptor (PTHR2) is activated by PTH but not PTHrP.[399-402] The PTHR2 is particularly abundant in the brain and pancreas but is also expressed in the growth plate; its natural ligand is TIP39.[403-405] The function of the PTHR2 is largely unknown.[399,400]

The PTHR1 has a large aminoterminal extracellular domain containing six conserved cysteine residues.[399] Ligand binding induces the PTHR1 to interact with G_s and G_q proteins, leading to activation of the adenylyl cyclase/protein kinase A and phospholipase C/protein kinase C second-messenger pathways, respectively.[406-411] Interestingly, mutations in i2 interfere with coupling of the PTHR1 to G_q without interfering with coupling to G_s—whereas mutations in i3 disrupt coupling of the receptor to both G proteins.[412,413] Binding of PTH to the PTHR1 leads to internalization of a portion of plasma membrane containing a ternary complex of activated receptor-Gsα-adenylyl cyclase that exhibits sustained production of cyclic AMP.[414] By contrast, PTHrP binding to the PTHR1 receptor leads to formation of a complex that remains on the cell surface and generates cyclic AMP for only a short period of time.[414]

Biallelic loss-of-function mutations in the PTHR1 gene cause Blomstrand chondrodysplasia.[399] This lethal disorder is characterized by accelerated chondrocyte differentiation, resulting in short-limbed dwarfism, mandibular hypoplasia, lack of breast and nipple development, and severely impacted teeth.[399,415] One patient with this rare condition was found to be homozygous for a point mutation that resulted in a Pro132Leu substitution in the N-terminal domain that interferes with ligand binding.[416,417] Another patient was found to be homozygous for a frameshift mutation that results in a truncated receptor lacking TM5-7, and contiguous intracellular and extracellular domains.[418]

A third patient was found to have a maternally inherited mutation that altered splicing of maternal mRNA, resulting in a PTHR1 with a deletion of residues 373 through 383 in TM5 (which also interferes with ligand binding).[419] In spite of heterozygosity for the mutation, the patient was unable to produce normal PTHR1s because for unknown reasons the paternal allele was not expressed.[419] Heterozygosity for somatic or germline Arg150Cys missense mutations in the PTHR1 was

identified in two out of six patients with enchondromatosis,[420] a condition that is usually sporadic and which is attributed to a postzygotic somatic cell mutation. Enchondromas are benign cartilage tumors that develop in the metaphyses and may become incorporated into the diaphyses of long tubular bones, in close proximity to growth plate cartilage; there is an increased risk of malignant transformation to osteosarcoma.[16] Patients with multiple enchondromatosis (OMIM ID: 166000) have Ollier disease (World Health Organization terminology), a disorder characterized by the presence multiple enchondromas with an asymmetric distribution of lesions that vary in size, number, and location. When multiple enchondromatosis occurs with soft tissue hemangiomas, the disorder is known as Maffucci syndrome. In vitro studies showed that the Arg150Cys mutation was mildly activating but led to stimulation of phospholipase C rather than adenylyl cyclase.[420] A transgenic knockin mouse expressing the mutant PTHR1 under the control of the collagen type 2 promoter showed development of tumors that are similar to those observed in human enchondromatosis.[420] The clinical significance of these observations are uncertain, as most cases of enchondromatosis are caused by mutations in the IDH1 and IDH2 genes.[421,422]

Some cases of Jansen metaphyseal chondrodysplasia have been found to be caused by constitutively activating mutations of the PTHR1 gene.[423-425] This autosomal-dominant disorder is characterized by short-limbed dwarfism due to impaired terminal chondrocyte differentiation and delayed mineralization accompanied by hypercalcemia.[423,424] Interestingly, constitutive activation appears to result predominantly in excessive $G\alpha_s$ activity because adenylyl cyclase activity is increased and PLC activity is unchanged in COS-7 cells expressing mutated receptors.[423-425]

Other Class B Receptors That Transduce Hormone Action

Other class B receptors that transduce hormone action include glucagon-like peptide-1, glucagon, calcitonin, and corticotrophin-releasing factor receptors.[426] Class B receptors usually couple with heterotrimeric G_s proteins, leading to the activation of adenylyl cyclase—which in turn leads to elevated intracellular cAMP levels.[426,427] (See Chapter 19 for a discussion of the role of GLP1 in promoting insulin secretion and the use of GLP1 analogues or inhibitors of GLP1 breakdown in therapy.)

CLASS C RECEPTORS THAT TRANSDUCE HORMONE ACTION

Calcium-Sensing Receptors

The calcium-sensing receptor (CaSR) is located on the long arm of chromosome 3 (3q21.1).[428] The CaSR has a large aminoterminal domain that contains nine potential glycosylation sites.[429] Binding of ionized calcium to the CaSR leads to activation of phospholipase C via activation of $G_{q/11}$ proteins.[429,430]

The CaSR is an integral component of a feedback system that utilizes PTH and renal tubular calcium reabsorption to keep the serum concentrations of ionized calcium within a narrow physiologic range.[431] Increased extracellular ionized calcium concentrations activate CaSRs in parathyroid chief and renal tubular epithelial cells, leading to decreased PTH release and renal tubular calcium reabsorption.[429,432] When ionized calcium concentrations fall, CaSR activation decreases—leading to increased PTH release and enhanced renal tubular calcium reabsorption.[429,432]

The CaSR also binds magnesium, and thus PTH secretion can be inhibited by elevated serum concentrations of magnesium with consequent hypocalcemia.[433] The CaSR may participate in magnesium homeostasis by altering reabsorption of magnesium in the thick ascending limb of Henle in the kidneys.[434,435] It is probable that increased peritubular levels of magnesium activate renal CaSRs, leading to inhibition of reabsorption of magnesium from the thick ascending limb of Henle—which in turn leads to increased renal excretion of magnesium.[434,435]

Familial (benign) hypocalciuric hypercalcemia (FBH or FHH) and neonatal severe hyperparathyroidism (NSHPT) are caused by loss-of-function mutations of the CaSR gene.[436,437] Most of these mutations are located in the N-terminal extracellular domain.[438,439] With few exceptions, individuals heterozygous for loss-of-function mutations have FBH, a benign condition characterized by very low urinary calcium excretion, mild hypercalcemia, normal or slightly elevated serum PTH levels, and few if any symptoms of hypercalcemia or hyperparathyroidism. By contrast, individuals homozygous for such mutations will develop NSHPT, a life-threatening condition characterized by severe hypercalcemia, markedly elevated serum PTH levels and skeletal defects.[440,441] Therefore, children of consanguineous FBH parents are at risk for NSHPT.[438,442,443] Occasionally, infants with NSHPT are heterozygous for CaSR gene mutations.[444] In most cases FHH is transmitted in an autosomal dominant manner, but autosomal recessive inheritance has been described in one kindred in which the CaSR mutation was only weakly inactivating.[445]

Decreased CaSR function impedes calcium ion suppression of PTH release and renal tubular calcium reabsorption.[437] Thus, FBH is characterized by mild hypercalcemia that is accompanied by inappropriately normal or elevated serum PTH levels and by relatively low urinary calcium excretion.[440,446,447] Individuals with FBH may also have hypermagnesemia as a result of decreased peritubular inhibition of magnesium reabsorption from the thick ascending loops of the kidneys by the CaSR.[435] There are three type of FBH: FBH type 1 (FBH1), FBH type 2 (FBH2), and FBH type 3 (FBH3).[448]

FBH1 is due to heterozygous loss-of-function mutations of the CaSR gene on 3q21.1.[448] Two other chromosomal loci have been identified in patients with FBH who do not have CaSR gene mutations. FBH2 has been mapped to 19p13.3 and is biochemically and clinically similar to FBH1.[448,449] FBH3, which is also known as the Oklahoma variant (FBH_{OK}), has been mapped to 19q13.[448,450] Adults with FBH3 have hypophosphatemia, elevated serum PTH levels, and osteomalacia in addition to the clinical and biochemical findings found in individuals with FBH1 and FBH2.[448,451] NSHPT is characterized

by severe hypercalcemia accompanied by elevated circulating PTH levels, undermineralization of bone, rib cage deformity, and multiple long-bone and rib fractures.[440]

Activating mutations of the CaSR gene cause autosomal-dominant hypocalcemic hypercalciuria (ADHH), also known as autosomal dominant hypocalcemia, as increased CaSR function leads to increased calcium ion suppression of PTH release and suppression of renal tubular calcium reabsorption.[430,448,452-456] ADHH is characterized by hypocalcemia and hypomagnesemia accompanied by inappropriately normal or increased urinary calcium excretion and inappropriately normal or low serum PTH levels.[430,454-456] Patients with ADHH may be asymptomatic or may present with tetany, muscle cramps, or seizures during infancy or childhood.[454-457] Similar to inactivating mutations, most activating mutations are located in the N-terminal extracellular domain.[452,454,455,457] Treatment of patients with ADHH with activated forms of vitamin D (e.g., calcitriol) is complicated as normalization of serum calcium levels is associated with worsening of hypercalciuria, hence further increasing the risk of nephrolithiasis, in nephrocalcinosis, and in renal impairment.[454,455]

Some patients with activating mutations of the CaSR gene will develop Bartter syndrome type V, which similar to other types of Bartter syndrome, is characterized by hypokalemic metabolic alkalosis and by hyperaldosteronism due to elevated renin levels.[458,459] Patients with Bartter syndrome type V, unlike patients with other types of Bartter syndrome, may also have symptomatic hypocalcemia and are at risk for developing nephrocalcinosis due to hypercalciuria.[458,459] Evidence from in vitro functional expression studies suggests that patients with mild or moderate heterozygous gain-of-function mutations of the CaSR develop ADHH, whereas those with severe heterozygous gain-of-function mutations of the CaSR will also develop Bartter syndrome type V.[458-460]

Some single–amino-acid polymorphisms of the CaSR gene appear to predict whole-blood ionized and serum total calcium levels and may increase the risk for bone and mineral metabolism disorders in individuals with other genetic and environmental risk factors for these disorders.[461-463] Individuals heterozygous or homozygous for a Gln1011Glu CaSR gene polymorphism tend to have higher calcium levels than individuals with the polymorphism.[463,464] The 15.4% of 387 healthy young Canadian women with at least one CaSR gene allele with an Ala986Ser polymorphism were found to have higher total calcium levels than the remainder of the women without the polymorphism.[462]

Another study of 377 unrelated healthy Italian adult males and females found that 24% of study subjects were heterozygous or homozygous for the Ala986Ser polymorphism and confirmed the finding that individuals without the polymorphism have lower whole-blood ionized calcium levels than individuals with the polymorphism.[463] The Ala986Ser polymorphism has also been associated with Paget disease and primary hyperparathyroidism.[464-466] Individuals with a less common Arg990Gly polymorphism tend to have lower whole-blood ionized calcium levels than individuals without the polymorphism.[463] The Arg990Gly polymorphism has been found to be associated with hypercalciuria and nephrolithiasis.[466,467]

Auto-antibodies against the CaSR that interfere with binding of calcium to the receptor may cause autoimmune hypocalciuric hypercalcemia.[468] These patients have primary hyperparathyroidism with the clinical and biochemical features of patients with FBH.[468] Conversely, auto-antibodies that activate the CaSR are a cause of autoimmune-acquired hypoparathyroidism.[469] Both conditions may occur in association with other autoimmune conditions (such as autoimmune thyroiditis), with celiac disease in patients with autoimmune hypocalciuric hypercalcemia, and with autoimmune thyroiditis and autoimmune polyglandular syndrome types 1 and 2 in patients with autoimmune-acquired hypoparathyroidism.[468-470] Auto-antibodies that activate the CaSR were found in approximately one third of individuals with acquired hypoparathyroidism.[470]

G PROTEIN GENE DISORDERS

A growing number of human disorders are associated with somatic or germline mutations in genes that encode the subunits of G proteins and lead to either a gain of function or a loss of function in the signaling protein.[471] Here we will limit discussion to disorders associated with mutations of the *GNAS* gene that encodes $G\alpha_s$, as these mutations are the principal causes of endocrine disorders.

Inactivating Mutations of the *GNAS* Gene

Pseudohypoparathyroidism type 1a (PHP-1a; Albright hereditary osteodystrophy) and pseudopseudohypoparathyroidism (PPHP) are caused by heterozygous inactivating mutations of the GNAS gene that encodes $G\alpha_s$.[472-477] PHP-1a is characterized by end organ resistance to PTH with consequent hypocalcemia, hyperphosphatemia, and elevated circulating PTH levels. In addition, patients also manifest GHRH and TSH resistance as well as obesity and mildly impaired neurocognitive development. PHP Ia patients also show a constellation of developmental defects that have been termed Albright hereditary osteodystrophy (AHO) and which include heterotopic ossifications, short stature, mental retardation, brachydactyly of the hands and feet characterized by shortened fingers and short fourth and fifth metacarpals.[472-475] Patients with the associated condition PPHP have the same features of AHO as PHP-1a, but with the absence of hormone resistance to PTH.[472,473,476] The distinction between these two manifestations of the same gene defect is not stochastic but results from a complex mechanism of genomic imprinting that controls transcription of the GNAS gene. Hence, patients with a GNAS mutation on a maternal allele will develop a more severe form of Gsα deficiency with hormone resistance (i.e., PHP-1a), whereas patients with identical mutations on the paternal GNAS allele will have a milder condition with normal hormone responsiveness (i.e., PPHP).[472-476]

Although most cells express Gsα from both parental alleles, in some cells Gsα expression is suppressed from the paternal GNAS allele. Thus, patients with PHP Ia

develop hormone resistance that is limited to the thyroid, pituitary somatotrophs, and proximal renal tubule cells because in these cells $G\alpha_s$ is derived principally from the maternal GNAS allele.[478] Thus, patients with maternally inherited inactivating GNAS gene mutations express very little $G\alpha_s$ in these cells and develop hormone resistance.[478] Because Gsα is not expressed from the paternal allele in imprinted tissues, PPHP patients with paternally inherited inactivating GNAS gene mutations do not experience a deficit in Gsα protein in these cells, as they will have a normal amount of Gsα protein that is produced from the wild-type maternal GNAS allele.[478] Patients with either PHP Ia or PPHP express only 50% of the normal amount of Gsα protein in cells in which Gsα transcription is not controlled by the imprinting mechanism, which likely accounts for the similar features of AHO that occur in these two conditions. Subjects with paternally inherited GNAS mutations have variable features of AHO without hormonal resistance and have been described to have pseudopseudohypoparathyroidism (PPHP), progressive osseous heteroplasia (POH),[479] or osteoma cutis[480-482] based on the clinical phenotype. The basis for these distinctions is unknown.

Subjects with PHP type 1b (PHP Ib; MIM 603233) lack typical features of AHO but may have mild brachydactyly. PTH resistance is the principal manifestation of hormone resistance, but some patients have slightly elevated serum levels of TSH and normal serum concentrations of thyroid hormones as evidence of partial TSH resistance. It was initially thought that PHP-1b is caused by inactivating mutations in the PTHR1 gene.[483] However, no deleterious PTHR1 gene mutations have been found in patients with PHP-1b.[484,485]

Epigenetic defects in imprinting of GNAS are the cause of PHP-1b. There are three alternative first exons for GNAS (i.e., NESP55, XLαs, and exon A/B) that splice onto exons 2 through 13 and are associated with differentially methylated regions (DMRs). Most relevantly, the exon A/B DMR is methylated in the maternal germ cells and seems to be the principal control element for transcription from exon 1.[478,486] Loss of methylation in the DMR upstream of exon A/B of the maternal allele is a consistent finding in patients with PHP 1b, and this epigenetic defect accounts for decreased Gαs expression from the affected allele.[487-489] Most cases of autosomal dominant PHP 1b are caused by microdeletions on the maternal allele that include exons 3 to 5 or 4 to 6 of the gene encoding syntaxin-16 (STX16) (reviewed in the journal Current Molecular Medicine[487]). Three other maternally inherited microdeletions involving NESP55 and AS (delNESP55/ASdel3-4) or AS (delAS3-4) alone[490] have been identified, and these deletions produce a more global disruption of methylation that includes three GNAS DMRs (A/B, XL/AS, and NESP55). The genetic basis for most cases of sporadic PHP 1b remains unknown and does not appear to be associated with the GNAS locus.[491] These patients have global epigenetic defects in methylation that affect all three DMRs. In some cases, partial[491] or complete[492] paternal uniparental disomy (UPD) for chromosome 20 has been identified, in which two normal copies of GNAS are both derived from the father. Paternal UPD would predict a near complete deficiency of Gαs in imprinted cells and tissues in which Gαs is not transcribed from the paternal allele.

$G\alpha_s$ is not expressed in the renal proximal tubules of these patients due to lack of a GNAS allele with a maternal epigenotype. By contrast, both of the GNAS alleles with paternal epigenotypes are normally expressed in nonimprinted cells in which expression of Gsα from the paternal allele is not suppressed.[493]

Activating Mutations of the GNAS Gene

When a GPCR is activated by a ligand, the activated receptor interacts with the heterotrimeric G protein and allows release of bound GDP from the Gα subunit with replacement by GTP. The GTP-bound Gα dissociates from the Gβγ dimer, and both complexes are free to associate with downstream signal generating molecules.[6,7,9] The generation of second messengers is terminated by an intrinsic GTPase within the Gα subunit that acts as a timer; hydrolysis of GTP to GDP inactivates Gα and increases its affinity for Gβγ—leading to reassociation of an inactive heterotrimeric G protein that is ready for another cycle of receptor-induced activation.[6,7,9] For Gsα, the amino acids Arg^{200} and Gln^{226} are critical to GTPase activity.[493] GNAS mutations that result in substitutions of these amino acid residues lead to abrogation of GTPase activity and therefore prolong the active state of $G\alpha_s$ thereby leading to constitutive (i.e., receptor ligand-independent) stimulation of adenylyl cyclase.[493] Somatic mutations of these residues that disrupt GTPase activity are present in approximately 40% of growth-hormone–secreting and some ACTH-secreting and nonsecreting pituitary tumors; in some parathyroid, ovarian, testicular, thyroid, and adrenal tumors; and in some intramuscular myxomas.[92,494,495]

More widespread mosaic Arg^{200} $G\alpha_s$ mutations that decrease GTPase activity cause fibrous dysplasia or (when tissue distribution of the mutation is very widespread) McCune-Albright syndrome, which is characterized by the triad of café-au-lait spots, polyostotic fibrous dysplasia, and primary endocrine hyperfunction, particularly gonadotropin-independent precocious puberty.[496-500]

Patients with McCune-Albright syndrome may also have excessive growth hormone production, hyperthyroidism, and hypercortisolism, as well as nodularity of the pituitary, thyroid, and adrenal glands due to the growth-promoting effects of excessive cyclic AMP in these tissues.[497,501] Hypophosphatemia, which is not uncommon in patients with McCune-Albright syndrome, appears to be due to excessive production of the phosphatonin FGF-23 by fibrous dysplasia skeletal lesions.[502,503] Patients with McCune-Albright syndrome may also have nonendocrine problems such as hepatobiliary abnormalities, cardiomyopathy, optic neuropathy, and sudden death.[501,504,505]

CYTOKINE RECEPTORS

Cytokines are molecules produced by one cell that act on another cell.[506] Thus, the term *cytokine* can apply not only to molecules with immunologic functions but also to

hormones. Therefore, growth hormone, prolactin, and leptin are classified as type 1 cytokines.[507] These and other type 1 cytokines (including ILs 2–9, 11–13, and 15; erythropoietin; thrombopoietin; and granulocyte-colony–stimulating factor) are characterized by a four α-helical bundle structure and signaling via type 1 cytokine receptors.[507] Type 2 cytokines include the interferons and IL-10 and do not include hormones.[507]

Type 1 cytokines are divided into long-chain and short-chain cytokines.[507] Prolactin, leptin, and growth hormone belong to the long-chain subclass of type 1 cytokines because their helixes are 25 amino acids in length.[507] The short-chain type 1 cytokines, including IL-2 and stem cell factor, have helixes of approximately 15 amino acids in length.[507]

Structure and Function of Type 1 Cytokine Receptors

All type 1 cytokine receptors have four conserved cysteine residues, fibronectin type 2 modules, a Trp-Ser-X-Trp-Ser motif in the extracellular domain, and a proline-rich Box 1/Box 2 region in the cytoplasmic domain.[507,508] With the exception of stem cell factor, type 1 cytokine receptors do not contain catalytic domains such as kinases.[507]

Type 1 cytokine receptors for long-chain type 1 cytokines require homodimerization for activation.[507,509] First, the ligand binds a monomeric receptor.[507,509] Then, the ligand interacts with a second receptor to induce receptor dimerization and activation.[507,509] Activated receptors then stimulate members of the Janus family of tyrosine kinases (Jak kinases) to phosphorylate tyrosine residues on both the kinase itself and the cytoplasmic region of the receptors.[507,510] Signal transducers and activators of transcription (STATs) then dock on the phosphorylated cytoplasmic receptor domains or Jak kinases via an SH2 domain and are tyrosine phophorylated.[507] The phosphorylated STATs then dissociate from the receptors or Jak kinases, form homo- or heterodimers, and translocate to the nucleus.[507,511,512] In the nucleus, the STAT dimers bind and alter the activity of regulatory regions of target DNA.[507,511,513]

There are four Jak kinases.[511,514] Jak3 is only expressed in lymphohematopoietic cells, whereas Jak1, Jak2, and Tyk2 are expressed in every cell.[507,515,516] There are seven STATs (Stat1, Stat2, Stat3, Stat4, Stat5a, Stat5b, and Stat6), which have different SH2 domain sequences that confer different receptor specificities.[507,510-512]

Cytokine Receptors That Transduce Hormone Action

The actions of growth hormone, prolactin, and leptin are mediated via specific type 1 cytokine receptors.[507] Mutations of the growth hormone receptor (GHR) and the leptin receptor have been identified as the bases of specific endocrine disorders (Table 3-3).

Growth Hormone Receptors

The GHR gene is located on the short arm of chromosome 5 (5p13.1-p12), and 9 of the 13 exons of the gene encode the receptor.[517-520] A secretion signal sequence is encoded by exon 2, the N-terminal extracellular ligand binding domain is encoded by exons 3 through 7, the single transmembrane domain is encoded by exon 9, and the C-terminal cytoplasmic domain is encoded by exons 9 and 10.[517-520] Growth hormone binding protein (GHBP) is produced by proteolytic cleavage of the extracellular domain of the GHR from the rest of the receptor.[521] Approximately 50% of circulating growth hormone is bound to GHBP.[521]

Binding of growth hormone to its receptor induces receptor dimerization and association with JAK2, a member of the Janus kinase family, which results in self-phosphorylation of the JAK2 and a cascade of phosphorylation of cellular proteins, including Stat1, Stat3, and Stat5.[522-526] The most critical of these proteins is STAT5b, which couples GH binding to the activation of gene expression that leads to the intracellular effects of GH, including synthesis of IGF-I, insulin-like growth factor binding protein 3 (IGFBP3), and ALS. The phosphorylated STATs translocate to the nucleus, where they regulate growth hormone–responsive genes.[523-526] In particular, growth hormone indirectly controls growth by regulating production of insulin-like growth factor-1 (IGF-1)—which has direct effects on cell proliferation and hypertrophy.[527] Jak2 also activates the mitogen activated protein (MAP) kinase and insulin receptor substrate pathways.[528-530] However, the extent to which these pathways contribute to growth hormone action is as yet unknown.[520]

Patients are considered to have growth hormone insensitivity (GHI) if they do not exhibit appropriate growth and metabolic responses to physiologic levels of growth hormone.[521] The phenotype of GHI is variable and ranges from isolated moderate postnatal growth failure to severe postnatal growth failure accompanied by

TABLE 3-3 **Cytokine Receptors and Clinical Conditions Associated with Receptor Mutations**

Receptor	Germline Mutation	Endocrine Disorder
Growth hormone receptor	Some inactivating (heterozygous)	Partial growth hormone insensitivity with mild to moderate growth failure
	Inactivating (homozygous, compound heterozygous)	Growth hormone insensitivity/Laron syndrome with moderate to severe postnatal growth failure
Leptin receptor	Inactivating (homozygous)	Obesity and hypogonadotropic hypogonadism

the classic features of Laron syndrome in Ecuadorean patients with GHR deficiency.[521,531-535] Features of GHR deficiency include frontal temporal hairline recession, prominent forehead, decreased vertical dimension of face, hypoplastic nasal bridge, shallow orbits, blue sclera, small phallus prior to puberty, crowded permanent teeth, absent third molars, small hands and feet, hypoplastic fingernails, hypomuscularity, delayed age of onset for walking, high-pitched voice, increased total and low-density lipoprotein cholesterol, and fasting hypoglycemia.[521,535] All patients with GHI have normal or elevated circulating growth hormone levels, markedly decreased circulating IGF-1 levels, and a delayed bone age.[521]

Patients homozygous or compound heterozygous for deletion of exons 5 and 6—or homozygous or compound heterozygous for numerous nonsense, missense, frameshift, and splice-point mutations throughout the GHR gene—have been found to have GHI characterized by severe postnatal growth failure and usually low or absent circulating GHBP levels.[521,536-545] Patients homozygous or compound heterozygous for the Arg274Thr or the Gly223Gly splice mutations that result in a truncated receptor that cannot be anchored to the plasma membrane (or that result in the Asp152His missense mutation that interferes with GHR dimerization) have normal circulating GHBP levels.[521]

Patients heterozygous for mutations that alter the GHR have dimerization complexes that consist of two wild-type receptors, a wild-type receptor and a mutant receptor, and two mutant receptors. Thus, heterozygosity for loss-of-function GHR gene mutations may have a dominant negative effect because the wild-type receptor/mutant receptor dimers may not be able to function normally.[546] As expected from this phenomenon, some patients with moderate to severe growth failure have been found to be heterozygous for loss-of-function point or splice mutations of the GHR gene that alter the cytoplasmic or extracellular domains.[521,547-550] In some cases nonsense mediated mRNA decay can lead to degradation of the aberrant mRNA and prevent a potential dominant negative effect.[551]

Some patients with severe short stature and GHI do not have GHR mutations. Rather, they have defects in GHR-mediated intracellular signaling—including impaired STAT activation.[552] Some patients with GHI were found to have STAT5b mutations.[553-557] Unlike patients with GHR mutations, patients with STAT5b mutations also exhibited severe neurocognitive delay, chronic lung disease, and abnormal T-cell function.[554] Patients with GHI can now be successfully treated with recombinant IGF1,[558] but this does not result in a normal adult height, in contrast to GH deficiency in which GH therapy can achieve normal adult height.

LEPTIN RECEPTORS

The leptin receptor (LEPR, also known as Ob-R) gene is located at 1p31. There are five isoforms of LEPR due to alternative splicing of the LEPR gene transcript (Figure 3-5).[560] Only the Ob-Rb isoform contains both the Jak kinase binding and STAT motifs necessary to maximally transduce the effects of leptin.[560] The Ob-Ra, Ob-Rc, and Ob-Rd isoforms contain intact extracellular and transmembrane but are missing the STAT motif from their cytoplasmic domains.[560] The Ob-Re isoform is missing the transmembrane and cytoplasmic domains.[560] Thus, the Ob-Rb isoform is thought

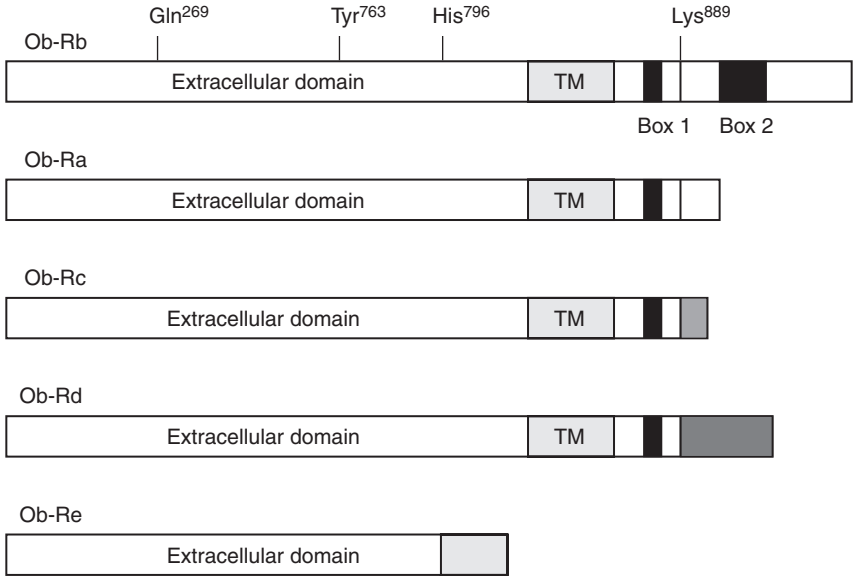

FIGURE 3-5 ■ Leptin receptor isoforms. There are five leptin receptor isoforms. Box 1 represents the Jak kinase binding motif, and box 2 represents the STAT motif. The Ob-Rb isoform is the only isoform that contains Jak kinase binding and STAT motifs, and it is thus thought to be the main isoform involved in mediating the effects of leptin. The Ob-Ra, Ob-Rc, and Ob-Rd isoforms are missing the STAT motif. The Ob-Re isoform is missing the transmembrane (TM) and cytoplasmic domains. (Reproduced with permission from Chen, D., & Garg, A. [1999]. Monogenic disorders of obesity and body fat distribution. *J Lipid Res, 40,* 1737.)

to be the main isoform involved in mediating the effects of leptin.[560]

Three sisters from a consanguineous kindred were found to be homozygous for a splice mutation in the LEPR gene that resulted in expression of an 831-amino- acid protein (Ob-Rhd) that lacks transmembrane and cytoplasmic domains.[561] They had been hyperphagic and morbidly obese since birth.[561] They were found to have elevated circulating leptin levels, decreased TSH and GH secretion, and failure of pubertal development due to hypogonadotropic hypogonadism.[561] Heterozygous carriers of the mutation are not morbidly obese and do not have delayed or absent puberty.[561]

Nonsense or missense LEPR mutations were identified in 3% of a selected cohort of 300 subjects with early onset obesity. Individuals with mutations had hyperphagia, severe obesity beginning in the first year of life with a mean BMISDS of +5.1, altered immune function, and delayed puberty due to hypogonadotropic hypogonadism. Importantly, circulating leptin levels were within the range predicted by the elevated fat mass, and clinical features were less severe than those of subjects with congenital leptin deficiency.[562] Heterozygous family members had an average BMISDS of +0.6 similar to that of family members with normal leptin receptors. Functional characterization of these missense mutations revealed defects causing intracellular retention, misfolding, or failure to signal to downstream pathways.[563] Additional novel mutations have been reported that cause similar phenotypes.[564,565]

RECEPTOR TYROSINE KINASES

The receptor tyrosine kinase (RTK) superfamily consists of 15 receptor tyrosine kinase families (Figure 3-6).[566] With one exception, these families consist of receptors with one membrane-spanning domain (see Figure 3-6).[566] The single-membrane–spanning receptors typically contain an N-terminal extracellular portion, a transmembrane helix, a juxtamembrane region, a tyrosine kinase (TK) domain, and a C-terminal region (see Figure 3-6).[566] These receptors require dimerization to be maximally activated.[566-568] Receptors belonging to insulin RTK family differ from other RTKs, as they contain two membrane-spanning polypeptide chains linked by disulfide bonds to two intervening extracellular peptide chains and thus do not dimerize (see Figure 3-6).[562]

Activation of RTKs leads to phosphorylation of tyrosine residues in the activation loop (A-loop) in the TK domain(s), resulting in activation of the TK(s).[562,569] Activation of the TK(s), in turn, induces the transfer of phosphate from adenosine triphosphate (ATP) to tyrosine residues in the cytosolic portion of the receptor and in cytosolic proteins that serve as docking sites for second messengers.[562]

There is a growing body of evidence suggesting that members of the receptor tyrosine kinase superfamily can directly and indirectly interact with heterotrimeric G proteins. The insulin, insulin-like growth factor-1, and insulin-like growth factor-2 receptors appear to directly interact with $G_{i/o}$ and $G_{q/11}$, $G_{i/o,}$ and G_i, respectively.[570] The fibroblast growth factor receptors appear to directly and indirectly interact with G_s.[570] Congenital alteration of function of receptors in the insulin and the fibroblast growth factor RTK families leads to endocrine disorders (Table 3-4).

Insulin Receptor Tyrosine Kinase Family

The insulin RTK family includes the insulin receptor (INSR) and the insulin-like growth factor-1 receptor (IGF1R).[570] These receptors are heterotetramers consisting of two α and β subunits in an αββα configuration (Figure 3-7).[571-573] The cysteine-rich extracellular α

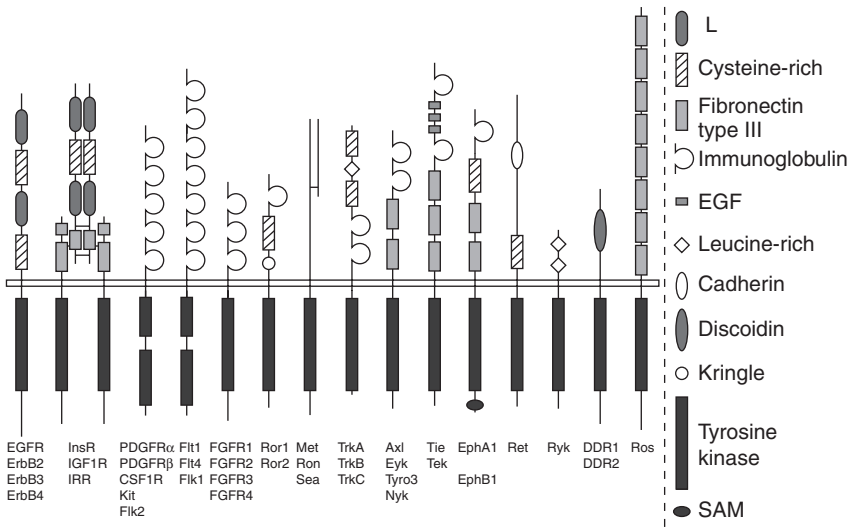

FIGURE 3-6 ■ The 15 RTK families. Each family has a characteristic extracellular portion and a cytoplasmic portion that contains a tyrosine kinase domain. (Reproduced with permission from Hubbard, S. R. [1999]. Structural analysis of receptor tyrosine kinases. *Prog Biophys Mol Biol, 71*, 344.)

TABLE 3-4 **Receptor Tyrosine Kinases and Clinical Conditions Associated with Receptor Mutations**

Receptor	Germ-Line Mutation	Endocrine Disorder
Insulin receptor	Inactivating (heterozygous)	Some cases of type A syndrome
	Inactivating (homozygous, compound heterozygous)	Rabson Mendenhall, Donohue (leprechaunism), and some cases of type A syndromes
IGF-1 receptor	Gene deletion (heterozygous)	Pre- and postnatal growth failure
FGFR1	Inactivating mutation (heterozygous)	Kallmann syndrome, missing teeth, cleft palate
FGFR3	Activating mutations (heterozygous)	Achondroplasia, severe achondroplasia with developmental delay and acanthosis nigricans, thanatophoric dysplasia types I and II, and platyspondylic lethal skeletal dysplasias (San Diego types)

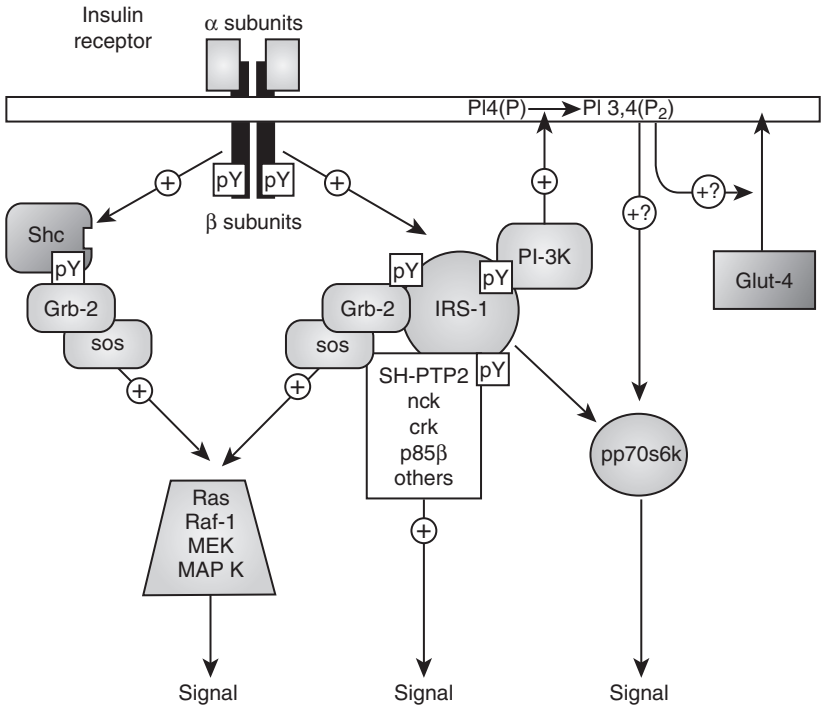

FIGURE 3-7 ■ Insulin receptor signaling. IRS proteins, SH2-domain–containing proteins (including Grb-2 and Shc), and other proteins (including SOS) interact to activate the Ras/Raf-1/MAP K cascade, the PI-3K/PKB cascades, and other enzymes—including SH-PTP2 (SHP2) and p70(s6k). (Adapted with permission from White, M. F. [1997]. The insulin signaling system and the IRS proteins. *Diabetologia, 40*, S10.)

subunits are linked by disulfide bonds, and each α subunit is linked to a plasma membrane-spanning and cytosolic β subunit by disulfide bonds.[573,574] Each β subunit contains a TK domain and a C-terminal region that contain tyrosine residues.[562]

Both insulin and insulin-like growth factor-1 (IGF-1) can bind INSRs and IGF1Rs. However, insulin has greater affinity for the INSR and IGF-1 has greater affinity for the IGF1R. Ligand binding alters the conformation of the receptor, resulting in *trans*-autophosphorylation of the C-terminal tyrosine residues on one β subunit by the TK on the other β subunit.[575,576] The phosphorylated tyrosine residues create motifs that can be bound by Src homology 2 (SH2)-domain-containing proteins, including Shc, Grb-2, SHP2, nck, phosphatidylinositol-3-kinase (PI3K), and Crk.[577-581] The receptor TK also phosphorylates tyrosine residues in insulin receptor substrate proteins (IRS), including IRS-1 and IRS-2, that bind INSRs and IGF1Rs.[581-584] When phosphorylated, these tyrosine residues create motifs that are bound by SH2-domain-containing proteins.[577,578,580,581,584] Thus, insulin receptor substrates can serve as docking proteins—allowing SH2-domain-containing proteins to indirectly interact with INSRs and IGF1Rs when stearic constraints do not permit direct interactions between the proteins and the receptors.[577,578,581] Ultimately, IRSs, SH2-domain-containing proteins, and other proteins (including mSOS) interact to activate the Ras/Raf/MAPKK/MAPK and PI3K/protein kinase B (PKB) cascades (see Figure 3-7).[580,581,584]

Activation of the Ras/Raf/ MAPKK/MAPK cascade increases mitogenesis and proliferation, and activation of the PI3K/PKB cascade increases glucose uptake and

glycogen synthesis.[573,585-590] Evidence suggests that IGF1 has a greater effect on cell growth than on glucose metabolism because activation of the IGF1R stimulates the Ras/MAPK cascade more than INSR activation.[573,589] Conversely, it appears that insulin has a greater effect on glucose metabolism because INSR activation stimulates the PI3K/PKB cascade more than IGF1R activation.[573,590]

THE INSULIN RECEPTOR

The INSR gene is located on 19p and contains 22 exons.[591] αβ half-receptor precursors are derived from proteolysis of a single proreceptor comprised of α and β subunits in tandem and disulfide linkage of these subunits.[581,591,592] These αβ half-receptor precursors then join to form a single αββα heterotetrameric insulin receptor.[592] Interestingly, αβ half-receptor precursors encoded by one allele may combine with αβ half-receptor precursors encoded by the other allele to form a single insulin receptor.[593] This phenomenon explains how heterozygous mutations resulting in impaired β subunit tyrosine kinase activity can have a dominant negative effect because activation of the INSR requires trans-autophosphorylation of one β subunit by the other β subunit.[593]

Mutations in the insulin receptor lead to Donohue syndrome (leprechaunism), Rabson-Mendenhall syndrome, or "type A insulin resistance syndrome." Patients with leprechaunism or Donohue syndrome are severely insulin resistant.[602,603] They present during infancy with severe intrauterine and postnatal growth retardation, lipoatrophy, and acanthosis nigricans.[600,602] They also have dysmorphic features that include globular eyes, micrognathia, and large ears.[600,602] Affected male infants commonly have penile enlargement, whereas affected female infants often have clitoromegaly and hirsutism.[600,602] In spite of hyperinsulinemia associated with glucose intolerance or diabetes mellitus, the major glucose metabolism problem for these patients is fasting hypoglycemia.[600,602] Many patients with this condition do not survive past the first year of life.[600,602] Unlike patients with Rabson-Mendenhall syndrome, patients with leprechaunism do not present with diabetic ketoacidosis. [601]

Patients with Rabson-Mendenhall syndrome present during childhood with severe insulin resistance.[599-601] Although patients with this disorder may present initially with fasting hypoglycemia, eventually they develop severe diabetic ketoacidosis that is refractory to insulin therapy.[601] Patients with this condition also have acanthosis nigricans, accelerated linear growth, dystrophic nails, premature and dysplastic dentition, coarse facial features, and pineal hyperplasia. [597,599-601]

Patients with "type A insulin resistance syndrome" have acanthosis nigricans and severe inherited insulin resistance in the absence of INSR autoantibodies.[594-596] Patients with this syndrome tend to be lean and develop glucose intolerance.[596,597] Females with this syndrome also exhibit signs of ovarian hyperandrogenism, including hirsutism, severe acne, clitoromegaly, oligomenorrhea, and infertility. [594-596]

Patients with "type B insulin resistance syndrome" are distinguished from patients with type A insulin resistance syndrome by the presence of anti-INSR antibodies in the plasma that block insulin binding.[594-596,598] Patients with "type B insulin resistance syndrome" present during adulthood with acanthosis nigricans, ovarian hyperandrogenism, and severe insulin resistance in association with signs of autoimmune disease—including alopecia areata, vitiligo, primary biliary cirrhosis, arthritis, and nephritis.[594-596,598] Surprisingly, these patients may present with fasting hypoglycemia that may or may not be accompanied by postprandial hyperglycemia.[594-596,598] Hodgkin disease and ataxia-telangiectasia are also associated with this syndrome.[596] The term *HAIR-AN* (hyperandrogenism, insulin resistance, and acanthosis nigricans) has also been used to describe women with features of types A and B insulin resistance syndromes in association with obesity.[596] However, this term is imprecise because many women who have been labeled as having HAIR-AN may actually have type A or B insulin resistance syndrome or severe polycystic ovary syndrome. [596]

Mutations in the INSR have been found in all patients with leprechaunism and Rabson-Mendenhall syndrome and in 10% to 15% of patients with type A insulin resistance syndrome.[596,603,604] These mutations are divided into five classes.[596,597,605] Class I mutations are frameshift or nonsense mutations that prematurely terminate translation and thus interfere with INSR synthesis. Class II mutations interfere with post-translational processing and intracellular trafficking of the INSR. Class III mutations decrease insulin binding to the INSR. Class IV mutations are point mutations usually located on the intracellular region of the β subunit that decrease INSR TK activity. Class V mutations increase INSR degradation by increasing insulin-induced endocytosis and degradation of the receptors.

Patients with Rabson-Mendenhall syndrome and leprechaunism are homozygous or compound heterozygous for these mutations.[596,606-616] Some patients with type A syndrome have been found to be heterozygous for dominant negative β-subunit mutations that reduce TK activity by 75%.[605,610,617-621] Other patients with type A syndrome have been found to be homozygous or compound heterozygous for α-subunit mutations that interfere with receptor trafficking to the plasma membrane, β-subunit mutations that interfere with TK activity, or mutations that interfere with proreceptor cleavage into α and β subunits. Still other patients have been found to have decreased INSR mRNA levels that may be due to a loss-of-function mutation in the INSR gene promoter.[597,622-626] Interestingly, one patient with leprechaunism with parents with type A syndrome has been described.[610] The proband was found to be homozygous for an INSR mutation that decreases TK activity, and the parents were found to be heterozygous for the mutation.[610]

THE INSULIN-LIKE GROWTH FACTOR-1 RECEPTOR

The growth-promoting effects of IGF-1 are mediated by IGF1Rs. IGF1R αβ subunits are encoded by a single

gene.[592] Like the insulin receptor, an αβ half-receptor precursor is produced that then joins with a half-receptor precursor that may be encoded from the other allele to form a complete heterotetrameric IGF1R.[592] The IGF1R has 100-fold less affinity for insulin than for IGF1.[627]

Patients who are heterozygous for a ring chromosome 15, resulting in deletion of the IGF1R gene, present with intrauterine growth retardation and postnatal growth failure accompanied by delayed bone age, mental retardation, cardiac abnormalities, cryptorchidism, and dysmorphic features that include microcephaly, triangular face, frontal bossing, hypertelorism, and brachydactyly.[628,629] Similarly, IUGR and postnatal growth failure are commonly found in patients heterozygous for deletion of distal 15q that results in deletion of the IGF1R gene. Patients with deletion of distal 15q often have microcephaly, triangular facies, hypertelorism, high-arched palate, micrognathia, cystic kidneys, and lung hypoplasia or dysplasia.[627,630-632] However, the ring chromosome and deleted area of distal 15q may also be missing other genes—and it is unknown to what extent absence of the IGF1R gene contributes to the phenotype found in these patients.[627,629]

It has been suggested African Efe Pygmies are short due to resistance to IGF1.[627] T-cell lines established from Efe Pygmies have decreased IGF1R gene expression, cell surface expression, receptor autophosphorylation, and intracellular signaling when compared with T-cell lines established from American controls.[627] However, no IGF1R gene mutation has been identified in Efe Pygmies that can account for these findings. [627]

No human homozygous IGF1R mutations have been identified and total loss of IGF1R function may be lethal as demonstrated in the mouse model.[633-635] Heterozygous and compound heterozygous mutations are associated with severe intrauterine growth retardation, microcephaly, and short stature with compound heterozygous mutations having a more severe phenotype.[633,636-638]

In addition to defective INSR function, some patients with leprechaunism and Rabson-Mendenhall syndrome are resistant to the glucose lowering or growth promotion of IGF1 and have abnormal IGF1R function—resulting in decreased ligand binding or altered intracellular signaling.[627,639-643] No deleterious IGF1R gene mutation has been identified in patients with these syndromes, and many patients with leprechaunism and Rabson-Mendenhall syndrome have normally functioning IGF1Rs and no evidence of IGF1 resistance.[627,644]

THE FIBROBLAST GROWTH FACTOR RECEPTOR FAMILY

There are four members of the fibroblast growth factor receptor (FGFR) tyrosine kinase family.[562] These are FGFR1, FGFR2, FGFR3, and FGFR4. These receptors consist of a single polypeptide chain that contains an N-terminal extracellular region, a transmembrane region, and a cytosolic region (see Figure 3-6).[562] The extracellular region contains three immunoglobulin-like domains: IgI, IgII, and IgIII (see Figure 3-6).[645] The cytosolic region contains a TK domain split into two segments (TK1 and TK2) by an intervening amino acid segment.[645]

Fibroblast growth factors, or FGFs, are a family of growth factors involved in angiogenesis, wound healing, and embryonic development. The FGFs are heparin-binding proteins and interactions with cell surface-associated heparan sulfate proteoglycans have been shown to be essential for FGF signal transduction. FGFs are key players in the processes of proliferation and differentiation of wide variety of cells and tissues. In humans, 22 members of the FGF family have been identified, all of which are structurally related signaling molecules.[645,646] As monomers, FGFs can only bind a single FGFR—forming an inactive 1:1 complex.[567] FGFR activation by dimerization occurs when two or more FGF molecules in 1:1 complexes are linked by heparan sulfate proteoglycans.[567]

Activation of FGFRs increases receptor TK activity.[645] Increased TK activity leads to autophosphorylation of a tyrosine residue in the C-terminal region, resulting in a binding site for the SH2 domain of phospholipase Cγ (PLCγ).[647,648] Once PLCγ is bound to this site, it is phosphorylated and activated.[647,648] In chondrocytes, activation of FGFR3 also induces activation of STAT1.[649]

Fibroblast Growth Factor Receptor 1

Inactivating mutations of the FGFR1 gene are a cause of autosomal-dominant Kallmann syndrome (KS).[650] Individuals with KS have anosmia and isolated hypogonadotropic hypogonadism.[651,652] The FGFR1, which is located on 8p12, plays a role in olfactory and GnRH neuronal migration from the nasal placode to the olfactory bulb and in the subsequent migration of the GnRH neurons to the hypothalamus.[650] Prior to identification of these FGFR1 gene mutations, X-linked KS was found to be caused by inactivating KAL1 gene mutations.[651,653,654] The KAL1 gene is located on the X chromosome and encodes anosmin-1.[651,653,654] Anosmin-1 is a ligand for the FGFR1 receptor.[655] Like FGFR1s, anosmin-1 plays a role in olfactory and GnRH neuronal migration to the nasal placode, and in the subsequent migration of GnRH neurons to the hypothalamus.[651,655,656]

There is a high penetrance for anosmia and signs of hypogonadotropic hypogonadism (including lack of puberty, microphallus, and cryptorchidism) in the 10% of KS patients with X-linked KS due to KAL1 gene mutations.[651] Female carriers of KAL1 gene mutations do not have anosmia or isolated hypogonadotropic hypogonadism.[651] In contrast to patients with KS due to KAL1 gene mutations, the approximately 10% of KS patients with FGFR1 gene mutations (even within the same kindred) exhibit variable phenotypes ranging from anosmia and complete hypogonadotropic hypogonadism (characterized by cryptorchidism and microphallus in males and absent pubertal development in both genders) to anosmia or delayed puberty.[650,657,658]

It has also been noted that in most kindreds with FGFR1 gene mutations females present with more mild KS phenotypes than males.[650,658] Female carriers may even be asymptomatic.[650,658] Because the KAL1 gene is located on the X chromosome, females may produce

more anosmin-1 than males.[650] Thus, a possible explanation for milder KS phenotypes in females with FGFR1 gene mutations may be that the increased anosmin-1 levels in females may lead to increased anosmin-1–induced activation of the mutant FGFR1s that may partially compensate for the mutation.[650] Interestingly, missing teeth and cleft palate are not an uncommon finding in individuals with KS due to FGFR1 gene mutations, whereas unilateral renal agenesis and bilateral synkinesia are associated with KS due to KAL1 gene mutations.[657]

Fibroblast Growth Factor Receptors 2-4

Gain-of-function mutations in the other three genes encoding FGFRs 2-4 cause many conditions—including Pfeiffer syndrome (activating mutations of FGFR1 and FGFR2), Crouzon syndrome (gain-of-function FGFR2 mutations), Crouzon syndrome with acanthosis nigricans (an FGFR3 mutation), Apert syndrome (FGFR2 mutations), and craniosynostosis (gain-of-function FGFR3 mutations).[645] Several autosomal-dominant short-limb dwarfism syndromes—including achondroplasia, severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN), hypochondroplasia, and three types of platyspondylic lethal skeletal dysplasias (PLSD) [thanatophoric dysplasia I (TDI), thanatophoric dysplasia II (TDII), and San Diego types (PLSD-SD)]—are often caused by heterozygous constitutively activating FGFR3 gene mutations.[659-662]

Individuals with achondroplasia have activating mutations in the transmembrane domain of FGFR3, with the Gly380Asn found in > 95% of achondroplastic patients.[660,663-665] From 40% to 70% of individuals with hypochondroplasia have an activating Asn540Lys mutation in the TK1 domain.[660,666-669] All individuals with TDII have an activating Lys650Glu mutation in the activating loop of the TK2 domain, and > 90% of individuals with TDI and PLSD-SD have FGFR3 mutations.[660,662] Patients with SADDAN have an activating mutation in the same codon as patients with TDII.[670] Instead of the Lys650Glu mutation associated with TDII, patients with SADDAN have a Lys650Met mutation.[670] However, unlike patients with TDII patients with SADDAN do not have craniosynostosis and a cloverleaf skull—and often survive past childhood.[670]

The FGFR3 gene is primarily expressed in endochondral growth plates of long bones, brain, and skin pre- and postnatally.[671,672] Constitutional activation of FGFR3s in chondrocytes leads to growth arrest and apoptosis.[649,673,674] In addition, constitutive activation of FGFR3s is also postulated to alter neuronal migration because patients with SADDAN, TDI, and TDII have neurologic abnormalities that may include developmental delay, paucity of white matter, polymicrogyria, dysplastic temporal cortex, dysplasia of nuclei, and neuronal heterotopia.[670,675-677] Furthermore, constitutive activation of FGFRs in skin fibroblasts and keratinocytes is thought to cause the acanthosis nigricans seen in patients with SADDAN and Crouzon syndrome with acanthosis nigricans.[678] However, it is not yet known why some activating FGFR3 mutations affect the skeletal system, central nervous system, and the skin, whereas other activating FGFR3 mutations only affect the skeletal system.[670]

Loss of function mutations in FGFR3 also have been associated with human disease. An uncommon syndrome characterized by camptodactyly, tall stature, scoliosis, and hearing loss (CATSHL syndrome) has been associated with a heterozygous missense mutation that is predicted to cause a p.R621H substitution in the tyrosine kinase domain and partial loss of FGFR3 function.[679] These findings indicate that abnormal FGFR3 signaling can cause human anomalies by promoting as well as inhibiting endochondral bone growth.[680]

NUCLEAR RECEPTORS

Using a phylogenetic tree based on the evolution of two highly conserved nuclear receptor domains (the DNA-binding C domain and the ligand-binding E domain), Laudet divided nuclear receptors into six related subfamilies. Subfamily 0 contains receptors, such as the embryonic gonad (EGON) and DAX1 receptors, that do not have a conserved C or the E domain (Figure 3-8).[681,682] Subfamily 1 includes the peroxisome proliferator-activated retinoic acid, thyroid hormone, and vitamin D_3 receptors. Subfamily 2 includes the hepatocyte nuclear factor-4α (HNF-4α) and retinoid X receptors (RXRs). Subfamily 3 contains the steroid receptors. Evidence suggests that subfamily 3 (which includes the glucocorticoid, androgen, progesterone, and mineralocorticoid receptors) rapidly evolved from a common steroid receptor gene about 500 million years ago.[683]

Subfamilies 4 to 6 contain several nuclear receptors, namely NR4A1-3, NR5A1-2, NR6A1.[684-686] The nomenclature is as follows: nuclear receptor subfamily 4, group A, members 1 for NR4A1. NR5A1 is also known as steroidogenic factor-1 or SF-1.[685]

General Structure of the Nuclear Receptors

Nuclear receptors are made up of four domains: A/B, C, D, and E (Figure 3-9).[681] Supporting the notion that nuclear receptor subfamilies are derived from a common ancestral orphan receptor, the C and E domains are highly conserved among the subfamilies.[681] Mutation of several nuclear receptors are associated with endocrine disorders (Table 3-5).

The A/B domain is located at the N-terminal and contains the activation function 1 (AF-1)/τ 1 domain.[687] The AF-1/τ 1 domain regulates gene transcription by interacting with proteins (such as the Ada and TFIID complexes) that induce transcription.[688,689] This transactivation function of the AF-1/τ 1 domain is not dependent on binding of the nuclear hormone receptor to its ligand and is not specific in its choice of DNA target sequences.[681,690-692] Thus, specificity of action of the nuclear hormone receptor is determined by the function of other nuclear hormone receptor domains.

The C domain has characteristics that help to confer specificity of action on each nuclear hormone receptor.

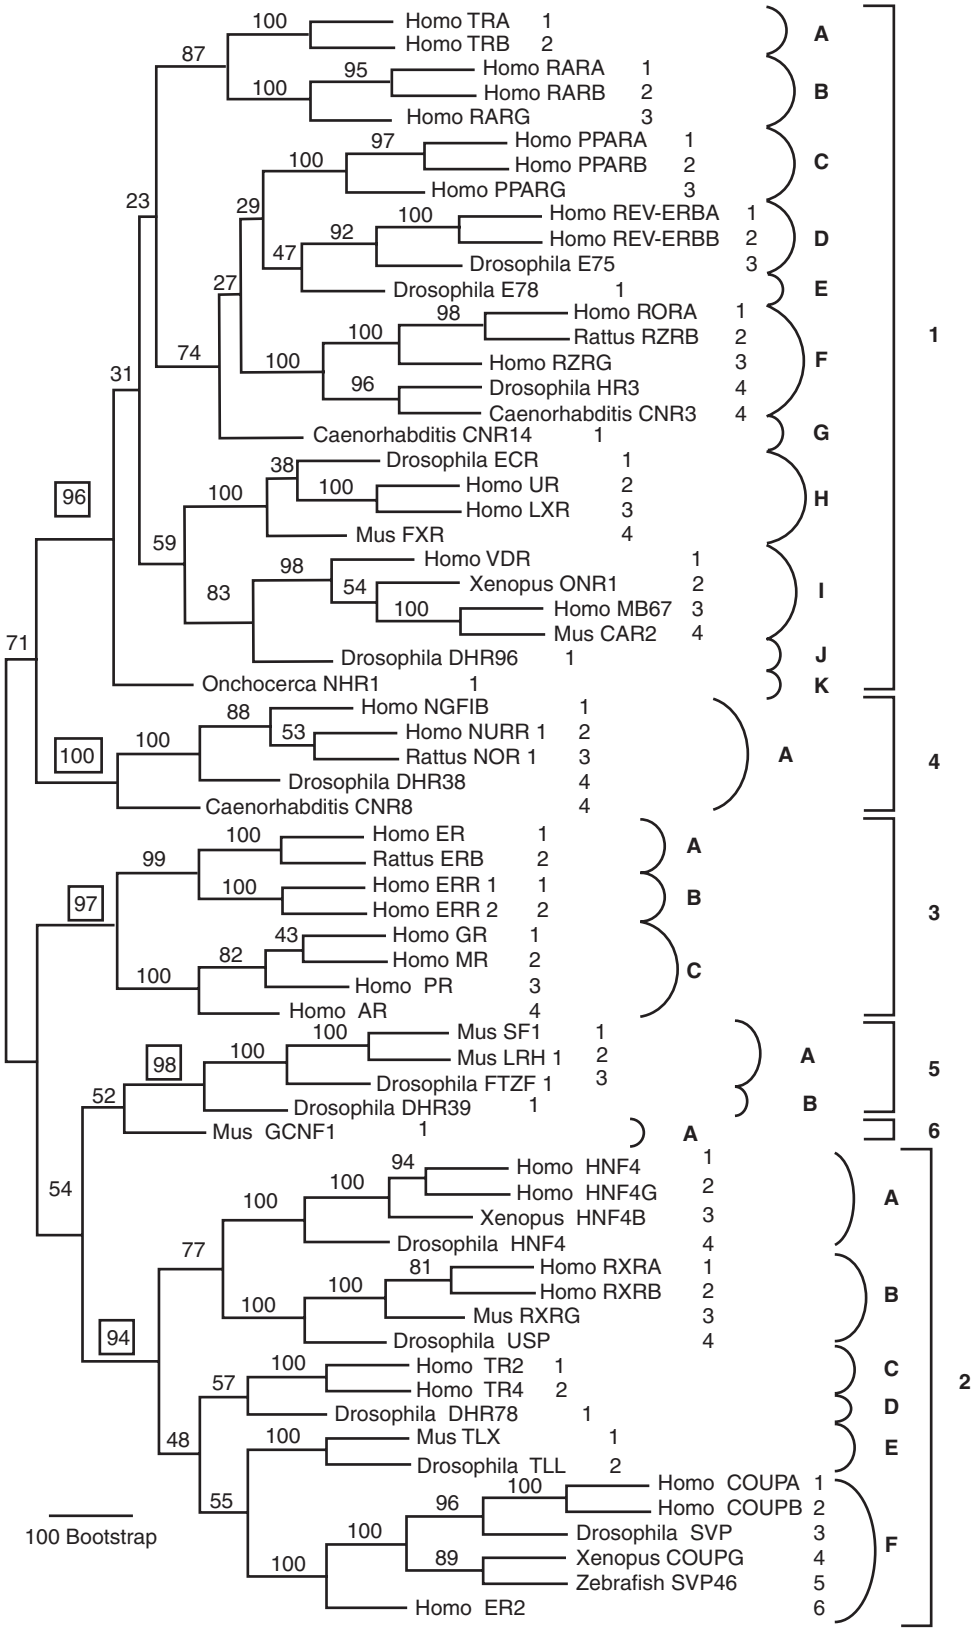

FIGURE 3-8 ■ Phylogenetic tree of nuclear receptors based on the evolution of the highly conserved C and E domains. Numbers at the right side of the figure represent subfamilies, and capital letters represent groups of more closely related receptors. The small numbers to the right of the receptor names are used in combination with the subfamily letters and group letters in a proposed nuclear receptor nomenclature. This nomenclature proposes that nuclear receptors should be named NR, followed by subfamily number, group letter, and individual receptor number. Thus, the mineralocorticoid receptor is named NR3C2 and the PPARγ receptor is named NR1C3 according to this nomenclature. Numbers to the left of the receptor names represent bootstrap values. Values that define subfamilies with more than one member are boxed. (Reproduced with permission from the Nuclear Receptors Nomenclature Committee [1999]. A unified nomenclature system for the nuclear receptor subfamily. *Cell*, *97*, 161.)

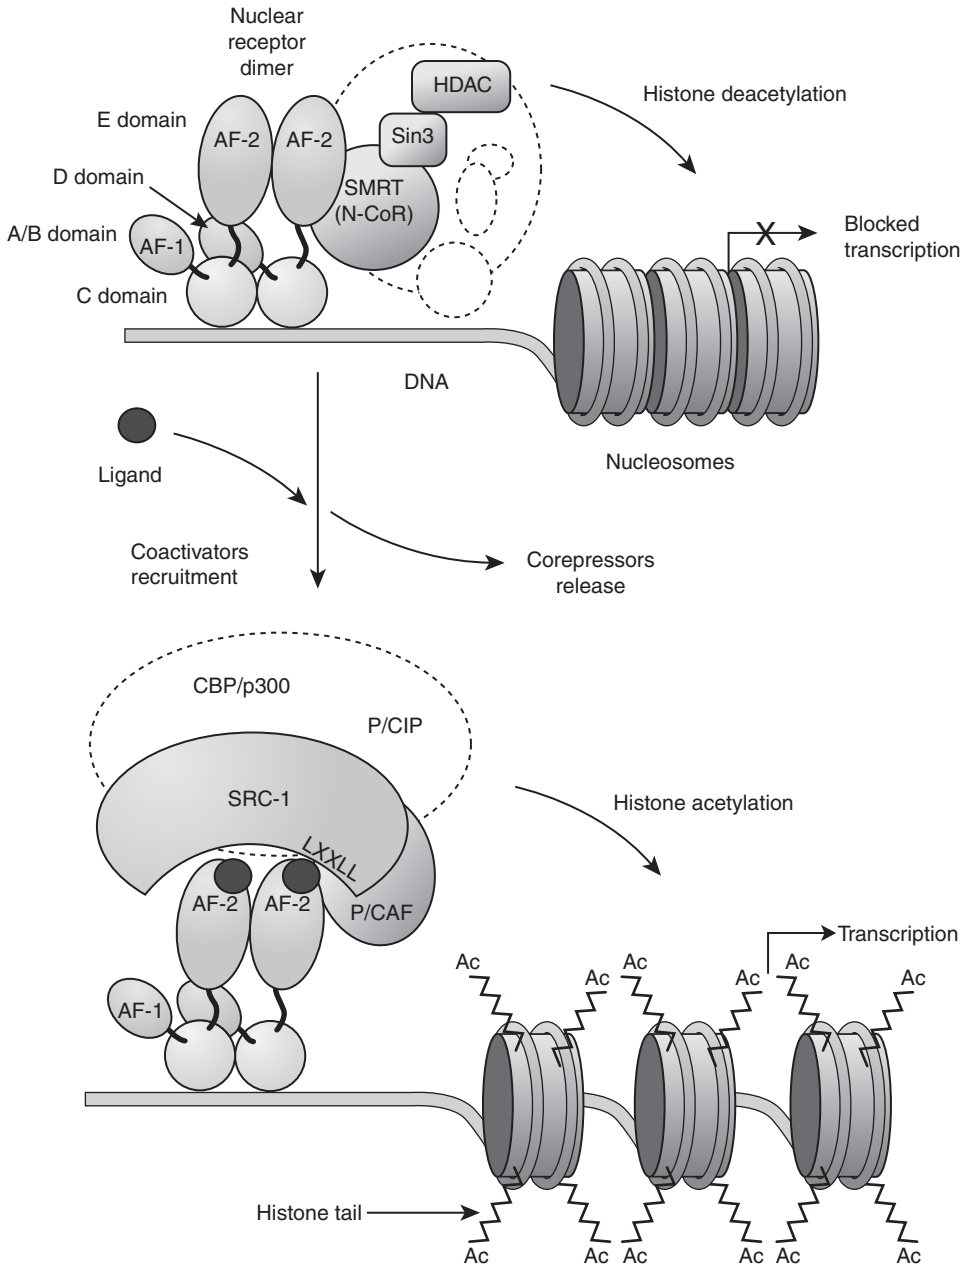

FIGURE 3-9 ■ Ligand-induced activation of transcription by nuclear receptors. Often, corepressors, including SMRT and nuclear receptor copressor (N-CoR), bind a nuclear receptor that is not bound by its ligand. These corepressors then associate with Sin3, which in turn associates with a histone deacetylase (HDAC). Then, HDAC represses transcription by deacetylating histone tails—resulting in compaction of the nucleosomes into structures that are inaccessible to transcription factors. Ligand binding induces structural changes in the E domain that result in release of the corepressor/Sin3/HDAC complexes from the receptor and binding of coactivator complexes that may include steroid receptor coactivator 1 (SRC-1), p300/cAMP responsive element binding protein (CBP), p300/CBP-associated factor (P/CAF), or p300/CBP cointegrator-associated protein (pCIP) to the LXXLL motif of the AF2-AD. Then, the coactivator complexes induce transcription by acetylating (Ac) the histone tails—resulting in decompaction of the nucleosomes into structures that are accessible to transcription factors. Dashed lines are used to represent coactivator and corepressor complexes because their composition in vivo is yet unknown. (Adapted with permission from Robyr, D., Wolffe, A. P., & Wahli, W. [2000]. Nuclear hormone receptor coregulators in action: diversity for shared tasks. *Mol Endocrinol, 14*, 339. Copyright 2000, The Endocrine Society.)

This domain consists of two zinc-finger motifs responsible for the DNA-binding activity of the receptor and the selection of dimerization partners.[693,694] Each zinc-finger module consists of a zinc ion surrounded by the sulfurs of four cysteine residues, resulting in a tertiary structure containing helices.[693,694] The P-box lies near the cysteines of the first zinc finger and contains the three to four amino acids responsible for specificity of binding to response elements.[694,695] The D-box consists of a loop of five amino acids attached to the first two cysteines of the second zinc finger that provides the interface for nuclear receptor dimerization.[694]

TABLE 3-5 **Nuclear Receptors and Clinical Conditions Associated with Receptor Mutations**

Receptor	Germ-Line Mutation	Endocrine Disorder
Thyroid hormone receptor β (TRβ)	Inactivating mutations (heterozygous and homozygous)	Generalized resistance to thyroid hormones
Vitamin D_3 receptor	Inactivating mutations (homozygous)	Vitamin D_3 resistance
PPARγ2	Inactivating mutations (heterozygous)	Obesity or early-onset type 2 diabetes mellitus
HNF-4	Inactivating mutations (heterozygous)	Maturity-onset diabetes of the young (MODY) type 1
Glucocorticoid receptor	Inactivating mutations (heterozygous)	Glucocorticoid resistance
Androgen receptor	Inactivating mutations (X-linked recessive)	Androgen insensitivity syndrome, Kennedy's disease
Estrogen receptor α (ERα)	Inactivating mutations (homozygous)	Tall stature and incomplete epiphyseal fusion
Mineralocorticoid receptor	Inactivating mutations (heterozygous, homozygous)	Pseudohypoaldosteronism type 1
	Activating mutations (homozygous)	Syndrome of apparent mineralocorticoid excess
DAX1	Inactivating mutations (X-linked recessive)	X-linked adrenal hypoplasia congenita

The D "hinge" domain contains nuclear localization signals and contributes to the function of the adjacent C and E domains.[681] Thus, the N-terminal portion of the domain contributes to DNA binding and heterodimerization and the C-terminal portion contributes to ligand binding.[695-698] The nuclear localization signal plays a particularly important role in the function of glucocorticoids and mineralocorticoid receptors because these receptors bind their ligand in the cytoplasm and must then localize to the nucleus to alter gene transcription.[687]

The E domain is known as the ligand-binding domain (LBD) or the hormone-binding domain. In addition to ligand binding, the E domain has effects on dimerization and transactivation.[681] The LBD consists of 11 to 12 α helices (named H1 through H12) and contains a ligand-binding pocket that is made up of portions of some of the different helices.[699-703] For example, the thyroid receptor (TR) LBD has a ligand-binding cavity that includes components from H2, H7, H8, H11, and H12.[703] The contribution of different parts of LBD to the ligand-binding pocket accounts for the finding that mutation of single–amino-acid molecules in different helices of the LBD can interfere with ligand binding.[687]

Unlike the AF-1/τ 1 transcriptional activating factor, the E domain activation factor 2 (AF2-AD) requires ligand binding to function (see Figure 3-9).[700-707] Often, when the receptor is not bound by its ligand, corepressor complexes simultaneously bind the LBD and transcriptional machinery consisting of protein complexes that place transcription factors on nucleosome binding sites (see Figure 3-9).[700-707] The corepressor complexes then suppress gene transcription by using histone deacetylases to compact the nucleosomes into inaccessible structures (see Figure 3-9).[708-711] Ligand binding induces structural rearrangements in the E domain that lead to release of these corepressor complexes from the transcriptional machinery and the LBD, and exposure of the transcriptional machinery and the LXXLL motif of the AF2-AD to coactivator complexes (see Figure 3-9).[700-707] These coactivator complexes have histone acetyltransferase activity that acts to relax nucleosome structures, enabling transcription factors to access nucleosome binding sites (see Figure 3-9).[712]

Most nuclear receptors are capable of binding their hormone response element and repress transcription when they are not bound by their ligand.[713] However, in the absence of ligand, steroid receptors are bound to a complex of heat-shock proteins instead of their response element and do not appear to repress transcription.[714]

Agonists and antagonists have different effects on the interaction between the ligand binding pocket and AF2-AD. For example, when 17β-estradiol binds to the estrogen receptor the position of the AF2-AD containing H12 is altered so that coactivators can access the LBD-binding coactivator binding site.[699] However, when the estrogen antagonist raloxifene binds at the same site the coactivator binding site on H12 remains blocked by other portions of H12.[699]

Although some of the nuclear receptors are fully active when bound as monomers to DNA, the hormone receptors in the nuclear receptor superfamily are most active when bound as homodimers or heterodimers (see Figure 3-9).[681] RXRs, hepatocyte nuclear factor 4, and the steroid receptors can bind DNA as homodimers or heterodimers.[681,715,716] The α isoform of the estrogen receptor (ESR1) is particularly promiscuous, and is able to heterodimerize with HNF4-α and retinoic acid receptors, the β isoform of the estrogen receptor (ESR2), RXR and the thyroid receptors.[715,716] As a homodimer, RXR binds the dINSRect repeat 1 (DR1).[717] It can also join the thyroid, vitamin D_3, and peroxisome proliferator–activated receptors to form heterodimers.[681,718-720]

Interestingly, it has also been suggested that some steroid hormones also act on transmembrane receptors—and these interactions may be responsible for the acute cellular effects of steroids.[721] Progesterone has been shown to interact with the G protein–coupled uterine oxytocin, nicotinic acetylcholine, $GABA_A$, NMDA, and sperm cell membrane progesterone receptors.[722-727] Cell membrane estrogen and glucocorticoids receptors have also been identified. [728-731]

SUBFAMILY 1 NUCLEAR RECEPTORS: THYROID HORMONE, VITAMIN D_3, AND PEROXISOME PROLIFERATOR–ACTIVATED RECEPTORS

Thyroid Hormone Receptors

The two thyroid hormone receptor (THR) isoforms—thyroid hormone receptor α (THRA) and thyroid hormone receptor β (THRB)—are encoded by different c-erbA genes on chromosomes 17 and 3, respectively.[698,732] Alternate splicing leads to expression of TRα1, TRβ1, and TRβ2 with different tissue distributions. TRα1 is the predominant subtype in cardiac and skeletal muscle, bone, and the central nervous system. TRβ1 is the predominant subtype in kidney and liver, whereas TRβ2 is expressed in hypothalamus and pituitary as well as retina and cochlea. THRs that are not occupied by the thyroid hormone triiodothyronine (T3) exist as homodimers or heterodimers with RXRs that are attached to DNA thyroid hormone response elements in association with corepressor proteins.[733] Thyroid hormone binding induces the release of the corepressors from the THR.[733] A coactivator, steroid receptor coactivator-1 (SRC-1), is then able to attach to the THR—enabling activation of transcription.[733]

Generalized resistance to thyroid hormones (GRTH) is due to mutations in the THRB gene.[732,734,735] Patients with this syndrome have impaired receptor response to triiodothyronine (T3).[732] They have elevated T3 and thyroxine (T4) levels with normal TSH levels.[732,734,735] The clinical manifestations are variable but may include goiter, attention deficit disorder, hearing defects, learning disabilities, poor weight gain, mental retardation, and delayed bone age.[732,734,735]

Mutations have been found in the D and E domains of THRBs of GRTH patients.[732,736,737] Thus, these mutations alter ligand binding or transactivation.[732,737,738] However, most mutant THRBs retain the ability to repress transactivation of target genes through interactions with corepressors.[737,738] Some of the GRTH mutant receptors continue to associate with corepressors and are unable to bind the coactivator SRC-1 even when bound by T3.[738,739] Thus, mutant THRBs have a dominant negative effect in the heterozygous state because they are able to interfere with the function of wild-type receptors by repressing transcription of target DNA.[732,737,738]

Patients who are homozygous for deleterious mutations of THRB demonstrate more severe clinical abnormalities than patients who are heterozygous for these mutations. One patient with a deletion of both THRB alleles presented with deaf mutism, dysmorphic features, and stippled epiphyses.[740] This condition is inherited in an autosomal recessive mode because the mutant allele is missing the THRB gene and is therefore unable to produce a THRB with corepressor function.[740] Another patient homozygous for a THRB mutant ("kindred S receptor") with an amino acid deletion in the ligand-binding domain presented with mental retardation, very delayed bone age, and very elevated T3 and T4 levels.[736,741] Heterozygous carriers of the kindred S receptor mutation have milder clinical manifestations of GRTH because this mutant THRB retains corepressor activity and thus has dominant negative effects.[736,741,742]

Mutations in THRA were not identified until recently.[743,744] The first described proband is heterozygous for a nonsense mutation (E403X) that inhibits the wild-type receptor in a dominant negative fashion.[743] The patient had growth retardation developmental delay and constipation in the setting of low T4 and free T4, low reverse T3, normal T3 and free T3, and normal TSH. After thyroxine treatment, normalizing T4 levels, T3 levels became elevated. The mutant receptor failed to bind radiolabeled T3 and failed to activate a thyroid hormone responsive reporter gene and inhibited the activity of the wild-type receptor. The second report described a 1 base insertion in a father and a daughter causing a frameshift and premature termination at codon 406.[744] Analyses of the mutant receptor in vitro after expression in cultured cells revealed that the mutant receptor fails to respond to stimulation by T3 and exerts a strong dominant negative effect on the wild-type receptor.

Vitamin D Receptor

Severe rickets, hypocalcemia, secondary hyperparathyroidism, and increased 1,25-dihydroxyvitamin D (calcitriol) levels occur in patients with the autosomal recessive syndrome of "vitamin D resistance."[745] These patients have defective vitamin D receptors (VDRs). Mutations causing this syndrome have been found in the zinc fingers of the DNA-binding domain (C domain), leading to decreased or abolished receptor binding to regulatory elements of target genes.[746] Causative mutations have also been found that lead to the production of receptors that have decreased or abolished ability to bind calcitriol and heterodimerize with retinoid X receptors (RXRs), which are required for the VDR to maximally transactivate target genes.[746,747]

Less severe mutations in the VDR are associated with decreased gastrointestinal calcium absorption and bone mineral density, even during childhood, and an increased risk for osteoporosis and fractures.[748-753] However, it has not been possible to replicate these findings in some ethnic groups.[754-758] Thus, other factors (such as estrogen receptor genotype, dietary calcium, and age) probably contribute to the effects of VDR polymorphisms on bone mineral metabolism.[751,753,759,760] Certain VDR polymorphisms are associated with decreased pre- and postnatal linear growth.[761,762]

Other important associations have been found with VDR polymorphisms. Homozygous polymorphisms have been reported to be associated with primary hyperparathyroidism.[763] In addition, the presence of certain VDR alleles is associated with increased risk for the development of early-onset periodontal disease.[764] Conversely, absence of such alleles has been associated with familial calcium nephrolithiasis.[765] Absence of certain alleles may be a risk factor for the development of sarcoidosis.[766] However, the presence of these alleles is associated with hypercalciuria and nephrolithiasis and increased risk in women for the development of metastatic breast cancer.[767,768] VDR polymorphisms have also been associated with increased susceptibility to psoriasis, tuberculosis, leprosy, and other infections.[769-773]

PPARγ

PPARγ has a role in regulating adipocyte differentiation and metabolism. This formerly orphan receptor was adopted by the ligand prostaglandin J2. Mutations in the gene encoding PPARγ cause familial partial lipodystrophy type 3 (FPLD3).[774]

Patients with FPLD3 exhibit fat loss in the arms and legs, severe insulin resistance, early-onset type 2 diabetes mellitus, and severe hypertriglyceridemia Some heterozygous mutations have a dominant negative effect on the wild-type receptor (V290M and P467L).[775,776] These mutations lead to amino acid substitutions that disturb the orientation of H12 in the E domain leading to decreased ligand-dependent transactivation by AF-2/AD and coactivator recruitment.[775] Other mutations are point mutations that cause FPLD3 simply due to haploinsufficiency without a dominant negative effect.[777-784] In addition a frameshift mutation that causes a similar phenotype was identified.[785] A mutation in PPARγ expanded the phenotype to include muscular, immune, and hematologic features.[786] This mutation is thought to induce a conformational change affecting transcriptional activation by the receptor.

A missense mutation leading to a Pro115Gln substitution near a site of serine phosphorylation at position 114 that suppresses transcriptional activation in PPARγ2 was found in some morbidly obese patients.[787] The Pro115Gln substitution interferes with phosphorylation of the serine at position 114, leading to increased transcriptional activation by PPARγ2—which in turn leads to increased adipocyte differentiation and triglyceride accumulation.[787]

SUBFAMILY 2 NUCLEAR RECEPTORS: HEPATOCYTE NUCLEAR FACTOR AND RETINOID X RECEPTORS

This subfamily includes the HNF receptors and the RXR. RXRs form heterodimers with other nuclear receptors (including the estrogen, vitamin D, and thyroid hormone receptors) and with PPARγ (RXRs are discussed elsewhere in this chapter).

HNF Receptors

Alteration of another orphan nuclear receptor, HNF-4α, also causes an endocrine disorder. Mutations of the HNF-4α gene on chromosome 20 that alter the ligand-binding domain (E domain) or the DNA-binding domain (C domain) have been found in patients with maturity-onset diabetes of the young type 1 (MODY1).[788-791] Patients with MODY usually develop diabetes mellitus by the end of the third decade of life. They have a defect in glucose-mediated stimulation of insulin secretion.[789,792] Several studies have now described a biphasic phenotype of neonatal hyperinsulinism and macrosomia with later onset of diabetes in patients with HNF-4α mutations.[793-797] In most cases, the hyperinsulinism is transient but can be persistent requiring diazoxide treatment.[795,796]

Carriers of a glycine-to-serine substitution in codon 115 in the DNA-binding domain (C domain) appear to be at increased risk for developing low-insulin diabetes mellitus.[798] Hepatocyte nuclear factors 3 (HNF-3α, -3β, and -3γ) are also regulators of the early-onset type 2 diabetes genes HNF-1 α, HNF-4 α, and IPF-1/PDX-1—which are associated with MODY types 3, 1, and 4, respectively.[799-802]

SUBFAMILY 3 NUCLEAR RECEPTORS: THE STEROID RECEPTORS AND GLUCOCORTICOID, ANDROGEN, ESTROGEN, AND MINERALOCORTICOID RECEPTORS

Glucocorticoid Receptors

Mutations in glucocorticoid receptors cause primary generalized glucocorticoid resistance (PGGR) or primary generalized glucocorticoid hypersensitivity (PGGH).[803] PGGR is clinically characterized by the presence of elevated plasma cortisol and ACTH levels, accompanied by the effects of hyperaldosteronism and hyperandrogenism in the absence of striae and central fat deposition.[698,803,804,805] ACTH excess leads to adrenocortical hyperplasia increased cortisol secretion and increased production of adrenal steroids with androgenic (androstenedione, DHEA, DHEA-S) and mineralocorticoid activity (cortisol, deoxycorticosterone and corticosterone). The clinical spectrum is broad, ranging from asymptomatic to severe hyperandrogenism (characterized by severe acne, hirsutism, irregular menses, and infertility), mineralocorticoid excess (characterized by hypokalemic alkalosis and hypertension), and fatigue.[804-806,] Girls may present with ambiguous genitalia and both girls and boys may present with isosexual precocity.[807] Clinical manifestations of glucocorticoid deficiency are infrequent and largely limited to fatigue.[806,808,809] However, there were reports of childhood hypoglycemia.[810,811]

Both homozygous[809,810,812,813] and heterozygous[813-817] mutations have been described. Heterozygous mutations that cause PGGR generally do so by exerting a dominant negative effect on the wild-type receptor.[803]

ACTH-secreting pituitary macroadenomas can also be caused by a frameshift mutation in the GR gene that interferes with signal transduction.[818] Patients with this mutation manifest the symptoms of glucocorticoid resistance. The tumor develops as a result of impaired negative feedback regulation by glucocorticoids of the hypothalamic-pituitary axis.

PGGH was described in a patient who presented with obesity, hypertension, and hyperlipidemia and was found to have a mutation in the GR (D401H) that demonstrated increased transactivation glucocorticoid responsive genes.[819]

Androgen Receptors

The human androgen receptor (AR) gene is located on the X chromosome. Known disorders characterized by AR dysfunction due to AR gene mutations are only expressed in patients with a 46 XY karyotype.[820] Thus, these disorders are either transmitted by X-linked recessive inheritance or are due to sporadic mutations.

More than 1000 mutations have been described in the AR gene with more than 500 mutations causing androgen insensitivity syndrome (AIS; testicular feminization).[821] The phenotype of this syndrome can vary in severity and has been divided into mild, partial and complete forms (MAIS, PAIS, and CAIS).[822] CAIS is characterized by intraabdominal testes, absence of mullerian structures, absence of androgen-induced body hair such as pubic and axillary hair, and a female appearance.[820,823,824] PAIS refers to individuals with ambiguous external genitalia with an enlarged clitoris or microphallus and patients with Reifenstein syndrome.[823] Reifenstein syndrome is characterized by severe hypospadias with scrotal development and severe gynecomastia.[823] MAIS refers to patients with AR mutations who are otherwise normal phenotypic males who present with adolescent gynecomastia or later infertility.

The phenotypic heterogeneity of AIS is due to the wide variety of locations for the mutations causing AIS. Functional consequences of each mutation causing AIS relate to the function of the domain in which the mutation is located. However, the degree of impairment of mutated receptor function in in vitro studies does not always correlate with the phenotypic severity of the syndrome.[825]

Mutations in exons that code for the AR hormone-binding domain decrease hormone-binding affinity.[826] However, these mutations do not abolish the hormone-binding capability of the receptor.[826] Thus, patients with these mutations usually present with PAIS or occasionally with CAIS.[826-829] Patients with mutations in the hormone-binding domain do not appear to respond to treatment with high doses of testosterone.[826] Mutations in the DNA-binding domain lead to failure of target gene regulation. Thus, patients with these mutations usually manifest the CAIS.[830,831]

CAIS is also caused by a point mutation that results in a premature termination condition, leading to transcription beginning downstream of the termination signal and the AF1/tau1 domain.[832] Numerous other mutations have been described that cause truncation or deletion of the AR and complete AIS.[833-836] Two patients with ambiguous genitalia and partial virilization were found to be mosaic for mutant ARs.[837,838]

Some patients with Reifenstein syndrome have been found to have a mutation in the DNA-binding domain that abolishes receptor dimerization.[839] Other patients have been found to have a mutation in a different area of the DNA-binding domain that does not affect receptor dimerization, or to have mutations in the hormone-binding domain in the E domain.[840-843] The Ala596Thr mutation in the D-box area of the DNA-binding domain has been associated with an increased risk of breast cancer.[844]

AIS is also a feature of Kennedy disease, which is an X-linked recessive condition causing spinal and muscular atrophy.[827] This condition is caused by extension of a poly-CAG segment in the AR gene exon that codes for the N-terminus of the AR, leading to an increased number of glutamine residues in the A/B domain.[845,846] ARs with a polyQ region increased to 48 glutamine residues accumulate abnormally in transfected cells due to misfolding and aberrant proteolytic processing.[847] Because polyQ extension does not completely abolish of transactivation, patients with Kennedy disease exhibit a mild partial AIS phenotype consisting of normal virilization accompanied by testicular atrophy, gynecomastia, and infertility.

Gain-of-function mutations in the AR have been described in prostate, breast, testicular, liver, and laryngeal cancers.[821]

Estrogen Receptors

Two major full-length estrogen receptor isoforms have been identified in mammals. Estrogen receptor α (ESR1) was discovered first and mediates most of the known actions of estrogens.[698] ESR1 is expressed primarily in the uterus, ovaries, testes, epididymis, adrenal cortices, and kidneys.[848] Estrogen receptor β (ESR2) was discovered in 1996.[849] ESR1 and ESR2 share 95% and 50% homology in the DBD and LBD, respectively.[850] There is little homology in the N-terminal between the two isoforms.[850] ESR2 is expressed primarily in the uterus, ovaries, testes, prostate, bladder, lung, and brain.[848] Although ESR2 has a high affinity for estrogens, it has less transactivating ability than ESR1 and has not yet been found to be involved in any pathologic condition.[698,851,852]

There is evidence supporting the existence of other functional estrogen receptors.[853] Some of these putative estrogen receptors localize to the cell membrane instead of or in addition to the nucleus. A 46-kDa amino terminal truncated product of ESR1, named ER46, localizes to the cell membrane and mediates estrogen actions that are initiated at the cell membrane.[854] Another of these putative estrogen receptors has been named ER-X and is postulated to be a G protein–coupled receptor that localizes to the cell membrane.[855] Another putative receptor is the aptly named heterodimeric putative estrogen receptor (pER), which has been found on the cell and nuclear membranes.[856] The pER acts as a serine phosphatase.[856] Five other estrogen-binding proteins have also been identified, and at least three of them localize to the cell membrane.[857-860]

It had been thought that androgens are the main hormones responsible for closing the epiphyses during puberty. In 1994, however, it was shown from extensive studies of a 28-year-old man with incomplete epiphyseal closure and continued linear growth (in spite of otherwise normal pubertal development) that the estrogen receptor mediates epiphyseal closure.[861] He was found to have a homozygous C-to-T point mutation of codon 157 of the second exon in the ESR1 gene, introducing a premature termination signal. Expression of this gene leads to the production of a nonfunctional ESR1 lacking both the DNA- and hormone-binding domains. He was also found to have increased estradiol levels, impaired glucose tolerance with hyperinsulinemia, and decreased bone density.

Further strengthening the association between ESR1 and epiphyseal closure is the observation that women with ESR1-positive breast cancer and a mutation in the B domain (B′ allele) of ESR1 have an increased incidence of spontaneous abortion and tall stature.[862] These

associations were not found in female carriers of the allele without breast cancer or with ESR1-negative breast cancer. Thus, a second (as yet undiscovered) mutation is likely to play a role in the development of tall stature and spontaneous abortions in female carriers with ESR1-positive breast cancer.

Mineralocorticoid Receptors

Mineralocorticoid resistance is also known as pseudohypoaldosteronism (PHA). Both sporadic and familial cases with either autosomal-dominant or autosomal-recessive cases have been reported.[863-867] Clinical presentation of patients with PHA ranges from asymptomatic salt wasting; to growth failure; to chronic failure to thrive, lethargy, and emesis; to life-threatening dehydration accompanied by severe salt wasting.[864-866,868-870] Patients with the severe forms of PHA typically present within a year of birth and may even present in utero with polyhydramnios due to polyuria.[871] Biochemically, the condition is characterized by urinary salt wasting, hyponatremia, elevated plasma potassium, aldosterone, and renin activity and urinary aldosterone metabolism that are unresponsive to the mineralocorticoid treatment.[872-874]

Two forms of PHA are recognized (types I and II). Autosomal recessive (generalized) PHAI results from mutations in the epithelial sodium channel (ENaC), whereas autosomal dominant (renal) PHAI is due to mutations in the mineralocorticoid receptor (MR). PHAII is the result of mutations in a family of serine-threonine kinases known as WNK1 and WNK4, which are downstream of aldosterone action.[875] PHAI is characterized by renal tubular mineralocorticoid resistance, whereas PHA II results from mineralocorticoid resistance in the kidney, intestine, salivary or sweat gland and is also known as Gordon syndrome.[876] Patients with these conditions present with hyperkalemia that only responds to treatment with nonchloride ions, such as bicarbonate or sulfate, which increase delivery of sodium to the distal tubule.[877] In general, patients with autosomal dominant PHA1 have a mild salt wasting syndrome and improve with age, whereas patients with autosomal recessive PHA1 have severe salt wasting, hyperkalemia, as well as increased sweat and salivary sodium and frequent respiratory tract infections that fails to improve with age.[878]

More than 50 different mutations of the MR causing autosomal dominant PHAI have been described (all heterozygous).[878-889] There is clear heterogeneity of clinical manifestations within families. Haploinsufficiency due to mRNA or protein degradation is clearly sufficient to cause autosomal dominant PHAI.[884,887,890] Yet some mutations have been shown to exert dominant negative effects on the wild-type receptor.[887]

Mutations causing constitutive activation of the MR have been described and cause severe early-onset hypertension.[890] An interesting syndrome involving overactivation of the MRs is the syndrome of apparent mineralocorticoid excess. Patients with this autosomal-recessive condition can exhibit pre- and postnatal growth failure, hypervolemic hypertension, medullary nephrocalcinosis, and hypokalemic metabolic alkalosis accompanied by hyporeninemic hypoaldosteronism.[892-895] Patients with this syndrome may also be asymptomatic and exhibit only biochemical abnormalities.[896] Patients with this syndrome also have increased serum and urinary cortisol-to-cortisone ratios.[895] This syndrome is caused by mutations in the 11 β-hydroxysteroid dehydrogenase type 2 (11 β-HSD2) genes that reduce the activity of the enzyme.[894,895,897-899] 11 β-HSD2 converts the active glucocorticoid cortisol to inactive cortisone. Thus, decreased activity of 11 β-HSD2 increases cortisol levels in MR-containing tissues, leading to increased binding and activation of MRs by cortisol.[894,895]

A transient form of mineralocorticoid resistance, probably due to abnormal maturation of aldosterone receptor function, also exists.[891] This variant of PHA is known as the syndrome of early-childhood hyperkalemia. Children with this disorder present with failure to thrive or linear growth failure accompanied by hyperkalemia and metabolic acidosis. This condition resolves spontaneously by the second half of the first decade of life.

SUBFAMILY 0 NUCLEAR RECEPTORS: DAX1

Subfamily 0 nuclear receptors include DAX1.[682] DAX1 plays a role in the regulation of steroid, mullerian-inhibiting substance, and gonadotropin production.

DAX1

The dosage-sensitive sex-reversal adrenal hypoplasia congenital critical region on the X chromosome gene 1 (DAX1) is an orphan nuclear receptor because its ligand has not yet been identified.[900] It has homologies in the E domain to other orphan receptors, including RXRs.[901] However, DAX1 has an unusual DNA-binding C domain that contains a tract of amino acid repeats instead of zinc finger motifs.[901] DAX1 inhibits steroidogenic factor 1 (SF-1)-mediated transcription. SF-1 is another orphan nuclear receptor that regulates transcription of adrenal and gonadal steroid hydroxylases, mullerian-inhibiting substance, and gonadotropin genes.[902,903]

DAX1 gene mutations have been identified that cause X-linked adrenal hypoplasia congenita.[901] Patients with this condition have congenital adrenal insufficiency and are therefore deficient in glucocorticoid, mineralocorticoid, and androgen production.[901,904] Gonadotropin deficiency and azoospermia also occur in these patients.[904,905] Female carriers may have delayed puberty.[905] All mutations that have been found to cause X-linked congenital adrenal hypoplasia are either located in or prevent transcription of the area of the E domain that inhibits SF-1- mediated transcription.[900,906-908] Thus, DAX1 mutations may cause X-linked congenital adrenal hypoplasia by altering SF-1 regulation of gonado- and adrenogenesis.[906] DAX1 deletion may also occur in the setting of the contiguous gene deletion syndrome, resulting in complex glycerol kinase deficiency (cGKD) if individuals have deletions extending from the GK gene into the Duchene muscular dystrophy (DMD) gene or involving a significant extension telomeric from DAX1.[909]

SUMMARY

Understanding of receptors that transduce or influence hormone action has increased dramatically. As molecular biology techniques improve, it is expected that knowledge of receptor action will continue to increase at a rapid pace. It is likely that subtle defects in receptor function (such as regulatory or promoter region mutations that increase or decrease receptor gene expression, or mutations in second messenger proteins) will be found that cause endocrine disorders. It is also likely that new receptors will be discovered that transduce or influence hormone action and that endocrine roles will be found for receptors that were not previously thought to mediate or alter hormone action.

QUESTIONS

1. A 15-year-old male presents with hypertension. He has a family history of stroke in father and grandfather. Lab evaluation reveals a potassium level of 3.4mEq/L. plasma renin activity is suppressed and aldosterone level is high. Urine and serum metanephrines and catecholamines were normal. Renal ultrasound with Doppler was normal. Adrenal CT was normal.

Which of the following tests is most likely to make the diagnosis?
   a. Measuring the cortisol to cortisone ratio
   b. Normal saline and dexamethasone suppression of aldosterone
   c. Sequencing of the mineralocorticoid receptor
   d. Adrenal venous sampling
   e. MRI of the adrenal glands

Answer: b

2. A 16-year-old female presents with 1 year of oligomenorrhea and hirsutism. She had menarche at age 12 and had regular periods for 1.5 years followed by a steady decline in frequency of menses. Her last menstrual period was 1 year ago. On examination, her weight and height are at the 50th percentile and have not changed significantly over the past year. Her blood pressure is 156/102. She is Tanner 5 for breast and pubic hair development without clitoromegaly. She has facial acne, back acne and facial hair (sideburns, upper lip and chin). She has no striae or a buffalo hump. The LH to FSH ratio is not increased.

What is the most likely diagnosis?
   a. ACTH dependent Cushing syndrome
   b. Late onset Congenital adrenal hyperplasia
   c. Glucocorticoid resistance
   d. Polycystic Ovarian Syndrome
   e. Glucocorticoid-remediable aldosteronism

Answer: c

3. You are called to see an 18-day-old boy in the cardiac ICU. He was found unresponsive and in ventricular tachycardia. EMTs resuscitated him. His potassium was 9 and his sodium was 114. His newborn screen for congenital adrenal hyperplasia was normal. Serum 17-hydroxyprogesterone is pending. Adrenal ultrasound was performed and is normal. His ACTH on arrival was 10 times the upper limit of normal and his cortisol was 2.34. His triglycerides were elevated.

What is the most likely diagnosis?
   a. 21-hydroxylase deficiency
   b. Pseudohypoaldosteronism type I
   c. Adrenal hypoplasia congenita
   d. Addison's disease
   e. Adrenoleukodystrophy

Answer: c

4. You are called by the newborn nursery to see a baby with ambiguous genitalia. Pregnancy and delivery were unremarkable. Prenatal ultrasound demonstrated hypospadias vs. ambiguous genitalia. Amniocentesis revealed a karyotype of 46XY. Exam is remarkable for presence of testes in a bifid scrotum with incomplete fusion of the labioscrotal folds, distal shaft hypospadias and a stretched phallic length of 3.2cm. Electrolytes were normal. Anti-Mullerian Hormone was >180ng/ml on day of life 2. Abdominal ultrasound revealed no Mullerian structures. Labs obtained on week 3 of life reveal an LH of 4.7, testosterone of 898ng/dL, a dihydrotestosterone of 245ng/dL, 17-hydroxyprogesterone of 241ng/dL, 17-hydroxypregnenolone of 839ng/dL, androstenedione of 78ng/dL.

What is the most likely diagnosis?
   a. 3 beta HSD deficiency
   b. 5 alpha reductase deficiency
   c. SRY deletion
   d. Partial androgen insensitivity
   e. P450 oxidoreductase deficiency

Answer: d

5. A 3-year-old boy is found to have an elevated calcium after she was admitted to the hospital with a bronchiolitis. He is otherwise healthy. His mother and father have no significant past medical history. There is no family history of kidney stones. His lab evaluation reveals an ionized calcium of 6.0 mg/dL (4.5-5.6) and calcium of 12.5mg/dL. Magnesium was 2.6 mg/dL (1.8-2.4) and phosphorus was 3.5 mg/dL (3.5-6). Intact PTH done on the same sample was 28pg/ml(16-87). Fractional excretion of calcium was 0.92%. 25-hyroxyvitamin D and 1,25-hyroxyvitamin D levels are normal. Renal ultrasound was normal.

What is the most appropriate next step?
   a. Technetium sestamibi scan
   b. Measure serum calcium in the parents
   c. Skeletal survey
   d. PTHrp
   e. Parathyroid surgery

Answer: b

6. A 4-year-old boy is referred for short stature. His height SDS is -4. His weight is $<3^{rd}$ percentile. His birth weight was 3.5SD below the mean and his birth length was 5SD below the mean. He was proportional. IGF1, IGFBP3 and acid-labile subunit levels were elevated. Bone age was delayed. Growth hormone stimulation testing with clonidine and arginine peaked at 50ng/ml.

Which of the following will make the diagnosis?
   a. Overnight growth hormone sampling
   b. IGF1 generation test
   c. SNP array
   d. Trial of growth hormone
   e. Sequencing of the IGF-1R gene

Answer: e

7. A 4-year-old Caucasian boy is referred for obesity. His BMISDS is +5. His parents report an insatiable appetite since birth. He is on hydrocortisone for a diagnosis of adrenal insufficiency. On exam he has red hair.

What is the most appropriate test?
   a. Obtain an MRI of the hypothalamus and pituitary
   b. Sequence the MC4R gene
   c. Sequence the POMC gene
   d. Sequence the PC1/3 gene
   e. Indirect calorimetry

Answer: c

CHAPTER 4

Laboratory Methods in Pediatric Endocrinology

Donald Walt Chandler, PhD • Dennis J. Chia, MD • Jon Nakamoto, MD, PhD • Kelly Y. Chun, PhD • Samuel H. Pepkowitz, MD • Robert Rapaport, MD

CHAPTER OUTLINE

INTRODUCTION

Pediatric endocrinology evaluations are often accompanied by requests for laboratory tests. Each clinician must determine the correct lab test to be ordered, establish the circumstances for proper testing (e.g., fasting, time of day, stimulation protocol), and choose a specific laboratory method to be utilized. When the results return, the pediatric endocrinologist must interpret them correctly to arrive at the appropriate diagnosis and to determine management. If treatment is initiated, monitoring methods, which may include specific laboratory tests, must be instituted. The evaluation of laboratory assays is an essential component of pediatric endocrinology practice. One could suggest that of all specialties in medicine, pediatric endocrinology is the one most dependent on laboratory tests. It is thereby apparent that for optimal endocrine diagnosis and management, thorough understanding of laboratory methodology is crucial. Therefore, a section on laboratory techniques is an integral component of any instructional manual of pediatric endocrinology.

Hormones circulate at remarkably low levels, yet relatively small perturbations can distinguish health from disease states. As a frame of reference, the major extracellular cation, sodium, circulates at approximately 140 millimolar (10^{-3} mol/L), whereas normal glucose levels are in the 4 millimolar range. In contrast, relatively abundant hormones such as cortisol have concentrations in the low micromolar range (10^{-6} mol/L), and others such as growth hormone and thyroglobulin are only in the low picomolar range (10^{-12} mol/L) (Figure 4-1). Given this thousand- to billion-fold difference, it is not surprising that assays using chemical analysis are not applicable in the measurement of hormones. To reach an appropriate level of sensitivity and specificity at these concentrations of an analyte, two types of assays are generally employed: immunoassays and tandem mass spectrometry (MS/MS) coupled with chromatography.

Endocrine hormone assays have applied improved technology to evolve from colorimetric tests and radioimmunoassay (RIA) with monoclonal antibodies, sensitive detection techniques, extensive automation, and, increasingly, tandem mass spectrometry. With automation, the sudden availability of platforms with a menu of commonly ordered hormone tests has rapidly broadened access of endocrine testing so that currently more than 3000 laboratories offer a wide range of endocrine tests.[1] In most general laboratory settings, one of five common immunoassay analyzers is used for hormone detection (Table 4-1). These analyzers consolidate more than 20 to 30 hormone or other assays on a single platform that can operate in batch or random access mode with unattended capability, timely turnaround, and cost-effective throughput. Despite these practical advantages, there are some challenges to consider. In many laboratories utilizing such high-throughput instruments, appropriate in-depth knowledge of endocrinology and the technical aspects of the analytic systems is limited, such that troubleshooting is often outsourced to device manufacturers whose primary focus may not be on analytic accuracy. Furthermore, platforms of consolidated analyzers may not be appropriate for specimens from pediatric-age patients for several reasons: available normal

reference range data may be inadequate; the assay may perform well at a normal adult range but be unsatisfactory in the pediatric range; or the failure to remove cross-reacting contaminants by extraction and chromatography steps may lead to falsely elevated results.[2-4] Similar pitfalls may be encountered as mass spectrometry technology is expanded to more laboratories.

This chapter is intended as a reference work for pediatric endocrinologists in training or in practice to assist in the requisition and interpretation of laboratory tests to facilitate optimal clinical diagnosis and management. It will first cover the two main assay formats used to measure hormone levels, namely (1) antibody-based immunoassays and (2) mass spectrometry. Later sections discuss preanalytic variables and then validation techniques, both analytic and clinical. Dispersed throughout the chapter are short clinical vignettes that illustrate how a strong foundation in laboratory methods can impact clinical care. This chapter is not intended to provide a comprehensive review of all laboratory assays. Principles of molecular endocrinology testing are discussed in Chapter 2.

HORMONAL ASSAYS

Immunoassays

Immunoassay is an important methodology in the endocrine laboratory. Understanding the basic principles involved allows specialists to (1) identify when a particular immunoassay is or is not appropriate for a particular clinical scenario, (2) anticipate potential physiologic and technical issues affecting the interpretation of laboratory results, and (3) understand how to work with the clinical laboratory to investigate unanticipated or clinically discordant test results.

Competitive Immunoassay versus Immunometric (Sandwich) Assay

There are two main immunoassay formats relevant to endocrinology laboratory testing, and understanding some of the basic differences between these formats helps both interpretation of results and troubleshooting of unexpected situations.[5] The first class of assays is termed *competitive*, with the classic radioimmunoassay (RIA) as the archetypal example. A primary antibody against the substance ("analyte") of interest is added to the patient's sample, together with a radiolabeled version of the analyte ("tracer") that competes with the endogenous analyte for binding to the primary antibody (Figure 4-2, upper panel). After a sufficiently long incubation time, the primary antibody is precipitated using a second anti-IgG antibody, polyethylene glycol, or (most commonly nowadays) by using primary antibody attached to a solid support such as a bead, which allows a simple centrifugation step to collect the primary antibody. Any unbound tracer or analyte is washed away, and the amount of tracer in the precipitate is then quantified.

To convert this tracer signal into a concentration, a standard curve is prepared from samples where varying concentrations of a known amount of analyte have been added. For a competitive immunoassay, the amount of signal detected (amount of tracer bound to antibody) decreases as the analyte in the patient's sample increases. Importantly, *anything* that prevents the tracer from binding to the primary antibody would also decrease signal and increase apparent analyte concentration. For example, taking an immunoassay optimized for serum and using it for an extremely concentrated urine sample or in a body fluid where the protein concentration is extremely high can significantly alter the results. Because high salt or high protein concentration can inhibit tracer binding to antibody, tracer signal will be low and the apparent analyte concentration very high, even in the complete absence of any analyte.

The second class of immunoassays is termed *immunometric*, with the most important example being the noncompetitive, so-called sandwich assay. Typically, as shown in Figure 4-2 (lower panel), an antibody attached to a solid support (plate, wall of a tube, or a bead) is used to

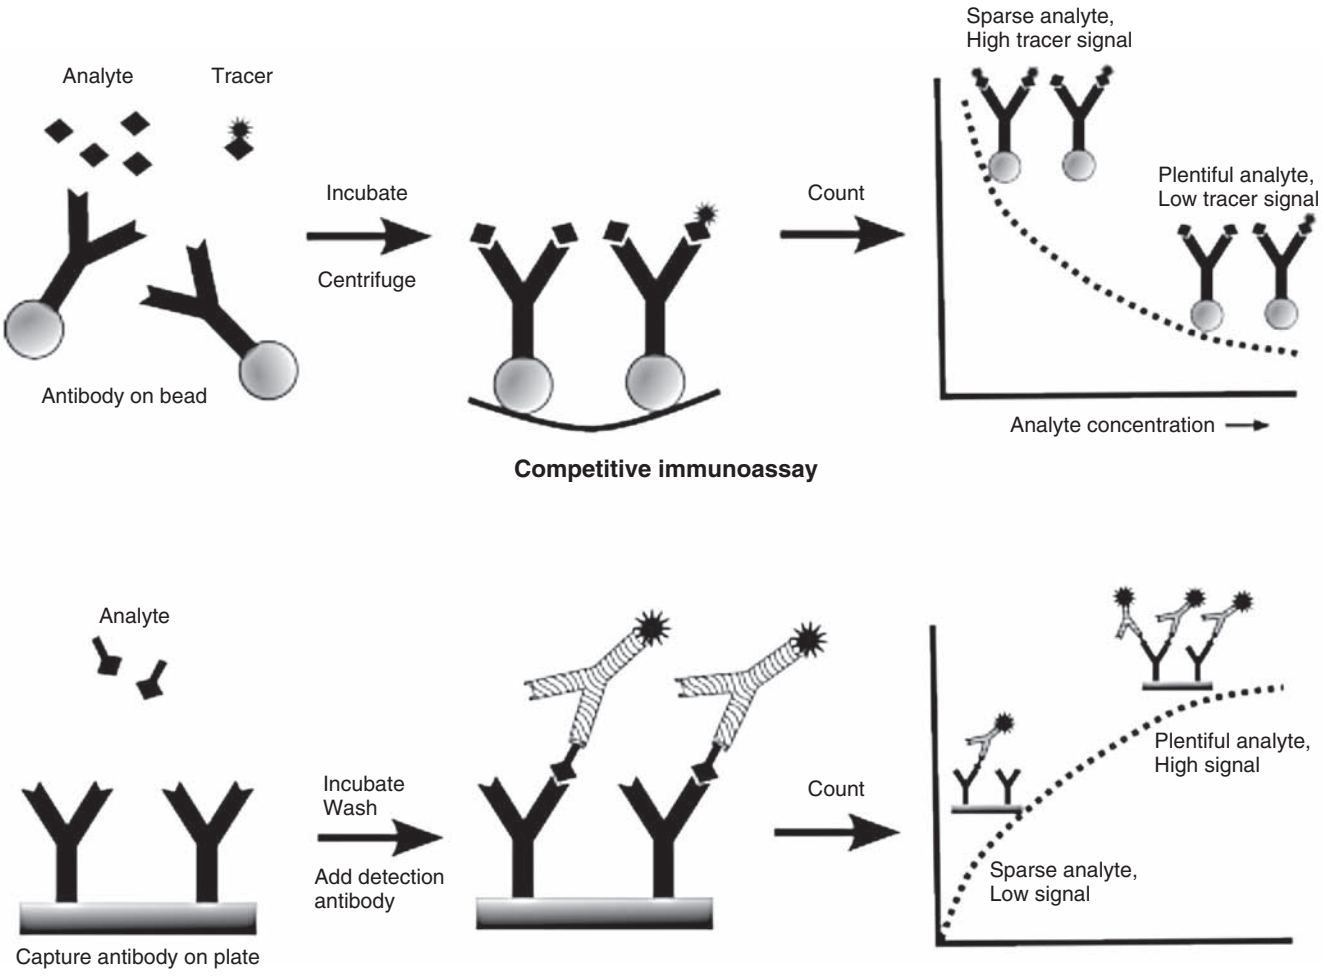

FIGURE 4-2 ■ Comparison of competitive versus immunometric immunoassays. In competitive immunoassay (top), the labeled tracer (signal conjugated analyte) and unlabeled (analyte) compete to bind specific antibody sites. In the two-site method (bottom), analyte of interest is sandwich between the capture and signal antibodies.

capture the analyte of interest, followed by the addition of a second, labeled antibody that binds to a different site on the analyte, creating an antibody-analyte-antibody sandwich. After unbound detection antibody is washed away, that which remains generates a radioactive (immunoradiometric [IRMA]), chemiluminescent (immunochemiluminometric [ICMA]), colorimetric (enzyme-linked immunosorbent assay [ELISA]), or fluorescent (immunofluorescence assay [IFMA]) signal, depending on the label chosen.

The immunometric assays offer certain inherent advantages over competitive immunoassays. First of all, the fact that two antibodies are involved, each binding to a separate epitope on the analyte, greatly increases analytic specificity, including the ability to select very specific isoforms of an analyte.[6] For example, one antibody can be directed at the N-terminus of a peptide, whereas the other antibody can be directed at the C-terminus, ensuring that only full-length peptide is detected. A second advantage is that immunometric assays tend to be more analytically sensitive than their competitive assay counterparts.[7] This arises from the fact that the sensitivity of a competitive immunoassay largely depends on the affinity of the antibody used in the assay—and developing very high affinity antibodies is not an easy or predictable task. In contrast, the sensitivity of an immunometric assay can be improved by use of a higher activity signal, which is more easily detected even when analyte concentrations are very low. As signal detection technology continues to improve, increasingly sensitive immunometric assays can be developed. A third advantage of immunometric assays arises from the ability to use monoclonal antibodies, which can be more easily produced in quantity and have more predictable characteristics than polyclonal antibodies.

Potential Confounders in Immunoassays

Clinical Scenario

A 16-year-old girl with schizophrenia has recently developed galactorrhea and secondary amenorrhea. Her prolactin is elevated at 43 μg/mL, which her attending psychiatrist states is a level commonly seen for young women treated with risperidone. A medical student on the service asks whether the level could also be consistent with a prolactinoma and a "hook effect" accounting for a falsely low level.

Sandwich immunometric assays are potentially vulnerable to what has been termed the "hook" or "prozone" effect that can lead to falsely normal or low values in the presence of large amounts of the analyte[8] (Figure 4-3). Generally, as analyte concentration increases, more antibody-analyte-antibody sandwiches are formed, leading to more signal detected. At extremely high analyte concentrations, however, it is possible for both capture and detection antibodies to be saturated with analyte prior to formation of a sandwich complex, leading to the detection antibody being washed away and the low signal being misinterpreted as a low concentration of analyte. This phenomenon is not seen with competitive immunoassays. To minimize the chances of a hook effect, most immunometric assays have now modified their methods as follows: analyte is allowed to bind to capture antibody, a thorough wash step removes excess unbound analyte, and only then is the detection antibody added. In the now extremely rare situation where a hook effect is still suspected, serial dilutions of the sample may be performed to see if the apparent concentration of the analyte actually rises with increasing sample dilution.

There is some inconsistency in the literature around the terms *heterophilic antibody* and *human antianimal antibody* (HAAA) or *human antimouse antibody* (HAMA).

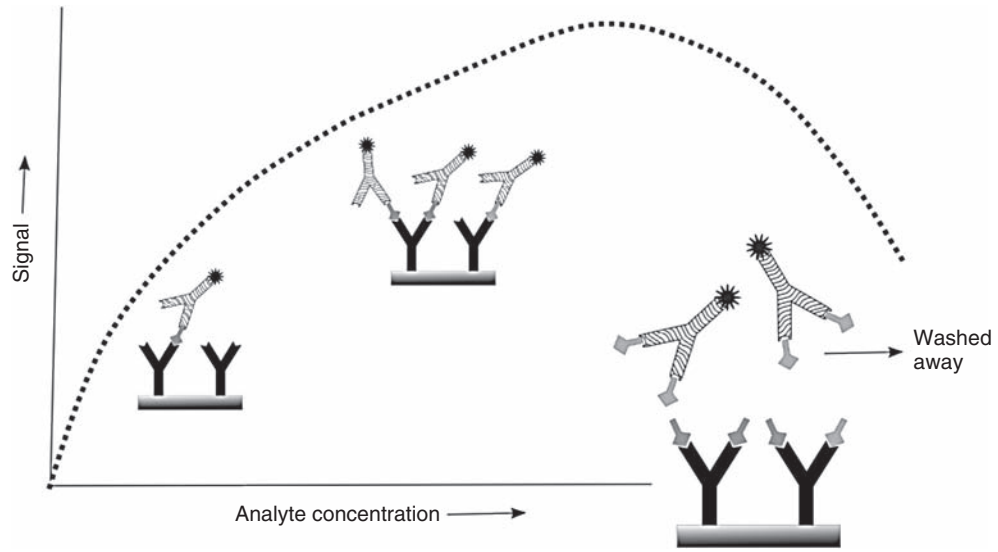

FIGURE 4-3 ■ Hook (prozone) effect leading to falsely low results. Extremely high analyte concentration leads to occupancy of all binding sites without creating the assay "sandwich" configuration. Signal antibody is washed away and the low signal is interpreted as a low concentration of analyte (dotted line). Dilution of sample may lead to increasing signal and an apparent increase in the measured analyte concentration.

Some authors use these terms interchangeably; others reserve the term *heterophilic* for low-affinity antibodies that spontaneously arise against multiple, poorly defined antigens and use HAMA or HAAA only for those patients who develop specific high-affinity antibodies due to treatment with a murine monoclonal antibody or due to recurrent exposure to a particular animal species (e.g., scratches endured by a rabbit handler). Regardless of the term used, any given patient may have antibodies present that bind to and interfere with animal (mouse monoclonal; rabbit, goat, or donkey polyclonal) antibodies used in a particular immunoassay,[9] even without previous exposure to that particular animal. These antibodies can bridge the capture and detection antibodies in an immunometric assay, as shown in Figure 4-4 (left panel), creating a sandwich and a high signal (false elevation) even in the absence of analyte. Alternatively, they could attach at the binding site of the capture antibody and prevent binding of the analyte (Figure 4-4, right panel), eliminating formation of the sandwich, and causing a falsely low value. Competitive immunoassays are less often affected, although they may show falsely high values if the interfering antibody outcompetes the assay antibody for tracer, or falsely low values if they bind preferentially to the analyte over the tracer.

When a heterophilic/HAAA/HAMA effect is suspected, the sample should be assayed on a different immunoassay platform, as the interference is often specific for one manufacturer's assay but not another's. Such a maneuver is often the quickest to accomplish, but the sending lab must ensure that the second lab is truly using a different platform. Another option is to use heterophilic antibody blocking agents, which are a mixture of animal immunoglobulin fragments or other proprietary agents that soak up the interfering antibodies. A disadvantage of this approach for pediatrics is that a significantly larger volume of sample is required to assay both with and without use of the blocking agent. A third, more labor-intensive option is to assay the sample on serial dilutions, as those showing antibody interference effects tend not to show linear responses on dilution.

Clinical Scenario

An adolescent with papillary thyroid cancer is treated by total thyroidectomy and radioactive iodine. Several months postoperatively, a thyroglobulin measured by ICMA (Tg-ICMA) is undetectable and thyroglobulin antibodies (TgAb) are negative, which is taken as proof that cancer has not recurred. However, great consternation occurs when a sample is sent for a different TgAb assay that is positive (the original TgAb assay remains negative), calling into question the undetectable Tg-ICMA. Thyroglobulin measured by a competitive assay (Tg-RIA) is consistently detectable at a low level and does not decrease despite other favorable prognostic indicators (decreasing titer of TgAb, no lymph node involvement) or additional radioactive iodine treatment.

Specific autoantibody interferences appear to be rare compared to the heterophilic/HAAA/HAMA interferences described in the previous section, with the notable exception of TgAb in patients with thyroid cancer. TgAb is present in about 20% to 25% of thyroid cancer patients and leads to false depression of thyroglobulin levels by immunometric assay (e.g., Tg-ICMA). In addition, different thyroglobulin antibody assays may report discordant (negative versus positive) results in some cases. Although a competitive assay such as Tg-RIA is less often affected by TgAb interference than is the Tg-ICMA, if the autoantibody is of sufficiently high affinity to outcompete the assay antibody, a Tg-RIA may show false elevation in the presence of such TgAb.[10] Overall, any Tg immunoassay result, whether performed by Tg-ICMA or Tg-RIA, must be viewed as potentially affected in a patient with TgAb present (and even possibly in patients whose TgAb is reportedly negative). Helpful proxies for Tg include following TgAb titer, which should fall over time in patients without cancer recurrence.[11] Imaging studies may also help assess the probability of recurrence. Although rare, autoantibodies may be of sufficiently high affinity to affect both competitive and immunometric assays alike. Consequently, they would be less likely to show differences when assayed on different platforms and are not affected by heterophilic antibody blocking agents. In these scenarios, diagnosis may require measurement of specific autoantibody

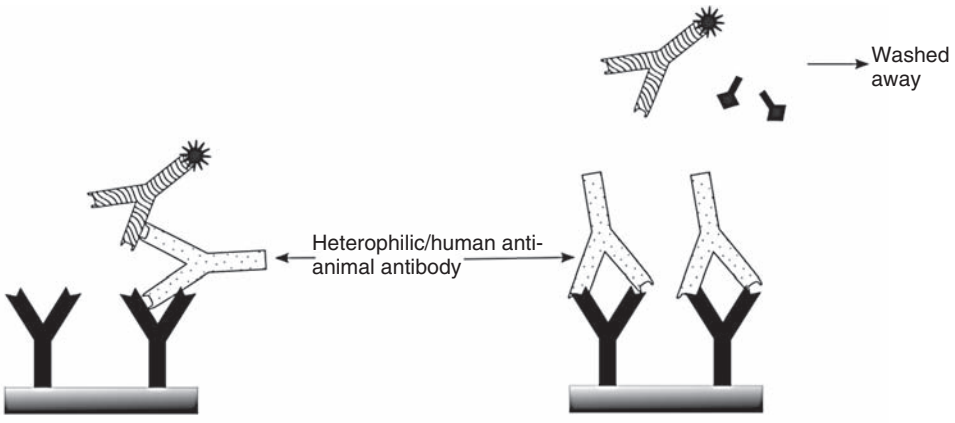

FIGURE 4-4 ■ Mechanism of immunometric assay interference by heterophilic or human antianimal antibodies. See text for details.

(e.g., a parathyroid hormone [PTH] antibody assay in someone with a discordantly high or low PTH level).

Limitations of Immunoassays

The ability of an antibody to bind a specific target with high affinity is remarkable, yet there are limitations. The small size and relatively poor immunogenicity of steroid molecules make it difficult to obtain an antibody that can clearly distinguish a specific steroid from other similar steroids. For example, an antibody raised against testosterone may show significant cross-reactivity with a conjugated form such as testosterone glucuronide, or with the structurally similar dihydrotestosterone molecule. A solvent extraction step to remove water-soluble conjugates such as glucuronides, coupled with a chromatographic step to separate out structurally similar molecules, will greatly improve the analytic specificity of the assay[12] (Figure 4-5A). The extraction step also separates testosterone from binding proteins that can interfere with accurate measurement.

Testosterone immunoassays that do not involve such extraction and chromatography steps, including the majority of assays found on most automated laboratory platforms, may perform adequately at the higher levels found in adult males (> 300 ng/dL) but will frequently measure inappropriately high values in the range most pertinent to women and prepubertal children (Figure 4-5B). Because in practice the lower values are more concordant with the clinical picture, endocrinologists caring for women and children have traditionally relied on immunoassays that involve extraction and chromatography steps, or assays involving chromatography and tandem mass spectrometry.

Free and Bioavailable Hormone Tests

Clinical Scenario

A pediatrician caring for a newborn male infant is informed of an abnormal newborn screening result with a low total T4 and normal TSH. He contacts his colleague in pediatric endocrinology about how to initiate a workup for hypopituitarism that may accompany central hypothyroidism. Instead, the pediatric endocrinologist recommends a repeat set of tests that includes a free T4 measurement.

The free hormone hypothesis states that free, or unbound, steroids or thyronines, vitamins, or peptides are

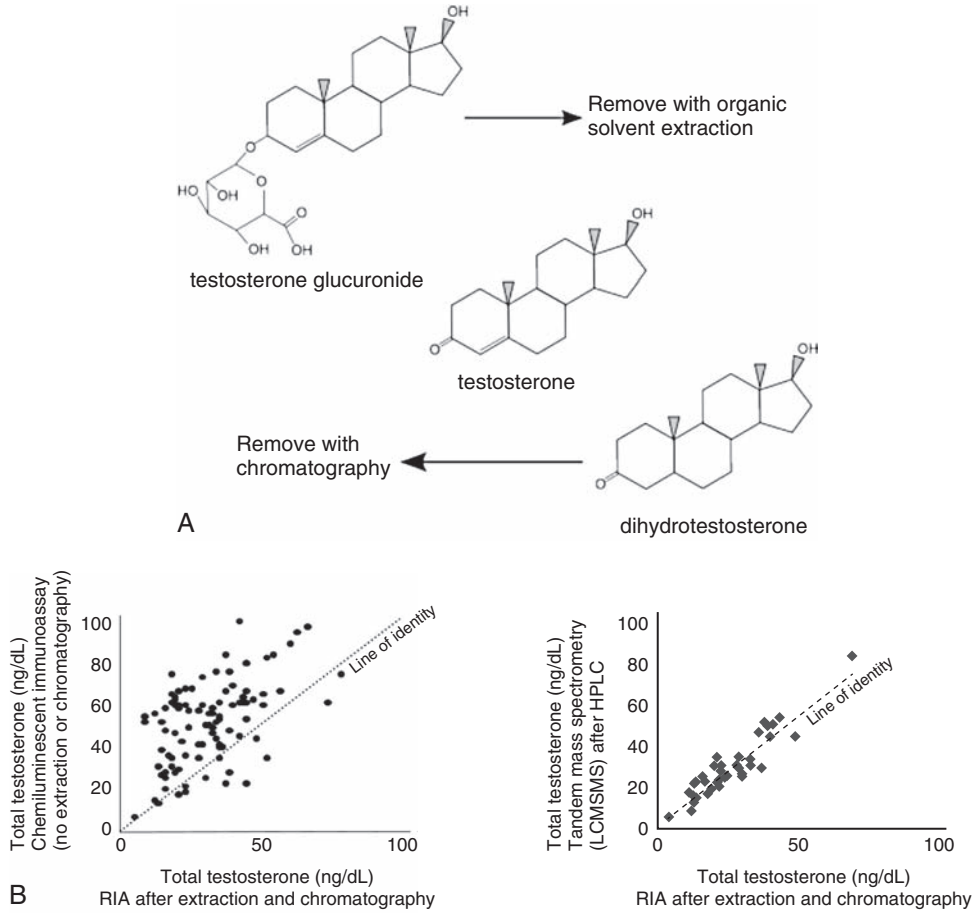

FIGURE 4-5 ■ **A,** Increasing specificity of analysis via extraction and chromatography. After organic solvent extraction, water-soluble conjugates remain in the aqueous phase while steroid molecules generally remain in the organic phase. Similar steroid molecules can be separated by an additional chromatography step. **B,** Correlation of testosterone assays (extraction/chromatography/RIA versus nonextraction immunoassay or tandem mass spectrometry). Left panel: Steroid immunoassays without additional preparation steps prior to assay tend to give higher values than immunoassays after extraction and chromatography, likely because of steroid conjugates and compounds of similar structure (occasional lower values may reflect issues with incompletely removed steroid binding proteins). Right panel: Measurement of steroids by HPLC-mass spectrometry (which also involves extraction and chromatography) produces testosterone results very similar to those obtained with immunoassay after extraction and chromatography.

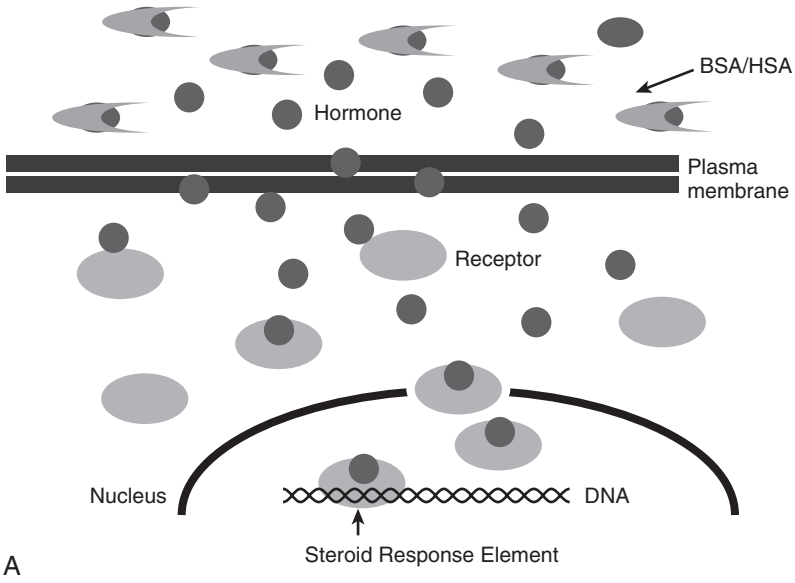
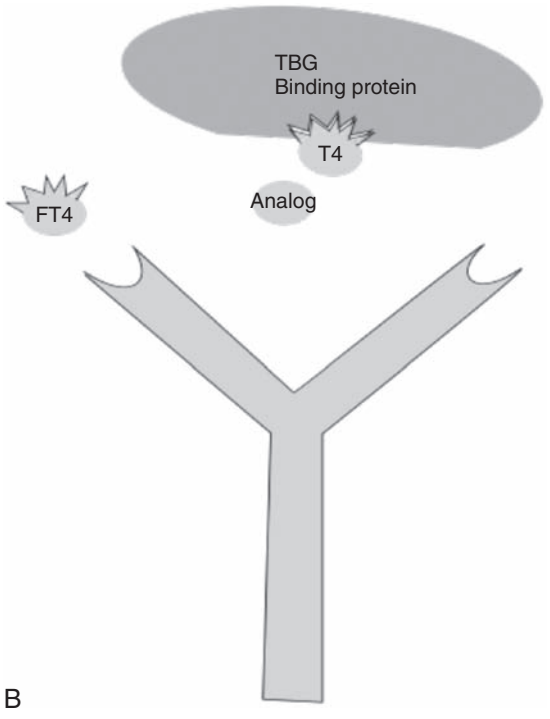
available to enter cells or interact with cellular proteins by virtue of their small size and sometimes their hydrophobic nature.[13] Free hormone in this section means not liganded to a binding protein. As free and bound hormone pass through a tissue bed, the free hormone may be taken up by the tissues, additional free hormone may become available from the bound fraction, or the complexed hormone may be taken up by cells.[14] The systems may be further complicated by multiple binding proteins. Clearly, the activities of several steroids, thyronines, and even protein hormones are reduced by binding to specific high–affinity binding proteins and albumin. Conversely, the absence of binding proteins can reduce the total hormone level, but the free hormone level may be unaffected. For example, the majority of thyroid hormone in circulation is carried by thyroxine-binding globulin (TBG). TBG deficiency is characterized by low total thyroid hormone levels, normal free thyroid hormone levels, normal TSH (in equilibrium with the free T4), and clinical euthyroidism.

Testosterone binds to sex hormone binding globulin (SHBG) and serum albumin. Testosterone binds SHBG with much higher relative affinity, but SHBG is present in much lower concentrations than albumin. Free testosterone may be measured by equilibrium dialysis, which is accepted as the best indication of the physiologic availability of testosterone (Figure 4-6A). The free fraction may also be estimated mathematically from the testosterone, SHBG, and albumin concentration; however, not all assumptions may be valid in calculated free



A



B

FIGURE 4-6 ■ **A,** Free steroids may enter cells by passive diffusion through plasma membranes. Bound steroids may not diffuse through membranes. Once in the cell, steroids may interact with enzymes, or nuclear receptors. **B,** Free thyroxine (FT4) measurements, routinely made by analog immunoassay largely reflect total thyroxine. (Fritz KS, Wilcox RB, Nelson JC [2007]. A direct free thyroxine [T4] immunoassay with the characteristics of a total T4 immunoassay. Clin Chem 53:911-915.) Dialysis with HPLC and tandem mass spectrometry or dialysis and immunoassay methods provide theoretic accuracy. Dialysis methods should be used where binding proteins vary from the norm. T4 interacts with the antibody used in the FT4 test and competes with the analog; however, the analog does not bind thyroxine-binding globulin (TBG).

testosterone.[15, 16] Analog methods measure free testosterone directly using a competitive test in automated assay instruments (Figure 4-6B), but the analog methods may at best weakly reflect free hormone activity. Similarly, free T4 measured by analog methods can perform poorly in some settings.

Bioanalytic testosterone refers to the fractions of testosterone bound to serum albumin plus the free hormone; for this reason this fraction is also called free and weakly bound testosterone. The dissociation rate of albumin bound is very fast relative to that of the SHBG bound, and for that reason it is thought to be available to the tissues for actions. This idea, supported by empirical evidence, is in contrast to the free hormone hypothesis, as free and protein-associated hormone may be available to the tissues.[14] In practicality, measurement of free or bioavailable hormones provides the same information to the clinical encounter.

Mass Spectrometry

Mass spectrometry is a qualitative and quantitative analytic technique that separates molecular ions based on their mass and charge, or more exactly according to the mass/charge ratio (Figure 4-7). In clinical laboratories, mass spectrometry is invariably preceded by chromatographic assays that separate hormones. Separation techniques include high-pressure liquid chromatography (HPLC), column chromatography, gas chromatography, thin-layer chromatography, electrophoresis, and other variations limited only by the imaginations of the inventors. In all chromatography assays, the hormone is attracted to both a mobile phase and a stationary phase, and separation occurs by variations in attraction of hormone to the two phases. Table 4-2 highlights some of the chromatographic techniques used in endocrinology.

Clinical Scenario

A pediatrician is notified that a male infant she discharged on day-of-life 2 had a filter paper newborn screen performed by mass spectrometry, and the result of this test was highly suspicious for congenital adrenal hyperplasia. She reaches the family by phone, and the baby is evaluated in the office on day-of-life 7. Laboratory testing reveals sodium 134, potassium 6.1, and markedly elevated 17-OH progesterone concentration, confirming the diagnosis. The baby is admitted to the hospital, and the pediatric endocrinology team is consulted.

Mass spectrometry is increasingly employed in endocrine laboratories. In the late 1990s, incorporation of mass spectrometry technology led to a significant expansion of newborn screening programs, particularly for inborn errors of metabolism and extending to congenital adrenal hyperplasia, as illustrated in the preceding case scenario. Detection systems have become increasingly sensitive and sophisticated. New-generation liquid chromatography (LC)-MS/MS steroid assays have shown

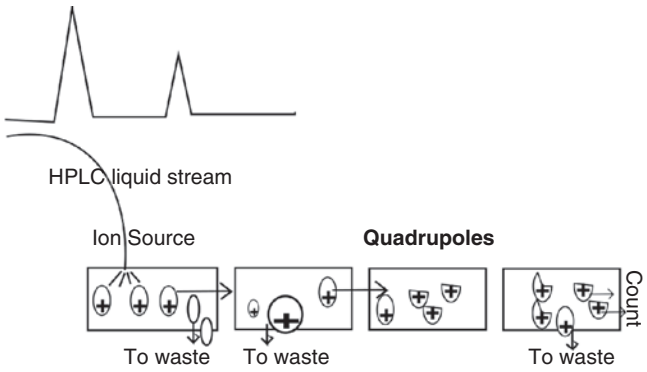


FIGURE 4-7 ■ (left to right) Box 1. The liquid stream from HPLC is vaporized and ions are formed. Un-ionized molecules are swept to waste. Box 2. Ions are selected by mass/charge whereas other mass/charge molecules are swept to waste. Box 3. Ions are fragmented. Box 4. Fragments of the selected mass/charge are counted, others are swept to waste.

TABLE 4-2 **Common Chromatographic Assay Types**

Acronym	Description	Typical Mobile Phase	Typical Stationary Phase
GC	Gas chromatography	Helium, nitrogen	Polymer coated inside a capillary column
HPLC	High pressure liquid chromatography	Water, acetonitrile, methanol	Polar or nonpolar additions to very tiny bead particles
Column chromatography	Various sorbents in a traditional column	Polar or nonpolar ion exchange or affinity	Buffers and solvents Salts or ligands that affect affinity
TLC	Thin layer chromatography	Methanol, acetone	Particles of silica coated on a glass plate
CE	Capillary electrophoresis	Electrical charge moves ions	Resin with fixed charge coated in a capillary

improved accuracy, precision, sensitivity, selectivity, and clinical utility over simple direct and complex reference immunoassays.[17, 18] Assay technology that employs mass spectrometry, especially for steroids and biogenic amines, is regarded as more accurate than immunoassay, such that it is now the standard assay for these molecules in reference laboratories. The performance characteristics of immunoassay and mass spectrometry are summarized in Table 4-3.

It is important to note that, as with immunoassay, assay design is crucial for accuracy and specificity with mass spectrometry. Detection systems such as flame ionization detection for gas chromatography (GC), visible or ultraviolet detection coupled with HPLC, and staining of thin layer chromatography (TLC) have a place in research but are generally not sufficiently specific, sensitive, and robust for clinical hormone measurement. Gas chromatography with mass spectrometry can have similarly useful specificity and sensitivity characteristics; however, generation of derivatives is required to help the molecules evaporate into the gas phase, adding complexity.

The mass/charge ratio is the fundamental feature that allows discrimination of compounds by mass spectrometry. Steroid hormones, normally neutral, for example, are charged in an interface and then accelerated as gas-phase ions into a mass spectrometer operated under vacuum. At the same time the solvent is dried and swept away along with other uncharged molecules. In tandem mass spectrometry (MS/MS), molecules (gas-phase ions) of interest are selected and fragmented, then products specific to the analyte are again selected for detection. Thus, the tandem mass spectrometer adds levels of selection with each process. Experimental sequences can be derived that allow simultaneous measurement of similar analytes from a single sample. The whole process is controlled by addition of fixed amounts of an internal standard. Optimally, in isotope dilution mass spectrometry, the standard is the same molecule as the target analyte except that heavy stable isotopes, such as deuterium or carbon-13, are inserted.[19] Because the mass is different, the internal standard is read separately, and the analysis is based on the ratio of analyte to internal standard. The specificity of HPLC and isotope dilution mass spectrometry theoretically offers a means for sensitive, robust assays.

The specificity of mass spectrometry methodology is not derived from an antibody-antigen interaction, thus it does not depend on potentially limited antibody reagent. Still, just as there are potential pitfalls in immunoassay measurements, there can be barriers to accurate HPLC mass spectrometry measurements (Table 4-4). Extraction and good HPLC chromatography solve many of the issues for steroid tests, reducing interference and suppression of ionization.[20] Review of molecular fragments can often reveal interference; these are called qualifier ions.

Protein mass spectrometry has been slower to displace immunoassay techniques because the immunoassays remain effective tools and mass spectrometry may be challenging. Large proteins are difficult to measure by HPLC tandem mass spectrometry because of instrument limitations and because variations in posttranslational

TABLE 4-3 **Performance Characteristics of Endocrine Methods**

Method	Analytic Sensitivity	Analytic Precision	Analytic Specificity	Interference	Remarks
Competitive Immunoassay —RIA —EIA —FIA	Poor to excellent µg to pg	Poor to good 10% to 30% CV	Poor to good Polyclonal Ab	Nonspecific—pH, ionic strength, degradative enzymes, matrix Specific—cross reactants	Poor specificity maybe clinically advantageous in some cases (e.g., RIA method may capture all biologically active forms of growth hormone), whereas highly specific method may only measure selected isoform of growth hormone and can exclude polymorphism with LCMS method.
Two-site "sandwich" immunoassay —IRMA —ELISA —ICMA	Good to excellent ng to pg	Good to excellent < 5% to 20%	Good to excellent Monoclonal Ab Affinity purified poly Ab	Same as above in addition to: —Autoantibodies —HAMA —High dose hook effect	Automated methods exhibit excellent precision but may suffer accuracy and sensitivity.
LCMSMS	Good to excellent ng to pg	Good to excellent < 10% to 20%	Excellent	Matrix Isomers	Performance characteristic highly dependent on performing laboratory, as most methods are laboratory developed and manual.

RIA, radio immunoassay (RIA); EIA, enzyme immunoassay; FIA, fluorescence immnoassay; IRMA, immunoradiometric; ELISA, enzyme-linked immunosorbent assay; ICMA, immunochemiluminometric; LCMSMS, high pressure liquid chromatography with tandem mass spectrometry; HAMA, human antimouse antibody; LCMS, liquid chromatography with mass specrometry.

TABLE 4-4 **Common Problems and Solutions for HPLC Mass Spectrometric Assays**

Potential Problem	Effect	Detection and Solution
Interference	High results if analyte is affected Low results if internal standard is affected Isobaric compounds Ions that have the same mass to charge, as the analyte can cause high results	Peak review and review of alternant qualifier fragment
Poor standardization	Inaccuracy	Various governmental and industry agencies have standardization programs
Matrix effects	Interference with ionization	Identification of and HPLC separation of interferences Heavy isotope internal standards
Use of nonspecific derivative to increase sensitivity	Interference if the derivative becomes the measured ion	Avoid measurement of derivative fragment ions
Noise	Background ions from nonspecific interferents such as serum separator can reduce precision	Avoid or improve extraction and chromatography

HPLC, high-pressure liquid chromatography.

modification and natural abundance of heavy stable isotopes creates groups of mass species to measure that are difficult to discriminate. Several types of mass spectrometers are available and may be used clinically in the future. One type is matrix-assisted laser desorption/ionization coupled with time of flight mass (MALDI-TOF) spectrometry, which has been used largely as a discovery tool and has not found general utility in quantitative experiments. Protein capture with antibodies followed by digestion into peptides has been used to develop commercial tests. Thyroglobulin, for example, can be measured in this way to avoid autoantibody interference; however, currently the sensitivity does not quite match immunoassay. These techniques are new and less is known about their reliability.[21]

INTERPRETATION OF TEST RESULTS

Laboratory studies should provide reliable information to aid in the diagnosis and management of patients. It is crucial that potential confounders that can lead to misinterpretation be promptly and correctly recognized. Method validation is the responsibility of the laboratory and includes components mandated by regulatory agencies such as the Clinical Laboratory Improvement Amendments (CLIA), Food and Drug Administration (FDA), and Clinical Laboratory Standards Institute (CLSI) in the United States. Many laboratories have internal programs that assure that their assays are performing within stringently defined limits.[22, 23] Meanwhile, preanalytic variables, defined as factors related to the subject and specimen collection and delivery but independent of the assay itself, can also lead to erroneous interpretation.[23, 24] Finally, one must always recognize that assay validation and clinical validation of assay utility are not interchangeable concepts. Clinical validation lies at the interface of the laboratory and the clinician. Frequent communication between clinical and laboratory personnel facilitates optimal care.

Preanalytic Variables

Normal endocrine physiology, nonendocrine illness,[25] sample collection and handling, and drugs or interference factors influence measured hormone levels (Table 4-5).

TABLE 4-5 **Preanalytic Physiologic Variables Affecting Hormonal Measurements**

Variable	Hormone
Episodic secretion	Pituitary hormones, cortisol, testosterone
Exercise (acute)	Adrenocorticotropic hormone (ACTH), antidiuretic hormone (ADH), aldosterone, cortisol, epinephrine, glucagon, growth hormone (GH), prolactin, norepinephrine, testosterone
Circadian rhythm, diurnal variation	ACTH, cortisol, dehydroepiandrosterone sulfate (DHEAS), epinephrine, estradiol, follicle-stimulating hormone (FSH), GH, luteinizing hormone (LH), norepinephrine, prolactin, testosterone
Seasonal variation	Estradiol, prolactin, testosterone
Postural change	Aldosterone, epinephrine, norepinephrine, renin
Nutrition	C peptide, estradiol, glucagon, insulin-like growth factor-I (IGF-I), insulin-like growth factor binding protein-1 (IGFBP-1), insulin, proinsulin, thyroxine-binding globulin (TBG), renin, aldosterone

Many hormones are secreted in an episodic manner. Chronologic age, pubertal stage, emotional and physical stress, nutritional status, and postural effects contribute to variation. Consequently, some hormones, growth factors, or surrogate markers may have very wide normal basal ranges and large intrasubject variability. Intrasubject variability can be demonstrated with diurnal variation, for example, in levels of luteinizing hormone (LH), follicle-stimulating hormone (FSH), estradiol, and testosterone.[26] Variability has also been verified for 24-hour integrated concentrations[26, 27] and for dynamic responses.[28]

Valid test results are dependent on proper patient preparation, specimen handling and transport, and timely accessioning into the laboratory system.[29, 30] Quality management stipulates that the laboratory provide a collection manual, and current electronic online availability allows almost any location ready availability to this information at any time. When stimulation and timed testing are desired, access to the variables of specimen collection is essential: the details of patient preparation, attention to the time and site of specimen collection, specifics of testing protocols, and influences of concomitant medications should all be clearly stated in collection manuals. Container specifications and acceptable preservatives must be listed for each analyte, and minimal and ideal volumes to allow retesting or add-on of additional tests should be stipulated. Immediate postcollection handling, such as the time until serum separation from a clot and intervals until refrigeration or freezing must occur, should be specifically mentioned and easily located in the instructions. Clinical data required for proper interpretation may be included in a test description. Should any questions arise, the clinician should consult with the specific laboratory to understand collection and handling requirements for a particular assay.

Analytic Validation, Quality Assurance, and Quality Control

Clinical Scenario 1

An investigator inadvertently runs two tubes containing nothing but water on a peptide RIA and is nonplussed when the results show a significant level of the peptide in these tubes.

Clinical Scenario 2

A laboratory declines to run a tumor marker immunoassay ordered on viscous cyst fluid due to a lack of analytic validation data, but relents when the physician insists that the laboratory run the sample with a disclaimer "nonvalidated sample type; interpret with caution." Despite the disclaimer, the laboratory is later sued successfully for inappropriate diagnosis and unnecessary treatments based on what turns out to be a falsely positive result.

Both of these brief clinical vignettes illustrate why regulatory agencies and anyone concerned with quality laboratory testing place such emphasis on analytic method validation. A peptide RIA may give accurate results in serum, but totally inaccurate results in a protein-free fluid; perhaps the tracer in scenario 1 stuck to the sides of the plastic tube, leading to decreased tracer binding and an apparent detectable level of peptide where none was actually present. Scenario 2 represents a situation of misdiagnosis; the viscosity of the solution might have affected the interaction of the assay components, with substantial impact on the patient and legal consequences for all involved.

Analytic validation is meant to ensure that an assay method is accurate for its intended use.[31] Components of an analytic validation include the following: (1) linearity/reportable range; (2) precision; (3) analytic sensitivity; (4) analytic specificity, interferences, and recovery; (5) accuracy/method comparison; (6) sample types and matrix effects; (7) stability; and (8) carryover. Determining reference intervals is an important part of many analytic validations and crosses over to clinical validation. Note that even though not all of these components are always required from a regulatory point of view, all represent good-quality laboratory practice.

Linearity/Reportable Range

Also referred to as the "analytic measurement range" (AMR), this is the range of concentrations over which the assay is known to be reliable. Standards of known concentration (calibrators) are assayed and plotted against the signal generated in the assay. For the hypothetical study shown in Figure 4-8, the upper limit of the AMR would likely be at the concentration represented by calibrator D, because the higher concentration represented by calibrator E does not result in a similar degree of increased signal. However, it may be possible to dilute the sample so that one can make a measurement within the AMR, thereby allowing for assay of concentrations above the upper limit of the

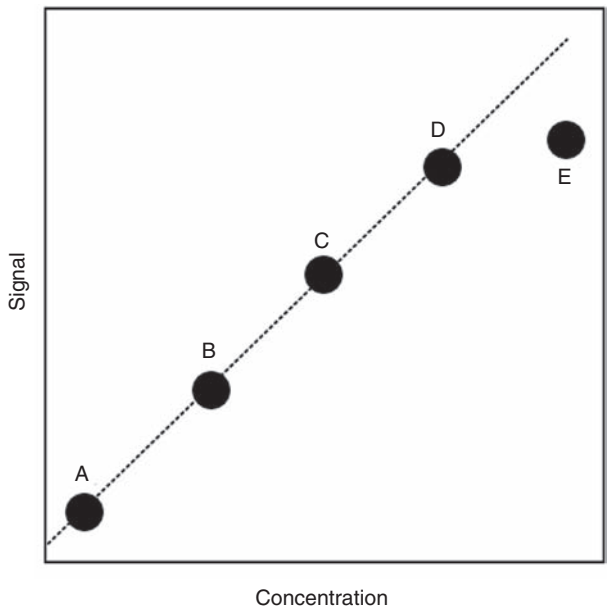

FIGURE 4-8 ■ Linearity study used to determine analytic measurement range. The concentrations represented by points A and D represent the likely minimum and maximum concentrations of the analytic measurement range. Higher concentrations such as that represented by point E may still be measured on a diluted sample if it can be proven that the response remains linear when a dilution is performed.

AMR. The calibrator choice may alter the absolute value reported, particularly with peptides and proteins where the standard may represent only one of a mixture of differentially modified (e.g., glycosylated or cleaved) forms present in the circulation.

Precision

Also known as reproducibility or replicability, this defines whether the random error of the assay is small enough to make the assay clinically useful. A commonly used analogy is that of the target shooter: how close together are the bullet holes? Note that precision is distinct from accuracy (a different part of the validation study); precision addresses only if the shots are close together, not whether they are actually hitting the bulls-eye. Both intra-assay (e.g., 20 measurements done on the same assay run) and inter-assay (1 measurement done daily for 20 days) precision are studied and the standard deviations (SDs) of the replicate measurements calculated. Generally precision is presented as the *coefficient of variation* (CV), which is the SD divided by the mean, expressed as a percentage. For example, at a mean value of 100 ng/mL, an assay with an SD of 5 ng/mL would have a CV of 5%. Note that the concentration of the analyte factors into the assay's precision, as CV values tend to be higher at either limit of the AMR (Figure 4-9).

Clinical Scenario

A 14-year-old boy is referred to the pediatric endocrinology clinic for evaluation of delayed puberty. A serum testosterone level drawn 3 weeks prior to the visit was reported as 36 ng/dL by the hospital lab, which had been taken as evidence that the boy had indeed initiated puberty. Repeat testing in the clinic returns a value of <30 ng/dL. The pediatric endocrinologist becomes concerned that the patient is demonstrating regression in his testosterone production and contacts the laboratory director, who explains the functional sensitivity for the testosterone assay on the platform is indeed 30 ng/dL.

Analytic Sensitivity

This part of a validation study determines how low an analyte concentration can be measured with acceptable precision. It is distinct from "diagnostic sensitivity" (how often a result is positive in a patient with disease), which is a general part of a clinical validation study done well after the analytic validation has been completed. A frequent problem is the use of many different terms for analytic sensitivity, for example *minimal detectable concentration*, *limit of detection (LOD)*, or *limit of absence*, all of which describe the lowest possible concentration that can be confidently distinguished from zero. Although an assay developer might cite the LOD to make the assay look as sensitive as possible, the clinician should realize that values down near the LOD are hugely variable and not really quantitative. A more conservative and clinically useful analytic sensitivity limit is the limit of quantitation (LOQ), also known as functional sensitivity and typically defined as the lowest concentration that can be measured with a CV of less than 20%. In the previous scenario, a CV of 20% at 30 ng/dL equates to a SD of 6 ng/dL. Therefore, it is inappropriate to conclude the change in testosterone from 36 ng/dL to < 30 ng/dL is absolutely indicative of diminished testosterone production. Here, the clinician should specify that the testosterone assay include extraction and chromatography, rather than simply a direct measurement on an automated laboratory platform, which should improve the assay performance at lower testosterone levels.

Analytic Specificity, Interferences, and Recovery

Specificity in this context refers to the ability of the assay to measure a specific analyte without cross-reacting with other substances in the sample. Analytic specificity studies may involve the addition of known amounts of similar analytes to a sample; for example, a cortisol assay may be tested

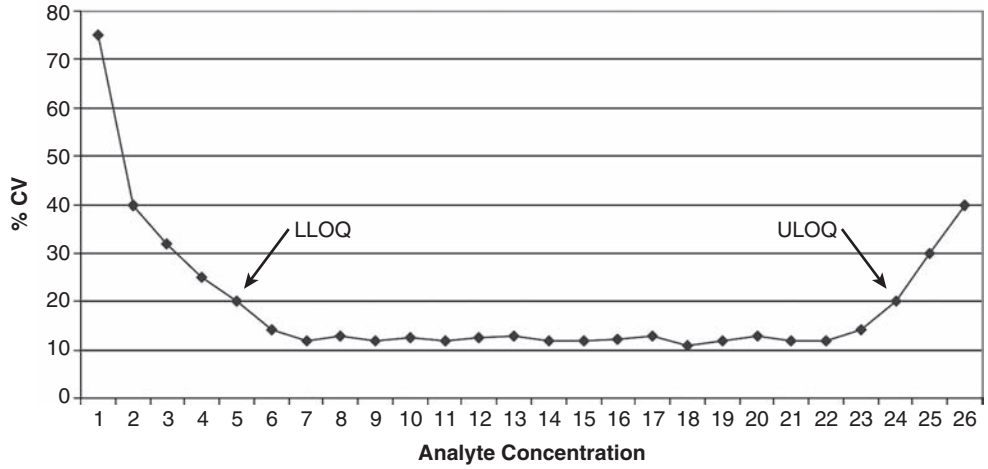

FIGURE 4-9 ■ Estimating the Precision profile over a range of analyte concentration. Lower limit of quantitation (LLOQ) is defined as the lowest concentration at which interassay precision is 20%. Upper limit of quantitation (ULOQ) is the highest measuring concentration at which interassay precision is 20%.

for cross-reactivity with cortisone, prednisone, prednisolone, dexamethasone, 17-hydroxyprogesterone, and other steroids. Closely related are interference studies to see if commonly encountered situations such as hemolysis, hyperbilirubinemia, and lipemia affect the test results. Recovery studies are less often performed; here, a standard of known concentration is added into a sample, and the sample assayed to see what percentage of the added standard is detected (ideally 100%, but frequently less).

Accuracy/Method Comparison

Determining the accuracy of an assay is a multistep process, not all of which can be addressed in a typical analytic validation study. Accuracy may be part of the original test development decision-making process—for example, including an extraction and chromatography step to avoid otherwise problematic cross-reactions. Full determination of the clinical accuracy of a test may not be possible until the analytic validation is completed and the test released to investigators for clinical validation studies. Therefore, so-called accuracy studies in an analytic validation are by necessity limited to just a small portion of the whole accuracy process. The interference and recovery studies mentioned earlier are pertinent to test accuracy, but the most common approach is to compare the new test method to another comparator method. Ideally, the method used for comparison will be some type of gold standard reference method, but often such a method is not available. As a proxy, the method under validation is compared to a well-accepted method, and the results shown (new method result on the y-axis, comparison method result on the x-axis) on a correlation plot (Figure 4-10, left panel). Also frequently used is a difference plot (Figure 4-10, right panel), which better shows intermethod differences that may escape notice on a simple correlation plot.

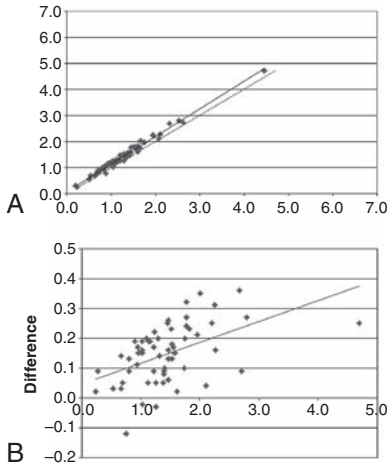

FIGURE 4-10 ■ A correlation plot compared with a difference plot. For the correlation plot (**A**), values for free T4 from a new assay (y-axis) are compared with values from an established free T4 assay (x-axis) showing a best fit (solid line) deviating slightly from the line of identity (dotted line). For the difference plot (**B**), the difference between the values from the new versus the old assay is plotted on the y-axis, whereas the mean value of the results from both assays is plotted on the x-axis. The systematic upward bias of the new assay is seen more clearly on the difference plot.

Sample Types and Matrix Effects

Sample types are not automatically interchangeable. EDTA plasma from a lavender top tube may perform fine in an assay, whereas heparin plasma from a green top tube may not. One parathyroid hormone assay may give comparable results from both EDTA plasma and red top tube serum, whereas a different parathyroid hormone assay may not. As noted in our vignettes, the matrix (e.g., protein-free, viscous, high salt, containing high levels of paraproteins) may have a profound effect on the accuracy of a laboratory assay. Whatever sample types/matrices will be used should be studied to ensure the accuracy of results.

Stability

Typically, sample stability is studied at ambient (about 22° to 26° C), refrigerated (about 2° to 6° C), and regular frozen (around −18° to −20° C) temperatures. For assays used in clinical studies where specimens may be banked for prolonged periods, stability studies should also be performed at deeper frozen (e.g., −70° C) temperatures. Aliquots stored at these temperatures for varying periods of time are recovered and assayed to see if results are stable relative to baseline. Stability limits are an inherent property of the assay rather than the analyte: an osteocalcin assay designed to pick up only full-length molecules may have a short stability limit for samples at room temperature, whereas another assay that detects osteocalcin molecule fragments as well as full-length protein may have a much longer stability limit. Stability limits for common hormone assays are listed in Table 4-6, but consultation with the specific laboratory is recommended. It is also worthwhile to understand the routine laboratory protocol for freezing aliquots for add-on studies.

Carryover

Another important quality process is to ensure that there is no cross-contamination between samples, and that a sample with very high values will not "carry over" and falsely elevate results in the next sample to be assayed. Assays should be designed to minimize this problem, but there should also be awareness on the part of the laboratory staff to check for carryover whenever a sample with an extremely elevated value is encountered.

CLINICAL VALIDATION

Analytic validation assures that the laboratory assay accurately reflects the true quantitative value of an analyte. The issue of whether the laboratory value reflects a pathophysiologic process and can be used in diagnosis and management of an endocrine disease requires clinical validation. To provide context to laboratory values, reference intervals are an absolute requirement in clinical

TABLE 4-6 **Hormone Assays: Preanalytic and Other Considerations**

Hormone	Patient Preparation, Sample Collection, and Hormone Stability	Assay Notes
Adrenocorticotropic hormone (ACTH)	EDTA 6-hour RT, 4° C Ship frozen Avoid FT	1-24 ACTH, used for stimulation studies, and pro-opiomelanocortin (POMC) fragments can lower ACTH levels as measured by two-site methods.
Antidiuretic hormone (ADH)	EDTA Avoid FT Ship frozen	Solid-phase purification required as extraction before assay.
Aldosterone	Patient: posture and sodium Stability: 6 hours at RT, 2 days at 4° C	Spironolactone and tetrahydroaldosterone 3-glucuronide may cross-react in some assays.
Calcitonin	1 day at RT 1 day at 4° C	Large calcitonin and others cross-react in some radioimmunoassay (RIA) methods. High dose suppression of values possible with two-site methods. Heterophile antibodies and human antianimal antibodies may give falsely elevated results in two-site methods.
Cortisol saliva	Sampling time important Stable refrigerated or RT 6 days Avoid tooth brushing and eating	Any blood in the sample invalidates the salivary cortisol result due to much higher cortisol levels in blood.
Cortisol, urine-free cortisol	With boric acid 5 days at RT and 14 days at 4° C	Prednisolone and 6-beta-hydroxycortisol may cross-react.
C peptide	EDTA: 1 day at RT RT: 1 day at 4° C Ship frozen	C peptide immunoreactivity may be unstable. Some immunoassays may be affected by anti-insulin antibodies.
DHEA, serum	4 hours RT 12 days 4° C	Delta 5 steroids unstable at RT.
Dopamine, epinephrine, norepinephrine—plasma	Patient preparation: posture and activity Stability: 0 days at 4° C Must freeze sample ASAP	Very unstable analytes present in low concentrations.
Dopamine, epinephrine, norepinephrine—urine	Stable if acidified below pH3 Stability: 14 days at 4° C Must freeze sample ASAP	Unstable at neutral or basic pH.
Estradiol	2 days at RT 6 days at 4° C	RU-486, Efavirenz, and steroid-binding proteins may interfere with some assays.
Free IGF-I	Avoid FT Ship frozen	Direct methods controversial.
Growth hormone (GH)	2 days at RT 2 days at 4° C	20-kD GH react in certain RIA methods. Human placental lactogen (hPL) may augment or suppress hGH levels. 44-191 GH in RIA methods. High hGH concentrations may require sample dilution if accurate results are needed. After treatment, anti-GH antibodies may suppress GH levels in sandwich assays.
Glucagon	EDTA Avoid FT Ship frozen	Unstable; keep frozen.
Insulin-like growth factor (IGF)-I	2 days at RT 2 days at 4° C	IGF binding proteins react in methods that do not exclude or block. Variable reactivity with therapeutic IGF-I and IGF-I/IGF-BP3 complex with some assays.
Insulin	6 hours at RT 1 day at 4° C Ship frozen	Variable reactivity with various recombinant insulins. On treatment, hook effect possible for two-site assays. Human anti-insulin antibodies may interfere (use free and total measurements to avoid this issue). Assays typically most reactive with human insulin, less reactive with porcine insulin, and least reactive with bovine insulin.

Continued

TABLE 4-6 **Hormone Assays: Preanalytic and Other Considerations—cont'd**

Hormone	Patient Preparation, Sample Collection, and Hormone Stability	Assay Notes
IPTH, intact parathyroid hormone	EDTA 4 hours at RT 1 day at 4° C	Assay terminology: second-generation N-terminal anti-1-24, third-generation N-terminal anti-1-6 Second- and third-generation typically use C-terminal anti-39-84. Midrange parathyroid hormone RIAs (MPTH) recognize parathyroid hormone (PTH) molecules containing amino acid sequences 44-68. C-terminal (CPTH) assays recognize molecules containing amino acids 39-84. Circulating PTH fragments are not biologically active unless they have key N-terminal residues (1-24) and can lower or raise results from two-site methods. Third-generation assays do not detect PTH 7-84 that is not biologically reactive. Fragments are especially high with renal failure. Human anti-PTH antibodies may interfere with assays.
LH and FSH	2 days at RT 2 days at 4° C	HCG for stimulation or due to tumor may augment RIA values and suppress two-site methods.
Osteocalcin	EDTA Avoid FT	Some RIAs more sensitive to degradation.
Proinsulin	1 day at RT 1 day at 4° C	High insulin levels associated with treatment may suppress proinsulin levels in two-site assays. Human antibodies specific to insulin or proinsulin.
Prolactin	2 days at RT 2 days at 4° C	Macroprolactin or big prolactin a complex of prolactin and IgG lacks biologic activity because not freely available to tissues. Two-site assays may demonstrate suppression (high-dose hook) at extremely high prolactin levels.
PTH-rP, parathyroid-hormone-related protein	Plasma with protease inhibitor Avoid FT Ship frozen	Unstable; collect with protease inhibitor and keep frozen. PTHrp N terminal contains key PTH sequences and is biologically active. Also known as the humoral hypercalcemia of malignancy factor.
Renin	EDTA Process at RT and snap freeze Ship frozen Do not leave cold	Process ambient and freeze rapidly to avoid plasma renin activity (PRA) increases due to cold-activated proteases. Activity assays known as PRA. Also direct renin assays.
Testosterone	2 days at RT 6 days at 4° C	Use assays certified by Centers for Disease Control and Prevention for accuracy
Thyroglobulin	2 days at RT 2 days at 4° C	Circulating anti-TG antibodies significantly suppress two-site methods. RIA methods are less likely to be impacted.
TSH, thyroid-stimulating hormone	2 days at RT 2 days at 4° C	bHCG or alpha subunit with some methods causing falsely lower results. Heterophile antibodies have been reported as causing falsely high values. Controversy about TSH reference ranges.
Vitamin D 25 OH	Ship frozen	Some assays may or may not efficiently measure D2 form and C-3 epimer.

Notes: Stability: RT = room temperature. FT = freeze/thaw cycle. Stability studies using normal sera have shown that all hormone levels except ACTH, ADH, DHEA, dopamine, epinephrine, glucagon, 17-hydroxypregnenolone, insulin, norepinephrine, osteocalcin, IPTH, pregnenolone, and renin are relatively stable when kept at ambient temperature (20° to 25° C) for 1 day. Stability may be worse for patient samples and for samples kept at elevated temperatures, and may vary with the method. For most reliable hormone data, patient samples generally should be separated as soon as possible and kept frozen until measurement. Consult your laboratory for proper handling. Circulating antihormone antibodies will usually suppress two-site assay data. Hormone assay precision, the 95% confidence interval for a hormone level, ranges from ±10% to 20% to ±15% to 30%, depending on the absolute hormone concentration and the method used.

practice. Because most tests are not standardized, values vary by method and by laboratory. Reference intervals are key to applying test results from different sources. Laboratories use one of several methods to develop or validate a set of reference data for each analyte.

Clinical Scenario

A 13-year-9-month-old boy presents for evaluation of short stature and delayed puberty. He reports that he has always been among the shortest kids in his class, but the difference has become magnified in the past 1 to 2 years. His parents are of average height, and his father states that he grew well past his high school graduation. On exam, the patient appears younger than his stated age and his height is at the second percentile for his age. He shows no evidence of puberty. His bone age is read as closest to the 11-year-6-month-standard. The pediatric endocrinology fellow notes that his insulin-like growth factor (IGF)-1 level returns at a Z score of −2.3 for his age. On the other hand, his IGF-1 level is at a Z score of only −0.6 for his bone age and −0.5 for his height age. She asks her attending which reference range is most appropriate to interpret the IGF-1 level and whether this influences the suspicion for growth hormone deficiency.

Healthy individuals are tested and the results are evaluated using statistics. Published reference intervals also can reflect the population norm but not reflect physiologic health; for instance, obesity or vitamin D insufficiency may be the population norm. To generate a reference interval, a minimum of 120 individuals should be tested[32]; however, in practice the numbers are often lower. For pediatric-age patients, nearly all hormone values must be interpreted with regard to age. Moreover, several hormones will also change significantly during the course of puberty independently of chronologic age. Therefore, depending on the hormone assay, reference intervals that are partitioned to capture specific populations should be provided. Generating reference intervals for multiple subpopulations poses a challenge to the clinical laboratory, and in the absence of laboratory-derived data, practitioners must rely on the literature for comparison.

Evaluation of results of a reference interval study may be accomplished using simple or more complex statistics. A frequency plot of the results shows the number of individual results at each concentration range (Figure 4-11). If the smoothed curve describing the frequency distribution is bell shaped, the curve is "normal" or Gaussian. More commonly the distribution is skewed, and results tail more on the high or low side. Results may be power transformed to reduce the skewness and then analyzed. When this approach is used, the standard deviation on each side of the mean may be different. Increasingly, as an adjunct to the reference interval, the laboratory will also report a Standard Deviation Score (SDS) or Z score that may aid in interpretation, which is simply the difference of the result from the mean divided by the standard deviation. Whether the distribution is normal or skewed, the reference interval, by definition, should encompass the central 95% of results.

For existing analytes, a reference method with an extensive normal data set allows for a less costly and more accessible way of establishing reference intervals. A subset of normal samples can be used to confirm the reference database if the results utilizing the newly implemented method are similar to those used to establish the reference

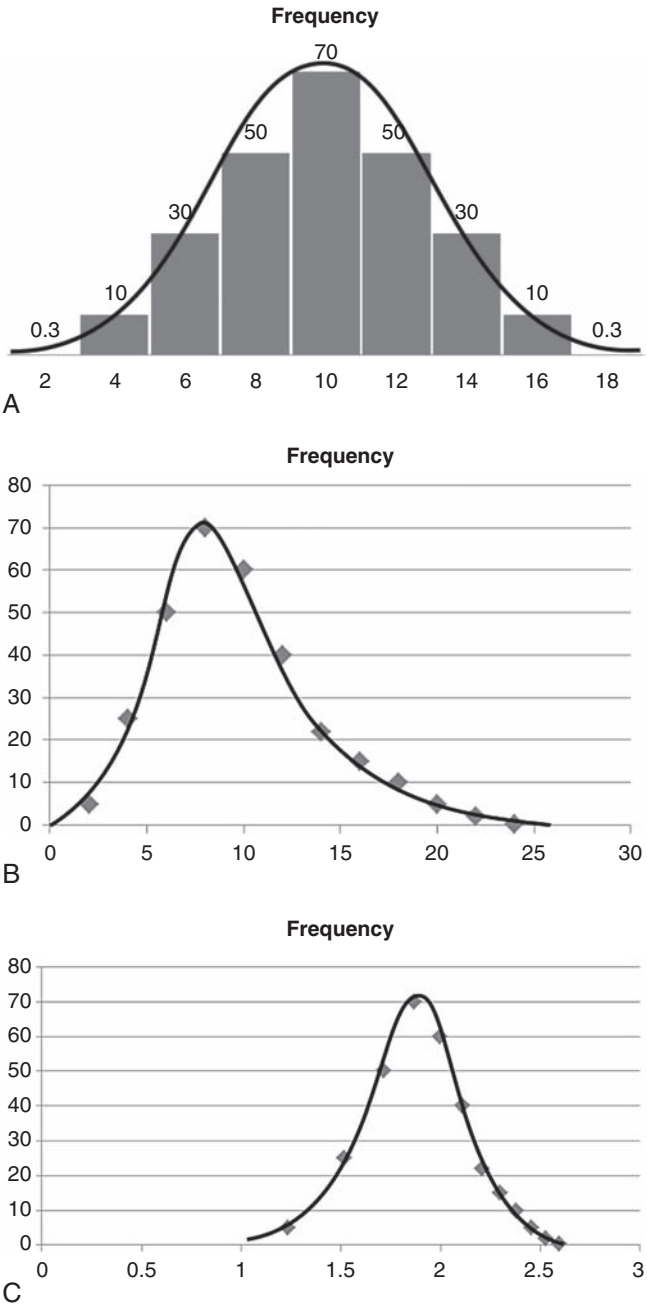

FIGURE 4-11 ■ **A,** Normal distribution has a symmetric frequency distribution. Quantities are indicated on the x-axis, and the frequency of individuals with any given quantity is indicated on the y-axis. **B,** A skewed distribution has an asymmetric frequency distribution. This picture is frequently found. A skewed distribution power transformed (0.3 power). **C**, After the curve is fitted, the central 95% are selected, and then the limits are "untransformed" by taking the (3.333 power) to return to the usual units.

population.[32] Ideally, the laboratory would also test specimens in subjects with disease to demonstrate that the test appropriately distinguishes them from the normal range. Laboratories now increasingly rely on device manufacturers to provide this base data set against which the smaller internally derived normal data are statistically evaluated for transference.[33] Current practice may fall short of these requirements because method differences and bias between

methods are sometimes unrelated to the differences in reference intervals.

A few tests for specific analytes, such as hemoglobin A1c or cholesterol, are standardized, and reference intervals and treatment goals are established by professional societies.[34] The laboratory must use a certified method to be certain that the test results meet the standards that allow interpretation according to guidelines. Standardization for testosterone by the Centers for Disease Control and Prevention (CDC) with the support of the Pediatric Endocrine Society, the Endocrine Society, and others is a current reality.[2] A standardized assay reference interval using large international population-based studies is being developed. Standardization of estradiol, vitamin D, growth hormone, and IGF-1 is likely to follow.

SUMMARY

Arriving at the correct diagnosis and management pathway for most pediatric endocrinology conditions involves a comprehensive history, careful physical examination, and laboratory investigations. The intent of this chapter is to help pediatric endocrinologists choose the appropriate tests and to aid in correctly interpreting the results obtained by the method used. The decisions of when and what tests to request, and how to correctly place the obtained data within the complex context of clinical decision making, remain the province of the physician at the center of the child's care team.

The clinical laboratory has an important collaborative and supportive role in optimizing patient care. A better understanding of the clinical laboratory's procedures, requirements, and limitations, can only improve the vital ongoing communication that should occur routinely between the clinicians and the personnel of the testing laboratory.

QUESTIONS

1. Which of the following terms is defined as the measurement of the replication of repeated measurements of the same specimen?
   a. Accuracy
   b. Linearity
   c. Precision
   d. Sensitivity
   e. Specificity

Answer: c

2. The presence of heterophile antibodies can lead to interference in immunometric (sandwich) antibody assays and false results. Which of the following is true regarding heterophile antibodies in immunoassay?
   a. Competitive immunoassays can have a false high report from a heterophile antibody mimicking antigen and bridging an interaction between the capture and signal antibodies.
   b. Immunometric assays can be subjected to a false low report because of blocking antibody preventing antibody-antigen interaction.
   c. Competitive immunoassays cannot be impacted by heterophile antibodies.
   d. All of the above
   e. None of the above

Answer: b

3. Which of the following is commonly measured via a receptor technique for biologic activity?
   a. TSH
   b. TSH receptor autoantibodies (TRAb)
   c. Thyroid-stimulating immunoglobulins (TSI)
   d. Thyroid peroxidase antibody (TPOAb)
   e. Total T4

Answer: c

4. A laboratory reports the analytic measurement range for a hormone assay as 10 to 550 units/mL. The lab technicians test blood samples in 180 normal individuals and establish the normal reference interval as 150 to 200 ng/mL. They perform replicate measurements at the lower limit of the reference interval and determine a mean of 150 ng/mL with a standard deviation of 10 ng/mL. What is the coefficient of variation at 150 units/mL for the assay?
   a. 6.7%
   b. 10%
   c. 15%
   d. 16%
   e. 20%

Answer: a

5. Several automated immunoassay systems that measure free thyroxine employ a labeled analog of thyroxine. How does the analog function in this assay?
   a. Competes with thyroxine for binding sites on thyroxine binding globulin
   b. Competes with free thyroxine for binding sites on a thyroxine antibody
   c. Competes with HAMA to negate interference
   d. Produces a light flash when it binds thyroxine binding globulin
   e. None of the above

Answer: b

6. Mass spectrometric assays often utilize a chromatographic step before measurement of steroids. The chromatographic step improves specificity of mass spectrometry. What physical property is the basis for the separation of steroids by mass spectrometry?
   a. Weight
   b. Polarity of the steroid
   c. Mass to charge ratio
   d. The functional groups on the steroid molecule
   e. None of the above

Answer: c

7. Isobars are distinct structures that have the same mass, which creates a challenge to assay specificity. For example, with mass spectrometric assays a chromatographic separation must be utilized, unless the two structures fragment uniquely. Which of the following pairs are isobars?
   a. Corticosterone and 11-desoxycortisol
   b. DHEA and testosterone
   c. 17-Hydroxyprogesterone and deoxycorticosterone
   d. All of the above
   e. None of the above

Answer: d

8. Immunometric assays offer some advantages over competitive immunoassays, leading them to become the preferred format of measurement for many hormones. Which of the following is *not* an inherent advantage of immunometric assays over competitive immunoassays?
   a. Potential for increased sensitivity with improved signal detection technology
   b. Increased specificity because of recognition of two distinct epitopes on the analyte
   c. Less prone to "prozone" or "hook" effect
   d. Readily utilize monoclonal antibodies, which have more predictable characteristics than polyclonal antibodies
   e. None of the above

Answer: c

SECTION **II**

ENDOCRINE DISORDERS IN THE NEONATE

CHAPTER 5

Ambiguous Genitalia

Selma Feldman Witchel, MD • Peter A. Lee, MD, PhD

CHAPTER OUTLINE

CHAPTER OUTLINE—cont'd

INTRODUCTION

Normal gonadal differentiation and sex development depend on the meticulous choreography and synchrony of a network of endocrine, paracrine, and autocrine signaling pathways reflecting the actions and interactions of specific genes, transcription factors, and hormones. Perturbations of this intricate network of gene regulation and gene expression governing fetal gonadal development result in disorders of sex development (DSD). Approximately 1 in 4000 infants is born with a DSD.[1]

These disorders include a spectrum of abnormalites in which chromosomal, genetic, gonadal, hormonal, or anatomic aspects of sex are atypical. Understanding the developmental biology and embryology of the urogenital system is crucial to categorizing and identifying the molecular basis of the disorder, and its treatment where possible in an individual patient. Knowledge of the many genes, proteins, and hormones involved in gonadal sex determination and sexual differentiation is rapidly increasing. Clarity in terminology provides a framework to approach the differential diagnosis in a patient. The pediatric endocrinologist's role in the care of a child with ambiguous genitalia begins at diagnosis or earlier for infants identified through prenatal testing. In such circumstances the physician's responsibility for the management of this child is only starting and will continue until transition to adult care providers is deemed appropriate.

TALKING WITH THE PARENTS

For parents, the birth of their child is a long-anticipated and exciting event. Due to the increased frequency of prenatal ultrasound examinations, parents have usually been told the sex of their child and have selected their infant's name. In some instances, abnormal genital development has been identified through ultrasound and the parents have been informed of this situation and educated regarding the likely diagnostic and treatment plans. In the absence of prior knowledge, the parents are suddenly confronted with a newborn with a birth defect involving the external genitalia and uncertainty regarding their infant's gender. The apprehension regarding the baby's health and gender are particularly traumatic if the parents had no prior awareness of the abnormal genital development.

Initially, the parents need to be congratulated on the birth of their child. They need to hear that their child has a problem of sex development and that this condition will be carefully and completely addressed. They need to learn that abnormalities of sex development involve the complex system that directs the development of reproductive system including external genital development. Explanation that it may be impossible to tell the sex of their child simply by examining the external genitalia is essential. It is important to emphasize that the atypical development is not the parents' fault and that they should not feel guilty. Physician and healthcare professionals should not offer guesses or presumptive diagnoses. The parents can be reassured that necessary studies will be obtained to provide information to ascertain their child's gender. These studies may also identify the etiology of the DSD. The infant's care should involve a multidisciplinary team that includes pediatric endocrinologists, pediatric urologists/surgeons, geneticists, neonatalogists, radiologists, behavioral health providers, and pediatric endocrine nurse educators. One team member needs to serve as the prinicipal communicator with the family.

Although contemporary society includes overt references to sex and sexuality, parents may have difficulty thinking of their child as a sexual being and feel embarrassed discussing their child's sex and future sexuality. Cultural attitudes, preexisting expectations, and family support systems impact the parent's responses. The medical team needs to promote an open and caring network to provide support for the parents and engage the parents in the medical decision-making process progressively as information becomes available.

The initial treatment goal is to determine if there is an underlying or associated life-threatening condition that requires specific urgent treatment. If the child's gender remains unclear, information needs to be obtained to assist the parents in determining the most appropriate sex of rearing. Usually, this can be accomplished within a matter of hours or days. In more complex instances, the diagnostic process may take longer. In situations in which

it is impossible to identify the specific etiology, the general DSD category (see later) provides a basis for decision making.

Factors to be considered in the medical decision-making process include the extent of external and internal reproductive system development, evidence of gonadal functionality (potential for pubertal hormone secretion and fertility), and hormone responsiveness. In some instances, these factors are more relevant than the karyotype. Genes and gene products mapped to diverse autosomal areas of the genome influence the sex development of the developing fetus and child. When consensus has been reached regarding a diagnostic category, available outcome information for that diagnosis should be reviewed. Knowledge of the specific etiology, including details of the diagnosis, enables planning therapeutic interventions and genetic counseling for future pregnancies. Although the exact details are unclear, the extent, timing, and duration of prenatal androgen exposure likely influences CNS differentiation and affects multiple functions. Hence, healthcare providers need to be cognizant that available outcome data to assist in the decision-making processes are limited. Currently accessible information in published reports is largely based on retrospective studies obtained using diverse methodologies.[2]

The first interview with the parents should set a positive and optimistic tone to promote parental bonding with their infant. Indeed, the emotional tone of this initial interaction is usually more meaningful than the factual information provided and is recalled by parents for many years. Respect for the family and individual perspectives together with a willingness to repeat or defer detailed explanations are crucial. In the midst of the emotional distress associated with the uncertainty of their infant's gender, parents cannot be expected to assimilate the vast amount of information that eventually needs to be shared. Repeated discussions with the parents will enable them to deal emotionally and intellectually with their concerns regarding their infant and to allow them to appropriately interact with their infant, family members, friends, and colleagues.

Factual explanations regarding the process of sexual differentiation with a focus on their infant's situation should be initially outlined. The primary goal at this point is to provide the parents with a basic understanding that the internal and external genital structures for both boys and girls develop from the same primordial tissues. It is also helpful to explain that there are not exclusively male and female hormones. Rather, the environments in which male and female fetuses develop are characterized by differing relative amounts of these hormones. The use of simple sketches and provision of pictures and diagrams can be helpful to explain the embryology of genital development to the parents. Some parents may benefit from practicing the words they will use to discuss the infant's health with other family members. Detailed explanations and discussion can be repeated multiple times as the child ages.

During the early dialogues, examining the infant with the parents to identify the specific physical findings of their infant is often beneficial. This can reduce their apprehension, increase their comfort when viewing their infant's genitalia, and reinforce their perception that their infant's needs are similar to those of all infants. Information can be presented in a manner that will minimize anxiety and better equip parents to participate in the decision-making process. To provide the best support for their infant, each parent must reach an individual resolution with a commitment to a positive perspective concerning this situation. Discussion of the many concerns (particularly those related to gender identity, pubertal development, sexual orientation, sexual function, and fertility) may be helpful. Honest discussions will engender positive feelings that enhance positive interactions and enable the parents to promote their child's self-esteem.

Unless the gender assignment is clear at this point, the healthcare team should recommend that the parents delay naming the infant, announcing the baby's birth, and registering the birth until more information becomes available. The message should be clear that they will be involved in deciding the appropriate gender of rearing for their child since it is their privilege and responsibility to participate in the process leading to a gender assignment. Until sex of rearing is established, it is best to refer to the infant as "your baby" or "your child." Terms such as *he*, *she*, and *it* should be avoided.

TERMINOLOGY

Under the auspices of the Pediatric Endocrine Society (North America) and the European Society for Pediatric Endocrinology, an international consensus statement was formulated that recommended a revised classification of the medical terminology used for disorders of sex development to avoid confusing and derogatory terms.[1] This descriptive classification attempts to be sensitive to concerns of parents and flexible enough to incorporate novel molecular genetic information. The updated classification system integrates molecular genetic considerations into the nomenclature for "disorders of sexual differentiation (DSD)"[1] and provides an approach to the diagnostic evaluation.

Terms such as *pseudohermaphrodite*, *intersex*, and *gender labeling* in the diagnosis should be avoided.[3] To accommodate all types of DSD, the classification system is broad and includes some conditions that do not present with obvious abnormalities of genital development (Box 5-1). The primary goal of this classification system is to provide a framework for diagnosis, assessment, and care management based largely on sex chromosome status. Currently, microarray and candidate gene analyses are increasingly available and utilized.The DSD categories include sex chromosome DSDs such as 45,X/46,XY (formerly mixed gonadal dysgenesis); ovotesticular DSD (formerly true hermaphroditism); 46,XY DSDs such as disorders of testicular development, disorders of androgen synthesis and action (replacing and expanding the former category of male pseudohermaphroditism), and XY sex reversal; and 46,XX DSDs such as masculinization of the XX individual (replacing female pseudohermaphrodite) and XX sex reversal. Because of the complexities of

BOX 5-1 Summary of Disorders Associated with Ambiguous Genitalia

Sex Chromosome DSD
- 45,X Turner syndrome
- 45,X/46,XY gonadal dysgenesis
- 46,XX/46,XY gonadal dysgenesis
- 46,XX gonadal dysgenesis

Disorders of Gonadal Differentiation
- Denys-Drash syndrome (WT1)
- Frasier syndrome (WT1)
- Meacham syndrome (WT1)
- WNT4
- SF1/NR5A1
- CBX2

46,XY DSD
- SRY
- Campomelic dwarfism (SOX9)
- Dosage sensitive sex reversal (duplications of DAX1)
- Desert hedgehog (DHH) mutations
- GATA4
- FOG2
- MAP3K1
- ATR-X syndrome
- Vanishing testes

Multiple Congenital Anomalies
- IMAGe syndrome (CDKN1C)
- Pallister-Hall syndrome (GLI3)
- ARX
- Genitopatellar syndrome (KAT6B)
- CHARGE syndrome (CHD7)

Ovotesticular Disorder

46,XX Testicular Disorder
- SRY positive
- SRY negative

46,XX Ovarian Disorder
- RSPO1
- FOXL2
- NOBOX
- FIGLA

Disorders of Cholesterol and Steroid Biosynthesis
- Leydig cell hypoplasia (LHCGR)
- Smith-Lemli-Opitz syndrome (DHCR7)
- Lipoid adrenal hyperplasia (StAR)
- Side chain cleavage deficiency (CYP11A1)

Virilizing Congenital Adrenal Hyperplasias
- 21-Hydroxylase deficiency (CYP21A2)
- 11β-Hydroxylase deficiency (CYP11B1)
- 3β-Hydroxysteroid dehydrogenase deficiency (HSD3B2)

Disorders of Sex Steroid Synthesis
- 17α-Hydroxylase/17,20-lyase deficiency (CYP17)
- Cytochrome b_5 Deficiency (CYP5)
- 3α-Hydroxysteroid Dehydrogenase Isozyme Deficiency (AKR1C2 and AKR1C4)
- P450 oxidoreductase deficiency (POR)
- 17β-Hydroxysteroid dehydrogenase deficiency (HSD17B3)
- 5α-reductase deficiency (SRD5A2)
- Placental aromatase deficiency (CYP19)
- Maternal hyperandrogenism

Disorders of Androgen Action
- Androgen insensitivity (AR)

Persistent Mullerian Duct Syndrome
- AMH mutation
- AMH-R mutation

Mullerian Duct Abnormalities
- Mayer-Rokitansky-Kuster-Hauser
- MKKS mutation

Other
- Hand-foot-genital syndrome (HOXA13)
- Environmental endocrine disrupters
- VACTERL syndrome
- MURCs syndrome
- Cloacal extrophy
- Aphallia

chromosomal and gonadal development, some diagnoses can be included in more than one of the three major categories. The number of genes identified to be involved in sex development continues to increase. Nevertheless, despite many recent advances the specific molecular etiology of the genital ambiguity in an individual cannot always be identified.

SEX DETERMINATION

Sex determination is the binary switch that launches the developmental destiny of the embryonic gonads to become testes or ovaries. Sexual differentiation refers to the process through which male or female phenotype develops. The gonads, internal genital ducts, and external genital structures all develop from bipotential embryologic tissues. Each cell in the developing gonad has the potential to differentiate into either a testicular or ovarian cell. How the transcriptome of the undifferentiated cell realizes its pathway to develop into an ovary or testis provides an opportunity to elucidate cell fate decision making. However, "the fate decisions in individual cells are highly coordinated such that cells of discordant fate are rarely seen."[4] Thus, male and female development depends on the regulated orchestration of the expression and interaction of specific genes and gene products. Sex determination is largely influenced through transcriptional regulation whereas secreted hormone and hormone receptors influence sex differentiation.

Through Alfred Jost's experiments with fetal rabbits in the 1940s and 1950s, the critical requirements for a testis

and testosterone for male sexual differentiation were established.[5] Chromosomal composition of the human embryo, XX or XY, determines gonadal sex. The genetic locus primarily responsible for this binary switch, the sex-determining region on the Y *(SRY)* gene on the Y chromosome, was identified through studies of patients with disorders of sexual differentiation. Studies involving creation of transgenic SRY+ mice confirmed the essential role of SRY and provided further molecular understanding of testicular differentiation.[6,7]

In the usual situation, the karyotype (46,XY or 46,XX) of the primordial gonad determines whether it differentiates into a testis or ovary, respectively. Local factors (such as hormones secreted by the developing gonads or tissue-specific transcription factors) influence the ensuing differentiation of the internal and external genital structures. This process integrates sex-specific pathway signals that appear to antagonize each other. Divergence from the normal sequence of events leads to disorders of sex differentiation that can manifest as abnormal gonadal differentiation, inconsistent internal genital differentiation, or ambiguity of the external genitalia. Although genital ambiguity is usually not considered to be a medical emergency, it may be highly distressing to the parents and extended family. Hence, prompt referral and evaluation by a multidisciplinary team with expertise in disorders of sex differentiation is strongly recommended. Information regarding our current knowledge of sex determination is presented, followed by a discussion of the various causes and treatments for ambiguous genital development.

DEVELOPMENT OF THE REPRODUCTIVE SYSTEM

Urogenital Development

The gonads are derived from intermediate mesoderm. In humans, at 4 to 6 weeks of gestation, the urogenital ridges develop as paired outgrowths of coelomic epithelium (mesothelium). The gonads, adrenal cortex, kidney, and reproductive tract derive from the urogenital ridge (Figure 5-1). Several genes are requisite for the development of the bipotential gonad. The Wilms tumor (WT1) gene codes a zinc transcription factor that is expressed in embryonic mesodermal tissues and appears to influence mesodermal-epithelial interactions.[8] GATA4 is expressed in the somatic cells of the urogenital ridge and bipotential gonad before showing sex specific expression. Chromobox homolog 2 (CBX2) appears to play a role in early gonadal development and may promote transactivation of steroidogenic factor-1 (NR5A1), which is encoded by NR5A1/SF1. NR5A1 is expressed in the urogenital ridge and appears to upregulate SRY expression. In addition to transcription factors and specific secreted factors (hormones), physical contact

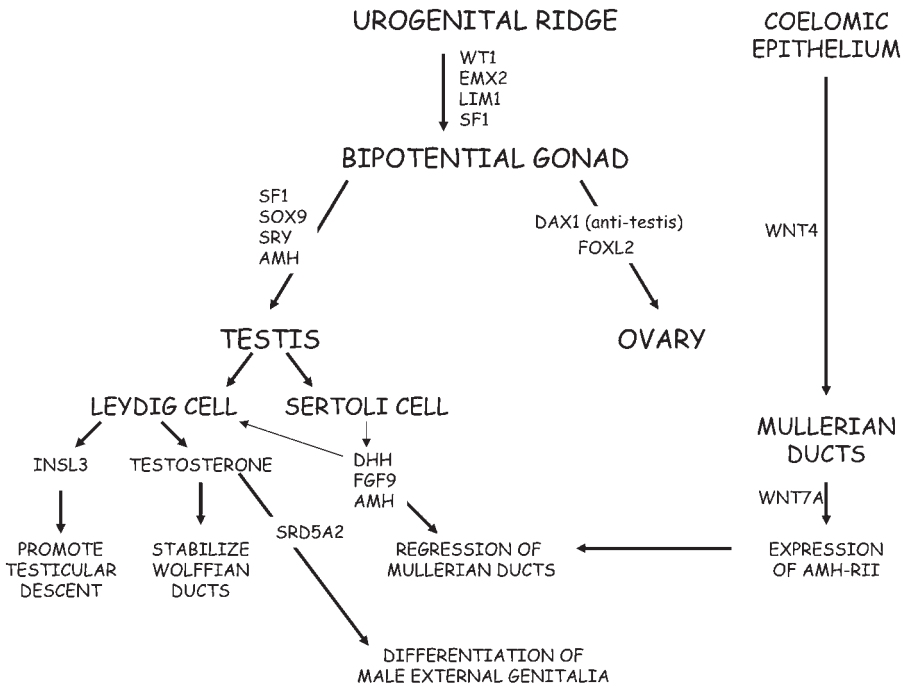

FIGURE 5-1 ■ Cartoon of the genes involved in the process of sexual differentiation. Wilms tumor (WT1), EMX2, LIM1, and steroidogenic factor-1 (SF1) play roles in differentiation of gonad from urogenital ridge. Genes involved in testicular differentiation include SF-1, SOX9, sex-determining region on Y (SRY), and anti-Mullerian hormone (AMH). The dosage-sensitive sex-adrenal hypoplasia congenital critical region on X (DAX1) appears to function as an anti-testis factor. Wnt4 promotes development of the Mullerian ducts, whereas Wnt7a promotes expression of the receptor for AMH (AMH-RII). Sertoli cells secrete AMH, which, acting through its cognate receptor (AMH-RII), promotes regression of the Mullerian ducts. Leydig cells secrete testosterone and insulin-like hormone-3 (INSL3). Testosterone stabilizes the Wolffian ducts and is converted to DHT by 5α-reductase in target tissues to promote differentiation of the prostate and development of male external genitalia. INSL3 is involved in transabdominal testicular descent.

with the mesonephros appears to be important for subsequent gonadal differentiation.[9]

Due to their origin as part of the developing urogenital system, ovaries and testes are initially located high in the abdomen near the kidneys. One of the earliest morphologic changes is increased proliferation and size of developing 46,XY gonads. The bipotential gonad consists of at least four cell lineages, which are germ cells, supportive cells, steroidogenic cells, and connective tissue. Although sex determination has been equated with testis differentiation, recent data challenge this dogma. Rather, specific signaling molecules activate or repress gonadal determination for both testes and ovaries. Competition between specific genes and proteins influences cell fate decisions in gonadal development.[10] Specific examples include Forkhead transcription factor 2 (FOXL2) vs. SRY-box 9 (SOX9) and SOX9 vs. Wingless-type MMMTV integration site family member (WNT)/β-catenin, which are discussed later.[11]

Germ Cell Development

Germ cells are not required for the initial development of ovaries or testes. Rather, the local environment directs the fate of the primordial germ cells. Until approximately 6 weeks of gestation in the human, primordial germ cells proliferate and migrate from the hindgut to colonize the genital ridges. This migration depends on intrinsic motility and external guidance cues as specified by attractive and repulsive signals.[12] When this migration process goes awry, the gonadal germ cell population is lacking. Factors important for germ cell migration and colonization of the genital ridges include WNT5A, NANOG, stromal cell–derived factor 1 (SDF1, also known as CXCL12) and its receptor CXCR4.

Meiosis is a sexually dimorphic regulated step governing terminal differentiation of germ cells with meiosis favoring oocytes and active inhibition of meiosis being essential for male germ cells.[13] The RNA binding protein Deleted in azoospermia-like (DAZL) plays a role in this branding of germ cells as male or female.[14] Factor in germline alpha (FIGLA) and newborn ovary homeobox (NOBOX) are oocyte-specific proteins that appear to repress male specific genes.[15] Subsequent stages of germ cell differentiation into a sperm or an egg are closely linked to the cell cycle decision between mitosis and meiosis.[16] Meiosis is dependent on retinoic acid, a morphogen, primarily synthesized in the developing gonad.[17] Expression of Stimulated by Retinoic Acid (*STRA8)* increases in the human fetal ovary concomitant with the initiation of meiosis in this tissue, but remains low in the testis. STRA8 is required for pre-meiotic DNA replication and progression through meiosis. In mice, the expression of CYP26B1, a cytochrome P450 enzyme that degrades retinoic acid, prevents meiosis in male germ cells. In human male fetuses, expression of CYP26B1 does not fully account of inhibition of meiosis in the germ cell.[18] Expression for NANO2 appears to be restricted to fetal testes.

The Sertoli cells envelope the germ cells to form seminiferous cords at approximately 7 to 9 weeks of gestation in the human XY gonad. The germ cells in the developing testis enter a state of mitotic arrest. In a human XX gonad, germ cell meiosis begins at 10 to 11 weeks of gestation. In the developing ovary, the germ cells initially form clusters connected by intracellular bridges. Selected oogonia enter meiosis and progress through meiotic prophase I (MPI) to arrest at the diplotene stage. The fetal ovary is characterized by the existence of multiple subpopulations of germ cells at different developmental stages. By approximately 20 weeks of gestation, the oogonia clusters break down to form primordial follicles. Primordial follicles destined for future ovulation remain quiescent. By the 24th week of gestation, most oogonia are surrounded by supporting cells. However, apoptosis is the fate for many oogonia. From a peak of 6.8 million oocytes at approximately 5 months of gestation, approximately 2 million are present at birth due to follicular atresia.[19] Accelerated follicular atresia contributes to the follicular depletion characteristic of streak gonads in X monosomy.

The internal environment throughout fetal ovary development has the potential to directly influence the fertility of the developing fetus (controlling the size of the ovarian reserve) and the quality of the oocyte that will eventually become her child (by influencing the extent of selection and apoptosis).[20] Although not associated with genital ambiguity, mutations in genes governing oocyte and ovarian development cause disorders of sex development characterized by delayed puberty or premature ovarian failure.

During gestation, maternal and paternal alleles are differentially imprinted such that monoallelic expression of specific genes occurs. During this process of imprinting, mature oocytes and sperm are differentially marked reflecting "parent-of-origin" specific methylation patterns. In the primordial immature germ cells, inherited imprints are erased shortly after the germ cells enter the gonadal ridge. Sexually dimorphic methylation imprinting is subsequently reestablished in male and female gametes. This process occurs late in fetal development in the male and postnatally in female germ cells.[21,22] The importance of this imprinting process has been elucidated through study of parent-of-origin–dependent gene disorders such as Beckwith-Wiedemann, Prader-Willi, and Angelman syndromes and some forms neonatal diabetes mellitus.

Human Testicular Development

Testicular differentiation occurs earlier than ovarian development. The testis consists of five cell types: supporting or Sertoli cells, endothelial cells, peritubular myoid cells, steroid-secreting Leydig cells, and germ cells. The first evidence of testicular differentiation is the appearance of primitive Sertoli cells at 6 to 7 weeks gestation in the human fetal testis. Cells, mostly endothelial cells, migrate from the mesonephros and interact with the pre-Sertoli cells to promote development of the testicular cords.[23] The testicular cords are precursors of the seminiferous tubules that will contain Sertoli and germ cells. Interactions between endothelial and mesenchymal cells appear to influence development of the testicular cords.[24]

The binary switch responsible for testicular development is the *SRY* gene located on the short arm of the Y chromosome. The SRY protein contains a high-mobility group (HMG) domain and is encoded by a single exon gene. Two nuclear localization signals are located in the HMG domain. The SRY protein is expressed in pre-Sertoli cells, where it triggers a molecular switch to induce Sertoli cell differentiation, thus, initiating the process of male sexual differentiation. The HMG domain of the SRY protein binds to the minor DNA groove, where it functions as a transcription factor by bending DNA to presumably permit other proteins access to regulatory regions and to promote assembly of nucleoprotein transcription complexes. A threshold SRY level must be achieved at a critical time during gestation to establish male sexual differentiation. otherwise, the ovarian differentiation pathway is activated.[25] Available data suggest that NR5A1 promotes SRY expression.

SRY expression is independent of the presence of germ cells. SRY increases the expression of the SRY-related HMG box-containing-9 (SOX9) gene. Phenotype-genotype studies of humans and mice demonstrate that SOX9 expression is a crucial step, downstream of SRY, in testis development. Upstream from the SOX9 transcription start site, there appears to be a testis specific enhancer element (hTES). Available data suggest that initially phosphorylated NR5A1 and SRY cooperate to activate the hTES leading to increased SOX9 expression; subsequently SRY, NR5A1, and SOX9 maintain SOX9 expression through actions at hTES.[26] In addition to SRY, SOX9, and NR5A1, sequential expression of several other genes is required for normal male sexual differentiation. These genes include fibroblast growth factor 9 (FGF9), anti-Mullerian hormone (AMH), dosage-sensitive sex reversal adrenal hypoplasia congenita critical region on X (DAX1),GATA-binding-4 (GATA4), desert hedgehog (DHH), patched (PTCH1), and WNT7A.

Using immunohistochemistry, NR5A1 and SOX9 proteins can be detected in human embryonic gonadal tissue at 6 to 7 weeks of gestation. At this time, SOX9 expression becomes limited to nuclei of Sertoli cells in a 46,XY fetus but remains cytosolic in a 46,XX fetus. NR5A1 and SOX9 protein expression precede AMH expression. After AMH protein expression increases, Wilms tumor (WT1) and GATA-4 protein expression increase in the fetal testis.[27] GATA4 belongs to a family of zinc finger transcription factors known as GATA-binding proteins because they bind to a consensus sequence in the promoter and enhancer regions of target genes. Sexually dimorphic expression of Doublesex- and MAB3-Related Transcription Factor 1 (DMRT1) was found in 6- and 7-week-old human fetuses, with expression limited to male fetuses.[28]

SOX9 induces expression of prostaglandin D synthase (Pgds), an enzyme involved in prostaglandin synthesis.[29] In a positive feedback loop, developing Sertoli cells secrete prostaglandin D2, which binds to its cognate receptor to up-regulate SOX9 expression and recruit additional Sertoli cells.[30] In addition, SOX9 promotes expression of fibroblast growth factor 9 (FGF9). FGF9 acting through the its receptor, FGFR2, helps to maintain SOX9 expression and promote Sertoli cell differentiation.[31] Normal testicular development appears to involve diffusion of FGF9 from the center to the poles of the undifferentiated gonad.[32] Through direct and indirect mechanisms, SOX9 interferes with genes promoting ovarian differentiation.

Vascular development in the gonad is sexually dimorphic with the endothelial cells in the developing testis, forming a characteristic pattern consisting of a prominent coelomic vessel on the antimesonephric surface with branches between the testis cords. This blood vessel is absent in the ovary. Peritubular myoid cells are testis-specific smooth muscle–like cells important to structural integrity and development of the testis cords. Factors relevant to peritubular myoid cell differentiation include desert hedgehog (DHH), which is secreted by Sertoli cells and its receptor Patched (Ptch1).[33] The peritubular myoid cells surround the Sertoli cells, separating them from the Leydig cells, which are then sequestered in the interstitium. Downstream of SRY, hedgehog signaling plays a role in cell-cell communication and cell fate determination to influence sex dimorphic development in gonads, reproductive tracts, and external genitalia.[33]

Leydig cell differentiation depends on paracrine signals, including platelet-derived growth factor receptor-alpha (PDGFR-α), DHH, PTCH1, and Aristaless-related homeobox (ARX). NR5A1 is expressed in Leydig cells to promote steroidogenic enzyme genes expression. The number of fetal Leydig cells reflects gonadotropin stimulation because the number is decreased in anencephalic male fetuses and increased in 46,XY fetuses, with elevated gonadotropin concentrations secondary to complete androgen insensitivity.[34] Differentiation of adult Leydig cells occurs postnatally.[34]

By 11 weeks of gestation, the testicular compartments, tubular and interstitial components, and the cell types of interest (Leydig, Sertoli, and germ cells) can be visualized. In human fetal testes, *HSD17B3*, *CYP11A1*, and *PTCH1* mRNA levels increased significantly through the second trimester without significant changes in *CYP17A1*, *LHR*, or *INSL3* levels. The most rapid growth in Sertoli cell number appears to occur during the latter half of the first trimester and the second trimester.[35]

Human Ovary Development

Although ovarian differentiation has long been considered the default pathway that occurs in the absence of *SRY* gene expression, accumulating evidence indicates that specific genes influence ovarian differentiation. Genes implicated in ovarian differentiation include wingless-related MMTV integration site 4 (WNT4), forkhead L2 (FOXL2), follistatin (FST), Iroquois-3 (IRX3), bone morphogenic protein-2 (BMP2), and R-spondin-1 (RSPO1).[36] FOXL2 functions to repress male-specific genes especially SOX9 beginning in the fetus and continuing through adulthood. FOXL2 and SOX9 expression appear to be mutually exclusive in developing gonads and in gonadal tissue obtained from patients with DSD conditions.[37]

In the absence of SRY, between 6 to 9 weeks of gestation, R-spondin-1(RSPO1) expression increases in the

developing human ovary. RSPO1 is a secreted factor that activates the β-catenin WNT signaling pathway.[38] WNT4 expression also increases. RSPO1 and WNT4 appear to stabilize and amplify β-catenin signaling to activate target gene transcription.[39] LIN28A, an RNA-binding protein is differentially expressed in the fetal ovary particularly in the germ cells; its expression appears to be restricted to primordial and premeiotic germ cells.[40] LIN28 blocks the production of mature *let*-7, which is a microRNA that interferes with translation of cell cycle regulators and metabolic pathway components.[41,42] In the absence of LIN28, *let*-7 inhibits production of BLIMP1, a factor involved with primordial germ cell development.[41] Expression of both let-7 and LIN28A decreases when germ cells transition from the stem cell state to meiosis.[41]

Persistent DAX1 expression appears to play a role in ovarian differentiation. The functions of WNT4 include suppression of the androgen-secreting interstitial cells, inhibition of coelomic vascularization, and support of Mullerian derivatives. FOXL2 is a forkhead transcription factor expressed in the ovary.

Two genes, factor in FIGLA and NOBOX, are expressed in fetal or neonatal germ cells where they recruit developing granulosa cells to form primordial and primary follicles. As noted previously, many oocytes degenerate through apoptosis. GATA 4 is expressed in the granulosa cells and is speculated to prevent granulosa cell apoptosis.[43] The second trimester human fetal ovary expresses proteins necessary to synthesize and respond to estrogenic, progestogenic, and androgenic signaling.[44]

Development of Internal Genital Structures

The Wolffian duct originates as the excretory duct of the mesonephros and develops into the epididymis, vas deferens, ejaculatory duct, and seminal vesicle. The epididymis consists of four functional portions: initial segment, caput, corpus, and cauda. Sperm mature in the caput and corpus, whereas the cauda is primarily for storage. The Mullerian or paramesonephric duct originates as an invagination of the coelomic epithelium and develops into the Fallopian tubes, uterus, and upper third of the vagina.

In the male fetus, the Sertoli cells secrete anti-Mullerian hormone (AMH), also known as Mullerian inhibitory hormone (MIH). In human 46,XY fetuses, AMH expression can be detected by 7 weeks of gestation, is not dependent on the presence of germ cells within the testis, and promotes regression of the Mullerian ducts. AMH, a member of the transforming growth factor-β (TGF-β) family, undergoes proteolytic cleavage to become biologically active. AMH binds to its receptor, AMH-RII, on the surface of the Mullerian duct mesenchymal cells to induce increased matrix metalloproteinase 2 expression.[45,46] The net result is degeneration and loss of basement membrane integrity of the epithelial and mesenchymal Mullerian cells, leading to regression of the Mullerian ducts.

AMH expression is highly regulated because inappropriate expression in a 46,XX fetus would lead to uterine agenesis. In the 46,XX fetus with absence of both AMH and testosterone, the Mullerian duct derivatives persist and the Wolffian ducts regress. When a female fetus is inappropriately exposed to AMH (as in freemartin cattle), Mullerian duct regression and ovarian masculinization occur. By 12 weeks in the XX fetus, the uterine corpus and cervix have begun to differentiate.[47]

The fetal hypothalamic-pituitary-gonadal (HPG) axis is active by mid-gestation, with peak fetal testosterone concentrations occurring at approximately 15 to 16 weeks of gestation. Prior to this time, placental hCG stimulates testosterone production by the fetal Leydig cells. Secretion of testosterone by the fetal Leydig cells stabilizes the Wolffian ducts in 46,XY fetuses. Region-specific signaling molecules such as bone morphogenic proteins (BMPs), homeobox genes (HOXA10 and HOXA11), growth differentiation factor 7 (GDF7), relaxin, an orphan G-protein–coupled receptor (LGR4), platelet-derived growth factor A (PDGFA), and its cognate receptor (PDGFRA) influence the development of the epididymis and seminal vesicle.

The prostate, a male accessory sex gland, contributes to seminal fluid plasma and develops from the urogenital sinus. After the initial testosterone-dependent induction of prostate differentiation, subsequent development involves epithelial-mesenchymal interactions that lead to cell differentiation and branching morphogenesis. The requisite signaling molecules FGFs, sonic hedgehog (SHH), BMPs, HOXA13, and HOXD13 are similar to those required for external genital differentiation.[48,49]

Development of External Genital Structures

The genital tubercle, urethral folds, and labioscrotal swellings give rise to the external genitalia. Under the influence of circulating androgens that are converted to dihydrotestosterone in target tissues, the urethral folds fuse to form the corpus spongiosum and penile urethra, the genital tubercle develops into the corpora cavernosa of the penis, and the labioscrotal folds fuse to form the scrotum.

In the normal 46,XY human fetus, a cylindrical 2-mm phallus with genital swellings has developed by 9 weeks of gestation. By 12 to 14 weeks of gestation, the urethral folds have fused to form the cavernous urethra and corpus spongiosum. By 14 weeks, the external genitalia are clearly masculine apart from testicular location. The high incidence of hypospadias in humans suggests that urethral fusion is a delicate and finely regulated process.

In the 46,XX fetus, in the absence of androgens the urethral folds and labioscrotal swellings do not fuse and develop into the labia minora and labia majora, respectively. The genital tubercle forms the clitoris, and canalization of the vaginal plate creates the lower portion of the vagina. By 11 weeks of gestation, the clitoris is prominent and the lateral boundaries of the urogenital sulcus have separated. Minimal clitoral growth, well-defined labia majora, hypoplastic labia minora, and separate vaginal and urethral perineal openings are present by 20 weeks of gestation.

By 33 days' postconception, the human fetal adrenal cortex is distinct from the developing gonad. Due to its role as the source of DHEAS for placental estrogen biosynthesis, the fetal adrenal cortex grows rapidly. By 50 to 52 days' postconception, expression of several steroidogenic enzymes, steroidogenic acute regulatory protein (StAR), 11β-hydroxylase (CYP11B1), 17α-hydroxylase/17,20-lyase (CYP17), and 21-hydroxylase (CYP21) in the fetal adrenal cortex have been demonstrated immunohistochemically.[50] Recent data indicate that transitory cortisol biosynthesis peaks at 8 to 9 weeks' gestation.[50] This early cortisol biosynthesis coincides with transient adrenal expression of both nerve growth factor IB-like (NGFI-B) and 3β-hydroxysteroid dehydrogenase-2 (HSD3B2).[50] At the same time, ACTH can be detected in the anterior pituitary—suggesting the presence of negative feedback inhibition during the first trimester.[50] During the time male sexual differentiation begins, this negative feedback inhibition may serve to prevent virilization of female fetuses to ensure normal female sexual differentiation.[50,51]

Anogenital Distance

The anogenital distance (AGD), the distance from the posterior aspect of the scrotum to the anal verge, shows sexually dimorphism. Longitudinal assessment of AGD defined as measurement from the center of the anus to the base of the scrotum in males and to the posterior fourchette in females showed that mean AGD (+/- SD) at birth was 19.8 +/- 6.1 mm in males and 9.1 +/- 2.8 mm in females. In both sexes, AGD increased up to 12 months and maintained the sex dimorphic pattern. AGD also showed positive correlation with penile length at birth and with the increase in AGD from birth to 3 months.[52] AGD provides an index of early fetal androgen exposure and masculinization.

Androgens play a time-dependent role in formation, differentiation, and growth of the fetal external genitalia; a role that is especially relevant for male reproductive organ development. Studies among rats suggest that there is a limited time during early fetal development known as the masculinization programming window (MPW). During the MPW the potential for masculinization is determined. Deficiency of androgen or androgen action in the MPW results in reduced penis length, which can not be rescued by postnatal T therapy.[53] The MPW predetermines potential organ size, while post-natal androgen action is required to realize normal potential.[54]

Indirect evidence suggests that the MPW occurs in the human. This window would likely precede or occur between 8 and 13 weeks of fetal life when the penis is forming. Thereafter, the penis grows at a rate of 0.7 mm/week from 14 weeks to term.[55] If, as in studies of rats, the MPW determines penis growth potential assuming normal androgen exposure subsequently during fetal and postnatal life,[56] this has implication for potential of human male genitalia. Thus, the AGD may indicate early in utero androgen exposure and can be used as a diagnostic tool. Measurement of AGD has also been used to indicate impact of potential environmental endocrine disruptors on external genital development.[57] AGD at birth predicts adult anogenital distance and has been found to be correlated with serum testosterone levels, sperm density, and paternity.[58,59]

Sexual Differentiation of the Brain

Clinical investigations suggest that the brain is sexually dimorphic and that testosterone is a masculinizing hormone in human. Males with aromatase deficiency manifest male psychosexual behavior and gender identity. Alternatively, 46,XY individuals with complete androgen insensitivity syndrome (CAIS) develop female gender identity.[60] However, preliminary data implicate genetic differences, independent of sex steroid exposure, as the molecular basis for some aspects of sexual dimorphism of the brain.[61] Nevertheless, the prenatal hormone milieu in conjunction with genetic factors and, perhaps postnatal environmental factors, may influence sexual orientation.[62] Postmortem histologic examination demonstrated that women have more synapses in the neocortex, whereas men have more neurons in this region.[63,64]

MOUSE MODELS

Sexual differentiation is a complex process in which precise spatiotemporal coordination and regulation of gene expression are crucial to achieve full reproductive capability. Despite expanded knowledge of the molecular details of sexual differentiation, additional factors and the precise sequence of biologic events in the human fetus remain to be elucidated. Investigation of animal models, especially mice, and transgenic mouse models has provided insight into the processes involved in sex development (Table 5-1). Investigation of normal and transgenic mice confirmed the crucial role of the *SRY* gene in male differentiation when XX mice carrying only a 14-kb fragment of the Y chromosome showed a male phenotype.[65] The caveat is that mouse and human developmental processes and phenotypes may differ; humans with a 45,X karyotype develop gonadal dysgenesis associated with infertility whereas XO mice are fertile. Despite this limitation, information gleaned from the developmental processes in mice may be applicable to the human situation.

The outcome of cell fate decisions involves antagonism between the male and female developmental programs. During the bipotential phase, both male and female specific genes are expressed with an over-representation of female genes.[66] Abnormal gonadal development has been described in mice homozygous for targeted deletions of genes involved in urogenital differentiation (i.e., Wt1, Sf1, Emx2, M33 [Cbx2], and Lim1). In mice, these genes are expressed earlier in gestation than Sry, which is expressed transiently at 10.5 to 11 days postcoitum (d.p.c.).[67] Wnt9b is expressed throughout the Wolffian duct epithelium from E9.5 to E14.5 where it plays a role in development of mesonephric tubules, metanephric tubules, and caudal extension of the Mullerian ducts.[68] Wt1 is expressed

TABLE 5-1 **Consequences of Loss-of-Function Mutations in Genes Associated with DSD in Humans and Mice**

Gene	Human Locus	Human Phenotype	Mouse Phenotype
WT1	11p13	Denys-Drash, Frasier, and Mecham syndromes	Homozygous: embryonic lethal with absence of kidney and gonads.
SRY	Yp11.3	46,XY gonadal dysgenesis	"Knock-in" female-to-male sex reversal.
SOX9	17q24-25	Campomelic dysplasia and gonadal dysgenesis	Overexpression in XX mice results in female-to-male sex reversal. Heterozygous null associated with perinatal death, cleft palate, and skeletal abnormalities.
DHH	12q13.1	Gonadal dysgenesis, with or without minifascicular neuropathy	Abnormal peripheral nerves, infertility due to impaired spermatogenesis in males.
ATRX/XH2	Xq13.3	α-Thalassemia, mental retardation, genital abnormalities, short stature, hypotonic facies	Phenotype of null is embryonic lethal. Overexpression associated with growth retardation, neural tube defects, and embryonic death.
ARX	Xp22.13	Lissencephaly, absence of the corpus callosum, microcephaly	Males have abnormal CNS development and abnormal testicular differentiation.
SF1/NR5A1	9q33	46,XY sex reversal with or without adrenal insufficiency 46,XX adrenal insufficiency, POF	Absent adrenal glands, absent gonads, abnormal pituitary differentiation.
EMX2	10q26.1	Schizencephaly	Absence of kidneys, ureters, gonads, and genital tracts.
FGF9	13q11-q12	Autosomal dominant multiple synostoses	Male-to-female sex reversal, lung hypoplasia.
WNT4	1p35	46,XX, Uterine agenesis 46,XY, Male-to-female sex reversal	Males are normal. Females manifest female-to-male sex reversal.
WNT7A	3p25	Limb malformation syndromes	Persistent Mullerian duct derivatives in males. Abnormal Mullerian duct differentiation in females.
DAX1/ NROB1	Xp21.3	Adrenal hypoplasia congenita; duplication associated with male-to-female sex reversal	Male infertility.
GATA4	8p23.2-p22	Congenital heart disease	Embryonic lethal, heart defects.
FOG2	8q23.1	Tetralogy of Fallot, diaphragmatic hernia	Embryonic lethal, heart defects.
MAP3K1	5q11.2	46,XY gonadal dysgenesis	Failure of eyelid development
CDKN1C	11p15.4	IMAGE syndrome	N/A
GLI3	7p14.1	Pallister-Hall syndrome, polydactyly	Polydactyly, fetal lethal
FOXL2	3q23	Blepharophimosis/ptosis/epicanthus inversus syndrome	Small, absence of eyelids, craniofacial anomalies, female infertility.
LHGCR	2p21	Leydig cell hypoplasia	N/A
DHCR7	11q12-q13	Smith-Lemli-Opitz syndrome	IUGR, cleft palate, neurologic abnormalities.
StAR	8p11.2	Congenital lipoid adrenal hyperplasia	All with female external genitalia. Neonatal death due to adrenal insufficiency.
CYP11A1	15q23-q24	Male-to-female sex reversal, adrenal insufficiency	Male-to-female sex reversal. Neonatal death due to adrenal insufficiency.
CYP19A1	15q21.1	Aromatase deficiency	Immature infertile female. Males are initially fertile, but develop disrupted spermatogenesis.
POR	7q11.2	Antley-Bixler syndrome	Embryonic lethal.
AMH	19p13.3-p13.2	Persistent Mullerian duct syndrome	Male has persistent Mullerian duct derivatives and infertility.
AMH-RII	12q13	Persistent Mullerian duct syndrome	Male has persistent Mullerian duct derivatives and infertility.
INSL3	19p13.2	Associated with cryptorchidism	Cryptorchidism in males. Overexpression in females associated with development of gubernaculum and aberrant ovarian location.
LGR8	13q13.1	Associated with cryptorchidism	Cryptorchidism.

Key: N/A, not available; POF, premature ovarian failure

throughout the intermediate mesoderm at 9 d.p.c. Subsequently, Wt1 is expressed in the developing gonad. The phenotype of Wt1 knockout mice includes embryonic lethality, failure of gonadal and kidney development, and abnormal development of the mesothelium, heart, and lungs.[69] Homozygous deletion of Emx2, a homeodomain transcription factor, results in an embryonic lethal phenotype associated with absence of kidneys, ureters, gonads, and genital tracts.[70,71] As Wt1 expression is initially normal in the metanephric blastema of Emx2 knockout mice, Emx2 is likely downstream of Wt1. Interestingly, adrenal gland and bladder development are normal in Emx2 knockout mice.

The polycomb group proteins function to establish imprinting patterns in developmental control genes and appear to be involved in recognition of methylated histones. One such protein is Cbx2 also known as M33. The phenotype of Cbx2 knockout mice includes male to female sex reversal and hypoplastic gonads for both sexes.[72] Based on available animal studies, Cbx2 appears to regulate Sry expression, modulate expression of Sf1/Nr5a1 and Lhx9 in both genders, and influence gonad proliferation and size. Lim1, also known as Lhx1, encodes a homeobox protein that is important in the differentiation of intermediate mesoderm and the urogenital system.[73] Homozygous deletion of Lim1 is associated with absence of kidneys and gonads and with anterior head structures.[73]

Steroidogenic factor 1 (Sf1), also known as Nr5a1, is an orphan nuclear hormone receptor that functions as a transcription factor. In mice, Sf1 is expressed from the earliest stages of gonadogenesis at 9 days post conception (d.p.c.) and regulates expression of steroidogenic enzyme genes in gonads and adrenals. At the onset of testicular differentiation, Sf1 expression becomes sexually dimorphic with increased expression in fetal testis, in both Sertoli and Leydig cells, and decreased expression in fetal ovaries.[74] In Sertoli cells, Sf1 and Sry act synergistically to promote Sox 9 expression. In Leydig cells, Sf1 promotes transcription of steroidogenic enzyme genes. The pathologic findings in mice homozygous for targeted deletion of Sf1 include absence of gonads, adrenal glands, and ventromedial hypothalamus with decreased number of gonadotropes in the anterior pituitary.[75] Sf1 knockout mice have female internal and external genitalia irrespective of genetic sex and die shortly after birth secondary to adrenal insufficiency.[75] Pituitary-specific Sf1 knockout mice manifest hypogonadotropic hypogonadism, confirming the essential role of Sf1 in pituitary function.[75]

Sf1 and Sry bind to a gonad specific enhancer (Tesco) to induce Sox-9 expression. Following the onset of testicular differentiation, Sox9 expression increases in the testis and decreases in the ovary by 11.5 d.p.c. Subsequently, Sox-9 and Sf1 bind to Tesco to maintain Sox9 expression. Thus, Sox9 binds to its own promoter to maintain its expression. Continued Sox9 expression is also dependent on Fgf9 and its receptor, Fgfr2, to maintain Sox9 expression and repress Wnt4 expression. Ectopic expression of Sox9 in XX mice leads to testicular differentiation. Mice with homozygous targeted deletion of the Sox9 gene die during mid-gestation.[76] Sox9 also plays a major role in chondrocyte differentiation and cartilage formation.

Dax1 is first expressed in the genital ridge at 10.5 to 11 d.p.c. With differentiation of the testicular cords, Dax1 expression becomes sexually dimorphic characterized by decreased expression in the fetal testis and continued expression in the fetal ovary where it appears to inhibit gonadal steroidogenesis. Dax1 may interfere with steroidogenesis by inhibiting StAR expression and/or Sf1-mediated transactivation.[77] Dax1 functions as an adaptor molecule to recruit the nuclear receptor corepressor N-CoR to the Sf1 promoter, thus interfering with transactivation.[78] Rather than functioning to promote ovarian differentiation, it appears that Dax1 acts as an anti-testis factor. In male mice with targeted disruptions of the Dax1 gene, abnormalities of testicular germinal epithelium and male infertility develop despite normal testicular appearance at birth. Female mice homozygous for targeted Dax1 mutation showed normal adult reproductive function. Testicular development is delayed in XY mice carrying extra copies of mouse Dax1, but sex reversal is not observed unless the mouse also carries weak alleles of the Sry gene.

At 11.5 days, Fgf9 is expressed in gonads of both sexes. By day 12.5, Fgf9 is detected only in testes. Mice homozygous for Fgf9-targeted deletions show male-to-female sex reversal with disruption of testis differentiation.[79] Loss of Fgf9 does not interfere with Sry expression, but its absence is associated with a premature decline in Sox9 expression leading to arrested Sertoli cell differentiation, upregulation of Wnt4 expression, and male-to-female sex reversal of germ cells.[80] Targeted deletion of Fgfr2 is associated with partial XY sex reversal.[81] Fgf9 signaling through Fgfr2 plays a major role in testicular differentiation by repressing Wnt4 expression to prevent activation of the female developmental program.[82]

At 11.5 to 12.5 d.p.c., in both sexes, Mullerian ducts arise from coelomic epithelium in the mesonephric region under the influence of Wnt4.[83] Male mice with homozygous targeted deletions of Wnt4 show normal testicular and Wolffian duct development, but Mullerian ducts never develop. At 11.5 d.p.c., Gata4 is expressed in the somatic cells of the bipotential gonad. By E13.5, Gata4 expression is up-regulated in XY Sertoli cells, down-regulated in XY interstitial cells, and down-regulated in XX gonads. The GATA4 protein interacts with several proteins such as Sf1/NR5A1 and friend of GATA protein 2 (Fog2). Mice with missense mutation in Gata4, that interfere with its interaction with Fog2, showed absence of testicular cord formation, abnormal Sertoli and Leydig cell development, and decreased expression of Sox9.[84]

Ovarian fate can no longer be considered as the default pathway caused by the absence of the Sry gene. Rather, specific genes influence development of the ovary. Gata2 is expressed in XX gonads with expression restricted to germ cells in XX gonads by E13.5.[85] By E13.5, Gata4 is down-regulated in XX gonads. The phenotype of female mice with homozygous deletions of Wnt4 includes absence of Mullerian duct derivatives, retention of Wolffian duct derivatives, and decreased oocyte development. In addition, the large coelomic

blood vessel (typical of testicular differentiation) develops in the ovaries of female mice homozygous for targeted deletion of Wnt4.[86] Wnt4 appears to be involved in differentiation of Mullerian ducts, repression of endothelial migration from the mesonephros into the gonad, and maintenance of oocyte development. Another ovary-specific gene is Foxl2; its expression begins at 12.5 d.p.c. Female mice with targeted Foxl2 deletions manifest hypoplastic uterine tubes, defective granulosa cell differentiation, premature depletion of the follicle pool, oocyte atresia, and infertility.[87] Follistatin and bone morphogenetic protein 2 (Bmp2) show similar patterns of expression becoming detectable at 11.5 d.p.c. Foxl2 and Wnt4 promote follistatin expression. Bmp2 appears to act in cooperation with Foxl2 during fetal ovary development.[88] Female-to-male sex reversal was observed in XX mice with targeted Rspo1 deletion. Activation of β-catenin in XY mice results in male-to-female sex reversal suggesting that β-catenin functions as a pro-ovarian and anti-testis signaling molecule.[89] Rspo1 appears to be upstream of Wnt4 in the signaling cascade and its actions are mediated by β-catenin.[90] In the adult female mouse, conditional loss of Foxl2 leads to post-natal ovary to testis transdifferentation with granulosa cells becoming Sertoli cells and increased Sox9 expression.[91]

Persistence of Mullerian duct derivatives and infertility were noted in male mice homozygous for targeted deletion of Wnt7a. One consequence of Wnt7a deletions is absence of Mullerian hormone receptor (Amh-rII) expression by Mullerian ducts. In females, although Mullerian duct derivatives develop, they are abnormal showing loss of uterine glands, reduction in uterine stroma, and deficient coiling and elongation of the Mullerian duct. Thus, Wnt7a appears to function as an epithelial-to-mesenchymal signal important in the sexually dimorphic differentiation of Mullerian duct derivatives.

The phenotype associated with targeted disruption of c-kit ligand, a receptor tyrosine kinase also known as Steel factor, is complete lack of germ cells in the gonads.[92] Affected animals are sterile, but show normal sexual differentiation.[93] In the Dazl knockout, germ cells migrate to the developing gonad, but genes required for male-specific and female-specific differentiation are not activated.[14] Both male and female mice homozygous for targeted deletion of the Stra8 gene show no overt phenotype apart from infertility.[94]

Mullerian inhibitory hormone (Amh) is first expressed at 12 d.p.c. Transcriptional regulation of Amh appears to involve both protein-protein and protein-DNA interactions with Sf1 and Sox9 being two of the proteins involved. Amh action is mediated by a heteromeric-signaling complex consisting of type I and type II serine/threonine kinase receptors. The Amh type II receptor binds Amh and recruits a type I receptor. Sf1 appears to regulate expression of the Amh type II receptor (Amh-rII) gene. The phenotypes of the Amh and Amh-rII knockout mice are identical. In XY mice, both male and female internal genital structures are found. Male mice are infertile because the retained uterus blocks passage of sperm through the vas deferens.

The phenotype of male mice with targeted deletion of desert hedgehog (Dhh) includes infertility and impaired spermatogenesis.[95] These mice also showed abnormal peripheral nerves with extensive minifascicles within the endoneurium.[96] During development, expression of Dhh is limited to Sertoli cells and Schwann cells in peripheral nerves.[97] In mice, other key molecules in the development of male external genital structures include sonic hedgehog (Shh), fibroblast growth factors, Wnts, Bmps, Hoxa13, and Hoxad13. Shh increases expression of Bmp4, Hoxa13, Hoxd13, and Ptc expression. Shh signaling, mediated through its membrane receptor complex consisting of Patched (Ptc) and Smoothed (Smo), plays a key role in regulation of mesenchymal-epithelial interactions and genital tubercle outgrowth. Expression of 5α-reductase in the genital tubercle mesenchyme occurs. Male mice homozygous for targeted deletions of the insulin-like hormone-3 (Insl3), Hoxa10, or leucine-rich repeat-containing Lgr8/Rxfp2 genes show bilateral cryptorchidism.[98-101]

Investigations involving normal and transgenic mice have provided much information about the genes and gene products involved in sexual differentiation. Nevertheless, differences do exist between rodents and humans. Thoughtful examination of patients with disorders affecting sexual differentiation has elucidated many of the factors involved in human sexual differentiation.

DISORDERS OF GONADAL DIFFERENTIATION

Wilms Tumor Gene

The Wilms tumor suppressor (WT1) gene, located at chromosome 11p13, plays an important role in both kidney and gonadal differentiation. Through alternative splicing, multiple translation start sites, and post-translational RNA editing, multiple isoforms can be derived from this one gene. The protein contains four zinc finger domains. The two major isoforms differ by the inclusion or exclusion of three amino acids, lysine, threonine, and serine (KTS), between the third and fourth zinc finger domains. Subnuclear localization studies have shown that the –KTS form colocalizes predominantly with transcription factors, whereas the +KTS form colocalizes mainly with splicing factors and plays a role in RNA processing.[102] The ratio of the +KTS/–KTS isoforms appears to be tightly regulated.

Depending on cellular context, WT1 can function as a transcriptional activator, a transcriptional repressor, or tumor suppressor. WT1 plays a role in the balance between mesenchymal-epithelial transitions.[103] The carboxyl terminal domain of the WT1 protein contains four zinc fingers that serve as the nucleic acid binding domain. Downstream target genes include WNT4 and AMHRII.[104] Distinct isoforms may have unique functions.

Phenotypic heterogeneity occurs among patients found to have mutations of the WT1 gene. Although Wilms tumor and genitourinary abnormalities can be associated with heterozygous WT1 deletions, only 6% to 15% of sporadic Wilms tumors are associated with WT1 mutations. Heterozygous deletions at chromosome 11p13 can be part of a contiguous gene deletion syndrome known as WAGR syndrome (Wilms tumor, aniridia, genitourinary anomalies, gonadoblastoma, and mental retardation). In

general, missense mutations in exons 6-9 are associated with severe gonadal dysgenesis and early-onset nephropathy. The −KTS form appears to be protective from development of Wilms tumor whereas mutations located in the N terminal repression domain are associated with development of Wilms tumor.

Denys-Drash syndrome is characterized by genitourinary anomalies, Wilms tumor, and nephropathy. Typically, the nephropathy begins during the first few years of life, manifests with proteinuria, and results in end-stage renal failure due to focal or diffuse mesangial sclerosis.[105,106] Among affected 46,XY individuals, the external genitalia can range from ambiguous to normal female. Affected 46,XX individuals show normal female external genital development. Internal genital differentiation varies because persistence of Wolffian and/or Mullerian structures is inconsistent. Typically, the gonads are dysgenetic in 46,XY individuals. The heterozygous missense mutations associated with Denys-Drash syndrome are believed to act in a dominant negative fashion.[107]

The features of Frasier syndrome include gonadal dysgenesis, progressive glomerulopathy, and an increased risk for gonadoblastoma. Wilms tumor is extremely rare in Frasier syndrome.[108] The typical renal lesion is focal glomerular sclerosis. The majority of cases are associated with a specific point mutation in intron 9 of WT1 associated with altered splicing and decreased amounts of the +KTS isoform.

Meacham syndrome is characterized by genital anomalies, cyanotic congenital heart defects, and pulmonary hypoplasia secondary to diaphragmatic abnormalities. In 46,XY infants, the spectrum of internal genital anomalies extends from presence of a uterus to a blind ending vaginal pouch. External genitalia have been described as ranging from normal female to ambiguous.[109]

In general, mutations in exons 1-5 appear to be associated with gonadal dysgenesis, Wilms tumor, and no nephropathy. Patients with exons 6-9 missense mutation manifest gonadal dysgenesis and early onset nephropathy; this phenotype has been attributed to a dominant negative mechanism whereas nonsense mutations are associated with haploinsufficiency. Analysis for WT1 mutations should be considered in patients with 46,XY DSD, complex hypospadias, and kidney disease.[110]

WNT4 Gene

WNT4 is a secreted molecule that binds to members of the frizzled family of receptors, resulting in transcriptional regulation of target genes. WNT4 increases follistatin expression, which inhibits formation of the coelomic vessel (anti-testis action) and supports ovarian germ cell survival (pro-ovarian action).[111] Duplication of the WNT4 gene, located at chromosome 1p31-1p35, has been associated with 46,XY male-to-female sex reversal. One such patient presented with ambiguous external genitalia accompanied by severe hypospadias, fibrous gonads, remnants of both Mullerian and Wolffian structures, cleft lip, microcephaly, and intrauterine growth retardation.[112] A female-to-male sex reversed patient with kidney, adrenal, and lung dysgenesis was found to have a homozygous loss-of-function WNT4 mutation.[113] Loss-of-function WNT 4 mutations have been detected in 46, XX women with primary amenorrhea secondary to Mullerian duct abnormalities and androgen excess.[1114-116] The phenotypes of these patients support the hypothesis that WNT4 plays a role in ovarian differentiation.

SF1/NR5A1 Gene

The SF1/NR5A1 gene, located at chromosome 9q33, codes for a 461-amino-acid protein. This protein, also known as Ad4BP is involved in adrenal, gonadal, and hypothalamic development and plays an essential role in the regulation of steroidogenesis. Two distinct domains, a DNA-binding domain and a highly conserved Ftz-F1 box, are present in the protein. Genetic changes identified in the NR5A1 gene have included nonsense, frameshift, and missense changes that have affected DNA-binding and gene transcription. Most mutations are heterozygous. In some instances, these genetic changes have been inherited from the mother. Phenotype-genotype-functional correlations have yet to be established due to the phenotypic and genetic heterogeneity. Analyses of gonadal tissue obtained from 46,XY individuals shows intracellular lipid accumulation. In vitro functional studies indicate defective transactivation of CYP17A1. Individuals with SF1/NR5A1 mutations require longitudinal assessments with attention to changing gonadal and adrenal function.[117]

Two 46,XY patients with female external genitalia, Mullerian structures, gonadal dysgenesis, and adrenal insufficiency have been described. One patient was heterozygous for a de novo G35E mutation, which appears associated with decreased transactivation of NR5A1 responsive reporter genes. The second patient was homozygous for a R92Q change inherited in an autosomal recessive manner.[118] A 46,XX female with adrenal insufficiency, adrenal hypoplasia, and an NR5A1 mutation showed normal ovarian morphology.[119] Haploinsufficiency of NR5A1 can also manifest as a predominantly gonadal phenotype characterized by hypergonadotropic hypogonadism associated with delayed puberty or premature ovarian failure in 46,XX individuals.

The phenotypic spectrum associated with NR5A1 mutations has greatly expanded. Heterozygous mutations associated with 46,XY gonadal dysgenesis in the absence of adrenal insufficiency have been reported. These patients can present with ambiguous genitalia, urogenital sinuses, and small inguinal testes. Mullerian structures are generally absent. Penoscrotal hypospadias, bilateral anorchia, and testicular regression syndrome have been described. The phenotypic spectrum extends to include 46,XY girls who present with delayed puberty, primary amenorrhea, and low testosterone concentrations in the absence of adrenal insufficiency.[120]

Chromobox Homolog 2 (CBX2)

The CBX2 gene, mapped to chromosome 17q25, is a subunit of the chromatin-associated polycomb repressive

complex 1. As noted earlier, the polycomb group proteins function to establish imprinting patterns in developmental control. Loss of function missense mutations in CBX2 were identified in a 46,XY infant who had normal female external genitalia and a normal uterus; ovarian biopsy showed normal ovarian tissue with primordial follicles. The phenotype of 46,XY sex reversal in this patient suggests that this protein functions upstream of *SRY* and that it may act to repress ovarian development in developing XY gonads.[121]

46,XY Disorders of Sex Development (Gonadal Dysgenesis)

Phenotype/genotype studies of 46,XY sex-reversed patients played a major role in the localization of the Y chromosome gene responsible for the initial signal-promoting testicular differentiation. Subsequently, this gene was identified to be the *SRY* gene located at Yp11.3 near the pseudoautosomal region on Yp. Identification of mutations in SRY in 46,XY females confirmed the vital role of SRY in testicular differentiation.

Individuals with sex chromosome DSDs due to partial or mixed gonadal dysgenesis usually present with asymmetrical genital ambiguity (Figure 5-2). Somatic features of Turner syndrome such as short stature, webbed neck, cubitus valgus, and gonadal failure may be present. Multiple cell lines, including a monosomic X cell line, may be detected. The most common karyotype is 45,X/46,XY. However, there is much phenotypic heterogeneity associated with 45,X/46,XY karyotype in that internal and external genital differentiation ranges from normal male to ambiguous to female. Whereas the typical histologic features consist of poorly developed seminiferous tubules surrounded by wavy ovarian stroma, gonadal differentiation can range from normal testis to streak gonads. At the time of puberty, virilization can occur.

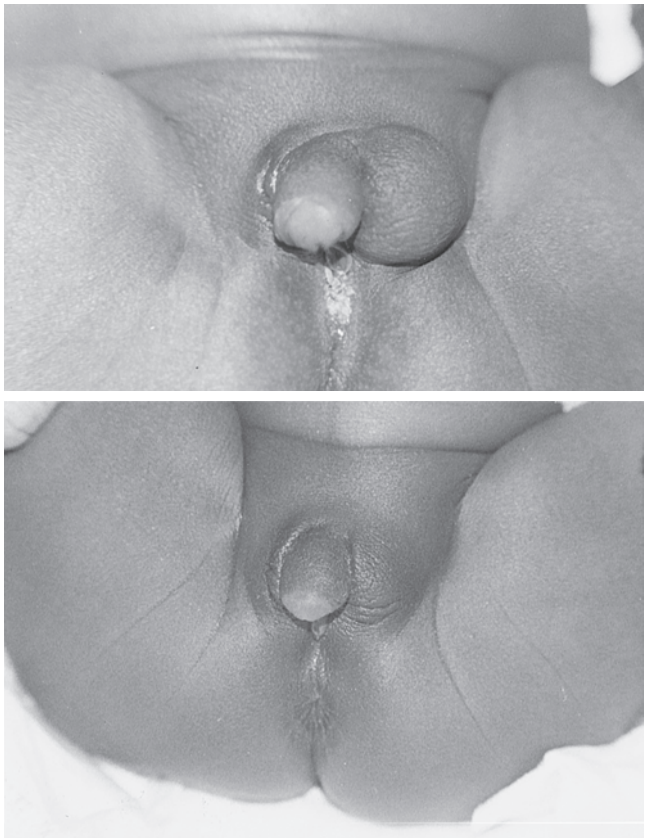

FIGURE 5-2 ■ Genital ambiguity with asymmetry in patient with 46,XY disorder of sexual differentiation (mixed gonadal dysgenesis).

Individuals with sex chromosome DSDs due to gonadal dysgenesis have an increased risk of developing gonadal tumors such as gonadoblastoma or dysgerminoma because a dysgenetic gonad carrying a Y chromosome has an increased risk for neoplastic changes.[121] Although gonadal tumors typically do not develop until the second decade of life, they can occur earlier.[122]

SRY

SRY is a single exon gene encoding a 204-amino-acid protein. The protein contains an HMG DNA-binding domain flanked by nuclear localization signals (NLS). The majority of sex-reversing SRY mutations are located in the HMG/NLS domain and affect DNA-binding affinity, DNA bending ability, or nuclear localization. Mutations located in the N-terminal and C-terminal domains have been identified in 46,XY sex reversed individuals. Mutations in the non-HMG domains may influence transcriptional activation, DNA binding, or protein-protein interactions.[123] Paternal mosaicism for SRY mutations in which different cells carry different *SRY* genes has been described.[124,125] More puzzling are the pedigrees in which fathers and unaffected brothers carry the identical mutant SRY allele as the propositus.[126,127] These paradoxical findings implicate involvement of other genes, gene-gene interactions, and gene-environment interactions in the process of sexual differentiation. Nevertheless, only 15% to 20% of cases of 46,XY DSD due to gonadal dysgenesis can be attributed to SRY mutations. Mutations in the *SRY* gene have also been reported in patients with stigmata typical of Turner syndrome and 45,X/46XY karyotype.[128]

SOX9

SOX9 is a member of the SRY-related HMG domain gene family located at chromosome 17q24.3-17q25.1. It is a 508-amino-acid protein containing an 80-amino-acid HMG domain involved in DNA binding and bending; a 41-amino-acid proline, glutamine, and alanine motif; and a C-terminal transactivation domain. SOX9 is highly expressed in Sertoli cells where it functions to promote Sertoli cell differentiation. Mutations in SOX9 can affect DNA-binding affinity, DNA bending ability, nuclear import, transactivation, and nuclear export. Haploinsufficiency is the mechanism responsible for the many of the consequences of SOX9 mutations. Somatic cell mosaicism, de novo germline mutations, and mitotic gene conversion events have been described. Patients have been reported with balanced chromosome rearrangements involving the

17q24 region and with deletions upstream of SOX9 implicating cis-regulatory elements upstream and/or downstream of the gene as additional mechanisms responsible for this disorder.

Heterozygous loss of function mutations in the SOX9 gene are associated with autosomal-dominant campomelic dwarfism and male-to-female sex reversal.[130] Features of campomelic dwarfism include congenital bowing of long bones, hypoplastic scapulae, 11 pairs of ribs, narrow chest, congenital dislocated hips, and clubfeet. Facial features include micrognathia, cleft palate large head, flat nasal bridge, and low-set malformed ears. Although the severity of the bone malformations varies, most affected individuals die shortly after birth due to respiratory failure. Approximately 75% of affected 46,XY fetuses show sex reversal, with external genital differentiation ranging from ambiguous to female. Gonadal dysgenesis and persistence of Mullerian duct derivatives are typical. Phenotypic heterogeneity with differing phenotypes including ovotesticular DSD and complete sex reversal has been described in affected siblings.[131] Acampomelic dysplasia lacks the typical limb anomalies, but manifests other features associated with the syndrome such a small thorax, limb shortening, and respiratory distress. Patients with acampomelic dwarfism and sex reversal have been reported.[132] Some affected individuals show longer survival presumably due to milder phenotype. Familial campomelic dysplasia associated with a deletion upstream of SOX9 has been described in a mother and 46,XY child with female external genitalia, normal uterus, and streak gonads.[133]

DAX1

DAX1 is an orphan nuclear receptor that lacks a typical zinc finger DNA-binding domain. The gene (NROB1) coding for DAX1 is located on the short arm of the X chromosome and consists of two exons. The N terminus of the 470-amino-acid protein contains a novel DNA-binding domain whereas the C terminus shows characteristics of a nuclear hormone receptor ligand-binding domain. DAX1/NROB1 is expressed throughout the HPG axis. The DAX1 protein functions as a transcriptional repressor of many genes, including NR5A1 and some steroidogenic enzyme genes.

Duplication of the DAX1/NROB1 locus is associated with male-to-female sex reversal.[134] External genital differentiation ranges from female to ambiguous. Descriptions of internal genitalia include the presence of Mullerian and Wolffian structures. Gonads are typically described as streaks. Using high-resolution array comparative genome hybridization (CGH), a submicroscopic interstitial duplication of the DAX1/NROB1 gene was discovered during thorough evaluation of two sisters.This 637-kb duplication included DAX1, four MAGEB genes, CXorf21, glycerol kinase (GK), and part of the MAP3K7IP3 gene. The older sister had presented with primary amenorrhea, female external genitalia, 46,XY karyotype, and gonadal dysgenesis; the younger phenotypic female sister was prepubertal, but found to have 46,XY karyotype.[135]

Loss-of-function mutations are associated with X-linked adrenal hypoplasia congenita (AHC). In this disorder, development of the fetal adrenal cortex is normal. However, the adult or definitive adrenal cortex fails to develop. Adrenal insufficiency may not be evident in the immediate neonatal period, but may become obvious during early infancy. Although adrenal insufficiency generally manifests in infancy or early childhood, phenotypic heterogeneity in severity and age at presentation occurs.[136] Unilateral or bilateral cryptorchidism can also occur. At the age of expected puberty, hypogonadotropic hypogonadism due to hypothalamic and pituitary dysfunction may occur among affected males.[137] Delayed puberty has been recognized in heterozygous females.[138] One female homozygous for DAX1 mutations has been reported. Her phenotype was hypogonadotropic hypogonadism.[139] As part of a contiguous gene deletion syndrome, X-linked AHC can be associated with glycerol kinase deficiency, Duchenne muscular dystrophy, ornithine transcarbamylase deficiency, and mental retardation.[140]

Nonsense mutations have been identified throughout the gene. Missense mutations account for 20% of mutations associated with AHC. These mutations tend to cluster in the carboxyl terminal of the protein corresponding to the putative ligand-binding domain and impair the transcriptional repression activity of the protein. One missense point mutation, located in the hinge region of the protein, was identified in an 8-year-old girl with clinical and laboratory features indicative of adrenal insufficiency. Additional studies showed that this mutation hindered nuclear localization of the protein. Curiously, the hemizygous father and heterozygous younger sister of the proband did not manifest the AHC phenotype.[141]

Desert Hedgehog

The desert hedgehog (DHH) gene is located on chromosome 12q12-q13.1 and encodes a protein consisting of 396 amino acids. DHH is a member of the hedgehog family. Hedgehog family proteins play roles in regulating morphogenesis. One patient's phenotype consisted of female external genitalia, polyneuropathy, a testis on one side, and a streak gonad on the other side. Additional evaluation of this patient revealed 46,XY karyotype, and homozygosity for a single nucleotide substitution at the initiation codon, ATG→ACG, of the DHH gene. This variation was predicted to abolish initiation of translation at the normal start site. Histologic analysis of the sural nerve revealed extensive formation of minifascicles within the endoneurium.[142] Mutations in the DHH gene have been reported in several additional 46,XY patients with gonadal dysgenesis and hypoplastic Mullerian structures.[143,144]

GATA4

GATA proteins comprise a family of organ-specific transcription factors and contain two zinc finger domains. Mutations in GATA4, mapped to 8p23.1, are typically associated with congenital heart disease. Three males in one family were reported to manifest congenital heart disease and varying abnormalities in male sex

development were identified to carry a heterozygous missense GATA4 mutation; the female carrier had congenital heart disease, but no ovarian phenotype was noted. This mutation abrogated the ability of the GATA4 protein to interact with the FOG2 protein.[145]

FOG2

The friends of GATA (FOG) protein are transcriptional cofactors that modulate the activity of GATA proteins. The FOG2 gene maps to chromosome 8q23.1. One boy with a balanced translocation and breakpoint with intron 4 of the FOG2 gene had congenital heart disease, retractile testes, and hypergonadotropic hypogonadism. At 11.5 years, he was noted to have early pubertal changes in increased penile size and pubic hair development. Subsequently, he showed no spontaneous pubertal development and was noted to have small firm testes.[146]

MAP3K1

The MAP3K1 gene is located on the long arm of chromosome 5. This gene encodes a protein involved in mitogen-activated protein kinase (MAPK) signaling. genetic mapping studies were used to identify mutations in this gene in two families with multiple affected members. Phenotypes of affected individuals include 46,XY complete gonadal dysgenesis, perineoscrotal hypospadias, and cryptorchidism. Inheritance appears to be sex-limited autosomal dominant.[147]

Chromosome 9p Monosomy

Monosomy for distal chromosome 9p has been reported in male-to-female sex reversal. Most deletions associated with sex reversal have involve the region 9p24.3 where the three DMRT genes are located.[148,149] DMRT1 appears to be involved in Sertoli and cell differentiation. External genitalia have been described as ambiguous or female. The external genitalia may appear symmetric or asymmetric. Differentiation of internal genitalia is highly variable, with the presence of Mullerian and Wolffian remnants being reported. In addition to sex reversal, clinical features include mental retardation, low-set ears, trigonocephaly, wide nasal bridge, single palmar creases, heart defects, epilepsy, and scoliosis. Genital anomalies reported in XY individuals include gonadal dysgenesis, ovotestis, hypospadias, penoscrotal inversion, and cryptorchidism. Gonadoblastoma have been reported.[150] Although phenotype/genotype correlations are not apparent, haploinsufficiency for DMRT1 appears to be sufficient to cause gonadal dysgenesis.[151]

ATR-X Syndrome

ATR-X (α-thalassemia, mental retardation, X-linked protein) syndrome is an X-linked disorder characterized by mild alpha-thalassemia, severe mental retardation, and genital abnormalities. This disorder is due to mutations in the ATRX (also known as XH2 or XHP) gene located at Xq13.3.[152] The ATRX gene product is a member of the SWI/SNF DNA helicase family and contains functional domains involved in protein-protein and protein-DNA interactions. The protein appears to function as an epigenetic factor involved in transcriptional regulation, nuclear architecture, and chromosome stability.[153] The ATRX and DMRT1 expression patterns overlap in germ and somatic cells.[154]

Urogenital anomalies occur in approximately 80% of patients and include ambiguous genitalia, cryptorchidism, hypoplastic scrotum, hypospadias, shawl scrotum, and small penis.[155] The urogenital anomalies are associated with mutations that truncate the protein and with mutations located in the plant homeodomain-like domain. Other typical features include short stature, psychomotor retardation, microcephaly, seizures, talipes equinovarus, and gastrointestinal problems. The facies are described as coarse with midface hypoplasia, short nose, and widely spaced incisors. The hemoglobin H inclusions can be demonstrated on brilliant cresyl blue stained peripheral blood smears.[156] Typically, Wolffian duct structures are present whereas Mullerian duct structures and germ cells are absent indicating at least partial Sertoli and Leydig cell function. Histologic studies of testes suggest aberrant Leydig cell development.[157] Phenotype-genotype correlations are inconsistent. Most carrier females show preferential inactivation of the X chromosome carrying ATR-X mutations. Greater than 75% of cases are inherited from carrier mothers. Carpenter-Waziri, Juber-Marsidi, and Smith-Fineman-Myers syndromes and X-linked mental retardation with spastic paraplegia are also associated with mutations in the ATRX gene.[158]

Vanishing Testes

The terms *testicular regression syndrome* and *vanishing testes* are used to describe testicular absence in boys with undescended testes. In some instances, this situation is associated with ambiguous genitalia and undervirilization which presumably represents regression of testicular tissue occurring between 8 and 14 weeks of gestation. Physical findings reflect duration of testicular function. At operation, a rudimentary spermatic cord and nubbin of testicular tissue may be identified. Histologic examination of the testicular nubbins often reveals hemosiderin-laden macrophages and dystrophic calcification.[159] It has been suggested that an antenatal vascular accident associated with antenatal testicular torsion is a cause of testicular regression.[160] Although usually sporadic, familial testicular regression has been described.[161]

Multiple Congenital Anomalies

CDKN1C

In affected 46,XY infants, the IMAGe syndrome is characterized by intrauterine growth retardation, metaphyseal dysplasia, adrenal hypoplasia, cryptorchidism, and micropenis in the absence of DAX1 or NR5A1/SF1 mutations.[162] Both sporadic and familial cases have been described. Heterozygous missense mutations in the

CDKN1C gene have been detected in some cases. This gene is located at chromosome 11p15, encodes a protein involved in inhibiting cell cycle progression, and is imprinted with expression of the maternal allele. Mutations associated with the IMAGe syndrome appear to be localized to the PCNA-binding domain resulting in gain of function with excessive inhibition of growth and differentiation. Curiously, mutations affecting the cyclin-dependent kinase binding domain of this protein are associated with overgrowth syndromes such as Beckwith-Wiedemann syndrome.[163]

GLI3

Autosomal dominant Pallister-Hall syndrome, mapped to chromosome 7p13, is associated with micropenis, hypospadias, hypothalamic hamartoma, postaxial polydactyly, and imperforate anus. Mutations in the GLI3 gene are associated with Pallister-Hall syndrome.[164] In male patients, hypospadias, micropenis, and bifid or hypoplastic scrotum have been described; affected female patients had hydrometrocolpos and/or vaginal atresia.[165]

ARX

Mutations in the Aristaless-related homeobox gene (ARX), mapped to the X chromosome, are associated with intellectual disability.[166] Additional features in affected XY individuals include genital ambiguity, X-linked lissencephaly, absence of the corpus callosum, and hypothalamic dysfunction including temperature instability.[167]

KAT6B

The genitopatellar syndrome is a rare disorder characterized by skeletal dysplasia, genital anomalies, craniofacial defects, and developmental delay. The skeletal features include hypoplastic or absent patellae, flat temporal bones, and brachydactyly. Genital anomalies include hypoplastic labia, clitoromegaly, scrotal hypoplasia, and cryptorchidism. Cardiac anomalies and hydronephrosis have been described in several patients. Mutations in the lysine acetyltransferase 6 gene, KAT6B, located at chromosome 10q22have been identified in affected patients.[168] The KAT6B protein is the catalytic subunit of a complex involved in chromatin modeling. The majority of defective alleles are de novo mutations that generate truncated proteins that disrupt histone acetylation.[169]

CHD7

The CHARGE syndrome is associated with mutations in the chromodomain helicase DNA binding protein-7 (CHD7). Features of this syndrome include eye coloboma, heart malformations, choanal atresia, short stature, genital anomalies, ear abnormalities, and hearing loss. Micropenis and cryptorchidism are found in males. Hypogonadotropic hypogonadism can occur. Although usually sporadic, autosomal dominant cases have been described. The CHD7 gene, located at chromosome 8q12.1-q12.2, codes for a large protein that participates in chromatin remodeling and transcription.

Ovotesticular Disorder of Sex Development

Ovotesticular DSD is defined as presence of ovarian tissue with follicles and testicular tissue with seminiferous tubules in the same individual. Although an ovotestis is the most commonly identified gonad in ovotesticular DSD, there can be an ovary on one side and a testis on the other. In most ovotestes, ovarian and testicular tissue show distinct separation in an end-to-end arrangement. Karyotypes are usually 46,XX. Mosaic karyotypes (46,XX/46,XY and 46,XX/47,XXY) have been described.[170] In some instances, Y chromosomal material such as the *SRY* gene can be detected by PCR amplification. However, ovotesticular DSD in the absence of Y chromosomal material has been reported.[171] In one patient in whom the peripheral blood karyotype was 46,XX, molecular genetic analysis showed a deletion of the promoter region of the *SRY* gene in the testicular tissue of an ovotestis.[172]

Several pedigrees in which both XX males and XX individuals with ovotesticular disorder coexist have been described.[173,174] These families likely represent incomplete penetrance of mutations of genes involved in sexual differentiation.[175] Although most patients present in infancy or childhood, phenotypic males can present with bilateral gynecomastia.[176] Available outcome data indicate rare fertility and only among women. In a series of 33 patients followed longitudinally, germ cells identified in the testicular tissue during infancy degenerated—resulting in azoospermia. Although normal menstrual cycles have been reported in a few females, no pregnancies were documented in one series.[171] Yet, another report indicated that pregnancies can occur in some females with ovotesticular DSD.[177]

46,XX Testicular Disorder of Sex Development

Testicular DSD is characterized by a male phenotype with a 46,XX karyotype. The frequency of the XX male syndrome is approximately 1 in 25,000 males.[178] This form of DSD can be sub classified as SRY-positive and SRY-negative groups. The SRY-positive 46,XX males generally have normal male external genitalia, small azoospermic testes, hypergonadotropic hypogonadism, and often present with infertility.[179] In most instances, the *SRY* gene is located on an X chromosome due to recombination between the X and Y chromosomes. However, translocation to an autosome can occur. One example was the incidental finding small testes, azoospermia, and translocation of the *SRY* gene onto the terminal end of chromosome 16q in a 61-year-old 46,XX man.[180]

Approximately 10% of these patients are SRY negative. The phenotypic spectrum ranges from genital ambiguity to normal male external genitalia[181] Molecular etiologies are more diverse for the SRY-negative 46,XX patient. Overexpression of the SOX10 gene at 22q13was found in one patient with 46,XX sex reversal

in association with multiple congenital anomalies.[182] Duplication of SOX9 was described in one family; all affected family members had normal male secondary sexual characteristics and azoospermia.[183] The SOX3 gene maps to Xq27, a highly conserved region of the X chromosome. Gain-of-function SOX3 mutations have been associated with XX male sex reversal.[184,185] Hypoplasia of the anterior pituitary and ectopic position of the posterior pituitary has been described in two patients.[186] It has been speculated that this group of disorders is due to impaired action of other genes involved in male sexual diffentiation.[187]

RSPO1

The R-spondin 1 (RSPO1) gene codes for a secreted furin-like domain protein that stabilizes β-catenin in the Wnt-signaling pathway. Mutations in this gene, located at chromosome 1p34, are associated with 46, XX sex reversal. This gene was initially identified by investigating individuals with palmoplantar hyperkeratosis, squamous cell carcinoma of skin, and sex reversal in one family.[188] Affected XX, sex-reversed individuals lack Mullerian structures.[189] A 46,XY individual, homozygous for mutations in RSPO1, fathered 2 children. An XX individual with ovotesticular disorder and palmoplantar keratoderma was found to be homozygous for a splicing mutation in the RSPO1 gene.[190]

XX Disorder of Sex Development/ Premature Ovarian Failure

46,XX gonadal dysgenesis is a rare disorder associated with delayed puberty and premature menopause associated with hypergonadotropic hypogonadism. Affected individuals typically present with lack of spontaneous pubertal development, primary amenorrhea, and uterine hypoplasia. Typically, external genital development is female.

More recently, it has been recognized that development of the ovary is an active process involving multiple genes. However, mutations of genes involved in ovarian development are not typically associated with ambiguous genitalia. Rather, these disorders typically present with delayed puberty, primary amenorrhea, and premature ovarian failure.[15] In these disorders, follicles may fail to develop or may undergo premature atresia. Mutations in genes involved in ovarian development such as FOXL2, NOBOX, and FIGLA have been described. Mutations in the FSH receptor gene have been described as an autosomal recessive etiology. A heterozygous missense mutation in BMP15 was associated with X-linked XX gonadal dysgenesis.[191] Ovarian leukodystrophy is a leukoencephalopathy characterized by vanishing white matter and ovarian dysgenesis associated with mutations in the eukaryotic initiation factor genes, EIF2B2, EIF2B4, and EIF2B5.[192] A mutation in the proteasome 26 subunit, ATPase, 3-interacting protein (PSMC3IP) gene has been described in autosomal recessive 46,XX gonadal dysgenesis; this loss of function mutation reduces estrogen-induced transcriptional activation of the protein encoded by this gene.[193]

FOXL2

Forkhead box L2 (FOXL2) is a member of the winged helix/forkhead transcription family. The protein contains a DNA-binding domain, which is primarily located in the nucleus. The protein contains three α-helices. Mutations in FOXL2, located at chromosome 3q23, are associated with the autosomal dominant blepharophimosis ptosis epicanthus inversus syndromes (BPES).[194] BPES is characterized by eyelid dysplasia consisting of small palpebral fissures (blepharophimosis), ptosis, epicanthus inversus, and a broad nasal bridge. The phenotype of BPES type 1 consists of eye findings and premature ovarian failure. Patients with BPES type 2 manifest only the eye features. Patients heterozygous for FOXL2 mutations generally experience spontaneous pubertal development culminating in menarche, but undergo premature follicle depletion leading to premature ovarian failure. The histologic appearance of ovaries in patients with BPES type 1 is reported to vary from the presence of primordial follicles with some atretic follicles to the complete absence of follicles.[195] Mutations generating nonsense mutations, predicted to generate truncated proteins lacking the transrepression domain, are associated with BPES type 1. Expansion of the polyalanine tract is associated with BPES type 2.[194-196]

One major role of FOXL2 in the ovary appears to be transrepression of genes involved in steroidogenesis such as StAR, P450scc, and aromatase to prevent premature differentiation and proliferation of granulosa cells.[197] Loss of the transrepressor activity due to nonsense mutations likely contributes to the premature depletion of ovarian follicles and POF.[198] One patient with ovotesticular disorder was found to have expression of both FOXL2 and SOX9.[37] However, in general, expression of these proteins is mutually exclusive.

Curiously, in goats mutations in this locus are responsible for the autosomal dominant phenotype characterized by the absence of horns in male and female goats (polledness) and XX female-to-male sex reversal in a recessive manner.[199]

NOBOX

The newborn ovary homeobox (NOBOX) gene, expressed in the ovary, encodes a transcription factor involved in the transition from primordial to primary follicles. The NOBOX gene is located at chromosome 7q35. The phenotype of patients with NOBOX mutations includes delayed puberty with primary amenorrhea and secondary amenorrhea.[200]

FIGLA

Factor in germline alpha (FIGLA) is a germ cell specific transcription factor that is located at chromosome 2p13.3. FIGLA is expressed in the human fetal ovary. Women with FIGLA mutations have been reported to have secondary amenorrhea and ovaries devoid of follicles.[201]

DISORDERS OF CHOLESTEROL AND STEROID BIOSYNTHESIS (also discussed in Chapter 13)

Genital ambiguity can be due to abnormalities in the biosynthetic pathways involved in cholesterol, cortisol, and sex steroid synthesis. Steroidogenesis refers to the multiple enzyme processes through which cholesterol is converted to biologically active steroid hormones. This process depends on the coordinated regulation of cholesterol uptake into cells, transfer into mitochondria, and actions of tissue specific enzymes.[202] Many of the steroidogenic enzymes are cytochrome P450 heme-containing proteins that absorb light at 450 nm in their reduced state or hydroxysteroid dehydrogenases. The P450 enzymes receive electrons from the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) and use their heme center to mediate catalysis. The type 1 enzymes are located in mitochondria and receive electrons from NADPH from a flavoprotein, ferredoxin reductase, and an iron-sulfur protein, ferredoxin. The type 2 enzymes are located in the endoplasmic reticulum and receive electrons from NADPH from another protein, P450 oxidoreductase.

The hydroxysteroid dehydrogenase enzymes utilize NAD+ and NADP+ as cofactors; these enzymes do not contain heme groups. The hydroxysteroid dehydrogenases are classified into two groups. One group is the short-chain dehydrogenase reductase family. The other group is the aldo-keto reductase family. These enzymes function as dehydrogenases and reductases. Although many of these enzymes show both dehydrogenase and reductase activities in vitro, most function unidirectionally.[203]

During fetal life, steroidogenic enzymes are expressed in placenta, testis, and adrenal (Figure 5-2). The fetal testis secretes testosterone that is converted to dihydrotestosterone (DHT) in target tissues such as the prostate and external genitalia. Inborn errors of testosterone biosynthesis can lead to undervirilization and ambiguous genitalia in 46,XY fetuses. Specific proteins necessary for testosterone biosynthesis include NR5A1, LH receptor, steroidogenic acute regulatory peptide (StAR), 17α-hydroxylase/17,20-lyase, 3β-hydroxysteroid dehydrogenase type 2, 17β-hydroxysteroid dehydrogenase type 3, P450-oxidoreductase, and 5β-reductase type 2 (Figure 5-3). Inborn errors of glucocorticoid biosynthesis are often associated with the virilizing congenital adrenal hyperplasias.

The fetal adrenal cortex is derived from coelomic epithelium and consists of two major zones: the fetal zone and the adult zone. The fetal zone is primarily responsible for DHEA synthesis, which is then sulfated to

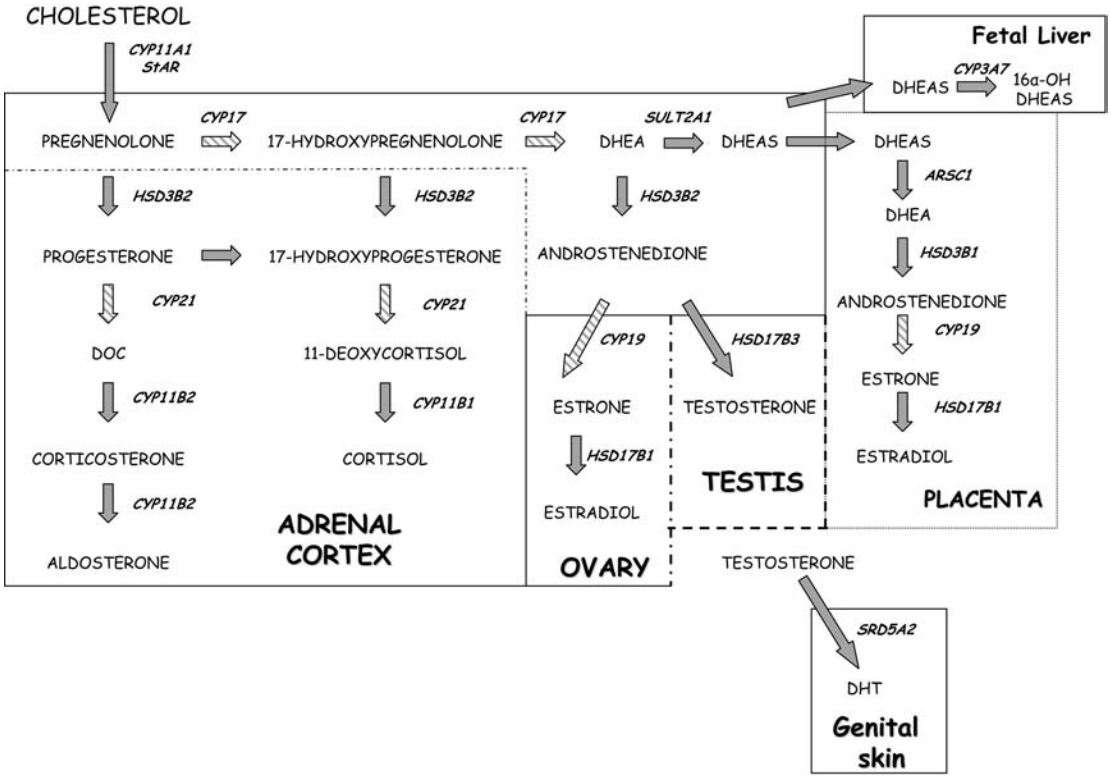

FIGURE 5-3 ■ Diagram of classical steroidogenic pathways. Substrates, products, and genes involved in adrenal, ovarian, testicular, and placental steroidogenesis are indicated. Genes are 17α-hydroxylase/17,20-lyase (CYP17), 3β-hydroxysteroid dehydrogenase (HSD3B2), 21-hydroxylase (CYP21), 11β-hydroxylase (CYP11B1), aldosterone synthase (CYP11B2), aromatase (CYP19), 17β-hydroxysteroid dehydrogenase type 1 (HSD17B1), 17β-hydroxysteroid dehydrogenase type 3 (HSD17B3), 5α-reductase type 2 (SRD5A2), sulfotransferase (SULT2A1), and steroid sulftase/arylsulfatase C (ARSC1). CYP3A7 is a cytochrome P450 enzyme expressed in fetal liver, where it catalyzes the 16α-hydroxylation of estrone (E1) and DHEA. Its expression decreases postnatally. Steroidogenic enzymes that utilize P450 oxidoreductase, a flavoprotein encoded by POR, to transfer electrons are indicated by hatched arrows.

provide substrate for placental estrogen biosynthesis (see Figure 5-3). The adult zone, which after birth differentiates into the three zones of the adult adrenal cortex, is primarily responsible for cortisol biosynthesis. By 10 weeks of gestation, the adrenal is secreting DHEAS and the hypothalamic-pituitary-adrenal axis is functional. Prior studies indicated that CYP17A1 was not expressed in the human placenta.[204] Newer in vitro data indicate CYP17A1 is expressed in the trophoblast and can generate androgens.[205]

Through investigations of the tammar wallaby and patients with disordered steroidogenesis, the presence of another pathway leading to dihydrotestosterone synthesis was uncovered.[206] In this "backdoor pathway", 17-hydroxyprogesterone (17-OHP) undergoes 3α- and 5α-reduction followed by 17,20-lyase, 17β-hydroxysteroid dehydrogenase, and 3α-oxidation steps to generate dihydrotestosterone in the absence of the intermediates, DHEA, androstenedione, and testosterone, requisite to the classical pathway. In humans, since 17-OHP is not a favored substrate for the 17,20-lyase reaction, this pathway acquires functional importance in disorders of steroidogenesis associated with increased 17-OHP concentrations.

Luteinizing Hormone Choriogonadotropin Receptor Gene

Leydig cell hypoplasia is an autosomal recessive disorder characterized by failure of testicular Leydig cell differentiation secondary to inactivating LHCGR mutations and target cell resistance to LH.[207] The LHCGR gene is mapped to chromosome 2p21. The 674-amino-acid protein is a seven-transmembrane domain G-protein–coupled receptor. Specific mechanisms through which the loss-of-function mutations induce LH resistance include decreased receptor protein, decreased ligand binding, altered receptor trafficking, and impaired ability to activate G_s. Exon 6A in the LHCGR gene can generate three splice variants; the consequence of one specific mutation in exon 6 was aberrant gene transcription which altered ratios of the LHCGR transcripts.[208]

Complete inability to respond to hCG or LH results in substantially decreased Leydig cell testosterone biosynthesis. The phenotype of affected 46,XY infants ranges from undervirilization to female external genitalia. Affected individuals raised as females often seek medical attention for delayed breast development. Mullerian duct derivatives are absent because AMH is secreted by the unaffected Sertoli cells. Testes are typically inguinal or intra-abdominal. Laboratory studies show elevated LH, low testosterone, and normal FSH concentrations. There is no significant testosterone response to hCG stimulation. Testicular histology reveals absence of Leydig cells, but relatively preserved seminiferous tubules and testicular volume due to normal FSH secretion and responsiveness. Undervirilization with hypospadias, micropenis, and cryptorchidism can occur with incomplete loss-of-function missense mutations. Genetic females, sisters of affected 46,XY individuals, who carry the identical mutations show normal female genital differentiation and normal pubertal development but have amenorrhea and infertility.[209-211] The uterus is small to normal in size. Ovarian cysts may develop. Estrogen concentrations generally fail to achieve the threshold required for ovulation. Genetic analysis may be helpful to distinguish LHCGR mutations from other disorders affecting testosterone biosynthesis.[212]

Smith-Lemli-Opitz Syndrome

Several enzymes catalyze the conversion of lanosterol to cholesterol. Decreased activity of these enzymes leads to cholesterol deficiency. The enzyme, 7-dehydrocholesterol reductase, encoded by the 7-dehydrocholesterol reductase (DHCR7) gene catalyzes the last step in cholesterol biosynthesis. Smith-Lemli-Opitz (SLO) syndrome is due to mutations in the 7-dehydrocholesterol reductase (DHCR7) gene located at chromosome 11q12-q13. Mutations in the DHCR7 gene are associated with elevated 7-dehydroxycholesterol concentrations. Demonstration of elevated 7-dehydroxycholesterol concentrations is required to confirm the diagnosis.

As anticipated, mutations in this cholesterol biosynthetic pathway are associated with decreased cholesterol and accumulation of sterol intermediates proximal to the defective enzyme. Decreased cholesterol concentrations lead to decreased steroid concentrations because cholesterol serves as the precursor for glucocorticoid, mineralocorticoid, and sex steroid biosynthesis. In addition to its role as the precursor for steroid biosynthesis, cholesterol modification of sonic hedgehog protein (SHH) is necessary for normal signaling through its cognate receptor, Patched (PTCH1), which contains a sterol sensing domain. In fibroblasts from patients with SLO, SHH signaling is impaired. Available data indicate that accumulation of sterol intermediates rather than cholesterol deficiency interferes with midline fusion of facial structures. These observations shed light on the molecular pathophysiology responsible for the cleft palate associated with SLO.[213]

Clinical features of this autosomal recessive disorder include multiple malformations, urogenital anomalies, mental retardation, failure to thrive, facial abnormalities, developmental delay, and behavioral abnormalities. The most common urogenital abnormalities include male-to-female sex reversal, hypospadias, and cryptorchidism. The facial abnormalities consist of a broad nose, upturned nares, micrognathia, short neck, and cleft palate.[213,214] Typical limb anomalies comprise short thumbs, syndactyly of the second and third toes, and post-axial polydactyly.

Infants often have hypotonia, feeding problems, and failure to thrive. Tube feedings may be necessary due to the poor weight gain. Although the efficacy remains unclear, dietary cholesterol supplementation is often prescribed.[214] The limited cholesterol biosynthesis may be associated with adrenal insufficiency, especially during stress. Thus, stress glucocorticoid dosing may be beneficial.

Prenatal diagnosis can be performed by measurement of amniotic fluid 7-dehydrocholesterol concentrations.[215] Low plasma estriol, elevated blood 16α-hydroxyestrogens

concentrations, and elevated urinary Δ^7 and Δ^8 unsaturated C_{18}, C_{19}, and C_{21} dehydrosteroid concentrations are found in women pregnant with affected fetuses, presumably due to impaired fetal cholesterol production.[215] The incidence of biochemically confirmed SLO is estimated at 1/20,000 to 1/60,000 live births.[216] With the identification of the molecular basis for this disorder, a surprisingly high heterozygote carrier rate for DHCR7 mutations has been found. Because the prevalence of SLO at 16 weeks of gestation is comparable to the prevalence at birth, early fetal loss and/or reduced fertility of carrier couples may be occurring.[216]

Congenital Lipoid Adrenal Hyperplasia

This autosomal-recessive disorder is characterized by a severe defect in the conversion of cholesterol to pregnenolone, leading to impaired steroidogenesis of all adrenal and gonadal steroid hormones. Impaired testosterone biosynthesis in utero prevents male sexual differentiation. Hence, all affected fetuses (46,XY or 46,XX) have female external genitalia. In the XY fetus, Sertoli cells are intact, AMH secretion is unaffected, and Mullerian duct elements regress. Low or undetectable steroid hormone concentrations, elevated ACTH concentrations, and elevated plasma renin activity are consistent with this diagnosis. Elevated 17-hydroxypregnenolone or pregnenolone concentrations distinguish 3β-hydroxysteroid dehydrogenase deficiency from congenital lipoid adrenal hyperplasia.

Following cloning of the gene for steroidogenic acute regulatory protein (StAR), mutations in the StAR gene were identified among patients with congenital lipoid adrenal hyperplasia.[217-219] The StAR protein facilitates cholesterol transport across the mitochondria to P450scc.[220] In congenital lipoid adrenal hyperplasia, the impaired mitochondrial cholesterol transport leads to accumulation of cholesterol esters and sterol auto-oxidation products. Ultimately, the lipid accumulation alters the cell cytostructure provoking cell destruction and complete loss of StAR-dependent steroidogenesis.[221] Hence, the pathogenesis of congenital lipoid adrenal hyperplasia can be characterized as having "two hits," one is defective steroidogenesis and the other is destruction of the steroidogenic cell. Since the definitive zone of the adrenal cortex is relatively quiescent during gestation, manifestations of aldosterone deficiency may not be apparent in the immediate newborn period. This two-hit mechanism allows for spontaneous pubertal development in affected girls because significant estrogen synthesis does not take place until puberty. Subsequently, the follicular cells are damaged resulting in hypergonadotropic hypogonadism.[222]

Nonclassic lipoid congenital adrenal hyperplasia (CAH) is a milder form with variable adrenal and gonadal function presenting in childhood and adolescence.[223,224] Nonclassic lipoid CAH may present with isolated glucocorticoid deficiency and resembles familial glucocorticoid deficiency due to mutations in the ACTH receptor (MC2R) gene.[225]

Side Chain Cleavage Cytochrome P450 Enzyme

The side chain cleavage enzyme (also known as cholesterol desmolase) is a cytochrome P450 enzyme encoded by the CYP11A1 gene mapped to chromosome 15q23-q24. This enzyme converts cholesterol to pregnenolone and is essential to steroidogenesis. This enzyme plays a crucial role in placental progesterone synthesis. Thus, mutations in this gene would be expected to be incompatible with term gestation. However, children with mutations in this enzyme have been reported. The children affected with this autosomal-recessive disorder have adrenal insufficiency and female external genitalia irrespective of the karyotype. Yet, the phenotypic spectrum has been extended to include adrenal insufficiency with or without hypospadias.[226-228] Postnatally, no enlargement of the adrenals and gonads is seen on ultrasound or magnetic resonance imaging.[229] The absence of adrenal/gonadal tissue has been speculated to result from lipid accumulation similar to the cell destruction observed in patients with StAR mutations. Genetic analysis may be necessary to distinguish this disorder from congenital lipoid adrenal hyperplasia.[230]

Virilizing Congenital Adrenal Hyperplasias

The virilizing congenital adrenal hyperplasias are a group of disorders due to mutations in the steroidogenic enzyme genes involved in cortisol biosynthesis. These genes are 3β-hydroxysteroid dehydrogenase type 2 (HSD3B2), 21-hydroxylase (CYP21A2), and 11β-hydroxylase (CYP11B1). These three disorders share a common pathophysiology. Insufficient cortisol production leads to decreased negative feedback inhibition, increased ACTH production, accumulation of steroid intermediates proximal to the deficiency enzyme, and increased androgen concentrations. The specific manifestations and laboratory abnormalities vary depending on which enzyme gene is involved. Indeed, the magnitude of glucocorticoid and mineralocorticoid deficiencies varies—generally in proportion to the severity of the enzyme deficiency.

Accumulation of steroid intermediates such as 17-OHP results in increased androgen concentrations. In the affected female, the increased androgen exposure promotes virilization of the external genitalia. Excessive 17-OHP can be converted through an alternate pathway to DHT. This alternate route (the "backdoor pathway") involves 5α and 3α-reduction of 17-OHP to 5α-pregnane-3α,17α-diol-20-one (pdiol), ultimately generating androstanediol, which is the substrate for 3α-oxidation and conversion to DHT[206] (Figure 5-4). During fetal life, accumulation of 17-OHP due to mutations in CYP21A2, CYP11B2, or P450-oxidoreductase (POR) may increase flux through this "backdoor pathway" leading to elevated DHT concentrations.[231]

21-Hydroxylase Deficiency

The most common type of CAH (accounting for 90% to 95% of cases) is 21-hydroxylase deficiency due to mutations in the 21-hydroxylase (CYP21A2) gene located at chromosome 6p21.3 in the HLA class III region.[232] The reported incidence of 21-hydroxylase deficiency ranges from 1 in 5,000 to 1 in 15,000, with

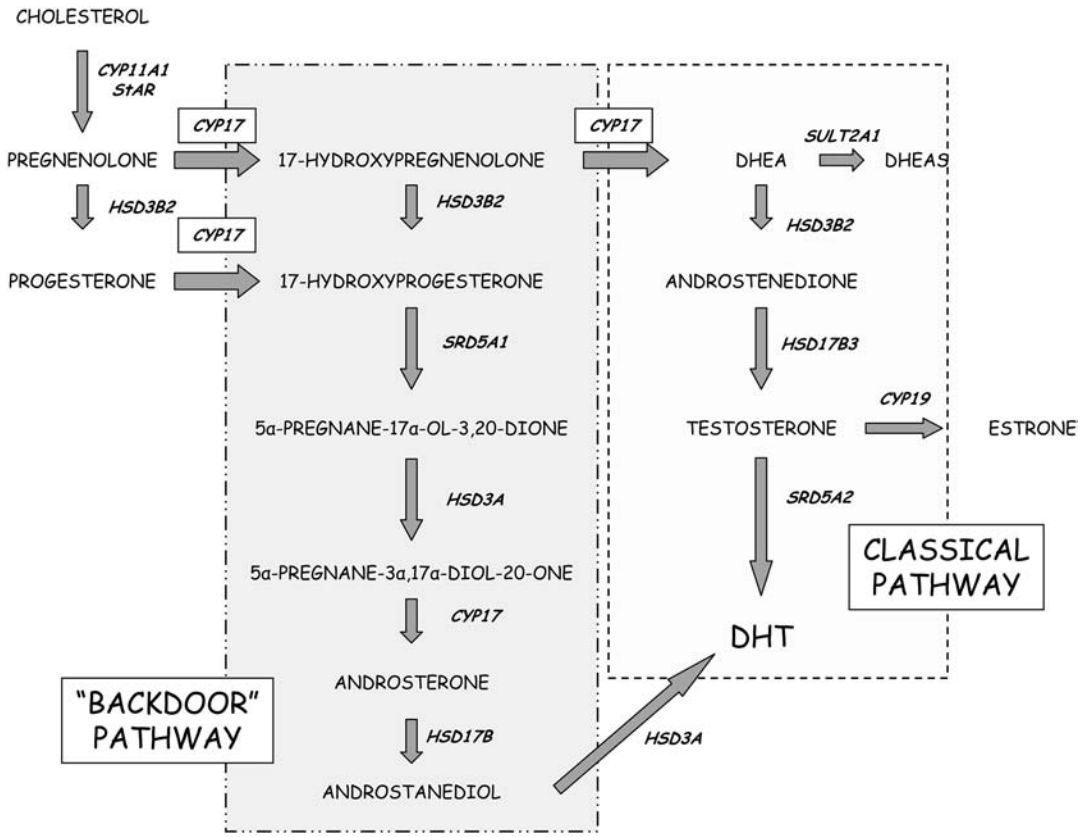

FIGURE 5-4 ■ Steroidogenic pathways relevant to fetal androgen biosynthesis. The classic steroidogenic pathway relevant to the testis (light background) and the "backdoor pathway" (dark background) are indicated. Both pathways can generate DHT through the actions of target tissue enzymes capable of converting substrates, testosterone, and androstanediol into DHT. In the presence of elevated ACTH and 17-OHP concentrations due to CYP21, CYP11B1, or POR mutations, the backdoor pathway may contribute to the excessive androgen concentrations responsible for virilization of XX fetuses.

variation among ethnic/racial backgrounds.[233,234] Decreased 21-hydroxylase activity impairs conversion of 17-hydroxyprogesterone to 11-deoxycortisol in the zona fasciculata (the primary site of cortisol biosynthesis) and conversion of progesterone to deoxycorticosterone in the zona glomerulosa, the primary site of aldosterone biosynthesis.

Infant girls with classic salt-losing 21-hydroxylase deficiency usually present in the immediate neonatal period due to genital ambiguity (Figure 5-5).[235] When the diagnosis is delayed, affected girls develop dehydration, hyponatremia, and hyperkalemia due to glucocorticoid and mineralocorticoid deficiencies. In affected females, the spectrum of genital virilization varies from clitoromegaly to perineal hypospadias to complete fusion of labiourethral and labioscrotal folds giving rise to a phallus with chordee and urethral meatus at the tip of phallus. The magnitude of external genital virilization may be so extensive that affected female infants appear to be males with bilateral undescended testes.[236,237] Unless identified by neonatal screening, infant boys typically present at 2 to 3 weeks of age with failure to thrive, poor feeding, lethargy, dehydration, hypotension, hyponatremia, and hyperkalemia. When the diagnosis is delayed or missed, congenital adrenal hyperplasia is potentially fatal. Newborn screening programs decrease the morbidity and mortality associated with acute adrenal insufficiency.

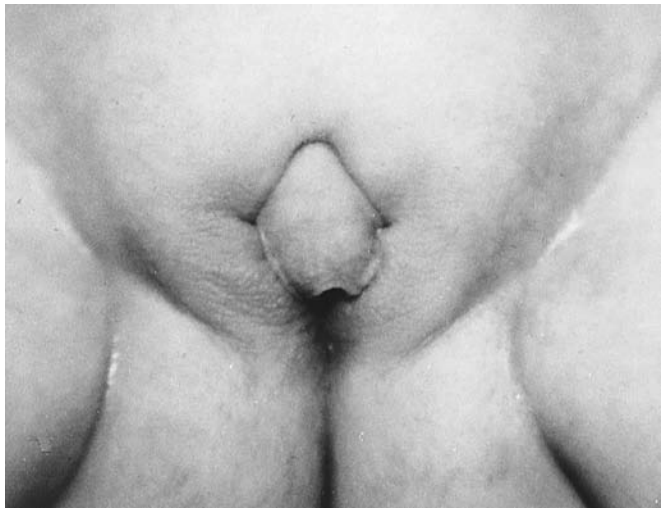

FIGURE 5-5 ■ Genital ambiguity in virilized female with 21-hydroxylase deficiency. The labioscrotal folds are fused, and the clitoris is enlarged.

In affected infants, random 17-OHP concentrations are usually elevated. Concentrations are greater than 5,000 ng/dL and may be much higher.[238] Androstenedione and progesterone concentrations are also typically elevated. In some instances, plasma renin activity (PRA) can be helpful to assess mineralocorticoid status.

Measurement of 21-deoxycortisol is extremely helpful, but availability of this hormone assay is limited. For female infants, a normal uterus is present and can be identified on ultrasound. Ovaries may be too small to be readily identified on ultrasound. Despite excessive antenatal androgen exposure, ovarian position is normal and internal Wolffian structures are not retained.

The spectrum of impaired 21-hydroxylase activity ranges from complete glucocorticoid and mineralocorticoid deficiencies to mild deficiencies manifested principally by compensatory excessive adrenal androgen secretion. Infants capable of adequate aldosterone synthesis do not usually manifest overt salt loss. Female infants capable of adequate aldosterone synthesis may still have sufficient androgen exposure in utero to virilize their external genitalia. In the absence of newborn screening programs, affected males capable of aldosterone biosynthesis may not be identified until they present with genital overgrowth or premature pubarche. Infants with the milder forms of congenital adrenal hyperplasia are generally not identified by most newborn screening programs.[239] Urinary steroid hormone GC/MS analyses showed increased ratios of 5α-pregnane-3α,17α-20-one (pdiol) to metabolites of the Δ^4 and Δ^5 pathways, which indicates postnatal activity of the backdoor pathway especially during early infancy.[240]

CYP21A2 is located approximately 30 kilobases from a highly homologous pseudogene, CYP21A1P. The tenascin-XB (TNXB) gene encoding an extracellular matrix protein is located on the DNA strand opposite CYP21A2.[241] At this time, more than 100 CYP21A2 mutations have been reported. However, only a few mutations account for the majority of affected alleles. Most of the common mutations represent gene conversion events in which CYP21A2 has acquired deleterious CYP21A1P sequences. The frequency of specific mutations varies among ethnic groups.[242] Molecular genotyping can be a useful adjunct to newborn screening. Caveats to bear in mind are that multiple mutations can occur on a single allele and that different CYP21A2 mutations can occur in one family.[243,244]

11β-Hydroxylase Deficiency

Congenital adrenal hyperplasia due to 11β-hydroxylase deficiency is characterized by glucocorticoid deficiency, excessive androgen secretion, and hypertension. This form of CAH is due to mutations in the 11β-hydroxylase (CYP11B1) gene. The enzyme is expressed in the zona fasciculata, where it converts 11-deoxycortisol to cortisol. Congenital adrenal hyperplasia, due to CYP11B1 mutations, is rare (3% to 5% of cases) apart from the high incidence among Moroccan Jews, for whom the incidence approaches 1 in 6,000.[245] Despite the presence of the identical mutation (R448H), phenotypic heterogeneity for the magnitude of virilization and hypertension occurs even in a single family. Affected females may present with ambiguous genitalia. The typical laboratory finding is an elevated 11-deoxycortisol concentration. Serum concentrations of 17-hydroxyprogesterone, androstenedione, and testosterone may be mildly elevated. PRA concentrations are low or suppressed. Nevertheless, infants may experience salt loss presumably due to mineralocorticoid resistance.[246] Patients with non-classic forms have been identified.[3] Although ACTH-stimulated hormone responses among heterozygotic carriers are usually normal, elevated 11-deoxycortisol and 11-deoxycorticosterone have been reported.

The CYP11B1 gene is located at chromosome 8q22 in close proximity to a highly homologous gene CYP11B2, which codes for aldosterone synthase. Novel mutations associated with classical and non-classic 11β-hydroxylase deficiency have been identified.[247-249] CYP11B1 is expressed in the zona fasciculata, whereas CYP11B2 is expressed primarily in the zona glomerulosa.

3β-Hydroxysteroid Dehydrogenase Deficiency

Congenital adrenal hyperplasia due to 3β-hydroxysteroid dehydrogenase type 2 deficiency leads to virilization of the external genitalia of 46,XX fetuses due to increased DHEA synthesis. Affected 46,XY fetuses have ambiguous genitalia characterized by undervirilization of the external genitalia secondary to testosterone deficiency. Despite decreased testosterone synthesis, affected 46,XY fetuses usually have intact Wolffian duct structures (including vas deferens). The NAD+-dependent enzyme 3β-hydroxysteroid dehydrogenase/Δ^5-Δ^4-isomerase catalyzes the conversion of the Δ^5 steroid precursors, pregnenolone, 17-hydroxypregnenolone, and DHEA into the respective Δ^4-ketosteroids, progesterone, 17-OHP, and androstenedione.[250]

Two isozymes encoded by two different highly homologous genes have been identified and mapped to chromosome 1p13.1. The type 1 (HSD3B1) gene is expressed primarily in skin, placenta, prostate, and other peripheral tissues. The type 2 (HSD3B2) gene is the form primarily expressed in the adrenal cortex and gonads. Mutations in HSD3B2, but not HSD3B1, have been detected in patients with 3β-hydroxysteroid dehydrogenase deficiency congenital adrenal hyperplasia.[251] Acute adrenal insufficiency occurs in the newborn period when complete loss of function mutations impair biosynthesis of mineralocorticoids, glucocorticoids, and sex steroids. Typical presentations for the non–salt-losing forms include premature pubarche and (in 46,XY infants) perineal hypospadias. Confirmatory laboratory findings include elevated pregnenolone, 17-hydroxypregnenolone, and DHEA concentrations with elevated ratios of Δ^5 to Δ^4 steroids. Because enzymatic activity of the type 1 isozyme is unimpaired, elevated 17-OHP and androstenedione concentrations may be found.

Defects in Sex Steroid Biosynthesis

17α-Hydroxylase/17,20-Lyase Deficiency

Synthesis of mineralocorticoids, glucocorticoids, and sex steroids is modulated by the enzyme, 17α-hydroxylase/17-20-lyase. This enzyme is encoded by a single gene,

CYP17A1 mapped to chromosome 10q24.3 and catalyzes two steps in steroidogenesis, pregnenolone is 17α-hydroxylated to 17α-hydroxypregnenolone, which then undergoes 17,20-lyase activity to form DHEA. Factors favoring the 17,20-lyase reaction include availability of P450 oxidoreductase and cytochrome b_5 and serine/threonine phosphorylation of the P450c17 protein.[232]

Loss-of-function mutations interfere with glucocorticoid and sex steroid biosynthesis. Affected males present with undervirilization of the external genitalia. Affected females have normal genital development and present with delayed puberty. Patients are often hypertensive due to the increased ACTH-stimulated mineralocorticoid synthesis. Serum levels of progesterone, deoxycortisone, corticosterone, 18-hydroxycorticosterone, and 18-hydroxy DOC are elevated and can be suppressed glucocorticoid replacement. Low or absent glucorticoids and sex steroids with poor ACTH-stimulated responses are consistent with this diagnosis. Mutations solely affecting the 17,20-lyase activity are extremely rare.[252,253] The phenotype of apparent isolated 17,20-lyase deficiency can be due to mutations in other genes such a cytochrome b_5, P450 oxidoreductase, and several aldo-keto reductase enzymes as described next.

Cytochrome b_5 Deficiency

Cytochrome b_5 participates in electron transfer for some cytochrome P450 reactions. Although it is not an effective electron donor to P450c17, this protein enables the interactions between P450c17 and oxidoreductase to promote the 17,20-lyase reaction essential for sex steroid synthesis. One 46,XY infant found to be homozygous for a loss of function mutation in the cytochrome b_5 (CYP5) gene was described to have micropenis, bifid scrotum, scrotal hypospadias, undetectable DHEAS concentration, low testosterone concentration, and elevated methemoglobin concentration.[254] A missense mutation associated with mild methemoglobinemia and undervirilized 46,XY siblings has been described.[255]

3α-Hydroxysteroid Dehydrogenase Isozyme Deficiencies

Re-evaluation of the families originally reported to have isolated 17,20-lyase deficiency led to identification of alternative pathways for androgen synthesis.[256,257] Investigation of one family revealed no mutations in CYP17A1, NR5A1, POR, or CYB5. Rather, mutations were detected in the 3α-hydroxysteroid dehydrogenase type III (AKR1C2) gene, which is mapped to chromosome 10p15.1. The phenotype, undervirilization of affected 46,XY individuals, followed a sex-linked recessive inheritance pattern. A splicing mutation in another closely related 3α-HSD gene, AKR1C4, was found in a second family. Digenic inheritance involving mutations in both AKR1C2 and AKR1C4 were found in this second family. Thus, both the classic and backdoor pathways appear to be necessary for normal male external genital development.[257] However, details regarding the specific roles of these enzymes remain to be elucidated.

Cytochrome P450 Oxidoreductase Deficiency

In 1985, a disorder with biochemical evidence suggesting decreased 17α-hydroxylase and 21-hydroxylase activity was initially reported.[258] This disorder was found to be associated with mutations in the cytochrome P450 oxidoreductase (POR) gene. The POR gene codes for a protein that functions as a mandatory electron donor to microsomal steroidogenic and hepatic P450 enzymes. The POR gene, mapped to chromosome 7q11-12, plays a major role in glucocorticoid and sex steroid synthesis. Loss-of-function mutations appear to be scattered throughout the gene.

Clinical features included genital ambiguity, craniosynostosis, midface hypoplasia, and radiohumeral synostosis. At birth, genital ambiguity was noted in both male and female infants. However, progressive postnatal virilization does not occur. Insufficient testosterone synthesis likely causes the undervirilization of male infants. Virilization of female fetuses is attributed to shunting of the excessive 17-OHP to the "backdoor pathway" resulting in increased DHT synthesis. During pregnancy, some mothers developed signs associated with androgen excess such as acne, hirsutism, and clitoromegaly.[259] Typical laboratory findings include elevated 17-OHP, low sex steroid, and normal mineralocorticoid concentrations. Some affected individuals may benefit from daily glucocorticoid replacement therapy. Others may need glucocorticoid treatment only for stress dosing.[260]

The skeletal malformations resemble those found in the Antley-Bixler syndrome, which is an autosomal dominant disorder associated with mutations in the fibroblast growth factor receptor 2 (FGFR2) gene. Patients with Antley-Bixler syndrome due to FGFR2 mutations have normal steroidogenesis, whereas patients with POR mutations have abnormal steroidogenesis.[261] The molecular basis of the skeletal anomalies is unclear but is suspected to be due to impaired activity of enzymes involved in sterol biosynthesis such as 14α-lanosterol demethylase (CYP51A1) and squalene epoxidase or retinoic acid metabolism.[262,263]

17β-Hydroxysteroid Dehydrogenase Deficiency

This disorder is due to mutations of the 17β-hydroxysteroid dehydrogenase type 3 gene (HSD17B3) located at chromosome 9q22. The enzyme is expressed almost exclusively in the testis where it converts androstenedione to testosterone. Loss-of-function mutations result in testosterone deficiency and subsequent undervirilization of 46,XY fetuses.[264] In this autosomal recessive disorder, external genitalia range from female with perineoscrotal hypospadias and a blind-ending vaginal pouch to ambiguous with labio-scrotal fusion to hypospadias. Testes are present and may be palpable in the labio-scrotal folds or incompletely descended. Despite the presence of female external genitalia, Wolffian structures are typically present.[265] In The Netherlands, incidence was estimated to be 1:147,000.[266]

When unrecognized, patients are usually considered to be female at birth. At puberty, progressive virilization

occurs. This virilization is attributed to extratesticular conversion of androstenedione to testosterone and may lead affected individuals to change gender identity from female to male. Increased conversion of androstendione to estrogens may cause gynecomastia.

Appropriate male gender assignment can be made in infancy when the diagnosis is suspected and confirmed. Diagnostic laboratory features include increased basal and hCG-stimulated androstenedione to testosterone ratios. The clinical features are similar to those of 5α-reductase deficiency and androgen insensitivity; molecular genetic analysis may be beneficial to confirm the diagnosis.[265] Affected 46,XX girls are usually asymptomatic, have normal female internal and external genitalia, and normal pubertal development; infertility has been reported for some.[267]

5α-Reductase Deficiency

This autosomal-recessive disorder is due to mutations in the 5α-reductase type 2 gene (SRD5A2) which is is located at chromosome 2p23. This gene is expressed primarily in androgen target tissues where it converts testosterone to dihydrotestosterone (DHT). Clusters of individuals with SRD5A2 mutations have been described in regions of the Dominican Republic, Papua New Guinea, Turkey, and the Middle East.

Affected 46,XY individuals have genital ambiguity characterized by differentiation of Wolffian structures, absence of Mullerian-derived structures, small phallus, urogenital sinus with perineoscrotal hypospadias, and blind vaginal pouch.[268] Four patients were reported who were raised as females and presented with primary amenorrhea; all had genital ambiguity.[269] Deletions, missense mutations, and uniparental disomy have been reported.[270] Due to the extensive heterogeneity in the clinical features, phenotype/genotype correlations are not well established. One study reported that T/DHT ratio greater than 10 detected almost 75% of the patients; hCG-stimulated T/DHT ratios were also used.[271] Caveats regarding this diagnosis include the need for hCG stimulation in prepubertal patients and accurate hormone determinations in which cross-reactivity between testosterone and DHT is minimized.[272]

At puberty, progressive virilization occurs with muscular development, voice change, and phallic enlargement. These features have been attributed to the actions of 5α-reductase type 1 (SRD5A1). SRD5A1, located at chromosome 5p15, is expressed in post-pubertal skin and scalp. Phenotypic heterogeneity occurs frequently. Some 46,XY individuals with this disorder who were raised as girls, develop a male gender identity and changed gender role in adolescence or adulthood. Despite the virilization, facial hair tends to be scanty, the prostate is hypoplastic, semen tends to be viscous, and the amount of ejaculate is low. Affected men often have azospermia or oligospermia. Intrauterine insemination with sperm from an affected male has resulted in pregnancy.[273]

Placental Aromatase Deficiency

Placental aromatase deficiency is a rare autosomal recessive disorder due to mutation in the aromatase gene, CYP19A1, which is located at chromosome 15q21.2 and codes for a 503-amino-acid protein.[274] Inactivating mutations of CYP19A1 impair conversion of androgens to estrogens, leading to increased androgens.[232] During pregnancies with affected fetuses, progressive maternal virilization characterized by hirsutism, clitoral hypertrophy, acne, and frontal balding occurs. During pregnancy, testosterone, DHT, and androstenedione concentrations are elevated and estradiol, estrone, and estriol concentrations are low. In the postpartum period, some clinical features of androgen excess regress and the elevated androgen concentrations return to normal levels.

At birth, 46,XX infants are variably virilized with labioscrotal fusion, clitoromegaly, and perineal scrotal hypospadias. Affected 46,XX individuals generally manifest delayed puberty characterized by minimal or absent breast development, primary amenorrhea, hypergonadotropic hypogonadism, multi-cystic ovaries, and decreased bone mineral density.[275,276] At birth, affected 46,XY infants have normal internal and external genital development. Affected males have generally presented after puberty with tall stature, skeletal pain, delayed skeletal maturation, and infertility.[277] Investigation of aromatase-deficient men suggests that estrogen deficiency is associated with abdominal obesity, insulin resistance, dyslipidemia, and relative infertility. Patients with less severe phenotypic features have been described.[278]

Aromatase is a cytochrome P450 enzyme that plays an important role in the biosynthesis of estrogens (C18 steroids) from androgens (C19 steroids). In addition to its role in estrogen biosynthesis in adolescents and adults, aromatase located in the human placenta converts fetal adrenal androgens to estrogens and protects the mother from the potential virilizing effects of the fetal androgens. Tissue-specific aromatase expression is governed by several different promoters associated with alternative first exon usage.[279,280]

MATERNAL HYPERANDROGENISM

During pregnancy, maternal hyperandrogenism can occur secondary to luteomas of pregnancy, androgen secreting tumors, and exposure to exogenous androgen. The excessive maternal androgen concentrations can cause virilization of the external genitalia of 46,XX fetuses. Endocrine disruptors are exogenous chemicals or mixtures of chemicals that interfere with any facet of hormone action.[281] Organochlorine pesticides, polychlorinated biphenyls (PCBs), and alkylpolyethoxylates are considered to be "endocrine disruptors" because of their estrogenic and/or antiandrogenic properties.

DISORDERS OF ANDROGEN ACTION

During the process of sexual development, androgen action is essential to promote retention of Wolffian duct derivatives, development of the prostate, and differentiation of male external genitalia. Androgen action is mediated by the androgen receptor (AR, also known as NR3C4), a member of the steroid/thyroid hormone

family of hormone receptors. Similar to other members of this receptor family, the androgen receptor is a ligand-dependent transcription factor with a characteristic modular structure. The major modules of the protein include the amino-terminus transactivation (AF1), DNA-binding, and ligand-binding domains. Other features include a nuclear localization signal, another transactivation domain (AF2) in the carboxy terminus ligand-binding domain, and the hinge region.[282] The AR has two polymorphic trinucleotide repeat regions located in the amino terminal domain encoding the polyglutamine (CAG) and polyglycine (GCN) repeat regions.[283,284]

Androgen insensitivity is an X-linked recessive disorder secondary to mutations in AR, which is located near the centromere at Xq11-12.[285,286] Approximately 30% of cases represent de novo mutations. Somatic cell mosaicism can occur when the mutation arises in the post-zygotic stage and is associated with a lower recurrence risk.[287] Complete androgen insensitivity (CAIS) is characterized by female external genitalia, absence of Mullerian duct derivatives, sparse sexual hair, inguinal masses, and primary amenorrhea in the adolescent girl. Among patients with CAIS, Wolffian duct derivatives (e.g., vas deferens and epididymides) are absent because of deficient androgen action. Although rare exceptions have been described, Mullerian-derived structures are usually absent because Sertoli cell function is normal with in utero AMH secretion. It has been suggested that 1% to 2% of girls with bilateral inguinal herniae may have androgen insensitivity. The finding of a gonad within the hernia sac should prompt cytogenetic studies.[288] The expected LH surge in testosterone concentrations during the first few months of life may be absent in some infants with CAIS.[289] Spontaneous pubertal breast development due to aromatization of androgens to estrogens occurs if the gonads are in situ.

Partial androgen insensitivity syndrome (PAIS) is characterized by clinical features suggestive of a partial biologic response to androgens.[290] Typical features include ambiguous genitalia with perineoscrotal hypospadias, microphallus, and bifid scrotum. Testicular position is variable, ranging from undescended to palpable in the scrotum. Infants with PAIS generally manifest the expected neonatal testosterone surge, suggesting that prenatal androgen responsiveness plays a role in imprinting of the HPG axis. Features of mild androgen insensitivity syndrome (MAIS) include gynecomastia and infertility in otherwise normal males. Older chronologic age at presentation is typical. In all instances, karyotype is 46,XY.

Typical laboratory findings are elevated LH and testosterone concentrations because testicular testosterone synthesis is unimpeded. Yet, there is loss of negative feedback inhibition of gonadotropins. LH concentrations are usually higher than FSH concentrations because testicular inhibin secretion is not impeded. FSH concentrations may be elevated or normal. Infants with PAIS may require dynamic endocrine tests to assess hCG-stimulated Leydig cell testosterone secretion and, more importantly, end-organ responsiveness to androgens. The risk for gonadal tumors is increased in the presence of a Y chromosome. Tumors associated with AIS include carcinoma-in-situ (CIS), seminoma, leiomyoma, and testicular stromal cell tumors.[291] In one series, only 2 of 44 subjects with CAIS had CIS. Both subjects were postpubertal.[292]

In the absence of ligand, the AR protein is located primarily in the cytoplasm where it is bound to chaperone proteins. Upon ligand binding, the conformation of the androgen receptor changes. The ligand-receptor complexes dimerize and move to the nucleus.[293] A key feature of androgen receptor dimerization is the intramolecular interaction between the N-terminal and C-terminal domains. Binding of ligand stabilizes the androgen receptor and slows its degradation.[294] The increased potency of dihydrotestosterone is attributed to the greater stability of the dihydrotestosterone-receptor complex compared to the testosterone-receptor complex. In the nucleus, the complex binds to androgen response elements (AREs) and alters target gene transcription. Nucleotide sequences of AREs in conjunction with specific AR amino acids confer greater specificity for transcriptional regulation of specific genes.[295]

Over 500 different AR mutations have been described in affected individuals.[296] In general, the phenotype correlates with degree of impaired androgen action. However, clinical features can vary despite the presence of the identical mutation (even within the same family). Complete and partial androgen insensitivity associated with the same AR mutation can occur in siblings.[297] Different missense mutations at the same position can also be associated with differing phenotypes.[298,299] Complete loss-of-function mutations and premature termination codons are typically associated with complete androgen insensitivity.[300] Partial loss-of-function mutations are typically missense mutations. Receptors with mutations in the DBD bind ligand normally but fail to transactivate target genes. Mutations in the LBD of the AR gene can be associated with decreased affinity for ligand, increased instability of the hormone-receptor complex, or increased susceptibility of the receptor to thermal denaturation. In addition to hormone determinations, diagnostic evaluation may include DNA sequence analysis of the AR gene (www.genetests.org and http://www.androgendb.mcgill.ca).

Phosphorylation, acetylation, ubiquitylation, and sumoylation are post-translational modifications that influence AR transactivational function. The DNA-binding domain (DBD) contains two zinc fingers that interact with DNA. X-ray crystallographic studies indicate that the three-dimensional structure of the ligand-binding domain (LBD) consists of 12 α-helixes that form the ligand-binding pocket. Kinetic and biochemical assays with molecular dynamic simulations of mutations identified in patients with CAIS indicate that the position of helix 12 is crucial to AR function.[301]

AR transcriptional activity also depends on other proteins including coactivators and corepressors. These other proteins presumably modulate physical interactions linking the basal transcription machinery, the ligand-receptor complex, and chromatin. For example, a missense AR mutation altered the interaction of AR with the melanoma

antigen A-11 (MAGE-11) protein by interfering with the stimulatory effects of the coregulator.[302,303]

In addition to androgen sensitivity, Kennedy disease (also known as spinal and bulbar muscular dystrophy) is mapped to the AR locus. Kennedy disease is a progressive neurodegenerative disorder with onset in the thirties or forties. This disorder is associated with excessive expansion of the CAG polyglutamine trinucleotide repeat region in exon 1 of AR.[304] Repeat lengths greater than 35 are associated with spinal and bulbar muscular atrophy. In Kennedy disease, aberrant degradation of misfolded AR generates insoluble aggregates leading to cellular toxicity. However, the precise mechanism responsible for the neuropathy remains elusive.[305] Mild symptoms of androgen insensitivity can be detected with slight decreases in AR mRNA and protein concentrations.

MULLERIAN DUCT ABNORMALITIES

Persistent Mullerian Duct Syndrome

Persistent Mullerian Duct Syndrome is an autosomal recessive disorder due to mutations in AMH or its receptor (AMH-RII).[306] The phenotypes of patients with AMH or AMH-RII mutations are comparable. AMH is a member of the TGF-β family and signals through two different interacting membrane-bound serine/threonine receptors. The ligand, AMH, binds to the type II receptor which leads to recruitment and phosphorylation of a type I receptor. The type II receptor is specific for AMH, whereas there are multiple subtypes of the type 1 receptors. AMH concentrations are low among patients with mutations in the AMH gene. Among patients with AMH-RII mutations, AMH concentrations are normal or elevated. Females who carry mutations on both AMH alleles appear to have normal fertility.

The typical clinical features of PMDS include cryptorchidism, testicular ectopia associated with inguinal hernia, and hernia uteri inguinalis. Testicular differentiation is usually normal, but the male excretory ducts may be embedded in the Mullerian duct remnants or incompletely developed. Infertility may ensue secondary to cryptorchidism, intertwining of vas deferens and uterine wall, or lack of proper communication between the testes and excretory ducts. Testicular torsion is not uncommon because the testes may not be anchored properly to the bottom of the processus vaginalis.

Mullerian Duct Abnormalties in 46,XX Individuals

Mayer-Rokitansky-Küster-Hauser syndrome refers to congenital absence of the vagina associated with uterine hypoplasia or aplasia. Primary amenorrhea is the typical presentation. Magnetic resonance imaging (MRI) is helpful in the diagnosis and management.[307] Renal anomalies and skeletal malformations may be present. Unilateral renal agenesis was found in 29.8% of cases of Mullerian duct anomalies on MRI.[308] No single gene defect has been identified. Rather, mutations in WNT4, LHX1, and several chromosome regions have been detected.[309] The aggregation of Mullerian duct aplasia, renal aplasia, and cervico-thoracic somite dysplasia has been labeled MURCS syndrome. Mullerian duct hypoplasia has been associated with facio-auriculo-vertebral anomalies such as Goldenhar syndrome.[310]

Transverse vaginal septa can occur sporadically or in association with other features, such as polydactyly in the McKusick-Kaufman syndrome, which is associated with mutations in the MKKS gene located at chromosome 20p12.[311] Mutations in the MKKS gene are also associated with Bardet-Biedel type 6.[311] Because of the high frequency associated anomalies, careful physical examination for skeletal malformations and renal sonography should be included in the diagnostic evaluation of women with abnormal development of the Mullerian duct system.

HOXA GENES

Hand-foot-genital syndrome is characterized by genitourinary tract malformations and distal limb anomalies. Genital anomalies include Mullerian duct anomalies in females and hypospadias with or without chordee. The typical limb abnormalities are hypoplasia of the first digit, shortening of the carpal and tarsal bones, and clinodactyly of the fifth digit. The inheritance pattern is autosomal dominant. Mutations have been identified in the HOXA13 gene in association with this syndrome.[312]

MICROPHALLUS, HYPOSPADIAS, AND CRYPTORCHIDISM

Hypospadias

Hypospadias is a congenital hypoplasia of the penis characterized by ventral displacement of the urethral meatus. It is often associated with chordee, cryptorchidism, and additional congenital anomalies. The reported incidence ranges from 1 in 100 to 1 in 1000. Familial hypospadias has been described. Genes involved in early genital tubercle patterning include BMP4, BMP7, HOXA4, HOXB6, FGF8, FGF10, and FGFR2. Deletions involving 19q13 are associated with intrauterine growth retardation, microcephaly, postnatal growth retardation, clinodactyly, and hypospadias. The Wilms tumor interacting protein (WTIP) is located in the deleted region.[313]

Cryptorchidism

During sexual differentiation, the gonads are positioned between two structures: the cranial suspensory ligament and the gubernaculum. Testicular descent is divided into two phases: intraabdominal and inguinoscrotal. Factors involved in gubernacular development during the intraabdominal phase include INSL3 and its receptor, LGR8/RXFP2. INSL3 is secreted by Leydig cells. Its receptor, LGR8, is a leucine-rich G-protein–coupled receptor expressed by the gubernaculum. By 13 or 14 weeks of gestation, the gubernaculum anchors the testis to the internal inguinal ring.[314] At approximately 22 to 25 weeks of gestation, the testes and epididymides are located at the internal rings of the inguinal canal. Androgen action during the intraabdominal phase

appears to be limited to regression of the cranial suspensory ligament. In females, the cranial suspensory ligament persists as the suspensory ligament of the ovary. Testicular descent through the inguinal canal is usually accomplished by the end of seventh month of gestation, with completion of the inguinoscrotal phase by the end of week 35.[315]

Cryptorchidism (undescended testes) is the most common disorder of sexual differentiation, affecting 3% of male infants.[316] Cryptorchidism can be associated with decreased number of germ cells, impaired germ cell maturation, and decreased number of Leydig cells.[317] In some instances of unilateral cryptorchidism, abnormal histology is apparent in the contralateral normally descended testis.[318] However, it is unclear if these features represent consequences or causes of cryptorchidism. In a prospective randomized study, orchidopexy at 9 months of age results in greater testicular volume and increased number of germ cells compared to orchidopexy at 3 years of age.[319]

Because spontaneous descent often occurs during infancy, the prevalence decreases to 1% by 6 months of age.[319] Cryptorchidism has been associated with hypothalamic hypogonadism, aberrant testicular differentiation, impaired testosterone biosynthesis, androgen insensitivity, holoprosencephaly, abnormal AMH production or action, abnormalities affecting INSL3/LGR8 function, and possibly environmental factors.[4] Other associations include prune belly syndrome, bladder exotrophy, and renal anomalies. Cryptorchidism is also a feature of many syndromes (Table 5-2). Maternal diabetes mellitus, including gestational diabetes, may be a risk factor.

Heterozygous missense INSL3 mutations have been identified in patients with cryptorchidism.[320] Mutations have also been identified in the LGR8 gene in males with cryptorchidism. Sequence variants have been identified in the HOXA10 gene in boys with cryptorchidism.[321] Yet, mutations in INSL3, LGR8, or HOXA 10 are rare causes of isolated cryptorchidism. Typically,

TABLE 5-2 **Disorders Associated with Small Penis or Cryptorchidism in Males**

Disorder	Gene	Human Phenotype
Aarskog-Scott syndrome	FGD1	Mental retardation, shawl scrotum, short stature
Börjeson-Forssman-Lehman syndrome	PHF6	Mental retardation, epilepsy, hypogonadism
Carnevale syndrome	COLEC11	Blepharophimosis, blepharoptosis
Cornelia de Lange syndrome	NIPBL	Low anterior hairline, arched eyebrows, synophrys, mental retardation, growth retardation
Holoprosencephaly		Holoprosencephaly, seizures, hypopituitarism, diabetes insipidus
• HPE1	21q22.3	Holoprosencephaly, seizures, hypopituitarism, diabetes insipidus
• HPE2	SIX3	Holoprosencephaly, seizures, hypopituitarism, diabetes insipidus
• HPE3	SHH	Holoprosencephaly, seizures, hypopituitarism, diabetes insipidus
• HPE4	TGIF	Holoprosencephaly, seizures, hypopituitarism, diabetes insipidus
IFAP Syndrome	MBTPS2	Ichthyosis follicularis, atrichia, photophobia
Johanson-Blizzard syndrome	UBR1	Short stature, SGA, microcephaly, congenital heart disease
Lenz-Majewski hyperostosis syndrome	NK	Mental retardation, progressive skeletal sclerosis, severe growth retardation
Lowe syndrome	OCRL	Congenital cataracts, mental retardation, renal failure
McKusick-Kaufman syndrome	MKKS	Congenital heart disease, renal anomalies, vaginal anomalies in females
Meckel-Gruber	MKS1	Cystic renal disease, CNS malformation, liver anomalies
Miller-Dieker syndrome	17p13.3	IUGR, microcephaly, lissencephaly
Multiple pterygium syndrome, Escobar variant	CHRNG	Webbing, arthrogryposis
Myotonic dystrophy	DMPK	Muscular dystrophy, cataracts
Noonan syndrome	PTPN11	Short stature, hypertelorism, congenital heart disease, bleeding diathesis
Pfeiffer	FGFR1, FGFR2	Craniosynostosis, skeletal anomalies
Popliteal pterygium syndrome	IRF6	Cleft lip, cleft palate, lower lip cysts, spina bifida occulta
Prader-Willi syndrome	NDN, SNRPN	Decreased fetal activity, hypotonia, obesity, short stature
Robinow syndrome	WNT5A, ROR2	Mesomelic limb shortening, hypertelorism
Rubinstein-Taybi syndrome	CREBBP	Microcephaly, short stature, broad thumbs, dysmorphic facial features
Seckel syndrome, type 1	ATR	Bird-headed facial appearance, IUGR, ataxia-telangiectasia
Simpson-Golabi-Behmel, type 1	GPC3	Pre- and postnatal overgrowth, coarse facies, congenital heart disease
Townes-Brocks syndrome	SALL1	Microcephaly, large ears, congenital heart disease, renal anomalies
VATER/VACTERL syndrome		Spectrum of anomalies including vertebral defects, anal atresia, tracheoesophageal fistula, renal anomalies
Weaver	NSD1	Overgrowth, developmental delay

the testes of patients with androgen insensitivity have completed the intraabdominal phase but fail to undergo inguineoscrotal descent because this second phase is androgen dependent. However, the more complete the androgen insensitivity the greater likelihood of finding abdominal testes. Exposure of XX fetuses to androgen does not promote significant ovarian descent in humans, as evidenced by normal ovarian position in females with congenital adrenal hyperplasia.[322]

HYPOGONADOTROPIC HYPOGONADISM

Hypogonadotropic hypogonadism associated with GnRH deficiency is characterized by a spectrum of reproductive, olfactory, and non-reproductive clinical features. Inheritance patterns include X-linked, autosomal dominant, and autosomal recessive. Nevertheless, sporadic cases are more common than inherited forms. Males infants with hypogonadotropic hypogonadism may present in the newborn period with microphallus and/or cryptorchidism. Additional anterior pituitary hormone deficiencies may be present. Genital ambiguity would not be anticipated because placental hCG secretion is unaffected. Decreased gonadotropin secretion presumably results in decreased testosterone secretion such that microphallus and cryptorchidism can occur.

The 1000 to 2000 GnRH neurons that reside in the postnatal hypothalamus originate in the olfactory placode and migrate during early fetal development from the nose through the forebrain to the hypothalamus. Investigation of families with inherited hypogonadotropin hyponadism has led to identification of specific genes involved in this process (Table 5-3). Kallmann syndrome is the eponym used for the X-linked recessive form of hypogonadotropic hypogonadism associated with anosmia due to failed migration of GnRH neurons from the olfactory placode into the forebrain along branches of the vomeronasal nerve.[323] Olfactory tract hypoplasia or aplasia has been found on MRI. The molecular basis of this X-linked form is mutations in the Kallmann (KAL) gene (located at Xp22.3). This gene escapes X-inactivation, codes for a 680-amino-acid protein, and helps target GnRH neurons to the hypothalamus.

Mutations in the GnRH receptor (GNRHR), fibroblast growth factor receptor 1 (FGFR1), FGF8, KISS1, KISS1R, NELF, GNRH1, and GPR54 genes are also associated with hypogonadotropic hypogonadism.[324-327] More recently, mutations in the genes coding for prokineticin receptor-2 (PROKR2) and its ligand [prokineticin-2 (PROK2)] have been associated with hypogonadotropic hypogonadism.[327] Mutations in TAC3 and its receptor TACR3 are associated with hypogonadotropic hypogonadism; the prevalence of microphallus among males carrying TACR3 mutations is high.[328] The Charge syndrome is another disorder associated with genital hypoplasia; addition features include ocular coloboma, heart defects, choanal atresia, short stature, and hearing loss. The Charge syndrome is associated with mutations in the chromodomain helicase DNA binding protein 7 (CHD7) gene.[329] GnRH deficiency can be due to mutations in several genes (an oligogenic disorder).[330,331]

TABLE 5-3 **Monogenic Disorders Associated with Hypothalamic Hypogonadism**

Gene	Location	Associated Phenotype
KAL1	Xp22.3	Anosmia, renal anomalies
FGFR1	8p11.2-p11.1	Anosmia, cleft lip/palate
FGF8	10q24	Anosmia, cleft lip/palate
NELF	9q34.3	Anosmia
PROK2	3p21.1	Anosmia/normosmia
PROKR2	20p13	Anosmia/normosmia
GNRH1	8p21-p11.2	Normosmia
KISS1	1q32	Normosmia
KISS1R	19p13.3	Normosmia
TAC3	12q13-q21	Normosmia
TACR3	4q25	Normosmia
SOX2	3q26.33	Optic nerve hypoplasia
HESX1	3p21.2-p21.2	Hypopituitarism (septo-optic dysplasia)
PITX2	4q25-q26	Hypopituitarism (Rieger syndrome)
PROP1	5q	Hypopituitarism
LHX3	9q34.4	Hypopituitarism

ROBINOW SYNDROME

Robinow syndrome is characterized by short stature, mesomelic limb shortening, hypertelorism, mandibular hypoplasia, irregular dental alignment, and hypoplastic external genitalia. Both autosomal dominant and autosomal recessive inheritance patterns have been observed. Heterozygous loss of function mutations in WNT5A have been identified in patients with the autosomal dominant form.[332] Loss-of-function mutations in the gene encoding the tyrosine kinase-like orphan receptor 2, ROR2, have been identified in the more severe autosomal recessive form. Hemivertebrae and scoliosis are found more often in patients with the recessive form whereas supernumerary teeth are found almost exclusively in the dominant form.[333] ROR2 has been identified as a putative receptor for WNT5A.

WARBURG-MICRO SYNDROME

Warburg-Micro syndrome is a heterogenous disorder associated with congenital cataracts, microphthalmia, postnatal microcephaly, developmental delay, micropenis, hypoplasia of the corpus callosum, and cryptorchidism. Mutations have been identified in several genes, including RAB3GAP1, RAB3GAP2, and RAB18.[334-336]

MAMLD1

The mastermind-like domain containing 1 (MAMLD1) gene was identified during studies to identify the genetic basis of X-linked myotubular myopathy. This gene is also known as chromosome X open reading frame 6

(CXorf6).[337] Mutations and polymorphisms have been identified in some patients with micropenis, bifid scrotum, and hypospadias.[338,339]

ENVIRONMENTAL DISRUPTORS

Prenatal treatment with diethylstilbestrol (DES), a nonsteroidal synthetic estrogen, has been associated with urogenital abnormalities of both male and female fetuses with cryptorchidism occurring in 46,XY fetuses.[340,341] It has been speculated that the frequency of cryptorchidism and poor semen quality is increasing because exposure to endocrine disruptors in the environment has increased.[342] The genital ambiguity, described in three 46,XY infants born in heavily agricultural areas, was attributed to fetal exposure to endocrine disruptors especially because no mutations were detected in the *SRY* or SRD5A2 genes.[342] Although no definite causation has been found, various environmental substances such as herbicides, fungicides, pesticides, and plasticizers have been considered to be potential endocrine disruptors. Potential mechanisms include binding to nuclear hormone receptors modulating gene expression or epigenetic changes. Reliable evidence confirming detrimental environmental effects on genital development is lacking.[343]

OTHER DISORDERS

The VACTERL association (VA) is characterized by several anomalies. These abnormalities include vertebral anomalies, anal atresia, cardiovascular malformations, tracheoesophageal fistula and/or esophageal atresia, renal anomalies, limb anomalies, and/or genital ambiguity. Mullerian hypoplasia/aplasia, renal agenesis, and cervicothoracic somite dysplasia (MURCS association) is characterized by primary amenorrhoea. Features of this disorder can include absence of uterus and fallopian tubes, cervical spine abnormalities, and renal anomalies. Complete absence of penis also known as aphallia is rare and may be associated with additional congenital anomalies of the genitourinary and gastrointestinal systems.

EXSTROPHY OF BLADDER

Bladder exstrophy is a primary field defect involving the pelvis, urinary tract, and external genitalia and should not be considered a disorder of sex development. Exstrophy of the cloaca is characterized by persistence of a common cloaca associated with failure of fusion of the genital tubercles. Spinal abnormalities may be present.

DIAGNOSIS

History

A detailed family history should be obtained. The family history should include ascertainment of unexplained infant deaths, consanguinity, and infertility. Infants with congenital adrenal hyperplasia may have died prior to diagnosis. Many DSDs are inherited as autosomal-recessive disorders. Infertility and gynecomastia may represent milder phenotypes for some DSDs. For X-linked disorders such as androgen insensitivity, there may be affected maternal family members (i.e., either amenorrheic or infertile aunts or partially virilized uncles). Pertinent questions include prenatal exposure to exogenous or endogenous androgens, estrogens, or potential endocrine disruptors. Maternal virilization during pregnancy should be queried.

Physical Examination

DSDs encompass a spectrum of physical findings. The specific physical findings range from micropenis, hypospadias, undescended testes, minimal clitoromegaly, and scrotalized labia to more extensive forms of genital ambiguity. Severe clitoromegaly with posterior labial fusion in an 46,XX patient may be difficult to distinguish from perineal hypospadias, undescended testes, and a bifid scrotum in a 46,XY individual. During the physical examination, attention should be focused on phallic size, symmetry of the external genitalia, presence and location of palpable gonads, and any additional anomalies.

The extent of virilization should be carefully documented, recording the configuration, stretched dorsal length, and diameter of the phallus (including the glans penis). The location of the urethral opening, degree of labiourethral fold fusion, and extent of labioscrotal fold fusion should also be noted. Labioscrotal folds fuse from posterior to anterior such that the appearance extends from posterior labial fusion, a partially fused hemiscrota, to completely fused scrotum with labiourethral fusion extending to a midline urethral opening. The position of the urethra should be noted, as well as whether one or two perineal openings are present.

Gonadal or adnexal structures may be identified upon careful palpation for content of the labioscrotal structures, scrotum or labia majora, inguinal region, and the lower abdomen. The groin area may be "milked" to maneuver the testis into the scrotum. The absence of palpable testes may indicate a genetic female with virilization, as occurs with adrenal hyperplasia or a genetic male with undescended or absent testes. Although structures palpated within the labioscrotal folds are usually testes, ovaries or even the uterine cervix can be found within the labioscrotal folds. Testes typically have a characteristic ovoid structure.

Symmetry or asymmetry of external genital differentiation may provide clues to the etiology of the genital ambiguity (Figure 5-6). Unilateral structures with asymmetry of other genital structures suggests ovotesticular or 45X/46,XY DSDs and is often associated with unilateral gonadal maldescent. Asymmetry implies differing local influences, which often reflect abnormalities in gonadal differentiation (Figures 5-6 and 5-7). Repeated examinations may be beneficial for diagnostic precision.

Penile length measurements extend from the tip of stretched penis from the pubic ramus. Normal length depends on gestational age, the lower limit (approximately –2.5 SD) at term being 2.0 cm. An isolated micropenis can be a consequence of decreased testosterone exposure in the second half of gestation due to Leydig cell failure, LH

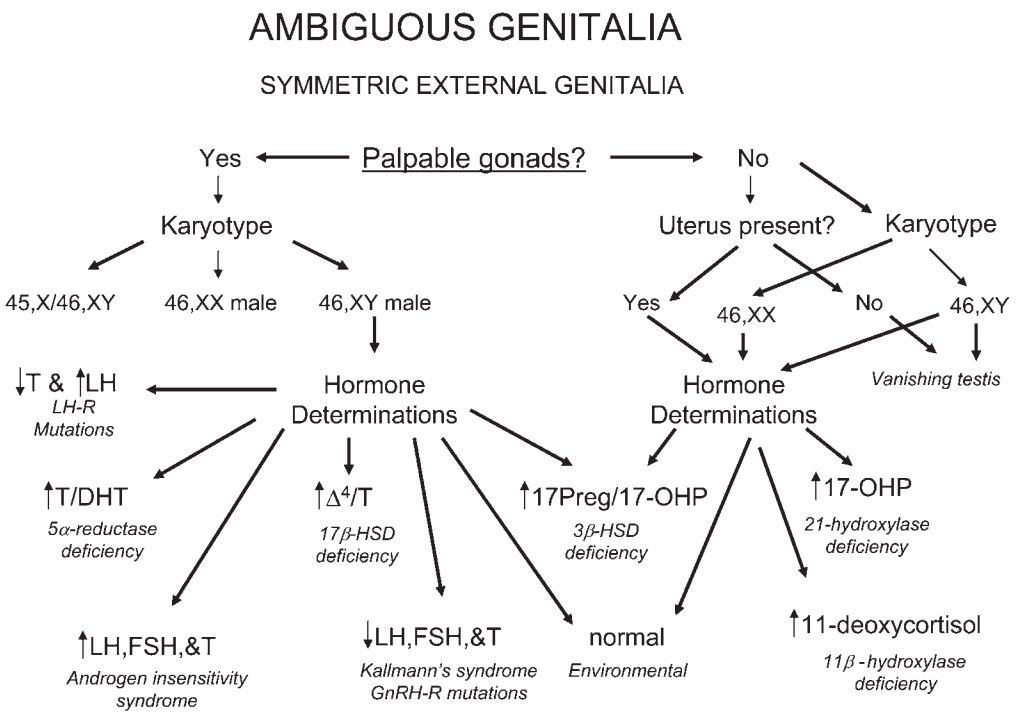

FIGURE 5-6 ■ Algorithm for the approach to the child with symmetric genital ambiguity. The configuration of the labioscrotal folds and presence/absence of palpable gonads is comparable on both sides. The presence or absence of palpable gonads directs the initial laboratory evaluation. Ultrasound examination to determine whether a uterus is present is helpful. For example, symmetric fusion of the labioscrotal folds, nonpalpable gonads, and presence of a uterus provide strong circumstantial evidence for the diagnosis of a virilized female with congenital adrenal hyperplasia.

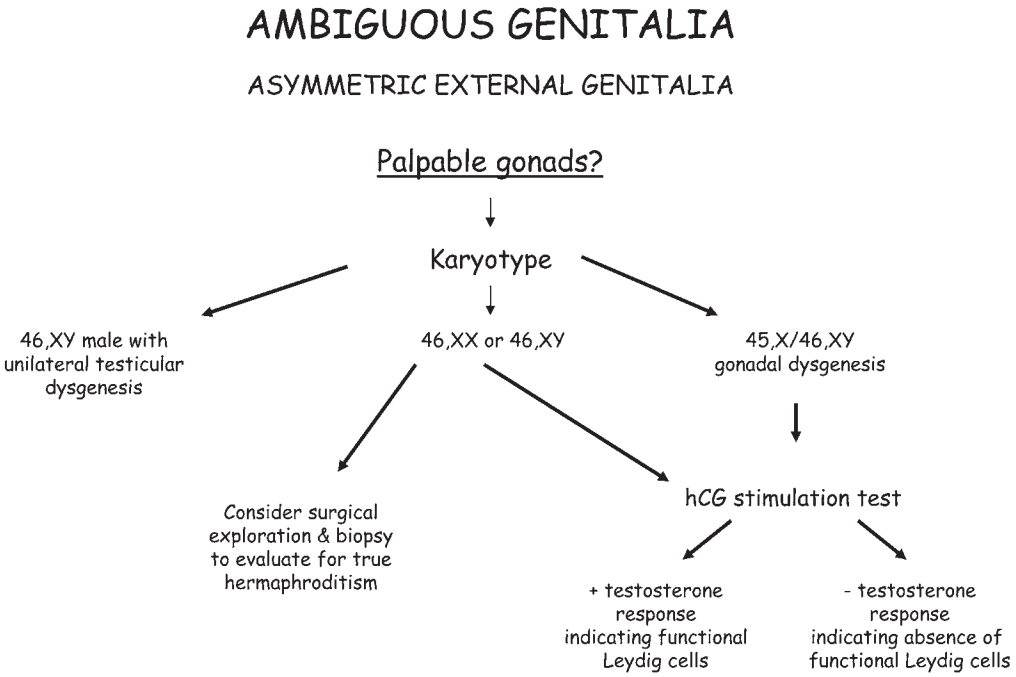

FIGURE 5-7 ■ Algorithm for the approach to the child with asymmetric genital ambiguity. In this instance, the labioscrotal folds may appear different or a gonad is palpable only on one side.

deficiency, androgen insensitivity syndrome, LHCGR mutations, or GH deficiency. A micropenis with hypospadias suggests a broader range of DSDs.

Clitoral length is usually less than 1.0 cm, although rare variations exist. Measurement of the clitoris requires a careful estimate of the proximal end and careful exclusion of overlying skin. The location of the urethral opening should be ascertained by visualization, witnessing the urinary stream, or with careful insertion of a firm catheter. If urination is observed, force, diameter, and direction of the urinary stream should be noted. The position of the inserted catheter may also provide crucial initial information.

If directed toward the anal opening and palpable under the perineal skin, the catheter is likely in a urogenital sinus as occurs often with virilization of a 46,XX fetus secondary to 21-hydroxylase deficiency. However, a penile urethra is anticipated if the catheter is directed anteriorly and is nonpalpable.

The anogenital ratio is measured as the distance between the anus and the posterior fourchette divided by the distance between the anus and the base of the phallus. If the ratio is >0.5, this suggests a component of female differentiation and hence virilization with posterior labial fusion.[344] Because pelvic ultrasound is part of the initial laboratory assessment, a rectal examination may not be necessary. If present, a midline uterine cervix can often be palpated upon rectal exam.

The Prader scale is often used to classify the appearance of the external genitalia: (1) normal female genitalia with clitoromegaly, (2) partial labial fusion and clitoromegaly, (3) labioscrotal fusion so that there is a single opening from the urogenital sinus and clitoromegaly, (4) fusion of labioscrotal folds so that the single opening is at the base of the phallic structure, and (5) complete male virilization with penis-size phallus, complete labial fusion, and meatus on the glands. A recent description extends this traditional Prader classification to include urogenital sinus characteristics by defining the vaginal confluence in relation to the bladder neck and the meatus.[345]

In addition to the genital examination, the examination should include weight, length, and other features to ascertain whether findings are consistent with gestational age particularly in the apparent female because the clitoris is more prominent in preterm infants in that there is scant subcutaneous fat and clitoral growth is completed before the last trimester of fetal life.[346] A careful examination includes inspection for additional dysmorphic features because genital ambiguity may occur in association with other anomalies. These include midline facial defects, head size, and ear and digital anomalies. Bladder exstrophy and epispadias represent a non-endocrine malformation of the urologic system. Infants with congenital adrenal hyperplasia, both male and female, may manifest hyperpigmentation of the genitalia and nipples due to ACTH hypersecretion.

Laboratory Studies

Initial laboratory studies to assess genital ambiguity should include an abdominal/pelvic ultrasound and karyotype. The ultrasound will provide information regarding the presence or absence of a uterus. Information regarding the size and location of the gonads and adrenals may be obtained on ultrasound. However, lack of visualization of gonads on ultrasound examination does not indicate absence of gonads. When gonads are not palpable, the external genitalia are symmetrically ambiguous, and a uterus and possibly ovaries are present, the most likely diagnosis is a virilized 46,XX fetus with congenital adrenal hyperplasia. However, the possibility of markedly dysgenetic testes cannot be excluded. If the differential diagnosis based on the presentation includes congenital adrenal hyperplasia, the initial laboratory studies should include electrolytes, plasma renin activity, and serum 17-hydroxyprogesterone and cortisol levels.

The karyotype is essential to determine chromosomal sex even if prenatal chromosome testing was performed. In general, peripheral blood karyotypes are sufficient. However, the patient may be a mosaic with one or more additional cell lines restricted to gonadal tissue.[347] Chromosomal microarray analyses are increasingly available and may identify submicroscopic genomic changes.[348]

Other initial studies depend on the physical findings. If the external genitalia are symmetrically virilized to any degree in the absence of palpable gonads, particularly if a normal uterus is present, additional studies should be directed toward causes of virilization of a female infant. Because 21-hydroxylase deficiency is the most common cause of virilization and genital ambiguity in 46,XX infants, initial laboratory studies should include determination of 17- hydroxyprogesterone concentrations. Generally, 17-OHP concentrations should be measured no earlier than 48 to 72 hours of age because of the potential for false positive results which may be due to cross-reacting steroid sulfates.[349] Nevertheless, extremely elevated 17-OHP concentrations may be detected at earlier time points in infants with classical CAH. If one or both gonads can be palpated, the intent of screening studies is to determine the adequacy of androgen synthesis and androgen action in a male infant. Determination of LH, FSH, and testosterone concentrations in infancy provides information regarding the function of the testes and the HPG axis (Table 5-3).

The pattern of steroid hormone concentrations provides evidence for specific defects in steroidogenesis (Table 5-3). The diagnosis of congenital adrenal hyperplasia due to 21-hydroxylase deficiency is confirmed by finding elevated 17-hydroxyprogesterone concentrations. Typically, 17-hydroxyprogesterone concentrations are greater than 10,000 ng/dL (300 nmol/L) in the affected neonate. For 11β-hydroxylase deficiency, 11-deoxycortisol and 17-hydroxyprogesterone concentrations are elevated. For 3β-hydroxysteroid dehydrogenase deficiency, pregnenolone, 17-hydroxypregnenolone, and DHEA concentrations are typically elevated. Steroid concentrations are low for patients with congenital lipoid adrenal hyperplasia and CYP11A1 mutations. When salt-losing forms of congenital adrenal hyperplasia are included in the differential diagnosis, serum electrolytes and plasma renin activity should be monitored. Typically, hyponatremia and hyperkalemia are not present at birth and develop during the first week of life.

Newborn screening programs have been established in all states and many countries to identify infants with classic congenital adrenal hyperplasia. Many screening programs measure whole-blood 17-hydroxyprogesterone concentrations eluted from a dried filter paper blood spot.[350] Whereas false negative 17-hydroxyprogesterone results are uncommon, slightly increased whole-blood 17-OHP concentrations are detected often enough (especially in preterm infants) to complicate clinical decision making regarding affected status and need to initiate glucocorticoid therapy. Etiologies of slightly increased 17-OHP concentrations include prematurity,

cross-reacting steroids, sampling prior to 48 to 72 hours of age, heterozygosity for 21-hydroxylase deficiency, and late-onset congenital adrenal hyperplasia.

To avoid an excessive number of false-positive screening results, the cutoff levels are typically selected to identify all infants with classic salt-losing or simple virilizing forms—often missing those infants with late-onset congenital adrenal hyperplasia. Improved specificity can be achieved by use of additional procedures such as organic extraction, chromatography, or LC/MS analysis.[351] The caveat for LC/MS is the need for precise quality control. Prenatal or neonatal treatment with glucocorticoids can result in a false negative screening result.[351] If the differential diagnosis includes CAH, specific laboratory testing is warranted even if the newborn screen results are reported as negative for 21-hydroxylase deficiency. GC/MS analysis of urinary steroids can also be used to diagnose other disorders of steroidogenesis.[352,353] In the future, GC/MS urine analyses may become standard of care in the management of patients with CAH.[353]

For the milder forms of congenital adrenal hyperplasia or other disorders affecting adrenal steroidogenesis, ACTH stimulation testing may be necessary to confirm the diagnosis. After a basal blood sample has been drawn, synthetic ACTH (0.25 mg) can be administered by intravenous bolus or intramuscular injection. A second blood sample to measure ACTH-stimulated hormone response can be obtained 30 or 60 minutes later. The milder forms of congenital adrenal hyperplasia generally do not affect external genital differentiation and are therefore not usually associated with genital ambiguity. Infants with late-onset congenital adrenal hyperplasia are generally not detected through newborn screening programs, presumably because the whole-blood 17-OHP concentrations determined from the newborn screening filter paper are lower than the values used as cutoffs.

In addition to the diagnostic evaluation for disorders of steroidogenesis, hormone measurements in the immediate neonatal period provide an index to the function of the HPG axis. Low testosterone and elevated gonadotropin concentrations in a 46,XY infant with ambiguous genitalia suggest inadequate testosterone biosynthesis. Elevated testosterone and gonadotropin concentrations in an infant with female external genitalia, bilateral labial masses, and 46,XY karyotype are consistent with the diagnosis of androgen insensitivity.

Measurement of AMH provides another assessment of testicular function because AMH concentrations reflect Sertoli cell function. AMH concentrations are sexually dimorphic, with high values in boys (20-80 ng/mL) during the first six years of life and low values in girls.[354] Thus, in the patient with nonpalpable gonads and absence of Mullerian structures AMH concentrations may help distinguish between anorchia and cryptorchidism.[355] In addition, AMH concentrations can be helpful in disorders of testicular dysgenesis or in virilized females to determine the presence of testicular tissue.[356] Inhibin B concentrations, lower in females than in males, provide another marker of Sertoli cell function.[356,357]

Assessment of the ability of a gonad to secrete testosterone may be helpful, especially for patients with evidence of testicular tissue by palpation or ultrasound and AMH levels indicating testicular tissue. This can be done by administering hCG and measuring hormone responses. To assess hormone responses, doses of 1,000 to 1,500 units can be injected subcutaneously either daily or every other day for one to five days—with blood sampling on the day after the last injection. Hormone determinations should include androstenedione, testosterone, and dihydrotestosterone.[358] Testosterone concentrations should more than double, and the T/DHT ratio should be $<10{:}1$.[359] Intermittent injections can be given for up to three weeks to stimulate penile growth to demonstrate both testosterone secretion and target tissue responsiveness. Total dosage should not exceed 15,000 units of hCG.

Endoscopic studies can be used to locate the vaginal-urethral confluence in relation to the bladder neck and the single opening of the urogenital sinus. Using a cystoscope and catheter placement, these distances can be determined before or in conjunction with retrograde contrast studies performed to outline the urethra and to demonstrate (if present) the vagina, uterus, cervix, and uterine cavity. Such information is needed to plan for reconstructive surgery, to assess the risk of medical complications, and in certain instances to provide information to determine the sex of rearing. If such procedures are unhelpful, laparoscopy may be necessary to visualize and biopsy gonadal and internal genital structures. MRI may be helpful to define anatomic relationships.

Some patients with DSDs present at puberty with delayed puberty or primary amenorrhea. The triad of clitoromegaly, hirsutism, and primary amenorrhea suggests 17β-hydroxysteroid dehydrogenase, 5α-reductase, P450 oxidoreductase, aromatase, or mild virilizing forms of CAH.

Molecular genetic analyses have become increasingly available to determine and confirm the molecular basis of the genital ambiguity. Knowledge regarding the specific mutation enables more accurate genetic counseling for inherited disorders of sexual differentiation (http://www.genecards.org/). The genetics laboratory can often perform fluorescent in situ hybridization (FISH), for the *SRY* gene, or other detailed chromosomal tests such as CGH microarrays. For some DSDs, molecular genetic analysis of specific genes is available through commercial laboratories. Information regarding the particular details can be obtained from an NIH-funded web-based resource, Genetests (http://www.genetests.org). In some instances, genetic testing is available through research laboratories.

TREATMENT

While awaiting results of the initial laboratory studies and imaging studies if necessary, attention is focused on the main decision: the gender of rearing. In the ideal situation, there is a specific DSD team comprised of a pediatric surgeon or pediatric urologist with expertise in urogenital reconstructive surgery, a behavioral science

professional (psychologist, social worker, or psychiatrist), a pediatric endocrinologist, and a neonatalogist.[360,361] Using all available data, the DSD team educates the family and helps them decide on the gender of rearing. Guessing is not appropriate.[362] In many instances, gender assignment is apparent based on the initial physical examination and laboratory findings.

Initially, the neonatalogist may facilitate coordination of care and communication with the parents. Long-term management needs to be delineated. In addition to the appointments necessary to the patient's medical, surgical, and psychological needs, additional sessions may benefit the parents to address their questions and concerns about their child.[363] These evaluations should be performed promptly and often necessitate transfer of the infant to a tertiary care facility.

The parents need to participate in discussions and decision making regarding the options for sex of rearing and possible surgical interventions. Honest, sensitive, and candid discussions with the parents can only benefit the child. As the child matures, honest explanations regarding the medical condition are essential. The child should progress from a silent partner to a full participating member in this decision-making process, with the child's wishes taking precedence where appropriate.

Once the diagnosis is confirmed as specifically as possible, therapy is instituted. When a specific diagnosis has been confirmed, decision making and therapy can be guided accordingly. Considerations for medical care include sex of rearing, possible need for surgery and a timeline for planned surgery, plan for medical treatment, and timely and appropriate psychological counseling and support.

Sex of Rearing

Decisions regarding the appropriate sex of rearing are based on the specific pathophysiology, external genital features, internal reproductive system anatomy, prognosis for spontaneous pubertal development, capacity for sexual activity and orgasm, and potential for fertility.[364] Using modern techniques to assist fertility, the potential for fertility is more likely than in the past. Although current surgical techniques spare more of the neurovascular bundle of the phallus, surgery should be avoided except in those instances of severe ambiguity or markedly discordant genitalia to preserve sexual responsiveness.

In instances where a decision regarding sex of rearing is necessary, each child evaluated for genital ambiguity warrants careful consideration of the physical findings, laboratory information, and available outcome data. In most instances, children are raised in the gender consistent with the karyotype, but acknowledging that there are rare exceptions that favor sex reversal (gender reassignment). Limited longitudinal outcome studies are available regarding adult function and gender identity. Most patients who are 46,XY with CAIS identify themselves as female.

About a quarter of patients with PAIS are dissatisfied with the gender assignment, regardless of whether they are raised as male or female. The majority of patients with 5α-reductase deficiency identify as male, whereas about half of those diagnosed with 17β-hydroxysteroid dehydrogenase self-reassign from female to male.[365,366] The majority of virilized 46,XX individuals with CAH identify as female. Thus, in spite of the accumulating evidence that androgen exposure to the CNS alters general and cognitive behavior, much remains to be learned about the influences of nature and nurture on gender identity.[62,367,368]

Because the majority of 46,XX virilized females (primarily those with CAH) identify as female, this sex of rearing is usually recommended if the question arises in infancy. For virilized 46,XX patients with Prader stage 4 or 5 genitalia, the recent consensus conference felt that the outcome data was insufficient to support a sex of rearing as male. Yet, a recent report suggests that this possibility warrants consideration and may be an appropriate option for some situations.[369] For most virilized females with CAH, the primary issue is not gender assignment but questions regarding genital surgery.

To date, more information and knowledge is available about physical sexual development than about psychosexual cognitive development. The primary factors, critical steps, and sequence of psychosexual development are unclear. Traditionally, psychosexual development has been viewed as having three components: gender identity, gender role, and sexual orientation. The development of gender identity begins as an infant with the self-recognition that one is a boy or girl. Gender role develops during childhood as a result of society's expectations concerning behavior and is influenced by prenatal hormonal exposure.

Gender roles are defined in part by the messages society relays concerning appropriate and inappropriate male and female behavior. Gender role may subsequently shift and even become fluid, depending on the individual's reaction to the shifting expectations of society. How prenatal factors such as hormones and environmental exposures impact gender role has been difficult to ascertain. Sexual orientation may be apparent prior to puberty or not expressed until late in adult life, underlying the unknown influencing factors.

The effects of prenatal androgen exposure on gender identity are uncertain.[370,371] Prenatal androgen levels apparently influence gender-related behavior and cognitive function during childhood.[370] Yet, the impact on degrees of femininity and masculinity and cognitive function (spatial and verbal abilities) and handedness does not appear to persist into adult life.[372,373] Among virilized 46,XX individuals with CAH, an increased rate of homosexual orientation has been reported primarily based on self-reported sexual imagery and sexual attraction, with reports of actual homosexual involvement being less well documented.[374-377]

Some females with classic CAH are more likely to question their female gender,[378] and the reported incidence of sex reassignment from female to male is greater than in the general population.[379] Among 46,XX CAH patients with gender self-reassignment, it was judged that factors contributing to this change were not genotype or phenotype, but rather gender-atypical behavioral, self-image and body image, and development

of erotic attraction to women.[380] Other studies concluded that psychological adjustment was comparable between females with CAH and their unaffected siblings.[381] In another study, gender identity of girls with CAH was comparable to the control group.[382] In these studies, the impact of environmental influences cannot be separated from the effects of prenatal hormonal exposures.

Female gender of rearing is appropriate for 46,XY individuals with complete androgen insensitivity because virilization and fertility are unattainable. The lack of androgen responsiveness limits androgen effect on the developing CNS of individuals with CAIS. Conversely, the decision regarding gender of rearing for individuals with partial androgen insensitivity may be problematic because the extent of androgen impact on CNS development and the androgen responsiveness of the genital development are uncertain.[383] The extent of clinical response to exogenous testosterone may benefit this decision-making process. Testosterone responsiveness may be ascertained by assessing penile growth following one or more intramuscular injections of 25-mg testosterone depot formulations.

Among individuals with DSD associated with gonadal dysgenesis, hCG-stimulated testosterone secretion and clinical response facilitate the decision regarding gender of rearing. The genital phenotype, ability of the Leydig cell to secrete testosterone, and extent of genital virilization in response to androgen stimulation are indicators regarding the potential for spontaneous pubertal development and need for hormone replacement therapy. Nevertheless, in gonadal dysgenesis the impact of prenatal androgen exposure on gender development processes is often indeterminate and cannot be reliably predicted from routine diagnostic studies in the newborn period.

Generally, with the exception of CAIS, 46,XY individuals with fetal androgen exposure manifested as partial genital masculinization should be raised as males unless there are extenuating individual circumstances. Ideally, 46,XY infants with 17β-HSD3 or 5α-reductase deficiency will be diagnosed in the newborn period. Caution, reflection, and dialog are essential before those with a 46,XY, karyotype are assigned female because fetal androgen exposure appears to impact strongly on self-concept as male despite compromised external genital development.

Medical Treatment

With the exception of disorders affecting glucocorticoid and mineralocorticoid biosynthesis, most DSD conditions do not require specific medical therapy in infancy. At the time of expected puberty, patients with hypogonadism will need appropriate hormone replacement therapy. In general, hormone replacement therapy is initiated using low doses of the appropriate sex steroid hormone with incremental increases designed to mirror spontaneous pubertal development. It is helpful to review with families the anticipated frequency of outpatient visits and how the adequacy of replacement therapy will be assessed.

For females, induction of puberty involves low-dose estrogen therapy—usually initiated between 10.5 to 12 years of age to avoid excessive acceleration of skeletal maturation. The initial estrogen dosage is usually the lowest available, such as 0.3 mg of conjugated estrogens every other day or 5 μg of ethinyl estradiol daily. Transdermal estrogen preparations which provide 0.007-0.025 mg daily can be utilized. Transdermal patches may be used only at night in an effort to mimic spontaneous puberty.[384] Matrix transdermal patches can also be cut into smaller pieces to provide a lower estrogen dosage. Based on clinical response and the patient's perception, the dose of estrogen can be increased in 6- to 12-month intervals such that complete replacement doses and development are achieved within 3 years.

Therapy involves the addition of a progestational agent after 12 months of estrogen therapy or when withdrawal bleeding occurs, whichever occurs sooner. Thereafter, cyclic estrogen-progesterone therapy should be used. Once full pubertal development has been reached, the estrogen dosage should be the minimum that will maintain normal menstrual flow and prevent calcium bone loss (equivalent to 0.625 conjugated estrogen or 20 μg ethinyl estradiol). Options for cyclic estrogen-progesterone therapy include low-dosage estrogen birth control pills or estrogen-progestin transdermal patches.

Another regimen involves a daily oral estrogen regimen or the transdermal form for 21 days with the addition of progesterone, 5 to 10 mg of medroxyprogesterone acetate, or 200 mg of micronized progesterone daily added for 12 days (day 10 to day 21). This is followed by a week of no hormones. At this point, the replacement regimen may be extended so that less frequent withdrawal bleeding occurs. In the absence of a uterus, progesterone therapy becomes optional. Among patients with low circulating androgen levels, sexual hair growth and libido may be improved by administering small doses of DHEA or methyltestosterone. Gonadotropins hCG and/or hMG (human menopausal gonadotropin/recombinant FSH) are only used to stimulate ovulation or during assisted fertility attempts.

For males, testosterone hormone replacement typically begins at 12.5 to 14 years. In instances where the psychological impact is felt to be needed, therapy may be initiated one or two years earlier. If therapy is begun earlier to assure the patient concerning physical changes, the rate of skeletal maturation should be carefully monitored. Conversely, treatment may be delayed to allow for psychological or emotional maturity or catch-up growth. Testosterone therapy may be given by depot intramuscular injections or topically by a patch or gel. Depot testosterone (such as enanthate or cyprionate) is begun at a dosage 50 mg IM every four weeks, followed by increased dosing and frequency over about 3 years to a full replacement dosage of approximately 200 mg every 2 weeks. Availability of the gel in metered-dose pumps allows gradual increases of dosage from 1.25 g daily upward. Among those with differentiated testes and gonadotropin deficiency, assisted fertility techniques may involve intratesticular germ cell retrieval or hFSH/hLH stimulation.

For patients with CAH, carefully monitored hormone replacement therapy is essential.[385,386] The goal of glucocorticoid therapy is suppression of excessive adrenal androgen secretion while maintaining normal growth and development. Typically, oral cortisol doses range from 8 to 20 mg/m^2/day. This range is based on provision of 1.5 to 2 times the daily cortisol production rate, 7 to 12 mg/m^2/day. Oral fludrocortisone (e.g., Florinef) is commonly used for mineralocorticoid replacement for patients with salt-losing CAH. Patients with simple virilizing CAH may benefit from mineralocorticoid replacement. The typical dose is 0.1 mg administered as a single daily dose. Neonates and infants may require higher fludrocortisone doses as well as salt supplementation because of relative mineralocorticoid resistance, higher aldosterone production rates, and relatively lower sodium intakes. Topics of discussion with parents include how to crush and administer tablets, what to do if doses are accidentally missed, use of medical alert identification IDs, and when to administer "stress" dosages.

For children with CAH, adequacy of replacement therapy is monitored by periodic reassessment of growth velocity, extent of virilization, and salt craving. Laboratory monitoring may include serum androgen and 17-OHP concentrations, skeletal maturation, and 24-hour urinary 17-ketosteroid excretion. Androstenedione concentrations are useful to assess adequacy of glucocorticoid replacement, whereas 17-OHP concentrations are useful to assess for overtreatment. Determination of testosterone concentrations is helpful in girls and prepubertal boys. In pubertal and postpubertal girls, menstrual cyclicity is a sensitive indicator of hormone replacement therapy. Adequacy of mineralocorticoid replacement can be judged using plasma renin activity. Boys with CAH need to be regularly assessed by ultrasound for the development of testicular adrenal rest tumors; these rest tumors may be too small to palpate on clinical examination.[387]

At times of physiological stress (such as fever greater than 101° F, persistent vomiting, significant trauma, and surgical procedures), the glucocorticoid dose should be increased. In general, two to three times the usual dose is sufficient to prevent adrenal insufficiency. Higher doses may be necessary for surgical procedures. All families should have at home and be able to administer injectable hydrocortisone (e.g., Solu-Cortef) intramuscularly in case of medical emergencies. Recommended intramuscular doses are 25 mg for infants, 50 mg for children less than 4 years of age, and 100 mg for all others.

During surgical procedures, additional hydrocortisone can be administered either as continuous intravenous infusion or intramuscular injection. Intravenous normal saline (0.9% NaCl) can be used if oral mineralocorticoid replacement is not tolerated by the patient. While receiving glucocorticoid replacement therapy (and occasionally in the newborn period), physiologically stressed individuals with 11β-hydroxylase deficiency may develop hyponatremia and hyperkalemia and benefit from mineralocorticoid therapy. At times of physiologic stress, individuals with Smith-Lemli-Opitz syndrome or P450 oxidoreductase deficiency may benefit from glucocorticoid treatment.

Considerations with Regard to Surgery

For the virilized female patient with female sex of rearing, the extent of ambiguity in combination with the magnitude of clitoromegaly and posterior fusion must be carefully evaluated to determine whether genitoplasty, including clitoral reduction or clitoroplasty, should be considered. Another factor in the decision-making process is the location of the urethral outlet. If located high in the urogenital sinus, early surgery may be indicated to decrease the risk of recurrent urinary tract infections by providing a direct urinary outflow path. The current perspective is that girls with mild to moderate degrees of clitoromegaly do not need surgery because of the potential risk of compromising genital sensitivity. Currently, there is no consensus regarding clitoral size requiring surgery.[388] Despite surgery, lower urinary tract symptoms such as stress incontinence and incomplete bladder emptying may persist among female DSD patients and among males with hypospadias.[5]

One important point to share with parents of a virilized girl with CAH is that the stimulated genital tissues will regress after glucocorticoid therapy is begun. On one hand, the parents need to be informed that some (including patient advocacy) groups discourage genital surgery until the child is old enough to make her own decision. On the other hand, they must be empowered to make the choice with which they will be comfortable. This must be done with the understanding that their daughter may criticize them for this decision when she is older. Many parents of daughters with severe ambiguity still choose surgery.

If there is agreement between the interdisciplinary medical team and the parents for surgery, the surgery is generally performed as soon as feasible. If surgery is anticipated, the operation should be described in a manner understandable to the parents. An experienced surgeon should discuss the options, risks, and benefits of surgery including the innervation of the clitoris or penis and the surgical approach to be used to attempt to spare the neurovascular supply.[389,390] Although opinions vary as to whether surgery should be done in one or more stages and whether vaginal reconstruction should be attempted during infancy, the parents need to be informed that subsequent vaginoplasty or vaginal dilatation may be required after puberty. Among patients who underwent vaginal reconstructive surgery during infancy, the frequency of postoperative vaginal stenosis has been reported to range from 0% to 77%.[391] Therapeutic goals for vaginal reconstruction surgery include adequate sexual function with minimal need for continual dilatation or lubrication.[392] Girls with Mayer-Rokitansky-Kuster-Hauser syndrome and individuals with CAIS can achieve increased vaginal size with dilator treatment.[393]

For the undervirilized male, decisions concerning genital surgery and when it occurs belong to the parents until the patient reaches adolescence and adulthood. Most decide for surgery, except in the instances of minimal to moderate hypospadias. When discussing surgery with the parents, pertinent topics include common male concerns about the importance of being able to stand to urinate, adequacy of genital development, and capability

for sexual activities. With hypospadias, the location of the meatus does not necessarily indicate that fusion is complete to that point since there may be more proximal inadequate development of the corpus spongiosum and surrounding tissues. Thus, the extent of surgery may not be known until labiourethral fusion is better visualized at surgery. Because correction of hypospadias and chordee is generally performed in stages, this discussion also needs to cover the details of the surgical approach, the proposed schedule for follow-up visits, the likely number of surgical procedures, and the optimal age for each surgical stage. The surgeon should review the options, risks, and anticipated outcomes. If the precise location and differentiation status of the testes are unknown, the parents should be aware that exploration and biopsy may be performed. As would be anticipated, individuals with 46,XY DSD have sexual concerns regardless of gender of rearing. In addition to reconstructive genital surgery, potential confounding factors include self-esteem, genital appearance, infertility, need for hormone replacement therapy, and lack of adequate counseling and support likely influence adult outcome.[394]

Outcome studies reflect the results of the type of surgery and timing of surgery. While former surgical techniques resulted in impaired genital sensitivity,[395] it is as yet unclear whether current surgical techniques sparing the neurovascular supply to the clitoris will result in better outcomes. While it is anticipated (and hoped) that current surgical techniques will have better outcome, it will be years before this information is available. In the meantime, available outcome studies can be informative.

The goals of genital reconstruction surgery have been and continue to be a good cosmetic appearance and the potential for functionality involving sensitivity for sexual responsiveness. Function after surgery is related to severity of genital ambiguity at birth, extent of surgery, and complications of surgery. For example, among females diminished vaginal diameter correlated with greater prenatal virilization. Among 21-hydroxylase deficiency CAH females, the outcome of surgery appears to be related to the specific mutations. Those with the null genotype have more surgical complications and poorer scores regarding sexual function.[396] Available outcome data indicate that most postsurgical patients have a female gender identity. Yet, studies show that a greater portion of women with CAH, even those with non-classic CAH (NCAH), are sexually attracted to other women compared to the general population. However, long-term outcomes are not well documented. Among 46,XX DSD patients, those living as females indicated that they preferred early surgery and felt that a satisfactory sex life was possible.[397] Nonetheless, decreased sexual desire, difficulty achieving orgasm, and later sexual debut were common concerns. Fertility is possible for women with CAH; reduction of progesterone concentrations is one important factor in fecundity for women with classical forms of CAH.[398-400]

Most males with 46,XY DSDs are satisfied with long-term results of genitoplasty. Recurrent complaints include penile size, sexual activity, and urinary symptoms. There is considerable variation in masculinization and virilization.[401] Despite improved understanding of DSDs and openness with patients and families, quality of life issues have not been fully resolved.[401-403]

Risks for Gonadal Tumors

The aberrant fetal gonadal environment and subsequent anomalous germ cell differentiation is associated with the development of germ cell tumors. The presence of Y chromosome material increases the propensity risk for gonadal tumors. Thus, another consideration regarding the need for and timing of surgery is the relative risk for gonadal tumors.

In general, CIS or gonadoblastoma are the most common germ cell tumors. The prevalence reported for gonadoblastoma ranges from 15% to 30%, depending on age of the patient, gonadal histology, and diagnostic criteria used for CIS/gonadoblastoma. Gonadoblastomas are mixed germ cell sex cord-stromal tumors that arise in dysgenetic gonads, are composed of immature germ cells and sex cord-stromal cells of indeterminate differentiation, and precede the development of the more invasive neoplasms such as dysgerminoma, seminoma, and nonseminoma. Assessment of FOXL2 and SOX9 expression in the tumor tissue can help to discriminate between those with a Sertoli cell component from those with a granulosa cell component.[404]

Increased and prolonged expression of immunohistochemical markers, OCT3/4 and testis-specific protein Y-encoded (TSPY), is common in CIS and gonadoblastoma.[404] In one series, TSPY was abundantly expressed in germ cells within dysgenetic testes and undifferentiated gonadal tissue suggesting upregulation when germ cells are located in an unfavorable environment.[404] It is hypothesized that the normal germ cell maturation process is interrupted, resulting in prolonged expression of OCT3/4, erased genomic imprinting, and subsequent immortalization of the cell.[405,406]

In one series of patients with Turner syndrome, 14/171 (8%) were positive for Y-chromosomal material. Among these 14 patients, the prevalence of gonadoblastoma was 33%.[407] A meta-analysis of 11 studies, all using PCR methodology, found that 5% of patients with Turner syndrome showed positive results for Y chromosome material.[407] Frasier syndrome is also associated with gonadoblastoma.

The prevalence of germ cell tumors is lower in androgen insensitivity and disorders of androgen biosynthesis. Since the risk for malignancy appears to be low in childhood and early adolescence, patients with CAIS and their parents often choose to retain the gonads. However, accurate details regarding long term risk for malignancy are unknown at this time.[408] Limited sample size, ascertainment bias, inconsistent diagnostic criteria for malignant cells, and confusing terminology leave many questions to be answered. For example, which patients with DSD benefit from gonadal biopsy to assess risk for neoplasia? Another consideration is how many biopsies are necessary to be representative of the histology of the gonad. Laparoscopy and video-assisted gonadectomy are invaluable techniques when the risk for malignancy is high. Ultimately, the decision regarding gonadectomy

involves consideration of the patient's phenotype (internal and external genital anatomy), karyotype, gender of rearing, psychosocial factors, and gonadal histology.[409]

Transition from Pediatrics to Adult Care

Parents and pediatric healthcare providers envision that children with DSD will become productive adults who will find fulfillment and gratification in their lives. In view of the report from England regarding loss of follow-up of patients with CAH, a planned transition program from the pediatric healthcare team to the adult healthcare team is essential.[410] This planned transition process needs to consider the medical, psychosocial, educational, emotional, cognitive, and vocational needs of the young adult. Differences in expectations between pediatric and adult healthcare situations should be reviewed. Explanation of the specific details of his/her diagnosis with the young adult is essential.[411] For many of these patients, the specific details of their disorder were reviewed with the parents at the time of diagnosis when the individual was too young to participate in these discussions. The young adult needs to know the etiology, basic genetics, pathophysiology of his/her disorder, recurrence risk, and fertility status. The young adult, especially those requiring glucocorticoid replacement therapy, needs to understand the rationale for treatment.[411,412]

Psychological and Genetic Counseling and Support and Ethical Considerations

Longitudinal continuity of care and provision for support systems are essential because of the medical and psychological aspects of DSDs. If an experienced social worker, psychologist, or psychiatrist is available, careful assessment and counseling are invaluable throughout childhood and adolescence. Although most such cases of 46,XY DSD may not require medical therapy during early childhood, intermittent visits with the pediatric endocrinologist are helpful to address the patient's and parents' concerns, update parents concerning new therapy and outcome data, and ensure that appropriate psychological support needs are being met. These visits can foster a positive relationship between the child and the physician. Some parents may find disorder- specific support groups (e.g., AIS, www.aissg.org; CAH, www.caresfoundation.org; Turner syndrome, www.turnersyndrome.org) to be helpful.

Many DSD conditions are inherited. The most common inheritance patterns are autosomal recessive or X-linked traits. Genetic counseling is indicated because parents are often interested to learn about recurrence risks. Phenotypic heterogeneity occurs in some DSD disorders, so it may be appropriate to perform hormone determinations and genetic analyses (when available) for other family members.

Ethical principles and recommendations have been published in a effort to provide a comprehensive view of the perspective of clinicians, patients and families, based on the principles of fostering the well-being of the child and future adult, uphold their rights to participate in decisions that impact them now and later, and to respect family and parent-child relationships.[413]

CONCLUSIONS

Identification of genes involved in sexual differentiation has elucidated some of the molecular events responsible for normal and abnormal sexual differentiation. Knowledge of the genetic, hormonal, and environmental factors that influence sexual differentiation benefits the affected children, their parents, and their healthcare providers. This information enables better parental education regarding the etiology, natural history, and prognosis for their child. With understanding of factors that affect sexual differentiation, recurrence risks can be estimated.

The evaluation and subsequent management of a child with ambiguous genitalia is based on history, physical examination, and laboratory data. Understanding the family's background enables the medical team to discuss the child's sex development using terminology that they can understand at the time of diagnosis as well as during the following years. Initial diagnosis and management are the beginning of a long term relationship between the family and healthcare providers.

Despite the advances in characterizing the molecular basis of ambiguous genitalia, sensitivity and compassion demonstrated by the team of healthcare professionals in their interactions with the patient and family remain an essential aspect in the management of an infant with genital ambiguity. The initial evaluation and diagnostic processes are merely the beginning of an extended relationship with the child and family ultimately culminating in successful transition to adult care providers. Respectful and empathetic interactions foster development of the infant with genital ambiguity to become an adult able to live a contented life. We, the healthcare providers, need to remain cognizant that knowledge regarding all aspects of sex determination, sex development, and gender identity determinants remains to be elucidated such that management of individuals with DSDs will still involve uncertainties and likelihoods.[362]

Glossary of Genes

Gene	Name	Locus
AKR1C2	Aldo-keto reductase family 1 member 2	10p15.1
AKR1C4	Aldo-keto reductase family 1 member 4	10p15.1
AMH	Anti-Mullerian hormone	19p13.3
AMH-RII	Anti-Mullerian hormone receptor	12q13.13
AR	Androgen receptor	Xq11-q12
ARX	Aristaless-related homeobox, X-linked	Xp21.3
BLIMP1/ PRDM1	B lymphocyte–induced maturation protein	6q21
ATR-X	Alpha-thalassemia/mental retardation, X-linked	Xq13
BMP2	Bone morphogenetic protein-2	20p12.3
BMP15	Bone morphogenetic protein-15	Xp11.22
CBX2/M33	Chromobox homolog 2	17q25
CDKN1C	Cyclin-dependent kinase inhibitor 1C	11p15.4
CYB5	Cytochrome b_5	18q22.3
CHD7	Chromodomain helicase DNA binding protein 7	8q12.1-12.2
CYP21A2	21-hydroxylase	6p21.33
CYP11B1	11β-Hydroxylase	8q21
CYP19A1	Aromatase	15q21.2
CYP11A1	Cholesterol side chain cleavage	15q23-q24
CYP17A1	17α-hydroxylase/17,20-lyase	10q24.3
CYP26B1	Cytochrome P450, subfamily XXVIB, polypeptide 1	2p13.2
CXCL12	Stromal cell-derived factor 1	10q11.21
CXCR4	Chemokine, CXC motif, receptor 4	2q22.1
DAX1/ NR0B1	DSS-AHC critical region on the X chromosome 1	Xp21.2
DAZL	Deleted in azoospermia-like	3p24.2
DHCR7	7-dehydrocholesterol reductase	11q13.4
DHH	Desert hedgehog	12q13.1
DMRT1	Doublesex- and MAB3-related transcription factor 1	9p24.3
EIF2B2	Eukaryotic translation initiation factor 2B, subunit 2	14q24.3
EIF2B4	Eukaryotic translation initiation factor 2B, subunit 4	2p23.3
EIF2B5	Eukaryotic translation initiation factor 2B, subunit 5	3q27.1
EMX2	Empty spiracles, drosophila, 2, homolog of	10q26.11
FIGLA	Factor in germline alpha, mouse, homolog of	2p12
FGF8	Fibroblast growth factor 8	10q24.32
FGF9	Fibroblast growth factor 9	13q12.11
FGFR1	Fibroblast growth factor receptor 1	8p11.23-p11.22
FGFR2	Fibroblast growth factor receptor 2	10q26.13
FOG2/ ZFPM2	Friend of GATA 2	8q23
FOXL2	Forkhead transcription factor 2	3q23
GATA4	GATA binding protein 4	8p23.1-p22
GDF7	Growth differentiation factor 7	2p24.1
GLI3	Gli-Kruppel family member 3	7p14.1
GNRHR	GnRH receptor	4q13.2
HOXA10	Homeobox A10	7p15.2
HOXA11	Homeobox A11	7p15.2
HOXA13	Homeobox A13	7p15.2
HSD3B2	3β Hydroxysteroid dehydrogenase 2	1p13.1
HSD17B3	17β Hydroxysteroid dehydrogenase 3	9q22
INLS3	Insulin like 3	19p13.11
IRX3	Iroquis homeobox protein 3	16q12.2
KAL1	Anosmin 1	Xp22.31
KAT6B	Lysine acetyltransferase 6B	10q22
LGR4	G-protein–coupled receptor 48	11p14.1
LGR8/RXFP2	Relaxin/insulin-like peptide receptor 2	13q13.1
LIM1/ LHX1	Lim homeobox gene 1	17q12
LHX9	Lim homeobox gene 1	1q31.3
LIN28A/ZCCHC1	Zing finger CCHC domain-containing protein 1	1p36.11
LHR/LHCGR	LH receptor	2p16.3

Glossary of Genes—cont'd

Gene	Name	Locus
MAMLD1/ CXORF6	Mastermind-like domain-containing protein 1	Xq28
MAP3K1	Mitogen-activated kinase kinase kinase 1	5q11.2
MKKS	McKusick-Kaufman syndrome	20p12.2
NANOG	Homeobox transcription factor nanog	12p13.31
NGFI-B/ NR4A1	Nuclear receptor subfamily 4, group A, member 4	12q13.13
NKB/TAC3	Neurokinin B/tachykinin 3	12q13.3
NK3R/TACR3	Neurokinin B receptor/tachykinin receptor 3	4q24
NOBOX	Newborn ovary homeobox, mouse, homolog of	7q35
PDGFA	Platelet-derived growth factor, alpha polypeptide	7p22.3
PDGFRA	Platelet-derived growth factor receptor, alpha	4q12
POR	P450 oxidoreductase	7q11.2
PROK2	Prokineticin 2	3p13
PROKR2	Prokineticin receptor 2	20p12.3
PTC/ PTCH1	Patched	9q22.32
ROR2	Receptor tyrosine kinase-like orphan receptor, 2	9q22.31
RSPO1	R-spondin family member 1	1p34.3
SHH	Sonic hedgehog	7q36.3
SMO/SMOH	Smoothened, Drosophila, homolog of	7q32.1
SOX3	SRY Box 3	Xq27.1
SOX9	SRY Box 9	17q24.3-q25.1
SOX10	SRY Box 10	22q13.1
SRD5A2	5α-Reductase 2	2p23
SRY	Sex determining region on Y	Yp11.3
SF1/NR5A1	Steroidogenic factor 1/nuclear receptor subfamily 5, group A, member 1	9q33
STAR	Steroidogenic acute regulatory protein	8p11.23
STRA8	Stimulated by retinoic acid	7q33
WNT4	Wingless-type MMTV integration site family, member 4	1p36.12
WNT5	Wingless-type MMTV integration site family, member 5A	3p14.3
WNT7A	Wingless-type MMTV integration site family, member 7A	3p25.1
WNT9B	Wingless-type MMTV integration site family, member 9B	17q21.32
WT1	Wilms tumor 1	11p13
WTIP	WT1-interacting protein	19q13.11

QUESTIONS

1. What is the most common disorder of sex development?
   a. Gonadal dysgenesis
   b. Cryptorchidism
   c. DAX1 duplication
   d. Congenital adrenal hyperplasia

Answer: b

2. What is the most likely diagnosis for an infant with symmetric external genitalia, fused labioscrotal folds, prominent phallus, and no palpable gonads
   a. Androgen insensitivity syndrome
   b. Mixed gonadal dysgenesis
   c. Persistent Mullerian duct syndrome
   d. Congenital adrenal hyperplasia

Answer: d

3. What is the phenotype associated with mutations in the RSPO1 gene?
   a. 46,XY sex reversal with adrenal insufficiency
   b. No obvious phenotype in 46,XX individuals
   c. 46,XX sex reversal with palmoplantar keratoderma
   d. 46,XY sex reversal with ovotesticular disorder

Answer: c

4. A 14 year old girl is referred for evaluation of primary amenorrhea. Her physical exam shows normal to tall stature for her family. She has Tanner 3 breast development, but lacks pubic and axillary hair. Family history reveals a maternal aunt who had infertility. Which of the following options should be avoided?
   a. Reassure the family that she has delayed puberty. Recommend waiting 6 months and re-evaluate
   b. Obtain pelvic ultrasound to assess for presence of uterus
   c. Measure LH, FSH, and testosterone
   d. Obtain karyotype

Answer: a

5. You are asked to evaluate a newborn infant with an abdominal wall defect, bifid phallic structure, and bilateral palpable gonads. Karyotype is 46,XY. What is this infant's diagnosis?
   a. Ovotesticular disorder
   b. Androgen insensitivity
   c. Hypopituitarism
   d. Exstrophy of the bladder/cloaca

Answer: d

CHAPTER 6

Hypoglycemia in the Newborn and Infant

Diva D. De León, MD • Paul S. Thornton, MD, BCh, MRCPI • Charles A. Stanley, MD • Mark A. Sperling, MD

CHAPTER OUTLINE

INTRODUCTION

One of the most important genetic and metabolic events to mark the transition from fetal to neonatal life is the adaptation from an environment that has a readily available and continuous source of glucose—maternal blood—to an environment in which glucose is provided in a limited and intermittent supply. The complex events involved in the maintenance of plasma glucose concentration must be coordinated to avoid hypoglycemia and resultant damage to the central nervous system. A newborn or infant with hypoglycemia presents an urgent diagnostic and therapeutic challenge. The clinical features must be rapidly assessed and a plan of action developed based on the infant's age, maternal and parturition history, severity and persistence of hypoglycemic state, and all other relevant clinical clues. In this chapter we will review the normal physiology of glucose metabolism and the pathophysiology of the most common disorders resulting in hypoglycemia in the neonate (first 4 weeks of life) and infant (1 month to 1 year of life) with an emphasis on the approach to the diagnosis and management of these pathologies.

PRINCIPLES OF GLUCOSE METABOLISM

A systematic approach to hypoglycemia in the newborn, infant, or child requires an appreciation of the central role of glucose in the body's fuel economy.[1] Glucose metabolism accounts for approximately half of basal daily energy needs and is the principal metabolic fuel of the human brain. Glucose can be stored for energy in the form of glycogen and fat, and its carbon can be used for synthesis of protein and for structural components (such as cell membranes). The aerobic oxidation of glucose yields high energy by producing 36 mols of adenosine triphosphate (ATP) for each mol of glucose.

All glucose extracted by the brain is oxidized, and thus cerebral glucose utilization parallels cerebral oxygen uptake. In 5-week-old infants, cerebral glucose utilization already represents 71% to 93% of the adult level in most brain regions (ranging from 13 to 25 μmol/100 g/min). At that age, the areas with highest metabolic rates for glucose are the sensorimotor cortex, thalamus, midbrain, brainstem, and cerebellar vermis. By 3 months, metabolic rates for glucose increase in the parietal, temporal, and occipital cortices, as well as in basal ganglia. By 8 months,

subsequent increases occur in the frontal cortex and various associative regions, concordant with the appearance of higher cortical and cognitive functions. Adult levels of cerebral glucose utilization (19 to 33 μmol/100 g/min) are reached by the time one is 2 years of age, and they continue to increase until 3 to 4 years of age—when they reach values ranging from 49 to 65 μmol/100 g/min, which are maintained to approximately 9 years of age. They then begin to decline, reaching adult levels by the end of the second decade.[2]

Glucose uptake by the brain occurs by means of a carrier-mediated facilitated diffusion process that is glucose concentration dependent, as well as energy, Na^+, and insulin independent.[3] This process is mediated by facilitative glucose transporter (GLUT) proteins. The human genome contains 14 members of the GLUT family. Each of these isoforms is expressed in a distinct tissue distribution. In most cells, GLUTs mediate the import of glucose, because hexokinase activity maintains low intracellular glucose concentrations. Characterization of the different members has provided new insights into the regulation and significance of glucose transport and its disorders in various tissues[3,4,5] (Table 6-1). Several members of the GLUT family have been detected in the brain. GLUT1 is located at the blood-brain barrier,[6] and although some neurons express GLUT2 and GLUT4, the majority use GLUT3 as their primary transporter.[7] The main isoform present in insulin-responsive tissues is GLUT4.[8,9]

Of major importance is the confirmation at a molecular level of biochemical evidence that glucose entry into brain cells and its subsequent metabolism are not

TABLE 6-1 **Characterization of Glucose Transporters**

Subfamily	Name	Tissue Distribution	Glucose Transport Activity	Location of Human Gene	Regulation by Insulin
Class I	GLUT1	Erythrocytes, brain (blood-brain barrier), placenta, pancreatic islets	Erythrocyte: asymmetric carrier with exchange acceleration; K_m,5-30 mmol/L (variable): Vmax (influx) < Vmax (efflux)	1p35-p31.3	Zero to minimal
	GLUT2	Liver, islet cells, kidney, small intestine, pancreatic islets	Low-affinity. Liver: simple, symmetric carrier; K_m,60 mmol/L; intestine: asymmetric carrier: Vmax (efflux) < Vmax (influx)	3q26.1-q26.2	Zero to minimal
	GLUT3	Brain (neuronal), testis, placenta, pancreatic islets	High-affinity; exchange K_m,10 mmol/L	12p13.3	Zero
	GLUT4	Adipocytes, muscle	High-affinity; adipocyte: simple, symmetric carrier; K_m,2-5 mmol/L	17p13	Dependent on insulin
	GLUT14	Testis	?	12p13.31	?
Class II	GLUT5	Testis, small intestine, kidney	No glucose transport activity, fructose transporter	1p36.2	?
	GLUT7	Small intestine (enterocytes brush border membrane), colon, testis, prostate	High-affinity transport for glucose (K_m = 0.3 mM)	1p36.2	?
	GLUT9	Liver, kidney. Expressed at preimplantation stage in mouse	Proven glucose transport activity	4p16-p15.3	?
	GLUT11	Pancreas, kidney, placenta, heart, skeletal muscle	Low affinity for glucose (possible fructose transporter)	22q11.2	Mediates insulin-stimulated glucose uptake in embryos
Class III	GLUT6	Brain, spleen, leukocytes	Low affinity for glucose	9q34	?
	GLUT8	Testis, brain (neuronal), adipocytes, preimplantation embryos	High-affinity glucose transporter (possible multifunctional transporter)	9q33.3	?
	GLUT10	Liver, pancreas	Glucose transport activity with K_m,3 mmol/L	20q13.1-q12	?
	GLUT12	Heart, prostate, breast cancer	Proven glucose transporter activity	6q23.2	?
	GLUT13 (HMIT)	Brain	No glucose transport activity, myo-inositol and related isomers transporter	12q12	?

dependent on insulin but rather are dependent on circulating arterial glucose concentration.[10] Therefore, a decrease in arterial glucose concentration or a defect in the glucose transport mechanism of the brain will result in intracerebral glucopenia and low cerebrospinal fluid glucose concentration (hypoglycorrhachia)—with attendant symptoms and signs of cerebral glucopenia as subsequently described.[10-12]

In normal humans, plasma glucose concentrations range from 3.9 to 7.1 mmol/L (70 to 128 mg/dL) and in the brain the range is from 0.8 to 2.3 mmol/L (14 to 41 mg/dL).[13] Brain glucose consumption will outstrip glucose transport at plasma glucose concentration < 2 mmol/L (36 mg/dL) (brain glucose will approach 0 mmol/L).[14] To prevent circulating arterial blood glucose from decreasing precipitously under normal physiologic conditions, and therefore to prevent impairment of vital function that depends on cerebral glucose metabolism, an elaborate defense mechanism has evolved.[1] This defense against hypoglycemia is integrated by the autonomic nervous system and by hormones that act synergistically to enhance glucose production through enzymatic modulation of glycogenolysis and gluconeogenesis while simultaneously limiting peripheral glucose use.[15,16] Thus, hypoglycemia is the result of a defect in one or several of the complex interactions that maintain a normal range of glucose concentration, preventing its fall to less than 3.9 mmol/L (70 mg/dL) during fasting and its rise to more than 7.8 mmol/L (140 mg/dL) during feeding.

These mechanisms are not fully developed at birth, when there is an abrupt transition from intrauterine life to extrauterine life. A neonate delivered prematurely whose enzymatic machinery mechanisms are not yet fully developed and expressed or one whose placental insufficiency resulted in intrauterine growth retardation with limited tissue nutrient deposits may be particularly vulnerable to hypoglycemia,[17] often with consequences to subsequent cerebral development or function.[18,19]

PHYSIOLOGY OF PERINATAL GLUCOSE HOMEOSTASIS

Glucose Metabolism in the Fetus

It is estimated that 80% of fetal energy comes from glucose and that the remaining 20% is derived from metabolism of lactate and amino acids.[20] Studies in human pregnancies as well as in other species suggest that fetal glucose is derived entirely from the mother through placenta transfer.[21-24] Thus, maternal and fetal glucose concentrations behave as a single pool, with no endogenous glucose production in the fetus. There are important clinical consequences implicit in these findings. For example, acute hypoglycemia in a mother with diabetes will result in acute hypoglycemia in the fetus—with no ability to acutely compensate for the abrupt reduction in blood glucose supply.

The transfer of glucose across the placenta to the fetus is mediated by sodium-independent facilitated diffusion along a concentration gradient. This process is dependent on specific isoforms of the glucose transporters. GLUT1 has been identified as the major isoform in the human placenta,[25] although other members of the family, such as GLUT3, are also expressed.[26] Of note is the fact that the placental GLUTs are not regulated by insulin, suggesting that maternal glucose concentration and (more specifically) the maternal-fetal glucose gradient is the major determinant of placental glucose transfer independent of the maternal insulin concentration perfusing the placenta.[27]

The fetus, from early gestation to time of delivery, has only slightly lower concentrations of plasma glucose than maternal concentrations with a mean fetal glucose concentration of approximately 4.4 mmol/L (79 mg/dL). This maternal-fetal gradient allows greater transfer of glucose from the maternal circulation.[28] There is a linear relationship between the maternal and fetal glucose concentration with glucose transported by facilitated carrier-mediated diffusion along the concentration gradient.[29] As gestation proceeds this maternal-fetal gradient increases, perhaps reflecting the increased utilization of the fetal placenta unit.[28] When maternal glucose rises > 20 mmol/L (360 mg/dL), glucose transport changes to simple diffusion. Of the maternal glucose taken up by the placenta, approximately 50% to 60% is used by the placenta and 40% to 50% transported to the fetus.[30]

In the second half of gestation, the fetal–placental unit secretes large quantities of human placental lactogen, progesterone, and estrogen, which cause increased maternal insulin resistance. Maternal insulin does not significantly cross the placenta unless it is bound to antibody.[31] Fetal insulin secretion cannot rapidly respond to rapidly changing glucose levels. In utero, the raised insulin-to-glucagon ratio drives metabolism toward anabolism, as evidenced by the rapid rate of growth of the fetus. The insulin resistance of the mother results in an increased availability of glucose, amino acids, and lipids to meet the ever-increasing energy demands of the fetus, which is in a constant anabolic state with glucose utilized for both energy production and the formation of triglycerides stores and protein anabolism. Throughout gestation, the balance of glycogen metabolism is toward anabolism and the building of glycogen stores. As gestation advances, the fetal glycogen content in the liver increases to about 24.6 mg/g liver by 120 days. At 36 weeks, gestation there is a steep increase in accumulation of glycogen, with levels rising to 50 mg/g liver at term.

As gestation progresses, the increasing demand of the fetus for glucose is accomplished by increasing uterine blood flow. There is excess capacity in the uterine blood flow, and it may be reduced as much as 50% without causing any fetal harm. However, reducing blood flow from the placenta to the fetus causes significant impact on the fetus with resultant intrauterine growth restriction (IUGR). In IUGR fetuses, the maternal fetal gradient is increased.

Changes at Birth: Transition Phase

The abrupt interruption of maternal glucose transfer to the fetus at delivery imposes an immediate need to mobilize endogenous glucose and to rapidly adjust insulin secretion to glucose concentration. Following birth and clamping of the cord, the newborn has to transition

from a state of glucose excess and anabolism to a rapidly fluxing state of glucose deficiency and excess. This is due to the change from a constant supply of glucose and amino acids from the mother to variable and intermittent oral intake. In addition, in breast-fed infants the colostrum is low in carbohydrates and high in fat. This transition is regulated by the interplay of hormones and enzyme induction. At birth, plasma epinephrine and norepinephrine rise three- to tenfold,[32] and may be responsible for changes in the insulin-to-glucagon ratio, which in utero is high and favors anabolism. Within the first 2 hours after birth, glucagon concentrations rise and continue to increase during the first 3 days of life; insulin, on the other hand, falls initially and remains in the basal range for several days.[33] These changes induce both pyruvate carboxylase (PC) and phosphoenolpyruvate carboxykinase (PEPCK).[34] By 8 to 12 hours, gluconeogenesis becomes fully effective.[35] The ability to develop significant ketosis is impaired for the first 12 hours of life, as shown by a study in appropriate for gestational age (AGA) infants fasted up to 8 hours after birth. In these infants, free fatty acid (FFA) levels averaged 1.41 mmol/L (appropriately elevated) and total ketones were approximately 0.36 mmol/L (low relative to the FFA); thus, although insulin levels fall and lipolysis occurs, fatty acid oxidation with ketone generation does not occur.[35] However, after 12 hours of life, ketone production and utilization occur at accelerated rates and equal those in adults starved for 48 to 72 hours.[36] Thus, ketone utilization can provide up to 25% of the energy needs of the neonate after the first 12 hours of life.

With the rise in glucagon and epinephrine and the fall in insulin, glycogen is mobilized to produce glucose by activation of glycogen phosphorylase. Indeed, levels of glycogen decline from a peak of 50 mg/g liver just prior to birth, to very low concentrations (< 10 mg/g liver) in the first 24 hours of life, and glycogen contributes to almost 50% of the newborn's glucose requirements during this time. Gluconeogenesis from pyruvate contributes approximately 20% to 30% of glucose needs and glycerol produced by lipolysis contributes approximately 20%.[24,37]

In summary, glucose concentration during intrauterine life is constant and > 3.9 mmol/L (70 mg/dL). Following birth, glucose concentration falls to a mean glucose of 3.1 mmol/L (56 mg/dL) at 2 hours (fifth percentile level 28 mg/dL), and as glycogenolysis and gluconeogenesis become established, glucose concentration rises to a mean of 3.5 mmol/L (63 mg/dL) (fifth percentile level 40 mg/dL) by 2 to 24 hours of life. By 24 hours of life, mean glucose concentrations are 3.8 mmol/L (68 mg/dL) (fifth percentile level 41 mg/dL) and by 48 hours they rise to a mean of 3.7 mmol/L (67 mg/dL) (fifth percentile level 48 mg/dL).[38] As a result of these changes, 30% of normal newborns will have glucose concentrations < 2.8 mmol/L (50 mg/dL) in the first 24 hours of life and thereafter the frequency of glucose concentrations < 50 mg/dL in newborns older than 24 hours of age is 0.5%.[17] This physiologic drop in glucose levels in the first 24 hours of life is *transitional hypoglycemia*, which by definition occurs in normal healthy newborns. It should be differentiated from both transient and persistent pathologic causes of hypoglycemia.

Abnormalities of Transition

Because low plasma glucose concentrations in normal neonates during this transitional hypoglycemia period are common, it can be difficult to identify newborn infants who have a pathologic hypoglycemia disorder. Thus, in neonates who are at risk for a pathologic hypoglycemia problem (e.g., genetic risk, large for gestational age [LGA], IUGR, infant of a diabetic mother, or perinatal stress), it is appropriate to monitor glucose concentrations closely and not merely treat any hypoglycemia expectantly. If such infants are treated and stabilized, formal evaluation or decisions about need for long-term treatment may be delayed until 2 to 3 days after birth, when diagnosis of the cause of hypoglycemia may be made by interpreting the critical sample drawn at a time of a spontaneous or fasting-induced glucose < 50 mg/dL. It is vital that the diagnosis of the cause of hypoglycemia and decisions about need for treatment be completed prior to discharge from the nursery in order to avoid the potential hazard of a hypoglycemic episode after the infant is at home.

In infants born IUGR, the diminished glycogen reserves may have a significant impact on glucose control in the first 24 hours of life, resulting in hypoglycemia greater than expected. However, there are data that also suggest that small for gestational age (SGA) infants have a transient state of hyperinsulinism persisting over the first days of life as they adjust to extrauterine life.[39] Premature infants may also not have accumulated adequate glycogen and will have immaturity of their enzyme systems also increasing the risk of hypoglycemia. Infants of diabetic mothers or infants with perinatal stress hyperinsulinism, or even those with genetic defects in insulin secretion or other conditions, will not have the sudden drop in insulin levels after birth, thus impairing glycogenolysis and lipolysis and increasing the risk of hypoglycemia. It is important for the clinician to recognize these at-risk neonates and neonates whose glucose control is out of the range of transitional hypoglycemia during this period and treat appropriately. In particular, it is important to recognize conditions in which insulin secretion is increased, as these infants will neither mobilize glycogen nor be able to oxidize fatty acids, thus putting their brains at risk of damage due to the combination of hypoglycemia and hypoketosis.

Management of Hypoglycemia in the First 24 Hours

Management of hypoglycemia in the first 24 hours of life is important from two points of view. First, the management plan should avoid treatment of infants who do not need treatment; second, it should include a management plan for those at risk of having a permanent hypoglycemic disorder that both identifies those neonates and threats them adequately. It is not currently recommended that all newborns have glucose concentration measured. However, if an infant has symptoms consistent with hypoglycemia—such as lethargy, apnea, or seizures, or is unwell or in the at-risk category (e.g., infants with siblings with known hypoglycemic disorders, preterm infants, LGA infants, SGA infants, infants of a diabetic mother, or infants who

had birth asphyxia)—the infant's glucose levels should be measured.

If the baby has symptoms of hypoglycemia or is unwell and the glucose is < 2.8 mmol/L (50 mg/dL), then IV glucose should be administered to keep the glucose > 3.3 mmol/L (60 mg/dL).[40] Typically doses of glucose would be a 200 mg/kg (2 mL/kg dextrose 10%) bolus dose followed by a starting glucose infusion rate (GIR) of 4 to 6 mg/kg/min (60 to 90 mL dextrose 10% /kg/day) and rising by GIR of 1.6 mg/kg/min (1 mL/kg dextrose 10%/hour) until glucose levels are > 3.3 mmol/L (60 mg/dL) are obtained. Glucose levels should be checked every 15 minutes and the glucose infusion rate increased until the desired range is achieved. If after two dose increases of 1.6 mg/kg/min (1 mL/kg dextrose 10%/hour) the glucose levels remain < 3.3 mmol/L (60 mg/dL), then an increase by 3.2 mg/kg/min (2 mL/kg dextrose 10%/hour) every 15 minutes is recommended.

For asymptomatic infants at < 2 hours of life, intravenous (IV) glucose should be given if glucose levels are < 1.7 mmol/L (30 mg/dL) and the goal is to raise the glucose to > 3.3 mmol/L (60 mg/dL). For asymptomatic infants at 2 to 24 hours of life, IV glucose should be given if glucose levels are < 2.2 mmol/L (40 mg/dL) and the goal is to raise the glucose to > 3.3 mmol/L (60 mg/dL). If newborns continue to have asymptomatic glucose concentrations < 50 mg/dL after 24-48 hours consideration should be given to providing IV dextrose with the goal of maintaining glucose > 3.9 mmol/L (70 mg/dL).

There is no evidence-based medicine to show us how to differentiate neonates who failed the preceding protocols because of a more severe transition from neonates with a more serious and potentially harmful cause of hypoglycemia. Both the American Academy of Pediatrics guidelines[41] and the Canadian Pediatric Society guidelines[40] recommend further testing to identify neonates who may needing longer-term treatment and to identify when glucose metabolism has returned to normal, but they do not recommend how and when this should be done.

We strongly recommend that neonates requiring intravenous glucose to maintain the blood glucose levels > 3.3 mmol/L (60 mg/dL) at any time, or those having glucose levels < 2.8 mmol/L (50 mg/dL) past 48 hours of age, should have the cause of their abnormality in glucose metabolism identified prior to discharge. This means a critical sample should be drawn during a spontaneous episode of hypoglycemia, whether on intravenous glucose or not, and if a spontaneous event does not occur, a simple fast should be done after the neonate has been weaned from intravenous fluids and is feeding. Those who require IV glucose at any time for the treatment of hypoglycemia should skip 1 to 2 feeds and fast a total of 6 to 8 hours. If plasma glucose levels remain > 3.6 mmol/L (65 mg/dL), one can conclude the infant is unlikely to have a hypoglycemic disorder. For those with glucose levels < 2.8 mmol/L (50 mg/dL) after 48 hours of life and not requiring IV glucose, the recommendation is to skip one feeding and have the infant fast for 6 hours. If the infant maintains the glucose > 3.3 mmol/L (60 mg/dL), it is unlikely that the infant has a hypoglycemic disorder. One should note that there is no evidence that proves these protocols will identify 100% of infants, so caution should be made if clinical circumstances warrant further thought. Finally, it is important to emphasize to anxious parents the consequences of missing a diagnosis of a hypoglycemic disorder. In our experience most parents are willing to lengthen the hospital stay by 6 to 9 hours to ensure the long-term safety of their child.

HORMONAL AND METABOLIC SYSTEMS OF FASTING ADAPTATION

Hypoglycemia in neonates, infants, and children is essentially always a problem with fasting adaptation. Postprandial hypoglycemia is exceedingly rare and is limited to a few unusual situations, such as postprandial hypoglycemia after Nissen fundoplication and gastric tube feedings, hereditary fructose intolerance, or the protein-induced hypoglycemia seen in some forms of congential hyperinsulinism. Therefore, a consideration of the major hormonal and metabolic pathways that maintain fuel homeostasis during fasting provides an important framework for understanding the causes, diagnosis, and treatment of different forms of hypoglycemia.

Three metabolic systems regulate the physiologic response to fasting: (1) hepatic glycogenolysis, (2) hepatic gluconeogenesis, and (3) hepatic ketogenesis. The key enzymatic steps in these pathways are shown in Figure 6-1. These metabolic systems are coordinated by the endocrine system, consisting of suppression of insulin (the most important endocrine response to fasting, as insulin suppresses all three metabolic systems) balanced by the secretion of glucagon, epinephrine, cortisol, and growth hormone. Table 6-2 summarizes the counter-balancing effects of these counter-regulatory hormones on key metabolic pathways. There is a hierarchic redundancy in the interaction of these counter-regulatory hormones that provides a margin of safety ("fail-safe mechanism") if only one counter-regulatory hormone is impaired. Epinephrine and glucagon are quick acting, each signaling its effects by activation of cyclic AMP. Deficiencies of glucagon, as occurs in long-standing type 1 diabetes mellitus, can be largely compensated for by an intact autonomic nervous system with appropriate α- and β-adrenergic, and cholinergic effects. Conversely, autonomic failure can be largely compensated for if glucagon secretion remains intact.[1]

Hepatic glycogenolysis is sufficient to meet energy requirements for only a few hours. Beyond that time, glucose must be produced by hepatic gluconeogenesis from precursors such as amino acids, glycerol, and lactate recycled from glycolysis. The major source of gluconeogenic precursors is muscle protein. Although the pool of muscle protein is large, it is required for body function and thus in contrast to stores of glycogen and fat there are no "reserves" of protein to draw on during fasting. To spare the use of essential protein during extended fasting, glucose consumption must be suppressed by switching on the mobilization and oxidation of fatty acids from adipose triglyceride stores, producing ketone bodies and glycerol. The ketone bodies inhibit phosphofructokinase,

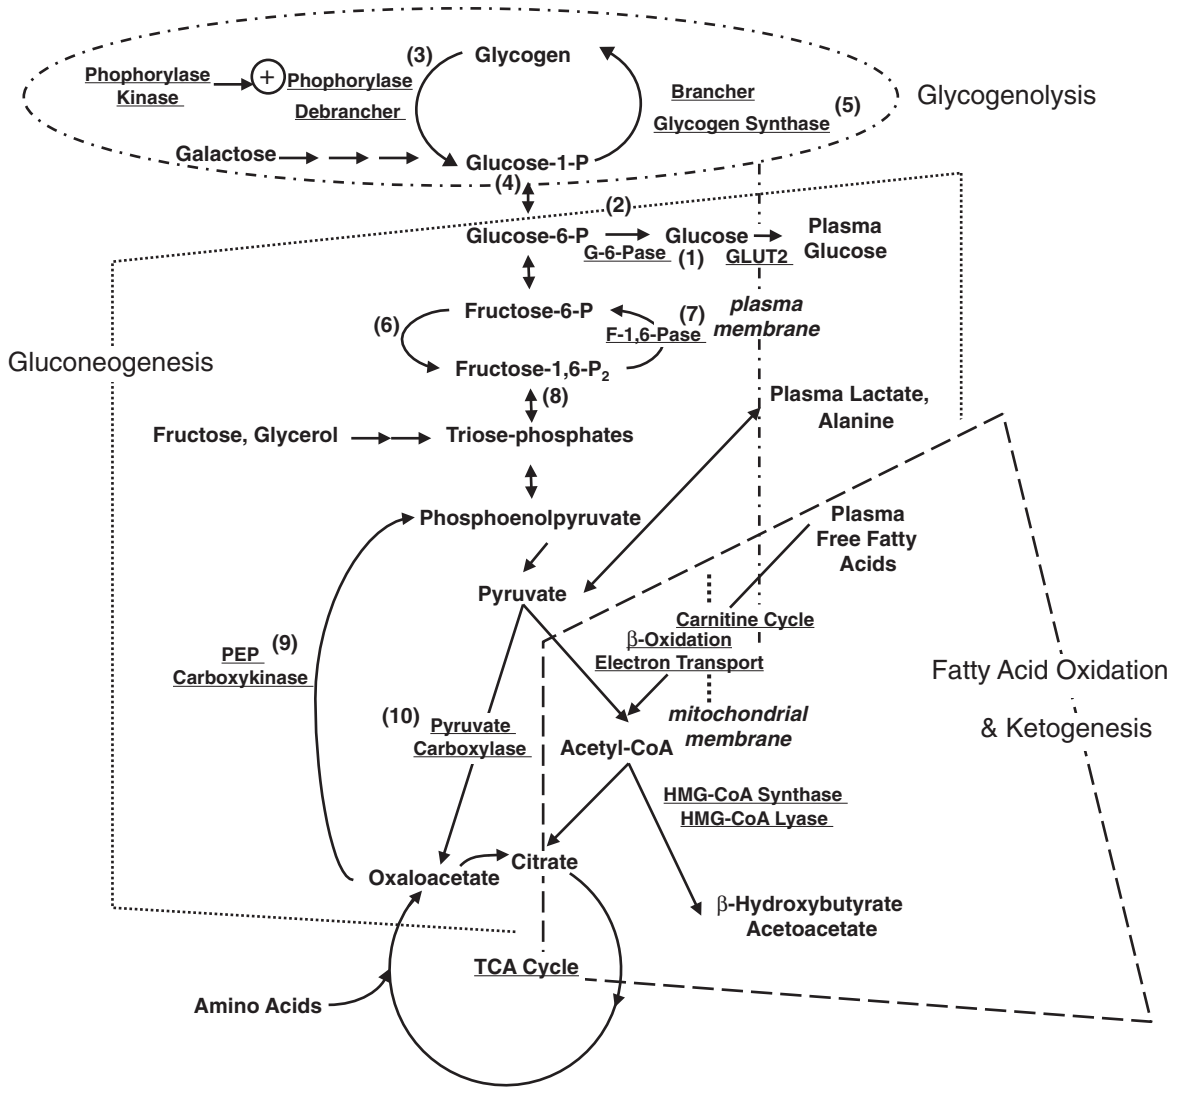

FIGURE 6-1 ■ Key metabolic pathways of intermediary metabolism. Disruption of the elements of these pathways may be pathogenetic in the development of hypoglycemia. Not shown is the hormonal control of these pathways. Indicated are (1) glucose 6-phosphatase, (2) glucokinase, (3) phosphorylase, (4) phosphoglucomutase, (5) glycogen synthetase, (6) phosphofructokinase, (7) fructose 1,6-diphosphatase, (8) fructose 1,6-diphosphate aldolase, (9) phosphoenolpyruvate carboxykinase, and (10) pyruvate carboxylase. (From Pagliara AS, Karl IE, Haymond M, Kipnis DM [1973]. Hypoglycemia in infancy and childhood. J Pediatr 82:365-379 and 82:558-577.)

TABLE 6-2 **Hormonal Regulation of Fasting Metabolic Systems**

Counter-Regulatory Hormone	Glycogenolysis	Gluconeogenesis	Lipolysis	Ketogenesis

Epinephrine	Stimulates		Stimulates	Stimulates

hexokinase, and inactivate pyruvate dehydrogenase, thus reducing glucose utilization in the liver and preserving glucose for those cells dependent of glucose alone.

The essential function of fasting adaptation is to maintain fuel supply to the brain. Glucose homeostasis is very limited in neonates and infants compared to adults, in part because of their smaller reserves of liver glycogen and muscle protein but also because of their relatively larger rates of glucose consumption due to their larger brain-to-body-mass ratio. For example, the fuel stores of a 10-kg infant are only 15% of those of an adult. However, the caloric needs are 60% of those of an adult and

glucose turnover rates per kilogram are two- to threefold greater. As shown in Figure 6-2, early in fasting, glucose is the primary brain fuel and accounts for over 90% of total body oxygen consumption. Glucose is provided chiefly from hepatic glycogenolysis, supplemented by hepatic gluconeogenesis utilizing amino acids released by muscle protein turnover. After 8 to 12 hours in normal infants (24 to 36 hours in adults), glucose production declines, because the supply of liver glycogen is limited and the rate of gluconeogenesis from amino acids remains constant. At this time, a transition to fat as the major fuel for the body begins, with accelerated adipose tissue lipolysis and increased fatty acid oxidation in muscle and ketogenesis in liver. Lipolysis also generates glycerol, which is an important gluconeogenic substrate once fasting adaptation is fully active. The brain cannot utilize fatty acids directly, because they do not pass the blood-brain barrier. However, the brain can substitute glucose consumption with the ketones acetoacetate and β-hydroxybutyrate, which are released by the liver as the end product of hepatic fatty acid oxidation. In late stages of fasting adaptation, fatty acid oxidation and ketone utilization account for 90% of total oxygen consumption.

The operation of the metabolic and endocrine systems of fasting adaptation is evidenced by the changes in circulating levels of metabolic fuels and hormones during a fast. As shown in Figure 6-3, in young infants a 24-hour fast is accompanied by a gradual fall in plasma glucose levels as hepatic glycogen stores are depleted, a progressive fall in concentrations of gluconeogenic substrate (e.g., lactate, alanine) as they are used for hepatic gluconeogenesis, a brisk rise in free fatty acids as lipolysis is activated, and a dramatic rise in β-hydroxybutyrate (the major ketone) as hepatic ketogenesis is turned on.[1,42]

By the time that plasma glucose concentration has fallen to < 2.8 mmol/L (50 mg/dL), all the metabolic systems and the hormonal responses described earlier will have fully engaged. A "critical sample" drawn at this time will therefore enable an evaluation of these systems and detect abnormalities of fasting adaptation. As an example, when insulin concentration is above the lower limit of detection according to the assay at the time when plasma glucose concentration is 2.8 mmol/L (50 mg/dL) or less, there is a hyperinsulinemic state reflecting failure of the mechanisms that normally result in suppression of insulin secretion during fasting or hypoglycemia.[43-45] Thus, a snapshot of the integrity of the metabolic and endocrine fasting systems can easily be obtained by measuring the plasma levels of the major fuels and hormones at the end of a fast, when the blood glucose approaches hypoglycemic levels ("critical samples") (Table 6-3; also see also Box 6-2, presented later in the chapter). The use of these critical samples in diagnosing the cause of hypoglycemia is discussed later.

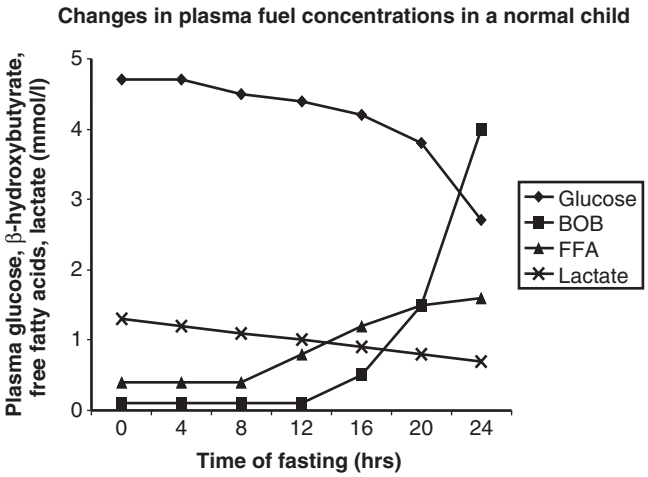

FIGURE 6-3 ■ In infants, a 24-hour fast is accompanied by a gradual fall in plasma glucose levels as hepatic glycogen stores are depleted, a progressive fall in concentrations of gluconeogenic substrate (e.g., lactate, alanine) as they are used for hepatic gluconeogenesis, a brisk rise in free fatty acids (FFA) as lipolysis is activated, and a dramatic rise in βhydroxybutyrate (BOB) (the major ketone) as hepatic ketogenesis is turned on.

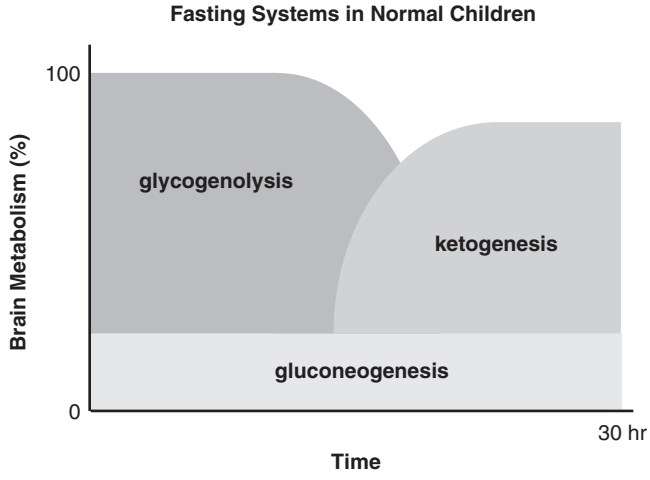

FIGURE 6-2 ■ Contribution of major fasting systems to brain metabolism over time in a typical normal infant. Note that glycogen stores are depleted by 8 to 12 hours and that ketogenesis becomes the major source of brain substrate by 24 hours.

DEFINITION OF HYPOGLYCEMIA IN NEONATES AND INFANTS

The classic definition of symptomatic hypoglycemia is "Whipple's triad"—symptoms, signs or both consistent with hypoglycemia, a low plasma glucose concentration, and resolution of symptoms/signs after the plasma glucose concentration is raised. These three criteria were originally used for diagnosing insulinomas in adults. However, in neonates and infants, who cannot dependably communicate their symptoms and in whom clinical signs of hypoglycemia are not specific, it may not be possible to satisfy Whipple's triad. In these cases, recognition of hypoglycemia may require confirmation by repeated measurements of plasma glucose concentrations on multiple occasions or by formal provocative testing.

Beyond the first 48 hours of life, normal plasma glucose concentration in neonates and infants are not different than in older children and adults. Thus, plasma glucose concentrations in the postabsorptive state range

GH, growth hormone; GSD, glycogen storage disease.

between 3.9 and 5.6 mmol/L (70 and 100 mg/dL), with a mean of 4.4 to 4.7 mmol/L (80 to 85 mg/dL). A plasma glucose level of 2.8 mmol/L (50 mg/dL) is conventionally used as an end point for provocative diagnostic tests for hypoglycemia. This value is low enough to strongly stimulate the endocrine and metabolic defenses against hypoglycemia for identifying the mechanism responsible for hypoglycemia. Falling glucose levels elicit a typical sequence of responses: plasma insulin levels begin to decrease when plasma glucose falls to the range of 4.4 to 4.7 mmol/L (80 to 85 mg/dL) and insulin secretion is generally "switched off" at glucose concentrations below 2.5 to 3 mmol/L (45 to 54 mg/dL); glucagon secretion increases when plasma glucose levels are in the range of 3.6 to 3.9 mmol/L (65 to 70 mg/dL); epinephrine, cortisol, and growth hormone responses are activated in the range of 3.6 to 3.9 mmol/L (65 to 70 mg/dL). As the plasma glucose falls below 3.3 mmol/L (59 mg/dL), auditory and visual reaction time is prolonged and cognitive function begins to decline as the plasma glucose concentration declines below 2.5 to 3.5 mmol/L (45 to 63 mg/dL), with some of this variability dependent of the testing employed.[13,46]

In some disorders, such as defects in ketogenesis, signs and symptoms may begin to appear during fasting at plasma glucose levels of 3.3 mmol/L (60 mg/dL). On the other hand, some patients (those with glucose 6-phosphatase deficiency) may have few symptoms of neuroglycopenia at plasma glucose levels as low as 1.1 to 1.7 mmol/L (20 to 30 mg/dL) because their high plasma levels of lactate provide an alternative substrate for the brain. Plasma glucose levels between 2.8 and 3.9 mmol/L (50 and 70 mg/dL) should be regarded as suboptimal and below the goal for therapy for hypoglycemia.

A number of potential artifacts can interfere with measuring glucose levels in neonates and infants (Box 6-1). Whole-blood glucose concentrations are 10% to 15% lower than plasma glucose levels because erythrocytes have a higher concentration of protein (hemoglobin) versus plasma with its higher water content, and hence higher dissolved glucose concentrations. The difference may be greater in neonates with higher hematocrits. Blood samples that are not processed promptly can have erroneously low glucose levels, owing to glycolysis by red and white blood cells. At room temperature, the decline of whole-blood glucose can be 5 to 7 mg/dL/hr. The use of inhibitors, such as fluoride, in collection tubes avoids this problem.

Hospital bedside glucose meters and similar home glucose meters are less precise than clinical laboratory methods and can be expected to have an error range of 10% to 15%. These methods are also prone to errors, such as outdated strips or inadequate sampling—most of which result in falsely low glucose values. For this reason, bedside monitors can be used for screening purposes—but any glucose value below 3.3 mmol/L (60 mg/dL) should be verified in the clinical laboratory. Falsely low (or high) glucose values may occur with samples drawn from indwelling lines without adequate flushing of the saline (or glucose) infusate.

For infants beyond the transitional period, treatment should be initiated promptly for plasma glucose values below 2.8 mmol/L (50 mg/dL). Plasma glucose values below 3.3 mmol/L (60 mg/dL) should be rechecked, and treatment considered if values are confirmed to be below 3.3 mmol/L (60 mg/dL). Symptomatic infants and neonates should be treated with intravenous dextrose (0.2 g/kg bolus, followed by infusion at 5 to 10 mg/kg/min). These rates approximate the normal hepatic glucose production rates in neonates and young infants (Figure 6-4). Asymptomatic neonates with plasma glucose levels below 2.8 mmol/L (50 mg/dL) may be treated with oral glucose, but only if there is good reason to believe the problem is a transient one that will not recur. This essentially only applies to otherwise normal neonates during the first 12 to 24 hours after birth who have delayed feedings, such as with initiation of breastfeeding. *Beyond the first day of life, all neonates with verified plasma glucose concentration less than 2.8 mmol/L (50 mg/dL) should be suspected of having a hypoglycemic disorder.*

BOX 6-1 Factors Affecting Measurement of Blood Glucose Concentration

- Whole-blood versus plasma glucose concentration (plasma is 10% to 15% higher)
- Duration between sample collection and sample measurement
- Presence or absence of glycolytic inhibitors in collection tubes
- Sample collection from indwelling lines without adequate flushing

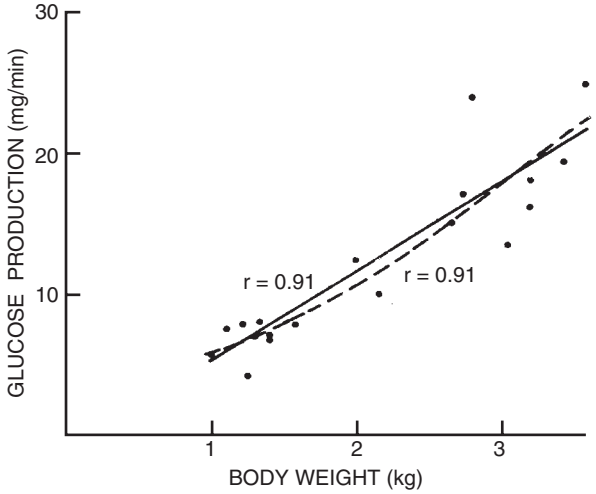

FIGURE 6-4 ■ Glucose production versus body weight determined in 19 newborns with the use of stable isotopic techniques. These studies provide support for the calculated rates of glucose administration required to correct hypoglycemia. (From Bier DM, Leake RD, Haymond MW, et al. [1977]. Measurement of "true" glucose production rates in infancy and childhood with 6,6-dideuteroglucose. Diabetes 26:1016.)

CLINICAL SYMPTOMS AND SIGNS ASSOCIATED WITH HYPOGLYCEMIA

The clinical features of hypoglycemia in infants may be associated with both neurogenic and neuroglycopenic components (Table 6-4). Symptoms are often subtle and not specific, therefore a high index of clinical suspicion must be maintained. Any alteration in clinical status in a newborn that suggests a change in neurologic behavior, fall in temperature, change in feeding pattern, or presence of tremors must be considered a possible initial presentation of a hypoglycemic episode. A seizure must always be considered a possible manifestation of hypoglycemia.

DIAGNOSTIC APPROACH

Treatment of hypoglycemia in neonates and infants requires making a specific diagnosis of the underlying cause. The diagnosis should be based on the combination of data obtained from the history, physical examination, laboratory findings, and, especially, the hormonal and fuel responses at the time of fasting hypoglycemia. A logical approach to diagnosis and treatment must be to analyze a hypoglycemic event as a maladaptation to fasting, and thus the most important information required for diagnosis comes from tests on the blood and urine specimens obtained at a time of hypoglycemia (also known as the critical samples).

Important facts from the history include the duration of fasting that provoked hypoglycemia. Onset within a few hours of a meal would be consistent with hyperinsulinism or glucose 6-phosphatase deficiency, whereas onset after 10 to 12 hours would be consistent with a defect in fatty acid oxidation. Pituitary deficiency with growth hormone or adrenocorticotropic hormone (ACTH)-cortisol deficiency might be suspected by the presence of midline facial malformations, microphthalmia, or microphallus (follicle-stimulating hormone [FSH]/luteinizing hormone [LH] deficiency in utero). Growth failure is also a prominent feature of glucose 6-phosphatase deficiency or debrancher deficiency glycogen storage disease after the first 3 months of life. Both of these disorders are associated with massive hepatomegaly. Abnormal results of liver function tests (transaminases) and hyperammonemia, with or without elevated creatine kinase level, would suggest a possible fatty acid oxidation disorder (see Table 6-3).

Figure 6-5 outlines an algorithm for diagnosis of different forms of hypoglycemia based on readily available laboratory tests on the "critical" blood and urine samples. The first discriminant is a measure of acidemia at the time of hypoglycemia using the serum bicarbonate. If the acidemia is caused by elevations of the ketoacids (β-hydroxybutyrate and acetoacetate), possibilities include a normal child fasted for too long (ketotic hypoglycemia), a defect in glycogenolysis (glycogen storage disease type 3), or counter-regulatory hormone deficiency (hypopituitarism). If the acidemia is caused by an elevation of lactic acid, a block of gluconeogenesis should be suspected (glucose 6-phosphatase or fructose 1,6-diphosphatase deficiency or ethanol ingestion).

If there is no acidemia (i.e., absence of the normal elevation of ketones) but free fatty acid levels are high, a defect in fatty acid oxidation and ketogenesis should be suspected (MCAD deficiency). If ketones are not appropriately increased but the free fatty acid concentrations are also suppressed, hyperinsulinism should be suspected. In the neonatal period, the features of hyperinsulinism can be mimicked by congenital pituitary deficiency. Further tests can then be planned using the initial critical specimens to confirm the suspected diagnosis. These may include physiologic tests (such as the glucagon stimulation test at a time of hypoglycemia to confirm hyperinsulinism) or specialized laboratory tests (such as a plasma acyl-carnitine profile) to identify a defect in mitochondrial β-oxidation.

TABLE 6-4 **Symptoms of Hypoglycemia in Infancy**

Neurogenic	Neuroglycopenic
SYMPTOMS DUE IN PART TO ACTIVATION OF AUTONOMIC NERVOUS SYSTEM (ADRENERGIC OR CHOLINERGIC)	SYMPTOMS DUE TO DECREASED CEREBRAL GLUCOSE AND OXYGEN USE
Shakiness, trembling, jitterness	Lethargy
Tachycardia	Irritability
Hunger	Poor feeding
Pallor	Seizures
Hypothermia	Cyanosis
	Tachypnea
	Apneic episodes
	Weak/High-pitched cry
	Floppiness
	Eye-rolling
	Lip smacking
	Twitching, convulsions

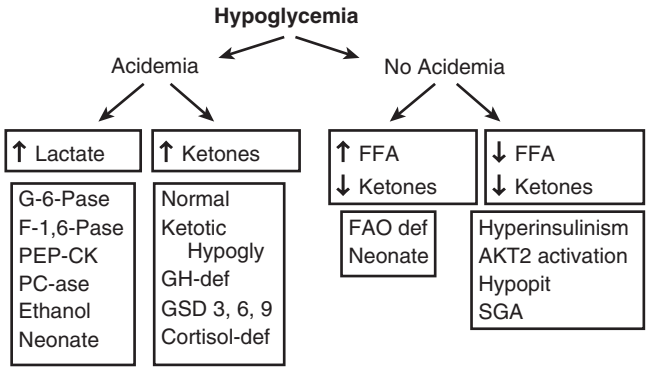

FIGURE 6-5 ■ Algorithm for diagnosis of hypoglycemia based on "critical" blood tests obtained during a period of hypoglycemia. FFA, free fatty acids; FAO: fatty acid oxidation; GSD, glycogen storage disorder; SGA, small for gestational age. (Modified from Stanley CA, Baker L [1978]. Hypoglycemia. In Kaye R, Oski FA, Barness LA (eds.), *Core textbook of pediatrics*. Philadelphia: JB Lippincott, 280-305.)

In some cases, a formal fasting test may be necessary to diagnose the cause of hypoglycemia. The goal of this test is to reproduce the setting in which hypoglycemia occurs in order to identify the underlying cause. The fasting test should be considered a method of testing a hypothesis that has already been developed, based on available clinical and laboratory data about the cause of the hypoglycemia. Thus, the test can be modified with additions or deletions to the basic protocol. This is important, because challenging an infant with fasting is not without risk—particularly if a genetic defect in fatty acid oxidation or adrenal insufficiency is present. Therefore, fasting or other diagnostic challenges should be done only in the hospital under carefully controlled settings with an experienced physician and nursing staff readily available.

Infants younger than 1 year are usually fasted for up to 24 hours, whereas in older children the maximum fast may be up to 36 hours. The fast is terminated when the plasma glucose falls below 2.8 mmol/L (50 mg/dL), but it may be ended sooner if plasma β-hydroxybutyrate rises to greater than 2.5 mmol/L or if there are any adverse signs or symptoms. Periodic blood samples are obtained for analysis of major fuels and hormones and for appropriate ancillary tests (e.g., serum total carnitine, acylcarnitine profile, liver transaminases, creatine phosphokinase, or urinary organic acids). If hyperinsulinism is suspected, the fasting test may be ended with glucagon (1 mg given intravenously) to evaluate the glycemic response.

Special note should be made that the most frequent cause of hypoglycemia in neonates, infants, and children (hyperinsulinism) often cannot be diagnosed based solely on the plasma insulin concentration. With very sensitive assays, serum insulin concentrations will be less than 1 to 2 μU/mL at times of hypoglycemia (i.e., below the sensitivity of most insulin assays). Therefore, the diagnosis must often be made based on evidence of inappropriate insulin effects: hypoketonemia, hypo-free fatty acidemia, and a positive glycemic response to glucagon.

CLASSIFICATION OF CAUSES OF PERSISTENT HYPOGLYCEMIA IN THE NEONATE AND INFANT (Box 6-2)

Disorders of Insulin Excess or Actions

Suppression of insulin secretion is critical for maintaining euglycemia during fasting through the activation of hepatic glycogenolysis, gluconeogenesis, and fatty acid oxidation. Indeed, failure to suppress insulin secretion or actions is the most common cause of persistent hypoglycemia in neonates and children. Whether this is the result of a genetic defect in factors involved in the insulin secretory pathway or in the insulin signaling cascade, the clinical and biochemical hallmarks in the neonate are: (1) increased birth weight because of the growth-promoting effects of insulin in utero, (2) increased glucose utilization, (3) suppression of lipolysis and ketogenesis (low free fatty acids and ketones at the time of hypoglycemia), and (4) inappropriate glycemic response to glucagon at time of hypoglycemia (an increase of > 30 mg/dL) (Box 6-3). These features are critical for making the diagnosis, but it is also essential to determine the underlying cause because the treatment and prognosis may vary among the different disorders. The potential risk of brain damage in an infant suffering from hyperinsulinism is high, placing this diagnosis in a critical position in the diagnostic evaluation of neonatal hypoglycemia.

BOX 6-2 Classification of Causes of Persistent Hypoglycemia in the Neonate and Infant

A. Disorders of Insulin Excess or Actions
  1. Hyperinsulinemic Hypoglycemia
    a. Perinatal Stress-Induced Hyperinsulinism
    b. Monogenic Hyperinsulinism
      K_{ATP} Hyperinsulinism
        Focal
        Diffuse
      GDH Hyperinsulinism
      SCHAD Hyperinsulinism
      GCK Hyperinsulinism
      HNF4Alpha Hyperinsulinism (HNF1Alpha)
      UCP2 Hyperinsulinism
    c. Beckwith-Wiedemann Syndrome
    d. Hyperinsulinemic Hypoglycemia after Fundoplication
  2. AKT2
B. Defects of Counter-Regulatory Response
  1. Hypopituitarism
  2. Congenital ACTH Deficiency (TBX19)
C. Defects in Glycogenolysis and Gluconeogenesis
  GSD Type 1
D. Defects in Fatty Acid Oxidation
  MCAD
E. Defects of Glucose Transporters
  GLUT1 Deficiency
  GLUT2 Deficiency

BOX 6-3 Criteria for Diagnosing Hyperinsulinism Based on "Critical" Samples (Drawn at a Time of Fasting Hypoglycemia: Plasma Glucose < 50 mg/dL)

1. Hyperinsulinemia (plasma insulin > 2 μU/mL)*
2. Hypofattyacidemia (plasma FFA < 1.5 mmol/L)
3. Hypoketonemia (plasma BOB < 2 mmol/L)
4. Inappropriate glycemic response to glucagon, 1 mg IV (delta glucose > 30 mg/dL)

*Depends on sensitivity of insulin assay.
BOB, β-hydroxybutyrate; FFA, free fatty acids.

Hyperinsulinemic Hypoglycemia

Transient Hyperinsulinism Resulting from Maternal Factors

Transient hyperinsulinism is a well-recognized complication in neonates after a pregnancy complicated by gestational diabetes. At birth, infants born to these mothers may be large and plethoric—and their body stores of glycogen, protein, and fat are replete. The classic clinical description of the effect of hyperinsulinism relates to the infant of the diabetic mother[47]:

> *These infants are remarkable not only because like fetal versions of Shadrack, Meshack, and Abednego, they emerge at least alive from within the fiery metabolic furnace of diabetes mellitus, but because they resemble one another so closely they might well be related. They are plump, sleek, liberally coated with vernix caseosa, full-faced, and plethoric. The umbilical cord and placenta share in the gigantism. During their first 24 or more extrauterine hours, they lie on their backs, bloated and flushed, their legs flexed and abducted, their lightly closed hands on either side of the head, the abdomen prominent and their respiration sighing. They convey a distinct impression of having had such a surfeit of both food and fluid pressed upon them by an insistent hostess that they desire only peace so that they may recover from their excesses. On the second day their resentment of the slightest noise improves the analogy when their trembling anxiety seems to speak of intrauterine indiscretions of which we know nothing.*

The hypoglycemia in infants of diabetic mothers is related chiefly to hyperinsulinemia and in part to diminished glucagon secretion. Hypertrophy and hyperplasia of their islets have been documented, as has their brisk, biphasic, and typically adult insulin response to glucose. This insulin response is absent in normal infants. Infants born to diabetic mothers also have a subnormal surge in plasma glucagon immediately after birth, subnormal glucagon secretion in response to stimuli, and (initially) excessive sympathetic activity that may lead to adrenomedullary exhaustion because urinary excretion of epinephrine is diminished. Thus, despite their abundance of tissue stores of available substrate, the normal plasma hormonal pattern of low insulin, high glucagon, and catecholamines is reversed. Their endogenous glucose production is inhibited and glucose utilization is increased compared with that in normal infants, thus predisposing them to hypoglycemia.

Mothers whose diabetes has been well controlled during pregnancy in general have near-normal-sized infants who are less likely to develop neonatal hypoglycemia and other complications formerly considered typical of maternal diabetes. Nevertheless, treatment of infants born to mothers with diabetes commonly requires provision of intravenous glucose for a few days until the hyperinsulinemia abates. For these infants, glucose should be provided at a rate of 5 to 10 mg/kg/min. However, the appropriate dosage for each patient should be individually adjusted.

During labor and delivery, maternal hyperglycemia should be avoided because it may result in fetal hyperglycemia—which predisposes to rebound hypoglycemia when the glucose supply is interrupted at birth. Other maternal factors that can result in transient neonatal hyperinsulinism include oral hypoglycemics (such as sulfonylureas) or other medications (terbutaline or propranolol).

By definition, transient hyperinsulinism as a cause of neonatal hypoglycemia in an infant of a diabetic mother should abate in 1 or 2 days. If the condition persists, prolonged or congenital hyperinsulinism must become a prominent consideration, and the index of suspicion must remain high until it is ruled out.

Prolonged Neonatal Hyperinsulinism: Perinatal Stress-Induced Hyperinsulinism

As shown in Figure 6-6, the risk of postnatal hypoglycemia is increased in neonates who are small for gestational age. There is increasing evidence that prolonged hypoglycemia in some neonates exposed to perinatal stress such as birth asphyxia, maternal toxemia, prematurity, or intrauterine growth retardation or other peripartum stress is due to hyperinsulinism.[48-50] The estimated incidence of prolonged neonatal hyperinsulinism is 1:12,000 live births.[50]

The clinical presentation of perinatal stress-induced hyperinsulinism is characterized by high glucose utilization, and the response to fasting hypoglycemia shows an elevated plasma insulin level (although it may be normal), low β-hydroxybutyrate and free fatty acid levels, and inappropriate glycemic response to glucagon at the time of hypoglycemia. Unlike the transient hyperinsulinism seen in the infant of the diabetic mother, perinatal stress-induced hyperinsulinism may persist for several days to several weeks. In a series of neonates with perinatal stress-induced hyperinsulinism, the median age of resolution was 6 months.[50] The mechanism responsible for the dysregulated insulin secretion is not known. Acute insulin responses (AIRs) show that in general the patterns of insulin response to secretagogues (calcium, tolbutamide, glucose, and leucine) in infants with prolonged neonatal hyperinsulinism resembled those of normal controls.[50]

Infants with prolonged neonatal hyperinsulinism usually respond very well to medical therapy with diazoxide.[48-50] Previously, it was common practice to use pharmacologic doses of glucocorticoids to treat such

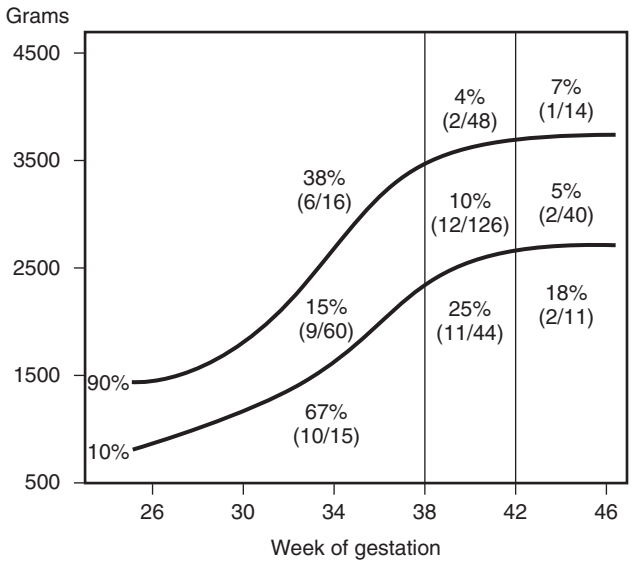

FIGURE 6-6 ■ Incidence of plasma glucose level being less than 30 mg/dL before first feeding at 3 to 6 hours of age in newborns, classified by birth weight and gestational age. (From Lubchenko LO, Bard H [1971]. Incidence of hypoglycemia in newborn infants by birth weight and gestational age. Pediatrics 47:831.)

neonates with persistent hypoglycemia. However, the use of glucocorticoids as nonspecific therapy for neonatal hypoglycemia is not recommended because they are not only ineffective but also can suppress the hypothalamic-pituitary-adrenal axis.

Hyperinsulinism in Beckwith-Wiedemann Syndrome

Beckwith-Wiedemann syndrome (BWS) is a heterogeneous disorder that results from various genetic and epigenetic anomalies in the imprinted 11p15.5 region. This region can be divided into two distinct imprinted domains separated by a nonimprinted region. The distal domain 1 contains the imprinted genes insulin-like growth factor 2 (*IGF2*), which is growth promoting and paternally expressed, and *H19*, a tumor suppressor expressed from the maternal allele. In the proximal domain 2, the imprinted region contains two genes that have been implicated in BWS, *KCNQ1OT1* (paternally expressed untranslated transcript) and *CDKN1C* (maternally expressed, encodes a negative regulator of cell proliferation). Molecular alterations affecting domains 1 and 2 associated with BWS include paternal uniparental disomy involving both imprinted gene clusters (20% of cases) and paternal duplications of 11p15 (approximately 1% of cases).[51]

The classical features of BWS include macrosomia, macroglossia, visceromegaly, abdominal wall defects, ear creases/pits, body asymmetry, and an increased risk for embryonal tumor development. Hypoglycemia due to hyperinsulinism is present in up to 50% of cases.[52] The mechanism responsible for hyperinsulinism in BWS has not been elucidated but may involve dysregulated insulin secretion due to loss of KATP channel function.[53] The pancreatic histology in BWS is characterized by hyperplasia of all pancreatic structures including ducts, acini, and islets with increased proliferation of endocrine cells.[54] However, is not known whether the hyperinsulinism in BWS is due to the increased β-cell mass, dysregulated insulin secretion, or both.

The hyperinsulinism in BWS may be mild and transient, although in some cases it can be severe and persistent.[52] Some BWS infants respond to diazoxide, whereas others require pancreatectomy to control the hypoglycemia. Because the hyperinsulinism will resolve within the first year of life in most cases, pancreatectomy should be reserved for those cases in which the hypoglycemia cannot be controlled with diazoxide, octreotide, or continuous enteral supplementation with dextrose or feedings.

Monogenic Hyperinsulinism

Congenital hyperinsulinism, also known as persistent hyperinsulinemic hypoglycemia of infancy, represents a group of clinically and genetically heterogeneous disorders characterized by dysregulated insulin secretion and resulting in severe and persistent hypoglycemia. First described in 1954 by MacQuarrie[55] as "idiopathic hypoglycemia of infancy," congenital hyperinsulinism is the most common cause of persistent hypoglycemia in children. Worldwide, the incidence of congenital hyperinsulinism is estimated at 1 in 50,000 live births with higher incidence of up to 1 in 2500 in areas of high consanguinity.[45]

To understand the pathophysiology of congenital hyperinsulinism, knowledge of the major pathways regulating insulin release by pancreatic β-cells is critical (outlined in Figure 6-7). Glucose-stimulated insulin secretion involves glucose uptake through glucose transporters (GLUT1, GLUT2, and GLUT3 are expressed in the islets[56]) and phosphorylation by glucokinase (GK), leading to glucose oxidation and an increased ATP/ADP ratio that results in inhibition of a plasma membrane ATP-dependent potassium (K_{ATP}) channel. The β-cell K_{ATP} channel is a hetero-octameric complex consisting of two subunits: a K^+-selective pore-forming subunit (Kir6.2) and a regulatory subunit (SUR-1). Four Kir6.2 subunits form the central pore, coupled to four SUR-1 subunits. The K_{ATP} channel is inhibited (closed) by sulfonylurea drugs (used therapeutically to stimulate insulin secretion in type 2 diabetes) and activated (opened) by diazoxide (the main medical treatment for congenital hyperinsulinism). In the unstimulated state, the β-cell ATP-sensitive potassium channels are open—keeping a resting membrane potential of approximately –65 mV. Following the uptake and metabolism of glucose, an increase in the intracellular ATP/ADP ratio results in closure of ATP-sensitive potassium channels, depolarization of the cell membrane, and subsequent opening of voltage-dependent Ca^{2+} channels. The resulting increase in cytosolic Ca^{2+} concentration triggers the release of stored insulin granules. Stimulation of insulin secretion by amino acids occurs through an allosteric activation of glutamate dehydrogenase (GDH) by leucine, which results in increased oxidation of glutamate—leading to an increased ATP/ADP ratio, inhibition of K_{ATP}-channel activity, and membrane depolarization.

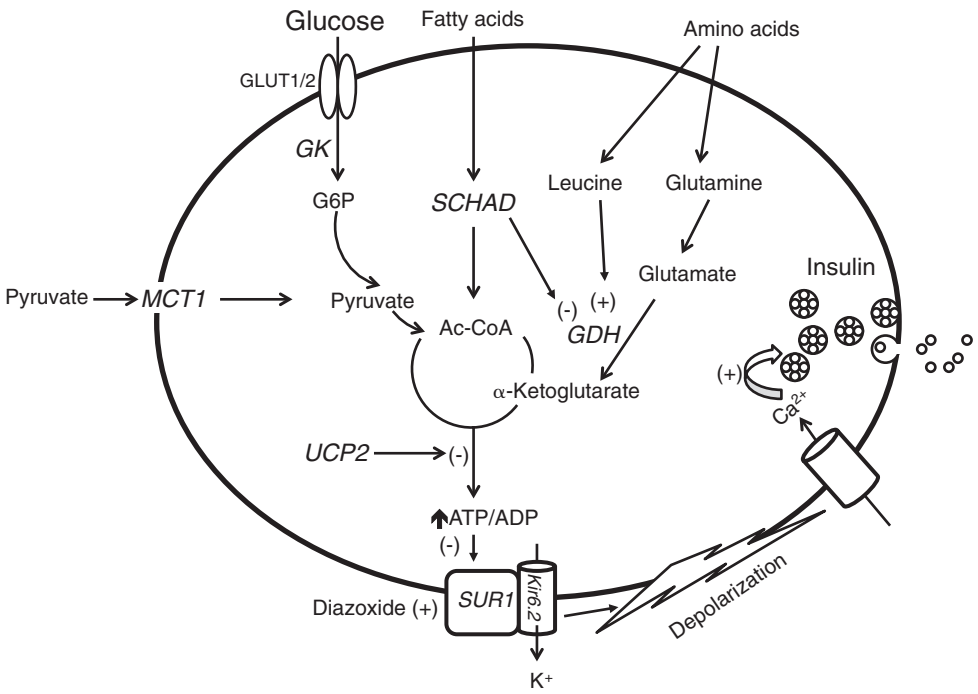

FIGURE 6-7 ■ Current model of mechanisms of insulin secretion by the beta cell of the pancreas. Glucose transported into the beta cell by the insulin-independent glucose transporter GLUT2/GLUT1 undergoes phosphorylation by glucokinase and is then metabolized, resulting in an increase in the adenosine triphosphate/adenosine diphosphate (ATP/ADP) ratio. The increase in the ATP/ADP ratio closes the K_{ATP} channel and initiates the cascade of events characterized by increase in intracellular potassium concentration, membrane depolarization, calcium influx, and release of insulin from storage granules. Leucine stimulates insulin secretion by allosterically activating glutamate dehydrogenase (GDH) and by increasing the oxidation of glutamate, thereby increasing the ATP/ADP ratio and closure of the K_{ATP} channel. Diazoxide inhibits insulin secretion by stimulating the K_{ATP} channel. The gene defects known to cause hyperinsulinism are shown in italics. Six are inactivating mutations: SUR1 (sulfonylurea receptor), Kir6.2 (potassium channel), SCHAD (short-chain 3-OH acyl-CoA dehydrogenase), UCP2 (uncoupling protein 2), HNF4a (hepatic nuclear transcription factor 4alpha), and HNF1a (hepatic nuclear transcription factor 1alpha). Three are activating mutations: GK (glucokinase), GDH (glutamate dehydrogenase), and MCT1 (monocarboxylate transporter 1). (−), inhibition; (+), stimulation.

Mutations in genes encoding nine different proteins involved in different steps of this pathway have been associated with congenital hyperinsulinism: the sulfonylurea receptor 1 (SUR-1, a member of the superfamily of ATP-binding cassette proteins), encoded by *ABCC8*[57]; Kir6.2, encoded by *KCNJ11*[58]; glucokinase (GK), encoded by *GCK*[59]; glutamate dehydrogenase (GDH), encoded by *GLUD1*[60]; the mitochondrial enzyme short-chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD), encoded by *HADH*[61]; monocarboxyl transporter-1 (MCT-1), encoded by *SLC16A1*[62]; uncoupling protein-2 (UCP2), encoded by *Ucp2*[63]; hepatocyte nuclear factor 4 alpha (HNF-4 alpha), encoded by *HNF4A*[64]; and hepatocyte nuclear factor 1 alpha (HNF-1 alpha), encoded by *HNF1A*.[65] In this chapter we review the forms more likely to present in the neonatal period. For a discussion of MCT-1 hyperinsulinism, see Chapter 6.

Treatment in neonates with suspected congenital hyperinsulinism should be initiated promptly, as their risk of brain damage is high because their brain is deprived not only of glucose but also alternative fuels (ketones). Brain injury due to hypoglycemia is particularly likely in K_{ATP}HI due to the severity of the hypoglycemia. In the Children's Hospital of Philadelphia experience, the prevalence of developmental delay in patients with congenital hyperinsulinism is approximately 30%.[66] Patients with K_{ATP}HI requiring surgical therapy have a higher incidence of neurodevelopmental problems than diazoxide-responsive patients.[66] A homogenous cohort of children with the known Ashkenazi mutations who were treated without surgery showed good neurologic outcome by school age, based on parental reports, although earlier developmental deficits were present.[67] A higher rate (44%) of long-term neurodevelopmental retardation was reported in a large series of children (49 medically treated, 65 treated surgically).[68] In another series of 90 patients, severe mental retardation was found in 8%, with milder disability in another 18%. Psychomotor delays were more common in patients with neonatal onset than in those with onset of hypoglycemia later in infancy presumably reflecting more severe hypoglycemia.[69] In general, the high risk of brain damage appears to be due to delays in diagnosis and treatment rather than a consequence of the K_{ATP} channel defect and, thus, potentially preventable.

The goal of therapy is to restore plasma glucose to the normal range (> 70 mg/dL) and to maintain it there. Intravenous glucose at high rates, up to five times the normal glucose requirement, is usually required and central lines may be needed for administration of highly concentrated dextrose. The first line of therapy for hyperinsulinism is diazoxide, an agent that acts as a K_{ATP}-channel opener that

requires functional channels to be present at the cell surface to have an effect; thus, most patients with K_{ATP}HI do not respond to diazoxide. In contrast, patients with GDH-HI, GK-HI, SCHAD-HI, and those with perinatal stress-induced hyperinsulinism do respond to diazoxide. The usual dose of diazoxide is 5 to15 mg/kg/day, given orally once or twice a day. The major adverse event with diazoxide in neonates is fluid retention. Concomitant use of a diuretic (chlorothiazide or furosemide) should be considered, especially in infants receiving intravenous fluids. The half-life of diazoxide is 24 to 36 hours in adults; limited data indicate that in children the half-life is 9.5 to 24 hours.[70] The response to diazoxide should thus be evaluated after at least 5 days of therapy. Successful response should be demonstrated by showing maintenance of plasma glucose above 3.3 mmol/L (70 mg/dL) after fasting. The duration of the fast should be determined on a case-by-case basis, based in part on the age of the child.

The second line of medical therapy for infants unresponsive to diazoxide is octreotide. This long-acting somatostatin analog inhibits insulin secretion by inducing hyperpolarization of β-cells, direct inhibition of voltage-dependent calcium channels, and more distal events in the insulin secretory pathway. Octreotide is administered subcutaneously every 6 to 8 hours at 5 to 20 μg/kg/day, or as a continuous infusion. The initial response to octreotide is good in most infants with hyperinsulinism, but tachyphylaxis develops after a few doses, rendering therapy inadequate for long-term use in most cases. The use of octreotide has been associated with the occurrence of necrotizing enterocolitis in neonates and should be used with caution in this population.[71] Treatment with a long-acting release octreotide has been shown to be effective in older children.[72] Glucagon, given as a continuous intravenous infusion (1 mg/day), can help maintain euglycemia in infants waiting for surgery, but its long-term use as a subcutaneous infusion[73] is limited by crystallization of the glucagon and clogging in the tubing.[74]

Mutation analysis to establish the genetic cause of the hyperinsulinism is particularly helpful in diazoxide-unresponsive cases, as it helps to distinguish those with diffuse pancreatic involvement who may require extensive pancreatic resection from children in whom focal hyperinsulinism is likely, thereby permitting curative resection of the focal lesion. Thus, once the diagnosis is established and initial therapy is initiated, samples for the child and the child's parents should be obtained for DNA molecular analysis. Figure 6-8 depicts the diagnostic and treatment approach for children with hyperinsulinism. A cardiac evaluation should also be considered in children with hyperinsulinism, as a large proportion of the cases have cardiac structural abnormalities, more commonly ventricular hypertrophy.[75]

K_{ATP} Hyperinsulinism. Inactivating mutations of the K_{ATP} channels are responsible for the most common and most severe form of congenital hyperinsulinism. According to the severity of the molecular defect and the phenotype, K_{ATP}HI can be classified in three subtypes:

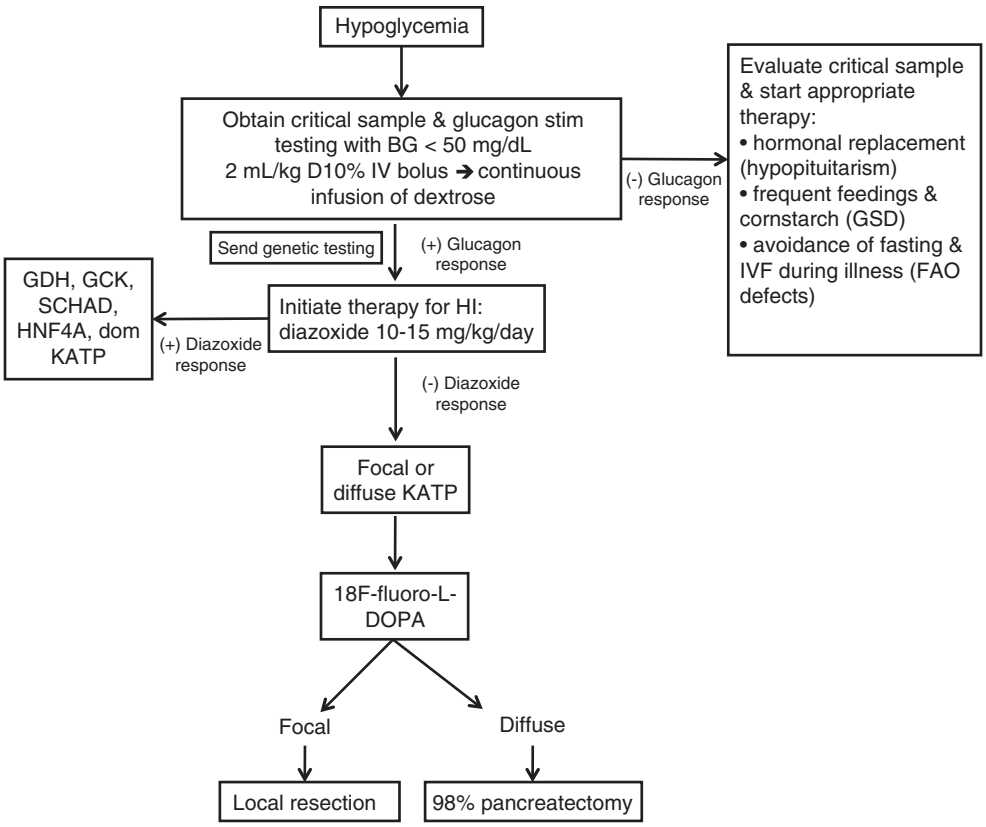

FIGURE 6-8 ■ Diagnostic and treatment approach in cases of hyperinsulinism.

(1) recessive, diazoxide-unresponsive; (2) dominant, diazoxide-unresponsive; and (3) dominant, diazoxide-responsive. Recessive mutations interfere with protein expression or channel trafficking, resulting essentially in a complete absence of channels on the plasma membrane, and therefore diazoxide is not effective. Recessive mutations are the most common defects identified in children with congenital hyperinsulinism. Dominant mutations allow normal trafficking of the channels to the plasma membrane but impair channel activity either completely or partially, resulting in a spectrum of phenotypes that go from severe, diazoxide-unresponsive to mild, diazoxide-responsive. To date, a total of 146 mutations in *ABCC8* (119 recessive and 27 dominant) and 22 mutations in *KCNJ11* (18 recessive and 4 dominant) have been reported.[76]

The clinical presentation of K_{ATP}HI then depends on the severity of the mutation effect. More commonly, these children are large for gestational age and have severe neonatal hypoglycemia that does not respond to diazoxide, except for the cases with a dominant diazoxide-responsive subtype in which birth weight is normal and the clinical presentation tends to occur later in life.[77]

The pathophysiology of K_{ATP}HI has been illustrated by functional evaluation of islet function in vivo and in vitro. The absence of functional K_{ATP} channels results in an uncoupling between plasma glucose and insulin secretion or β-cell "glucose blindness." Thus, insulin secretion is not turned off as plasma glucose decreases and fails to increase in response to a rapid raise in plasma glucose (Figure 6-9).[78-80] The former defect dominates the clinical manifestations in early infancy, whereas the latter may play a role in later development of glucose intolerance and, possibly, diabetes. In marked contrast with the failure to respond to changing concentrations of plasma glucose, these β-cells are hyperresponsive to stimulation with amino acids,[81] which results in protein-induced hypoglycemia.[82]

Other clinical features of infants with K_{ATP}HI include extremely high glucose requirements, frequently four to five times higher than normal to control plasma glucose (although in some cases the requirement may be normal), feeding aversion, and gastroesophageal reflux, likely consequences of force feeding. Treatment options for the diazoxide-unresponsive cases are limited. These infants often require pancreatectomy within the first few weeks after birth to manage the hypoglycemia. On the other hand, diazoxide is very effective for controlling hypoglycemia in cases with dominant diazoxide-responsive K_{ATP}HI. Octreotide, a long-acting somatostatin analog, is a second line medical therapy for infants unresponsive to diazoxide, although the Food and Drug Administration (FDA) has not approved it for this indication, and, as discussed earlier, because of concerns with a possible association with necrotizing enterocolitis, its use should be carefully considered.[71] A nonsurgical approach in diazoxide-unresponsive hyperinsulinism consisting of octreotide in combination with continuous or frequent enteral feedings has been proposed.[74] This approach is challenging for home management of these children, it requires feedings as frequently as every 2 to 3 hours during the day and continuously at night, frequent glucose testing, and may lead to loss of oral feeding skills.

There are two distinctive histologic forms of KATP-hyperinsulinism, focal and diffuse hyperinsulinism.

Focal K_{ATP}-Hyperinsulinism (Focal Adenomatosis). Approximately 40% to 60% of the cases of K_{ATP}HI (which require surgery) have focal disease.[83] Focal lesions arise by a "two-hit" mechanism of focal loss of heterozygosity for the maternal 11p15 region, leading to a somatic reduction to homozygosity (or hemizygosity) of a paternally inherited mutation of the *ABCC8* or *KCNJ11*

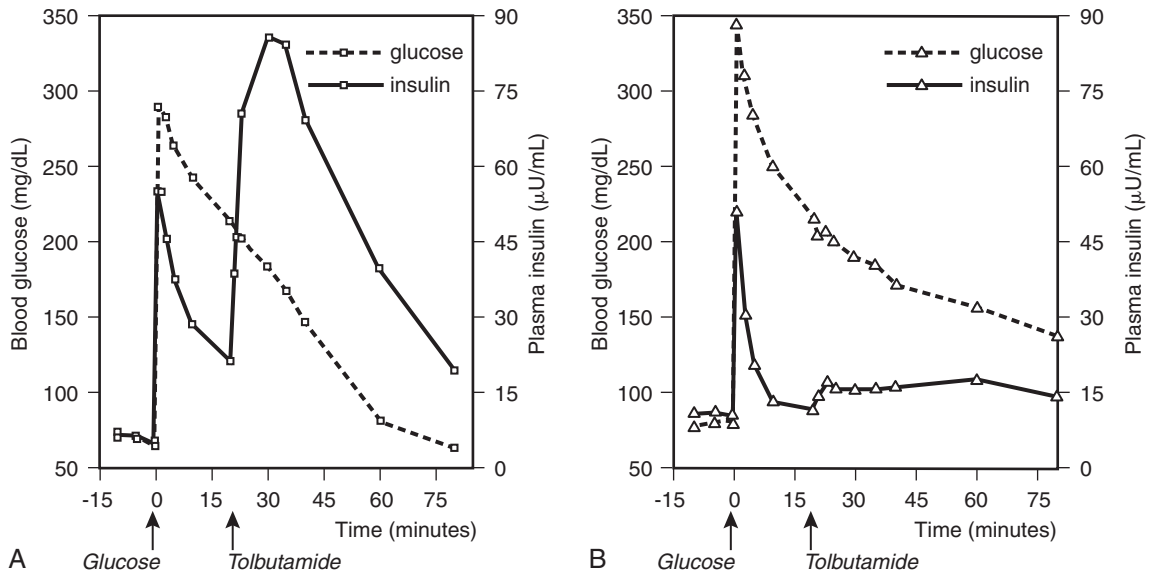

FIGURE 6-9 ■ AIR to glucose and tolbutamide in children with diffuse K_{ATP} hyperinsulinism (mean 11- and 13-minute increments). **A**, Normal adult control. **B**, Patient with diffuse K_{ATP} hyperinsulinism. (From Grimberg A, Ferry RJ, Kelly A, et al. [2000]. Dysregulation of insulin secretion in children with congenital hyperinsulinism due to sulfonylurea receptor mutations. Diabetes 50:322.)

gene. The 11p15 region, which carries the *ABCC8* and *KCNJ11* genes, contains several imprinted tumor suppressor genes (*H19* and *CDKN1C*) that are only expressed on the maternal chromosome, whereas IGF-II is expressed on the paternal allele. Loss of these growth-suppressing genes, while the paternal growth-promoting gene is active, may play an important permissive role in the clonal expansion of the cells expressing the mutated channel.[84] The majority of mutations causing the focal lesions involve the *ABCC8* gene.

Diffuse Hyperinsulinism. In diffuse hyperinsulinism, all β-cells in the pancreas are affected. It results from the inheritance of two recessive mutations in ABCC8 or KCNJ11 or a dominant mutation in these genes.

Clinically, the focal and diffuse forms of hyperinsulinism are identical in terms of the presentation and the lack of response to diazoxide. Histologically, they are distinct.[85] Diffuse hyperinsulinism is characterized by the presence of abnormally large islet cell nuclei distributed throughout the pancreas. In contrast, the pancreatic histology in focal hyperinsulinism is characterized by a lesion formed by the confluence of hyperplastic islets occupying more than 40% of the cross-sectional area of pancreatic lobules. In contrast to true adenomas, the focal adenomatous hyperplasia includes exocrine acinar cells intermixed within the lesion. The morphology of islets away from the focal lesion is normal.[86] The ability to interpret these histologic characteristics requires specialized training and is only available at centers with dedicated multidisciplinary teams to evaluate and treat hyperinsulinism.

Focal K_{ATP}HI is potentially curable by surgery, whereas diffuse K_{ATP}HI is not. Therefore, efforts to diagnose and localize focal lesions in infants with diazoxide-unresponsive hyperinsulinism before surgery are critical. Conventional imaging techniques, such as computed tomography (CT) or magnetic resonance imaging (MRI), are unable to detect focal lesions. Interventional radiology studies, such as transhepatic portal venous insulin sampling[87] and selective pancreatic arterial calcium stimulation,[88] have only modest success, are technically difficult, and are highly invasive. The gold standard technique to localize the focal lesions is positron emission tomography (PET) scanning with flurorine-18 L-3, 4-dihydroxyphenylalanine (^{18}F-fluoro-L-DOPA).[89-91] Pancreatic β-cells take up L-DOPA,[92] and DOPA decarboxylase is active in pancreatic islet cells.[93] In children with focal hyperinsulinism, there is localized accumulation of ^{18}F-fluoro-L-DOPA. Co-registration of PET and CT images allows the anatomic localization of the lesion (Figure 6-10; see also e-Figure 6-1 on the accompanying website for a full-color example).

Glutamate Dehydrogenase-Hyperinsulinism: The Hyperinsulinism Hyperammonemia Syndrome (HI/HA). Congenital hyperinsulinism due to gain-of-function mutations of *GLUD1* (encoding glutamate dehydrogenase, GDH) is the second most common form of genetic hyperinsulinism and the most common form that responds to treatment with diazoxide.[60,94-97] A total of 23 different disease-causing mutations have been identified. In approximately 70% of the cases, the mutations are de novo.[98] Among the 30% of familial cases, a clear autosomal dominant pattern of inheritance is evident.

The clinical presentation is characterized by hypoglycemia due to hyperinsulinism together with a characteristically persistent but asymptomatic elevation of plasma ammonia. Hypoglycemia is usually recognized by around 4 to 12 months of life and birth size is normal. Plasma ammonia levels in HI/HA are elevated three to five times above the normal range to approximately 60 to 150 μmol/L. Ammonia levels are quite constant, and in contrast to the urea cycle enzyme defects, do not increase with protein feeding. The hyperammonemia does not appear to cause symptoms and does not require treatment.

GDH is a mitochondrial matrix enzyme that is a key regulator of amino acid and ammonia metabolism in pancreatic β-cells, liver, kidney, and brain. As shown in Figure 6-7, GDH functions in the beta cell pathway of leucine-stimulated insulin secretion. Leucine is an allosteric activator of the enzyme, causing increased oxidation of glutamate to α-ketoglutarate and increased ATP production—which results in insulin release. The HI/HA mutations affect either the inhibitory GTP-binding site or the antenna loop of the enzyme, which communicates between adjacent subunits, impairing the inhibitory allosteric effect of GTP on GDH enzyme activity, thus leading to excessive insulin release.

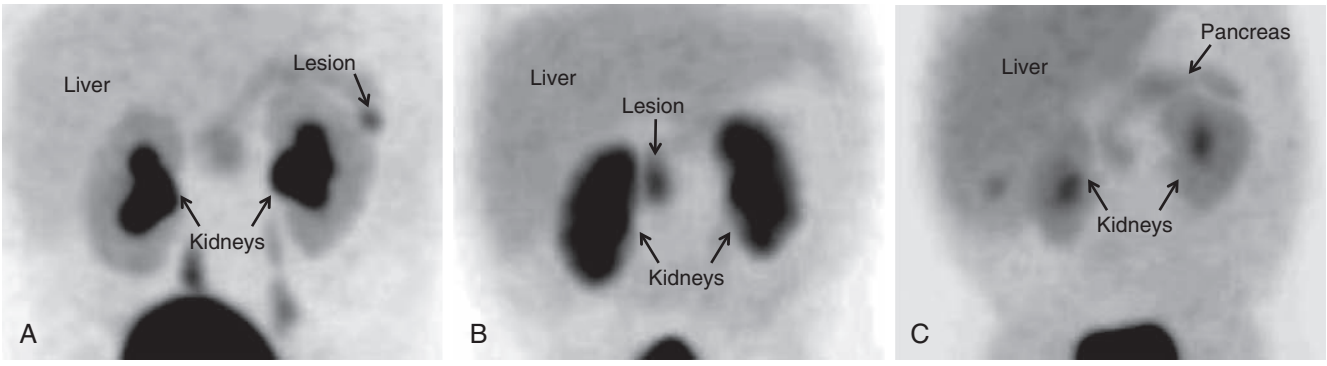

FIGURE 6-10 ■ ^{18}Fluoro-L-DOPA PET scan images showing L-DOPA uptake in the liver, kidneys, and pancreas. Note increased uptake in the tail (**A**) and head (**B**) of the pancreas demonstrating focal lesions. In contrast, diffuse hyperinsulinism uptake throughout the pancreas is uniform (**C**). *A full-color image of L-DOPA uptake can be viewed online at ExpertConsult.*

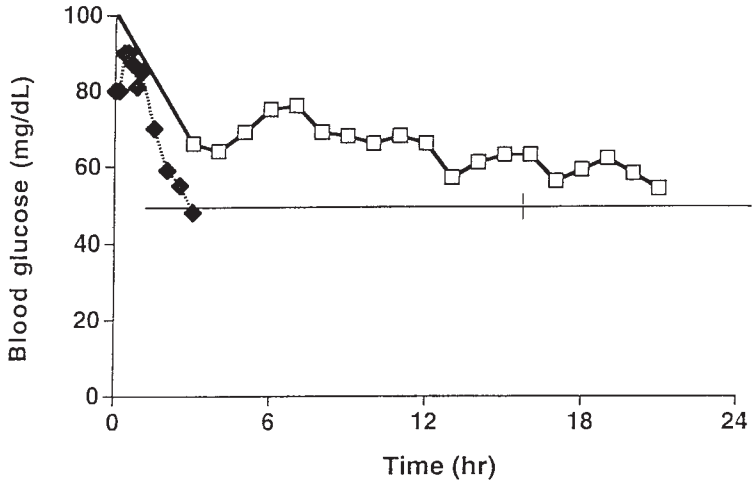

FIGURE 6-11 ■ Blood glucose responses to fasting (open squares) and protein feeding (solid diamonds) in a 16-year-old girl with the hyperinsulinism/hyperammonemia syndrome caused by a dominantly expressed R269H regulatory mutation of glutamate dehydrogenase. (From Hsu BY, Kelly A, Thornton PS, et al. [2001]. Protein-sensitive and fasting hypoglycemia in children with the hyperinsulinism/hyperammonemia syndrome. J Pediatr 138:383.)

The clinical phenotype of HI/HA is dominated by the effects of the activating mutations in the pancreatic β-cells. Isolated islets from transgenic mice expressing a mutated human GDH exhibit normal glucose-stimulated insulin secretion but enhanced leucine- and amino-acid–stimulated insulin secretion.[99] In children with HI/HA there is a dramatic increase in insulin following an intravenous bolus of leucine, but in contrast to children with K_{ATP}HI, they do not respond to calcium stimulation.[100] The hypoglycemia in children with HI/HA is provoked by fasting and by protein-rich meals. The fasting hypoglycemia may be relatively mild. Children may be able to fast for 8 to 12 hours before becoming hypoglycemic. However, these patients have dramatic protein-sensitive hypoglycemia—becoming severely hypoglycemic within 30 to 90 minutes of ingesting a protein meal[101] (Figure 6-11). Diazoxide therapy, 5 to 10 mg/kg/day, is usually effective in controlling both fasting and protein-induced hypoglycemia in HI/HA. Carbohydrate preloading may be helpful in avoiding the latter.[98]

Initially, the hyperammonemia was presumed to be due to the effects of the mutated enzyme in the liver; however, an alternative mechanism involving activation of renal GDH seems to be more likely.[102] The hyperammonemia is persistent and not associated to the classics signs of ammonia toxicity. It occurs in both the fed and fasted states and is unaffected by plasma glucose concentrations or protein intake.

GDH is also highly expressed in the brain, particularly astrocytes, but the consequences of increased GDH enzyme activity in the brain are less clear. Different groups have reported a propensity for seizures (atypical absence seizures, generalized tonic-clonic seizures, and focal motor seizures), learning disabilities, mental retardation, and behavior disorders in children with HI/HA.[103-105] The underlying mechanism responsible for the central nervous system manifestations is not known. It does not appear to be related to the hypoglycemia or the hyperammonemia, and it may be a direct effect of the activation of GDH.

SCHAD-Hyperinsulinism. A less common form of congenital hyperinsulinism also involving loss of regulation of GDH activity is due to inactivating mutations in *HADH* (the gene encoding the mitochondrial short-chain L-3-hydroxyacyl-CoA dehydrogenase [SCHAD]).[61,106,107] SCHAD-HI is an autosomal recessive disorder characterized by fasting hypoglycemia due to inappropriate insulin regulation. The cause of dysregulated insulin secretion was elucidated with the discovery that in the β cell, SCHAD plays an inhibitory role in GDH activity.[108] Thus, the insulin dysregulation observed in SCHAD deficiency is due to loss of this inhibition, explaining the clinical similarities between GDH-HI and SCHAD-HI.

In contrast to all other defects in fatty acid oxidation, children with SCHAD-HI have no signs of hepatic dysfunction or cardiomyopathy, or of affects on skeletal muscle, features usually recognized in children with fatty acid oxidation disorders. The clinical presentation of SCHAD-HI is heterogeneous, ranging from late onset of mild hypoglycemia to severe early onset of hypoglycemia in the neonatal period. In addition to fasting, hypoglycemia children with SCHAD-HI exhibit protein-induced hypoglycemia, similar to the children with GDH-HI.[109] The biochemical hallmarks, in addition to markers of increased insulin action, are increased levels of plasma 3-hydroxybutyryl-carnitine and increased levels of 3-hydroxyglutarate in urine, findings consistent with reduced SCHAD enzyme activity. In contrast to GDH-HI, children with SCHAD-HI do not have elevated ammonia, probably because of the lower expression of SCHAD in other tissues where GDH is expressed. Affected children are responsive to medical therapy with diazoxide.

Glucokinase-Hyperinsulinism. A less frequent form of congenital hyperinsulinism is due to activating mutations in *GCK* (encoding glucokinase-GK). Glucokinase is a hexokinase that serves as the glucose sensor in pancreatic β-cells[110] (see Figure 6-7). In contrast to other hexokinases, GK has a much lower affinity for its substrate with half-maximal activity ($S_{0.5}$) at a glucose

concentration of 7.6 mM. The properties of GK and the positive cooperative action of glucose on enzyme activity with a curve that is steep in the range of 5 mM glucose make GK well suited to tightly control plasma glucose in the normal physiologic range of 70 to 100 mg/dL.[111] In GK-HI, activating mutations result in increased affinity of glucokinase for glucose and insulin secretion at lower glucose concentrations. A total of 15 mutations have been associated with GK-HI[111]; some cases are sporadic, and some are dominantly inherited. All of the mutations have reduced glucose $S_{0.5}$ ranging from 1.1 to 4.5 mM.

The clinical presentation of GK-HI is characterized by large for gestational age birth weight, reflecting the growth-promoting effects of increased fetal insulin secretion. Hypoglycemia may present in the neonatal period but often is not recognized until later in infancy or childhood. The severity of the phenotype is variable with some mutations having a mild phenotype, with fasting hypoglycemia responsive to diazoxide, whereas others seem to lower the glucose threshold further and may be more difficult to treat. Based on the greater experience at the Children's Hospital of Philadelphia, diazoxide is uniformly unable to normalize blood glucose, although most children do not have frequent severe episodes of hypoglycemia. Treatment with octreotide has been tried in some children with GK-HI, with poor effect in our experience. Although some cases have undergone pancreatectomy, most children have continued to have hypoglycemia and required additional medical management after surgery. In some cases, it is necessary to provide continuous support with overnight feedings or glucose to prevent hypoglycemia.

From the few cases that have undergone a pancreatectomy, pancreatic histology has been reported to have little or no abnormal features.[112-114] Others have reported nuclear enlargement and increased islet size and β-cell proliferation.[115,116]

Uncoupling Protein-2 Hyperinsulinism. Loss-of-function mutations in the mitochondrial uncoupling protein UCP2 have been reported to cause congenital hyperinsulinism. UCP2 is a negative regulator of insulin secretion[117] that regulates insulin secretion by decreasing the ATP/ADP ratio in β-cells or modulating the production of reactive oxygen species.[118] The cases of UCP2 hyperinsulinism described to date were dominant and responsive to diazoxide.[63]

Hepatocyte Nuclear Factors and Hyperinsulinism: HNF1Alpha and HNF4Alpha-Hyperinsulinism. Hepatocyte nuclear factors 1 alpha and 4 alpha are transcription factors expressed in hepatocytes, pancreatic β-cells, intestinal epithelial cells, and renal tubular cells. In β-cells and hepatocytes, they form a feed-forward loop, such that the haploinsufficiency of either causes decreased expression of the other.[119] Both HNF1α and HNF4α play an important role on pancreatic β-cell function and heterozygous mutations in the genes encoding them: *HNF1A* and *HNF4A*, respectively, are known to cause familial monogenic diabetes (MODY 3 and MODY1). These autosomal dominant forms of diabetes are characterized by progressive impairment in glucose-stimulated insulin secretion leading to frank hyperglycemia usually manifesting before the age of 25.[120]

It has been demonstrated that heterozygous mutations in the *HNF4A* gene not only cause reduced insulin secretion leading to diabetes in early adolescence and young adulthood, but also lead to increased insulin secretion during fetal, neonatal, and childhood periods.[64,121-123] The consequences of the increased insulin secretion range from fetal macrosomia to persistent hyperinsulinism. The hyperinsulinism in neonates with *HNF4A* mutations in some cases is transient, but in some cases it persists into childhood. The hypoglycemia is well controlled with diazoxide.[124] The phenotype in children with *HNF4A* mutations may extend beyond the pancreatic β-cells, and an association with renal Fanconi tubulopathy and hepatomegaly with increased glycogen stores have been reported.[65]

HNF4 alpha hyperinsulinism represents 5% of all cases of diazoxide-responsive hyperinsulinism.[123] The precise mechanism by which mutation in *HNF4A* leads to hyperinsulinism is currently unknown, but it is likely that the defects in HNF4 alpha alter different gene expression patterns during early and later in life.

This dual phenotype of hyperinsulinism early in life and diabetes later is not limited to mutations in *HNF4A*, because dominant mutations in *HNF1A* have also been reported to present in the neonatal period with hyperinsulinemic hypoglycemia.[65] The phenotype of HNF1A hyperinsulinism is similar to that described in HNF4A mutation carriers: evidence of insulin excess in utero and early onset hyperinsulinemic hypoglycemia that resolves with age.

Hypoglycemia Due to Activating Mutations in AKT2

Recessive gain-of-function mutations in *AKT2*, a key component of the insulin signaling cascade, cause a phenotype similar to hyperinsulinemic hypoglycemia but without detectable plasma insulin levels despite classical signs of increased insulin action (suppressed free fatty acids and ketones).[125] The phenotype in these children is characterized by severe, persistent hypoglycemia unresponsive to medical therapy and requiring continuous intragastric feedings. These children also had overgrowth with body asymmetry.

Acquired Postprandial Hyperinsulinemic Hypoglycemia after Fundoplication

The Nissen fundoplication and other modified fundoplication procedures, frequently performed for the treatment of gastroesophageal reflux in neonates and children, have been associated with late dumping syndrome, particularly postprandial hyperinsulinemic hypoglycemia. In a study in neonates it was estimated that approximately 24% of those undergoing fundoplication developed postprandial hypoglycemia after the surgery.[126] Classically, dumping syndrome is characterized by early symptoms or "early dumping," thought to be due to the fluid shifts provoked by the osmotic load in

the small bowel,[127] and "late dumping" or postprandial hypoglycemia.[128] In our experience, dumping syndrome in children is characterized by severe postprandial hypoglycemia without the significant gastrointestinal symptoms observed in adults.[129] Very frequently, children with postprandial hyperinsulinemic hypoglycemia after fundoplication experience seizures, lethargy, and other symptoms of hypoglycemia for several months before the diagnosis is made. In the neonate particularly, the hypoglycemia may not be recognized unless these infants are screened with postfeeding blood glucose monitoring after the surgery.[126]

The pathophysiology of hyperinsulinemic hypoglycemia after fundoplication is poorly understood. Studies of the motor and sensory function of the stomach after fundoplication have shown significantly reduced postprandial gastric relaxation and significantly accelerated gastric emptying.[130] The rapid emptying of a meal into the small intestine results in rapid absorption of glucose into the bloodstream, with early hyperglycemia followed by an exaggerated insulin surge and subsequent hypoglycemia.[129] Increased secretion of the potent insulinotropic hormone, glucagon-like peptide-1 (GLP-1), after a meal may be partly responsible for the postprandial hyperinsulinemia.[131]

The diagnosis of hyperinsulinemic hypoglycemia in neonates and children after fundoplication is established based on the glucose and insulin profile after a mixed meal tolerance test or an oral glucose tolerance test.[131] The typical response is characterized by hyperglycemia that can reach up to > 11.1 mmol/L (200 mg/dL) within the first hour after the meal, followed by hypoglycemia at 90 to 120 minutes. Plasma insulin reach a peak that is > 200 μU/mL approximately 30 minutes after the meal. A variety of therapies have been used with varying success to treat dumping syndrome, including uncooked cornstarch,[132] pectin,[133] octreotide,[134] acarbose,[129] and dietary manipulations.[135] Many of the patients suffering from postprandial hyperinsulinemic hypoglycemia continue to have severe symptoms despite these interventions and require a regimen of continuous enteral feedings to avoid hypoglycemia but continue to be at high risk of hypoglycemic events if feedings are abruptly stopped. In most cases, the postprandial hyperinsulinemic hypoglycemia improves with time, especially after solids have been introduced to the diet.

Defects in Counter-Regulatory Response

Hypoglycemia associated with endocrine deficiency is usually caused by glucocorticoid or growth hormone deficiency, more commonly the combination of both. In children with panhypopituitarism, isolated growth hormone deficiency, or a combination of ACTH deficiency and growth hormone deficiency, the incidence of hypoglycemia is as high as 20%. In the newborn period, hypoglycemia may be the presenting feature of hypopituitarism. In males, a microphallus may provide a clue to a coexistent deficiency of gonadotropin[136,137] (Figure 6-12). Newborns with hypopituitarism may also have liver dysfunction resembling cholestatic liver disease, and some have midline malformations such as the syndrome of septo-optic dysplasia.[138]

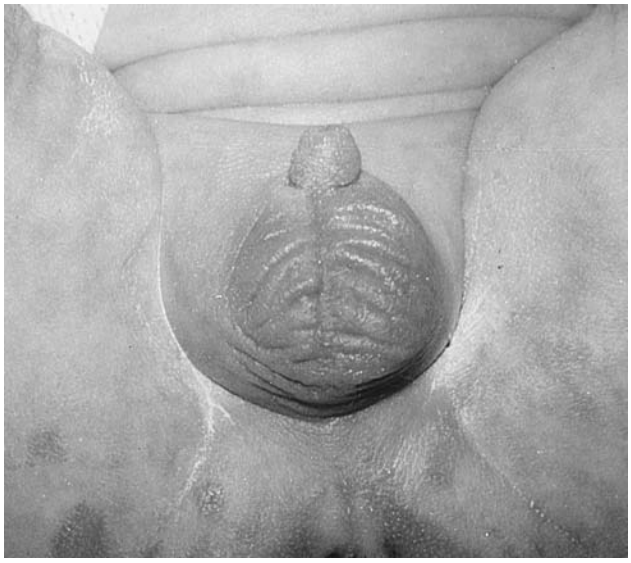

FIGURE 6-12 ■ Micropenis and undescended testes in an infant with congenital hypopituitarism. The infant was hypoglycemic at 12 hours of age (glucose, 24 mg/dL). At 72 hours of age, he was jaundiced—and a liver biopsy demonstrated neonatal hepatitis. His endocrine evaluation was positive for hypothyroidism, low cortisol level, undetectable growth hormone level, and an elevated prolactin level (confirming hypothalamic hypopituitarism).

Although older infants and children with pituitary deficiency present with ketotic hypoglycemia, in the neonatal period the hypoglycemia may mimic hyperinsulinism. However, their hypoglycemia is not responsive to diazoxide and only remits with replacement of deficient hormones (including thyroxine, as well as growth hormone and cortisol). When adrenal disease is severe, as in congenital adrenal hyperplasia, adrenal hemorrhage, or congenital absence or hypoplasia of the adrenals,[139,140] disturbances in serum electrolytes with hyponatremia and hyperkalemia or ambiguous genitalia may provide diagnostic clues.

Abnormalities of the ACTH receptor or adrenal hypoplasia may be phenotypically difficult to distinguish from cortisol deficiency of other causes, with the exception of the marked elevations of serum ACTH concentration noted if the ACTH receptor or adrenal gland is malfunctioning.[141] However, all states with ACTH elevations may be clinically suspected by virtue of the associated hyperpigmentation (see Chapter 13). These cases of isolated adrenal insufficiency very rarely cause hypoglycemia in neonates, whereas in older infants and children, treated congenital adrenal hyperplasia and isolated ACTH deficiency may cause profound stress-induced hypoglycemia. Congenital ACTH deficiency due to mutation in *TPIT*, which encodes TBX19, a transcription factor that is required for the expression of the proopiomelanocortin (POMC) gene and for terminal differentiation of the pituitary corticotroph lineage, is the exception, presenting in the neonatal period with severe and persistent hypoglycemia until hormonal replacement is established.[142] It is important to have in mind that a low growth hormone and cortisol level at the time of hypoglycemia is not

diagnostic of a true deficiency[143] and provocative testing may be needed to establish the diagnosis.

The mechanism of hypoglycemia in growth hormone deficiency may be the result of decreased lipolysis. The mechanism of hypoglycemia with cortisol deficiency may be reduced liver glycogen reserves plus diminished gluconeogenesis, owing to a failure to supply endogenous gluconeogenic substrate in the form of amino acids from muscle proteolysis. Investigation of a child with hypoglycemia therefore requires exclusion of ACTH, cortisol, or growth hormone deficiency—and if diagnosed appropriate replacement with cortisol or growth hormone.

Although glucagon deficiency[144,145] had been described, the authors have retracted their conclusions and now believe these patients had SCHAD hyperinsulinism; thus, this disorder is exceedingly rare and may be nonexistent. Epinephrine deficiency is also rare but must be a consideration in familial dysautonomia or in children treated with beta-blockers.

Defects in Glycogenolysis and Gluconeogenesis

Most of the disorders of glycogenolysis and gluconeogenesis that result in hypoglycemia are usually diagnosed in childhood and will be discussed in Chapter 6. The exception is glucose 6-phosphatase deficiency, which impairs the release of glucose from glycogenolysis and gluconeogenesis and presents in the neonatal period, although in some cases it is diagnosed later.

Glucose 6-Phosphatase Deficiency (GSD Type 1)

Glycogen storage disease type 1 is an autosomal recessive disorder caused by defects in the glucose 6-phosphatase (G6Pase) complex, which catalyzes the terminal steps of both hepatic gluconeogenesis and glycogenolysis, the hydrolysis of glucose 6-phosphate to glucose and inorganic phosphate. Deficiency of G6Pase activity in liver, kidney, and intestine results in the accumulation of glycogen in these organs, fasting hypoglycemia as a result of inadequate glucose production, and other secondary biochemical abnormalities including hyperlactacidemia, hyperuricemia, and hyperlipidemia.

Glucose 6-phosphatase is a multicomponent complex consisting of a catalytic unit, G6Pase, localized on the luminal side of the endoplasmic reticulum, and a G6P-specific bidirectional translocase (G6PT) that allow the entry of glucose 6-phosphate to the catalytic unit.[146] The gene for the catalytic unit has been cloned and located on chromosome 17,[147] whereas the gene for the glucose 6-phosphate translocase is located on chromosome 11.[148] Mutations in the catalytic unit cause GSD type 1a,[149] whereas mutations in G6PT cause GSD type 1b.[148] The phenotype for these two subtypes is identical, except that in type 1b, in addition to the liver phenotype, there are recurrent bacterial infections and inflammatory bowel disease associated with neutropenia and neutrophil dysfunction.[150] Although two additional types have been reported (GSD type 1c and GSD type 1d), there is insufficient available evidence to support the existence of these defects.

The estimated incidence of GSD type 1 is 1 in 100,000 live births, with GSD type 1a representing approximately 80% of cases. Clinically, GSD type 1 may present in the neonatal period with severe hypoglycemia occurring 2 to 2½ hours after a meal and tachypnea secondary to respiratory compensation for the metabolic acidemia. However, because lactate and ketones may provide adequate brain substrate to protect central nervous system function (and because in early infancy regular feedings are consistently provided) the diagnosis may be delayed for months until massive hepatomegaly brings the infant to medical attention, although the hepatomegaly may be missed because the liver is soft. After infancy, affected patients may be seen walking with a waddling gait secondary to their prominent abdomen and muscle weakness. Other consistent features are hyperuricemia, hypophosphatemia, a bleeding diathesis secondary to impairment of platelet adhesiveness, and growth retardation.

Hypoglycemia may occur anytime these children are exposed to even brief periods of fasting. They are completely dependent on the provision of glucose from exogenous sources, with the exception of the small amount of free glucose—which is released as part of the process of debranching glycogen. Because less than 10% of glycogen consists of branch points, this mechanism provides little protection against hypoglycemia during fasting. Hypoglycemia in the setting of suppressed insulin and increased glucagon promotes glycogenolysis, but the absence of G6Pase commits the glucose-1-phosphate produced by phosphorylase to glycolytic catabolism resulting in increased lactate production (see Figure 6-1). Another consequence of the impaired activity of G6Pase is the shunting of 6P through the pentose phosphate pathway, to yield ribose-6-phosphate, which ultimately yields uric acid, resulting in hyperuricemia. Hypertriglyceridemia results from increased triglyceride formation as a major route of disposal of pyruvate from lactate and amino acids when glucose yield is blocked in G6Pase deficiency.[151] Massive accumulation of fat in the liver is responsible for the massive hepatomegaly characteristic of GSD type 1.

Renal disease is a frequent complication of GSD type 1 (with an estimated prevalence of 30%).[152] Manifestations include proximal renal tubular dysfunction (Fanconi-like syndrome), distal tubular acidification defect, and hypercalciuria. There is an inverse relationship between age and citrate excretion, and the combination of low citrate excretion and hypercalciuria predispose these children to nephrocalcinosis and nephrolithiasis.[153] Citrate supplementation may prevent or ameliorate these complications.[154] The widespread prevalence and serious prognosis of kidney involvement is manifested by severe glomerular hyperfiltration and microalbuminuria over time, systemic arterial hypertension, and consequently renal failure.[155-157] The early implementation of treatment with angiotensin-converting enzyme inhibitors has been shown to delay the progression of renal damage.[152] The pathologic findings include focal segmental glomerulosclerosis with interstitial fibrosis. The etiology of the renal involvement is unclear, but it correlates negatively with metabolic control. It has been proposed that the dyslipidemia contributes to the kidney injury.[158]

In addition to the characteristic hepatomegaly, the liver undergoes adenomatous changes. Adenomas are usually first observed in the second and third decades of life but may appear before puberty.[157,159] The adenomas may undergo malignant degeneration or hemorrhage and are frequently associated with chronic iron resistant anemia.[160] Other complications of GSD 1 include osteopenia and growth retardation.

The diagnosis of GSD type 1 is based on the clinical and biochemical characteristics: hypoglycemia after a short period of fasting, hepatomegaly, lactic academia, and elevation of uric acid and triglycerides. Glucagon stimulation 2 to 4 hours after a meal containing carbohydrates results in increased lactate concentration, but plasma glucose does not rise.[160] The diagnosis can be confirmed by mutation analysis.

The goal of treatment of children with glucose 6-phosphate deficiency is to completely eliminate hypoglycemia and suppress secondary metabolic decompensation. Continuous nasogastric or intragastric feedings during the night have been demonstrated to either reduce or eliminate the metabolic and clinical findings through complete avoidance of hypoglycemia.[161] However, this approach places children at risk of severe hypoglycemia if feedings are abruptly stopped. A safer approach is the introduction of oral uncooked cornstarch, which helps prolonged the fasting tolerance[162,163] and can be used in older infants, usually older than 6 months of age. The doses of cornstarch used are approximately 1.6 g/kg per dose every 4 hours in infants and 1.7 to 2.5 g/kg per dose every 6 hours in older patients. A typical regimen consists of daytime feedings every 3 to 4 hours that are calculated to provide adequate carbohydrate calories to avoid the need for hepatic glucose output.[160] Most of these calories consist of carbohydrates, primarily providing pure glucose as an energy source and avoiding disaccharides containing fructose or galactose. At night, the regimen consists of an intragastric infusion of glucose with or without protein designed to infuse at rates of about 125% calculated hepatic glucose output[151] for normal young infants. For older children, a regimen of uncooked cornstarch can be implemented at nighttime.

Meticulous dietary control of blood glucose levels can lead to a significant clinical and metabolic improvement and prevention of complications. Adjunctive therapies should include careful monitoring of the uric acid level and treatment with allopurinol if the uric acid level is elevated. With increasing awareness of the renal tubular dysfunction, treatment of the hyperfiltration state with an angiotensin-converting enzyme inhibitor should be initiated promptly. Treatment with granulocyte-macrophage colony-stimulating factor to augment neutrophil production has been shown to ameliorate mouth ulcers and the enteritis in type 1b.[164]

Disorders of Fatty Acid Oxidation: Medium-Chain Acyl-Coenzyme A Dehydrogenase Deficiency (MCAD)

The inborn errors of metabolism associated with deficiencies of fatty acid oxidation (Figure 6-13) are inherited in an autosomal-recessive fashion. All of these disorders may be provoked by fasting and exhibit life-threatening events characterized by varying degrees of hypoglycemia associated with a relative deficiency in the generation of ketone bodies.[165] Disorders of fatty acid oxidation may be divided according to the site of the defect: defects of fatty acid and carnitine transport, β-oxidation defects, electron transport chain defects, and defects of ketone body synthesis and utilization. The presentation is usually beyond the neonatal period, but because of the severe consequences of the manifestations, newborn screening for the most common defect, MCAD deficiency, is now offered in all U.S. states and many other countries. In the United States, the screening also detects cases of long-chain L-3-hydroxyacyl-CoA dehydrogenase (LCHAD), carnitine transport defect, and very long-chain acyl-CoA dehydrogenase (VLCAD). We review the diagnosis, clinical characteristics, and treatment of MCAD deficiency in this chapter; other fatty acid oxidation defects are reviewed in Chapter 6.

MCAD deficiency is the most frequent defect on fatty acid oxidation. Neonatal screening in Pennsylvania has shown an incidence of 1 in 15,700 newborns.[166] MCAD (encoded by *ACADM*) is responsible for the initial dehydrogenation of acyl-CoAs with a chain length between 4 and 12 carbon atoms. Thus, defects in MCAD enzyme activity leads to accumulation of medium-chain fatty acids (between 6 and 10 carbons) that can be detected by mass spectrometry. The most prominent metabolite in MCAD deficiency is octanoylcarnitine (C8). Other metabolites presenting as abnormally elevated in MCAD deficiency include hexanoylcarnitine (C6), decanoylcarnitine (C10), and decenoylcarnitine (C10:1).

Children with MCAD deficiency may appear normal at birth, although symptoms may manifest before results from newborn screening are available.[167] The clinical presentation (if not detected by newborn screening) occurs between 3 and 24 months of life precipitated in response to prolonged fasting (at time of weaning from nighttime feedings) or during an intercurrent illnesses. The resulting metabolic stress may rapidly progress to coma and death. In children in which the diagnosis has not been previously established, the rate of death with the first episode is as high as 18%.[168]

Although there is significant heterogeneity in the presentation of MCAD, the most frequent clinical presentation is one of intermittent hypoketotic hypoglycemia with little or no acidemia, elevation of serum urea, ammonia, and uric acid, liver function abnormalities, and hepatic steatosis. The risk of severe complications and death is very high unless appropriate treatment to reverse the catabolic state is implemented. The diagnosis of these cases may be confused with Reye syndrome. Although hypoglycemia may be a prominent late feature with MCAD, the phenotype of a defect of a fatty acid oxidation disorder may not manifest if a fasting state is avoided. A high index of suspicion for fatty acid oxidation defects is important because appropriate therapy may result in an interruption and prevention of these potentially life-threatening episodes. Affected patients have also been misdiagnosed with idiopathic sudden infant death syndrome.[169] Decreased plasma carnitine levels and

an increase in the ratio of esterified to free carnitine is a frequently associated laboratory finding.

Evaluation of suspected errors in fatty acid oxidation should first include a determination of the profile of plasma acylcarnitines by mass spectrometry and measurement of plasma total, esterified, and free carnitine. Most, but not all, of the fatty acid oxidation disorders are associated with specific abnormalities of plasma acylcarnitines—octanoylcarnitine in cases with MCAD deficiency (Table 6-5). Determinations of urinary organic acids with assessment of the presence or absence of dicarboxylic aciduria are also very useful. Patients whose disorder cannot be identified by these tests may require further evaluations, including assays of fatty acid oxidation and specific enzyme assays in cultured skin fibroblasts or lymphoblasts. Since the early 1990s, the use of tandem mass espectometry has made newborn screening possible for most fatty acid oxidation disorders based on the acylcarnitine profile in blood spots. Presymptomatic identification of these individuals can prevent catastrophic events such as sudden death. Direct DNA mutational analysis can be performed for many of these defects, which is particularly useful in MCAD in which most cases are due to a single common mutations (Lys304Gly).[170]

The primary treatment of disorders of fatty acid oxidation is a devoted avoidance of fasting. For infants younger than 1 year old, 6 to 8 hours of fasting may be sufficient to precipitate an episode. On the other hand, as children become older they appear to be able to withstand periods of fasting of as long as 10 to 12 hours without decompensation. A high index of suspicion and rapid institution of intravenous glucose will often reverse an evolving episode. The presence of hypoglycemia is usually an event that occurs late in the evolution of an episode of metabolic decompensation. High-fat diets should be avoided, although normal amounts of dietary fats do not appear to be toxic. An adjunct approach may involve the use of cornstarch (as used for the treatment of type 1 glycogen storage disease) in doses of 1.5 to 2 g/kg.[171]

Defects of Glucose Transporters

GLUT1 Deficiency

Glucose transporter type 1 (GLUT1) deficiency syndrome is an autosomal dominant inborn error of glucose transport characterized by seizures, developmental delay, spasticity, acquired microcephaly, and ataxia. The biochemical hallmark is the finding of hypoglycorrhachia (low cerebrospinal fluid glucose concentration) despite normal plasma glucose concentrations.

GLUT1, encoded by *SLC2A1*, is the fundamental vehicle that facilitates glucose entry into the brain. Diagnosis of GLUT1 deficiency is based on the finding of low

cerebrospinal fluid glucose, in the absence of hypoglycemia, and identification of *SLC2A1* mutation (located on chromosome 1). The classic phenotype is a severe form of early onset epileptic encephalopathy in approximately 90% of cases (classic form). A nonepileptic form represents 10% of cases, which includes a broad phenotypic spectrum that may present with paroxysmal nonepileptic manifestations that have been reported to include intermittent ataxia, choreoathetosis, dystonia, and alternating hemiplegia.[172]

Treatment efforts have been based on providing alternative brain fuel sources by a ketogenic diet.[11,173] The ketogenic diet effectively controls the seizures and other paroxysmal activities, but it is has less effect on the cognitive function.

GLUT2 Deficiency

Originally described by Fanconi and Bickel as a syndrome characterized by hypoglycemia and ketonuria in the fasting state and hyperglycemia in the postabsorptive state,[174] Fanconi-Bickel syndrome is due to recessive mutations of the GLUT2 plasma membrane transporter for glucose (encoded by *SLC2A2*).[175] The defect on GLUT2 results in hepatorenal glycogen accumulation, proximal renal tubular dysfunction, and impaired utilization of glucose and galactose.[176] GLUT2 is expressed in hepatocyte, pancreatic β-cells, and the basolateral membranes of intestinal and renal tubular epithelial cells.[177] The clinical manifestations reflect impairment of glucose release from liver and of glucose reabsorption from renal tubular cells. Galactose clearance and conversion to glucose is delayed.

Patients with GLUT2 deficiency usually present at an age of 3 to 10 months. The typical clinical signs are hepatomegaly due to glycogen accumulation, a severe Fanconi-type renal tubulopathy with disproportionately severe glucosuria, glucose and galactose intolerance, hypophosphatemic rickets, and severely stunted growth.[178] These patients may present with a combination of fasting hypoglycemia and postprandial hyperglycemia. The hypoglycemia during fasting is explained by altered glucose transport out of the liver, resulting in an increased intracellular glucose concentration that may inhibit glycogen degradation, leading to glycogen storage and hepatomegaly. The hypoglycemia is exacerbated by renal loss of glucose due to a transport defect for glucose and galactose across the basolateral membranes of the tubular cells. Hyperglycemia (and hypergalactosemia) in the fed state is explained by decreased monosaccharide uptake by the liver and enhanced by an inappropriately low insulin secretion due to impaired glucose-sensing by the pancreatic β-cells.[175]

The therapeutic goal for patients with GLUT2 deficiency is to ameliorate the consequences of renal tubulopathy by replacing water, electrolytes, and alkali—and by providing phosphate and vitamin D supplementation. In terms of diet, an adequate caloric intake is recommended to compensate for renal and intestinal glucose loss—given as frequent feedings containing slowly absorbed carbohydrates (such as cornstarch) to avoid fasting hypoglycemia.

TREATMENT

A rational therapeutic approach to the treatment of hypoglycemia relies on a systematic diagnostic evaluation. The key to effective treatment is diagnosis specific. The maintenance of euglycemia is critical to the preservation of central nervous system function. Even in the presence of an uncertain diagnosis, every effort must be used to maintain euglycemia until a diagnosis is made or hypoglycemia resolves. Intravenous glucose infusion remains the mainstay of emergency therapy, particularly for the child with severe hypoglycemia. It is important to follow

an initial glucose bolus with a continuous glucose infusion to prevent further episodes of hypoglycemia until specific therapies are established.

The therapeutic goal is to maintain plasma glucose > 3.3 mmol/L (70 mg/dL). Ideally, treatment should maintain normoglycemia on a normal feeding schedule for the patient's age. It is advisable to periodically reassess the efficacy of the treatment for any form of hypoglycemia by a formal fasting study on treatment.

CONCLUSIONS

Since the early reports of neonatal hypoglycemia in the 1950s by McQuarrie[55] and Cornblath and colleagues,[179] our understanding of the pathogeneses and treatment of hypoglycemia in neonates and infants has progressed significantly. The ongoing identification of new molecular causes of congenital hyperinsulinism represents significant new discoveries. The development of noninvasive techniques (such as the ^{18}F-fluoro-L-DOPA PET scan) that can accurately identify patients with focal hyperinsulinism and the potential for cure with surgical removal of the lesion are promising advances in the treatment of these children. These and future discoveries should result in continued improvement in outcome for hypoglycemic patients.

QUESTIONS

1. An infant girl was admitted to a children's hospital on day 3 of life following an apneic episode at home for which emergency medical services (EMS) was dispatched after a 911 call. EMS recorded a glucose of 24 mg/dL (meter) and treated it with a bolus of 10% glucose followed by transfer to the children's hospital. History revealed an induced delivery at 34W gestation because of U/S confirmed IUGR presumed secondary to "placental insufficiency." The mother admitted to smoking half a pack per day during pregnancy but denied use of any other medication or drugs; a screening OGTT was normal. At birth, the baby weighed 2.6 kg, had Apgar of 9/9, and was found to have symmetric growth retardation. Despite feeding and intravenous glucose at 15 mg/kg/min, hypoglycemia persisted. A "critical sample" on day 5 of life was performed when the glucose was noted to be 33 mg/dL via meter and confirmed via laboratory glucose. In this "critical sample," insulin was 62 μU/mL, cortisol 32 μg/dL, growth hormone 35 ng/mL; βOHB 0.2 mmol/L. What should the net step be?
   a. Genetic mutational analysis with emphasis on KCNJ11, ABCC8.
   b. Liver biopsy to rule out GSD-1.
   c. Start diazoxide 10 mg/kg/D in divided doses.
   d. Refer to an institution for PET scan with ^{18}F-L DOPA immediately preceding scheduled surgery for pancreatectomy.

Answer: c

2. A 17-month-old female was admitted to a children's hospital for evaluation of a seizure. Three weeks before the seizure, she had a "spell" and was taken to a local emergency department where metered blood glucose was 17 mg/dL and a formal laboratory glucose was 30 mg/dL. In that sample, insulin concentration was < 2 μU/mL, GH 11.1 ng/dl, and cortisol 32 μg/dL. Because of the low insulin, a diagnosis of "ketotic hypoglycemia" was made and the infant discharged to her home. Past history revealed normal gestation, delivery and birth weight, normal developmental milestones, and normal weight gain and growth. While awaiting the results of an EEG and MRI of the brain, it was noted that the fasting blood glucose was 60 mg/dL and 1 hour post prandial glucose was 44 mg/dL. A "controlled fast" was begun after the child had her usual evening meal. Two hours after this meal, a metered blood glucose was 36 mg/dL and lab glucose was 37 mg/dL. Other results included the following:
   β-OHB of 0.27 mmol/L
   Lactate 1.8 mM/L
   Insulin 9 μU/ML
   NH_3 93 μM/L

Given the presentation beginning at approximately 17 months, what is the most likely diagnosis?
   a. Idiopathic ketotic hypoglycemia of infancy
   b. Hyperinsulinism due to an activating mutation in the insulin receptor
   c. Medium-chain acyl-CoA dehydrogenase deficiency
   d. Hyperinsulinism due to an activating mutation in GLUD1

Answer: d

What are the correct next steps for this condition?
   a. Frequent feedings, especially milk to avoid fasting hypoglycemia
   b. Diazoxide 10 mg/kg/day in divided doses
   c. Supplemental carnitine in all feedings
   d. Confirmation of the diagnosis by mutation analysis of glutamate dehydrogenase
   e. a and c
   f. b and d

Answer: f

3. A 4 month-old boy is referred to endocrine clinic for poor growth. He was the product of a full-term, normal pregnancy complicated by gestational diabetes treated with diet. A plasma glucose concentration at 2 hours of age was 40 mg/dL. He was formula-fed and a plasma glucose concentration at discharge on day of life 2 was 50 mg/dL. Over the past 2 months, his mother has noted that he has been increasingly fussy and sweaty if not fed every 2 hours. Despite the frequent feedings, his length and weight have decreased from the 50 and 80 percentiles, respectively, at birth to the 10 and 25 percentiles at 4 months of age. On physical examination, he seems irritable and is breathing rapidly; the liver is enlarged to 8 cm below the costal margin; the phallus is 3.2 cm in length and the testes are descended 2 mL in volume bilaterally. Lab tests show plasma glucose 25 mg/dL; normal sodium, potassium, and chloride, HCO_3; 11 mEq/L; calcium 10 mg/dL; phosphate 4.5 mg/dL; growth hormone 2 ng/mL, cortisol 8 μg/dL, insulin 3 μU/mL; and urine ketones small.

Which of the following is the most likely diagnosis?
   a. Hyperinsulinism associated with recessive mutations of short-chain 3-hydroxy-acyl-CoA dehydrogenase
   b. Hypopituitarism associated with recessive mutation of PIT1
   c. Recessive deficiency of the GLUT2 glucose transporter
   d. Mosaic paternal isodisomy for 11p
   e. Recessive deficiency of glucose 6-phosphatase (G6PC)

Answer: e

The diagnosis is best confirmed by which of the following results?
   a. Following injection of glucagon 1 mg IV, the plasma glucose rises from 35 to 90 mg/dL after 30 minutes.
   b. Following injection of glucagon 1 mg IV, the blood lactate rises from 3.5 to 7 mM/L after 15 minutes.
   c. Following ingestion of an oral protein supplement, 1 gm/kg, the plasma glucose falls from 75 to 45 mg/dL after 20 minutes.
   d. Following ingestion of oral glucose, 1.75 gm/kg, the plasma glucose rises to 250 mg/dL at 1 hour and then falls to 35 mg/dL at 1.5 hour.

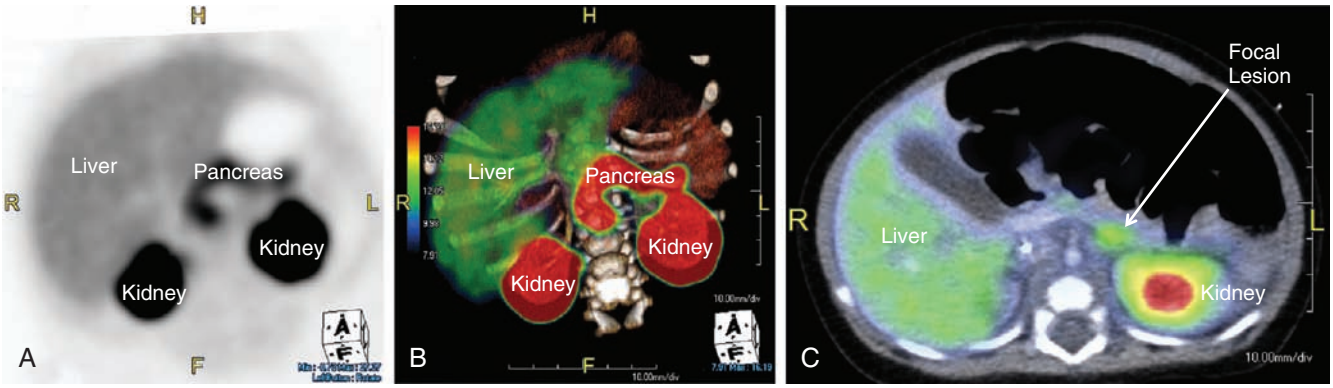
e. Following injection of calcium 200 mg/kg IV, the plasma insulin rises from 10 up to 45 μU/mL after 3 minutes.

Answer: b

What would be the most appropriate treatment for this condition?

a. A high-protein, low–glycemic index diet
b. Frequent feedings using a normal milk-based formula
c. Frequent feedings using a non–lactose-containing formula, with the addition of raw cornstarch after age 1 to 2 years old
d. Oral diazoxide plus a low-leucine diet
e. Growth hormone, 0.3 mg/kg/week, divided into twice daily injections

Answer: c



e-FIGURE 6-1 ■ A, ^{18}F-fluoro-L-DOPA PET scan image of a diffuse case of hyperinsulinism showing L-DOPA uptake in the liver, in the kidneys, and throughout the pancreas with equal intensity. **B,** Fused 3D image of a contrast-enhanced CT scan fused with an ^{18}F-fluoro-L-DOPA PET scan for the same case as in (**A**). **C,** An axial image of a contrast-enhanced CT scan fused with an ^{18}F-fluoro-L-DOPA PET scan showing a focus of increased uptake in the posterior body of the pancreas. CHAPTER 7

Disorders of the Thyroid in the Newborn and Infant

Guy Van Vliet, MD • Johnny Deladoëy, MD, PhD

CHAPTER OUTLINE

INTRODUCTION

The management of the fetus, newborn, and infant with disorders of thyroid function has benefited greatly from our ability, since the 1970s, to measure hormones in minute amounts of biologic fluids. Specifically, biochemical screening of newborns for congenital hypothyroidism (CH) is now routine throughout the industrialized world and has resulted in the disappearance of the overt intellectual disability that affected 8% to 28% of patients with this condition in the prescreening era.[1] More recently, the molecular basis of several monogenic disorders of thyroid development and function has been deciphered. However, most cases of abnormal thyroid gland development in humans, the most common cause of CH, are unexplained and constitute one of the remaining mysteries of thyroid physiopathology.[2] On the other hand, progress in ultrasound techniques has led to an increasing number of goiters being identified in the fetus in utero, which raises the possibility of prenatal treatment via the mother's amniotic fluid in highly selected cases.[3] This chapter reviews thyroid disorders in the fetus, newborn, and infant from a developmental, molecular, and clinical perspective.

EMBRYOLOGY, PHYSIOLOGY, AND PHYSIOPATHOLOGY

Development of the Thyrotropic Axis

As for all organs, anatomic development of the hypothalamic-pituitary-thyroid system occurs during the first trimester of gestation. The human embryonic forebrain and hypothalamus begin to differentiate by 3 weeks of gestation under the influence of a series of homeodomain proteins or transcription factors. Immunoreactive thyrotropin-releasing hormone (TRH) becomes detectable in human embryonic hypothalami by 8 to 9 weeks of postconceptional age and is also produced by the fetal gut and pancreas.[4,5]

Anatomically, the pituitary gland develops from two ectodermal anlagen: a neural component from the floor of the primitive forebrain and Rathke's pouch from the primitive oral cavity. The latter is visible by 5 weeks, evolving to a morphologically mature pituitary gland by 14 to 15 weeks. The pituitary-portal blood vessels are present by this time and mature further through 30 to 35 weeks. A wide spectrum of congenital malformations collectively named "midline defects," including holoprosencephaly

and septo-optic dysplasia, may be associated with central hypothyroidism and other anterior pituitary deficiencies.[6] The molecular mechanisms underlying these malformations have been identified in some cases.[7] Within the pituitary itself, PROP-1 and PIT-1 are terminal factors in the differentiation cascade of pituitary cells and PIT-1 or PROP-1 deficiency results in profound defects in growth hormone, prolactin, and thyroid-stimulating hormone (TSH) secretion as well as age-dependent pituitary hypoplasia.[8-10]

The human thyroid gland develops from a median anlage derived from the primitive pharyngeal floor and from paired lateral anlagen from the fourth pharyngeal pouches. The long-held belief that the lateral anlagen were the only source of calcitonin-producing cells has been challenged by the observation that sublingual thyroids that are derived exclusively from the median anlage contain calcitonin mRNA and protein.[11] Conversely, thyroid follicular cells can differentiate within the lateral anlagen, as illustrated by histologic observations[12] as well as by patients in whom the only thyroid tissue is a lateral ectopy.[13] Both the median and lateral structures are visible by day 16 to 17 of gestation; by 50 days they have fused and the thyroid gland has migrated to its definitive location in the anterior neck. The thyroglossal duct, from the foramen cecum to the final location of the thyroid, may persist and is constituted of degenerated thyroid follicular cells. Within the thyroid gland, iodine concentration, TSH receptors, thyroglobulin, and thyroid peroxidase mRNA and protein can be demonstrated by 70 days.[14]

Thyroid embryogenesis is dependent on the expression of a programmed sequence of homeobox and transcription factors, including thyroid transcription factors-1 and -2 (TTF-1 or TiTF-1, also known as NK2 homeobox 1 -NKX2-1- and TTF-2, also known as Forkhead box E1 -FOXE-1) and paired box gene 8 (PAX8).[15] Embryonic stem cells in which NKX2-1 and PAX 8 are overexpressed form fully differentiated thyroid cells and will form the typical follicular architecture under the influence of TSH.[16] In keeping with this concept, mice with a naturally occurring mutation inactivating the TSH receptor have a disorganized follicular architecture,[17] and this is also probably the case in humans with similar mutations in which a high serum thyroglobulin in spite of profound thyroid hypoplasia suggests leaky follicles.[18] In newborn mice, biallelic inactivation of Nkx2.1 results in absence of both pituitary and thyroid glands, with complete absence of both thyroid follicular cells and of calcitonin-producing C cells,[19] whereas that of PAX8 results in a small thyroid gland composed almost exclusively of C cells.[20] FOXE-1 null mouse embryos have either an absent thyroid or an ectopic sublingual gland, but all newborn pups have athyreosis in addition to cleft palate.[21] Mutations in the homologous genes, however, account for at most 2% of cases of thyroid dysgenesis in humans.[22]

Placental Transfer of Iodine, T4, TRH, Antithyroid Drugs, and Immunoglobulins

Iodine is an essential component of thyroid hormones. In this chapter, the term *iodine* is used to designate both iodine itself (I^2) and iodide (I^-). The human placenta expresses the sodium–iodine symporter throughout gestation,[23] which explains why the mother's iodine status is reflected in the fetus (Figure 7-1) . If the mother's iodine intake is suboptimal, the fetal thyroid cannot constitute appropriate stores of iodine and fetal hypothyroidism may ensue. Worldwide, inadequate maternal iodine intake leading to irreversible consequences, known as endemic cretinism, remains a major public health problem. Prevention of this condition by supplying the mother with adequate iodine is one of the best and most important examples of considering the fetus as a patient and of treating this patient through its mother.[24,25]

In contrast to iodine, thyroxine (T4) was for a long time thought not to cross the placenta in substantial amounts.[26] However, T4 is detectable in human embryonic tissues before the onset of fetal thyroid function and must, therefore, be of maternal origin.[27] Later in gestation, the transfer of T4 from mother to fetus must continue, because the concentration in cord blood from neonates with complete absence of thyroid function is 30% to 50% of that of normal neonates.[28] More recently, it was shown that normal neonates born to a mother who has chronically higher T4 concentrations due to a mutation inactivating the thyroid hormone receptor have lower birth weight and TSH concentrations at newborn screening than those born to normal mothers.[29] Taken together, these data indicate that maternal T4 must cross the placenta in physiologically relevant amounts throughout gestation.

That this transplacental transfer of T4 from mother to fetus might be of clinical relevance was suggested by the severe developmental delay observed in an infant with central hypothyroidism caused by a maternally inherited

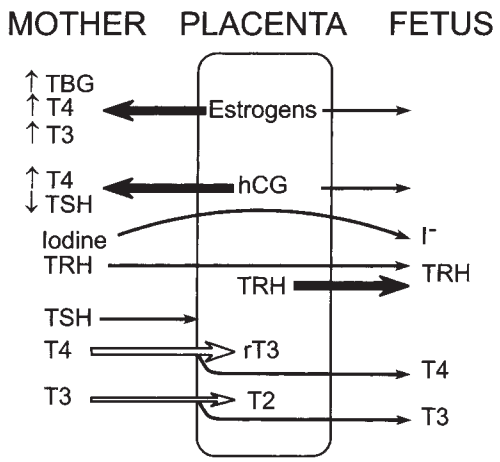

FIGURE 7-1 ■ The placental role in thyroid metabolism during human pregnancy. The placenta produces estrogens and a human chorionic gonadotropin (hCG), which increase maternal TBG levels and stimulate maternal thyroid hormone production, respectively. Both activities tend to increase maternal T4 and T3 concentrations and inhibit maternal TSH secretion. Iodide and TRH readily cross the placenta. In addition, the placenta synthesizes TRH. The placenta is impermeable to TSH and only partially permeable to T4 and T3. Placental type 3 iodothyronine monodeiodinase enzymes degrade T4 to reverse T3 and T3 to 3,3′ T2. The placenta is also permeable to the thiourea drugs used to treat maternal Graves disease.

heterozygous mutation inactivating PIT1, and whose equally hypothyroid mother had stopped thyroxine treatment at midpregnancy.[30] At the population level, children born to mothers who have low T4 concentrations during pregnancy have been reported to have lower IQ than children born to mothers with normal circulating concentrations of thyroid hormones.[31-33] However, in a randomized trial, developmental outcome was similar in the offspring of T4- and placebo-treated women who had either elevated TSH concentrations (> 97.5 percentile) or lower circulating T4 concentrations (< 2.5 percentile) when treatment was begun toward the end of the first trimester.[34] Moreover, in two recent case series of women with severe hypothyroidism diagnosed during pregnancy but corrected by the third trimester, the intellectual outcome of the offspring was normal.[35,36] Thus, universal screening for thyroid dysfunction during pregnancy remains questionable at this time. On the other hand, 85% of women who are already receiving T4 therapy require an increase in dose of about 30% to 50% during pregnancy because of the estradiol-induced increase in serum thyroxine-binding globulin (TBG).[37]

The transplacental transfer of T4 is not always sufficient to prevent the development of fetal goiter if the fetus has severe thyroid dyshormonogenesis. Fetal goiters may be big enough to interfere with the flow of amniotic fluid into the airways, causing progressive hydramnios and eventual lung hypoplasia. In such occurrences, levothyroxine can be injected into the amniotic fluid, which the fetus then swallows, leading to a decrease in the size of the fetal thyroid and in the degree of hydramnios.[38] The injection of thyroxine into the umbilical vein, which carries an even higher risk of triggering premature labor or fetal loss than amniocentesis, should be restricted to fetuses with a goiter that continues to increase in spite of repeated intra-amniotic injections. Invasive and potentially risky procedures should not be undertaken to protect the brain of affected fetuses: indeed, the fetal brain is, to a large extent, protected from the deleterious effect of hypothyroidism through upregulation of brain type 2 deiodinase, which converts the prohormone T4 into its biologically active derivative, T3.[39] This likely accounts for the observation that even in CH with delayed bone maturation at diagnosis (indicating a prenatal onset), the intellectual outcome is within normal limits if continuous and adequate treatment is instituted shortly after birth.[40] Thus, the in utero treatment of fetal hypothyroidism should only be considered in exceptional circumstances, such as for goiter causing progressive hydramnios. Although the identification of a goiter by prenatal ultrasound may be increasing,[41] it remains rare and even direct examination at birth often fails to detect goiters that are obvious on scintigraphy. Goiters can also be observed in fetuses borne by women with Graves disease if they are overtreated with antithyroid drugs, which readily cross the placenta. Reducing the dose of the antithyroid medication given to the mother should decrease the size of the fetal thyroid in such circumstances[42] (Figure 7-2).

Although the placenta produces a pro-TRH molecule, TRH concentrations in the maternal circulation are very low and thus have little effect on fetal thyroid function. However, TRH, with its tripeptide structure (the smallest of the hypothalamic hypophysiotropic peptides), crosses the placenta readily and, when injected to the mother, increases thyroid hormone concentrations in the fetus. Because thyroid hormones stimulate fetal lung maturation, maternal TRH treatment to decrease neonatal respiratory distress syndrome has been attempted, but without successful outcome.[43]

Because immunoglobulins of the IgG type cross the placenta, transient fetal/neonatal hyperthyroidism from transplacental transfer of TSH-receptor activating antibodies can occur in women with past or present Graves disease. On the other hand, when pregnant women are overtreated with antithyroid drugs, which also cross the placenta readily, their fetus may develop goitrous hypothyroidism, as noted previously. However, in the Québec database for neonatal thyroid screening, only one case out of 30,000 births is attributable to this mechanism (unpublished observations). Lastly, transient neonatal hypothyroidism from materno-fetal transfer of TSH-receptor–blocking antibodies can also occur, but only accounts for 2% of cases of neonatal hypothyroidism identified by screening[44]; hence, for babies born to women with Hashimoto thyroiditis, a specific screening strategy is not required. However, thyroid function tests are often ordered clinically in newborns whose mother has a history of thyroid disease and, if abnormal, require special consideration of optimal approach to therapy. For example, hypothyroidism at birth caused by treatment of maternal Graves disease with antithyroid medication may only require observation, in the expectation that the effects of the drugs will dissipate over a few days; hyperthyroidism may follow, albeit exceptionally. For hypothyroidism or hyperthyroidism resulting respectively from maternal TSH receptor blocking or stimulating antibodies, treatment will be required as these effects may last several months.[45]

Maturation of Thyroid Hormone Synthesis and Secretion

Maturation of thyroid function in the fetus reflects changes at the level of the hypothalamus, pituitary, and thyroid. Serum TRH concentrations are relatively high in the human fetus, because it is produced at both hypothalamic and extrahypothalamic sites and because of the TRH-degrading activity of fetal blood is low.[46] Fetal serum TSH increases from a low concentration at 18 to 20 weeks to a peak value of approximately 7 to 10 mU/L at term. After delivery, in response to exposure to the cold extrauterine environment, there is an acute release of TSH with mean serum concentrations peaking at 30 minutes at approximately 70 mU/L. The subsequent increase in serum T4 concentration immediately after birth is TSH dependent.

Only free thyroid hormones enter cells, and hormones bound to serum TBG and other transport proteins are not available to tissues. In addition, T4 is a prohormone and it is T3 that is biologically active to exert intracellular effects, so that deiodination of T4 is essential for tissue euthyroidism. Both serum transport

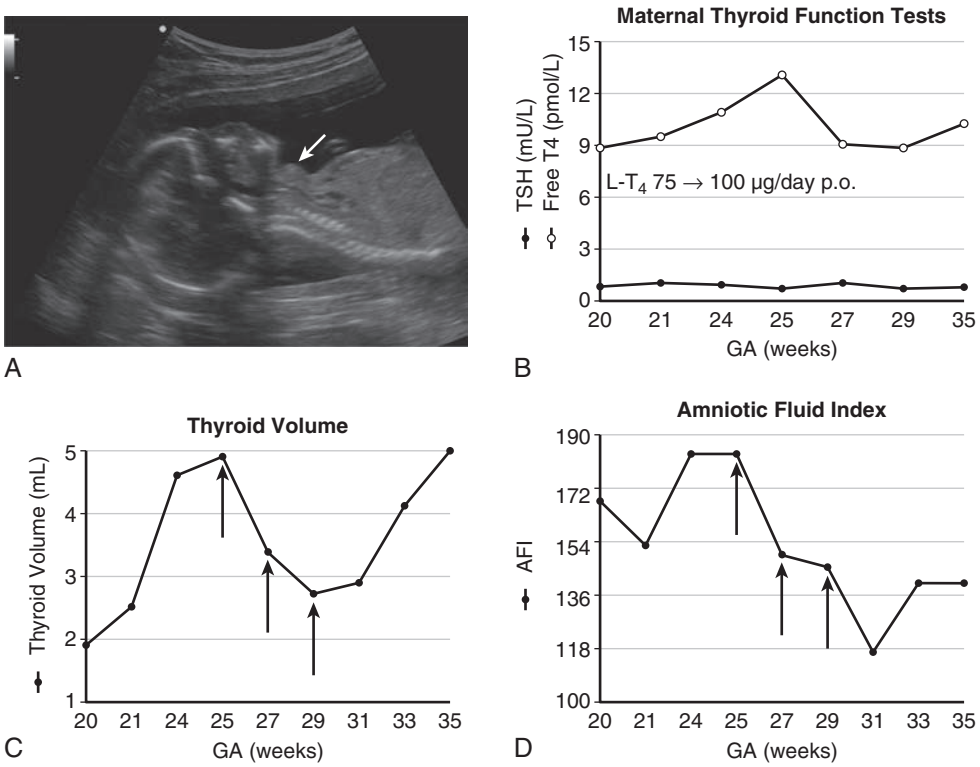

FIGURE 7-2 ■ **A,** Fetal goiter discovered at a routine ultrasound at 19 weeks (white arrow). The mother was euthyroid and had no autoantibodies. Cordocentesis showed a serum TSH of 90 mU/L. **B,** initial management was through oral treatment of the mother with increasing doses of levothyroxine; this resulted in increased maternal free T4 concentrations, but presumably not enough to cross the placenta in sufficient amounts to prevent the progression of the fetal goiter (panel C) and the development of hydramnios (panel D). **C,** Effect of 3 intra-amniotic injections of 200 μg of levothyroxine (black arrows) on fetal thyroid size. **D,** Effect of three intra-amniotic injections of 200 μg of levothyroxine (black arrows) on amniotic fluid index. At birth, cord serum TSH was 224 mU/L and thyroglobulin was low at 3.55 μg/L; thyroglobulin deficiency was confirmed by molecular genetic analyses. Treatment with 50 μg of levothyroxine orally from day 1 has allowed this child, now age 4 years, to have normal intellectual development. (Adapted and updated from Stoppa-Vaucher S, Francoeur D, Grignon A, et al. [2010]. Non-immune goiter and hypothyroidism in a 19-week fetus: a plea for conservative treatment. J Pediatr 156:1026-1029.)

proteins and intracellular deiodination change during development. As previously mentioned, the fetal thyroid gland is capable of iodine concentration and iodothyronine synthesis as early as 70 days of gestation, a reflection of a sharp increase in the expression of the sodium-iodine symporter and of the appearance of a follicular architecture.[47] Starting at 18 to 20 weeks, total T4 and TBG concentrations in fetal serum increase steadily until the final weeks of pregnancy.

The study of free T4 concentrations in fetal/neonatal blood has been hampered by the relative inadequacy of the commercially available immunoassay systems for measurements in these samples.[48] The fetal serum T3 concentration remains low until 30 weeks due to two factors: first, the low activities of type 1 iodothyronine monodeiodinase result in relatively low rates of T4 to T3 conversion in fetal tissues; second, active type 3 monodeiodinase in placenta and selected fetal tissues degrades T3 to T2. After 30 weeks, serum T3 increases slowly until birth. This prenatal increase in serum T3 is due to progressive maturation of liver type 1 deiodinase activity increasing hepatic conversion of T4 to T3, and to decreased placental T3 degradation. Postnatally, T3 and T4 serum concentrations increase two- to sixfold within the first few hours, peaking on the second day of life. These levels then gradually decline to levels characteristic of infancy over the first 4 to 5 weeks of life (Figures 7-3 and 7-4).

In the human, the fetal thyroid gland grows and its production increases under the influence of the increasing serum TSH level during the second half of gestation, as illustrated by the severely atrophic and hypofunctional glands observed in newborns with mutations that inactivate either the β-subunit of TSH[49] or the TSH receptor.[50] On the other hand, the maturation of the negative feedback control system appears to occur earlier than previously thought, as an elevated TSH in serum obtained at cordocentesis can be seen in fetuses with primary hypothyroidism as early as 18 weeks.[51]

Thyroid function in the premature infant (before 30 to 32 weeks) is characterized by low circulating concentrations of T4 and free T4, a normal or low concentration of TSH, and a normal or prolonged TSH response to TRH, suggesting a degree of relative hypothalamic (tertiary) hypothyroidism. In summary, fetal thyroid hormone secretion results from increasing hypothalamic TRH secretion that stimulates the secretion of TSH from the pituitary and increased thyroid follicular cell sensitivity to TSH. In turn, this process is regulated by increasing pituitary sensitivity to inhibition by thyroid

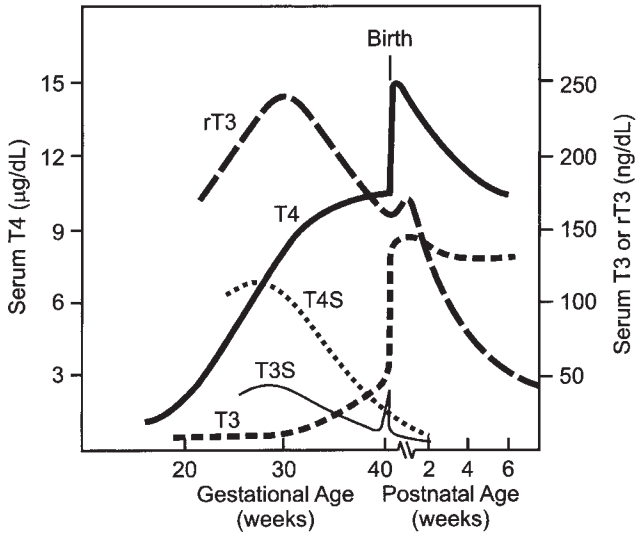

FIGURE 7-3 ■ The pattern of change in fetal and neonatal thyroid function parameters during pregnancy and extrauterine adaptation. Fetal serum thyroxine (T4) concentrations begin to increase at midgestation and increase progressively thereafter to term. This increase is due largely to the increase in thyroxine-binding globulin concentration, but free T4 concentrations (not shown) also increase progressively between 20 and 40 weeks. T4 in the fetus is metabolized predominantly to inactive reverse triiodothyronine (rT3) and sulfated analogs (T4S, T3S). Monodeiodination of T4 to active triiodothyronine (T3) increases at about 30 weeks to levels approximating 50 ng/dL at term. The TSH surge (not shown), which peaks at 25 to 30 minutes after extrauterine exposure, stimulates thyroidal T4 and T3 secretion. Neonatal T4 and T3 peak at 2 to 3 days. Serum T3 concentrations remain at higher postnatal levels because of the increased T4-to-T3 conversion mediated by increased type 1 iodothyronine deiodinase activity in newborn tissues.

hormone of TSH release. The marked cold-stimulated TRH-TSH surge at birth is associated with a marked increase in T4 secretion and free T4 concentration with a new equilibrium reached by 1 to 2 months. During infancy and childhood, there is a progressive decrease in T4 secretion rate (based on a μg/kg/day) correlating with a decreasing metabolic rate.[52]

Maturation of Thyroid Hormone Metabolism and Transport

The thyroid gland is the sole source of T4. Most of the circulating T3 after birth is derived from conversion of T4 to T3 via monodeiodination in peripheral tissues. Deiodination of the iodothyronines is the major route of metabolism, and monodeiodination may occur either at the outer (phenolic) ring or the inner (tyrosyl) ring of the iodothyronine molecule. Outer ring monodeiodination of T4 produces T3, the form of thyroid hormone with greatest affinity for the thyroid nuclear receptor. Inner ring monodeiodination of T4 produces reverse T3 (rT3), an inactive metabolite. In adults, between 70% and 90% of circulating T3 is derived from peripheral conversion of T4, and 10% to 30% from direct glandular secretion. Nearly all circulating rT3 derives from peripheral conversion, with only 2% to 3% coming directly from the thyroid gland. T3 and rT3 are progressively metabolized to diiodo, monoiodo, and noniodinated forms of thyroxine, none of which possess biologic activity.

Two types of outer ring iodothyronine monodeiodinases have been described.[53] Type 1 deiodinase (predominantly expressed in liver, kidney, and thyroid) is a high-Km enzyme inhibited by propylthiouracil and stimulated by thyroid hormone. Type 2 deiodinase (predominantly located in brain, pituitary, placenta, skeletal muscle, heart, thyroid, and brown adipose tissue) is a low-Km enzyme insensitive to propylthiouracil and inhibited by thyroid hormone. Types 1 and 2 deiodinases contribute to circulating T3 production, whereas type 2 acts to increase local tissue levels of T3 as well. An inner ring deiodinase (type 3 deiodinase) has been characterized in most fetal tissues, including placenta. This enzyme system catalyzes the conversion of T4 to rT3 and T3 to diiodothyronine. All three deiodinase enzymes are selenoproteins (Figure 7-5).

Deiodination is developmentally and thyroid-state regulated. In the human fetal brain, type 2 deiodinase activity in the cortex increases between 13 and 20 weeks gestation and by about 50% over the last third of gestation. There is a general inverse correlation of type 2 and type 3 activities. Both of these deiodinase species are thyroid hormone responsive.

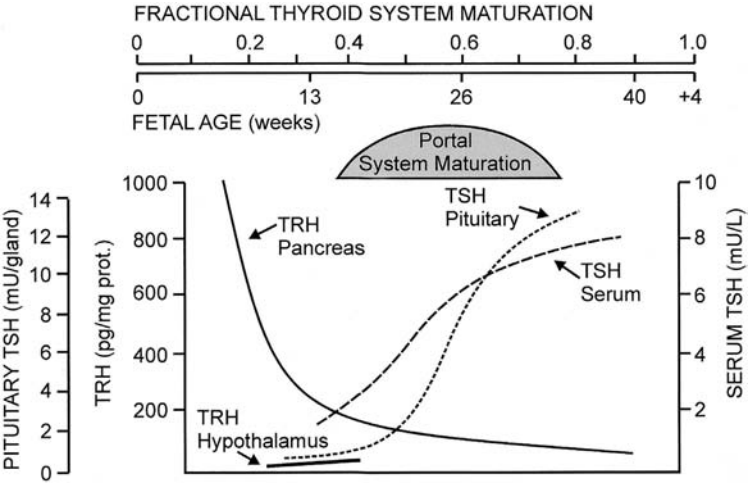

FIGURE 7-4 ■ Changes in fetal TRH and TSH levels in pancreas, hypothalamus, serum, and pituitary during human gestation. Hypothalamic TRH concentrations increase progressively after midgestation, but the pattern of change has not been documented in the human fetus. (Reproduced with permission from Fisher DA, Polk DH [1994]. Development of the fetal thyroid system. In Thorburn GD, Harding R [eds.], *Textbook of fetal physiology*. Oxford, UK: Oxford University Press, 359-368.)

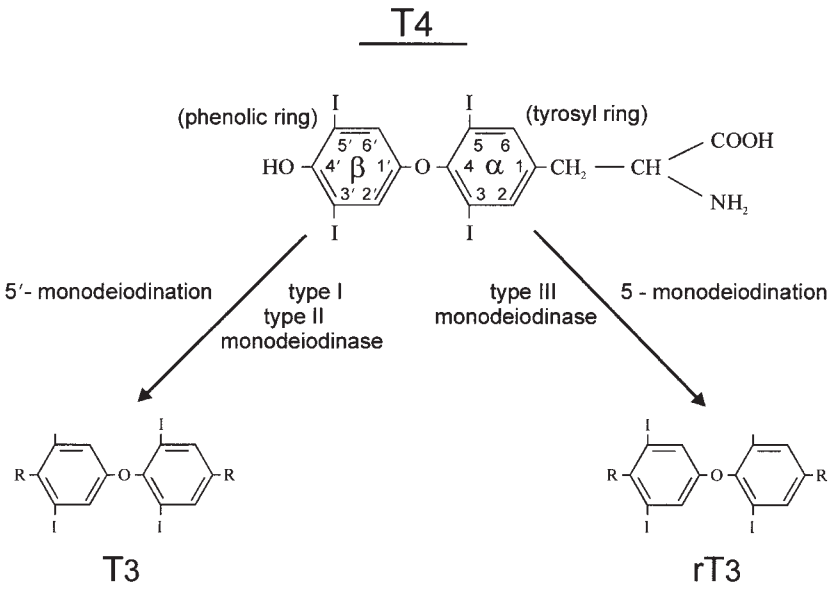

FIGURE 7-5 ■ The deiodination of thyroxine by types 1, 2, and 3 iodothyronine monodeiodinase enzymes. The type 1 enzyme is also capable of inner ring monodeiodination, particularly of the sulfated conjugates (not shown).

Fetal thyroid hormone metabolism is characterized by a predominance of type 3 enzyme activity (particularly in liver, kidney, and placenta), accounting for the increased circulating concentrations of rT3 observed in the fetus. However, the persistence of high circulating rT3 concentrations for several weeks in the newborn indicate that type 3 deiodinase activity expressed in nonplacental tissues is important. The mixture of type 2 and type 3 deiodinase activities in the placenta provides for the conversion of T4 to T3 and of T4 and T3 to rT3 and T2, respectively.

Sulfated iodothyronines are the major thyroid hormone metabolites circulating in the fetus.[54] Sulfokinase enzymes are present early in fetal life, and sulfation of the phenolic hydroxyl group of the iodothyronine molecule may be a normal prerequisite step for monodeiodination. The sulfated iodothyronines are preferred substrates for the type 1 deiodinase, and concentrations are high in fetal serum in part because of low type 1 deiodinase activity. However, increased production of sulfated metabolites is also involved. There is evidence that T3S has biologic activity (i.e., suppresses TSH in vivo), suggesting that it can be de-sulfated by one or more tissue sulfatase enzymes. The low production rates and low levels of T3 metabolites and the high ratio of inactive to active metabolites suggest that fetal thyroid hormone metabolism is largely oriented to inactivating T4, presumably to avoid tissue thermogenesis and to potentiate the anabolic state of the rapidly growing fetus. This is mediated by early activation of type 3 monodeiodinase, inactivation of type 1 monodeiodinase, and augmented iodothyronine sulfation.

The developmental expression of type 2 deiodinase in brain and other tissues provides for local T3 supply to specific tissues (particularly in the event of T4 deficiency) and helps guarantee provision of T3 during gestation, when brain development is thyroid hormone dependent.[39]

Extrauterine Thyroid Adaptation

At the time of parturition, the neonate must rapidly convert from the fetal state of predominant thyroid hormone inactivation to a state of relative thyroidal hyperactivity. During the first hours after birth, there is an acute increase in circulating T4 and T3 levels. This is due to the abrupt increase in hypothalamic TRH stimulating increased pituitary TSH secretion and, in turn, thyroid hormone secretion. The cold-stimulated TRH-TSH surge is short lived and mean TSH concentrations decrease progressively to normal infant levels by 3 to 5 days, but the serum-free T4 level remains elevated for several weeks.[55]

Serum T3 levels increase in response to the TSH surge, because of stimulation of thyroidal T3 secretion and of increased hepatic type 1 deiodinase activity. Placental separation decreases T3 deiodination (to inactive T2), contributing to the early postnatal increase in serum T3 concentration. The type 2 deiodinase activity in brown adipose tissue increases during the last weeks of gestation to potentiate catecholamine-stimulated brown adipose tissue thermogenesis, thereby contributing to the maintenance of the body temperature of the neonate.[53]

Thyroid Hormone Actions

Evidence suggests that all thyroid-sensitive cell populations express iodothyronine membrane transporters. These belong to several families of integrin, organic anion, amino acid, and monocarboxylate solute carriers. The importance of these transporters is highlighted by the role of mutations inactivating human monocarboxylate transporter 8 (MCT8) in an X-linked syndrome of severe psychomotor retardation (previously called the Allan-Herndon-Dudley syndrome) combined with mild abnormalities of thyroid function, characterized by high T3, low T4, and normal or high TSH.[56,57] MCT8 is thought to play a role in the entry of T3 into neurons,

after deiodination of T4 to T3 in neighboring astrocytes. In addition, MCT8 is involved in the transfer of T3 across the blood-brain barrier. Lastly, the abnormalities in thyroid hormone levels and TSH are also due to the effect of MCT8 on deiodination.[58]

Thyroid hormone effects are mediated predominantly via nuclear thyroid hormone protein receptors (TR), which act as DNA-binding transcription factors regulating gene transcription. Two mammalian genes code for TR, TRα and TRβ, and alternative mRNA splicing lead to the production of four major thyroid hormone-binding transcripts: TRα1, TRα2, TRβ1, and TRβ2. The TRs exist as monomers, homodimers, and heterodimers with other nuclear receptor family members such as the retinoid X receptors. TRα1 is the predominant subtype in the bone, gastrointestinal tract, heart, and brain. TRβ1 is expressed in liver, kidney, heart, lung, brain, cochlea, and pituitary. TRβ2 is expressed in pituitary gland, retina, and cochlea. The receptors function redundantly, as indicated by knockout studies in mice, but predominant effects of one or another TR have been described.

In humans, the specific roles of TRα and TRβ are illustrated by the phenotypes observed in patients with inactivating mutations in the corresponding genes. The syndrome of thyroid hormone resistance initially described in 1967 was later found to be generally due to mutations inactivating TRβ that occur either *de novo* or are inherited in an autosomal dominant fashion; however, in some patients with thyroid hormone resistance, TRβ is normal and the molecular defect remains elusive.[59] Mutations in TRα have been described, occurring de novo in one patient[60] and transmitted from father to daughter in one pedigree.[61]

Thyroid hormone-programmed development of fetal tissues requires the interaction of local tissue monodeiodinase 1 and 2, TRs, thyroid receptor coactivators, and thyroid-responsive genes. In most responsive tissues, the timing of maturation events is controlled by the TRs acting as a molecular switch. In the absence of T3, the unliganded receptor recruits corepressors, thereby repressing gene transcription. Local tissue maturation events are stimulated by the coincident availability of T3, liganded T3 receptor, T3-mediated receptor exchange of corepressors with coactivators, and activation of responsive gene transcription.[62]

In the human fetus, low levels of TR binding have been detected in brain tissue at 10 weeks gestational age—and liver, heart, and lung TR binding is observed at 16 to 18 weeks. TR levels in human fetal cerebral cortex and cerebellum increase markedly during the second and third trimesters.[63] Information is limited regarding the timing of the appearance of thyroid hormone tissue effects in the human fetus.

The birth length of the athyroid human neonate is within normal limits: the linear growth of the human fetus is programmed independently of thyroid hormones by a complex interplay of genetic, nutritional, and hormonal factors, as well by the mechanical uterine constraint.[64] However, 50% to 60% of athyroid newborns manifest delayed epiphyseal maturation and have large fontanelles.[65] At birth, severe CH may be suspected in the presence of a large anterior fontanelle, a persistent posterior fontanelle at term with diastasis of the parietal bones, macroglossia and umbilical hernia; delayed meconium emission, feeding difficulties, and prolonged jaundice may be noted soon thereafter.[66] However, the classic clinical manifestations of CH appear progressively during the early months of life. These include soft-tissue myxedema, a slow linear growth, and retarded central nervous system (CNS) development.[64] The normal IQ in most athyroid infants treated early thanks to newborn screening[1] seems attributable to the low but significant levels of maternal thyroxine derived from placental transfer, shown in humans,[28] and the upregulation of type 2 monodeiodinase in fetal brain tissue in the face of low fetal serum thyroxine concentrations, shown in rats.[39]

Postnatal thermogenesis is mediated via the brown adipose tissue prominent in subscapular and perirenal areas in the mammalian fetus and neonate. Heat production in brown adipose tissue is stimulated by catecholamines via β-adrenergic receptors and is thyroid hormone dependent. The uncoupling protein thermogenin unique to brown adipose tissue is located on the inner mitochondrial membrane and uncouples phosphorylation by dissipating the proton gradient created by the mitochondrial respiratory chain. The type 2 monodeiodinase in brown adipose tissue mediates local T4 to T3 conversion. Full thermogenin expression in brown adipose tissue requires both catecholamine and T3 stimulation.[67] Brown adipose tissue matures progressively in the fetus but remains thermoneutral until stimulated by catecholamines in the perinatal period. Brown adipose tissue thermogenesis is immature in small premature infants, and brown adipose tissue mass decreases in the neonatal period in full-term infants as the capacity for nonshivering thermogenesis develops in other tissues.[68] Uncoupling protein-2 is found in many tissues, but it does not appear to be regulated by β-adrenergic agonists or thyroid hormone. Uncoupling protein-3 is expressed in muscle and white adipose tissue as well as brown adipose tissue. Muscle uncoupling protein-3 is regulated by β3-adrenergic stimulation and thyroid hormone and presumably contributes to nonshivering thermogenesis in humans. mRNA levels for uncoupling protein-3 are also regulated by dexamethasone, leptin, and starvation, but the regulation differs in brown adipose tissue and muscle. Starvation increases muscle and decreases brown adipose tissue uncoupling protein-3, suggesting that muscle serves a larger role in thermoregulation during starvation.[69]

The critical role of thyroid hormones in CNS maturation has long been recognized. Nervous system development involves neurogenesis, gliogenesis, neural cell migration, neuronal differentiation, dendritic and axonal growth, synaptogenesis, myelination, and neurotransmitter synthesis. Thyroid hormones have been shown to stimulate a number of developmentally regulated nervous tissue genes, but the role of these factors in the CNS developmental program remains undefined. Available evidence suggests that deficiency or excess of thyroid hormones alters the timing or synchronization of the CNS developmental program, presumably by initiating critical gene actions or other genetic CNS maturation events.[70]

There is increasing evidence for a critical period for thyroid-dependent brain maturation in utero. Early maternal hypothyroxinemia in the rat alters histogenesis and cerebral cortical architecture of the progeny.[71] As noted earlier, maternal hypothyroxinemia in humans has been reported to be associated with IQ reduction in offspring,[31-33] but association does not mean causation as shown by the negative results of the randomized controlled trial of T4 treatment.[34] In contrast, iodine supplementation in pregnant women in geographic areas of severe iodine deficiency improves developmental outcome of the offspring if given before the third trimester of gestation.[24] The reasons for the discrepancy between the effect of iodine in iodine-deficient women and the lack of effect of T4 in hypothyroid women are unknown. Studies of the dose and timing of thyroid hormone therapy in infants with CH suggest a second critical period of thyroid hormone action during the very early neonatal period,[72] but the period of CNS thyroid hormone dependency extends further, to at least 2 years of age.[73]

CONGENITAL HYPOTHYROIDISM

Newborn Screening

CH screening tests are usually carried out in dried blood spot samples collected via skin puncture, although a few programs use cord serum.[74-76] The historical controversy between the proponents of using total T4[77] or TSH[78] as the primary test was related in part to the greater precision of T4 measurements around the cutoff value, but this is no longer an issue. Because primary hypothyroidism is at least 10-fold more common than central hypothyroidism and because only 19% of cases of central hypothyroidism have T4 below the cutoff,[6] primary TSH screening makes more sense. About half of the states in the United States and the Netherlands still use a primary T4 strategy, but, in effect, all are screening for elevated serum TSH concentrations as the secondary screening test. In the Dutch program, for instance, TSH is measured in almost half of the population: all those with a T4 below 0.8 SD *and* all infants born with a weight $\leq$ 2.5 kg or a gestational age of $\leq$ 36 weeks.[79] Conversely, the Québec program uses T4 to sort cases with borderline TSH elevation (15 to 30 mU/L) as shown on the algorithm in Figure 7-6.

With the trend toward earlier discharge of newborns in the 1990s, the minimal age at which TSH screening should be performed was assessed: in the first 24 hours, 9% of the population had a TSH above 15 mU/L (a reflection of the neonatal surge), but this percentage dropped precipitously to only 0.2% to 0.3% from days 2 to 5. Thus, any sample collected after 24 hours is acceptable.[80]

A more recent controversy relates to the threshold value for a significant TSH elevation, with cutoffs varying from 6 to 20 mU/L of whole blood.[81] Predictably, the lower the cutoff, the greater the number of children labeled as having CH. However, the additional cases identified have mostly functional disorders whose impact on cognition and behavior, if left untreated, is unknown.[82]

False-negative results are very rare and most are due to errors in specimen handling, testing and data analysis, or reporting of results. Some jurisdictions obtain screening samples in addition to the initial one in low-birth-weight infants, based on observations of a delayed TSH rise in some.[83,84] The mechanisms for such delayed rises are unknown, but the widespread use of dopamine infusions, a potent inhibitor of TSH secretion, in the first few days of life may play a role.[85] An update on a subset of

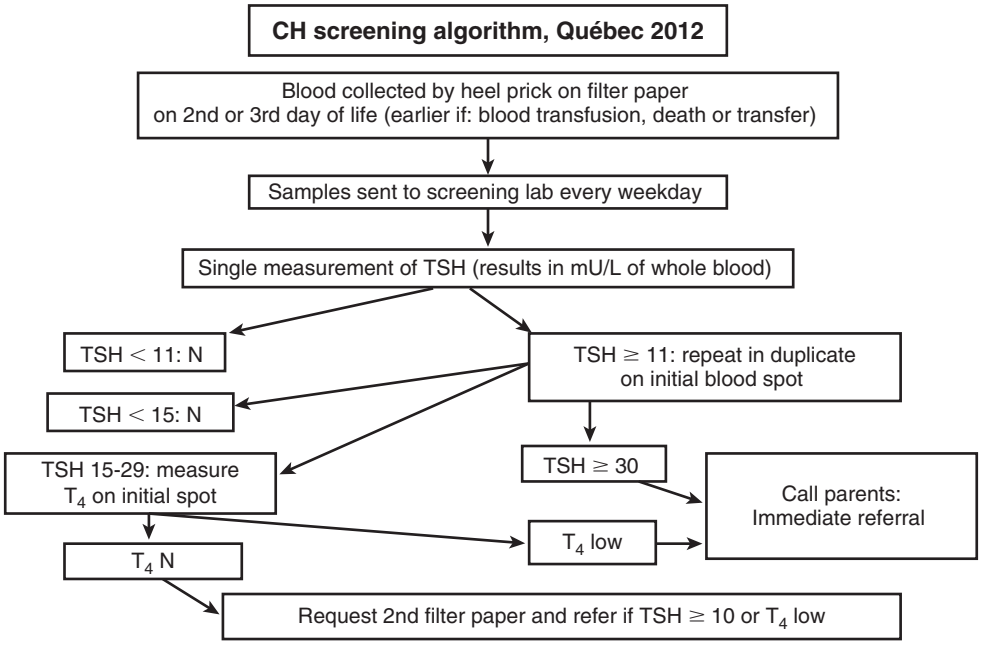

FIGURE 7-6 ■ Algorithm presently used in Québec for screening newborns for hypothyroidism.

low-birth-weight newborns with a delayed TSH rise has shown that the problem was transient, with no evidence of benefit from treatment.[86] Thus, the repeat screening policy in low-birth-weight newborns remains debatable.[87] By contrast, the case for a repeat screening policy in same-sex twins risk is stronger, as fetal blood mixing may lead to a falsely negative screening TSH in the affected member of a monozygotic twin pair.[88]

As is obvious from the previous discussion, estimating the prevalence of CH depends on the ascertainment method. Before population-based biochemical screening of neonates, it was 1 in 6700 births.[89] Over the almost four decades of the screening era, it has increased progressively from 1 in 4000 to 1 in 2500 with our current screening algorithm [82] or even 1 in 1500 in some jurisdictions.[90,91] Geographical and temporal variations are due almost exclusively to differences or changes in screening algorithms.[92] In keeping with this concept, permanent CH due to thyroid dysgenesis documented by radionuclide imaging is not increasing, whereas the prevalence of dyshormonogenesis, a group of autosomal recessive conditions, is predictably higher in inbred populations[93] or in those with a founder effect.[94] Interestingly, the introduction of folic acid fortification, which has resulted in a marked decrease in the prevalence of neural tube defects[95] and of some heart malformations,[96] has not affected the prevalence of CH due to thyroid dysgenesis in the same jurisdiction.[82] Universal newborn screening has also provided estimates of the relative birth prevalence of various congenital thyroid disorders at the population level (Table 7-1).

TABLE 7-1 **Estimated Birth Prevalence of Various Types of Permanent Thyroid Disorders in Iodine-Sufficient Populations, Based on Universal Newborn Screening with Either TSH or T4**

Type of Permanent Congenital Disorder	Estimated Birth Prevalence
Thyroid dysgenesis	
—Ectopy	1:5,000
—Athyreosis	1:15,000
Thyroid dyshormonogenesis	1:30,000
Hypothalamic-pituitary hypothyroidism	1:21,000
Thyroid hormone resistance	1:40,000

Thyroid Dysgenesis

Dysgenesis is defined as abnormal organogenesis, a process that occurs during the embryonic period. The most common developmental defect, currently accounting for about half of CH cases,[82] is a defect in the migration of the median anlage, resulting in an ectopic (sub)lingual thyroid. These ectopic thyroids are round structures, lacking lateral lobes, and are the only thyroid tissue present in affected individuals. They can only be unequivocally visualized by radionuclide scanning.[97] In almost 10% of cases, there is a dumbbell appearance, with two adjacent areas of ectopic tissue.[98] Histologically, ectopic thyroids are fully differentiated with a normal follicular architecture. Thus, the associated hypothyroidism, which is variable in severity, is likely due to a smaller number of cells, due to the absence of lateral lobes, and to a limitation to TSH-induced cell growth.[99] The second category of thyroid dysgenesis, athyreosis, is heterogeneous. Indeed, about half of newborns with CH and undetectable technetium uptake on imaging have a detectable serum thyroglobulin.[100] We have proposed to call this situation "apparent athyreosis." Apparent athyreosis can be permanent in patients with a severely hypoplastic and hypofunctional orthotopic thyroid due to mutations that completely inactivate the TSH receptor.[50] The term *transient athyreosis* has been used to describe the absent uptake that can be observed in babies with CH due to the transplacental transfer of TSH receptor-blocking antibodies.[101]

Thyroid dysgenesis is usually sporadic but familial cases occur more often than by chance alone.[102] On the other hand, monozygotic twins are almost always discordant.[88] To reconcile these seemingly discrepant findings, a two-hit model combining germ-line susceptibility and early postzygotic mutations has been proposed,[22] but its validation requires access to ectopic thyroids, which generally do not need to be removed. The limited data available seem to exclude somatic mutations in TTF-1, TTF-2, and PAX-8[99] and suggest the implication of the Wnt-beta catenin pathway in thyroid migration.[103]

Also inconsistent with simple Mendelian genetics is the observation that thyroid dysgenesis is about twofold more prevalent in female than in male infants. In most series, the skewing of the sex ratio is more pronounced in ectopy than in athyreosis.[104] Thyroid dysgenesis is less prevalent in blacks, who are more genetically diverse than Caucasians, and this supports an oligogenic first-hit susceptibility.[105] In some of the rare multiplex families, mutations in TTF-1, TTF-2, or PAX8 can be found but these genes have been excluded by linkage analysis in other multiplex families.[106] TTF-2 mutations appear to be the least common, having been found in the homozygous state in only three consanguineous pedigrees in which probands present with true athyreosis and cleft palate, sometimes associated with kinky hair, choanal atresia, and a bifid epiglottis.[107] TTF-1 heterozygous mutations, de novo or dominantly inherited, present with a spectrum of anomalies, the "brain-lung-thyroid syndrome," in which CH is usually mild and associated with normal thyroid gland morphology[108,109] but may rarely be severe with apparent athyreosis.[110] Heterozygous

mutations in PAX8 can occur de novo or be inherited in an autosomal dominant fashion.[111] They have been associated with hypothyroidism of greatly variable severity and age of onset, even within the same pedigree, with either apparent athyreosis or orthotopic thyroid hypoplasia. In spite of the ubiquitous expression of PAX8, the phenotype is generally limited to hypothyroidism.[112] Lastly, mutations of another transcription factor (GL1S3) have been described as the cause of a rare syndrome of CH with apparent athyreosis or normal thyroid anatomy, neonatal diabetes, congenital glaucoma and deafness, liver, kidney, and pancreas abnormalities.[113,114] Thus, all transcription factor mutations in humans have been found to cause true athyreosis (TTF2), apparent athyreosis, or orthotopic thyroid hypoplasia (TTF1, PAX8, GLIS3) (Table 7-2) but thyroid ectopy, the most common form of thyroid dysgenesis, remains unexplained.

Newborns with trisomy 21, as a group, have a slight skewing of their T4 distribution toward low values and of TSH toward higher values.[115] However, these shifts are very subtle so that TSH rarely exceeds screening cutoffs. In fact, not a single case of CH was found in a newborn with trisomy 21 over 20 years in Québec (1.6 million births), so that previous statements that the prevalence of CH is markedly increased in trisomy 21 are clearly unfounded.[82]

An increased prevalence of extrathyroid abnormalities has consistently been found in several large series; specifically, defects in heart septation are observed in about 5% of dysgenetic CH cohorts.[104,116,117] The molecular mechanisms underlying this association are unknown. These septal defects are usually mild and close spontaneously so that, beyond a careful clinical examination, they do not need to be searched for by other tests.

Overt CH due to defects in TSH binding/action resulting in severe thyroid hypoplasia at birth[18] represents a developmental disorder (growth being part of development), and we therefore think it is more appropriate to discuss this entity under dysgenesis rather than under dyshormonogenesis. Severe TSH resistance was postulated in 1968[118] and the molecular characterization of the TSH receptor, a member of the family of G-protein–coupled receptors,[119] has led to the identification of homozygote or compound heterozygote loss-of-function mutations of the TSH receptor gene in several patients with this phenotype.[18,50,120] However, the phenotype resulting from biallelic TSH receptor inactivating mutations is generally milder.[121,122] When only one allele bears a mutation inactivating the TSH receptor, carriers are typically normal as expected in traditional autosomal recessive transmission, although some may have asymptomatic hyperthyrotropinemia.[123] Likewise, TSH resistance from defects in the Gs subunits, as seen in pseudohypoparathyroidism, is typically mild (although it may be picked up on neonatal screening[124]), and these patients usually maintain normal serum T4 concentrations.

Thyroid Dyshormonogenesis

General Features

The thyroid gland can be envisioned as an iodine pump coupled to an assembly line destined to return iodine to the bloodstream in a hormonally active form.[125] The major substrates for thyroid hormone synthesis are iodine and tyrosine. Tyrosine is not rate limiting even in individuals with phenylketonuria, in whom tyrosine becomes an essential amino acid. Iodine, by contrast, is a trace element that can be rate limiting in thyroid hormone synthesis. The process of thyroid hormone biosynthesis is initiated by TSH binding to the follicular cell TSH receptor and cAMP activation.[126]

Processes stimulated by cAMP include cell membrane iodine transport, thyroglobulin synthesis, oxidation and organification of trapped iodine, activation of colloid endocytosis and intracellular phagolysosome formation, hydrolysis of thyroglobulin to release the iodotyrosines (monoiodotyrosine [MIT] and diiodotyrosine [DIT]) and iodothyronine (T4 and T3) residues, deiodination of MIT and DIT by a dehalogenase leading to intracellular iodine recycling, and release of T4 and T3 into the circulation.[127] Significant amounts of thyroglobulin

TABLE 7-2 **Thyroid and Extrathyroid Phenotypes Associated with TSHR and Transcription Factor Mutations and Mode of Inheritance**

Thyroid Phenotype	Other Features	Gene	Transmission
From apparent athyreosis to normally appearing gland	None	*TSHR*	AR

RDS, respiratory distress syndrome; TTF, thyroid transcription factor; AR, autosomal recessive; AD, autosomal dominant.

also escape from the gland, predominantly via the thyroid lymphatic system. These events are summarized in Figure 7-7. Infants with CH due to dyshormonogenesis leading to goiter constitute some 10% to 15% of newborns with CH.

The causes of thyroid dyshormonogenesis include decreased iodine trapping, defective organification of trapped iodine, abnormalities of thyroglobulin structure, and deficiency of iodotyrosine deiodination and recycling. With few exceptions, these disorders are transmitted as autosomal recessive traits.[128] Except for the familial incidence and tendency for affected individuals to develop goiter, the clinical manifestations of CH due to a biochemical defect are similar to those in infants with thyroid dysgenesis. Thyroid enlargement may be manifest at birth or even before, but in many patients development of the goiter is delayed. From surveys of the specific molecular defects, it appears that mutations in thyroperoxidase are the most common cause of thyroid dyshormonogenesis.[129] However, identifying the specific disorder in an individual patient is not required as it does not affect management: a risk of 25% in siblings of affected subjects can be given empirically, treatment is lifelong except in DuOX2 deficiency (discussed later), and surveillance for the development of multinodular goiter, a frequent occurrence, is required.

Sodium-Iodine Symporter Defects

The transport of iodine across the thyroid follicular cell membrane from plasma to cytosol is the first step in thyroid hormone biosynthesis. Under normal circumstances, the thyroid cell membrane iodine pump generates a thyroid/serum (T/S ratio) concentration gradient in excess of 20 to 30. This gradient can reach several hundredfold when the thyroid gland is stimulated by a low-iodine diet, by TSH, by thyroid-stimulating immunoglobulins in Graves disease, or by drugs that impair the efficiency of hormone synthesis. Other tissues (such as the salivary glands, gastric mucosa, mammary glands, ciliary body, choroid plexus, and placenta) are also capable of concentrating iodine against a gradient. However, these tissues are not capable of organifying inorganic iodine.

The discovery of the gene encoding the sodium-iodine symporter (NIS; called *SLC5A5* and which has been mapped to chromosome 19) has allowed detecting the presence of mutations in 31 patients with a defect in iodine transport as of 2006. The patients present most frequently with neonatal or infantile hypothyroidism (which may rarely be transient) and the diagnosis is based on the presence of a goiter on clinical examination or ultrasound imaging contrasting with limited or absent uptake on scintiscanning. The timing of onset of hypothyroidism tends to correlate with the genotype-specific residual NIS activity and iodine intake. Neonatal onset is likely with mutations associated with lower radioactive iodine uptake. Importantly, infantile onset after normal neonatal TSH screening has been reported, sometimes with neurodevelopmental sequelae.[130]

Pendred Syndrome

Pendred syndrome, defined as congenital bilateral neurosensory deafness and goiter, is transmitted as an autosomal recessive trait. By some estimates, it is the cause of 10% of cases of congenital deafness.[131] The etiology of the deafness remains controversial but it is characteristically associated with dilated semicircular canals on CT scanning of the temporal bone (an abnormality named "Mondini's cochlea"). The thyroid phenotype is usually mild, appears to depend on nutritional iodine intake, and is seldom identified by neonatal TSH screening.[132,133] Over time, affected subjects may develop a goiter and subtle hypothyroidism.

One century after its clinical description, the gene responsible for this syndrome was discovered. This gene, *SLC26A4*, maps to chromosome 7, and the predicted

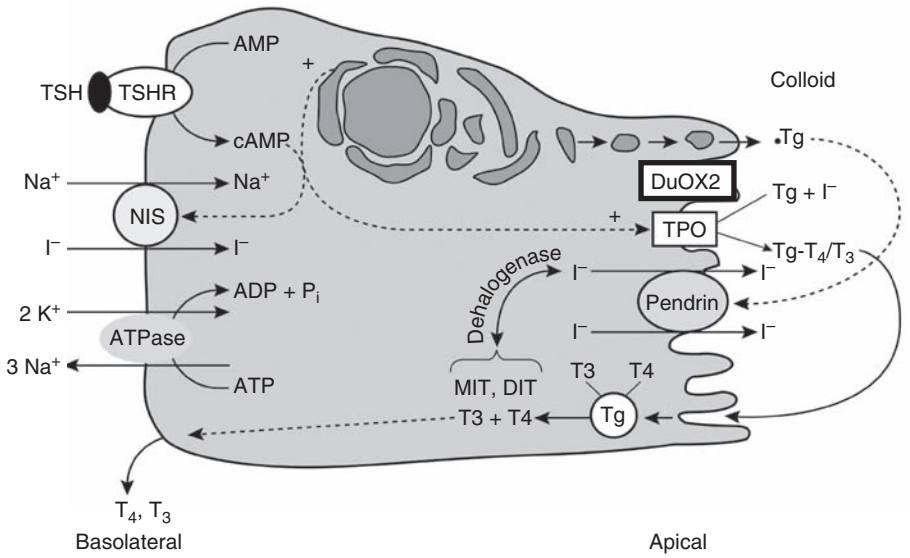

FIGURE 7-7 ■ Schematic representation of a thyroid follicular cell indicating all the important steps in thyroid hormone biosynthesis.

protein, named pendrin, is a multifunctional anion exchanger.[131] It is mainly expressed in the thyroid, the inner ear, and the kidney. In the thyroid, pendrin localizes to the apical membrane of thyrocytes, where it may be involved in mediating iodide efflux. In the inner ear, pendrin is important in the maintenance of a normal anion transport and of the endocochlear potential. Molecular studies in affected families from different geographic areas have shown independent point mutations and no large deletions.[134]

Thyroperoxidase Defects

Normally, iodide concentrated by the thyroid follicular cell is rapidly oxidized and bound in organic form. Organification of iodide involves two processes: oxidation of iodide and iodination of thyroglobulin-bound tyrosine. Trapped iodide is oxidized to an active intermediate, followed by iodination of thyroglobulin-bound tyrosyl residues to form the iodotyrosines MIT and DIT. Two DIT residues are "coupled" to form T4, while MIT and DIT couple to form T3. Tyrosyl iodination and coupling are catalyzed by a thyroid peroxidase enzyme system located at the apical membrane of the thyroid follicular cell in association with thyroid (NADPH) oxidases. Thyroid peroxidase (TPO) is a membrane-bound heme protein that requires peroxide and an acceptor, which in the normal thyroid gland is thyroglobulin but can be albumin or other proteins or peptides. The clinical presentation of thyroperoxidase deficiency is permanent goitrous CH with high uptake on scintiscanning and a high serum thyroglobulin. Historically, complete iodide organification defects were identified by a rapid and profound discharge of the thyroidal radioiodine trapped after administration of perchlorate (the "perchlorate discharge test").[127] This test is not specific for TPO deficiency (it can also be positive in Pendred syndrome and in DuOX2 deficiency, as discussed later) and clinical grade perchlorate is not available in all jurisdictions. Detecting mutations in the TPO gene will establish the diagnosis if this is deemed important, such as in atypical pedigrees due to uniparental disomy[135] or other mechanisms.[128]

The thyroid peroxidase gene is located on chromosome 2 and encodes a glycoprotein that is located at the apical membrane of the thyroid follicular cell. Since the 1990s, a variety of mutations have been described, including homozygous and compound heterozygous missense mutations, frame-shift mutations, base pair duplications, and single-nucleotide substitutions,[136,137] but no systematic genotype-phenotype correlations have been established. In about 17% of patients with a TPO deficiency phenotype, only one TPO mutations is found and the TPO deficiency may arise from the monoallelic expression of mutant TPO in the thyroid.[138]

Defects in H_2O_2 Generation

Since the first description of mutations inactivating DuOX2,[139] one of the enzymes generating H_2O_2 at the apical membrane, DuOX2 mutations have been found with increasing frequency.[127] It was initially suggested that monoallelic mutations led to transient CH while mutations on both alleles led to permanent CH. It is now clear that even patients with biallelic mutations can have a transient phenotype[140] and that their phenotypic variability, even within a family, is wide. It has been speculated that iodine intake is a possible disease modifier[141] but genetic variants in DuOX1, the other H_2O_2-generating enzyme in the thyroid (and also located on chromosome 15), may also play a role in the variable phenotype of DuOX2 deficiency.[140] By contrast, in a patient with a phenotype reminiscent of DuOX2 deficiency, the DuOX2 gene was normal but the gene encoding the "DuOX2 maturation factor" (that is required for translocation to the plasma membrane of functional DuOX2[142]) was mutated.[143] Other clinical observations show redundancy between the two DuOX enzymes and their respective maturation factors.[127]

Thyroglobulin Defects

Thyroglobulin is an essential substrate for organification and is the major protein component of the colloid in the thyroid follicular lumen. It is an iodinated glycoprotein with a molecular weight approximating 650,000 daltons. It consists of two monomeric chains, each with 67 tyrosine residues. About one third of the tyrosine residues are spatially oriented so that they are susceptible to iodination. The thyroglobulin gene is located on chromosome 8 and encodes a 300-kilodalton monomer molecule.[144]

Genetic defects can lead to thyroglobulin deficiency or structural/functional abnormalities of the protein. Goiter and hypothyroidism are usually manifest at birth or even before, and a low or undetectable serum thyroglobulin in this context points to thyroglobulin mutations. Interestingly, five of the cases of nonautoimmune fetal goiters in whom the gene defect was searched for have had thyroglobulin defects,[42,145-147] whereas a thyroperoxidase defect has been found in only one.[148] To date, 52 mutations in thyroglobulin have been described, leading to various defects including defective transport with carbohydrate-deficient thyroglobulin sequestered in Golgi or cytoplasmic membranes, thyroglobulin with deficient tyrosine residues or tyrosine residues buried within the molecule and not available for iodination, and sialic-acid–deficient thyroglobulin (due to a sialyltransferase deficiency) containing MIT and DIT but manifesting defective coupling.[149]

Dehalogenase Defects

Iodotyrosine deiodinase recycles the iodine contained in MIT and DIT as they are released from thyroglobulin within the thyroid follicular cell. Failure to deiodinate MIT and DIT leads to their being leaking out of the thyroid and being excreted in the urine. Iodotyrosine deiodinases are present in both thyroid cells and peripheral tissues, and abnormalities involving both systems have been described.

A clinical phenotype was originally described in the 1950s, combining hypothyroidism; goiters with early, rapid thyroid radioiodine uptake and rapid spontaneous discharge; and high serum and urine concentrations of MIT and DIT. The cloning of the gene encoding

iodothyronine dehalogenase (DEHAL1, IYD, located on chromosome 6) has led to the identification of mutations of the DEHAL1 gene in five consanguineous pedigrees. The variability of the phenotype between siblings carrying the same mutation in the homozygous state and in time of onset of hypothyroidism between pedigrees may be due to variation in iodine intake but appears to also involve yet unidentified modifier genes.[150-152] The development of the phenotype between ages 9 and 15 years in one patient with a single mutated allele is unexplained, but monoallelic expression in the thyroid was ruled out.[151] Importantly, some patients had intellectual disability as a consequence of early-onset, but not congenital, hypothyroidism.[150] This emphasizes that hypothyroidism should be looked for in any infant with suggestive signs, even if TSH was normal at neonatal screening.

Abnormal Thyroid Hormone Metabolism

Selenium Incorporation Defects

As discussed previously, iodothyronines are metabolized via three iodothyronine monodeiodinases (types 1, 2, and 3). To date, no defects have been identified in the genes encoding the enzymes themselves. All are selenoproteins requiring the incorporation of selenocysteine (sec) during biosynthesis. Incorporation of selenocysteine into the iodothyronine monodeiodinase enzymes requires several components: a selenocysteine insertion sequence (SECIS) element, a SECIS-binding protein (SECISBP2), and a selenoprotein-specific elongation factor (EFSec) and its transfer RNA $tRNA^{sec}$.

Homozygous or compound heterozygous mutations in the SECISBP2 gene on chromosome 9 have been reported in four probands (including one who had had a high TSH at neonatal screening, but no follow-up because of normal T4), ascertained for transient delay in growth, and found to have elevated T4, reverse T3 and TSH, and decreased T3.[153-155] A broader and more severe phenotype including myopathy[156] azoospermia and photosensitivity,[157] in addition to abnormal thyroid function tests, has also been described, consistent with the ubiquitous functions of selenoproteins other than thyroid deiodinases. All subjects with biallelic inactivation of SECISBP2 have had low serum selenium levels, which is therefore a helpful diagnostic clue to detect this disorder.

Thyroid Hormone Resistance

Receptor Defects

Patients with thyroid hormone resistance classically present with increased circulating levels of T4 and T3 with a (inappropriately nonsuppressed) normal or increased serum TSH concentration. In the newborn, TSH may be sufficiently high to be picked up at screening.[158] The prevalence of this condition estimated from two population-based studies of infants with a high T4 on the neonatal blood spot is 1 in 40,000 births.[159,160] Resistance to thyroid hormone has been classified into three phenotypes (generalized, pituitary, and peripheral), but this classification is somewhat artificial because patients and even siblings with the same mutation in TRβ can have different phenotypes.

Inheritance is generally autosomal dominant but 15% to 20% of cases appear sporadically. Many patients are asymptomatic or demonstrate nonspecific symptoms. Deafness is observed in 20%, and a syndrome of attention deficit hyperactivity has been documented in half of affected patients. Hypothyroid features include growth retardation, delayed bone maturation, and intellectual impairment. Some children exhibit features of thyrotoxicosis, including failure to thrive, accelerated growth, and hyperkinetic behavior.

Thyroid hormone action is mediated via nuclear thyroid hormone receptor proteins with zinc-finger DNA-binding regions and thyroid hormone-binding domains. The latter have a 10:1 relative binding affinity for T3 rather than for T4. The receptors act as DNA-transactivating factors to stimulate or suppress responsive genes. Two genes coding for the TR proteins have been described: an alpha gene on chromosome 17 and a beta gene on chromosome 3. To date, the most common molecular defect in all cases studied has involved the TRβ1 gene on chromosome 3. In about 80% of subjects with features of resistance to thyroid hormone, specific TRβ gene mutations can be demonstrated. More than 120 different defects have been described, mostly involving single-amino-acid deletions or substitutions in the hormone-binding domain at the carboxy terminal end of the receptor molecule. A few in-frame deletions and frame-shift insertions have been described. Only very recently have the first mutations in TRα been described, and the markedly retarded bone maturation and severe constipation found in these three patients is consistent with the known tissue distribution of this receptor isoform.[60,61]

TRs (like other steroid hormone superfamily receptors) bind to DNA response elements as monomers, homodimers, or heterodimers—and heterodimerization can involve another TR, including the TRα2 receptors, or other transactivation factors. Affected members of most families studied have one normal and one abnormal TRβ allele. The abnormal TRβ with minimal or reduced T3 binding fails to mediate T3-regulated transcription and may block the action of the normal allele. This dominant negative effect is presumably mediated by binding of the defective allele with normal TRβ and producing an inactive homodimer.[59]

Treatment of thyroid hormone resistance remains a challenge, especially in severely affected individuals, such as the rare homozygotes.[161] Symptomatic treatments with beta-blockers or attempts to override or bypass the hormone resistance with high-dose thyroxine or TRIAC, a thyroid hormone analog, have been reported.[161,162] Anti-thyroid drugs result in increasing TSH and goiter size,[163] with the theoretical risk of developing a tumor of the pituitary or the thyroid in the long term. In the majority of patients with only biochemical abnormalities and mild clinical manifestations, the dictum *primum non nocere* applies.[164]

Membrane Transporter Defects

Among the proteins involved in carrier-mediated energy-dependent transport of thyroid hormones for which

there is in vitro evidence, only the monocarboxylate transporter MCT-8 (encoded by the SLC16A2 gene on the X chromosome) has now been shown to be involved in human disease.[56,57]

Interestingly, Allan-Herndon-Dudley syndrome, an X-linked mental retardation syndrome described in 1944,[165] was also found to be due to MCT8 mutations. It is not surprising that the neurologic phenotype was recognized decades earlier, as it is much more severe than the abnormalities of thyroid function. It develops from infancy or childhood with hypotonia, poor head control, involuntary athetoid and dystonic movements, hyperreflexia, nystagmus, and severe mental retardation. Thyroid function test reveal elevated serum T3, low serum T4, free T4, and normal or slightly elevated TSH without signs of hypothyroidism.

The gene defects have included deletions and missense mutations. The MCT-8 gene in mice is expressed in brain (choroid plexus, cerebrum, hippocampus, amygdala, striatum, and hypothalamus), liver, kidney, and pituitary and thyroid tissues. In brain tissues, MCT-8 transporters seem localized to neuronal rather than to glial cells. Much of the brain damage due to decreased neuronal T4 content occurs in utero, and the phenotype resembles that of severe endemic cretinism. Accordingly, women hemizygous for MCT8 mutations should be counseled regarding pregnancy, not only about genetic risk but also because they may be prone to gestational hypothyroxinemia.[166] In affected children, the thyroid hormone analog DITPA, which has been shown in mice not to require MCT8 to enter tissues,[167] could be an effective alternative.[168]

Consumptive Hypothyroidism

This entity, which typically develops in infants, may be considered under thyroid hormone resistance, because it is characterized by the need for extremely high amounts of thyroxine to maintain euthyroidism. This is because both endogenous and endogenous thyroxine is inactivated, most often within hemangiomas that express high levels of deiodinase 3.[169] Hemangiomas are not typically present at birth but grow rapidly during the first few months of life. Accordingly, hypothyroidism is generally not congenital but develops during early infancy. Large cutaneous hemangiomas are easy to diagnose but consumptive hypothyroidism was the clue that led to diagnosing a liver hemangiomas in one infant.[170] An elevated reverse T3 concentration in serum may also be suggestive.[171] Thyroid scintigraphy shows a gland of normal size but with increased uptake.[170] It is unclear whether the series reported by Ayling and colleagues represents a different entity, because immunohistochemical studies of deiodinase 3 were not performed.[172] Aside from high-dose T4, treatment with T3 has also been reported.[169,171] With disappearance of the hemangiomas, either spontaneously or through medical or surgical treatment, euthyroidism is restored. The exact prevalence of this entity is unknown but it is likely low: in a retrospective review of 1555 patients with hemangiomas, 92 had thyroid function tests but only 3 had overt hypothyroidism.[169]

Hypothalamo-Pituitary Hypothyroidism

Congenital central hypothyroidism is uncommon, and isolated TRH/TSH deficiency is exceedingly rare. Multiple pituitary hormone deficiencies are estimated to be present in about 1 in 20,000 to 30,000 newborns.[173] However, these patients usually do not come to medical attention because of thyroid hormone deficiency. Rather, hypoglycemia reveals growth hormone or adrenocorticotropic hormone (ACTH)/cortisol deficiency or micropenis and cryptorchidism reveal gonadotrophin deficiency. Although hypothyroidism may reduce bile flow,[174] the major factor leading to jaundice in primary CH is immature glucuronoconjugation[175] and the hyperbilirubinemia is mostly unconjugated. By contrast, in congenital ACTH or cortisol deficiency, it is *conjugated* because cortisol is necessary for neonatal choleresis.[176,177] Congenital hypopituitarism is most often associated with the "classical triad" (ectopic posterior pituitary, interrupted stalk, and small anterior pituitary) on magnetic resonance imaging.[178] This malformation occurs almost always sporadically and its cause is generally unknown.

TRH Defects

No mutations of TRH itself have been described to date in humans. By contrast, homozygosity and compound heterozygosity for loss-of-function mutations of the TRH receptor gene, located on chromosome 8, have been described. The phenotype of the probands was mild, with ascertainment at 9 and 11 years because of short stature and delayed bone maturation. The clue to the diagnosis was a complete absence of response of both TSH and prolactin (which were measurable at baseline) to exogenous TRH. In the first proband, a low T4 had been measured on the neonatal blood spot but IQ was similar to that of unaffected siblings.[179] In the other family, an affected sister had breastfed her two children, showing that the TRH receptor is not required for lactation.[180]

Isolated TSH Deficiency

Severe congenital hypothyroidism due to isolated TSH deficiency was first described in consanguineous Japanese pedigrees.[181] Cloning of the gene encoding the TSHβ subunit gene, located on chromosome 1, quickly led to the identification of homozygous mutations in the Japanese patients,[182] but also in patients with similar phenotypes from different parts of the world.[183] Typically, serum TSH is undetectable or low and the response to TRH is blunted but, in contrast to what is observed in patients with TRH receptor mutations, prolactin increases after TRH. Serum TSH may be slightly elevated with some radioimmunoassays.[49] There may be no isotope uptake on scintigraphy but the thyroid becomes visible after exogenous TSH stimulation.[49] The most prevalent mutation involves a 1–base pair deletion from codon 105 and has been identified in different populations, which may indicate common ancestry[184] or a mutational hot spot.[183]

Transient Neonatal Hypothyroidism, Hyperthyrotropinemia, and Hypothyroxinemia

A blood-spot TSH above the screening cutoff but with spontaneous normalization in serum taken at the time of diagnostic evaluation could be described as "false positive" of CH screening or as transient neonatal hyperthyrotropinemia. Its prevalence obviously depends on screening cutoffs. In Québec, it occurs in approximately 1 in 18,000 births and is generally ascribed to transplacental passage of either antithyroid drugs or TSH receptor-blocking antibodies. In both of these situations, overt hypothyroidism has also been reported but is transient, lasting a few days in the former and a few months (and therefore justifying treatment, until TSH receptor antibody levels are cleared) in the latter.

Transient CH can also result from iodine deficiency or excess. In severe iodine deficiency, up to 10% of newborns have severe primary CH[185] associated with the increased thyroid hormone requirements in the neonatal period.[52] In borderline iodine deficiency, transient CH may be provoked by a superimposed acute iodine overload (the Wolff-Chaikoff effect), especially in premature newborns.[186] On the other hand, iodine in quantities more than 10-fold the upper limit of the recommended intake, from nutritional supplements taken throughout pregnancy, can also cause transient CH.[187] Amiodarone, an iodine-rich anti-arrhythmic drug, can also lead to hypothyroidism when given either to the pregnant woman[188] or to the newborn or infant.[189] The use of povidone-iodine disinfection of the skin or of the mediastinum in infants undergoing heart surgery may also induce hypothyroidism,[190] although this is not common in North America.[191]

Asymptomatic hyperthyrotropinemia is a relatively common disorder at all ages and, when detected at newborn screening, may be permanent and reflect either a large ectopic thyroid,[82] thyroid hemiagenesis,[192] heterozygous inactivating mutations in the TSH receptor,[123] or dominant TSH resistance of unknown origin.[193]

Transient isolated hypothyroxinemia is a very common finding in premature neonates and is correlated with poorer outcome in terms of mortality, morbidity, and developmental outcome. However, the results of a long-term randomized placebo-controlled trial do not suggest causation.[194,195] Pending the results of an ongoing trial comparing placebo, thyroxine, and iodine,[196] hypothyroxinemia of prematurity should be viewed as a state of physiologic adaptation that does not need to be screened for or treated routinely. The same likely applies to the nonthyroidal illness syndrome (low free T4, T3, and TSH), which is sometimes observed in severely ill infants[197] who, upon recovery, may have transient hyperthyrotropinemia.

Evaluation of Newborns with Positive Screening Results

A positive screening report for CH is only the beginning of a process that should lead to confirmation of the diagnosis, establishment of etiology, optimal treatment, and documentation of outcome.

Family history should focus on consanguinity, which increases the likelihood of dyshormonogenesis,[94] and on the existence of even distant relatives with CH.[102] Given the very high prevalence of thyroid disorders with onset in later life, a family history of these disorders is usually irrelevant. However, a maternal history of thyroid disease of documented autoimmune etiology[198] or of consumption of iodine-rich nutritional supplements[187] is relevant. Personal history should include length of gestation and birth weight, and the mother should be asked if she has noticed the baby is hypotonic or is feeding poorly. Physical examination may reveal large fontanelles, persistent jaundice, macroglossia, dry and mottled skin, and an umbilical hernia.[66,199] However, only 1% to 4% of newborns are under clinical suspicion of CH when the results of biochemical screening become available.[76,200] Even with the infant's neck hyperextended, experienced clinicians often fail to detect a goiter that will only be evidenced on imaging. Physical examination should also include a search for dysmorphic features[201] and for a heart murmur suggesting a defect in heart septation.[104,116,117]

At a minimum, the diagnosis of CH should be confirmed biochemically with a serum TSH and free T4. Indeed, a low free T4 has been associated in several studies with a higher risk of neurocognitive sequelae.[202,203] When a thyroid ectopy or a goiter is documented on nuclear medicine scanning, no other tests are required for clinical management. In cases with undetectable radioisotope uptake, serum thyroglobulin will allow distinguishing true athyreosis (a permanent condition) from apparent athyreosis (which may be transient if due to antibodies to the TSH receptor[100,101]).

The role of nuclear medicine in establishing the etiology of CH cannot be overemphasized.[204] In 50% of the cases, it will reveal a sublingual thyroid ectopy,[82] a permanent condition that is almost always sporadic. In 15%, there will be no detectable uptake and, if serum thyroglobulin is also undetectable, the condition is also sporadic and will be permanent. In about 10%, it will reveal a goiter reflecting dyshormonogenesis, in which case the hypothyroidism will almost always be permanent and the recurrence risk in siblings is one in four. Thus, a clear etiology can be established on the day of diagnosis, and this is an important decision that can offer help for physicians and families (Figure 7-8).

We favor the use of sodium pertechnetate, which is available daily in all nuclear medicine services and allows imaging in 20 minutes,[205] in contrast to iodine scintigraphy, which requires several hours. Care should be taken to feed the baby after the injection of the tracer, to avoid tracer accumulation in the salivary glands[205] and to ensure that the baby will sleep while under the camera. Although thyroid scintigraphy can be postponed until reevaluation of the diagnosis at 3 years of age, it is much easier to perform in a sleepy 10-day-old. We do not advise the routine use of ultrasound scanning, which is prone to movement artifacts, does not unequivocally allow the identification of a sublingual ectopy, and may constitute a diagnostic trap.[97] By contrast, demonstrating absence of the knee epiphyses

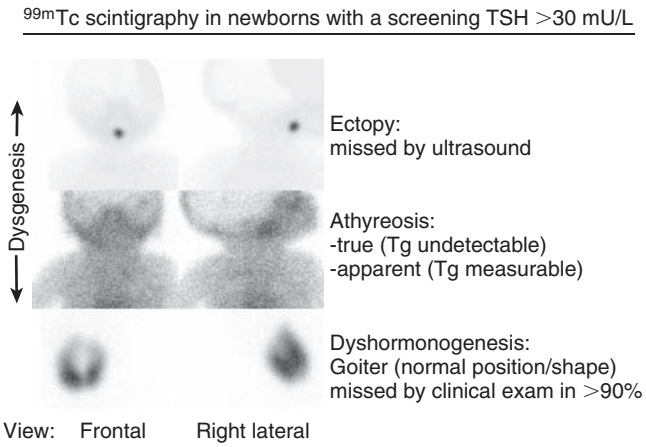

FIGURE 7-8 ■ The three most commonly seen etiologies of congenital hypothyroidism as evidenced by nuclear medicine scintigraphy using sodium pertechnetate.

on an antero-posterior x-ray, which indicates hypothyroidism of prenatal onset, has prognostic value for neurocognitive development.[206,207]

Although it has been repeatedly and rightly stated that delay in obtaining imaging should not delay treatment, it has been our experience that nuclear medicine services can be motivated to carry out a sodium pertechnetate scan with a 24-hour notice. In severe cases, it can even be performed after a few days of treatment,[208] as long as serum TSH is still above 30 mU/L. Treating an asymptomatic newborn on the basis of TSH alone may give the parents the impression that a number, rather than a patient, is being treated. This may account for the observation that about 40% of patients labeled as having CH by neonatal screening laboratories in the United States are no longer treated after 4 years of age,[209] without the recommended documentation of outcome of such thyroxine withdrawal.[210]

Treatment of Congenital Hypothyroidism

The following discussion applies to infants with definite CH from ectopy, athyreosis, or goiter and not to those with a normal gland in situ whose hypothyroidism is usually milder but who represent about half of contemporary CH cohorts.[82] Treatment should be instituted as soon as the diagnosis is confirmed. The goal of newborn CH screening is the institution of early adequate thyroid hormone replacement therapy. Most of the brain cell thyroid hormone is derived from local T4-to-T3 conversion. Thus, the preferred thyroid hormone preparation for treatment of infants with CH is thyroxine, and the addition of T3 offers no advantage.[211]

There is only one randomized controlled trial of different starting doses of thyroxine in CH, the results of which support the practice of giving 50 μg/day of thyroxine to infants weighing 3 to 4 kg. Indeed, not only does this dose most rapidly normalize serum TSH,[212] it is also associated with the best neurodevelopmental outcome at 5 years.[213] This starting dose leads to a mean serum fT4 concentration of 56.3 pmol/L (4.37ng/dL) after 2 weeks of treatment; although this figure seems high, it should be pointed out that the mean serum fT4 in normal children at 1 to 4 days of age is 48.1 pmol/L (3.73 ng/dL).[214] Later during infancy, there appears to be a resetting of the feedback threshold for T4 suppression of TSH release in CH. This resetting may occur in utero and its mechanisms remain obscure.[215] Accordingly, serum fT4 is often high but T3 is generally normal and TSH remains measurable with no clinical evidence of hyperthyroidism.[40] Unless serum TSH is persistently suppressed, the thyroxine dose does not need to be decreased: although there is evidence that overtreatment may be associated with greater distractibility at school age,[216] there is also evidence that undertreatment is associated with school delay.[217] The frequency at which infants are seen and thyroid function tests obtained varies greatly between jurisdictions but should be no less than 3 months in the first year and 6 months in older infants.

Growth in length and weight of infants with CH are normal if they are treated early and adequately. Head circumference is, on average, 0.8 SD above the mean[218] and in some infants this relative macrocrania leads to unnecessary imaging: it is a reflection of an immaturity of the skeleton and not of the size of the brain or cerebral ventricles.[219] Bone maturation is normal at 3 years of age, showing complete catch-up and no undue advancement, again suggesting that hyperthyroxinemia during treatment does not indicate iatrogenic hyperthyroidism.[40]

Although neurocognitive development and behavior is, on average, within normal limits in CH regardless of severity,[40] a few children still have clinically significant learning difficulties.[202,203] Their exact number and whether their difficulties are due to disease- or treatment-related factors remain controversial. Importantly, the known influence of the family's socioeconomic status on child development interacts with the biologic effect of CH: there is a steeper IQ decline with decreasing social class in CH than in controls.[203] Clinicians should therefore be particularly alert to developmental delay in children with severe CH from an economically disadvantaged family.

CONGENITAL HYPERTHYROIDISM

Graves Disease

Symptomatic Graves disease in a fetus or neonate is very uncommon: in the United States, a population-based study based on follow-up of newborns with a high total T4 on the neonatal screening specimen yielded an estimate of at most 1 in 80,000 births.[159] The incidence may be higher in Japan[160] or if only premature neonates are considered.[220] On the other hand, new-onset hyperthyroidism is diagnosed in about 1 in 500 to 1 in 1000 women of childbearing age,[221] to which women with established or even cured Graves disease (who may still produce thyroid-stimulating immunoglobulins [TSIs]) should be added. It must therefore be concluded that not all fetuses borne by women with positive TSIs develop overt hyperthyroidism. Although exceptional, fetal/neonatal hyperthyroidism is nevertheless a serious condition that should not be missed. However, earlier mortality estimates, as high as 25%, likely no longer apply to the present, when

awareness of the diagnosis is higher and supportive therapy more sophisticated. No death occurred in the seven infants reported by Smith and colleagues (and in our own unpublished experience), in spite of confounding factors such as prematurity[220] and of delayed diagnosis in some.[222] On the other hand, in utero death from fetal hyperthyroidism still occurs, especially when referral to a highly specialized center is delayed.[223]

Ideally, all women with Graves disease should have serum TSIs measured in early pregnancy. This applies to those currently treated for hyperthyroidism as well as to those who are now euthyroid, spontaneously or on replacement after ablative therapy.[3] Indeed, a high TSI titer in maternal serum makes hyperthyroidism more likely in the fetus or newborn. Unfortunately, this information is often not available at first evaluation and clinicians are confronted at first with the classical signs heralding fetal hyperthyroidism, such as tachycardia and intrauterine growth retardation. In the hands of highly skilled radiologists, a fetal goiter may be the first sign but whether this will be generalizable remains unproven.[223]

Once fetal hyperthyroidism is suspected, it can generally be managed through the mother by initiating or increasing antithyroid drug treatment. Occasionally, the hyper- or hypothyroid nature of a goiter in a fetus cannot be made on the basis of maternal TSI concentrations and antithyroid drug dose, in which case the ultrasound characteristics of the goiter may be helpful,[224] although this is highly operator dependent. In exceptional cases, cordocentesis is necessary to determine fetal thyroid function and to guide management, but it should be kept in mind that this procedure carries a 1% to 2% risk of fetal loss.[225]

Traditionally, the mainstay of treatment of hyperthyroidism during pregnancy has been the administration of propylthiouracil (PTU) because of the risk of methimazole (MMZ)-induced embryopathy.[226] However, because of the greater liver toxicity of PTU,[227] it has been suggested that MMZ should be preferred after organogenesis is complete, but the practicality of switching from one drug to another has been questioned[228] and data suggest PTU may be teratogenic as well.[229] Whatever drug is used, maternal antithyroid treatment should normalize fetal heart rate within 2 weeks. The antithyroid drug dose can usually be decreased progressively.

Graves disease in the newborn is manifested by irritability, flushing, tachycardia, hypertension, poor weight gain, thyroid enlargement, and exophthalmos. Thrombocytopenia, hepatosplenomegaly, jaundice, hypoprothrombinemia, and cardiac failure may occur. The diagnosis is confirmed by an undetectable serum TSH, high levels of serum T4, free T4, and T3. By contrast, on blood drawn on the second day of life in normal children, free T4 is high but TSH is not suppressed. In some neonates, the onset of symptoms and signs may be delayed as long as 8 to 9 days, if they were born to a mother treated with antithyroid drugs, and also reflecting the switch from an inactivating to an activating conversion of T4 to active T3 by liver and other tissues after birth. Neonatal Graves disease resolves spontaneously as maternal TSIs are cleared from the infant's circulation. The usual clinical course of neonatal Graves disease extends from 3 to 12 weeks.

Newborns with symptomatic hyperthyroidism should be admitted and their heart rate monitored. Treatment includes propranolol (1 to 2 mg/kg/day divided into four doses) and methimazole in a dose of 0.5 to 1 mg per kilogram daily in divided doses at 8-hour intervals. Iodine is also often used, because it rapidly inhibits hormone release: Lugol solution (5% iodine and 10% potassium iodide, 126 mg of iodine per milliliter) is given in a dose of one drop (about 8 mg) three times daily. A therapeutic response should be observed within 24 to 36 hours. If a satisfactory response is not observed, the dose of antithyroid drug and iodine can be increased by 50%. Glucocorticoids in high doses diminish T4 to T3 conversion and may therefore be helpful. Radiographic contrast agents have also been used,[230] and exchange transfusions will also be effective.[231] In severe cases, sedatives and digitalization may be necessary.

Nonautoimmune Hyperthyroidism

Mutations that result in increased constitutive activity of the TSH receptor give rise to hyperthyroidism. Premature delivery and low birth weight are consistent features in these infants (as in unaffected children of mothers with thyroid hormone resistance[29]), suggesting that an increase in thyroid hormone levels in the fetus independently stunts growth and shortens gestation.[232] Hyperthyroidism is generally associated with a goiter, although this is not always present at diagnosis. Acceleration of bone maturation occurs very early and rapid linear growth, relative thinness, and microcephaly are observed.

Mutations activating the TSH receptor may occur de novo in the germline. The first cases described had very severe hyperthyroidism,[233,234] but subsequent cases have not all been as severe.[235,236] They can also be transmitted in an autosomal dominant pattern,[237] in which case they tend to lead to a less severe phenotype with variable age of onset. Although generally detected at later ages, some cases are recognized in the neonatal period or during infancy.[238] Lastly, mutations activating the TSHR may occur at the somatic level, leading to the development of a hyperfunctioning nodule and to hyperthyroidism. This is a common disease in adults, but can occur before birth[239] or in infancy.[240]

In contrast to neonatal Graves disease, nonautoimmune hyperthyroidism is life-long and thyroidectomy is the only curative approach and should be preferred in infants with a hyperfunctioning nodule. In those with a germline mutation and, consequently, a diffuse goiter, surgery is also often required.

DISORDERS OF THYROID HORMONE TRANSPORT

Several genetic abnormalities of the iodothyronine-binding serum proteins have been described and all are manifest at birth. These include complete TBG deficiency, partial TBG deficiency, TBG excess, transthyretin (TTR) (prealbumin) variants, and familial dysalbuminemic hyperthyroxinemia (FDH). Total T4 is low or high, but free T4 is normal and the patients are therefore euthyroid.

Nowadays, these abnormalities are only picked up by screening programs that measure total T4, in which an elevated total T4 is at least 10-fold more likely due to TBG excess than to Graves disease.[159] In institutions where total serum T4 is still measured at later ages, clinicians should be aware of abnormalities in TBG, which are common, and that total T4 should always be evaluated together with the serum TSH. Free T4, instead of total T4, is measured by an ever-increasing number of clinical laboratories but, depending on the assay method, free T4 can also be spuriously elevated in familial dysalbuminemic hyperthyroxinemia. Here again, considering the clinical context and the serum TSH will avoid an erroneous diagnosis of hyperthyroidism.[241]

QUESTIONS

1. A newborn screens positive for congenital hypothyroidism with a TSH of 25 mU/L on whole blood. At 9 days of life, the diagnosis is confirmed with a serum TSH of 45 mU/L, a free T4 of 12 pmol/L, and a Tg of 54 μg/L. Thyroid scintigraphy shows no uptake. What might explain these findings? (Choose all that apply.)
   a. TSH too low to induce isotope uptake
   b. Transplacental passage of maternal TSH receptor-blocking antibodies
   c. Use of povidone-iodine disinfection during delivery
   d. Inactivating mutations of the TSH receptor
   e. True athyreosis

Answers: b, c, and d

2. Among these statements regarding congenital hypothyroidism, which are true? (Choose all that apply.)
   a. Thyroid dysgenesis is an autosomal recessive disease.
   b. TPO and Tg mutations are the most common causes of dyshormonogenesis.
   c. A delayed bone age is a good prognostic factor for cognitive development.
   d. A low T4 is a poor prognostic factor for cognitive development.
   e. The initial recommended dose of L-T4 is 5 μg/kg/day.
   f. A child with congenital hypothyroidism from thyroid dysgenesis has a slightly increased risk of also having congenital heart disease.

Answers: b, d, and f

3. A 6-month-old infant with athyreosis was previously well controlled with 50 μg of levothyroxine daily and comes to your clinic with the following serum values: TSH 70 mU/L, free T4 5.6 pmol/L. Which of the following may explain this condition? (Choose all that apply.)
   a. The thyroxine was given in the morning, now it is given in the evening.
   b. There is noncompliance with the medication.
   c. The infant took cow's milk the first 5 months and now takes soy milk.
   d. The infant has started taking elemental iron simultaneously with thyroxine.
   e. The infant now receives thyroxine in liquid form.

Answers: b, c, and d

4. What is the likelihood that a mother with Hashimoto's thyroiditis will have a hypothyroid newborn?
   a. 50%
   b. 10%
   c. 5%
   d. < 1%

Answer: d

5. For the treatment of a newborn with symptomatic hyperthyroidism, which should *not* be used?
   a. Propranolol
   b. Propylthiouracil
   c. Methimazole
   d. Lugol solution
   e. Glucocorticoids

Answer: b

CHAPTER 8

Disorders of Calcium and Phosphorus Homeostasis in the Newborn and Infant

Allen W. Root, MD

CHAPTER OUTLINE

Calcium (Ca), phosphorus (as phosphate [HPO_4^{2-}], as phosphorus does not exist in the free state in living tissues), and magnesium (Mg) are essential nutrients that are indispensable for the structural integrity of the body and for the function of each of its cells.[1,2] The genetic and physiologic mechanisms that regulate normal mineral homeostasis and bone development, composition, and strength from the prenatal period through adolescence are complex. Table 8-2 lists some of the many genes that direct these processes. Figures 8-1 and 8-2 schematically depict the factors that regulate serum concentrations of calcium and phosphate, respectively.

CALCIUM

Calcium is an irreplaceable component of the mineral portion of bone and is required for the function of each of the body's cell. Together, calcium and phosphate form the hydroxyapatite crystal—$Ca_{10}(PO_4)_{10}(OH)_2$—of bone; hydroxyapatite accounts for 65% of bone weight and provides its mechanical and weight bearing strength and also serves as a reservoir for calcium that may be quickly mobilized for homeostatic and functional purposes. Although 99% of total body calcium is present in the slowly exchangeable, deeply deposited skeletal crystal, it is the rapidly exchangeable 1% of body calcium in recently accumulated surface bone and in the vascular, extracellular, and intracellular (soft tissues) spaces, with which it is in equilibrium, that modulates gene expression, intercellular communication and intracellular signal transduction, neural transmission, cell-to-cell adhesion, clotting, striated, smooth and cardiac muscular contraction, cardiac rhythmicity, enzyme action, synthesis and secretion of endocrine and exocrine factors, fertilization, and cellular proliferation and apoptosis.[3,4] Approximately 50% of total serum calcium is bound to albumin and globulin; 5% is complexed or chelated to citrate, phosphate, lactate, bicarbonate, and sulfate; and 45% is present as biologically active and closely regulated ionized extracellular calcium (Ca^{2+}_e). Approximately 75% of the variability in total serum calcium concentrations is accounted for by genetic factors. Serum total and ionized calcium concentrations are related to levels of albumin, creatinine, parathyroid hormone (PTH), phosphate, and serum pH. For every 1 g/dL decline in the serum concentration of albumin below 4 g/dL, the total serum calcium level declines by 0.8 mg/dL. The measured

TABLE 8-1 **Abbreviations**

$1,25(OH)_2D_3$	1,25-Dihydroxyvitamin D_3 (calcitriol)
$24R,25(OH)_2D_3$	24,25-Dihydroxyvitamin D_3
$25OHD_3$	25-Hydroxyvitamin D_3 (calcidiol)
ADHR	Autosomal dominant hypophosphatemic rickets
AF	Activating function
AKT	see PKB
AMP	Adenosine monophosphate
APC	Adenomatous polyposis coli
ARHR	Autosomal recessive hypophosphatemic rickets
ASARM	Acidic serine aspartate-rich MEPE-associated motif
ATP	Adenosine triphosphate
ATPase	Adenosine triphosphatase
BAP	Bone alkaline phosphatase
BMAD	Bone mineral apparent density (~volumetric BMD)
BMC	Bone mineral content
BMD	Bone mineral density
BMP	Bone morphogenetic protein
BRU	Bone remodeling unit
BTT	Bone transmission time
Ca^{2+}_e	Calcium—ionized, extracellular
Ca^{2+}_i	Calcium—ionized, intracellular
CaMK	Ca^{2+}/calmodulin dependent protein kinase
CART	Cocaine amphetamine regulated transcript
CaSR	Calcium sensing receptor
Cl^-	Chloride
CNP	Natriuretic hormone type C
COMP	Cartilage oligomeric protein
CREB	Cyclic AMP-responsive element binding protein
CTX	Carboxyl-terminal cross-link telopeptide α1 chain of type I collagen (see ICTP)
DAG	1,2-Diacylglycerol
DBP	Vitamin D binding protein
DEXA	Dual energy x-ray absorptiometry
DMP	Dentin matrix protein
DNA	Deoxyribonucleic acid
DPD	Deoxypyridinoline
DRIP	Vitamin D interacting protein
ECF	Extracellular fluid
EGF	Epidermal growth factor
ER	Estrogen receptor
ERK	Extracellular signal-regulated kinase
FGF	Fibroblast growth factor
FGFR	Fibroblast growth factor receptor
FOS	FBJ osteosarcoma oncogene
FRP4	Frizzled related protein-4
FRS	FGF receptor substrate
GABA	Gamma (γ)-aminobutyric acid
GDNF	Glial cell line-derived neurotrophic factor
$G_{i\alpha}$	Alpha subunit of inhibitory GTP-binding protein
$G_{s\alpha}$	Alpha subunit of stimulatory GTP-binding protein
$G_{q\alpha}$	Alpha subunit of a stimulatory GTP-binding protein
GH	Growth hormone
GMP	Guanosine monophosphate
GPCR	G protein–coupled receptor
GRB2	GRB2-associated binding protein 2
GRK	G protein–coupled receptor kinase
GSK3	Glycogen synthase kinase 3
GTP	Guanosine triphosphate
H^+	Hydrogen ion (proton)
HNRPD	Heterogeneous nuclear ribnucleoprotein D
HRpQCT	High-resolution peripheral quantitative computed tomography
IGF	Insulin-like growth factor
ICTP	Carboxyl terminal cross-link telopeptide of collagen type I generated by matrix metalloproteinase (see CTX)
IGF	Insulin-like growth factor (somatomedin)
Ihh	Indian hedgehog
IL	Interleukin
IP_3	Inositol-1,4,5-trisphosphate
ITAM	Immunoreceptor tyrosine-based motif
K^+	Potassium
LRP	Low-density lipoprotein receptor-related protein
μFE	Microfinite element
MAPK	Mitogen activated protein kinase
MARRS	Membrane-associated rapid response steroid binding protein (see TBP-2)
M-CSF	Macrophage colony stimulating factor
MEPE	Matrix extracellular phosphoglycoprotein
Mg^{2+}	Magnesium
MITF	Microphthalmia-associated transcription factor
MMP	Matrix metalloproteinase
MRI	Magnetic resonance imaging
Na^+	Sodium
NADPH	Nicotinamide adenine dinucleotide phosphate
NFκB	Nuclear factor-κB
NFATC1	Nuclear factor of activated T cells, cytoplasmic, calcineurin-dependent 1
NHERF	Sodium-hydrogen exchanger regulatory factor
NPT2	Sodium/phosphate transporter 2
NTX	Amino terminal cross-link telopeptide of collagen type I
OMIM	Online Mendelian Inheritance in Man
OPG	Osteoprotegerin
OSCAR	Osteoclast-associated receptor
OSTM1	Osteopetrosis-associated transmembrane protein 1
P3H1	Prolyl 3-hydroxylase-1
PHEX	Phosphate-regulating gene with homologies to endopeptidases on the X chromosome
PICP	Procollagen type I carboxyl-terminal propeptide
PINP	Procollagen type I amino-terminal propeptide
PIIINP	Procollagen type III amino-terminal propeptide
PI3K	Phosphoinositide-3-kinase
PKA	Protein kinase A

TABLE 8-1 **Abbreviations—cont'd**

PKB	Protein kinase B (AKT)
PLC	Phospholipase C
PO_4	Phosphate (HPO_4^{2-})
PPARγ	Peroxisome proliferator activator receptor gamma
PTH	Parathyroid hormone
PTHrP	PTH-related protein
PTH1R	PTH/PTHrP-1 receptor (PTH/PTHrP-1R)
PYD	Pyridinoline
QCT	Quantitative computed tomography
QUS	Quantitative ultrasonography
RANK	Receptor activator of NFκB
RANKL	RANK-ligand
RDA	Recommended dietary allowance
RNA	Ribonucleic acid
RXR	Retinoid X receptor
SIBLING	Small integrin-binding ligand, N-glycosylated (proteins)
SOS	Speed of sound
SOX	SRY-Box
SPP1	Secreted phosphoprotein1 (osteopontin)
Src	SRC oncogene
SRC	Steroid receptor coactivator
STAT	Signal transduction and transcription
SYK	Spleen tyrosine kinase
TALH	Thick ascending loop of Henle
TBP-2	Thioredoxin binding protein-2 (see MARRS)
TCF/LEF	T cell factor/lymphoid enhancer binding factor
TGF	Transforming growth factor
TALH	Thick ascending loop of Henle
TIP	Tuberoinfundibular protein (hypothalamic)
TNF	Tumor necrosis factor
TNSALP	Tissue nonspecific alkaline phosphatase
TR	Thyroid (hormone) receptor
TRAF	TNF receptor associated factor
TRANCE	TNF-related activation induced cytokine
TRAP5b	Tartrate resistant acid phosphatase type 5b isoform
TREM2	Triggering receptor expressed on myeloid cells-2
TRP	Transient receptor potential (channel)
VDIR	Vitamin D–interacting repressor
VDR	Vitamin D receptor
VDRE	Vitamin D response element
VEGF	Vascular endothelial growth factor
WIF	WNT inhibitory factor
WINAC	WSTF including nucleosome assembly complex
WSTF	Williams syndrome transcription factor
XHR	X-linked hypophosphatemic rickets

A=Adenine C=Cytidine G=Guanine T=Thymine

Ca^{2+}_e level is dependent on the serum pH (normal adult range 1.1 to 1.3 mmol/L at pH 7.4); increase in alkalinity (higher pH) raises calcium binding to albumin thus decreasing Ca^{2+}_e, whereas acidic changes (lower pH) decrease binding thereby increasing Ca^{2+}_e. The relationship between pH and Ca^{2+}_e is best described by an inversely S-shaped third-degree function.[5]

The serum concentration of Ca^{2+}_e is maintained within narrow limits by an integrated system involving the plasma membrane Ca^{2+}_e sensing receptor (CaSR), PTH and its receptor (PTH/PTH related protein [PTHrP]-1R), the thyroidal parafollicular C cell product calcitonin and its receptor, and the vitamin D hormone system acting on the intestinal tract, bone, and kidney (see Figure 8-1). With increase in serum Ca^{2+}_e concentration, the CaSR on the chief cell of the parathyroid gland is activated; the intracellular signal transduction pathway stimulated by the CaSR depresses PTH secretion instantly and decreases expression of *PTH*. Activation of the CaSR in the distal renal tubule decreases reabsorption of calcium filtered through the glomerulus and increases urinary calcium excretion. When the serum Ca^{2+}_e concentration falls, signaling through the CaSR also declines, thereby increasing PTH secretion and renal tubular reabsorption of filtered calcium, activating osteoclastic bone reabsorption, and somewhat later increasing synthesis of 1,25-dihydroxyvitamin D_3 (calcitriol) and intestinal absorption of ingested calcium.[1]

The intracellular concentration of cytosolic free calcium (Ca^{2+}_i) (approximately 100 nM) is 10,000-fold less than that in serum and extracellular fluid, a gradient maintained by exchange of Ca^{2+} across the cell's plasma membrane and across the membranes of intracellular structures. Within the cell, Ca^{2+}_i is primarily (99%) stored within the endoplasmic reticulum (sarcoplasmic reticulum in muscle cells) and mitochondria as well as

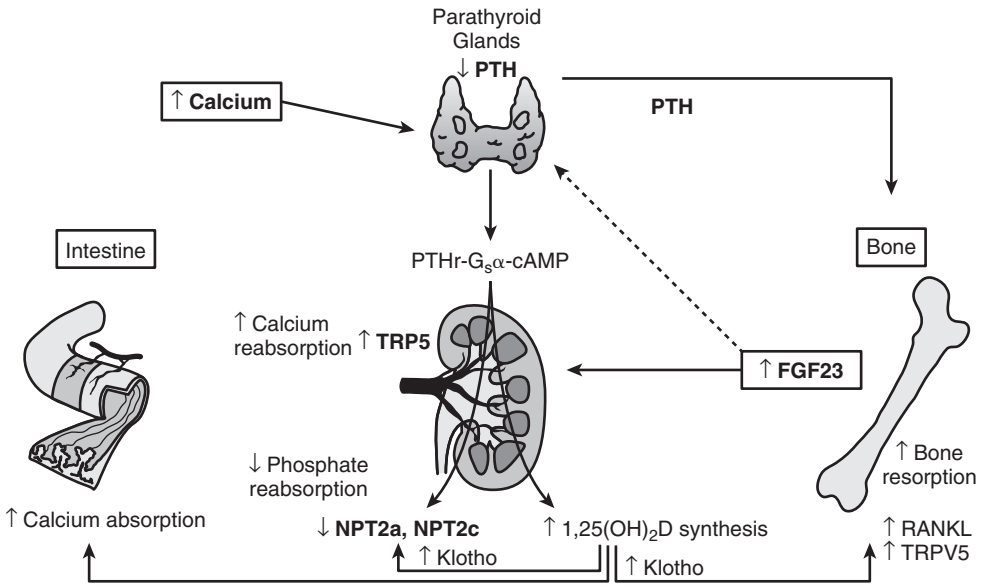

FIGURE 8-1 ■ Regulation of calcium homeostasis. Calcium (Ca^{2+}) is absorbed from the intestinal tract, kidney tubule, and bone in response to calcitriol [1,25$(OH)_2D_3$] and parathyroid hormone (PTH). Calcitonin inhibits resorption of calcium from bone. The Ca^{2+}-sensing receptor (CaSR) modulates Ca^{2+}-mediated activity of the parathyroid glands and the renal tubules. Both hypocalcemia and hypophosphatemia enhance renal tubular generation of calcitriol and absorption of intestinal phosphate. PTH inhibits renal tubular reabsorption of phosphate. Fibroblast growth factor-23 (FGF23), a phosphatonin secreted by osteoblasts and osteocytes, inhibits renal tubular reabsorption of phosphate and synthesis of calcitriol. (Please see Figure 8-2 and the text for further details.) (Reproduced from Levine, M. A. (2010). Investigation & management of hypocalcemia. ENDO 2010: Meet the Professor, The Endocrine Society, Bethesda, MD, with permission.)

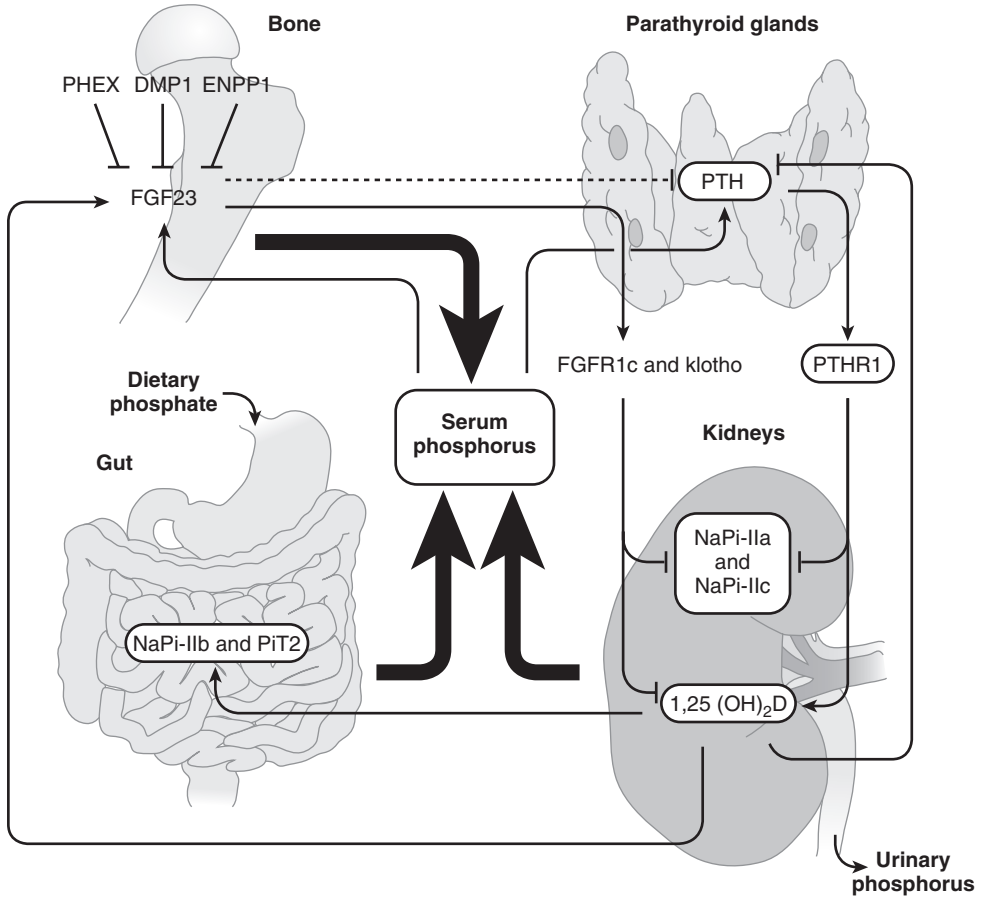

FIGURE 8-2 ■ Regulation of phosphate homeostasis. Serum concentrations of phosphate are depressed by parathyroid hormone (PTH) and fibroblast growth factor 23 (FGF23), both of which increase urinary excretion of this cation by decreasing renal tubular expression of phosphate cotransporter proteins. Synthesis of FGF23, a product of osteoblasts and osteocytes, is depressed by low serum phosphate levels and by PHEX (phosphate regulating gene with homologies to endopeptidases on the X chromosome), DMP1 (dentin matrix protein 1), and ENPP1 (ectonucleotide pyrophosphate-phosphodiesterase 1), all three of which proteins are also synthesized by bone cells. PTH increases and FGF23 depresses synthesis of calcitriol (1,25-dihydroxyvitamin D). (See text for details.) (Reproduced from Bergwitz, C., Collins, M. T., Kamath, R. S., & Rosenberg, A. E. (2011). within endosomes, lysosomes, the Golgi apparatus and secretory granules and bound to the inner plasma membrane from which sites it can be released by chemical signals—that is, inositol-1,4,5-trisphosphate (IP_3).[6] IP_3 acts on IP_3 receptors (encoded by *ITPR1*; see Table 8-2) located in the membrane of the endoplasmic reticulum to effect rapid egress of Ca^{2+} from storage, thereby quickly increasing $Ca^{2+}{}_i$ levels.[7] $Ca^{2+}{}_i$ serves as a second messenger and signal transducer that controls many cellular activities including gene transcription, cell division and growth, cell movement, and secretion of synthesized products. Ca^{2+} enters the cell through transmembrane protein pores such as voltage-gated and store-operated calcium channels. Voltage-gated Ca^{2+} channels are active in cells that are electrically excitable such as cardiac, skeletal, and smooth muscle cells, neurons, gastric mucosa, and pancreatic β cells and that open in response to depolarization of the plasma membrane permitting rapid influx of $Ca^{2+}{}_e$ into the cell cytoplasm leading to further depolarization of the membrane and activation of cell function.[8] They may be activated by high or low electrical voltage. The skeletal muscle high-voltage-activated calcium channel is composed of five subunits: α_1, α_2, β, γ, and δ. The voltage-sensing, pore-forming Ca^{2+}-binding α_1 subunit has four repeated domains, each with 6-transmembrane spanning regions (or helices) and intracytoplasmic amino and carboxyl terminals; transmembrane helix 4 serves as the voltage sensor; the α_1 subunit also has a sequence of amino acids between transmembrane helices 5 and 6 that is partially inserted into the membrane to serve as a selectivity filter.[8] The assembly, intracellular movement, interaction with other proteins, activation, and kinetic properties of the α_1 subunit are modified by the extracellular, glycosylated α_2 subunit, the β subunit (a cytoplasmic globular protein), a small membrane spanning δ subunit that is disulfide-linked to form dimeric $\alpha_2\delta$, and a second transmembrane subunit γ. The voltage-gated calcium channels are designated in accord with their cloned specific α_1 subunits and have been termed Cav 1.1, Cav 1.2, Cav 1.3, . . . Cav 3.3; formerly, they were designated in accord with the high- or low-voltage strength required for activation and for their sensitivity to specific inhibitors (e.g., L, N, P, Q, R, T subtypes). The high-voltage–dependent L type calcium channels (Cav1.1 through Cav 1.4) are present in skeletal, cardiac, and vascular smooth muscle cells; endocrine cells; neurons; and fibroblasts. L-type calcium channels are activated by the guanine triphosphate (GTP)-binding α_q subunit of G_q-proteins through stimulation of phospholipase C (PLC) leading to phosphorylation of the channel protein. L-type calcium channels modulate the growth and proliferation of fibroblasts and smooth muscle cells, the synthesis of extracellular matrix collagen proteins, and the activation of specific transcription factors.[9]

$Ca^{2+}{}_e$ also enters the cytosol through the plasma membrane store-operated Ca^{2+} channel, ORAI1 (also termed CRACM1 or TMEM142A [transmembrane protein 142A]).[7,10] Store-operated Ca^{2+} channels are active in cells that are electrically nonexcitable such as lymphocytes and other immune cells.[4] Nevertheless, both voltage-gated and store-operated Ca^{2+} channels often coexist in the same cell. Which type of Ca^{2+} channel is utilized in a specific cell is determined by the expression of *STIM1* (see Table 8-2) encoding a protein that transverses the membrane of the endoplasmic reticulum. When the Ca^{2+} content of the endoplasmic reticulum is depleted, STIM1 unfolds and bridges the cytosolic distance between the endoplasmic reticulum and the cell's plasma membrane where it binds to and opens the ORAI1 pore, thereby permitting Ca^{2+} influx into the cytoplasm and the restoration of Ca^{2+} stores within cytoplasmic organelles. At the same time that it activates the ORAI1 Ca^{2+} channel, STIM1 inhibits the voltage-gated Ca^{2+} channel.[4,11,12] Loss-of-function mutations in *ORAI1* have been identified in patients with severe combined immune deficiency and Kaposi sarcoma.[13,14]

In addition to traversing rapidly across the cell's plasma membrane through voltage-gated and store-operated channels, Ca^{2+} enters the cytosol, but at a markedly slower rate, through bifunctional membrane-associated IP_3 receptors that also serve as calcium channels.[7,15] Encoded by *ITPR1*, the tetrameric IP_3 receptor has six transmembrane domains and a pore-forming loop between the fifth and sixth transmembrane segments. Whereas many IP_3 receptor/channels are expressed in the membranes of the endoplasmic reticulum where IP_3 activation leads to depletion of Ca^{2+} stored in the endoplasmic reticulum thereby triggering store-operated calcium channel activation, only one to two such channels are expressed in the plasma membrane of each cell. Ca^{2+} is translocated not only through specific Ca^{2+} channels but also through paracellular transport channels[16]. $Ca^{2+}{}_i$ is extruded from cell cytoplasm by calcium and energy-dependent adenosine triphosphate (ATP)-driven calcium pumps and in exchange for sodium (Na^+) through H^+/ATPase and Na^+/Ca^{2+} exchangers.[3] The Ca^{2+}-ATPases are encoded by four genes; *ATP2B1* encodes a 1220-amino-acid plasma membrane protein with a cyclic AMP-dependent protein kinase domain and a carboxyl domain to which calbindin binds, which links hydrolysis of ATP with transport of cations across membranes. The Ca^{2+}-ATPases have the capacity to transport Ca^{2+} against high concentration gradients. The Na^+/Ca^{2+} exchangers are widely distributed plasma membrane Ca^{2+} export proteins.[1,3] A homologue of the human Na^+/Ca^{2+} exchanger is composed of 10 transmembrane domains consisting of two sets of five transmembrane helices in inverted reverse order with the amino and carboxyl termini within the cytoplasm.[17,18] Transmembrane helices 2, 3, 7, and 8 form an ion-binding pocket with three low-affinity Na^+ and one high-affinity Ca^{2+} binding sites symmetrically arranged in a diamond formation. Through conformational changes of the structure of the Na^+/Ca^{2+} exchanger, the Na^+ and Ca^{2+} binding sites are alternately exposed to either the intracellular or extracellular surfaces of the cell's plasma membrane. As Na^+ from the extracellular space occupies its three binding sites, the binding affinity for Ca^{2+} decreases, thereby releasing this cation into the cytosol and reversing the orientation of the Na^+/Ca^{2+} channel; inasmuch as cytosolic levels of Na^+ are low, these cations are then released into the cytosol restoring the affinity of the

exchanger for Ca^{2+}. The human cardiac Na^+/Ca^{2+} exchanger NCX1 (encoded by *SLC8A1*) has Na^+/Ca^{2+} binding configurations that are similar to those of the homologue.[17] The human skeletal muscle Na^+/Ca^{2+} exchanger NCX2 is encoded by *SLC8A2*. Within the cell, cytosolic Ca^{2+} is transported across the membrane and into the endoplasmic reticula of muscle cells through Ca^{2+}-ATPase channels encoded by *ATP2A2*; linkage of small ubiquitin-like modifier type 1 (sumoylation) to this Ca^{2+}-ATPase extends its half-life and increases its intrinsic activity.[19]

There are many intracellular calcium binding proteins (e.g., calcium binding proteins 1 and 4, calbindin, sorcin, calmodulin, and so forth). Calmodulin 1 (*CALM1*) is a widely distributed 149-amino-acid protein with an amino terminal lobe linked to a carboxyl terminal lobe that can assume more than 30 three-dimensional conformations.[8] Each lobe has two globular calcium binding domains consisting of two helix-loop-helix motifs connected by an α-helical linker; calcium binding exposes hydrophobic pockets that allow calmodulin to bind to and regulate the activity of target proteins.[20] When bound to a target protein, calmodulin can assume any one of an exceedingly large number of conformations. This versatility enables calmodulin to act as a calcium sensor for many different proteins subserving distinct processes within a single cell including voltage-gated calcium channels and calcium/calmodulin-dependent protein kinases.

In the gastrointestinal tract, calcium is absorbed by both active transcellular and passive paracellular processes.[21] During growth in younger subjects and when calcium intake and consequently intestinal calcium concentrations are low, active transcellular absorption of calcium predominates; when calcium intake is adequate or high, passive paracellular absorption of calcium is the major process by which calcium is absorbed.[21,22] Transcellular gastrointestinal absorption of calcium is an active and saturable process that is primarily stimulated by calcitriol by regulating the availability of transmembrane calcium "pumps" and channels on the luminal and basolateral surface membranes of duodenal enterocytes.[1] Calcitriol acting through the vitamin D receptor (VDR) increases duodenal expression of calcium transport protein-1 (epithelial calcium channel-2 encoded by *TRPV6*, transient receptor potential-vanilloid 6), a luminal calcium channel with six transmembrane domains and intracytoplasmic amino and carboxyl terminals and a pore region between the fifth and sixth transmembrane domains that forms a homotetramer or heterotetramer combined with TRPV5; TRPV5 and TRPV6 specifically permit Ca^{2+} permeation at physiologically levels of this cation.[22] Calcium is also actively absorbed in the intestinal tract by mechanisms that are independent of the VDR.[23] Thus, the expression of *TRPV6* can be increased by both estrogen and prolactin; prolactin can increase the transcellular absorption of calcium independently of calcitriol and the VDR.[24] After entering the enterocyte, Ca^{2+} diffuses across its interior within the cytosol or within a lysosomal vesical bound to calbindin D_{9k} (encoded by *CALB3*), a protein with two high-affinity calcium binding sites that transports calcium from the apical to the basolateral membrane of the enterocyte. After fusion of vesicle and basolateral plasma membrane, Ca^{2+} is extruded into the extracellular space (and circulation) through a basolateral Ca^{2+}-Mg^{2+}-dependent ATPase calcium channel (*ATPB21*), also termed plasma membrane Ca(2$^+$) ATPase, type 1 (PMCA1b). Experimental data in mice suggest that neither TRPV6 nor calbindin D_{9k} is essential for vitamin D–mediated intestinal absorption of calcium.[25,26] However, the applicability of these observations to human physiology is uncertain.[21] When calcium intake is adequate or high, the bulk of ingested calcium is passively absorbed through paracellular channels between enterocytes in the jejunum and ileum. Although calcitriol regulates synthesis of several tight junction proteins that may comprise the paracellular channels, including claudins-2 and -12, and cadherin-17, there is no known direct regulation of paracellular intestinal calcium absorption.[21,27]

Intestinal calcium absorption is influenced by vitamin D status, its food source (the bioavailability of calcium in cow milk formulas is 38%, that in human breast milk is 58%; leafy green vegetables are also a good source of dietary calcium), the form of the calcium salt in dietary supplements, and the presence in food of inhibitors of calcium absorption such as phytates, oxalates, or phosphates (e.g., cola beverages).[28] Intestinal calcium absorption is increased during adolescence, pregnancy, and lactation, and depressed in patients with nutritional or functional vitamin D deficiency, chronic renal disease, and hypoparathyroidism. The amount of calcium ingested influences the net amount of calcium absorbed; the lower the calcium intake, the greater is the efficiency of its absorption. In the adult when the dietary calcium intake is $<$ 200 mg/day, fecal calcium excretion exceeds intake; thus, active absorption of calcium cannot compensate for very low intake. As intake of dietary calcium increases from 200 to 1000 mg/day, active calcium absorption also increases but at a progressively decreasing rate. When dietary calcium exceeds 1000 mg/day, active calcium absorption remains relatively constant at 400 mg/day but passive absorption of calcium through paracellular channels continues to increase.[1] Thus, hypercalcemia may result from dietary calcium excess as in the milk-alkali syndrome. PTH indirectly increases intestinal calcium absorption by enhancing renal 25-hydroxyvitamin D-1α-hydroxylase activity and hence calcitriol synthesis. Growth hormone (GH) and estrogens also increase intestinal absorption of calcium; glucocorticoids and thyroid hormone inhibit this process. Calcium is excreted into the intestinal tract in the ileum and in pancreatic and biliary secretions.

Low calcium intake is associated with increased fracture rate in children and adolescents, and therefore, adequate dietary intake of calcium during infancy, childhood, and adolescence is necessary to attain a peak bone mass that may lessen the risk of fracture and the later development of osteopenia.[29] In an effort to ensure optimal mineralization of the developing skeleton, age-related dietary intakes of elemental calcium for infants, children, and adolescents have been recommended (Table 8-3).[30] Because calcium is an essential nutrient for bone mineralization, intake of calcium is optimal when skeletal calcium content is maximal for the age and gender of the subject.[2] In normally

TABLE 8-3 **Recommended Dietary Intakes of Calcium and Vitamin D in Infants, Children, and Adolescents**

Age (in years)	Calcium (mg/day)	Calcium (upper limit)	Vitamin D (IU/day)	Vitamin D (upper limit)	Minimum [25OHD] (ng/mL)
< 0.5	400		400	1000	20
0.5-1	600		400	1500	20
1-3	700	2500	600	2500	20
4-8	1000	2500	600	3000	20
9-13	1300	3000	600	4000	20
14-18	1300	3000	600	4000	20
Pregnant or lactating (14-18)	1300	3000	600	4000	20

Recommendations for calcium and vitamin D are the Recommended Dietary Allowance (RDA) intakes necessary for ≥97.5% of population. *Adapted from Ross, A. C., Manson, J. E., Abrams, S. A., et al. (2011). The 2011 report on dietary reference intakes for calcium and vitamin D from the Institute of Medicine: what clinicians need to know.* J Clin Endocrinol Metab, 96, *53–58; Holick, M. F. (2011). Vitamin D: evolutionary, physiological and health perspectives.* Curr Drug Targets, 12, *4–18; Holick, M. F., Binkley, N. C., Bischoff-Ferrari, H. A., et al. (2011). Evaluation, treatment, and prevention of Vitamin D deficiency: an Endocrine Society Clinical Practice Guideline.* J Clin Endocrinol Metab, 96, *1911–1930.*

weighted adolescents, a calcium intake above 1600 mg/day results in maximal calcium retention (approximately 35%).[31] (Thus, the recommended dietary allowance [RDA] of calcium for adolescents of 1300 mg/day [see Table 8-3] may be underestimated.) Calcium retention and bone mass increase as the body mass index rises when calcium intake is sufficient. The retention of oral calcium depends not only on the level of nutrient intake but also on gender and race: white adolescent males retain more calcium than do white girls (37% versus 30%); black adolescent girls retain more calcium than do white girls (38% versus 30%). Besides dietary intake of calcium and vitamin D status, the most significant modifiable determinant of bone mineralization is weight-bearing physical activity (discussed later).[32]

Calcium is excreted primarily by the kidney. Ultrafiltrable serum calcium (representing both the ionized Ca^{2+}_e form and calcium that is complexed or chelated) crosses the renal glomerular membrane; 98% of filtered calcium is reabsorbed in the renal tubule. Paracellular reabsorption of most (93%) of filtered calcium occurs in the proximal renal tubule and thick ascending limb of Henle (TALH). The renal distal convoluted tubule, connecting tubule, and first part of the collecting duct actively reabsorb approximately 5% of filtered calcium transcellularly through TRPV5 calcium channels expressed on the apical membrane of renal tubular epithelial cells.[22] In the cytoplasm, calbindin D_{9k} then shuttles Ca^{2+}_e across the cell for extrusion by ATPB1 channels and the Na^+-Ca^{2+} exchanger type 1 (encoded by *SLC8A1*) on the basolateral membrane of the renal tubular cell. Calcitriol, PTH, low dietary calcium, estrogens and androgens, and acid/base balance increase expression of *TRPV5*. PTH also enhances posttranslational phosphorylation of TRPV5 and hence its movement to and insertion into the apical membrane of the renal tubular cell and inhibits its endocytosis, the paired effects thus resulting in increased numbers of TRPV5 channels on the apical surface of the renal tubular cell.[22] Klotho (encoded by *KL*), a cofactor/coreceptor essential for normal phosphate homeostasis (discussed later) that also has intrinsic beta glucuronidase activity, increases the retention and hence the activity of the TRPV5 calcium channel by removing oligosaccharide chains during its posttranslational processing.[33,34] Calmodulin, an intracellular Ca^{2+}-sensing protein that binds to and inhibits the action of TRPV5, modulates renal tubular reabsorption of Ca^{2+}, a process reversed by PTH-mediated phosphorylation of the TRPV5 calbindin-binding site.[35] Although calbindin D_{9k} is not expressed in the proximal renal tubule, cells lining the lumen of this segment have deep invaginations shortening the distance that reabsorbed Ca^{2+} must travel by diffusion between apical and basolateral membranes before extrusion.[21] In the TALH, calcium and magnesium are reabsorbed through voltage-driven paracellular channels (in part through paracellin-1, a tight junction protein channel that is instrumental in renal reabsorption of filtered calcium and magnesium [discussed later]). Cells of the TALH also express the CaSR on their basolateral membrane; when activated by peritubular Ca^{2+}, this G protein–coupled receptor (GPCR) decreases renal tubular reabsorption of calcium through the paracellular channels by inhibiting activity of the Na^+-K^+-$2Cl^-$ transporter and lowering lumen-positive voltage. Increased glomerular filtration or decreased renal tubular reabsorption increase renal excretion of calcium, phosphate, and magnesium. Urinary excretion of calcium is augmented by increased dietary intake, hypercalcemia of diverse pathophysiology (with the exception of that associated with familial hypocalcemic hypercalciuria [discussed later]), expansion of extracellular volume, metabolic acidosis, and loop diuretics (furosemide).[1] PTH and PTHrP increase renal tubular reabsorption of Ca^{2+}, whereas glucocorticoids, mineralocorticoids, and Ca^{2+} itself suppress Ca^{2+} reabsorption.

Calcium Sensing Receptor

Plasma Ca^{2+}_e concentrations are monitored by the CaSR, a 1078-amino-acid cell membrane GPCR encoded by *CASR* whose extracellular domain recognizes and binds Ca^{2+}, Mg^{2+}, gadolinium, aromatic amino acids, antibiotics, and other compounds.[36,37] Functionally, the CaSR is a homodimer linked by disulfide bonds between extracellular

domain cysteine residues 129 and 131 of each CaSR. Homodimerization of the CaSR takes place in the endoplasmic reticulum after core N-linked glycosylation; homodimeric CaSR is then packaged within the Golgi apparatus where it is further glycosylated and transported to the cell membrane.[38] The amino terminal extracellular domain of the CaSR is composed of 612 amino acids with five likely Ca^{2+} binding sites constructed in a Venus flytrap configuration; there are 250 amino acids in the transmembrane domain composed of seven transmembrane helices and three alternating extracellular and intracellular loops, and 216 amino acids in the carboxyl terminal intracellular domain.[37] Transmembrane helix 5 may also be necessary for receptor dimerization. The second extracellular loop contains sites (Asp758, Glu759, Glu767) that modulate the sensitivity of the CaSR to Ca^{2+}. Within the intracellular domain of the CaSR are three protein kinase C (PKC) phosphorylation sites; phosphorylation of Thr888 downregulates Ca^{2+}-mediated CASR intracellular signal transduction.[36] Because Ca^{2+}-CaSR interaction stimulates PKC signaling, function of the CaSR can thus be autoregulated.[37] Through its binding of Ca^{2+}_e, the CaSR finely regulates the extracellular concentration of this cation by modulating the secretion of PTH and the renal tubular reabsorption of filtered calcium. The CaSR is encoded by *CASR* and is a member of the C family of GPCRs with extremely long extracellular domains (500- to 600-amino-acid residues) and homologies with receptors that bind glutamate, γ-aminobutyric acid, and pheromones as well as with the taste receptors. The very long extracellular domain is heavily glycosylated, a posttranslational modification essential for efficient movement of the receptor to the cell surface. The CaSR is expressed on the plasma membrane of parathyroid chief cells, at the apical or basolateral membranes of most renal tubular cells—particularly the TALH and the collecting ducts, on the cell membranes of the parafollicular (C) cells of the thyroid, in cartilage and bone, lungs, adrenals, breast, intestines, skin, lens, placental cytotrophoblasts, and nervous tissue.[39] Expression of *CASR* is regulated in part by *GCM2*, encoding a transcription factor essential for formation of the parathyroid glands, and enhanced by calcitriol, high Ca^{2+}_e levels, and interleukin (IL)-1β.[40]

The serum Ca^{2+}_e concentration is related to polymorphic variants of the CaSR; 70% of individuals are homozygous for alanine at amino acid position 986 within the intracellular domain, 3% are homozygous for serine, and the remainder are heterozygous for the two amino acids. In heterozygous Arg986Ser and homozygous Ser986 subjects, Ca^{2+}_e levels are significantly higher than in those who are homozygous for Ala986.[41] Also, there are cellular Ca^{2+} sensors that are unrelated structurally to the CaSR as well as subtypes of the CaSR itself.[39] The CaSR also serves as a Mg^{2+}_e sensor and modulates renal tubular reabsorption of this cation decreasing its reabsorption when Mg^{2+}_e levels rise. By binding to the CaSR, aromatic L-amino acids appear to "sensitize" the receptor to a given level of Ca^{2+}_e (discussed later).[36]

Although in the kidney the CaSR is found in greatest abundance in the medullary and cortical TALH, it is also found in glomerular cells and other segments of the renal tubule. *CASR* is expressed on the apical brush-border membranes of cells in the proximal renal tubule, on basolateral cell membranes in cells in the TALH, and on the apical (luminal) surface of cells in the distal renal collecting ducts where it is exposed to intratubular Ca^{2+}.[37] Increasing peritubular concentrations of Ca^{2+}_e and Mg^{2+}_e inhibit renal tubular reabsorption of filtered Ca^{2+} and Mg^{2+}. In the kidney, binding of Ca^{2+}_e to the CaSR decreases not only transcellular transport of filtered Ca^{2+} but also its paracellular transport in the TALH. Inactivating mutations in *CASR* result in familial hypocalciuric hypercalcemia, whereas gain-of-function mutations in this gene are associated with autosomal dominant hypoparathyroidism (familial hypercalciuric hypocalcemia).[37] Stimulation of the CaSR suppresses PTH-mediated renal tubular Ca^{2+} and phosphate reabsorption.[37,42] In addition to effects on renal tubular cation transport, the Ca^{2+}/CaSR complex inhibits antidiuretic hormone–induced renal tubular permeability to water by decreasing the number of apical aquaporin-2 water channels in the inner medullary collecting ducts, thus leading to polyuria. Stimulation of the CaSR expressed in cells of the renal distal collecting ducts also increases local H^+-ATPase activity resulting in urine acidification.[42]

Acting through the CaSR, rising serum Ca^{2+}_e concentrations stimulate release of calcitonin from thyroid C cells. The CaSR is expressed throughout the intestinal tract, where it may modulate the changes in intestinal motility that accompany low (increased) and high (depressed) serum Ca^{2+}_e values.[36] Additionally, in gastric cells stimulation of CaSR activity results in release of gastrin into the circulation and increased intragastric acidity.[37] Expression of the CaSR in the brain suggests a mechanism whereby Ca^{2+} may influence neural function locally by modulating neurotransmitter and neuroreceptor function (such as the metabotropic glutamate receptor which also recognizes Ca^{2+}). Cell membrane CaSRs are present in (mouse, rat, bovine) articular and hypertrophic chondrocytes of the epiphyseal growth plate and to a lesser extent in proliferating and maturing chondrocytes.[43] Osteoblasts, osteocytes, and osteoclasts also express the CaSR, and agonist (Ca^{2+}, neomycin, gadolinium) activation of the CaSR stimulates intracellular signal transduction in these cells. Increase in CaSR activity in osteoblasts enhances their proliferation.[37] The CaSR may mediate recruitment of osteoblast precursor cells to sites of high Ca^{2+} levels, the residue of local osteoclast activity, one of the factors linking the bone remodeling processes of resorption and formation (discussed later).[39] In mice in which expression of bone-specific *Casr* has been eliminated, skeletal development is impaired with diffuse decrease in bone mineralization.[37] In vitro, Ca^{2+} inhibits bone reabsorptive activity of (rabbit) osteoclasts by causing the osteoclast to decrease secretion of acid and proteolytic enzymes and to withdraw from the site of bone resorption.[44]

Through its intracellular carboxyl terminal, the CaSR is linked to G proteins and their Gα subunits that couple the ligand-receptor message to several intracellular signal transduction pathways.[36,37,39] After binding of Ca^{2+} to the extracellular domain of the CaSR, $G_{\alpha q/11}$ dissociates from its βγ subunit complex and activates membrane bound

PLC-β1; in turn, this enzyme hydrolyzes membrane-bound phosphatidylinositol 4,5-bisphosphate (PIP_2) to diacylglycerol (DAG) and IP_3, the latter leading to release of Ca^{2+} from the endoplasmic reticulum and increased cytosolic concentrations of $Ca^{2+}{}_i$. Activation of the CaSR also stimulates activity of phospholipases A_2 and D, mitogen-activated protein kinases (MAPK), and protein kinases B (Akt) and C but inhibits that of adenylyl cyclase, the latter through stimulation of adenylate cyclase-inhibitory Gαi activity.[37] Increases in plasma $Ca^{2+}{}_e$ and rising cytosolic levels of $Ca^{2+}{}_i$ within the parathyroid gland chief cells suppress expression of *PTH* and increase degradation of PTH mRNA, thereby limiting synthesis and secretion of PTH; CaSR signaling also inhibits the proliferation of chief cells.[37] A decline in $Ca^{2+}{}_e$ leads to a decrease in CaSR activity, lower $Ca^{2+}{}_i$ values, and thence to increased PTH secretion, thus enabling the CaSR to exercise minute-to-minute control over the release of PTH and hence of the concentration of $Ca^{2+}{}_e$.

Calcimimetics are agonist drugs that activate the CaSR; calcilytics are antagonists of the CaSR.[45] As noted, the CaSR binds and responds to not only $Ca^{2+}{}_e$ but also $Mg^{2+}{}_e$, selected L-amino acids, and some antibiotics; the latter are designated type I calcimimetics. Synthetic compounds (e.g., phenylalkylamines) that bind to the second and third extracellular loops of the transmembrane domain of the CaSR and allosterically modulate (increase or decrease) the sensitivity of the CaSR to ambient $Ca^{2+}{}_e$ are designated type II calcimimetic agonists or calcilytic antagonists, respectively.[36,37] The most widely employed of the clinical calcimimetics is cinacalcet [N-[1-(R)-(-)-(1-naphthyl)ethyl] -3-[3-(trifluoromethyl)phenyl]-1-aminopropane hydrochloride]; this agent has been effective in decreasing secretion of PTH in patients with either primary or secondary hyperparathyroidism.[46] Calcilytics decrease the sensitivity of the CaSR to $Ca^{2+}{}_e$ and thus increase the secretion of PTH and depress renal tubular reabsorption of Ca^{2+}. Mutations in CASR may prevent its normal biosynthesis (class I), disturb movement of the CaSR protein to the plasma membrane (class II), interfere with binding of ligand to the CaSR (class III), impair activation of the CaSR (class IV), or disrupt receptor function by an unknown mechanism (class V).

PHOSPHATE

Eighty-five percent of body phosphate is deposited in bone as hydroxyapatite. Fourteen percent of phosphate is intracellular (in the cytosol or mitochondria in the form of inorganic phosphate esters or salts, cell and organelle membrane phospholipids, and phosphorylated metabolic intermediate compounds involved in energy metabolism and formation of ATP and signal transduction and in the cytosol and nucleus as an essential component of RNA and DNA) or in interstitial fluid or serum (approximately 1%). There it circulates as free orthophosphate anions HPO_4^{2-} and $H_2PO_4^-$ (55%), bound to proteins (10%), or complexed to calcium, magnesium or sodium (35%).[1,47] At pH 7.4, serum HPO_4^{2-} and $H_2PO_4^-$ are present in a molar ratio of 4:1; in alkalotic states the ratio increases, with acidosis it declines. (At pH 7.4, 1 mmol/L of orthophosphate = 1.8 mEq/L = 3.1 mg/dL.) The serum concentrations of calcium and phosphate are reciprocally related under normal circumstances, and the calcium × phosphate product approximates 30. Intracellularly, cytosolic-free phosphate concentrations approximate those in serum—3 to 6 mg/dL.

The serum phosphate concentration is regulated by oral intake, intestinal absorption and excretion, renal tubular reabsorption and excretion of filtered phosphate, and release from bone by dissolution of hydroxyapatite by PTH and calcitriol, and it fluctuates with age, gender, growth rate, diet, and serum calcium levels (see Figure 8-2).[1,48,49] Inasmuch as phosphate is found in all cells and foods, dietary deficiency is unusual. Dietary phosphate is absorbed across the intestinal brush border as HPO_4^{2-} in direct proportion to its intake, principally in the duodenum and jejunum. Intestinal phosphate is absorbed by both passive paracellular diffusion related to the luminal concentration of this anion and by an active transcellular mechanism stimulated by calcitriol. The latter is an energy-requiring transport process with sodium through the type IIb Na^+-HPO_4^{2-} cotransporter protein (NPT2b; encoded by *SLC34A2*) with low affinity for phosphate whose activities are maintained by calcitriol-dependent Na^+,K^+-ATPase. Decreased intestinal absorption of phosphate is compensated by increased renal tubular reabsorption of this anion.[47] Phosphate is also secreted into the intestinal tract. When dietary phosphate intake falls below 310 mg/day in the adult, net phosphate absorption is negative. At low phosphate intakes, absorption is active in the duodenum, jejunum, and distal ileum, whereas at high intakes 60% to 80% of ingested phosphate is absorbed primarily by diffusion. Phosphate absorption can be impaired by its intraluminal precipitation as an aluminum or calcium salt and by intestinal malabsorption disorders.

The kidney regulates moment-to-moment phosphate homeostasis. Phosphate is filtered in the renal glomerulus and reabsorbed primarily in the proximal renal tubules. It is actively transported across the luminal membrane against an electrochemical gradient through renal specific type II Na^+-HPO_4^{2-} cotransporter proteins expressed on the apical (tubular) surface of cells in the proximal renal tubule—NPT2a encoded by *SLC34A1* and NPT2c encoded by *SLC34A3*—with the aid of a Na^+,K^+-ATPase pump.[1,47,50] Expression of *SLC34A1* is regulated by serum phosphate levels (hypophosphatemia increases expression), PTH, PTHrP, and fibroblast growth factor (FGF)-23 (discussed later). NPT2a actively transports approximately 70% and NPT2c 30% of proximal renal tubular reabsorbed phosphate in the mouse; in the human, NPT2c may be the major renal tubular transporter of phosphate. The Na^+-H^+ exchanger regulatory factor 1 (NHERF1; encoded by *SLC9A3R1*) is a scaffolding protein that is essential for trafficking of NPT2a and NPT2c to the luminal membrane of cells in the proximal renal tubule; NHERF1 also interacts with PTH1R.[50] Another family of phosphate transporters (PiT2, encoded by *SLC20A2*, OMIM ID: 158378) has also been identified in the renal proximal tubule. Phosphate exits the proximal

renal tubular cell with Na^+ by cation exchange for K^+ through channels located on the cell's basolateral membrane. The maximal tubular reabsorption of phosphate approximates the filtered load. Tubular phosphate reabsorption is increased by low phosphate intake and hypophosphatemia (due to decrease in filtered load), hypercalcemia (by decrease in the glomerular filtration rate), depletion of extracellular fluid volume, and metabolic alkalosis. Renal tubular reabsorption of phosphate is depressed by high phosphate intake, PTH (and PTHrP), and phosphatonins (discussed later) and is due to rapid internalization and subsequent destruction of NPT2a and NPT2c proteins.[47] The PTH-dependent degradative processes are mediated through the type 1 PTH/PTHrP receptor and transduced by PKA, PKC, and MAPK. Fibroblast growth factor-23 (FGF23) (a phosphatonin), calcitriol, glucocorticoids, and thiazide diuretics also decrease renal tubular reabsorption of phosphate. Phosphate is deposited in bone as hydroxyapatite dependent on local levels of calcium, phosphate, and alkaline phosphatase activity and reabsorbed by osteoclasts whose activity is stimulated by PTH, calcitriol, and other osteoclast activating factors (discussed later). Serum concentrations of phosphate are highest in infancy and early childhood (4 to 7 mg/dL) and then decline during mid-childhood and adolescence to adult values (2.5 to 4.5 mg/dL).

Phosphatonins

Phosphatonins are substances that regulate serum concentrations of phosphate by controlling its rate of renal tubular reabsorption and of calcitriol by regulating its rate of synthesis (see Figures 8-1 and 8-2). In addition to FGF23, other phosphatonins are matrix extracellular phosphoglycoprotein (encoded by *MEPE*), Frizzled related protein-4 (encoded by *FRP4*), and FGF7, all of which were first identified by analysis of tumors associated with hypophosphatemic osteomalacia.[49,51] In addition to many patients with tumor-induced osteomalacia, increased serum concentrations of FGF23 are found in patients with X-linked hypophosphatemic rickets (XHR) due to loss-of-function mutations in the membrane-bound, 749-amino-acid endopeptidase encoded by *PHEX* (phosphate-regulating gene with homologies to endopeptidases located on the X chromosome, OMIM ID: 307800), autosomal dominant hypophosphatemic rickets (ADHR—OMIM ID: 193100) due to activating mutations in *FGF23*, and autosomal recessive hypophosphatemic rickets (ARHR—OMIM ID: 241520/613312) due to loss of function mutations in *DMP1* (encoding dextrin matrix acidic phosphoprotein 1) or *ENPP1*(encoding endonucleotide pyrophosphatase/phosphodiesterase 1).[48,49] By inhibiting renal phosphate transport, phosphatonins lead to hyperphosphaturia and hypophosphatemia. They also decrease transcription of *CYP27B1*, thereby depressing activity of renal tubular 25-hydroxyvitamin D-1α-hydroxylase resulting in decreased synthesis of calcitriol and thus inappropriately normal or low serum concentrations of calcitriol and in impaired intestinal absorption of phosphate and calcium.[47,52-54] FGF23 is generated as a 251-amino-acid protein with a 24-amino-acid signal sequence; for optimal biologic function, FGF23 must be posttranslationally glycosylated by N-acetylgalactosaminyl transferase 3 encoded by *GALNT3*. FGF23 is proteolytically degraded by intracellular subtilisin-like proprotein convertase acting between amino acids 179 and 180 (. . . Arg_{176}-His_{177}-Thr_{178}-Arg_{179}-Ser_{180} . . .) that separates the amino terminal FGF-like domain from the carboxyl terminal tail. Spontaneously occurring (gain-of-function) mutations within this sequence of *FGF23* slow the inactivation of FGF23, thus prolonging its biologic life resulting in ADHR. *FGF23* is expressed primarily by osteoprogenitor cells, osteoblasts, and osteocytes and to a lesser extent by the thymus, brain, thyroid, parathyroid glands, cardiac muscle, liver, and small intestines. In osteoblasts and osteocytes, expression of *FGF23* is stimulated by high serum or dietary phosphate, PTH, calcitriol acting through the VDR, and in some patients parenteral infusion of iron.[47,55,56]

FGF23 induces renal phosphate excretion by down-regulating expression of *SLC34A1* (encoding NPT2a) and *SLC34A3* (encoding NPT2c), the Na^+-HPO_4^{2-} cotransporters that are expressed in the apical (luminal) membrane of cells of the proximal renal tubule (see Figure 8-2). FGF23 down-regulates expression of proximal renal tubular 25-hydroxyvitamin D-1α-hydroxylase encoded by *CYP27B1* and thus limits synthesis of calcitriol; FGF23 also increases the expression of 25-hydroxyvitamin D-24-hydroxylase (encoded by *CYP24A1*), thereby enhancing the catabolism of calcitriol—the two processes summating to lower calcitriol synthesis.[57] Inasmuch as calcitriol promotes synthesis of FGF23, there is a reciprocal feedback relationship between calcitriol and FGF23. FGF23 acts through binding to the c isoform of tyrosine kinase FGF receptors (FGFR) 1, 2, and 3. The genes encoding the FGFRs consist of 19 exons that may be alternatively spliced to include or to exclude either exon 8 or 9 (encoding the third extracellular immunoglobulin-like domain of the FGF receptor, which partially specifies the ligand bound by the receptor); when exon 8 is included in the mRNA transcript, the b isoform of the FGFR is formed; when exon 9 is included in the transcript, the c isoform is produced. Although it is likely that FGF23 binds to multiple FGFR c isoforms, it is the multifunctional protein α-klotho that serves as a coreceptor thereby converting FGFR into specific FGF23 receptors in the parathyroid glands and kidney.[49,50,58] FGFR1 mediates the effects of FGF23 on renal phosphate transport, whereas FGFR3 and FGFR4 translate the effects of FGF23 on renal calcitriol synthesis. There are several isoforms of α-klotho encoded by *KL*. As a coreceptor for FGF23, α-klotho is a 130-kDa transmembrane protein with a very short (10 amino acids) intracellular domain; without the transmembrane domain (encoded by exon 3), it is an 80 kDa secreted protein whose levels are measurable in serum; removal of the sequence of amino acids that tethers the extracellular domain to the cell membrane results in another form of circulating α-klotho.[47] Interestingly, *KL* is expressed in the renal distal convoluted tubule, not the proximal tubule, implying that it is circulating α-klotho that serves as the coreceptor for FGF23/FGFR1(IIIc) in the proximal renal tubule where phosphate is reabsorbed.[47]

KL is also expressed in the parathyroid gland; there, FGF23 interacting with α-klotho and FGFR1(IIIc) decreases transcription of *PTH* and thereby reduces PTH synthesis and secretion. Reciprocally, PTH increases synthesis of FGF23 by bone cells, establishing yet another feedback loop regulating FGF23 synthesis and secretion.[54] After binding of the FGF ligand to the FGFR, the receptors dimerize, autophosphorylate, and then phosphorylate intracellular proteins involved in signal transduction such as phospholipase-Cγ (PLCγ), growth factor receptor bound (GRB)-14, son of sevenless (SOS), and FGF receptor substrate (FRS)-2, a docking protein that links the activated FGFR to the phosphoinositide-3-kinase (PI3K), MAPK, and ERK1/2 signaling pathways.[59] Immunoreactive species of FGF23 are measurable in normal adult sera, but values vary depending on the epitopes recognized by the antibodies employed (i.e., whether they are specific for the full-length FGF23 protein or only for its carboxyl terminal fragment) and on the assay methodology (e.g., enzyme-linked immunosorbent assay or chemiluminescent immunoassay).[60-62] In assays that recognize full-length FGF23 and carboxyl terminal fragments of FGF23, intact FGF23 values varied diurnally and there was marked interindividual variability in FGF23 levels.[61] The serum FGF23 concentration rises when dietary phosphate increases (or during infusion of phosphate) and declines with phosphate restriction.[49]

Serum values of FGF23 are increased in patients with XHR, ADHR, ARHR, tumor-induced osteomalacia, and fibrous dysplasia associated with hypophosphatemia. In patients with ADHR, gain-of-function mutations (e.g., Arg179Trp) in *FGF23* result in resistance to degradation of FGF23, a protein that is normally cleaved between Arg179 and Ser180; in subjects with tumor-induced osteomalacia, the production of FGF23 is greatly increased. In familial tumoral calcinosis (OMIM ID: 211900), loss-of-function mutations in *FGF23* lead to accelerated intracellular degradation of FGF23 that prevents secretion of intact protein resulting in decreased renal excretion of phosphate, hyperphosphatemia, relatively increased calcitriol levels, and diffuse ectopic calcification.[49,63]

Tumors associated with hypophosphatemic osteomalacia also express the phosphatonins encoded by *FRP4* (Frizzled related protein-4), *MEPE* (matrix extracellular phosphoglycoprotein), and *FGF7*.[49,51] FRP4 is a secreted 346-amino-acid glycosylated protein that shares the structure of the extracellular domain of transmembrane Frizzled receptors. The natural ligands of Frizzled receptors are WNT proteins, and their coreceptors are cell surface low-density lipoprotein receptor-related protein (LRP) 5/6; these heterotrimeric complexes stabilize intracellular β-catenin and the attendant signal transduction systems that are essential for bone formation (discussed later). Secreted FRP4 serves as a decoy receptor competing with the Frizzled receptor for binding to WNT, thus inhibiting the function of the Frizzled receptor. *FRP4* is expressed in bone cells and in large amounts by tumors with associated osteomalacia. FRP4 inhibits sodium-dependent renal tubular phosphate reabsorption by inhibition of WNT signaling leading to hypophosphatemia; it also reduces expression of *CYP27B1*, the gene encoding 25-hydroxyvitamin D_3-1α-hydroxylase.[52] *MEPE* is primarily expressed by osteoblasts, osteocytes, and odontoblasts as well as by tumors associated with hypophosphatemic osteomalacia. It encodes a 525-amino-acid, 58-kDa protein, a matrix extracellular phosphoglycoprotein that is a member of the short-integrin-binding, ligand-interacting glycoprotein (SIBLING) family (discussed later). Expression of *MEPE* is inhibited by calcitriol. MEPE modulates osteoblast and osteoclast function and may both inhibit and support bone mineralization.[49] Although MEPE is able to inhibit sodium-dependent renal tubular phosphate reabsorption, its role in phosphate metabolism may be more complex inasmuch as knockout of *Mepe* in mice results in increased bone mass without altering serum phosphate or calcitriol values.[64] MEPE contains an acidic serine aspartate-rich MEPE-associated motif (ASARM) that binds to hydroxyapatite where it inhibits mineralization; ASARM is the physiologic substrate for PHEX, which degrades it, enabling further hydroxyapatite formation; loss-of-function mutations in *PHEX* lead to X-linked hypophosphatemic rickets (XHR).[54,65]

The short integrin-binding ligand-interacting glycoproteins (SIBLINGs) are related noncollagenous matrix proteins: MEPE, dentin-matrix acidic phosphoprotein 1 (DMP1), dentin sialo-phosphoprotein (DSPP), osteopontin (also termed secreted phosphoprotein 1 [SPP1]), and bone sialoprotein (BSP), whose encoding genes are clustered on chromosome 4q.[54] These proteins share several common structures including an acidic serine aspartate-rich MEPE associated motif (ASARM) near their carboxyl terminals and an Arg-Gly-ASP (RGD) tripeptide motif that interacts with and binds to integrins on the surface of interacting cells. The basic ASARM motif consists of 23 amino acids; several of the serine residues are specifically phosphorylated by casein serine kinase. ASARM is released from MEPE by cathepsins B and K; phosphorylated ASARM from MEPE binds avidly to hydroxyapatite and prevents further deposition of calcium and phosphate; it also inhibits phosphate uptake by both the intestinal tract and the renal tubule. (MEPE also is involved in the osteocytic response to a mechanical load [discussed later].) Phosphorylated and nonphosphorylated ASARMs released by MEPE, DMP1, DSPP, and SPP1 are resistant to proteolysis except by the zinc metalloendopeptidase PHEX (phosphate regulating gene with homologies to endopeptidases on the X chromosome). Thus, inactivating mutations of *PHEX* result in X-linked hypophosphatemic rickets, in part, by inability to degrade the ASARM peptide coating of hydroxyapatite.[54] PHEX may also be involved in the expression of *FGF23* and the stability of FGF23.[54] Carboxyl to the ASARM motif of DMP1 is an additional sequence of 35 amino acids that is termed the minfostin motif; a mutation in this region of *DMP1* results in one form of ARHR. It has been suggested that in the normal osteocyte, the ASARM region of DMP1 binds to PHEX expressed on its plasma membrane, thereby suppressing expression of *PHEX* and that displacement of binding by excessive free ASARM peptides (as in patients with XHR, ARHR) increases *FGF23* expression.[54] PHEX, DMP1, and FGF23 may also be involved in the regulation of energy metabolism (discussed later).

MAGNESIUM

Magnesium (Mg^{2+}) is the fourth most abundant of the body cations. Approximately 1% of body Mg^{2+} is present in the ECF compartment, ~14% in muscle and soft tissue, and ~85% in bone where it is found on the surface of the hydroxyapatite crystal and of which ~50% is freely exchangeable.[1,3,66] In blood, magnesium (1.7 to 2.4 mg/dL = 0.7 to 1 mmol/L) is partially bound to proteins (~30%), complexed to phosphate and other anions (~15%), and free Mg^{2+}_e (~55%). As with Ca^{2+}_e, Mg^{2+}_e levels rise as pH falls (increased acidity). Intracellularly, magnesium (0.5 mmol/L) is bound to ATP and other molecules; ~10% is in the ionic form and ~60% is within mitochondria. Mg^{2+}_e is a cofactor in many enzymatic reactions, including those that consume or produce ATP. Mg^{2+}_e alters free radicals and influences nitric oxide synthase, cyclic guanosine monophosphate generation, endothelin production, and immune function. Mg^{2+}_e decreases membrane excitability in nerve and muscle cells and blocks the excitatory N-methyl D-aspartate receptor. It is a necessary cofactor for the regulation of neuromuscular excitability, nerve conduction, oxidative metabolism by mitochondria, glycolysis, phosphorylation, and transcription and translation of DNA. It is essential for the secretion (but not the synthesis) of PTH by the parathyroid chief cell. Net intestinal magnesium absorption is directly related to dietary intake and independent of calcitriol.[1] Magnesium is passively absorbed by diffusion through voltage-dependent paracellular channels in the small intestine and colon in proportion to the intestinal luminal concentration of this cation. In addition, a small component of active, transcellular magnesium absorption takes place in the colon through transient receptor potential melastatin (TRPM)-6 cation transport channels complexed with TRPM7 channels.[22,67] Loss-of- function mutations in *TRPM6* result in autosomal recessive hypomagnesemia with secondary hypocalcemia due to impairment of intestinal (and renal tubular) absorption of this cation. The intestinal absorption of magnesium may be impaired by high phosphate intake, intestinal dysfunction, or chronic laxative abuse. Magnesium is also excreted into the intestinal tract.

Seventy percent of serum Mg^{2+}_e is ultrafiltrable and passes through the renal glomerular membrane; ~95% of filtered Mg^{2+} is reabsorbed—~15% in the proximal tubule and ~70% in the cortical TALH by passive paracellular means and ~10% in the distal convoluted tubule—in the latter site by an active transcellular reabsorption process.[1,66] Approximately 3% to 5% of filtered Mg^{2+} is excreted in the urine. In the proximal renal tubule, the reabsorption of water results in an increased intratubular Mg^{2+} concentration that facilitates its paracellular reabsorption.[66] In the TALH, Mg^{2+} reabsorption occurs through a paracellular pathway that is impermeable to water and is propelled by a transepithelial voltage gradient that is lumen positive and generated by a Na^+-K^+-ATPase.[66] The voltage gradient requires the integrated action of a Na^+-K^+-Cl^--coupled cotransporter (NKCC2 encoded by *SLC12A1*), a Cl^- channel (CLC-Kb encoded by *CLCNKB*), and a K^+ channel (ROMK encoded by *KCNJ1*). Barttin encoded by *BSND* is an essential beta subunit of the ROMK Cl^- channel.

Mg^{2+} is conducted from the lumen of the TALH to the interstitial space and into the vasculature by tight junction proteins encoded by the claudin gene family, specifically claudins 16 and 19. Tight junction proteins bridge intercellular gaps and regulate the movement of ions across an epithelial sheet. Paracellin-1 (encoded by *CLDN16*) is a 305-amino-acid, tight junction claudin protein whose gene is expressed primarily in the renal cortical TALH and distal convoluted tubule; paracellin-1 has four transmembrane domains with intracellular carboxyl and amino terminals.[16] Paracellin-1 is also utilized for paracellular reabsorption of Ca^{2+} in the TALH. Homozygous or compound heterozygous loss-of-function mutations of *CLDN16* lead to familial, autosomal recessive renal hypomagnesemia (type 3) characterized by renal wastage of Mg^{2+} in association with hypercalciuria and renal calcification (OMIM ID: 248250).[68] Claudin 19 is a 224-amino-acid tight junction protein. Biallelic inactivating mutations in *CLDN19* result in renal wasting of Mg^{2+}, hypomagnesemia, hypercalciuria, and nephrocalcinosis leading to renal failure; additionally, because *CLDN19* is expressed in the eye, affected subjects have decreased vision due to retinal malformation (hypomagnesemia type 5, OMIM ID: 248190).

It is primarily in the distal convoluted tubule—the last segment of the nephron in which Mg^{2+} is reabsorbed—that Mg^{2+} is actively transported through apical (luminal) membrane TRPM6 channels.[22,66,69] The renal tubular expression and intracellular movement of TRPM6 is regulated by dietary magnesium, estrogens, acid-base balance, and pro-epidermal growth factor (pro-EGF). TRPM7 (OMIM ID: 605692) is also expressed on the luminal surface of renal cells in the distal convoluted tubule where it too facilitates reabsorption of Mg^{2+}.[69] Other magnesiotropic proteins expressed in the distal convoluted tubule are the thiazide sensitive Na^+:Cl^- cotransporter, potassium channels Kv1.1 and Kir4.1, and hepatocyte nuclear factor 1B (HNF1B). Biallelic inactivating mutations in *TRPM6*—encoding an ion channel positioned on the luminal membranes of colonic cells and cells in the renal distal convoluted tubule—result in hypomagnesemia type 1 with secondary hypocalcemia (OMIM ID: 602014); this disorder presents in early infancy with tetany and seizures and is due to both impaired absorption of intestinal Mg^{2+} and reabsorption of renal tubular Mg^{2+}. Pro-EGF regulates the availability and activity of TRPM6 by enabling its movement from intracellular sites of storage to the luminal plasma membrane of renal distal convoluted tubular cells and colonic epithelial cells; biallelic loss of *EGF* leads to hypomagnesemia type 4 (OMIM ID: 611718). Loss of *SLC12A3* and its encoded product—the thiazide sensitive Na^+:Cl^- cotransporter—leads to reduced TRPM6 activity or abundance and the Gitelman syndrome (OMIM ID: 263800) of hypomagnesemia, hypocalciuria, and hypokalemic metabolic alkalosis. Loss of the voltage-gated K^+ channel Kv1.1 (encoded by *KCNA1*) that colocalizes with TRPM6 alters the polarization of the renal epithelial cell of the distal convoluted tubule, a functional abnormality that impairs activity of TRPM6 and hence of Mg^{2+} transport resulting in autosomal

dominant hypomagnesemia with episodic ataxia, tetany, muscular cramping, and myokymia (involuntary, localized quivering of a few muscle fibers within a muscle) (OMIM ID: 160120). The pathogenesis of hypomagnesemia (OMIM ID: 612780) that results from the loss-of-function mutations in *KCNJ10* encoding the inwardly rectifying K^+ channel, Kir4.1, is similar to that described for loss of *KCNA1*. Inactivating mutations of *KCNJ10* not only lead to hypomagnesemia but are also associated with the SESAME syndrome (seizures, sensory neural deafness, ataxia, mental retardation, electrolyte imbalance, OMIM ID: 612780). (In addition to the described Mg^{2+} transport proteins, there are several other well-characterized Mg^{2+} membrane transporters and solute carriers.[69])

PTH increases Mg^{2+} reabsorption in the renal TALH and distal convoluted tubule; hypermagnesemia and hypercalcemia (acting through the CaSR) decrease renal tubular magnesium reabsorption, as do expansion of extracellular fluid volume, metabolic alkalosis, phosphate depletion, loop diuretics, aminoglycoside antibiotics, and impaired renal function.[1]

ALKALINE PHOSPHATASE

The gene (*ALPL*) encoding tissue-nonspecific alkaline phosphatase (TNSALP) is expressed in bone (synthesized by the osteoblast), liver, kidney, and skin fibroblasts. Bone ALPL is a 507-amino-acid protein that is generated by alternative processing of *ALPL* utilizing one of two leading exons during transcription and translation, permitting the osteoblast to synthesize and release a specific bone isoform. Although TNSALP circulates as a homodimer, in tissue it is a homotetrameric ectoenzyme (ectophosphatase) located on the osteoblast's cell surface anchored through its carboxyl terminal to cell membrane phosphatidylinositol-glycan. In bone, alkaline phosphatase (1) binds to collagen type I and prepares skeletal matrix for mineralization; (2) hydrolyzes organic phosphates, principally pyrophosphate and other polyphosphates (discussed later) as well as phosphoethanolamine and pyridoxyl-5'-phosphate, the major circulating form of vitamin B_6, thereby increasing the local concentration of phosphate to values that exceed the calcium × phosphate product encouraging deposition of calcium phosphate as hydroxyapatite on collagen type I fibers; (3) transports inorganic phosphate and Ca^{2+} into the cell; and (4) inactivates pyrophosphate and other inhibitors of mineralization (e.g., phosphorylated ASARM derived from MEPE) by removing their phosphate moieties. The hepatic form of TNSALP is formed by alternative splicing of dual exons 1 of *ALPL*. Hepatic alkaline phosphatase converts pyridoxal-5′-phosphate to pyridoxal, a compound essential for normal synthesis of neural γ-aminobutyric acid (GABA), an inhibitory neurotransmitter; without pyridoxal-5′ phosphate central nervous system levels of GABA are low and seizures may occur. Loss-of-function mutations in *ALPL* lead to infantile, childhood, and adult forms of hypophosphatasia. Three genes encoding tissue-specific intestinal, placental, and germ cell alkaline phosphatase isoenzymes are clustered at chromosome 2q34-q37.

PARATHYROID HORMONE; PARATHYROID HORMONE–RELATED PROTEIN; PTH/PTHRP RECEPTORS

Parathyroid Hormone

Parathyroid hormone increases concentrations of plasma Ca^{2+}_e, lowers serum phosphate values, stimulates synthesis of calcitriol, and exerts both anabolic and catabolic effects on bone. PTH is synthesized and secreted by the chief cells of four paired parathyroid glands that are derived from the endoderm of the dorsal segments of the third (paired inferior glands) and fourth (paired superior glands) pharyngeal pouches; occasionally, there may be a fifth parathyroid gland embedded within the substance of the thyroid gland or in the mediastinum.[70] The thymus is formed by the endoderm of the third pharyngeal pouch and calcitonin-synthesizing parafollicular (C) cells of the thyroid by that of the fourth pharyngeal pouch. A critical transcription factor for the development of the parathyroid glands is the nuclear DNA binding transcription factor encoded by *GCM2* (OMIM ID: 603716). Although essential for neural glial cell development in insects, *Gcm* is not expressed in mammalian brain but is expressed primarily in the rodent placenta and thymus (*Gcm1*) and in the parathyroid gland (*Gcm2*); the pharyngeal pouch expression of *Gcm2* is maintained by a number of homeobox and transcription factors including those encoded by *Hoxa3*, *Pax1*, *Pax9*, and *Eya1*. The human homologue of *Gcm2* (*GCM2* or *GCMB*) is expressed in the parathyroid glands and in intrathymic PTH-secreting adenomas but not by normal human thymus.[71] Intragenic deletion or missense mutations of *GCM2* have been identified in subjects with familial, autosomal recessive hypoparathyroidism.

PTH is synthesized as a 115-amino-acid preprohormone that is translated into a full-length peptide of 84 amino acids ($PTH^{1\text{-}84}$). Its synthesis and secretion by chief cells of the parathyroid glands is regulated by Ca^{2+}_e concentrations acting through the CaSR (discussed earlier) that either enhance (when Ca^{2+}_e concentrations are low) or repress (when they are high) transcription of *PTH* and secretion of PTH; Ca^{2+}_e values also modulate the rate of chief cell proliferation, a response mediated by the CaSR. Calcimimetic drugs have inhibitory effects on PTH secretion, a property that has made these agents useful in the management of patients with excess secretion of PTH such as mild hyperparathyroidism and autosomal dominant familial hypocalciuric hypercalcemia. Higher serum phosphate values enhance production of PTH not only indirectly by lowering of Ca^{2+}_e values but also by stabilizing PTH mRNA permitting greater translation of PTH and by stimulation of chief cell replication. 1α,25-Dihydroxyvitamin D_3 (calcitriol) and its synthetic analog inhibit transcription of *PTH*, secretion of PTH, and proliferation of chief cells; FGF23 also decreases PTH release.[70] In response to acute hypocalcemia, PTH stored in secretory vesicles is rapidly released; when hypocalcemia is prolonged, the secretion of $PTH^{1\text{-}84}$ is augmented by a decrease in its rate of intracellular degradation and an increase in the rate of transcription of *PTH*; when hypocalcemia is extended, PTH synthesis and

secretion are amplified by increase in chief cell number. When Ca^{2+}_e values rise, the secretion of PTH is decreased acutely by degradation of stored $PTH^{1\text{-}84}$ by calcium-responsive proteases within the parathyroid glands; if prolonged, hypercalcemia leads to a decrease in the expression of *PTH*, possibly by destabilization of PTH mRNA, and to a decline in the number of chief cells.[70] *PTH* is composed of three exons; exon 1 is transcribed but not translated; the second and third exons of *PTH* encode the prepro-PTH sequence of 115 amino acids.

The stability, translation, and intracellular translocation of PTH mRNA are regulated by binding of cytosolic proteins to the 3′-untranslated region of PTH mRNA; these proteins include a member of the dynein complex that also binds to microtubules within the parathyroid chief cell and heterogeneous nuclear ribonucleoprotein D (HNRPD or AUF1) that directs mRNA into the proteasomal pathway of degradation.[72] The amino terminal 25-amino-acid signal sequence (encoded by exon 2) of 115-amino-acid prepro-PTH is removed by furin, a prohormone convertase, as the polypeptide leaves the endoplasmic reticulum forming the 90-amino-acid pro-PTH (encoded by exon 3) that is then further processed in the Golgi apparatus by furin to mature human 84-amino-acid PTH. $PTH^{1\text{-}84}$ is stored in secretory vesicles and granules from which it is either secreted by an exocytic mechanism or degraded by calcium-sensitive proteases (cathepsins B and H co-localized within the vesicles) to smaller amino and carboxyl terminal fragments of PTH. PTH degradation represents an important mechanism that regulates the release of intact bioactive $PTH^{1\text{-}84}$ and is accelerated when the plasma Ca^{2+}_e concentration is elevated. The full biologic activity of $PTH^{1\text{-}84}$ is found in its first 34-amino-acid sequence and all of its skeletal and renal affects (discussed later) are localized within the segment $PTH^{1\text{-}31}$. Amino acids numbers 1 and 2 (ser-val) comprise an activation sequence that is essential for bioactivity of the amino terminal portion of $PTH^{1\text{-}84}$. Amino acids 20 through 26 constitute a core sequence necessary for binding to the amino-terminal ectodomain of the PTH receptor (discussed later); within this 7-amino-acid sequence, Arg^{20} and Trp^{23} are critically important for binding of the PTH ligand to its receptor.[73] In addition to intact $PTH^{1\text{-}84}$, the parathyroid glands secrete a phosphorylated form of $PTH^{1\text{-}84}$ and carboxyl terminal PTH fragments of varying length, but they do not secrete amino terminal fragments of $PTH^{1\text{-}84}$.[74,75] The half-life of circulating $PTH^{1\text{-}84}$ is approximately 2 minutes; it is rapidly metabolized by the liver and excreted by the kidney. In the hepatic Kupffer cells, $PTH^{1\text{-}84}$ is cleaved usually either between amino acids 33 and 34 or between amino acids 36 and 37 to carboxyl terminal PTH peptides with half-lives of approximately 15 to 20 minutes. In the kidney, intact and carboxyl terminal fragments of PTH are filtered by the glomerulus, reabsorbed across the apical membrane of proximal renal tubular cells, and then degraded to smaller fragments. Megalin, a multifunctional low-density lipoprotein-related receptor (encoded by *LRP2*) expressed in coated pits on the luminal/apical surface (as well as endocytic vacuoles and lysosomes) of proximal renal tubular cells specifically recognizes intact $PTH^{1\text{-}84}$ and amino terminal fragments of PTH and mediates the renal tubular endocytosis of intact $PTH^{1\text{-}84}$ that has been filtered through the glomerulus.

The classical functions of $PTH^{1\text{-}84}$ as well as its shorter amino peptide derivatives $PTH^{1\text{-}34}$ and $PTH^{1\text{-}31}$ upon regulation of calcium and phosphate homeostasis are carried out through the seven-transmembrane, G-protein coupled type 1 PTH/PTHrP receptor (discussed later) expressed in the renal tubule and osteoblast. Thus, with equal potency $PTH^{1\text{-}84}$, $PTH^{1\text{-}34}$, and $PTH^{1\text{-}31}$ (1) inhibit renal tubular reabsorption of phosphate thereby increasing its urinary excretion; (2) increase renal tubular reabsorption of Ca^{2+}; (3) augment renal synthesis of calcitriol by enhancing expression of *CYP27B1* (encoding 25-hydroxyvitamin D_3-1α-hydroxylase) thereby amplifying intestinal absorption of calcium; (4) stimulate osteoblast production of receptor activator of nuclear factor κB-ligand (RANKL), thus enhancing osteoclastogenesis and osteoclastic reabsorption of calcium; and (5) mediate the anabolic effects of PTH on the volume and microarchitecture of bone.[76] $PTH^{1\text{-}84}$, $PTH^{1\text{-}34}$, and $PTH^{1\text{-}31}$ stimulate intracellular signal transduction through several G protein–coupled pathways including the $G_s\alpha$ subunit-adenylyl cyclase-cyclic adenosine monophosphate (AMP)-PKA and the G_{q11}-phospholipase C (PLC)-IP_3/diacylglycerol (DAG)-Ca^{2+}-PKC-MAPK signal transduction pathways. Furthermore, $PTH^{1\text{-}84}$ and $PTH^{1\text{-}34}$ can induce cell function through β-arrestin that does not involve a G protein (discussed later) that in turn activates intracellular signaling pathways mediated by MAPK, protein kinase B (PKB), and PI3K.[75,77]

As noted, multiple carboxyl-terminal peptides derived from $PTH^{1\text{-}84}$ circulate; they are either secreted directly by the parathyroid chief cells or return to the circulation after metabolism of intact $PTH^{1\text{-}84}$ by hepatic Kupffer cells.[75] Indeed, carboxyl terminal fragments of $PTH^{1\text{-}84}$ are secreted in greater abundance from the parathyroid glands than is intact $PTH^{1\text{-}84}$, and the proportion of carboxyl terminal fragments secreted increases as the ambient Ca^{2+} concentration rises. Amino terminal fragments generated by hepatic degradation of $PTH^{1\text{-}84}$ are degraded further within the liver and do not recirculate. $PTH^{1\text{-}84}$ and the carboxyl terminal fragments of PTH are filtered by the kidneys; the carboxyl terminal fragments are reabsorbed by the renal tubules and further degraded intracellularly. The kidneys are not a major source of circulating carboxyl terminal fragments of PTH. Among the carboxyl terminal fragments of PTH found in circulation are $PTH^{7\text{-}84}$,$PTH^{24\text{-}84}$,$PTH^{34\text{-}84}$,$PTH^{37\text{-}84}$,$PTH^{41\text{-}84}$,$PTH^{43\text{-}84}$. They are also extracted from serum by the kidneys, muscle, and bone.

In addition to their classical effects on mineral homeostasis, several nonclassical actions of $PTH^{1\text{-}84}$ have been identified, including (1) rapid and direct stimulation of intestinal calcium absorption independent of its effects on vitamin D metabolism, (2) stimulation of hepatic gluconeogenesis, (3) acute natriuresis and calciuresis, and (4) enhancement of neutrophil movement in vitro.[75] Inasmuch as many of these nonclassical biologic effects of intact PTH are not replicated by the amino terminal fragment $PTH^{1\text{-}34}$, it has been suggested that they may be related to the carboxyl terminal portion of the protein. Indeed, the carboxyl terminal fragments of PTH may

have biologic functions that oppose those of the amino terminal portion of PTH—namely, hypocalcemic properties that are perhaps mediated by pro-apoptotic effects on both osteoclasts and osteocytes.[78] Thus, $PTH^{7\text{-}84}$ lowers serum calcium levels in parathyroidectomized rats maintained eucalcemic by diet and antagonizes $PTH^{1\text{-}84}$-stimulated increase in calcium concentrations, urinary phosphate excretion, and bone turnover.[55] $PTH^{7\text{-}84}$ directly lowers the rate of bone resorption and suppresses the bone resorbing effects of $PTH^{1\text{-}34}$, calcitriol, prostaglandin E_2, and interleukin (IL)-11. However, $PTH^{39\text{-}84}$ and $PTH^{53\text{-}84}$ augment the biologic effects of $PTH^{1\text{-}34}$. $PTH^{7\text{-}84}$ does not bind to the PTH/PTHrP receptor nor does it inhibit $PTH^{1\text{-}84}$–mediated increase in cyclic AMP generation implying that $PTH^{7\text{-}84}$ likely acts through a receptor other than PTH1R (discussed later).

Because there are multiple circulating forms of PTH, its immunologic measurement is dependent on the specificity of the antibody(ies) employed in the assay. When a first-generation polyclonal PTH radioimmunoassay is utilized, both intact and carboxyl terminal fragments of PTH are usually measured. Use of second-generation immunoradiometric and immunochemiluminometric assays employing dual monoclonal antibodies, the first directed toward an epitope within the amino terminal of PTH (amino acids 20 to 25) and the second specific for an epitope in the carboxyl terminal of PTH (e.g., amino acids 59 to 78), improves the specificity of immunologic assays for intact $PTH^{1\text{-}84}$. Nevertheless, most of these assays detect both intact and selected carboxyl-terminal fragments of PTH and consequently measured PTH values may be inappropriately high, particularly in patients with chronic renal insufficiency in whom circulating levels of carboxyl terminal fragments of PTH are high.[79,80,81] Furthermore, the comparability of PTH assays from different commercial sources is often limited.[82,83] Employing a two site immunochemiluminescent assay, serum PTH concentrations average approximately 11 to 13 pg/mL and range between 2.3 and 24.5 pg/mL in children and adolescents 2 to 16 years of age; values do not vary with age but are a bit higher in girls than boys.[84] Development of "third-generation" of PTH assays that employ antibodies that are directed to an epitope of the first four amino acids of PTH has improved the specificity and stability of assays for $PTH^{1\text{-}84}$, but their clinical advantage is uncertain.[85,86] A "fourth generation" of PTH assays is under development that employs immunoaffinity, in situ digestion, liquid chromatography, and tandem mass spectrometry to separate $PTH^{1\text{-}84}$ from smaller PTH fragments.[81]

The synthesis and secretion of $PTH^{1\text{-}84}$ and its various fragments are modulated for the most part by the serum $Ca^{2+}{}_e$ concentration acting through the CaSR expressed on the plasma membrane of the parathyroid chief cell. Because a change in serum $Ca^{2+}{}_e$ concentration sensed by the parathyroid chief cell CaSR is quickly reflected in changes in cytosolic $Ca^{2+}{}_i$ levels, the release of PTH can be regulated on a minute-to-minute basis. Rapidly declining as well as steady-state low serum concentrations of $Ca^{2+}{}_e$ increase PTH secretion by accelerating its release from storage sites in secretory vesicles; hypocalcemia also raises intracellular levels of PTH mRNA by increasing the transcription rate of *PTH* and enhancing the stability of PTH mRNA by its posttranscriptional binding to cytosolic proteins.[3,70] Hypercalcemia decreases *PTH* transcription and destabilizes and thence lowers cellular levels of PTH mRNA. The serum $Ca^{2+}{}_e$ concentration also determines the form of PTH released by the parathyroid gland; during hypocalcemia, $PTH^{1\text{-}84}$ is the predominant form secreted; in hypercalcemic states, carboxyl terminal fragments of PTH are released in abundance.

Low serum phosphate concentrations exert an independent and direct inhibitory effect on the transcription of *PTH*, posttranscriptional PTH mRNA stability, PTH secretion, and proliferation of parathyroid chief cells; hyperphosphatemia increases PTH secretion by lowering plasma concentrations of Ca^{2+} and by enhancing the stability of PTH mRNA.[70] Prolonged hyperphosphatemia contributes to hyperplasia of the parathyroid glands frequently encountered in patients with chronic renal disease. Calcitriol directly inhibits *PTH* transcription acting through the VDR and the vitamin D response element (VDRE) in the 5′-untranslated region of *PTH* that associates with a transcriptional repressor factor (discussed later). Calcitriol also controls expression of *CASR* and of *VDR* and decreases proliferation of parathyroid cells. However, chronic hypocalcemia overcomes the suppressive effects of calcitriol on *PTH* transcription by decreasing the VDR number in the parathyroid chief cell. FGF23 released by osteocytes and osteoblasts directly impedes synthesis and secretion of PTH. Both hypomagnesemia and hypermagnesemia inhibit release but not synthesis of PTH. Other agents that increase PTH release include β-adrenergic agonists, dopamine, prostaglandin E, potassium (by decreasing cytosolic $Ca^{2+}{}_i$ levels within the parathyroid chief cell), prolactin, lithium (by resetting the set-point for PTH release), glucocorticoids, estrogens, and progestins. Prostaglandin $F_{2\alpha}$, α-adrenergic agonists, and fluoride suppress PTH release by increasing $Ca^{2+}{}_i$ values.

PTH regulates the serum concentration of $Ca^{2+}{}_e$ directly by stimulating its reabsorption in the distal renal tubule and from the skeleton and indirectly by augmenting the intestinal absorption of calcium by increasing the synthesis of calcitriol. In bone, PTH enhances osteoclast differentiation and maturation indirectly by acting on and through stromal cells and osteoblasts to increase synthesis of RANKL, an activator of osteoclastogenesis, and to suppress that of osteoprotegerin, a decoy receptor for RANKL (discussed later). When administered intermittently, $PTH^{1\text{-}84}$ and $PTH^{1\text{-}34}$ exert anabolic effects on skeletal mass by increasing osteoblast number by accelerating their differentiation from progenitor cells and from inactive bone-lining cells. They do so in part by decreasing the stimulatory effects of the peroxisome proliferator activator receptor gamma (PPARγ) on mesenchymal stem cell differentiation into adipocytes permitting their differentiation into osteoblasts, by augmenting the rate of osteoblast proliferation, and by reducing the rate of apoptosis of osteoblasts.[76,87] The anabolic effects of PTH on bone formation are further mediated by enhancing synthesis and release of matrix-embedded growth factors such as locally generated insulin-like growth factor-I

(IGF-I), which has positive effects on differentiation and survival of osteoblasts, by stimulating the WNT-Frizzled-β-catenin pathway of osteoblastogenesis, and by inhibiting antagonists to bone formation such as sclerostin. Additionally, through promotion of β-arrestin–mediated intracellular signal transduction, PTH increases trabecular number and volume.[76,77] Thus, PTH stimulates anabolism of bone mineralization, whereas bisphosphonates exert an antiresorptive effect.[88] PTH stimulates calcitriol synthesis by increasing renal tubular expression of *CYP27B1*, the gene encoding 25-hydroxyvitamin D_3-1α-hydroxylase, the enzyme that catalyzes the synthesis of calcitriol from calcidiol (discussed later). PTH depresses the proximal and distal renal tubular reabsorption of phosphate by decreasing the expression of *SLC34A1*, encoding a Na^+-HPO_4 cotransporter, thus increasing the urinary excretion of this anion (discussed previously). In addition, PTH directly stimulates secretion of bone-derived FGF23, thereby further increasing urinary phosphate excretion; PTH also indirectly stimulates FGF23 release by lowering serum phosphate concentrations and increasing those of calcitriol.[89]

Parathyroid Hormone–Related Protein

Parathyroid hormone–related protein (PTHrP) was initially identified as a major cause of humoral hypercalcemia of malignancy. PTH and PTHrP have evolved from a common ancestral gene through gene duplication. They share 8 of their first 13 amino acids (the site of the activating domain for the common PTH/PTHrP receptor); although their amino acid sequences diverge thereafter, the predicted three-dimensional structures of the next 21 amino acids are similar.[90,91] Both peptides bind to the PTH/PTHrP receptor (PTH1R), although their receptor binding domains are distinct; PTH binds more avidly to PTH1R and elicits a greater hypercalcemic response than does PTHrP.[91] PTHrP is synthesized by many fetal and adult tissues (cartilage, bone, smooth, cardiac and skeletal muscle, skin, breast, intestines, parathyroid glands, pancreatic islets, pituitary, placenta, and central nervous system) and plays a crucial role in chondrocyte differentiation and maturation, formation of the mammary gland and eruption of teeth, epidermal and hair follicle growth, and other developmental events.[90,91] Whereas PTH acts as an endocrine hormone on tissues distant from its source—the parathyroid glands, except in patients with humoral hypercalcemia of malignancy when PTHrP or segments thereof are secreted into the circulation and during lactation—PTHrP is synthesized locally and acts primarily as a paracrine, autocrine, or intracrine messenger. Although the secretion of PTH is regulated by Ca^{2+}_e levels and fluctuates rapidly, the production of PTHrP is constitutive and is controlled at the point of expression of its encoding gene (*PTHLH*). *PTHLH* is transcribed and translated into 139-, 141-, and 173-amino-acid isoforms.[3,87] In addition, amino ($PTHrP^{1\text{-}36}$) and midregion and carboxyl terminal ($PTHrP^{38\text{-}94}$,$^{38\text{-}95}$,$^{38\text{-}101}$,$^{107\text{-}138}$,$^{109\text{-}138}$) products of *PTHLH* are formed by the actions of prohormone convertases during posttranslational processing in specific tissues.[90,91] The smaller peptides ($PTHrP^{1\text{-}36}$,$^{38\text{-}95}$,$^{38\text{-}101}$,$^{108\text{-}138}$,$^{109\text{-}138}$) may act as paracrine factors or be secreted into the circulation. PTHrP secreted by fetal parathyroid glands and the $PTHrP^{37\text{-}94}$ midregion fragment synthesized by the placenta increase placental calcium transport. Intact PTHrP binds only to PTH1R, through which receptor it exerts its biologic effects on mineral homeostasis. Carboxyl terminal fragments of PTHrP may act through as yet unidentified receptors. Because transcription of *PTHLH* can begin in an exon downstream of the exon that encodes the signal peptide of this protein, after synthesis PTHrP can remain in the cytoplasm and be directly imported into the nucleus.[91] (A nuclear localization sequence is present between amino acids 84 and 93 in the PTHrP molecule.) PTHrP is shuttled into the nucleus bound to importin β1 where it binds to and perhaps regulates RNA trafficking, protein translation, and ribosomal dynamics, thereby influencing cell proliferation and survival.[90,91] Acting through the vitamin D nuclear receptor, calcitriol impairs the synthesis of PTHrP by down-regulating transcription of *PTHLH* and decreasing stability of PTHrP mRNA, thereby increasing the rate of intracellular degradation of the PTHrP protein.

Although the effects of $PTHrP^{1\text{-}36}$,$^{1\text{-}141}$ on calcium, phosphate, and vitamin D metabolism are similar to those of PTH, the major roles of this and other segments of PTHrP in many developmental processes, including those of breast, teeth, cartilage, and endochondral bone, distinguish PTHrP from PTH (Table 8-4). In the fetus, periarticular chondrocytes located at the ends of long bones synthesize PTHrP in response to Indian hedgehog (IHH), a protein secreted by late proliferative–early prehypertrophic chondrocytes that functions through its receptor, Patched 1 (please refer to Figure 8-9, presented later in the chapter). PTHrP enters into and diffuses through the growth plate and signals prehypertrophic chondrocytes through PTH1R to slow their rate of differentiation to hypertrophic chondrocytes—thus prolonging the stage of proliferation and delaying ossification, thereby increasing the length of the cartilaginous growth plate and the long bone.[90,91] In addition to stimulating the secretion of PTHrP, IHH increases the rate of growth plate chondrocyte proliferation, which also directs differentiation of perichondrial cells to osteoblasts. In the postnatal mouse, PTHrP is produced by the proximal resting/undifferentiated and early proliferating chondrocytes in response to IHH.[92] Biallelic loss of PTHrP in knockout mice is lethal due to bony malformations. In $Pthlh^{-/-}$ mice, there is decrease in the number of resting and proliferating chondrocytes; the columnar organization of the growth plate is disrupted, there is premature acceleration of chondrocyte maturation and apoptosis, and inappropriate ossification resulting in a dwarfing phenotype (a domed and foreshortened cranium, short limbs, small thorax) that is similar to that of Blomstrand chondrodysplasia (OMIM ID: 215045), a disorder associated with loss-of-function mutations of *PTH1R*.[93] Mice in which expression of *Pthlh* has been maintained only in chondrocytes survive but display small stature, cranial chondrodystrophy, and failure of tooth eruption. In the heterozygous state ($Pthlh^{+/-}$), mouse fetal development is normal but by 3 months of

TABLE 8-4 **Parathyroid Hormone–Related Protein: Sites of Expression and Action**

Site	Action
Mesenchyma	
Subarticular cells/ prechondrocytes	PTHrP depresses the rate of differentiation of late proliferating chondrocytes to hypertrophic chondrocytes and delays ossification, thus permitting increased longitudinal growth of the cartilaginous growth plate
Bone	Enhances or depresses bone resorption
Smooth muscle	Relaxation
Vascular system	
Myometrium	
Urinary bladder	
Cardiac muscle	Positive chronotropic and inotropic effects
Skeletal muscle	
Epithelia	
Skin	Regulates proliferation of keratinocytes
Breast	Induces ductal branching and formation of breast epithelium, secreted into milk, drives mobilization of calcium from maternal bone for transfer to nursing infant
Teeth	Stimulates resorption of overlying bone enabling eruption
Endocrine system	
Parathyroid glands	Stimulates transport of calcium
Pancreatic islets	Stored and cosecreted with insulin
Placenta	Enhances calcium transport from mother to fetus
Central nervous system	Neuroprotective by antagonizing excessive calcium-related excitotoxicity

Compiled and adapted from Wysolmerski, J. J. (2008). Parathyroid hormone-related protein. In C. J. Rosen (Ed.), Primer on the metabolic bone diseases and disorders of mineral metabolism *(pp. 127–133) (7th ed.). Washington DC: The American Society of Bone and Mineral Metabolism.; Wysolmerski, J. J. (2012). Parathyroid hormone-related protein: an update.* J Clin Endocrinol Metab, 97, *2947–2956.*

age the trabeculae of the long bones are osteopenic; a similar bone phenotype is noted when loss of *Pthlh* expression is confined to osteoblasts.[94] For comparison, in mice in which *Pth* has been knocked out, there is decreased mineralization of cartilage matrix, expression of vascular endothelial growth factor (VEGF) and neovascularization, osteoblast number, and trabecular bone volume.[95] Thus, both PTH and PTHrP are necessary for normal fetal endochondral bone development. Cortical thickness of long bones is increased in both *Pth*- and *Pthlh*-null mouse models, indicating that the regulation of endochondral and periosteal osteoblast function differs. The production of PTHrP by mice osteoblasts in vitro can be increased by mechanical deformation, suggesting that PTHrP may play a role in the response to skeletal loading.[90]

The placental transport of calcium is dependent on PTHrP produced by the placenta itself, as the maternal-fetal calcium gradient is lost in its absence and may be restored by administration of a midmolecular fragment.[90,91,94] Both PTH and PTHrP are required for normal mineral homeostasis in utero. In mice that lack parathyroid glands, fetal serum calcium and magnesium concentrations are low and phosphate levels are elevated; to a lesser extent similar changes occur with loss of expression of *Pthlh*.[96] PTH does not regulate placental calcium transfer, whereas PTHrP is critically important for this process.[91] PTHrP is essential for normal nipple and mammary gland development in utero; this protein promotes differentiation of mesenchymal tissue surrounding the budding epithelial mammary ducts; PTHrP is also important for terminal differentiation of the mammary system during puberty.[90,91] During lactation, mammary expression of *PTHLH* and secretion of PTHrP increases whereas production of estrogens declines, permitting unopposed PTHrP-induced mobilization of maternal skeletal calcium necessary for the breastfed infant but substantially decreasing maternal bone mineral content, a process that is reversed when lactation ceases.[97] PTHrP also is expressed and presumably functional in smooth muscle (stomach, urinary bladder, vasculature), cardiac muscle, pancreatic islet cells, and central and peripheral nervous systems; it is essential for the eruption of developing teeth.[90] Serum concentrations of PTHrP are low except when it is secreted by tumors leading to humoral hypercalcemia of cancer. There are high levels of PTHrP in breast milk and low concentrations of PTHrP may be measurable in the serum of lactating women.

Parathyroid Hormone and Parathyroid Hormone–Related Protein Receptors

PTH and PTHrP bind with equal affinity to a common receptor (PTH1R) through which most of the classical mineral homeostatic physiologic functions of these peptides are exerted. PTH1R is a 585-amino-acid protein that is a member of the class B family of GPCRs (whose ligands are calcitonin, growth hormone releasing hormone, secretin, glucagon, glucagon-like peptide 1, gastric inhibiting polypeptide, vasoactive intestinal polypeptide, corticotropin-releasing hormone, and pituitary

adenylate cyclase activating protein 1) that are characterized by long extracellular amino terminal domains (~160-amino-acid) residues) with multiple cysteine residues forming disulfide bridges. PTH1R has an extracellular domain, 7 transmembrane spanning segments connected by three extracellular and three intracellular loops, and an intracellular domain with which the signaling G-protein interacts. *PTH1R* is composed of 15 exons; there are three promoters that regulate expression of *PTH1R*. As a result of alternative mRNA splicing, there are several isoforms of the PTH/PTHrP receptor. The amino terminal sequences of PTH and PTHrP are essential for activation of PTH1R and for binding to the extracellular domain of PTH1R.[3,75,98] The amino terminal extracellular domain of PTH1R contains six conserved cysteine residues that form three disulfide bonds; clustered near the first transmembrane domain are four glycosylated asparagine residues. Prior to association with its ligands, PTH1R is present as a homodimer—the carboxyl portion of the amino terminal extracellular domain (amino acids 29-187, the core domain linking the extracellular domain to the first transmembrane helix) of one PTH1R molecule forms an α helix that mimics the receptor binding structure(s) involving amino acids 20-26 of PTH/PTHrP that is recognized by and binds to the ligand binding groove of the extracellular domain of its companion PTH1R, thus forming a homodimer of two PTH1Rs.[98] Of critical importance to PTH1R dimerization are amino acid residues Arg179 and Val183, as their experimental loss renders PTH1R incapable of dimerization but still able to bind PTH and signal through $G_{s\alpha}$. Interaction with ligand disrupts the homodimeric structure of PTH1R that then acts as a monomer to activate intracellular signal transduction.

The most important core region for binding of PTH to the ectodomain of PTH1R lies between PTH:Arg20-Lys26 and requires both Arg20 and Trp23.[73] Trp23 interacts with Ile38, Leu41, and Ile135 within the extracellular domain of PTH1R. The first 10 amino acids of PTH within which is the PTH1R activating region do not interact with the ectodomain of PTH1R but rather with its extracellular loops (also termed the "J" or juxtamembrane domains). Interaction of PTH with PTH1R activates both G_{as} and G_{aq11} proteins and their respective signal transduction pathways.[3] After inducing intracellular signaling, PTH1R is phosphorylated by GPCR kinases (GRKs), thereby facilitating binding of β-arrestin (encoded by *ARBB2*, OMIM ID: 197841) leading to inactivation of PTH1R, its internalization, and subsequent destruction or reutilization.[77] The latter processes require ubiquitination of PTH1R and β-arrestin and proteasomal processing. By an alternate pathway, carboxyl terminal PTH peptides may also promote endocytosis of PTH1R.[75] Once internalized, PTH1R may be degraded, recycled to the cell membrane, or directed to the nucleus by importins-α_1 and -β where it is found in the nucleoplasm.[99] The role of nuclear PTH1R in relaying the biologic effects of PTH and PTHrP is unknown.

Interaction of PTH with PTH1R activates $G_{s\alpha}$, resulting in adenylate cyclase–mediated cyclic AMP production leading to intracellular signal transduction through PKA. Binding of PTH to PTH1R also activates $G_{q/11}$ signal transduction through PLC, leading to the formation of IP_3 and DAG from cell membrane-bound phosphoinositide, mobilization of Ca^{2+} from the endoplasmic reticulum, and activation of PKC.[77] (In the kidney, PTH1R is expressed on the apical and basolateral surfaces of cell in the proximal renal tubule; binding of PTH to apical PTH1R preferentially signals through cyclic AMP-PKA, whereas interaction of PTH with basolateral PTH1R activates the PLC-PKC signal transduction pathway.) Through both PKA and PKC, PTH/PTH1R activates the MAPK signal transduction system of extracellular signal-regulated kinases (ERK)-1,2 allowing regulation of cell differentiation, division, growth, and apoptosis. In addition to participating in the internalization of the PTH-PTH1R complex, β-arrestin enables it to stimulate intracellular signaling in a manner that is *independent* of G-proteins; the GRK-mediated patterns of proline phosphorylation of PTH1R and β-arrestin likely determine their conformations and functional activities.[100] Thus, interaction of PTH-PTH1R with β-arrestin may also activate the MAPK signaling system and facilitate PI3K and PKB (AKT) intracellular signal transduction pathways.[77] PTH-PTH1R activation of the MAPK pathway through the G-protein pathway is rapid and brief, lasting only a few minutes, whereas activation through the β-arrestin pathway is slow and sustained over hours. Another mechanism through which PTH/PTH1R interaction affects cellular function is by the binding of PTH1R to the Na^+-H^+ exchanger regulatory factor 2 (NHERF2, encoded by *SLC9A3R2*) with consequent stimulation of PLC activity and inhibition of adenylyl cyclase activity.[101] In the kidney, PTH1R binds to NHERF1 (encoded by *SLC9A3R1*), an essential factor for trafficking of the phosphate channel NPT2a to the luminal membrane of cells in the proximal renal tubule.[50] In the proximal renal tubule, linking of PTH to PTH1R increases cyclic AMP production leading to a decrease in the internalization and expression of the sodium-phosphate cotransporters and an increase in urinary phosphate excretion; association of PTH1R with NHERF1 blunts the phosphaturic effect of PTH.[50] Therefore, disruption of PTH1R-NHERF1 interaction leads to renal wasting of phosphate. Agonists of PTH have been synthesized that can bias the selection of the signal transduction pathway utilized; a biased agonist might stabilize a receptor conformation that stimulates a specific signal transduction sequence or activate one pathway while simultaneously inhibiting another.[77,100] Thus, $PTH^{1\text{-}34}$ stimulates $G_{s\alpha}$, G_{aq11}, and β-arrestin intracellular signaling systems, whereas $PTH^{1\text{-}31}$ preferentially enhances signaling through $G_{s\alpha}$ and $PTH^{3\text{-}34}$ through $G_{q/11}$. D-Trp^{12}, Tyr^{34} -$PTH^{7\text{-}34}$ is a PTH1R agonist that acts through the β-arrestin pathway.

PTH1R is expressed in renal tubular cells and osteoblasts, skin, breast, heart, and pancreas, among other tissues—the latter sites reflecting the paracrine targets of PTHrP. PTH, PTHrP, and calcitriol decrease expression of *PTH1R*. Targeted loss of *PTH1R* is accompanied by impaired proliferation of chondrocytes and acceleration of chondrocyte maturation and calcification, an outcome mimicked by targeted loss of $G_{s\alpha}$ in chondrocytes.[75,94]

Clinically, inactivating mutations in *PTH1R* result in hypocalcemia and Blomstrand chondrodysplasia (OMIM ID: 215045), whereas constitutively activating mutations of *PTH1R* lead to hypercalcemia and Jansen metaphyseal chondrodysplasia (OMIM ID: 156400). The abnormalities of chondrocyte maturation seen experimentally with inactivating mutations of *Pth1r* are mimicked to an extent by loss-of-function mutations of *Pthlh* as well. The loss of PTH results in an aberrant formation of primary spongiosa of long bone and defective mineralization.[95]

A second PTH receptor (PTHR2) is selectively activated by PTH but does not recognize PTHrP; PTH specificity is determined by Ile[5] and Trp[23] in native PTH, sites that affect activation and binding, respectively.[75] *PTHR2* encodes a 539-amino-acid GPCR with 50% homology to PTH1R that activates adenylyl cyclase; it is expressed predominantly in brain, testis, placenta, and pancreas, but not in bone or kidney; its physiologic role is uncertain. In response to $PTH^{1\text{-}84}$, PTHR2 enhances both cyclic AMP generation and Ca^{2+} mobilization. However, the naturally occurring endogenous ligand for PTHR2 is not PTH but the 39-amino-acid PTH-related hypothalamic tuberoinfundibular peptide (TIP39); this protein is also expressed in the testis and various central nervous system regions.[91] A third PTH receptor that recognizes amino terminal sequences of PTH has been identified in zebra fish and termed type-3 PTH receptor (zPTHR3); rat PTH binds to this receptor and activates adenylyl cyclase[75]. Specific receptors recognizing the amino terminal sequences of PTHrP have been found in brain and skin; PTHrP stimulates the release of arginine vasopressin from the supraoptic nucleus in vitro.[75]

Although as yet not molecularly characterized, receptors for carboxyl terminal fragments of $PTH^{1\text{-}84}$ have been identified as renal and bone cell binding sites for $PTH^{1\text{-}84}$ from which intact hormone can be only partially displaced by $PTH^{1\text{-}34}$ but can be further displaced by $PTH^{53\text{-}84}$ and $PTH^{69\text{-}84}$.[75] In addition, in osteocytes, osteoblasts, and chondrocytes from which the PTH/PTHrP receptor has been "knocked out" and to which intact $PTH^{1\text{-}84}$ but not $PTH^{1\text{-}34}$ binds, labeled $PTH^{1\text{-}84}$ can be displaced by carboxyl terminal $PTH^{19\text{-}84}$,$^{28\text{-}84}$,$^{39\text{-}84}$ fragments. Important determinants for binding of PTH to the carboxyl terminal selective receptor(s) appear to be amino acids 24-27 (Leu-Arg-Lys-Lys) and 53-54 (Lys-Lys). Furthermore, carboxyl terminal fragments of PTH exert biologic effects in intact and *PTH1R*-null cells such as regulation of alkaline phosphatase activity in osteosarcoma cells and osteoblasts (but not generation of collagen type I), stimulation of Ca^{2+} uptake by osteosarcoma cells and chondrocytes, and cell survival in vitro. Thus, the physiologic actions of PTH likely reflect the integrated sum of the individual functions of the intact hormone and its carboxyl terminal fragments. The membrane sites that bind carboxyl terminal fragments of PTH do not recognize carboxyl terminal fragments of PTHrP.

CALCITONIN

Calcitonin is a 32-amino-acid peptide that in mammals is secreted by the neural crest-derived parafollicular (C) cells of the thyroid gland in response to rising concentrations of $Ca^{2+}{}_e$.[3] Calcitonin lowers concentrations of $Ca^{2+}{}_e$ by inhibiting osteoclastic bone resorption. After binding of calcitonin to its GPCR expressed on the osteoclast cell membrane, the morphology of the ruffled membrane of the functioning osteoclast flattens causing it to withdraw from the bone reabsorption site, thereby lowering $Ca^{2+}{}_e$ concentrations.[102] Calcitonin also decreases renal tubular reabsorption of filtered calcium. Calcitonin is encoded by a six-exon gene (*CALCA*) that by alternative transcription and translation forms a 141-amino-acid protein from which calcitonin (exon 4) and katacalcin, a 21-amino-acid hypocalcemic peptide adjacent to the carboxyl terminus of calcitonin, are derived, and a 128-amino-acid protein from which is gleaned the 37-amino-acid calcitonin gene–related peptide-α (exon 5), a vasodilator and neurotransmitter that also interacts with the calcitonin receptor. Calcitonin is also expressed by cells in the adenohypophysis and brain and by neuroendocrine cells in the lung and elsewhere. Calcitonin is produced in excess by medullary carcinoma of the thyroid and, at times, by other neuroendocrine tumors. The calcitonins of multiple species share similar structures including five of the first seven amino terminal amino acids, a disulfide bridge between amino acids 1 and 7, glycine at amino acid residue 28, and a proline amide residue at carboxyl terminal amino acid 32. In the interior of the peptide, species other than human have several basic amino acids that make them more stable and easily recognized by the human calcitonin receptor and thus more biologically potent (e.g., therapeutically useful salmon calcitonin).

Calcitonin secretion is stimulated primarily by increasing concentrations of $Ca^{2+}{}_e$ transduced by the CaSR expressed on the plasma membrane of the C cell.[3] Members of the gastrin-cholecystokinin intestinal peptide hormone family (gastrin, glucagon, pancreozymin), glucocorticoids, and β-adrenergic agonists are also potent calcitonin secretagogues[3,102]. Calcium, pentagastrin, and glucagon are effective stimuli employed to assess calcitonin secretion clinically. Somatostatin, calcitriol, and chromogranin $A^{1\text{-}40}$ inhibit and chromogranin $A^{403\text{-}428}$ stimulates calcitonin secretion. Calcitonin secretion falls as the $Ca^{2+}{}_e$ concentration declines. The half-life of calcitonin is brief; it is metabolized primarily by the kidney and also by liver, bone, and thyroid gland. Serum levels of calcitonin are high in the fetus (when serum total calcium concentrations are normally 12 to 13 mg/dL) and newborn, fall rapidly after birth as $Ca^{2+}{}_e$ values decline and then fall more slowly until 3 years of age, remaining relatively constant thereafter (< 12 pg/mL). After 10 years of age, serum concentrations of calcitonin are higher in males than in females. The physiologic role of calcitonin is unclear as serum calcium concentrations are normal in patients with both decreased (primary congenital or acquired hypothyroidism) and increased (medullary carcinoma of the thyroid) secretion of this peptide. However, disposal of a calcium load is slower in the calcitonin-deficient subject. Immunoassayable concentrations of calcitonin are increased in patients with medullary carcinoma of the thyroid, chronic renal insufficiency, and pycnodysostosis.[102] Individual commercial immunoassays for

calcitonin may detect differing epitopes, have altered intra-assay dynamics, and provide inconsistent measurements.[103]

The biologic effects of calcitonin are mediated through its 490-amino-acid class B GPCR encoded by *CALCR*. Intracellular signaling of the CALCR is transduced through the $G_{s\alpha}$ adenylyl cyclase-cyclic AMP-PKA and $G_{q\alpha}$-PLC-IP_3 signal transduction pathways. Alternative splicing of *CALCR* results in two isoforms of the calcitonin receptor, one of which has an additional 16 amino acids inserted into its first intracellular loop between transdomains I and II. Accessory proteins that modulate function of the calcitonin receptor have also been described. The calcitonin receptor is expressed in osteoclasts; when exposed to calcitonin the osteoclast shrinks and bone-resorbing activity declines quickly. Thus, calcitonin lowers serum calcium and phosphate levels particularly in patients with hypercalcemia. In lactating women, serum levels of calcitonin rise and calcitonin is excreted in breast milk. Women who are breastfeeding their infants lose 5% to 10% of their trabecular bone mineral during 6 months of lactation; it is recouped rapidly when lactation ceases, much more quickly than when bone mass is lost because of other problems (e.g., glucocorticoid excess, bed rest). Experimentally, in the female mouse in which the gene encoding calcitonin has been eliminated, loss of calcitonin has no effect on maternal bone mineralization during pregnancy or on the rate of skeletal remineralization after weaning of the pups. However, 21 days of lactation are associated with much more marked demineralization of the spine of the nursing mother without calcitonin, a response that is reversible by the administration of exogenous calcitonin during the interval of lactation.[104] Thus, in mammals calcitonin may be essential for protection of maternal skeletal mass during lactation

VITAMIN D

Synthesis and Biologic Activity of Vitamin D

Cholecalciferol (vitamin D_3) is synthesized in skin from cholesterol: 7-dehydrocholesterol is converted to previtamin D_3 by ultraviolet B radiation at 290 to 315 nm and heat (37° C) from sunlight and thence to cholecalciferol (Figure 8-3).[105,106] Previtamin D_3 is also metabolized into products such as lumisterol$_3$ and tachysterol$_3$ and to inactive photoproducts when exposure to sunlight is excessive, thereby preventing vitamin D intoxication by exposure to sunlight alone. Cutaneously synthesized vitamin D_3 enters the circulation directly. Vitamin D_3 is present in oily fish such as wild salmon, herring, cod, and mackerel and in shiitake mushrooms. Ergocalciferol (vitamin D_2) is derived from the plant and yeast sterol—ergosterol. Vitamin D_2 differs structurally from vitamin D_3 by the presence of a double bond between carbons 22 and 23 and a methyl group on carbon 24. Vitamins D_3 and D_2 exert similar biologic effects when ingested in equivalent physiologic doses; however, the increase in the serum concentration of 25-hydroxyvitamin D (calcidiol) is less after ingestion of vitamin D_2 than vitamin D_3 when quantitatively similar amounts of both vitamins are consumed.[105,107] The latitude, season of the year, and time of day influence the rate of cutaneous synthesis of vitamin D_3 in response to exposure to sunlight; in higher latitudes the path through which ultraviolet B radiation from the sun travels is longer and more of the ultraviolet radiation is absorbed by the ozone layer; thus, less reaches the surface of the earth. Exposure of the back of a white adult to intense summer sun (mid-July) for 10 to 12 minutes in the northeastern United States generates ~10,000 to 20,000 IU of vitamin D_3 over the next 24-hour interval.[108] (For persons of color, 30 to 120 minutes of exposure to sunlight may be required for comparable effects.) Sun blocking topical creams and aging also decrease the cutaneous formation of cholecalciferol in response to sunlight. Both forms of vitamin D undergo similar chemical modifications to bioactive metabolites. Orally ingested vitamin D is packaged into chylomicrons and absorbed into the intestinal lymphatic system and then the circulation. Both vitamins D_3 and D_2 are transported to the liver linked to vitamin D–binding protein (DBP), a polymorphic variant of the serum α2-globulin synthesized by the liver termed Gc (group-specific component) encoded by *GC* (see Table 8-3). DBP binds vitamin D and its hydroxylated metabolites with high affinity and capacity.[109] In the liver, vitamin D is hydroxylated to 25-hydroxyvitamin D (25OHD; calcidiol is 25OHD_3) primarily by the vitamin D-25-hydroxylase encoded by *CYP2R1*, a 501-amino-acid microsomal cytochrome P450 enzyme.[106] A homozygous missense mutation in *CYP2R1* has been identified in a patient with vitamin D–dependent rickets due to a defect in vitamin D-25 hydroxylation.[110] Additionally, there are three other widely expressed vitamin D 25-hydroxylases encoded by *CYP2J2*, *CYP3A4*, and *CYP27A1* whose activities affect bile acid and drug metabolism.[106,111] Calcidiol exerts only a minimal inhibitory effect on its production; thus, serum concentrations of 25OHD reflect available body stores of vitamin D.

Because of decreased exposure to sunlight and marginal dietary intake of vitamin D, body stores of this vitamin have been considered to be deficient or insufficient in many North American subjects.[108] Thus, in populations living in sun-rich environments, the lower normal concentration of serum 25OHD has been reported to be 32 ng/mL with an upper limit of 100 ng/mL. However, there is substantial controversy concerning this stated normal range of 25OHD values (discussed later). Physiologic data pertaining to calcium homeostasis and skeletal health such as the relationship between serum concentrations of 25OHD and a plateau value for PTH values, intestinal absorption of calcium, and optimal bone mineralization have been utilized to advocate the position that a serum 25OHD level of approximately 30 ng/mL is the minimum normal value in adult men and that 25OHD concentrations between 10 and 30 are insufficient.[112,113] If a serum 25OHD value of 30 ng/mL were the actual lower normal limit, then approximately 50% of white, Hispanic, and African-American youth and 31% of white, 63% of Hispanic, and 82% of African-American adults would be vitamin D deficient.[113,114]

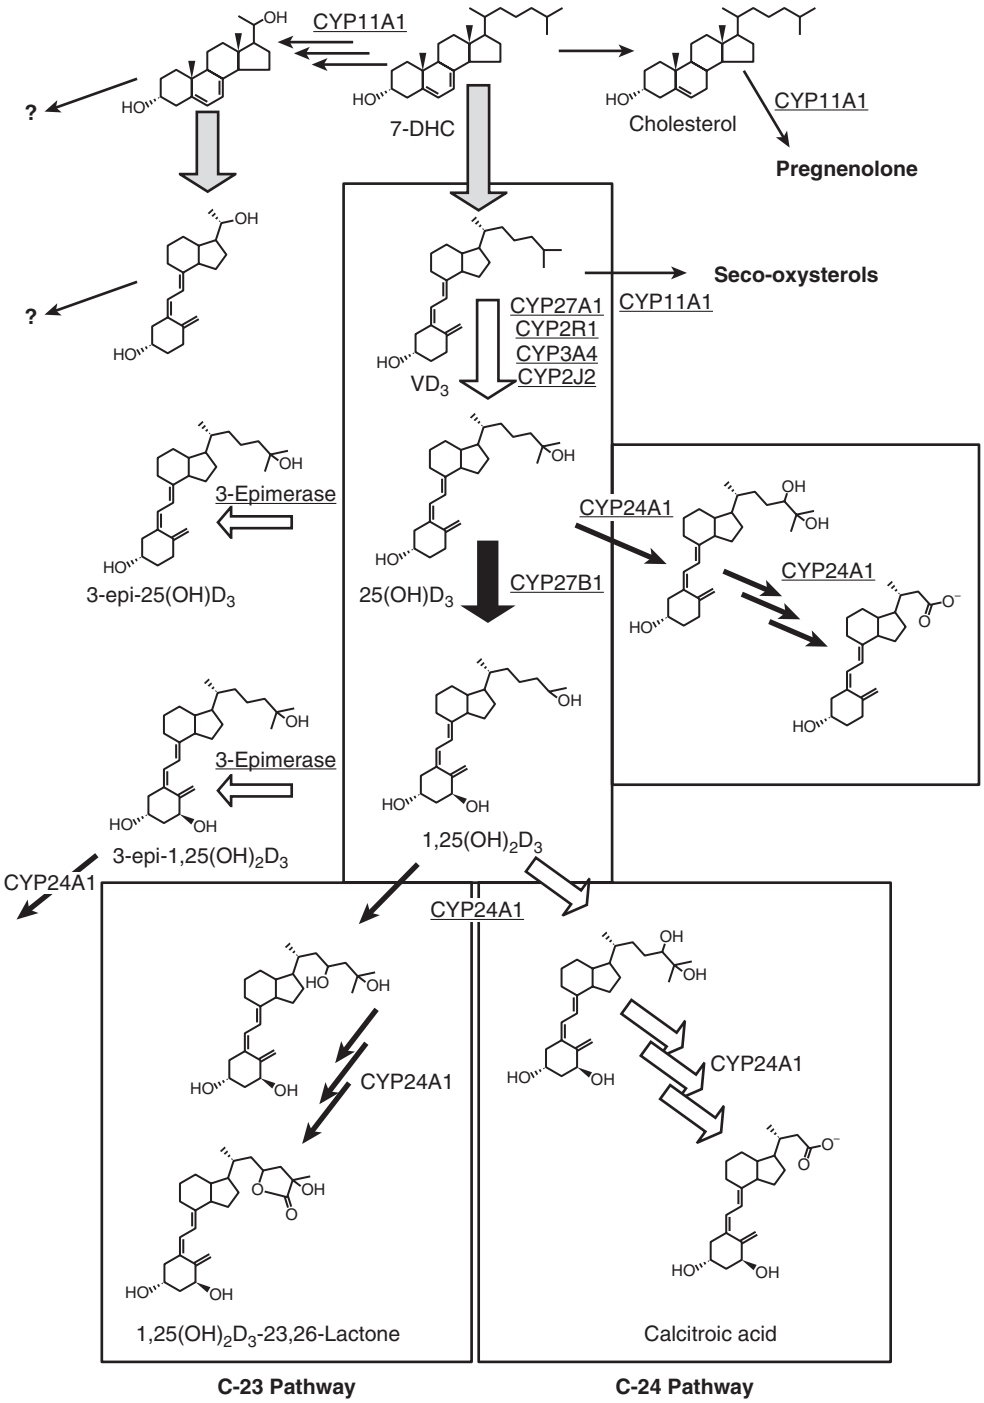

FIGURE 8-3 ■ Genetic regulation of the synthesis and metabolism of vitamin D. In skin, 7-dehydrocholesterol (7-DHC) is metabolized to cholecalciferol (vitamin D_3) that is then hydroxylated at carbon 25 in the liver to form calcidiol ($25OHD_3$) and at carbon 1 in the kidneys to form calcitriol [$1,25(OH)_2D_3$]. Calcitriol is inactivated by hydroxylation at carbon 24 in the kidney (see text). (Reproduced from Schuster, I. (2011). Cytochromes P450 are essential players in the vitamin D signaling system. *Biochim Biophys Acta, 1814,* 186–199, with permission.)

However, further data in adults, children, and adolescents indicate that the relationship between serum concentrations of 25OHD and PTH is linear and that there is no one clearly identifiable inflection point for suppression of PTH values relative to levels of 25OHD.[115,116] Additionally, there are substantial differences (often > 5 ng/mL) in 25OHD values measured by different commercially available calcidiol assays.[117] Critical analysis of these data has led the American Academy of Pediatrics and the Institute of Medicine to define the lower limit of normal of the serum 25OHD concentration as 20 ng/mL (50 mmol/L).[30,118] Utilizing the 25OHD level of 20 ng/mL as the lower limit of normal, investigators have concluded that the reported prevalence of vitamin D deficiency has been vastly overestimated. Some authors have concluded that vitamin D deficiency should be defined as a 25OHD

concentration below 12 ng/mL (< 30 mmol/L) and that 25OHD values above 16 ng/mL (40 mmol/L) are adequate to maintain calcium homeostasis and bone health.[119] Guidelines for calcium and vitamin D intakes in children and adolescents as recommended by the Institute of Medicine and the Endocrine Society are presented in Table 8-3. Clinically, oral intake of 400 U/day of vitamin D per day in healthy infants is sufficient to prevent vitamin D deficiency if administered conscientiously.[120] The recommended upper limit of vitamin D intake is 4000 IU/day for all age groups above 8 years. Serum values of 25OHD above 50 ng/mL (125 mmol/L) are presently considered excessive.[119]

Bound to DBP, 25OHD is filtered through the glomerular membrane and reabsorbed by cells in the proximal renal tubule by the multifunctional receptor, megalin (LRP2), expressed in coated pits on the luminal/apical surface, endocytic vacuoles, and lysosomes of proximal tubular cells.[121] After uptake by the lysosomes, the megalin-calcidiol complex is disrupted and calcidiol is released into the cytosol. It then enters mitochondria where it is further hydroxylated to the biologically active metabolite 1,25-dihydroxyvitamin D_3—$1,25(OH)_2D_3$ is calcitriol—by the cytochrome P450 mono-oxygenase 25-hydroxyvitamin D-1α-hydroxylase encoded by *CYP27B1*.[106] *CYP27B1* has nine exons that encode a 507-amino-acid protein with a mitochondrial signal sequence at its amino terminal and ferredoxin and heme-binding sites within its structure. As a class I mitochondrial cytochrome P450 enzyme, 25OHD-1α-hydroxylase requires for its catalytic activity electrons from reduced nicotinamide adenine dinucleotide phosphate (NADPH) that are ferried to the enzyme protein by the electron transport proteins—NADPH-ferredoxin and ferredoxin reductase.[111] Although *CYP27B1* is expressed primarily in renal proximal convoluted and straight tubular cells, it is also expressed by keratinocytes and hair follicles, osteoblasts, placental decidual and trophoblastic cells, the gastrointestinal and central nervous systems, lung, testes, breast, and pancreatic islets as well as monocytes and macrophages. In proximal convoluted renal tubular cells, expression of *CYP27B1* is stimulated by PTH and PTHrP acting through PTH1R-adenylyl cyclase-cyclic AMP-PKC. Phosphorylation of methyl-CpG-binding domain protein 4 (MBD4, OMIM ID: 603574) by PKC enables this demethylase to remove transcription-repressing methyl groups from the CpG island in the 5′ promoter region of *CYP27B1*, thus enabling gene expression.[122] The 1α-hydroxyl group of calcitriol is essential for its binding to the vitamin D receptor (VDR).[123]

In the straight renal tubules, *CYP27B1* expression is increased by calcitonin by a pathway independent of cyclic AMP—one that involves the C/EBPβ transcription factor and the SWI/SWF helicase chromatin remodeling complex.[111] Expression of *CYP27BI* and hence activity of 25OHD-1α-hydroxylase are also increased by hypocalcemia and hypophosphatemia, 24R,25-dihydroxyvitamin D, growth hormone, IGF-I, and prolactin. In monocytes and macrophages, expression of *CYP27B1* may be induced by inflammatory cytokines such as interferon-γ but is not regulated by concentrations of $Ca^{2+}{}_e$ or phosphate or by PTH or calcitriol.[106,124] Increased serum and tissue levels of Ca^{2+} and phosphate directly suppress expression of *CYP27B1* and thus depress 25OHD-1α-hydroxylase activity. Calcitriol exerts a direct autoinhibitory effect on renal *CYP27B1* expression acting through the VDR and thus on its own synthesis (discussed later); it also exerts an indirect inhibitory effect on *CYP27B1* expression by impairing PTH synthesis in the parathyroid gland.[105,125] (In activated monocytes, calcitriol actually enhances transcription of *CYP27B1*.[124]) The osteocyte product FGF23 depresses 25OHD-1α-hydroxylase activity, whereas calcitriol up-regulates *FGF23* expression, effectively establishing a reciprocal control system for these compounds.[54,55,126] Biallelic inactivating mutations of *CYP27B1* result in vitamin D–dependent rickets type I (OMIM ID: 264700), a disorder associated with hypocalcemia, hypophosphatemia, secondary hyperparathyroidism, severe rickets, and often also alopecia.[127]

Calcitriol is inactivated in bone, intestine, liver, and kidney by glucuronidation, sulfation, multisite (carbons-23, -24, -26) hydroxylation, and lactone formation to water-soluble compounds (such as calcitroic acid) that are excreted in urine and bile.[105,106,125] In the kidney, 25OHD and $1,25(OH)_2D$ are converted to $24R,25(OH)_2D$ and $1,24R,25(OH)_3D$, respectively, by mitochondrial 25OHD-24-hydroxylase encoded by *CYP24A1*, the first in a series of hydroxylations that increase the water solubility of the products enabling their biliary and renal excretion (see Figure 8-3). The expression of *CYP24A1* is increased by hypercalcemia, hyperphosphatemia, FGF23, and calcitriol as well as retinoic and lithocholic acids, rifampicin, carbamazepine, and phenobarbital and suppressed by hypocalcemia and PTH.[111] *CYP24A1* is also expressed by fibroblasts, lung, intestine, oocytes, brain, thyroid, and other tissues.[106] Cleavage of the side chain between carbons 23 and 24 that have been hydroxylated by hepatic cytochrome P450-3A (*CYP3A4*)–dependent enzymes generates water-soluble calcitroic acid that is excreted in bile.[105,106] Phenobarbital, phenytoin, carbamazepine, and rifampicin impair bone mineralization by inactivating calcitriol and do so by increasing its state of hydroxylation by binding to and activating the nuclear pregnane X receptor (*NR112*) that in turn increases expression of *CYP3A4*.[128] Calcitriol may also induce expression of hydroxylases that utilize cytochrome P450-3A, thereby enhancing its own hydroxylation and degradation. Inactivating mutations of *CYP24A1* result in some forms of idiopathic hypercalcemia of infancy by reducing the rate of degradation and thereby prolonging the biologic life of calcitriol.[129]

Although emphasis has been placed on the vitamin D endocrine system in the regulation of mineral homeostasis and bone health, its role as a paracrine factor may also be considered. For example, epidermal keratinocytes within the basal layer of skin express all of the enzymes necessary for genesis of calcitriol (discussed earlier), and this locally synthesized compound is critical for regulation of the proliferation and terminal differentiation of keratinocytes and hair follicles.[106] Adipocytes not only store excessive vitamin D, but these cells also express vitamin D-25-hydroxylase and 1α-hydroxylase activities, suggesting that fat may be a site of calcidiol and calcitriol synthesis.[106] The bulk of circulating calcitriol is bound to

DBP, but it is its free fraction that is biologically active. Indeed, the serum level of DBP does not affect the calcitriol pool that enters the cell and regulates gene transcription.[111] Approximately 0.04% of calcidiol and 0.4% of calcitriol are present in free form in serum. Normal ranges of calcitriol concentrations are neonates, 8 to 72 pg/mL; infants and children, 15 to 90 pg/mL; and adults, 21 to 65 pg/mL.

Calcitriol exerts its biologic effects by binding to the VDR, a nuclear transcription factor, after which it regulates gene expression (discussed later). Through binding to the nuclear VDR, calcitriol regulates the expression of more than 900 target genes involved in mineral and bone metabolism and processes that likely influence cell growth, musculoskeletal, cardiovascular, immune, skin, and pancreatic islet cell functions and energy metabolism.[113,123,125,130] The nuclear effects of calcitriol take place over hours to days as the processes of transcription, translation, posttranslational modifications to the encoded protein(s), storage, and secretion occur in multiple cytosolic compartments (discussed later). The VDR also associates with caveolae of the cell plasma membrane, flask-shaped invaginations of the membrane composed of sphingolipids and cholesterol where, after binding to ligand, the VDR is able to interact with intracellular signal transduction systems to exert rapid functional cell responses.[131,132] The rapid cell responses to calcitriol generated by association with the caveolar VDR are evident within seconds to minutes after contact and include immediate intestinal absorption of calcium (transcaltachia), opening of voltage-gated calcium and chloride channels in osteoblasts, endothelial cell migration, and pancreatic β cell secretion of insulin. It is the flexible three-dimensional configuration of calcitriol that enables this ligand to exert both genomic and nongenomic (rapid response) actions.[123,131] The protean three-dimensional structure of calcitriol is the result of (1) rotation of side chain carbon pairs 17-20, 20-22, 22-23, 23-24, and 24-25; (2) rotation of the carbon 6-7 bond around the B ring; or (3) chair-chair interconversion with formation of either an α- or a β- configuration of the cyclohexane-like A ring (Figure 8-4). Rotation about the carbon 6-7 bond of the B ring allows calcitriol to assume either an extended 6-s-*trans* configuration or a 6-s-*cis* conformation. It is the *trans* form of calcitriol with the β-chair configuration of the A ring that is recognized and bound by the hydrophobic pocket of the nuclear VDR. Ligand-bound VDR then interacts with the retinoid X receptor (RXR), forming a heterodimer that is recognized by specific hexameric sequences of DNA bases (the vitamin D response element [VDRE]) in the regulatory 5′ region of target genes (discussed later).[106] The calcitriol/VDR-RXR heterodimer recruits transcription-activating or transcription-repressing coregulatory proteins enabling its genomic transcriptional effects. The *cis* form of calcitriol permits its rapid cell membrane–related actions. For binding to DBP, calcitriol assumes yet another shape.[131]

Calcitriol primarily controls intestinal, skeletal, and renal function by regulating expression of genes encoding calcium transporters (calbindin-D_{28K}, calbindin-D_{9K}), calcium channels (TRPV5, expressed primarily in the kidney; TRPV6, expressed predominantly in the intestinal tract), bone matrix proteins (osteocalcin, osteopontin, type I collagen, alkaline phosphatase), and osteoclast activators (RANKL). Calcitriol promotes endochondral bone formation; it increases length of the long bones by amplifying volume, proliferation, and differentiation of epiphyseal chondrocytes and promotes mineralization of cartilage matrix.[133] Calcitriol increases trabecular and cortical bone formation by augmenting osteoblast number and function; it increases alkaline phosphatase activity, osteocalcin synthesis, and type I collagen formation and represses bone resorption by osteoclasts. It does so by a direct cellular effect independent of endogenous PTH as it is active in the mouse in which both *Cyp27b1* and *Pth* have been "knocked out."[133] Calcitriol directly suppresses transcription of *PTH* in the parathyroid gland

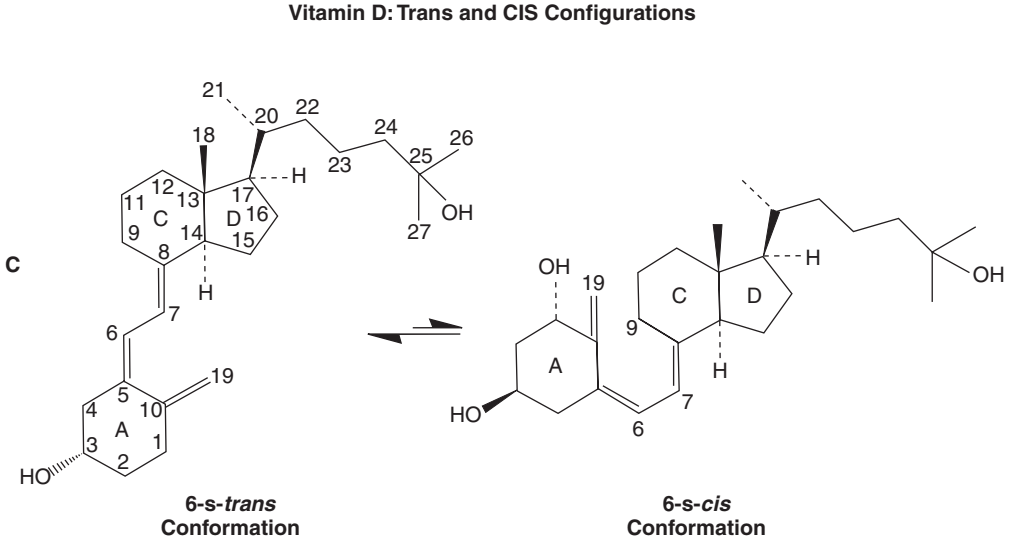

FIGURE 8-4 ■ **Cis and trans structures of calcitriol.** (Reproduced from Norman, A. W. (2006). Minireview: vitamin D receptor: new assignments for an already busy receptor. *Endocrinology*, *147*, 5542–5548, with permission.)

acting through the VDR. Vitamin D is also important for normal muscle development and strength.

Mediated by the nuclear VDR, calcitriol stimulates the absorption or reabsorption of calcium in the intestines, bone, and kidney. In the duodenum and proximal small intestine, calcitriol increases the efficiency of calcium uptake from the intestinal lumen by increasing the number of epithelial calcium transport channels (TRPV6) in enterocytes, its movement through the cytoplasm, and its transfer across the basal lateral membrane into the circulation—in part by the induction of calbindin$_{9k}$ (a calcium binding protein), alkaline phosphatase, Ca-ATPase, calmodulin, and other proteins.[134] Calcitriol also increases jejunal and ileal absorption of phosphate through a transcellular mechanism utilizing the type II Na^+-HPO_4^{2-} cotransporter protein (NPT2) (encoded by *SLC34A1*) expressed on the luminal surface of the enterocyte. When vitamin D stores are replete, 40% of dietary calcium and 80% of dietary phosphate may be absorbed. Even greater efficiency of mineral absorption is realized during periods of rapid growth, pregnancy, and lactation. A major task of calcitriol is to maintain calcium and phosphate concentrations in blood at levels sufficient to sustain mineralization of osteoid (collagen) containing bone matrix synthesized by osteoblasts. Paradoxically, in states of calcium deficiency, calcitriol acts indirectly within bone to induce monocytic stem cell differentiation into osteoclasts by stimulating osteoblast/stromal cell synthesis of osteoclast activating factors such as RANKL (discussed later). During periods of calcium deficiency, calcitriol is able to promote bone resorption through increased osteoblast production of osteopontin, a bone matrix noncollagenous protein to which osteoclast cell surface integrin receptors bind that leads to bone destruction. Calcitriol also stimulates osteoblasts to produce osteocalcin, bone specific alkaline phosphatase, osteoprotegerin, and various cytokines.

A number of synthetic vitamin D_3 analogs have been synthesized, including alfacalcidol [1α-(OH)D_3], calcipotriol [1α,25-(OH)$_2$-24-cyclopropyl-D_3], maxacalcitol [1α,25-(OH)$_2$-22-oxa-D_3], and tacalcitol [1α,24R-(OH)$_2D_3$]. These vitamin D analogs have been engineered to retain the noncalcemic actions of the parent compound while reducing their calcemic properties. Calcitriol and vitamin D_3 analogs exert many immunomodulatory effects.[135] In animal models of autoimmune diseases such as experimental autoimmune encephalitis, systemic lupus erythematosus, autoimmune thyroiditis, autoimmune diabetes mellitus, and inflammatory bowel disease, calcitriol exerts a protective effect. Calcitriol and its analogs inhibit T-lymphocyte differentiation into Th1 cells that secrete IL-2, tumor necrosis factor (TNF)-α, and interferon-γ, thereby experimentally modifying disease induction, course, and severity. Calcitriol and analogs also exert differentiating and antiproliferative effects on a variety of cells; thus, calcitriol induces differentiation of promyelocytes into monocytes and macrophages. These agents enhance differentiation of keratinocytes and when administered orally or topically to patients with psoriasis vulgaris effectively ameliorate the disease; they are particularly effective when coadministered with a topical glucocorticoid. In vitro, calcitriol and its analogs inhibit growth of prostate, breast, and colon cancer cell lines; in vivo, experimentally calcitriol and its analogs prevent or reduce mammary tumor formation, whereas in the absence of the VDR mammary tumor growth is enhanced.[135] Calcitriol prevents hypertension and cardiac hypertrophy in mice in whom *VDR* or *CYP27B1* have been knocked out. In humans, inferential but not clinically proven data suggest that vitamin D plays a role in the pathophysiology of several nonskeletal disorders including hypertension and cardiovascular disease, autoimmune disorders, multiple sclerosis, and infectious illnesses such as tuberculosis, leprosy, and influenza.[113,130,136]

Vitamin D Receptor

The vitamin D receptor is a 427-amino-acid nuclear transcription factor that is encoded by the 11 exon gene, *VDR*. Because there are two potential start site codons for transcription of *VDR* in exon 2, there is a second isoform of VDR with 423 amino acids. At its 5′ terminus, *VDR* has three noncoding exons (1A, 1B, 1C) followed by exons 2 through 9 that encode the active protein enabling transcription of three unique mRNA isoforms depending on the splicing pattern of exons 1B and 1C. As a member of the steroid-thyroid–vitamin D receptor gene superfamily of nuclear transcription activating factors, the VDR has multiple domains: a short amino-terminal segment of 24 amino acids (domains A and B) that houses a ligand-independent transcription activating function termed activation function-1 (AF-1) that interacts with the general transcription factor IIB, a DNA binding domain (C) with two zinc fingers (exons 2, 3), a "hinge" region (D), and a long carboxyl terminal domain (E) with ligand and retinoid X receptor α (RXRα) binding sites and a second transcription activating sequence (AF-2) (exons 7, 8, 9). Two nuclear localization signals are found within and immediately distal to the zinc finger DNA binding domain, the first of which specifically recognizes the vitamin D response element (VDRE), whereas the second zinc finger permits heterodimerization with RXRα (discussed later).[130] Structurally, the E domain is composed of 12 α-helices (H1-H12) and has two ligand-dependent transactivating regions—E1 between amino acids 232-272 and AF2 between amino acids 416-424—that recruit transcriptional coactivating factors when the VDR is activated by binding to calcitriol; it also contains sequences that enable heterodimerization with RXRα.[130]

Among the factors that enhance transcription of *VDR* are calcitonin, retinoic acid, estrogen, and transcription factor SP1. β-catenin potentiates the transcriptional activity of VDR by binding to its carboxyl terminal AF2 segment. In part, estrogens increase expression of *VDR* through binding to estrogen receptors present in the caveolae of the cell membrane that then activate the MAPK signal transduction pathway.[137] PTH downregulates expression of *VDR*. The VDR is widely expressed in the intestinal tract, distal renal tubule, osteoblast, keratinocyte, hair follicle, fibroblast, smooth and cardiac muscle, lung, bladder, thyroid, parathyroid, pancreas, adrenal cortex and medulla, pituitary, placenta, uterus,

ovary, testis, prostate, activated T and B lymphocytes, macrophages, monocytes, spleen, thymus and tonsil, brain, spinal cord, and sensory ganglia. Inactivating mutations of *VDR* result in vitamin D–resistant rickets (vitamin D–dependent rickets, type 2A, OMIM ID: 277440).

Whereas most members of the superfamily of nuclear receptor transactivating factors pair as homodimers to bind to their specific hormone response elements in the 5′-untranslated region of the target gene, the calcitriol-VDR complex teams through its E (ligand binding) domain with its obligate partner, unliganded RXRα (encoded by *RXRA*), to form a heterodimer that then binds to a VDRE. The endogenous ligand for RXRα is 9-cis-retinoic acid. RXRβ and RXRγ also bind to the VDR. When unliganded, the bulk of the VDR is cytoplasmic; binding of calcitriol to the VDR leads to heterodimerization with RXRα and translocation of the tripartite complex to the nucleus. Unliganded VDR can also be guided to the VDRE in the 5′ region of its target gene by interaction with the Williams syndrome transcription factor (WSTF, encoded by *BAZ1B*), a component of a multiprotein, chromatin-remodeling complex termed WINAC (WSTF including nucleosome assembly complex); there the VDR remains inactive until bound to calcitriol (discussed later).[138,139] There are three classes of VDREs located in the 5′ upstream promoter region of target genes: designated generic positive, conventional negative, and E-box–like negative.[122] The generic positive or transcription activating VDRE is composed of two repeated hexanucleotide sequences linked by three nonspecific nucleotide bases: 5′ . . . (A/G)GGTCA-nnn-AGGACA . . . 3′.[109,122] RXRα binds to the 5′ half of the VDRE and VDR to its 3′ segment. The conventional negative or transcription repressing VDRE is composed of a single copy of the generic positive VDRE with the nucleotide sequence, 5′ . . . (A/G) G(G/T)TCA . . . 3′; it is through the conventional negative VDRE that calcitriol inhibits expression of *PTH* and *PTHLH*. The nucleotide sequence of the E-box–like negative VDRE is 5′ . . . CANNTG . . . 3′. After binding to the designated VDRE, the calcitriol-VDR-RXRα-WINAC complex recruits coactivating or corepressing modulating proteins (e.g., steroid receptor coactivators [SRC]-1, -2, -3/p160 family with histone acetyl transferase activity, the chromatin remodeling complex—SWI/SNF, and other comodulators of transcription such as C/EBPβ, TRIP/SUG1, CPB/p300, TIF1) into the promoter site as well as the general transcription activating apparatus of the target gene (TFIIA, -B, TAF family).[109,122,140] Histones are lysine-containing protein components of chromatin, a complex of protein and DNA of which a chromosome is composed; 147 base pairs of DNA wrap around a histone octamer comprised of two copies each of histones H2A, H2B, H3, and H4 forming a nucleosome, a structure that regulates replication, repair, and expression of genes.[139] Epigenetic regulation of gene expression is achieved, in part, by histone modifying enzyme complexes that remodel chromatin by altering the state of histone methylation, acetylation, phosphorylation, ubiquitination, sumoylation, and proline isomerization.[141] WSTF is a component of three ATP-dependent chromatin remodeling complexes that alter nucleosome position and thus affect gene exposure to the primary transcription apparatus and accordingly gene expression or silencing; they are directed to sites of action by specific histone modifications.[139] Within the WSTF protein are a chromatin-binding domain (PHD), a tyrosine kinase domain that enables it to phosphorylate histone tyrosine residues, and a binding site for the VDR. In addition to WSTF, the WINAC ATP-dependent chromatin remodeling complex is composed of 12 other subunits; it plays a role in chromatin assembly and cell cycle progression and facilitates activation of *CYP24A1* encoding 25-hydroxyvitamin D-24-hydroxylase while repressing *CYP27B1* encoding 25-hydroxyvitamin D-1α-hydroxylase (Figure 8-5).

Gene activation by the calcitriol-VDR-RXR-WINAC complex is initiated by recruitment of a histone acetyl transferase–helicase complex (e.g., SRC/SWI/SNF) to the promoter segment of the target gene; acetylation of a lysine residue within a histone protein destabilizes the region enabling DNA to unwind, thereby granting basal transcription factors and RNA polymerase II access to the transcription start site, thus bringing about RNA modeling of the target gene. Another VDR coactivator is the vitamin D interacting protein (DRIP, encoded by *MED4*) that links the VDRE and the initiation start site of the target gene to RNA polymerase II and its cofactors.[130] Corepressors cause chromatin to compact by removal of acetyl or addition of methyl groups to lysine residues within a histone protein, thereby silencing gene expression. Inasmuch as the E-box–negative VDRE lacks the common hexameric VDRE, this VDRE binds to and gene transcription is inhibited (e.g., *CYP24A1* encoding vitamin D–24-hydroxylase) by the interaction of unliganded VDR with the VDR-interacting repressor (VDIR encoded by *TCF3*), a process that involves recruitment of a histone deacetylase. Calcitriol inhibits activation of *CYP27B1* encoding 25-hydroxyvitamin D-1α-hydroxylase by binding to VDR that links to the VDIR-WINAC complex and replacing histone acetyltransferase with a histone deacetylase, thus halting transcription activation (see Figure 8-5).[122,139] In addition to regulatory effects on gene expression by alterations of histone lysine residues, calcitriol-VDR-RXR–induced methylation of DNA cytosine residues at CpG sites in the promoter region 5′ to *CYP27B1* (another epigenetic modification) also represses expression of this gene.[122] Positive and negative regulation of target gene expression by the VDR may also be achieved by interaction of the VDR complex with other transcription factors.[140] As illustrated in Figure 8-5, WINAC is involved in both calcitriol-VDR-VDIR mediated gene transcription and repression.[122] Deletion or inactivating mutations of *BAXBI* (encoding WSTF) impair the linkage between calcitriol, VDR, and WINAC and thus impede the inhibitory effects of calcitriol on transcription of *CYP27B1*, likely resulting in increased synthesis of 25-hydroxyvitamin D-1α-hydroxylase and excessive synthesis of calcitriol, perhaps the pathophysiologic process that leads to hypercalcemia in patients with Williams syndrome.

Some of the more than 900 genes whose expression is regulated by the VDR are listed in Figure 8-6.[106,140] That there may be approximately 2000 VDREs (vitamin D response elements) within the human genome indicates the potentially widespread effects exerted by the vitamin D system.[142] Calcitriol acting through the VDR stimulates transcription of genes encoding calcium transport proteins (TRPV5/6), bone matrix proteins (osteopontin, osteocalcin), bone resorption factors (RANKL), and 25OHD-24-hydroxylase and represses those that encode PTH, PTHrP, and 25-hydroxyvitamin

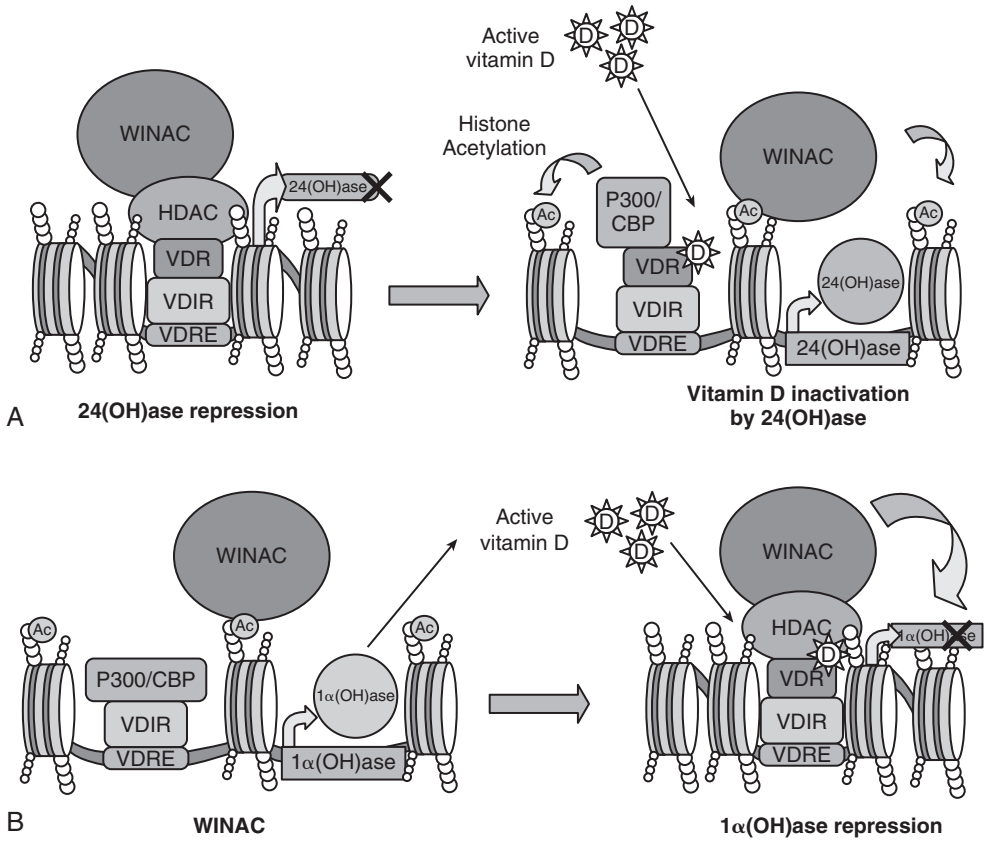

FIGURE 8-5 ■ Regulation of vitamin D receptor (VDR) action by interaction with WINAC (WSTF including nucleosome assembly complex) and VDIR (VDR-interacting repressor). **A,** Under basal conditions, histone deacetylase (HDAC), unliganded VDR-RXR, and VDIR bind to the vitamin D response element (VDRE) of *CYP24A1* encoding 25-hydroxyvitamin D-24-hydroxylase and suppress gene expression; after calcitriol binds to VDR-RXR, HDAC is replaced by a histone acetyltransferase activation complex (p300/CBP) leading to active transcription of *CYP24A1*. **B,** The autoregulatory effect of calcitriol on its own synthesis is mediated by its interaction with the VDR-RXR-VDIR-WINAC complex and replacement of histone acetyltransferase by histone deacetylase. D-1α-hydroxylase. The calcitriol-VDR complex also suppresses expression of multiple cytokines (IL-2, interferon-γ, granulocyte macrophage-colony stimulating factor) by negatively interacting with transcription factors that enhance their transcription (e.g., NF-κB).

Although the VDR is necessary for the actions of calcitriol in the intestines, kidney, bone, skin, and elsewhere, its loss does not interfere with embryogenesis and fetal development in humans with loss-of function mutations in *VDR* and vitamin D resistance or in mice in which *Vdr* has been knocked out. Newborn mice homozygous for targeted deletions that result in truncation of the VDR survive fetal life, appear normal at birth, and grow well for the first 24 days of life.[143] However, after weaning their rates of weight gain and linear growth and serum $Ca^{2+}{}_e$ and phosphate levels decline and serum PTH concentrations and parathyroid gland weights increase. In $Vdr^{-/-}$ mice as young as 15 days of age osteoid surface is increased, bone mineralization decreased, and epiphyseal plate cartilage formation disorganized with irregular columns of chondrocytes, increased matrix, and excessive vascularity relative to wild-type or heterozygous ($Vdr^{+/-}$) mice.[143] In addition, hair loss begins at 4 weeks of age and is complete by 4 months of age in homozygous $Vdr^{-/-}$ animals and is due to a defect in the growth cycle of hair follicles, a phenocopy of the generalized alopecia associated with loss of hairless (*HR*), a transcriptional corepressor that interacts with the VDR.[140] Maintenance of normal serum concentrations of calcium and phosphate by the feeding of high calcium-phosphate diets to $Vdr^{-/-}$ pups beginning at 16 days of age prevents the development of all of the skeletal abnormalities, indicating that the main physiologic effects of calcitriol and the VDR are on the intestinal absorption of calcium and phosphate and the maintenance of normal serum concentrations of these ions.[143]

As discussed, calcitriol also has rapid, nongenomic effects mediated through plasma membrane caveolae-associated VDRs (Figure 8-7).[132] A membrane protein that binds calcitriol—1,25-dihydroxyvitamin D membrane associated rapid response steroid-binding protein (1,25-dihydroxyvitamin D-MARRSBP encoded by *TXNIP*)—has been identified that may interact with the classic VDR to bring about the rapid responses to calcitriol.[130] After binding of calcitriol to the plasma membrane-associated VDR, its signal is transmitted by several classical intracellular signal transduction systems including (1) adenylyl cyclase induction of cyclic AMP and PKA; (2) PLC- and PLD-mediated increase in phosphoinositide turnover, resulting in generation of DAG and IP_3 that increases the permeability of Ca^{2+} channels and releases Ca^{2+} from storage sites in the endoplasmic reticulum; (3) G_q-protein through PLC-β1 activation and intracellular redistribution of PKC isoforms (α, β, δ); and (4) Jun-activated kinase and the MAPK pathway.[144] Within minutes after exposure of a vitamin D responsive tissue (e.g., intestine, chondrocyte, osteoblast) to calcitriol, there is increase in the intracellular concentration of $Ca^{2+}{}_i$ (transcaltachia) and activation of PLC, PKC, and MAPK.[131] In osteoblasts from $VDR^{-/-}$ mice and in fibroblasts from patients with inactivating mutations of *VDR*, the rapid actions of calcitriol are lost as is the association of the VDR with caveolae, evidence of the importance of the VDR for membrane-initiated responses to calcitriol. In chondrocytes, there is MARRS-dependent enhancement of calcium flux, PKC activity, and matrix vesicle

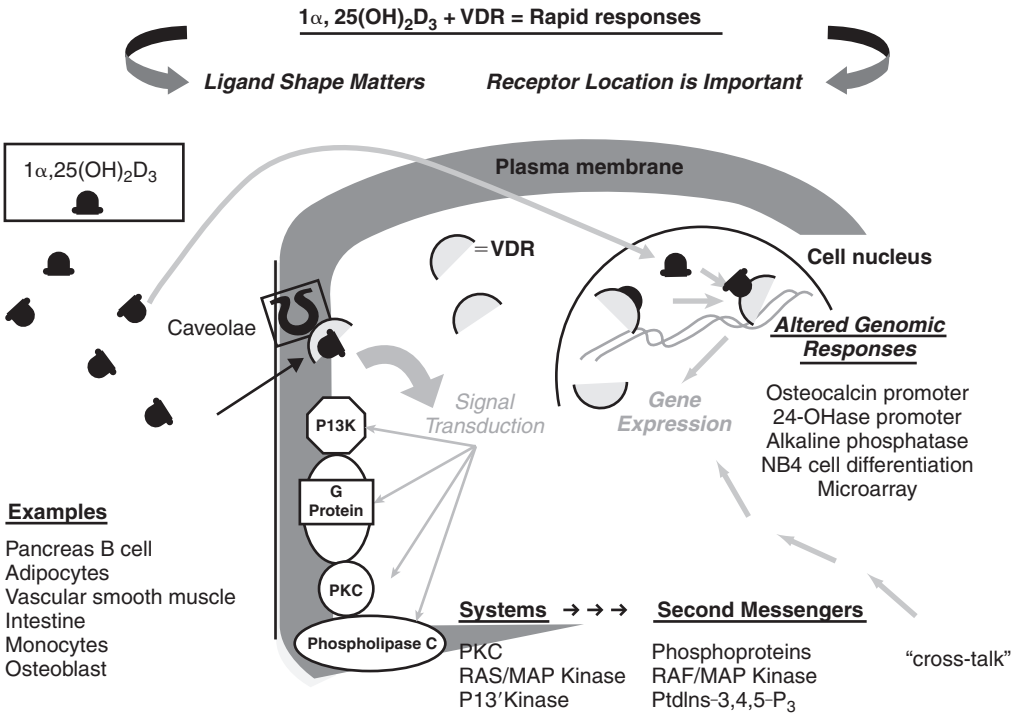

FIGURE 8-7 ■ Genomic and nongenomic (rapid) responses to calcitriol. (Reproduced from Norman, A. W., & Bouillon, R. [2010]. Vitamin D nutritional policy needs a vision for the future. *Exp Biol Med, 235*, 1034–1045, with permission.)

mineralization.[145] The plasma membrane caveolae-associated VDR may link to $G_{s\alpha}$ and thence to a calcium channel or adenylyl cyclase or PLC or with caveolin, a protein that interacts with the nonreceptor tyrosine kinase (Src) and in turn with PLC or the kinase h-Ras.[144,146] The rapid effects of vitamin D may optimize its genomic effects by phosphorylation of proteins required by the VDR transcriptional complex.

SKELETON: CARTILAGE AND BONE

Cartilage and Bone Differentiation and Formation

The skeleton is the framework of the body. It is composed of cartilage and bone, specialized cells and forms of connective tissue that provide (1) mechanical support for muscle/tendon insertion that enables movement; (2) protective shield for soft tissue organs; (3) repository for bone marrow; (4) reserve source of calcium, phosphate, magnesium, and other metabolically important ions; and it serves as (5) an endocrine organ as the secreted products of bone cells regulate the function of distant organs—for example, the osteocyte secretes sclerostin, an inhibitor of bone formation, and FGF23, a factor that depresses renal tubular reabsorption of phosphate and the synthesis of calcitriol.[147,148] Bone differentiation begins in utero when transformation of mesenchymal cells into chondrocytes that secrete collagen type II form the skeletal anlagen; the shape of the skeleton is complete by the ninth week of gestation following which there are many fold increases in skeletal dimensions, volume, and mass.[148-151] In the normal full-term neonate, skeletal weight approximates 200 to 300 g, 30 g of which is calcium. There are two primary bone shapes: flat bones (e.g., cranium, scapula, pelvis) and long bones (e.g., humerus, radius, ulna, metacarpal, femur, tibia, fibula, metatarsal).[152] Flat bones develop by membranous bone formation in which embryonic mesenchymal cells differentiate directly into osteoblasts, which then form bone; long bones are derived by both endochondral and membranous bone formation. Endochondral bone formation is the process by which the cartilaginous pattern of a bone is replaced by bone tissue.[149] The external surface of bone is enveloped by periosteum (containing blood vessels, nerve terminals, osteoblasts, and osteoclasts), whereas the interior of bone next to marrow is lined by endosteum. Long bones consist of a central hollow shaft (diaphysis) distal to which are the metaphyses, cartilaginous growth plates, and epiphyses. The diaphysis is composed of cortical bone, and the metaphysis/epiphysis consists of trabecular bone enveloped by cortical bone. Eighty percent of the adult skeleton is dense cortical bone; 20% is cancellous and composed of a network of trabeculae.

In addition to its cellular constituents (osteoblasts, osteocytes, osteoclasts, stromal and hematopoietic cells), bone is composed of solid mineral—hydroxyapatite = $Ca_{10}(PO_4)_6(0H)_2$—that has been deposited on collagen fibrils within extracellular matrix.[153] Bone extracellular matrix is comprised primarily of the secreted products of the osteoblasts and is composed of collagenous fibrils (collagen types I, III, V) on which the mineral phase of bone is deposited. Also within the extracellular matrix are noncollagenous, multifunctional proteins that organize, regulate, and coordinate mineralization, serum proteins (e.g., albumin, α2HS-glycoprotein, growth factors; e.g., IGF-I), proteoglycans (proteins with acidic polysaccharide side chains; e.g., chondroitin sulfates such as aggrecan, perlecan, glypican), glycosylated proteins with cell attachments (e.g., alkaline phosphatase, osteonectin), SIBLING proteins (e.g., osteopontin, BSP, DMP1, MEPE) (discussed earlier), fibronectin, fibrillins 1 and 2, and γ-carboxylated (gla) proteins (e.g., osteocalcin, matrix gla protein, protein S). Type I collagen and alkaline phosphatase promote bone mineralization, a process modulated by osteocalcin and matrix gla protein.[153]

Modeling of bone is the process that takes place during growth in which the shape and size of a bone are determined. *Remodeling* of bone is a continual process in which portions of formed bone are periodically reabsorbed and replaced by new bone; remodeling occurs in both the growing child and the adult. During early embryogenesis, bone is formed by condensation of mesenchymal cells in genetically determined patterns of position, arrangement, size, and shape.[154,155] Individual mesenchymal cells then differentiate either into chondrocytes that secrete a matrix of collagen type II in the anlagen of endochondral bones or directly into osteoblasts in precursor regions of intramembranous bone where they secrete a matrix rich in collagen type I. Osteoprogenitor pluripotent stromal mesenchymal stem cells provide a continuous supply of bone-forming osteoblasts, the network of osteocytes embedded throughout bone that monitors bone integrity and strength, and bone surface lining cells. Osteoclasts derived from hematopoietic precursor cells mediate bone resorption. Chondroblasts, osteoblasts, adipocytes, myoblasts, and fibroblasts are derived from a common mesenchymal cell (Figure 8-8).[156] Bone morphogenetic proteins (BMP) are members of the transforming growth factor-β (TGFβ) superfamily that direct the transformation of a pluripotent mesenchymal cell into the pathway leading to formation of chondrocytes and osteoblasts. BMP-2, -4, and -7 are important factors that direct the process of osteoblast differentiation, although there is substantial redundancy in the system and other BMPs also participate. The BMPs act through designated cell membrane threonine/serine kinase receptors (e.g., BMPRIA; BMPR2); depending on the interaction of the BMP receptors involved, intracellular signaling is transduced by the SMAD (mothers against decapentaplegic homolog) or MAPK pathways and induces synthesis of specific transcription factors that further the differentiation process.[157]

Chondrogenesis

In cartilaginous bones, longitudinal growth occurs by differentiation, proliferation, and hypertrophy of chondrocytes and by formation of extracellular matrix. Chondrocytes secrete an extracellular matrix that in

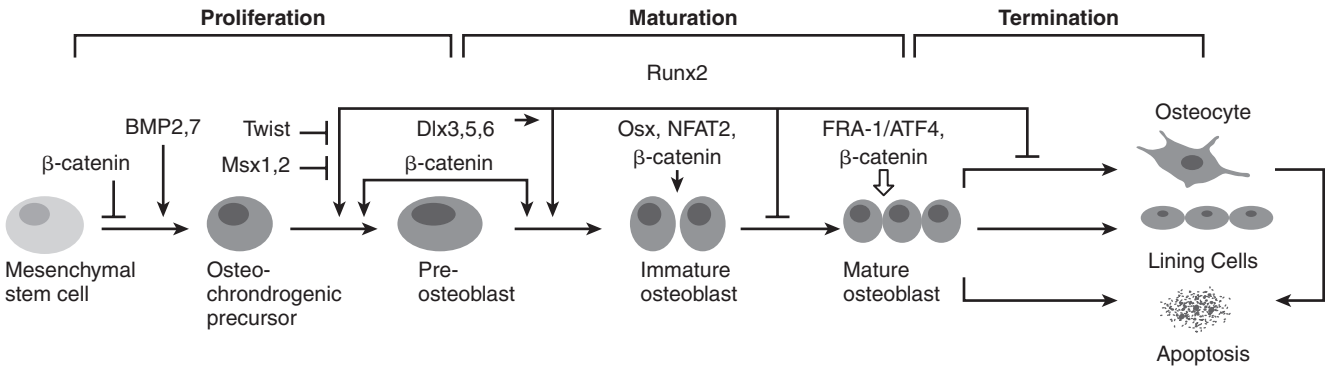

FIGURE 8-8 ■ Osteoblastogenesis. A common mesenchymal stem cells gives rise to chondroblasts, osteoblasts, myoblasts, fibroblasts, and adipocytes in response to specific differentiating factors. Bone morphogenetic proteins (BMP) are involved in the earliest steps leading to the differentiation of the common mesenchymal precursor cell into the osteoblast-chondrocyte lineage. RUNX2 and β-catenin are necessary for osteoblastic differentiation of the common progenitor cell of chondrocytes and osteoblasts and for further maturation of osteoblasts. (SOX9 is critically important for the differentiation and function of chondroblasts. PPARγ2 [peroxisome proliferator-activated receptor γ2] stimulates the differentiation of adipocytes. Osteoblasts and adipocytes may be interconverted depending on whether RUNX2 or PPARγ2 is the activated transcription factor. MyoD is a muscle-specific transcription factor necessary for development of myoblasts.) (Reproduced from Krause, C., de Gorter, D. J. J., Karperien, M., & ten Dijke, P. (2008). Signal transduction cascades controlling osteoblast differentiation. In C. J. Rosen (Ed.), *Primer on the metabolic bone diseases and disorders of mineral metabolism* (pp. 10–16) (7th ed.). Washington, DC: American Society for Bone and Mineral Research, with permission.)

addition to collagen type II is composed of large aggregates of aggrecan and the glycosaminoglycan hyaluronan, the latter two products enabling cartilage to compress and expand.[149] Other components of the extracellular matrix of cartilage include collagens types VI, IX, X, XI, and XIV; the large proteoglycan perlecan; cartilage oligomeric protein (COMP; also termed thrombospondin-5); and matrilins-1 and -3. COMP, matrilin-3, and collagen type IX are essential for normal growth plate structure as mutations in the genes encoding each of these proteins lead to pseudohypochondroplasia (*COMP*) or forms of multiple epiphyseal dysplasia. Expression of many of the genes encoding components of cartilage extracellular matrix (including those encoding collage type II and aggrecan) is dependent on the transcription factor SOX9.

The expression of *SOX9* is stimulated by FGF signaling through the MAPK pathway. SOX9 is a 509-amino-acid protein with an SRY homology domain that is also expressed in the testis where it is responsible for differentiation of Sertoli cells. Inactivating mutations of *SOX9* lead to camptomelic dysplasia and sex reversal in males (OMIM ID: 114290). Target genes of SOX9 include those that encode collagen type II(α1) and aggrecan, a chondroitin sulfate proteoglycan core protein; a mutation in the gene-encoding aggrecan leads to an autosomal dominant form of spondyloepiphyseal dysplasia associated with premature degenerative arthropathy (OMIM ID: 608361). *SOX9* is expressed not only in chondrocytes in the resting phase but also those in the proliferative phase but not in chondrocytes in the hypertrophic phase of maturation.[155]

The *pattern* of endochondral bone development is directed by factors that are independent of bone formation (e.g., in transgenic mice in which *Runx2* is inactivated, the cartilage skeleton forms normally but is not ossified).[158] (In humans, heterozygous inactivating mutations in *RUNX2* result in cleidocranial dysplasia [OMIM ID: 119600], manifested by growth retardation, hypoplasia of the clavicle and pelvis, delayed closure of cranial sutures, and defective tooth eruption.) Vertebrae evolve from the condensation and segmentation of paraxial mesoderm into somites under the direction and control of multiple genes including *NOTCH1*, *SHH*, and *PAX1* and Notch ligands encoded by *DLL3* and *JAG1*.[158] The appearance of limb buds, proliferating mesenchymal cells that grow out from the lateral body wall and are capped by an apical ectodermal ridge, heralds development of the cartilage anlagen of the long bones, a process of segmentation directed experimentally by homeobox genes (*Hoxa13*, *H0xd13*), *Sbh*, *Wnt7a*, *Gli3*, *Tgf*β, *Fgf4*, *Fgfr1*, *Fgfr2*, *Bmp2*, *Bmp4*, *Bmp6*, *Bmp*7, *Lmx1b*, *Pitx1*, *Tbx4*, *Tbx5*, *Twist*, and other signaling, receptor, and transcription regulating factors involved in differentiation, paracellular communication, and cell-to-cell interaction.[158,159] Mitochondrial RNA-processing endoribonuclease encoded by *RMRP* is a ribonucleoprotein that is essential for assembly of ribosomes and cyclin-dependent cell cycle activity as well as chondrocyte proliferation and differentiation. Inactivating mutations of *RMRP* result in anauxetic dysplasia (OMIM ID: 607095), a spondylometaepiphyseal dysplasia characterized by intrauterine and postnatal growth retardation with adult stature < 85 cm.[160] Histologically, the growth plates of these patients are depleted of chondrocytes. Different mutations of *RMRP* result in varying clinical manifestations (e.g., cartilage hair hypoplasia [OMIM ID: 250250] and metaphyseal dysplasia without hypotrichosis [OMIM ID: 250460]).

Chondrocyte differentiation within the resting zone of the cartilaginous growth plate is stimulated by growth hormone that also prompts local synthesis of IGF-I that then mediates chondrocyte proliferation and hypertrophy acting through the IGF type 1 receptor (encoded by *IGF1R*). Chondrocyte differentiation and proliferation is also enhanced by IHH, a 336-amino-acid product of prehypertrophic and early hypertrophic chondrocytes that

acts through its cell membrane receptor Patched 1 (encoded by *PTCH1*) and coreceptor Smoothened (*SMOH*) to stimulate the synthesis of PTHrP. Differentiation of proliferating chondrocytes into prehypertrophic chondrocytes and of the latter into hypertrophic chondrocytes is inhibited in paracrine fashion by PTHrP functioning through PTH1R; PTHrP is secreted in utero by cells in the proximal periarticular perichondrium and postnatally by chondrocytes in the resting zone of the cartilaginous growth plate and diffuses into the zone of proliferating chondrocytes where it delays further differentiation, thus maintaining their replicative capacity (Figure 8-9).[92,161,162] Ultimately, the more distal proliferating chondrocytes escape from the inhibitory effects of PTHrP, undergo hypertrophy, and then die. In humans, inactivating mutations of *PTH1R* result in rapid chondrocyte maturation and Blomstrand chondrodystrophy (OMIM ID: 215045), whereas activating mutations in *PTH1R* lead to impaired chondrocyte maturation and Jansen metaphyseal chondrodysplasia (OMIM ID: 156400). Thus, the rate of prehypertrophic and terminal hypertrophic differentiation of chondrocytes is regulated locally by both PTHrP and IHH, the latter by encouraging chondrocyte hypertrophy.[161] IHH is also able to stimulate the conversion of perichondrial cells into osteoblasts.[162] The synthesis of IHH is increased by several BMPs. During the process of chondrocyte hypertrophy, individual cell length increases 6- to 10-fold; as the chondrocyte dies collagenous fibers are enzymatically digested, the extracellular matrix calcifies, and vascular endothelial growth factor (VEGF) is produced.[163] Surrounding the cartilage anlagen is a periosteal collar of bone deposited by recently differentiated osteoblasts; in response to VEGF blood vessels, chondroclasts, osteoclasts, osteoblasts, stromal, marrow, and other cells then invade the underlying cartilage and establish a primary center of ossification. A secondary ossification center forms at the distal ends of long bones (defining the epiphyses) with intervening areas of cartilaginous growth plates that permit bone lengthening by continued proliferation and hypertrophy of chondrocytes and formation of extracellular matrix.

As the chondrocyte progresses through its maturational stages of differentiation, proliferation, hypertrophy, and death, the patterns of expression of hundreds of genes change as do the components of secreted extracellular matrix.[149,164,165] For example, experimentally the mesenchymal stem cell expresses, among many other genes,

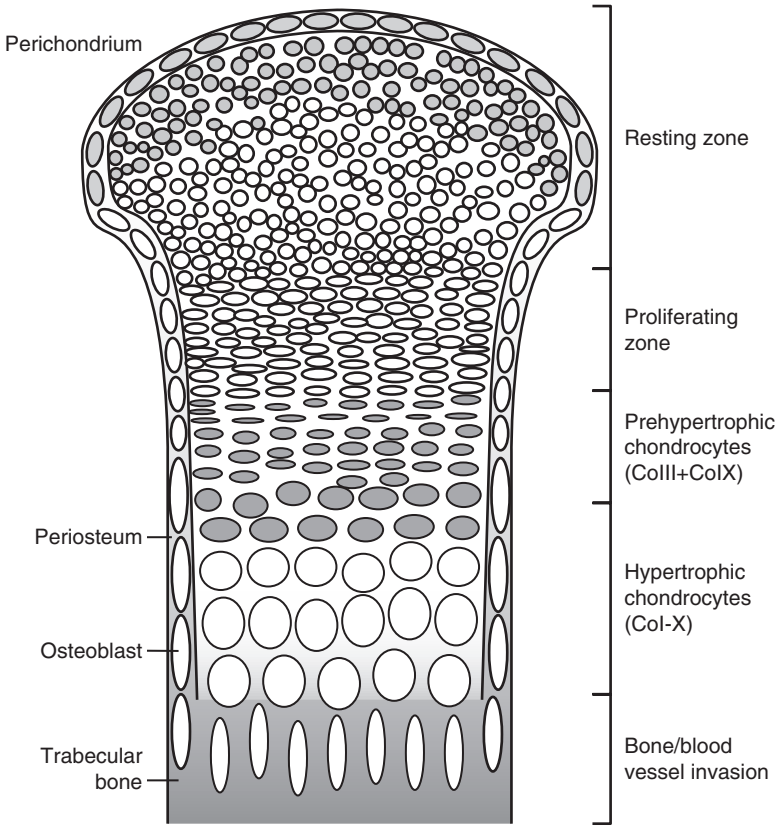

FIGURE 8-9 ■ The epiphyseal cartilage growth plate is composed of zones of resting, proliferating, prehypertrophic, and hypertrophic chondrocytes that develop longitudinally and a transitional zone in which apoptotic hypertrophic chondrocytes and surrounding matrix are replaced by bone. Indian hedgehog (IHH) is synthesized by prehypertrophic chondrocytes. Receptors for parathyroid hormone–related protein are expressed by proliferating and transitional chondrocytes. IHH stimulates secretion of parathyroid hormone–related protein (PTHrP) by periarticular cells and this in turn blocks further differentiation and maturation of late proliferating chondrocytes to hypertrophic chondrocytes, thus prolonging the period of cartilage growth. IHH also acts through bone morphogenetic proteins (BMP) and the WNT-β-catenin pathway to enhance chondrocyte hypertrophy. Fibroblast growth factors (FGF) also influence chondrocyte proliferation and maturation. (Reproduced from Yang Y: Skeletal morphogenesis and embryonic development. IN Rosen CJ: Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism (8th ed.). New York: John Wiley & Sons, 2013. Fig 1-4. © 2013 American Society for Bone and Mineral Research.)

Sox9 and *Col2a1*; the resting chondrocyte expresses *Srfp5*, *Sox9*, *Col2a1*, *Agc1*, and *Pthlh*; the proliferating chondrocyte expresses *Sox9*, *Col2a1*, *Agc1*, *Fgfr3*, and *Runx2*; the prehypertrophic chondrocyte expresses *Bmp*, *Col2a1*, *Col10a1*, *Agc1*, *Pth1r*, *Runx2*, and *Vegf*; the hypertrophic chondrocyte expresses *Col10a1*, *Alpl*, *Ihh*, *Runx2*, and *Vegf*; and the terminal hypertrophic chondrocyte expresses *Col10a1*, *Vegf*, and *Mmp13*. During the transition from the resting to the proliferating chondrocyte, functional gene pathways that are involved include the VDR/RXR and BMP signaling systems: in the transition from the proliferative to the hypertrophic chondrocyte prominent functional gene systems include BMP signaling and components of cellular growth and the cell cycle such as p53; during the senescent phase of chondrocyte maturation the most prominently expressed signaling pathways are those involving VDR/RXR, MAPK, and WNT/β-catenin.[164] When the postproliferative chondrocyte begins to hypertrophy, the production of collagen type II declines and that of collagen type IX increases, whereas late hypertrophic and dying chondrocytes synthesize the collagenase, matrix metalloproteinase 13. In addition to IHH, transition from a proliferative to a hypertrophic chondrocyte is stimulated by triiodothyronine working in concert with IGF-I and FGFR3. Triiodothyronine acts through nuclear thyroid hormone receptor α to increase intracellular signaling through the WNT4/β-catenin pathway. Triiodothyronine also inhibits expression of *Pthlh*, thus shortening the proliferative phase of chondrogenesis. Increase in activity of FGFR3 accelerates the hypertrophic process. As discussed, IHH inhibits chondrocyte hypertrophy acting through PTHrP that in turn down-regulates expression of *RUNX2* and impedes its regulation of hypertrophy associated genes.[149]

FGF-1, -2, -6, -7, -9, and -18 acting through one of four FGF receptors are also important for normal chondrocyte differentiation and development.[163] Normal chondrogenesis is dependent on the balance between the positive regulation of chondrogenesis exerted through FGFR2 and FGFR4 and the negative regulation transmitted through FGFR1 and FGFR3. Mutations in *FGFR1* and *FGFR2* have been associated with syndromes of premature craniosynostosis (Jackson-Weiss, Pfeiffer, Crouzon, and Apert syndromes), whereas alterations in *FGFR1* have also been identified in patients with hypogonadotropic hypogonadism. Gain-of-function mutations in *FGFR3*, expressed in chondrocytes in utero and postnatally, are associated with achondroplasia, hypochondroplasia, and related chondrodystrophies. Interestingly, mutations in *FGFR4* have not been identified in patients with osteochondrodystrophies to date. BMPs affect chondrogenesis by increasing production of IHH, thus increasing chondrocyte proliferation, but also advance chondrocyte maturation.[162]

Chondrocytes within the late hypertrophic zone of the cartilage growth plate disintegrate and discharge their contents as they die. Blood vessels with their cellular cargo invade the extracellular matrix; chondroclasts and osteoclasts digest the extracellular matrix that has been degraded by proteolysis by matrix metalloproteinases, and crystals of calcium phosphate are deposited in the debris. These are later reabsorbed by osteoclasts after which osteoblasts secrete a matrix of collagen type I into which hydroxyapatite crystals are deposited to form bone. Ultimately, growth plate cartilage disappears as primary and secondary centers of ossification meet and fuse, a process regulated by estrogen, which appears to accelerate the senescent process in late hypertrophic chondrocytes.[149]

Although Runt-related transcription factor 2 (encoded by *RUNX2*) inhibits the initial differentiation of the multipotential mesenchymal stem cell into the chondrocyte pathway, it is essential for progression of the chondrocyte through its later stages of differentiation as well as for the early stages of osteoblastogenesis.[166] RUNX2 is the alpha subunit of a transcription factor complex that binds to the promoter region of target genes such as *COLA1* and *MMP13*.

Osteoblastogenesis

During osteoblastogenesis, RUNX2 guides pluripotent mesenchymal stem cells into the osteoblast lineage and up-regulates the expression of genes encoding collagen 1A1, osteocalcin, and several other osteoblast products (see Figure 8-8). After initial osteoblast differentiation, the expression of *RUNX2* declines as the mature osteoblast evolves. Stromal mesenchymal stem cells differentiate not only into chondroblasts (under the direction of SOX9) and osteoblasts (through WNT-induced signaling of RUNX2, DLX5, and SP7 [osterix]), but also into adipocytes (through PPARγ2), myoblasts, and fibroblasts. Committed osteoblasts and adipocytes are capable of redifferentiating into the other cell type depending on whether the expression of *RUNX2* or *PPARG* is paramount; this process is directed by WNT10b, which enhances expression of *RUNX2*, *DLX5*, and *SP7* while suppressing that of *PPARG*.[156,167] The nuclear NAD-dependent protein deacetylase encoded by *SIRT1* also inhibits the adipocyte differentiating effects of PPARγ2 by docking corepressors to this transcription factor, thereby diverting mesenchymal stem cells into the osteoblastogenic pathway.[168] BMP -2, -4, and -7 induce osteoblastogenesis acting through their heterodimeric cell surface receptors and transduce their intracellular signals through receptor-regulated Smads 1, 5, and 8 that heterodimerize with DNA-binding SMAD 4 to induce expression of *RUNX2*, *DLX5*, and SP7; TGFβ signals through Smads 2 and 3 to promote *RUNX2* expression; platelet-derived growth factor, FGFs, and IGF-I also enhance the proliferation and further differentiation of committed osteoblast precursors.[156]

Differentiation of the pluripotent mesenchymal stem cell into the osteoblast lineage is also under the guidance of WNT-stimulated intracellular signaling transduction pathways (Figure 8-10).[158,169,170] (WNT is a term derived by combining the names of the *Drosophila* gene *Wingless* with the corresponding mouse gene *Int*.) Secreted WNT cytokines, a 19-member family of lipid-modified signaling glycoproteins with 350 to 400 amino acids and a conserved sequence of 22 cysteine residues (e.g., WNT1, WNT3a, WNT5a, WNT7b, WNT9a, WNT10b), bind to the GPCR Frizzled receptors (encoded by *FZD1*) and to low-density lipoprotein receptor-related proteins (LRP) 5/6 coreceptors (encoded by *LRP5*, *LRP6*), both of which are long chain proteins with a single transmembrane domain situated on the mesenchymal stem cell's

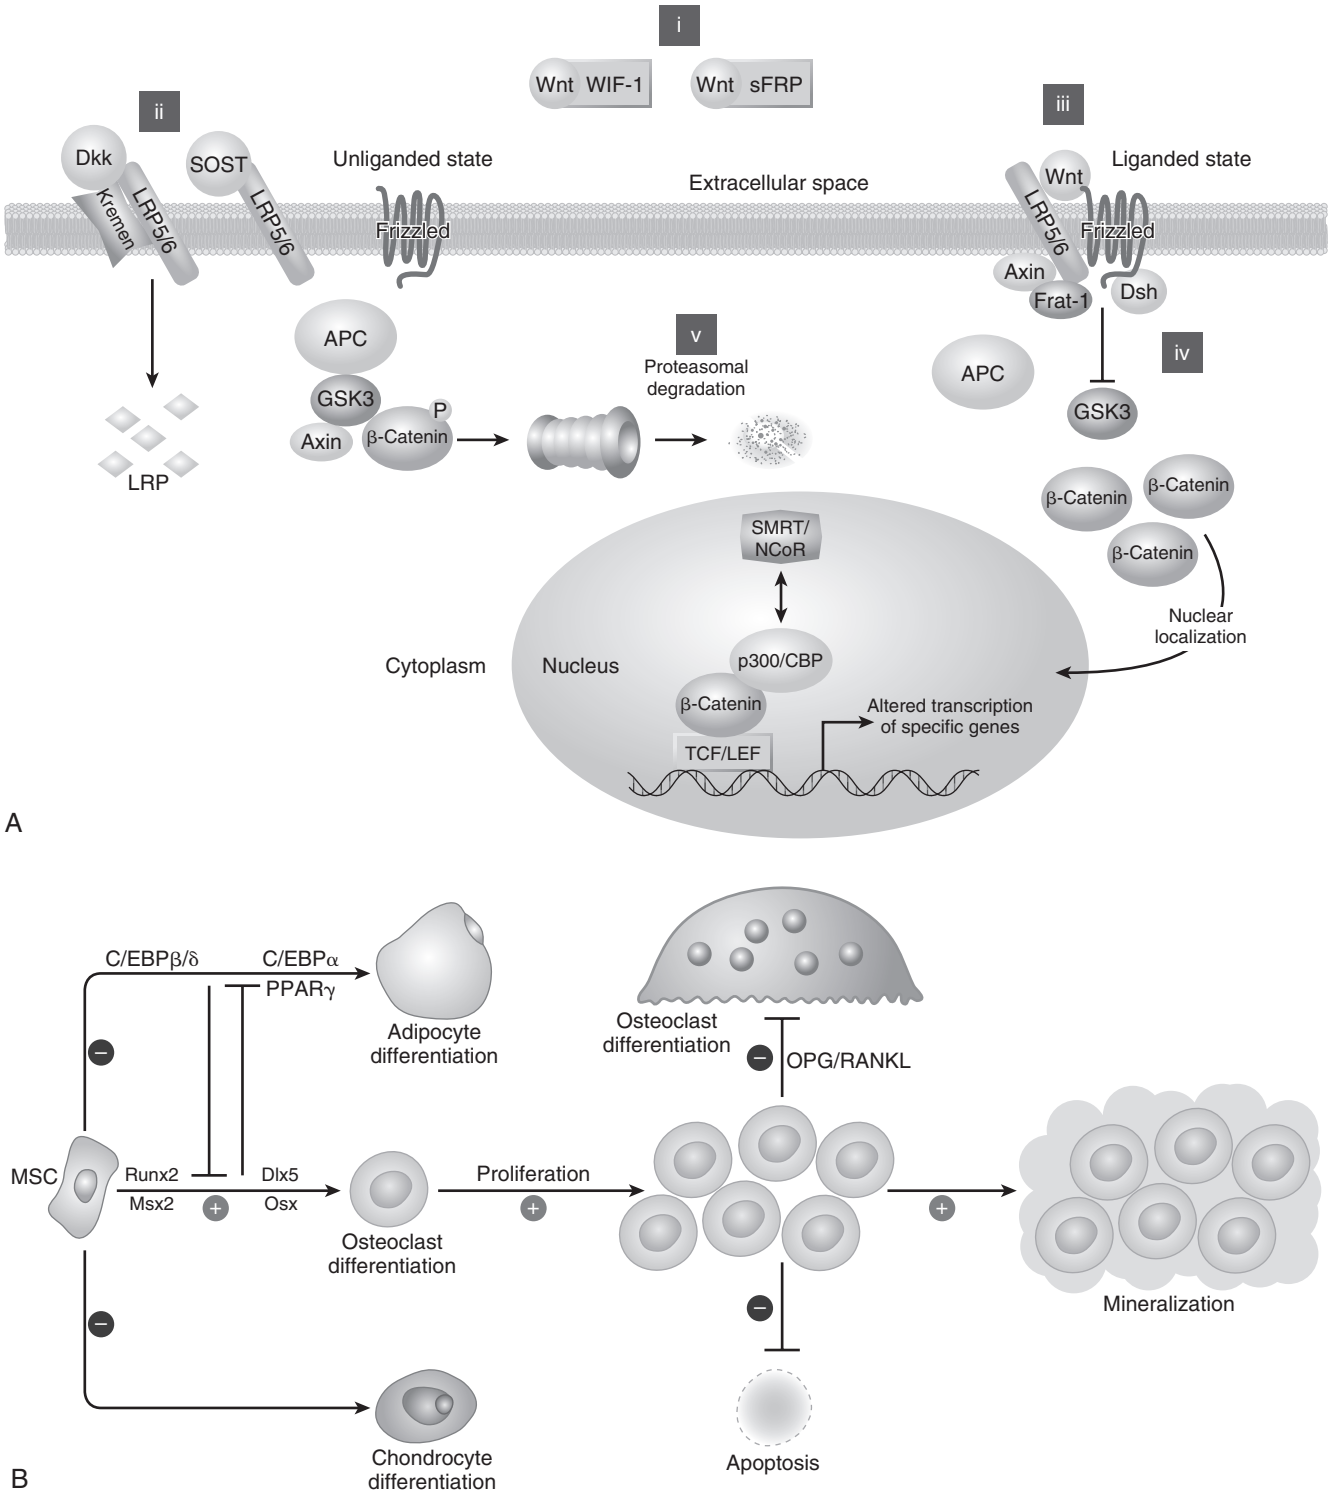

FIGURE 8-10 ■ Influence of WNT-β-catenin signal transduction pathway on osteoblastogenesis. When a WNT ligand binds to its Frizzled receptor and its coreceptors lipoprotein receptor-related proteins (LRP) 5/6, phosphorylation, and degradation of β-catenin cease, enabling its transport into the nucleus where it serves as a cofactor for the TCF/LEF transcription factor complex and enhances osteoblast differentiation. The WNT signaling system can be inhibited by binding of sclerostin (SOST) and Dikkopf (DKK) to the coreceptors and of WNT inhibitory factor (WIF1) and secreted frizzled-related protein (sFRP) to the WNT ligand. (See text for details.) (Reproduced from Krishnan, V., Bryant, H. U., & MacDougald, O. A. (2006). Regulation of bone mass by Wnt signaling. *J Clin Invest*, *116*, 1202–1209, with permission.)

plasma membrane. WNT binding to Frizzled and LRP 5/6 leads to intracellular signaling through canonical (β-catenin) and noncanonical (the $G\alpha_q$-protein and PLC) signal transduction pathways. The canonical signal transduction pathway is mediated by increasing cytosolic concentrations of β-catenin (encoded by *CTNNB1*) (see Figure 8-10).[149,169,171] β-Catenin is a transcription enhancing factor that in its free state enters the nucleus and associates with the T cell factor/lymphoid enhancer binding factor (TCF/LEF) transcription activating complex. In the inactive state in cytosol, β-catenin is bound to a multiprotein complex of adenomatous polyposis coli (APC), axin, and glycogen synthase kinase 3 (GSK3). Phosphorylation of β-catenin by GSK3 directs it into the degradative ubiquitin/proteasomal pathway. Binding of a WNT ligand to its Frizzled receptor and to its LRP 5/6 coreceptors leads to linking of the intracellular protein Disheveled-1 (encoded by *DVL1*) to the Frizzled receptor and to inhibition of GSK3-mediated phosphorylation of β-catenin, which slows its rate of degradation and releases it from binding to axin (encoded by *AXIN1*) increasing cytoplasmic levels of β-catenin and accelerating its transport into the nucleus.[169,172] In the nuclei of mesenchymal stem cells, β-catenin serves as a nuclear transcriptional cofactor by binding to TCF/LEF (thus displacing transcriptional corepressors and recruiting coactivating factors) and thereby stimulating expression of *RUNX2* (also termed core-binding factor alpha subunit 1 or CBFA1) and other target genes. RUNX2 activity may also be enhanced by WNT acting through a signaling pathway that is independent of β-catenin—that is, prostaglandin E_2 (PGE_2) is also able to activate *RUNX2* transcription.[170] In turn, RUNX2 serves as a transcription factor that stimulates the expression of *SP7* (encoding osterix). RUNX2 and SP7/osterix, a 431-amino-acid nuclear transcription factor, are essential for further differentiation of mesenchymal stem cells into osteoblasts and for their synthesis of osteocalcin (*BGLAP*) and collagen type I(α1) (*COL1A1*).[158,166] Osteocalcin plays an important role in normal mineralization of bone matrix. Other gene targets of RUNX2 include those encoding BMP4, FGFR1, Dickkopf, WNT10a, WNT10b, FGF18, and TGFβR1.[173] RUNX2 is not only central to initiation of osteoblastogenesis but also to its maintenance. WNT signaling increases the production of osteoprotegerin (OPG) by the stromal cell/osteoblast, a protein that inhibits osteoclastogenesis, thereby further increasing bone mass (discussed later).

Also essential for osteoblast differentiation and proliferation and, hence, normal bone development is FGF18. Expression of *FGF18* is directly stimulated by the WNT-Frizzled-LRP 5/6-β-catenin pathway through TCF/LEF.[174] Interestingly, the 5′ promoter site for TCF/LEF of *FGF18* also harbors a RUNX2 binding site. Thus, the WNT-Frizzled-LRP 5/6-β-catenin signal transduction system and RUNX2 coordinately enhance *FGF18* expression. FGF18 affects chondrogenesis, osteogenesis, and osteoclastogenesis. FGF18 inhibits chondrocyte proliferation and antagonizes the effects of BMPs acting through its cell surface tyrosine kinase receptor (FGFR3).[155,158] RUNX2 increases expression of the gene encoding TGFβ type 1 receptor through which TGFβ enhances the transcriptional activity of TCF/LEF.[170]

The WNT signaling pathway is opposed by several factors: secreted Frizzled-related proteins and WNT inhibitory factor 1 (encoded by *WIF1*) bind to WNT, thus interfering with ligand binding to its Frizzled receptor and to LRP 5/6; also, the complex of Dickkopf (encoded by *DKK*)/Kremen and sclerostin (encoded by *SOST*) binds to LRP 5/6, increasing their internalization and degradation and thus decreasing the number of LRP 5/6 coreceptors available for linkage to WNT and to its Frizzled receptor. Additionally, the axin-binding function of LRP5 is inhibited by binding of its extracellular domain to Dickkopf. WNT signaling results in an increase in the rates of osteoblast differentiation and proliferation, a decrease in the rate of osteoblast apoptosis, repression of mesenchymal stem cell differentiation into chondrocytes or adipocytes, and a decrease in osteoclastogenesis—the various processes summing to increase osteoblast number and hence the tempo of bone formation and remodeling.

Activating mutations of *LRP5* are associated with an autosomal dominant form of relatively benign high bone mass (OMIM ID: 601884) or, in some patients, autosomal dominant osteopetrosis type 1 (OMIM ID: 607634), whereas inactivating mutations of *LRP5* result in the autosomal recessive osteoporosis-pseudoglioma syndrome (OMIM ID: 259770) in which, in addition to decreased bone formation due to subnormal rate of osteoblast proliferation, the hyaloid vessels of the embryonic eye fail to regress.[175] (Some experimental data have suggested that it is expression of *LRP5* in the enterochromaffin cells of the intestinal tract [rather than in bone itself] that modulates bone mass through regulation of serotonin production by these cells.[176,177] In this proposed pathway, intestinal LRP5 negatively controls the production of tryptophan hydroxylase and consequently the synthesis of serotonin; thus, a loss of LRP5 results in increased serotonin synthesis and secretion by the enterochromaffin cells that is transported through the circulation to the bone osteoblasts where it inhibits osteoblast proliferation. However, these observations have not been supported by the studies of other investigators; currently, it has been concluded that LRP5 primarily acts locally in bone to regulate bone differentiation and mineralization.[178]) Experimentally, a loss of *Lrp6* also results in low bone mass; however, it but does not do so by impairing osteoblast function but rather by increasing osteoclastogenesis. LRP4, a third member of the LRP family, exercises an *inhibitory* influence on skeletal mineralization by enabling Dickkopf and sclerostin to interact with LRP 5/6.

Osteoblasts have a life span of 3 months. They are heterogeneous and express diverse genes that may be dependent or independent of the stage of the cell cycle and extent of differentiation.[167] The heterogeneity of osteoblasts may relate to the many different bone architectures and microenvironments in which they reside. Actively bone-forming osteoblasts have a large nucleus, plentiful Golgi apparatus, and abundant endoplasmic reticulum. When the rate of bone formation is low, osteoblasts are small and quiescent and incorporated into the endosteum separating bone mineral from marrow or into the undersurface of the periosteum. Differentiated, mature osteoblasts secrete collagenous and noncollagenous proteins including

collagen type I, bone-specific alkaline phosphatase, and the calcium and phosphate binding proteins—osteocalcin, osteopontin, and osteonectin—thus making bone matrix competent for mineralization.[179] Osteoblasts control mineralization of matrix by regulating local concentrations of phosphate through synthesis of cell membrane-bound alkaline phosphatase, which frees organically bound phosphate, and by reducing levels of inhibitors of bone formation such as pyrophosphates and the acidic serine aspartate-rich MEPE-associated motif (ASARM) peptide (discussed later). Calcium and phosphate can then precipitate in bone matrix as hydroxyapatite crystals.

When an osteoblast is surrounded by bone matrix, it is transformed into an osteocyte embedded in a bony lacuna, a process influenced by matrix metalloproteinases, dentin-matrix protein 1 (DMP-1), and other factors.[180] Within mature bone, osteocytes form a network of interconnected long cytoplasmic processes that lie within canaliculi that link with one another across gap junctions and connect deep osteocytes with newly formed osteocytes and with surface lining cells.[172] Osteocytes do not divide but have a half-life of approximately 25 years. They are capable of synthesizing a number of proteins including TGFβ, PHEX, DMP-1, matrix extracellular phosphoglycoprotein (MEPE), FGF23, and sclerostin. Although possibly capable of transiently destroying bone locally by osteocytic osteolysis, the primary roles of the osteocyte is to sense the mechanical load placed on the skeleton and the resultant deformation and strain (discussed later).[181] The osteocyte does so by monitoring movement of fluid and pressure within canaliculi within a basic multicellular unit (BMU) of osteoblasts and osteoclasts. In response to a strain, osteocytes synthesize a number of substances, some of which bring about the movement of osteoclasts and osteoblasts to the site of bone stress (e.g., microfracture) allowing the removal of injured bone and its replacement by new bone (bone remodeling), whereas others play an anabolic or catabolic role in the bone's response to mechanical loading and stress.[175]

Sclerostin (encoded by *SOST*) is a 213-amino-acid protein that binds LRP 5/6 and BMPs, thereby inhibiting WNT-LRP5/6-β-catenin–mediated osteoblast differentiation (see Figure 8-10) and suppressing bone formation; secondarily, sclerostin increases expression *RANKL*, thereby promoting osteoclastogenesis.[182] Sclerostin is primarily expressed and secreted by cortical and trabecular osteocytes in response to a decrease in mechanical forces ("unloading") exerted on the skeleton; as a consequence, the rate of bone formation decreases and that of bone resorption increases.[183] In response to mechanical loading, osteocyte expression of *SOST* decreases and the rate of bone formation increases. The inhibitory effect of mechanical loading on osteocyte production of sclerostin may be mediated by paracrine factors such as prostaglandins, nitric oxide, or oncostatin M (OMIM ID: 165095). In addition to mechanical forces, the expression of *SOST* or synthesis of sclerostin is suppressed by PTH functioning through PTH1R. (There is a high density of binding sites for carboxyl fragments of PTH on osteocyte membranes suggesting that these sequences may play a role in the mechanosensory activity of the osteocyte network.[75]) Estrogens, cytokines produced by osteoblasts and osteoclasts (oncostatin M, leukemia inhibitory factor, cardiotrophin-1, IL-33), prostaglandin E2, and hypoxia also suppress expression of *SOST*. Calcitonin, osterix, and TNFα exert a direct stimulatory effect on osteocyte expression of *SOST* and synthesis of sclerostin.

The "mechanostat" function of the osteocyte is indispensable for maintenance of optimal bone strength, mass, size, and shape. The stimulus for the functional adaptation of bone is mechanical strain ("the deformation of bone tissues that occurs with loading").[184,185] The magnitude of a strain is determined by its force, frequency, and distribution and is also dependent on the site on which the strain is exerted and by genetic characteristics of the individual on whom the mechanical load is placed. In response to mechanical deformation, fluid shifts in the lacunae and canaliculi provoke the osteocyte to release nitric acid and PGE_2 that recruit osteoblasts to the strain site where new bone is formed beneath the periosteum of long bones and on existing trabeculae (*formation modeling*). When mechanical force on bone is reduced (e.g., immobilization, bed rest, space flight), the rate of osteocyte apoptosis increases by uncertain mechanisms. The dying osteocyte releases both macrophage colony-stimulating factor (M-CSF) and soluble receptor activator of nuclear factor κB-ligand (sRANKL) leading to an increase in osteoclastogenesis and bone resorption (discussed later) primarily on the endosteal surface of long bones without a comparable increase in osteoblast-directed bone formation resulting in diminished cortical thickness and bone strength (*resorption modeling*). In sites of microfractures, signals (M-CSF, sRANKL) from dying osteocytes recruit osteoclasts that, in turn, attract osteoblasts for removal and reformation of bone, respectively (*targeted remodeling*).[185] Interestingly, bisphosphonates, sex steroids, and PTH prevent osteocytic apoptosis, a property that partially underlies the positive physiologic effects of these compounds on bone mass. The strain placed on long bones by muscular exertion and other forces (e.g., jumping) exerts a positive anabolic effect through stimulation of osteocyte function. The functional muscle-bone unit confers the ability of bone to modify its strength, mass, and shape in response to muscular force.[186]

$PTH^{1\text{-}84}$ functioning through PTH1R stimulates growth of osteoblast progenitor cells and inhibits apoptosis of osteoblasts and osteocytes, thereby enhancing bone formation and accounting for its therapeutic usefulness in treatment of osteopenic states; however, $PTH^{1\text{-}84}$ also promotes bone resorption by stimulating osteoblast production of RANKL, an osteoclast activating factor (discussed later). In osteoblasts, carboxyl terminal fragments of PTH affect the generation of alkaline phosphatase, procollagen I, and apoptosis, some of which effects may be opposite to those of $PTH^{1\text{-}84}$. Calcitriol, functioning through the nuclear VDR, increases osteoblast synthesis of several noncollagenous matrix proteins including osteocalcin. Glucocorticoids decrease bone mineralization by depressing osteoblast differentiation, function, and life span and by promoting osteocyte apoptosis. Glucocorticoids also enhance osteoclastogenesis and prolong their bone resorbing activity.[187] Estrogens stimulate osteoblast proliferation and synthesis of collagen type I and inhibit apoptosis of osteoblasts and osteocytes. Estrogens enhance trabecular and endosteal bone growth and exert a biphasic effect on

periosteal bone growth: in prepubertal children, small amounts of estrogens promote periosteal bone growth; in pubertal and adult subjects, estrogens oppose this process; estrogens also accelerate growth plate fusion and inhibit bone resorption—the latter by enhancing osteoclast apoptosis. Androgens primarily promote mineralization by conversion to estrogens, as evidenced by the osteopenia noted in adult males with aromatase deficiency or loss-of-function mutations in estrogen receptor-α (ERα).[188] Androgens also have a direct effect on bone mineralization; acting through the androgen receptor they increase periosteal bone growth during puberty in both males and females; however, the stronger bones of men compared to women reflect not increased volumetric bone mineral density but rather increased bone size due to greatly expanded periosteal bone width.[189] Increased periosteal bone width in males is due in part to the androgen-induced effect of increased muscle mass, strain, and mechanical loading on bones.[190] Nevertheless, estrogens too are necessary for normal periosteal bone growth as despite normal testosterone secretion the aromatase-deficient male has decreased periosteal bone width, a situation that can be reversed by administration of estrogen acting through ERα. A portion of the anabolic effects of estrogens and PTH on bone mineralization may be mediated through their stimulation of the GH/IGF-I axis. GH enhances the proliferation and differentiation of osteoblast precursors, whereas IGF-I increases osteoblast function and trabecular and cortical bone volume and decreases osteoblast and osteocyte apoptosis.[109,167] The endogenous GH secretagogue ghrelin promotes proliferation and differentiation of osteoblasts and bone mineralization in vivo.[191] Leptin secreted by adipocytes or osteoblasts acting locally in bone exerts anabolic effects and promotes bone formation. However, centrally active (hypothalamic ventromedial nucleus) leptin impairs bone formation (discussed later).[147]

Cortical or compact bone is present in the cranium, scapula, mandible, ilium, and shafts of the long bones; both its periosteal and endosteal surfaces are lined with layers of osteogenic cells. Cancellous (trabecular or spongy) bone is located in the vertebrae, basal skull, pelvis, and ends of the long bones. Because only 15% to 25% of trabecular bone volume is calcified (compared to 80% to 90% of cortical bone volume) and thus has a far greater surface area, trabecular bone is metabolically quite active; it has a high turnover rate, making it more vulnerable to disorders that adversely affect bone mineralization. In flat bones (skull, ilium, mandible), intramembranous ossification begins with the local condensation of mesenchymal cells that differentiate directly into preosteoblasts and osteoblasts and initiate the formation of irregularly calcified (woven) bone that is then replaced by mature lamellar bone. Membranous bones grow by apposition, a process supported by the development of new blood vessels induced by VEGF, a protein that also enhances bone formation.[192] The periosteum is a fibrous network in which osteoblasts synthesize peripheral compact bone; cortical bone reinforces bone strength and complements and extends that provided by trabecular and endosteal bone. Tendons and ligaments insert and are fixed into cortical bone.

Osteoclastogenesis

In addition to their pivotal role in bone formation, osteoblasts and bone marrow stromal cells regulate bone resorption by controlling the differentiation, maturation, and function of osteoclasts (Figures 8-11A and 8-11B). Osteoclasts are multinucleated giant cells that adhere to

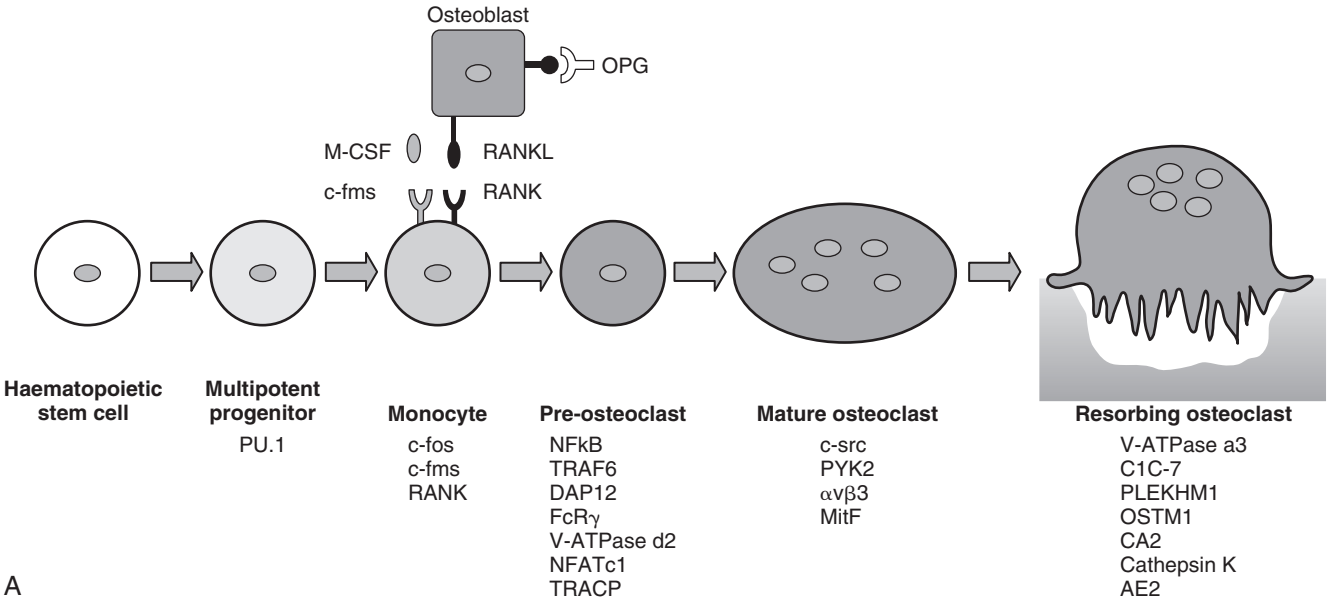

FIGURE 8-11 ■ **A,** Genetic regulation of osteoclastogenesis. After initial differentiation following exposure of a mesenchymal stem cell to M-CSF, RANKL synthesized by stromal cells and osteoblasts binds to RANK expressed on the plasma membrane of preosteoclasts which signals through SRC, TRAF6, and MAPK to enable NFκB and c-Fos to translocate NFATC1 to the nucleus where it assists in the maturation of the preosteoclast into a mature osteoclast and serves as a transcription factor for osteoclast-specific proteins (tartrate-resistant acid phosphatase, cathepsin K, β_3-integrin, calcitonin receptor).

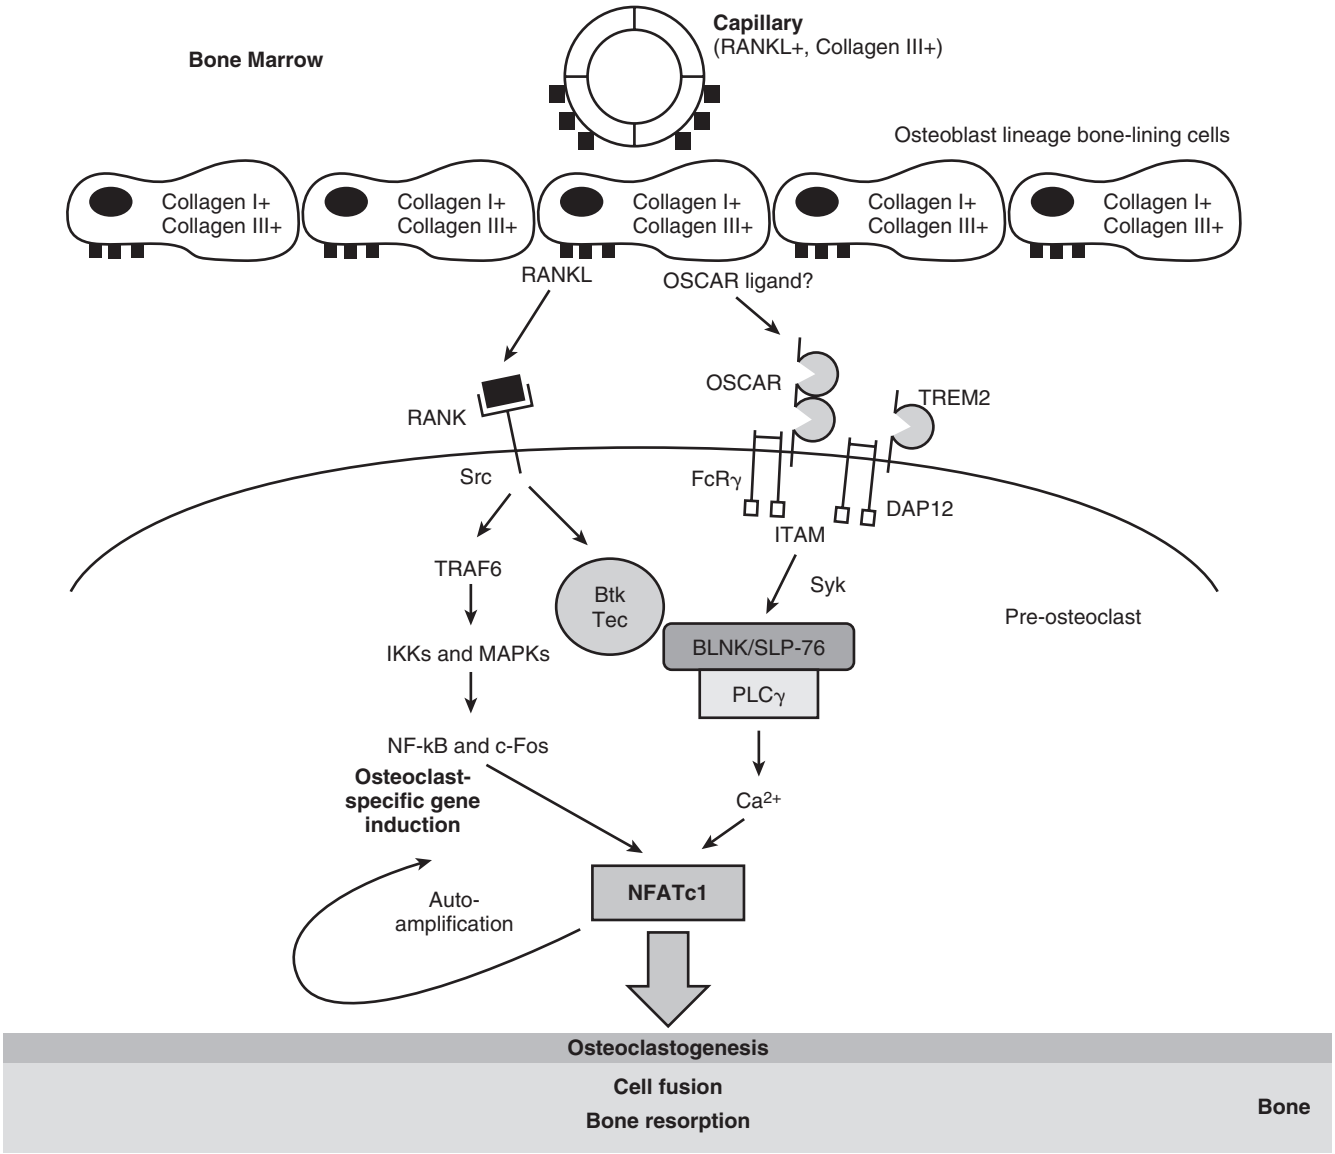

B

FIGURE 8-11, cont'd ■ B, RANKL produced by osteoblasts and stromal cells binds to RANK expressed on the surface of the osteoclast precursor cell; signal transduction trough TRAF6 and NFκB enables the translocation of NFATC1 into the nucleus and further maturation of the osteoclast. The costimulatory stimulus for osteoclastogenesis proceeds through OSCAR and TREM2, membrane proteins that recognize as ligands amino acid sequences within the structures of collagen types I and III. These receptors then signal through ITAM adaptors to stimulate PLCγ that converts membrane bound phosphatidylinositol to inositol triphosphate (and diacylglycerol) resulting in mobilization of Ca^{2+} from storage sites in the endoplasmic reticulum and increase in cytosolic Ca^{2+} concentrations that also activate NFATC1 and stimulate osteoclastogenesis. (See text for details.) BLNK, B-cell linker protein; ITAM, immunoreceptor tyrosine-based activation motif; NFATC1, nuclear factor of activated T cells, cytoplasmic, calcineurin-dependent 1; OSCAR, osteoclast-associated receptor; PLCγ, phospholipase Cγ; RANK, receptor activator of nuclear factor κB; RANKL, RANK ligand; LP-76, SH2 domain-containing leukocyte protein, 76 kD;TREM2, triggering receptor expressed on myeloid cells-2. (**A,** Reproduced from Henricksen R, Bollerslev J, Everts V, Karsdal MA [2001]. Osteoclast activity and subtypes as a function of physiology and pathology: implications for future treatments of osteoporosis. Endocr Rev 32:31-63, with permission. **B,** Reproduced from Barrow, A. D., Raynal, N., Andersen, A. L., et al. (2011). OSCAR is a collagen receptor that costimulates osteoclastogenesis in DAP12- deficient humans and mice. *J Clin Invest, 121*, 3505–3516, with permission.)

the surface of bone and form a subosteoclastic lacuna into which the osteoclast secretes hydrochloric acid to dissolve the mineral phase of bone (hydroxyapatite) and cathepsin K and matrix metalloproteinases to digest organic matrix.[193] Osteoclasts develop from hematopoietic stems cells of monocyte-macrophage lineage. In response to PTH (or PTHrP), calcitriol, IL-6 and -11, and several other cytokines (e.g., TNFα), and prostaglandins (discussed later), osteoblasts and bone marrow stromal cell synthesize both M-CSF and RANKL, essential stimuli for osteoclast differentiation.[187] Osteoblasts and stromal cells also synthesize a decoy acceptor protein for RANKL that inhibits osteoclastogenesis, osteoprotegerin (OPG). M-CSF, a cytokine that functions through its receptor, CSF1R/c-Fms, whose expression is induced by the transcription factor PU.1 (OMIM ID: 165170),

enables hematopoietic stem cells to differentiate into macrophage colony-forming units from which are derived macrophages and osteoclasts. M-CSF/CSF1R, signaling through the MAPK and PI3K3 transduction pathways, facilitates microphthalmia-associated transcription factor (MITF)-stimulated expression of the gene encoding B-cell leukemia/lymphoma 2 (Bcl-2), an anti-apoptotic factor that permits survival of osteoclast precursors. Subsequently, RANKL, a member of the TNF ligand superfamily encoded by *TNFSF11* and expressed on the surface of bone marrow stromal cells and osteoblasts, binds to M-CSF induced RANK expressed on the surface of osteoclast progenitor cells where it induces their further differentiation and activation.[187] RANKL is a 317-amino-acid protein composed of cytoplasmic (48 amino acids), transmembrane (21 amino acids), and extracellular (248 amino acids) domains with the binding site for RANK extending between amino acids 137 and 158. In the promoter region of *TNFSF11* is a response element for RUNX2, the osteoblast differentiating transcription factor. *RANKL* is also expressed in lymphoid tissue (where it is critical for development of the immune system), striated and cardiac muscle, lung, intestines, placenta, thyroid, prechondroblast mesenchymal cells, and hypertrophic chondrocytes. In addition to furthering osteoclast differentiation, RANKL enhances function of the mature osteoclast and inhibits its apoptosis. RANKL stimulates transcription of osteoclast-specific proteins such as tartrate-resistant acid phosphatase (TRAP), matrix metalloproteinase 9, carbonic anhydrase II, cathepsin K, the a3 subunit of vacuolar $[H^+]$-ATPase (encoded by *TCIRG1*), chloride channel 7 (encoded by *CLCN7*), osteopetrosis-associated transmembrane protein 1 (encoded by *OSTM1*), $\alpha_v\beta_3$-integrin, and the calcitonin receptor. RANKL also enhances the development of calcium resorption lacunae and pits (discussed later).[187] In RANKL knockout mice, loss of osteoclasts leads to osteopetrosis; because RANKL also affects differentiation and function of the immune system, these animals have thymic hypoplasia and lymph node agenesis. In humans, inactivating mutations of *TNFSF11* (encoding RANKL) and of *TNFRSF11A* (encoding RANK) result in osteopetrosis due to decreased osteoclast formation (OMIM ID: 259710 and 612310, respectively).[187] BMPs too stimulate osteoclast formation and function.[194]

By cell-to-cell interaction, RANKL expressed on the cell membrane of the stromal cell/osteoblast binds to RANK expressed on the cell membrane of osteoclast precursor cells. RANK, a member of the TNF receptor superfamily, is a 616-amino-acid protein with a signal peptide (28 amino acids), cytoplasmic domain (383 amino acids), transmembrane domain (21 amino acids), and extracellular domain (184 amino acids) that is expressed in osteoclasts, fibroblasts, and B and T lymphocytes. Binding of RANKL to RANK leads to transmission of an intracellular signal through SRC (OMIM ID: 190090), adaptor proteins that associate with RANK including TNF receptor-associated factor (TRAF) 6 (OMIM ID: 602642) and GRB2-associated binding protein (GAB) 2 (OMIM ID: 606203), and subsequently through c-Jun N-terminal kinases (JNK; members of the MAPK family) to activate NFκB and c-Fos (encoded by *FOS*), the latter a component of the activator protein-1 (AP-1) transcription factor complex (see Figure 8-11B).[195] The expression of c-Fos is regulated by Ca^{2+}/calmodulin-dependent protein kinases (CaMKs, OMIM ID: 604998) and cyclic AMP-responsive element binding protein (CREB, OMIM ID: 123810). NFκB, a family of five dimeric transcription factors of which NFκB1 and NFκB2 are crucial for osteoclastogenesis, is activated by degradation of the inhibitor of κB (IκB, OMIM ID: 164008), a protein that traps NFκB in the cytoplasm and is itself destroyed through the ubiquitination/proteasomal pathway after phosphorylation of its serine residues. Free NFκB then acts via c-Fos and AP-1 to stimulate osteoclastogenesis in concert with the 827-amino-acid master osteoclastogenic transcription factor–nuclear factor of activated T cells, cytoplasmic, calcineurin-dependent 1 (NFATC1, OMIM ID: 600489).[193,195]

Movement of NFATC1 from the cytoplasm into the nucleus is facilitated by calcineurin, a serine/threonine phosphatase activated by cytosolic Ca^{2+}; calcineurin is composed of a Ca^{2+}-binding protein and a calmodulin-binding catalytic subunit (encoded by *PPP3CA*, OMIM ID: 114105). Exposure of the nuclear localization signal of NFATC1 by dephosphorylation of its serine residues enables its translocation into the nucleus. Nuclear NFATC1 then interacts with AP.1, PU.1, MITF, and CREB in a transcriptional complex that stimulates expression of genes encoding osteoclast-specific proteins (e.g., TRAP, cathepsin K, β3 integrin, calcitonin receptor, OSCAR) and leads to terminal differentiation of osteoclasts.[195] RANKL/RANK signaling also stimulates tyrosine kinases (BTK [OMIM ID: 300300], TEC [OMIM ID: 600583]) that form an osteoclastogenic signaling complex with the adaptor protein BLNK (OMIM ID: 604515) that activates PLCγ leading to cleavage of membrane phosphatidylinositol-4,5- bisphosphate into DAG and IP_3, the latter mobilizing Ca^{2+} from intracellular storage sites within the endoplasmic reticulum resulting in increased cytosolic Ca^{2+} levels and activation of calcineurin and NFATC1.[196] In the preosteoclast, there is an essential costimulatory signaling system of immunoglobulin-like receptors through which NFATC1 is also activated. The osteoclast-associated receptor (OSCAR) and the triggering receptor expressed on myeloid cells (TREM)-2 are transmembrane costimulatory receptors expressed on the plasma membrane of preosteoclasts whose ligands are sequences of amino acids (. . . GPOGPX(GFX(. . .) derived from collagens types I, II, and III of extracellular matrix to which preosteoclasts are exposed at sites of bone formation (see Figure 8-11B).[195] The costimulatory receptors associate with intracellular adapter proteins that contain an immunoreceptor tyrosine-based motif (ITAM) such as the Fc receptor common γ subunit (FcRγ, OMIM ID: 147139) and DNAX-activating protein of 12 kDa (DAP 12, OMIM ID: 604142) that are phosphorylated by RANKL/RANK signaling. The complex of costimulatory receptors and ITAM-containing intracellular factors contribute to activation of NFATC1 by enhancing PLCγ activity working through spleen tyrosine kinase (SYK, OMIM ID: 600085) and BLNK, thus integrating the functions of the RANKL/RANK and OSCAR/ITAM signal transduction

systems.[193,195,196] Interestingly, NFATC1 autoamplifies its own expression by linking to an NFAT-binding site within the promoter region of *NFATC1*, a site that is activated by epigenetic mechanisms that regulate histone acetylation and methylation.[193]

During osteoclast differentiation, preosteoclast cell membranes fuse, forming the mature multinucleated giant cell osteoclast. Maturing osteoclasts develop circumferential podosomes (adhesion structures with abundant actin that can degrade matrix) that are critical for cell-cell fusion, a process requiring tyrosine phosphorylation of the adaptor proteinTks5 by PI3K and Src.[197,198] Syncytin-1 (OMIM ID: 604659), a plasma membrane protein, also plays a role in osteoclast fusion, as do f-actin and adhesion factors such as E-cadherin and integrins.[199,200] In addition to the contribution of the endoplasmic stores of Ca^{2+} to cytosolic Ca^{2+} concentrations, extracellular Ca^{2+} enters the differentiating and mature osteoclast through transient receptor potential (TRP) cation channels 4 and 5.[193] TRPV4 plays a role in osteoclast differentiation, whereasTRPV5 is important for the functional activity of the mature osteoclast. In the subosteoclast resorption lacuna, Ca^{2+} levels exceed 40 mM (serum Ca^{2+} values range between 1.1 and 1.3 mM); consequently, as intraosteoclast Ca^{2+} concentrations rise, bone resorbing activity is inhibited, and the osteoclast ages and dies. Concurrently, the high Ca^{2+} environment around the resorption lacuna attracts osteoblasts that produce the bone needed to fill the lacuna. Thus, the processes of bone resorption and formation are likely coupled by lacunar levels of Ca^{2+}.

OPG (OMIM ID: 602643) is a member of the TNF receptor superfamily and is synthesized and secreted by the stromal cell/osteoblast; it acts as a "decoy" receptor by binding to RANKL, thus inhibiting the interaction of RANKL and RANK and thereby osteoclastogenesis.[201] The 5 exon gene (*TNFRSF11B*) encoding human OPG is expressed also in the lung, liver, heart, kidney, intestinal cells, brain, thyroid, lymphocytes, and monocytes. Human OPG is synthesized as a 401-amino-acid propeptide; after cleavage of the 21-amino-acid signal peptide the mature protein of 380 amino acids contains 4 cysteine-rich amino terminal domains and two carboxyl terminal "death" domains; it is glycosylated and released into the paracellular space as a disulfide-linked homodimer. The synthesis of OPG is enhanced by IL-1α and -1β, TNFα, TNFβ, BMP-2, TGFβ, and estrogen, and it is antagonized by calcitriol, glucocorticoids, and PGE_2. Through binding to RANKL on the surface of the stromal cell/osteoblast or to its circulating secreted form, OPG inhibits the osteoclast activating and bone reabsorbing effects of calcitriol, PTH, and the interleukins. Overexpression of OPG in transgenic mice leads to osteopetrosis, whereas its knockout is associated with loss of cortical and trabecular bone and osteoporosis, multiple fractures, and hypercalcemia; the latter model is the experimental counterpart of juvenile Paget disease (OMIM ID: 239000).[202] OPG also binds to and neutralizes the TNF-related apoptosis-inducing ligand (TRAIL), a product of T lymphocytes that transduces apoptotic signals, and thus OPG is also likely to be a cell survival factor.[201]

When mature osteoclasts attach to bone, the inferior surface of the osteoclast develops a ring structure composed of β-actin filaments and $\alpha_v\beta_3$ integrins that bind to matrix-embedded osteopontin and other components that contain the amino acid sequence—Arg-Gly-Asp (RGD)—thereby forming a sealed zone and creating an isolated microenvironment between the osteoclast's inferior cell membrane and the outer bone surface, the resorption lacuna (Figure 8-12).[187] The inferior or apical surface of the osteoclast within the sealed zone develops an irregular ruffled border through which are secreted products of the

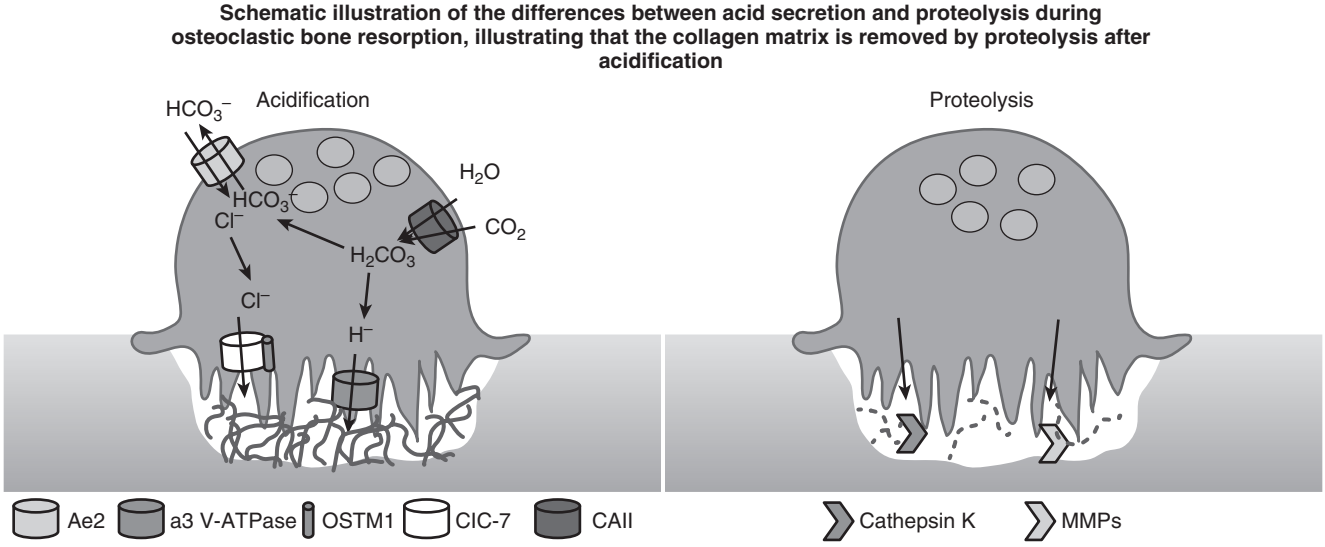

FIGURE 8-12 ■ Differentiated osteoclasts form a ruffled border by adhering to bone surface through αvβ3 integrin receptors. A subosteoclast lacuna is formed by the dissolution of bone mineral by osteoclast secreted hydrochloric acid (left panel) and the resorption of organic bone matrix by cathepsin K and matrix metalloproteins (right panel). Subsequently, osteoblasts are attracted to this pit (by the high local Ca^{2+} concentrations) as new bone is formed in the continuing process of bone remodeling. (Reproduced from Henricksen, R., Bollerslev, J., Everts, V., & Karsdal, M. A. (2011). Osteoclast activity and subtypes as a function of physiology and pathology: implications for future treatments of osteoporosis. *Endocr Rev, 32*, 31–63, with permission.)

osteoclast. Into the isolated sealed resorption lacuna the osteoclast pumps (1) acid (H^+ or protons) generated from carbon dioxide by carbonic anhydrase II (encoded by *CA2*) and actively transported via a vacuolar type ATPase proton pump (encoded by *TCIRG1*) and chloride ions passively transmitted through a chloride channel (encoded by *CLCN7*) that functions as a proton-chloride antiporter to form a highly acidic (pH 4.5) milieu that dissolves hydroxyapatite, the mineral phase of bone, and (2) lysosomal proteolytic enzymes (such as the cysteine proteases—cathepsins K, B, and L—and collagenases such as matrix metalloproteinase [MMP] −9 [OMIM ID: 120361]) that digest osteoid, the protein matrix of bone.[187,203] Osteopetrosis-associated transmembrane protein 1 (encoded by *OSTM1*) is a 334-amino-acid protein that is essential for normal processing of CLCN7 and hence for normal acidification of the subosteocytic resorption lacuna and consequent dissolution of hydroxyapatite. Osteopetrosis associated with large numbers of osteoclasts develops in patients with loss-of-function mutations in the genes encoding carbonic anhydrase II (OMIM ID: 259730), the vacuolar ATPase proton pump (OMIM ID: 259700), the chloride channel (OMIM ID: 166600, 611490), or its associated protein, OSTM1 (OMIM ID: 259720), whereas inactivating mutations in the gene encoding cathepsin K lead to pycnodysostosis (OMIM ID: 265800).[187] After the osteoclast contacts bone, it functionally polarizes into two realms: the inferior portion of the osteoclast above the ruffled membrane transports protons, chloride ions, and enzymes from the interior of the cell into the subcellular space and reabsorbs the products degraded by these agents; the superior portion of the osteoclast processes and excretes the reabsorbed materials. TRPV5, the calcium channel required for intestinal and renal tubular absorption/reabsorption of calcium, is also found on the ruffled membrane of the osteoclast.[22] Experimental disruption of *Trpv5* leads to osteoclast dysfunction and impaired ability to reabsorb calcium from bone. Paradoxically, however, *Trpv5*$^{-/-}$ mice are not osteopetrotic; rather, they are osteopenic due to excessive renal loss of calcium. *Trpv4* is also expressed in osteoclasts, and *Trpv4*$^{-/-}$ mice are osteopetrotic as osteoclast maturation is impeded. Multiple osteoclast subtypes have been described whose individual function depends on the genes the osteoclast expresses, the anatomic location of the osteoclast, and the functional response of the osteoclast to exogenous agents.[187] Thus, there are subtle distinctions between endochondral and membranous bone osteoclasts, trabecular and cortical osteoclasts, and osteoclasts involved in targeted and stochastic bone remodeling. (Targeted bone remodeling occurs locally and involves replacement of damaged bone by new bone in order to maintain bone strength; stochastic bone remodeling occurs systemically in response to PTH released as the Ca^{2+}_e concentration falls; it maintains and perhaps increases bone integrity.)

$PTH^{1\text{-}84}$, PTHrP, calcitriol, thyroid hormone, IL-1β, -3,-6, and -11, TNFα, PGE_2, and glucocorticoids stimulate expression of RANKL and M-CSF and depress that of OPG and hence favor osteoclast development and bone resorption. Calcitonin, estrogen, interferon-γ, IL-4, -10, and -18, TGFβ, and bisphosphonates antagonize these processes.[204] Estrogens, acting through nuclear ERα, maintain and augment bone mass by inhibiting its dissolution by suppressing T-cell production of osteoclast activating cytokines such as IL-1, -6, and TNFα and by suppressing expression of RANKL and increasing that of TGFβ. Additionally, estrogens interfere with RANKL/RANK–stimulated intracellular signal transduction through MAPK and also down-regulate expression of *ITGB3* (encoding $\alpha_v\beta_3$ integrin).[187] Calcitonin acting through its GPCR dissociates the processes of bone resorption and bone formation by transiently depressing the bone-resorbing activity of osteoclasts; it does so by impeding formation of the ruffled membrane. Although osteoclasts do not express *PTH1R*, $PTH^{1\text{-}84}$ enhances osteoclastogenesis by stimulating osteoblast and stromal cell production of RANKL. However, when $PTH^{1\text{-}34}$ is administered intermittently, it increases osteoblast activity and the rate of bone formation and slows the rate of osteoblast apoptosis, functioning in part through IGF-I. Interestingly, carboxyl terminal fragments of $PTH^{1\text{-}84}$ can inhibit osteoclast formation and function and antagonize the osteoclast stimulating effects of $PTH^{1\text{-}84}$, calcitriol, prostaglandins, and interleukins.[75] GH acting through IGF-I increases bone mass both by increasing bone size as well as the size and strength of muscles; it also stimulates intestinal calcium absorption (through activation of 25-hydroxyvitamin D-1α-hydroxylase and synthesis of calcitriol) and renal phosphate retention.

Bone modeling is accomplished by the independent action of osteoblasts and osteoclasts and is not dependent on prior bone resorption.[152] Bone remodeling is the process during which the strength, structure, and function of bone are renewed; bone resorption and deposition are sequentially linked. Bone remodeling is accomplished within the BRU of designated osteoclasts and osteoblasts; it is a continuous process in which old cancellous and cortical bone is reabsorbed and replaced by new bone and takes place in the growing as well as the mature skeleton. The BRU is 1 to 2 mm in length, 0.2 to 0.4 mm in width, led by osteoclasts, and trailed by osteoblasts; in the adult skeleton the life span of the BRU is 6 to 9 months and 10% of the skeleton is turned over each year. The site selected for remodeling is targeted by osteocytes sensing a mechanical or stress defect. Bone remodeling occurs in four stages: (1) *activation*, in which osteoclast precursor cells target a resting bone surface, evolve into osteoclasts, convert the area into a BRU composed of a subosteocytic bone resorption lacuna, and initiate (2) bone *resorption*, during which the mineral phase of bone is solubilized by acid and the protein component degraded by proteases; when complete the osteoclast dies; this phase is followed by (3) *reversal*, in which monocytes, osteocytes, and osteoblasts attracted to the BRU through their detection of the high Ca^{2+} concentrations in the resorption lacunae and by growth factors (IGF-I and -II, TGFβ, BMP) released from the matrix or secreted by osteoclasts enter the area of reabsorbed bone and initiate (4) renewed bone *formation*, by secreting osteoid, increasing local concentrations of calcium and phosphate to levels that exceed their solubility and degrading ASARM peptides, pyrophosphates, and proteoglycans that inhibit mineralization. The majority of osteoblasts and osteoclasts in the BRU are eliminated by programmed cell death, apoptosis, whereas some osteoblasts develop into osteocytes.

Bone Extracellular Matrix and Mineralization

Organic matrix proteins comprise 35% of bone, and type I collagen makes up 90% of these proteins.[179] Type I collagen is composed of a coiled triple helix of two polypeptide chains of collagen type I(α1) and one of type II(α2) that are cross-linked intra-molecularly by disulfide bonds and intermolecularly at the amino (N) and carboxyl (C) telopeptides by pyridinium compounds that permit bundling of collagen molecules into fibrils and fibers (Figures 8-13 and 8-14).[205,206] Every third amino acid in the collagen α peptides is glycine, which permits the chains to coil; proline, hydroxyproline and hydroxylysine are also incorporated in large quantities. Proline is hydroxylated to 4-hydroxyproline and 3-hydroxyproline by prolyl 4-hydroxylase and prolyl 3-hydroxylase-1 (P3H1), respectively; lysine is hydroxylated by lysyl hydroxylase and some hydroxylysine residues are glycosylated. P3H1 (also termed leprecan, encoded by *LEPRE1*) is an enzyme

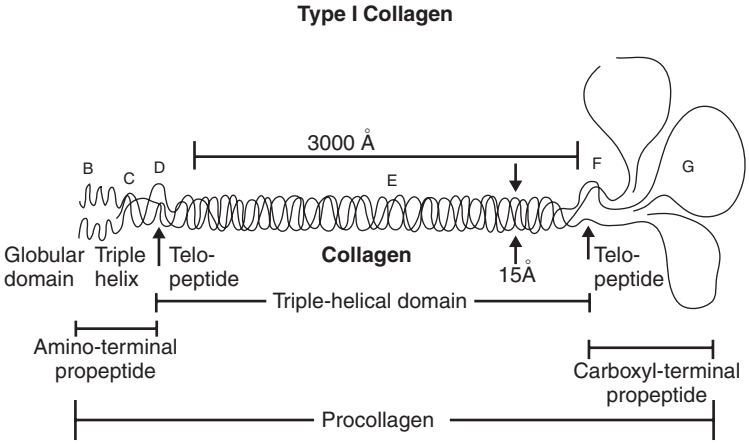

FIGURE 8-13 ■ Type I collagen is synthesized in the endoplasmic reticulum of osteoblasts as a larger procollagen molecule with amino (N) and carboxyl (C) terminal extensions that are cleaved into carboxyl (PICP) and amino (PINP) terminal propeptides after secretion of procollagen type I into extracellular matrix. Mature type I collagen is a coiled triple helix of two polypeptide chains of collagen α1(I) and one of α2(I) that are cross-linked intramolecularly by disulfide bonds and intermolecularly at the N and C terminals by nonhelical pyridinium telopeptides. (Reproduced from Byers, P. H. (1995). Disorders of collagen biosynthesis and structure. In C. R. Scriver, A. L. Beaudet, W. S. Sly, D. Vale (Eds.), *The metabolic and molecular bases of inherited disease* (pp. 4029–4077) (7th ed.). New York: McGraw-Hill, with permission.)

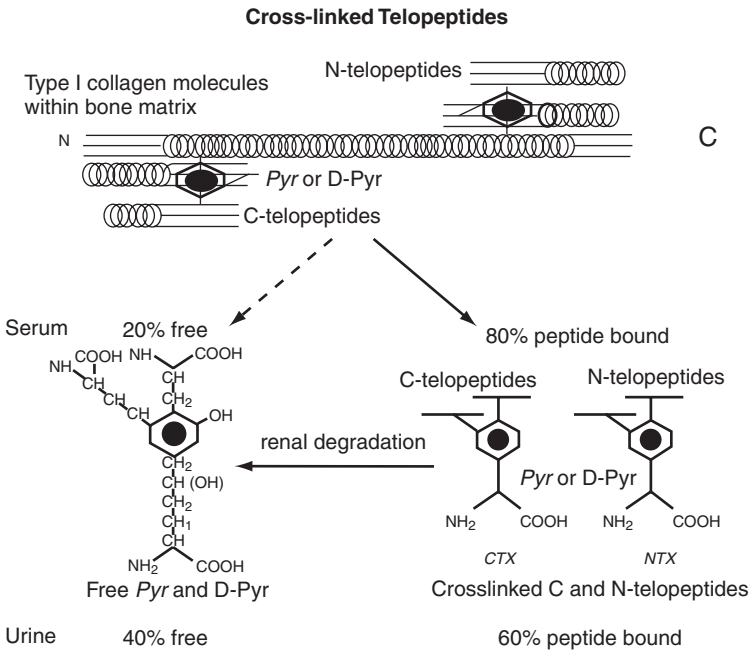

FIGURE 8-14 ■ Pyridinium and telopeptides of collagen. Pyridinoline (Pyr, hydroxylysyl-pyridinoline) and deoxypyridinoline (D-Pyr or Dpd, lysyl-pyridinoline) form nonreducible pyridinium cross-links between mature collagen fibers rendering them insoluble. Amino (N-) and carboxyl (C-) terminal regions (NTX, CTX) of collagen are proteolytically removed during degradation of mature collagen and secreted into extracellular space and serum. The carboxyl terminal telopeptide of type I collagen (ICTP) is a marker of collagen type I degradation. (Reproduced from Garnero, P., & Delmas, P. D. (1998). Biochemical markers of bone turnover: applications for osteoporosis. *Endocrinol Metab Clin NA, 27*, 303–323, with permission.)

that specifically hydroxylates *only* the proline residue at codon 986 in bone collagen type I(α1), a reaction that requires interaction of P3H1 with cartilage-associated protein (encoded by *CRTAP*) and cyclophilin B (encoded by *PIPB*). *CRTAP* is expressed in the proliferative zone of developing cartilage and at the chondro-osseous junction; cyclophilin B is a peptidyl-prolyl cis-trans isomerase. That posttranslational modifications of collagen type I(α1) are essential for normal bone formation is evidenced by the association of inactivating mutations of *CRTAP* with osteogenesis imperfecta types IIB (OMIM ID: 610854) and VII (OMIM ID: 610682) and of *LEPRE1* with osteogenesis imperfecta type VII.[207,208,209] Amino and carboxyl terminal extensions of the propeptides of collagen are removed by proteolysis during formation of the mature collagen molecule and are partially secreted into extracellular space and serum. Pyridinoline (PYR; hydroxylysyl-pyridinoline) and deoxypyridinoline (DPD; lysyl-pyridinoline) form nonreducible pyridinium crosslinks between mature collagen fibers thus making them insoluble (see Figure 8-14). Type I collagen predominates in bone but is also present in ligaments, tendons, fascia, and skin. Type II cartilage is composed of three procollagen type II(α1) chains and is primarily deposited in cartilage. Type III collagen (three procollagen type III[α1] chains) is present in bone, tendons, arteries, and intestine, and type IV (three procollagen type IV[α1]) cartilage is a component of cell basement membranes.

Measurement of serum (and urine) concentrations of markers of bone formation and bone resorption provide information about bone turnover in adults and children (Figure 8-15).[210] Assessment of serum levels of soluble (s) RANKL and OPG reflect osteoblast function as related to osteoclastogenesis.[211] Serum levels of soluble RANKL are higher in male children and adolescents and increase with age in both genders; the median concentration in males is 0.27 pmol/L (range nondetectable to 0.94) and in females it is 0.08 pmol/L (range nondetectable to 1.42). Serum concentrations of OPG do not vary with age or gender in children and adolescents; the median concentration of OPG is 3.7 pmol/L (range 1.02 to 6.63). Determination of the procollagen I extension peptides

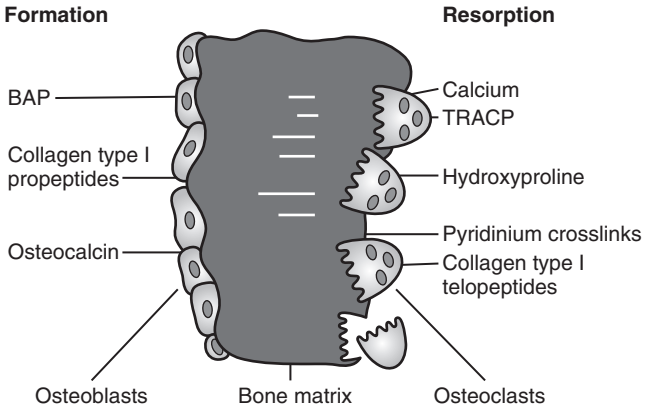

FIGURE 8-15 ■ Biochemical markers of bone formation and resorption. (Reproduced from Jurimae, J. (2010). Interpretation and application of bone turnover markers in children and adolescents. *Curr Opin Pediatr, 22,* 494–500, with permission.)

procollagen type I carboxyl terminal propeptide (PICP) and procollagen type I amino terminal propeptide (PINP) reflect collagen synthesis and thus osteoblast function, as does determination of the osteoblast products: osteocalcin and bone-specific alkaline phosphatase. Degradation of mature bone matrix collagen type I by osteoclast-secreted cathepsin K and matrix metalloproteinases releases pyridinoline (PYR), deoxypyridinoline (DPD), and the amino terminal (NTX) and carboxyl terminal (ICTP) telopeptides of type I collagen. The urinary excretion of hydroxyproline and hydroxylysine and measurements of PYR, DPD, NTX, CTX, and ICTP in urine or serum reflect catabolism of collagen type I and thus bone resorption. Osteoclast activity is also reflected by measuring serum concentrations of tartrate-resistant acid phosphatase type 5b isoform (TRAP5b).[210] In the normal pregnant woman, serum concentrations of sRANKL, OPG, and ICTP are highest in the second trimester, whereas osteocalcin values are maximal in the first trimester, suggesting that early in normal pregnancy the rate of bone formation is increased, whereas in the second trimester, the rate of bone resorption is amplified.[212] Serum levels of markers of both bone formation and resorption are higher in the fetus than mother (Table 8-5).[212-214] Fetal umbilical cord plasma PICP concentrations are highest in midgestation and decline in the last trimester to term values; after birth PICP values fall in preterm neonates during the first 3 days of life and then increase steadily to peak values at 36 weeks postconceptual age; PICP levels in cord plasma are higher in males than females and correlate with gestational age and birth weight.[214] In general, values of bone formation and resorption markers are highest in infants, fall during childhood, increase slightly during adolescence, and then decline to adult levels (Tables 8-6A and 8-6B).[210,215-220] In children and adolescents, serum concentrations of markers of bone turnover are unrelated to the body mass index (BMI); however, age and gender significantly influence values of serum bone markers with higher levels in younger subjects and earlier decline in values in females than in males.[218]

Serum concentrations of sclerostin reflect the function of osteocytes but vary with the assay employed.[221] Values of serum sclerostin are generally higher in healthy adult males than females (50 versus 37 pmol/L) and rise two to fourfold with aging; depending on age and gender, serum concentrations of sclerostin may correlate positively with bone mineral content and density (BMC, BMD) and negatively with serum levels of calcium, bone alkaline phosphatase, PINP, osteocalcin, and ICTP. Sclerostin values are decreased by physical activity and increased by immobilization. They are elevated in patients with hypoparathyroidism and decline after intermittent administration of PTH[1-34].[222-226] Serum sclerostin concentrations are higher in boys (median ~23 pmol/L) than girls (median ~19 pmol/L), peak at 10 years of age in girls and 14 years in boys, and fall during puberty in both sexes.[219]

The adult skeleton is composed of mineral (50% to 70%), organic matrix (20% to 40%), water (5% to 10%), and lipids (< 3%). Ten to 15 percent of bone matrix is composed of noncollagenous peptides secreted by the osteoblast including proteoglycans (chondroitin sulfate,

heparan sulfate), glycoproteins, growth stimulating proteins (BMP, TGFβ, IGF-I), cell attachment peptides (integrin ligands: osteopontin, osteonectin, fibronectin), and γ-carboxylated (Gla) proteins or proteins derived from serum (e.g., albumin).[179] Macromolecular proteoglycans are composed of glycosaminoglycans (acidic polysaccharide side chain) linked to a core protein and are important for normal synthesis of collagen and bone development. Osteonectin (encoded by *SPARC*) is a phosphorylated, 32-kDa glycoprotein that binds to Ca^{2+} in hydroxyapatite and to collagen fibrils enabling calcification of bone matrix. Bone alkaline phosphatase is an isoform of tissue nonspecific alkaline phosphatase (encoded by *ALPL*), an 80-kDa glycoprotein essential for bone mineralization (discussed earlier). Osteopontin (also termed bone sialoprotein or secreted phosphoprotein 1 and encoded by *SPP1*) is a 75-kDa sulfated and phosphorylated glycoprotein that contains the amino acid sequence—Arg-Gly-Asp (RGD)—necessary for linkage to integrins and hence for attachment of osteoclasts to bone; it also binds Ca^{2+} and hydroxyapatite and may play a role in the initiation of bone matrix mineralization. Osteopontin is secreted by osteoblasts in response to calcitriol. Osteocalcin (encoded by *BGLAP*) is a 49-amino-acid, γ-carboxylic acid–containing 6-kDa peptide that plays an essential role in bone mineralization; it is produced only by osteoblasts in response to BMP-7 and calcitriol acting through RUNX2, whereas its posttranslational synthesis is dependent on vitamin K. Interestingly, osteocalcin also regulates synthesis of testosterone by the testicular Leydig cell and stimulates release of insulin by pancreatic beta cells and adiponectin by white adipose tissue.[177,227,228]

Bone Mineralization

Although calcium and phosphate are costored in extracellular and intracellular fluid compartments, they are prevented from precipitating by inhibitors of precipitation such as polyphosphates (polymeric groups of phosphate anions linked together by oxygen bridges in linear chain or cyclic ring structures), pyrophosphate (the first member of a series of polyphosphates that is composed of two phosphate groups linked by an oxygen bridge), organic ion chelators (oxalate, citrate), and proteins (e.g., osteocalcin, osteopontin, SIBLING proteins).[6] (Pyrophosphate is generated by ectonucleotide pyrophosphatase/phosphodiesterase 1 [encoded by *ENPP1*] mediated cleavage of nucleotides.) Controlled formation and deposition of hydroxyapatite into the extracellular matrix of cartilage (collagen types II and X) and bone (collagen type I) occurs when the inhibitors of biomineralization are degraded locally. In the first phase of bone formation, hypertrophic chondrocytes and osteoblasts initiate bone crystal formation by generating 100-nm subsurface matrix vesicles containing calcium, phosphate, TNSALP, calbindin-D_{9K}, carbonic anhydrase, pyrophosphatases, osteocalcin, and osteopontin. TNSALP, synthesized by chondrocytes and osteoblasts and packaged within vesicles, is tethered

to the vesicular wall through the complex glycolipid, glycosylphosphatidylinositol. After the multipass transmembrane protein ANK (OMIM ID: 605145) transports pyrophosphate into the extracellular matrix, TNSALP cleaves inorganic phosphate from pyrophosphate and other polyphosphates, thereby increasing local phosphate concentrations. Phospho 1 (encoded by *PPP1R1B*) is a phosphatase present within matrix vesicles that when extruded from the matrix vesicle raises local levels of phosphate by releasing it from phosphoethanolamine and phosphocholine. After initial precipitation of calcium and phosphate as amorphous calcium phosphate within the matrix vesicles themselves, its extrusion into the extracellular matrix, and further increases in local concentrations of phosphate and Ca^{2+}; the structural properties of collagen fibrils direct the formation of the hydroxyapatite crystal.[6]

Mineralization of bone is partially dependent on the extent of phosphorylation of osteopontin; when 40% of the phosphorylation sites of osteopontin are phosphorylated bone mineralization is inhibited; when 95% of its sites are phosphorylated hydroxyapatite formation is promoted.[179,229] Matrix GLA protein, an 84-amino-acid vitamin K–dependent peptide containing γ-carboxylated glutamate that is related to but distinct from osteocalcin and encoded by *MGP*, has great affinity for Ca^{2+} and inhibits precipitation of calcium and phosphate; *MGP* is expressed in arteries and chondrocytes but not in osteoblasts; in patients with biallelic loss-of-function nonsense mutations in *MGP*, there is extensive calcification of cartilage (Keutel syndrome, OMIM ID: 245150).

The strength of the bone is determined by its size (height, width, depth), mineral mass, macro- and microarchitecture, and material properties (e.g., elasticity) of collagen that in turn are regulated not only by endocrine hormones and paracrine growth factors but also by mechanical forces exerted on the skeleton by the environment (gravity) and by the muscular system.[186,230,231] Bone mass and strength are determined in part by the loads placed on bone by biomechanical forces exerted by muscles—the mechanostat model. In this model, osteocytes monitor the stresses and strains (deformations) that are the result of mechanical forces placed on it. In response to mechanical force, (1) osteocytes synthesize less sclerostin and their rate of apoptosis declines and the rate of WNT-stimulated bone formation increases, and (2) stromal cells decrease their expression of RANKL and thus the process of osteoclastogenesis slows. Additionally, in response to mechanical stress multiple growth factors generated by the osteoblast (FGFs, IGF-I, TGFβ) act in an autocrine/paracrine manner on their respective tyrosine kinase receptors expressed in the cell membrane of the osteoblast to activate the PI3K, PKB, and MAPK signal transduction systems; prostaglandins activate GPCRs, adenylyl cyclase and PKA and the cyclic AMP responsive transcription factors; PLC generation leads to increase in cytosolic $Ca^{2+}{}_i$ and osteoblast function as does influx of Ca^{2+} through L-type calcium channels in the cell membrane.[232] One of the target genes affected by mechanical stimulation is *RUNX2* (discussed earlier) whose product is essential for osteoblast differentiation and expression and synthesis of osteoblast-specific proteins (discussed earlier). Repetitive bone strain (an applied deforming force that might be compressive, lengthening, or angulating) leads to enhanced quantity and quality of bone (bone strength). It is this property that enables various exercises to increase bone mineralization at all ages and states of mobility. The mechanisms that lead to increased bone mass are inactivated by decreased weight bearing such as immobilization or decreased gravity (e.g., space flight) and lead to bone loss (disuse osteoporosis). Although bone strength is in part dependent on bone mineralization, it is the size and integrity of bone that primarily determine its strength.[233] Clinically, this paradox is illustrated by the increased rate of fractures in children with osteopetrosis or marble bone disease despite extremely dense bones with thick cortices and trabeculae.

Skeletal accretion of calcium begins early in fetal life and progresses through childhood and puberty. The skeleton accumulates 25 to 30 g of calcium in utero and accrues 1300 g by adulthood. The average total body bone mineral content (BMC) of the adult male approximates 2800 g and of the adult female 2200 g with greater values in black than white individuals. Approximately 60% of total adult bone calcium is acquired during adolescence, and 25% is acquired in the 2 years prior to and after the peak velocity of BMC accrual; 30% of the mean BMC of the adult female lumbar spine (60 g) is deposited during this interval.[234] In both males and females, peak bone mass achieved in young adulthood is inversely related to the age of pubertal onset.[235]

As evidenced by the close concordance of bone mineral status between mothers and daughters, identical and fraternal twins and siblings, 60% to 80% of the peak or maximum adult bone mass is determined by genetic factors.[236] Candidate genes through which this parental relationship might be exercised include those encoding the vitamin D, calcium-sensing, estrogen, low-density lipoprotein-related, leptin and β-adrenergic receptors, cytokines (e.g., IL-6, TGFβ) and growth factors (BMPs, IGF-I), and bone matrix proteins such as type I collagen and osteocalcin emphasizing the fact that the regulation of bone mineralization is genetically complex and heterogeneous.[237] Genome-wide association studies have identified numerous genes that likely influence bone mineralization including those encoding corticotropin-releasing hormone receptor, β-catenin, RANK, and sclerostin.[238] In addition to intrafamilial factors, race, sex, body size, and composition are important determinants of bone calcium content. In black male and female youths, there is higher whole body BMC and BMD and lumbar spine, one-third radius, total hip, and femoral neck BMD than in white, Asian, or Hispanic youth.[239] Asian female children and adolescents have lower whole body and femoral neck BMD than do white and Hispanic subjects. Hispanic males have lower lumbar spine BMD than do white and Asian youth. Radial and femoral neck (peripheral) and vertebral (axial) BMDs correlate with sex, age, height, weight, body mass index, pubertal and postpubertal hormonal status, calcium intake, and exercise in children, adolescents, and adults.[240] In young women only 16% to 21% of peak vertebral and femoral bone mass can be accounted for by weight, height, physical activity as an adolescent, and the VDR genotype, emphasizing once more the essential role of multiple factors in this process. Because adult peak bone mass is inversely related to the risk

of osteopenia and osteoporosis in later adulthood (in adults, a 10% increase in BMD reduces the risk of femoral neck fracture by 50%), it is essential that bone mass be maximized during childhood and adolescence.[241]

The rate of accumulation of bone mass increases during puberty, and peak bone mass is achieved early in the third decade of life; calcium intake accounts for perhaps 5% of accrued peak bone mass, whereas exercise may contribute 10% to 22% of peak bone mass and is, therefore, one the factors that can be modified in the pursuit of the goals of attaining and maintaining maximum peak bone mass.[242] Thirty minutes of programmed weight bearing exercise thrice weekly increases BMC of the femoral neck and lumbar spine in prepubertal boys and girls as may resistance training of moderate intensity performed 20 to 40 minutes once or twice per day, 5 days per week; high-impact, weight-bearing exercises (ballet, tennis, volleyball, gymnastics, jumping, running, soccer, rugby, ice hockey) increase mass of weight-bearing bones, particularly in children and adolescents, an effect that may long outlast the period of exercise itself.[242,243] Weight-bearing/high-impact exercises do so in part by augmenting periosteal bone acquisition and increasing the cortical thickness of long bones particularly of the legs at their most distal extremes closest to the ground where weight bearing is maximal. At peak BMC velocity, the annual gain and total accumulation (over 2 years) of total body bone mineral in active boys and girls are 80 g/year and 120 g/year, respectively, greater than in inactive adolescents. One year after peak BMC velocity, the total body, femoral neck, and lumbar spine BMCs are 9% to 17% greater in active than in relatively inactive subjects. Even greater normal activities (such as walking longer distances to school) convey long-lasting salutary effects on bone mineralization and later fracture risks.[244] The effects of diminished physical activity on bone growth and strength are clearly illustrated by children with neurologic insults that prevent normal motion (Erb paresis, hemiplegia, spinal cord insults) and thus restrain limb growth. An abrupt decrease in the mechanical load on bone (e.g., bed rest, space flight) evokes rapid loss of bone mineralization as the rate of bone formation declines, whereas that of bone resorption is maintained. In patients with limited physical activity due to neurologic or muscular insults, bone density may be increased by high-frequency, low-amplitude mechanical stimulation.[242]

Systemic hormones and growth factors (GH, IGF-I, PTH, leptin, thyroid and sex hormones, glucocorticoids) have substantial effects on chondrocyte proliferation, maturation, and function.[245] GH acting through the GH receptor increases the synthesis of BMPs, directly enhances differentiation of prechondrocytes within the resting zone of the cartilaginous growth plate, supports proliferation of chondrocytes in the reserve or resting zone, and increases local expression of *IGF1*. GH receptors are expressed in chondrocytes in the reserve, proliferative, and hypertrophic zones and mediate chondrocyte proliferation and maturation and IGF-I synthesis through the Janus kinase 2-signal transduction and transcription 5b (JAK2-STAT5b) signaling system.[246] IGF-I, expressed predominantly in proliferating chondrocytes, functioning through the IGF type 1 receptor expressed in chondrocytes in the reserve, proliferative, and hypertrophic zones stimulates the clonal expansion of committed chondrocytes.[247] IGF-I coordinates chondrocyte proliferation and inhibits their apoptosis; it modulates their differentiation and maturation and their synthesis of matrix heparan sulfate proteoglycan, a matrix component that is necessary for efficient signaling of FGFs and their receptors.[248] IGF-I also influences the interaction of Ihh and PTHrP. IGF-binding proteins (IGFBP)-1 through -6 are synthesized by growth plate chondrocytes where they regulate levels of bioactive IGF-I as well as exert direct stimulatory/inhibitory effects on chondrocyte proliferation depending on the stage of chondrocyte differentiation.[249] In utero, both IGF-I and IGF-II are essential for normal fetal growth as denoted by the in utero growth retardation experienced by the fetus with a loss-of-function mutation in *IGF1*, *IGF2*, or *IGF1R*.[245,248] Neither GH nor IGF-I is necessary for patterning of the skeleton, however. Systemic loss of GH secretion or IGF-I production or inactivation of the IGF-I receptor greatly impairs linear growth of long bones postnatally. Selective loss of hepatic IGF-I production lowers total circulating levels of IGF-I to 25% of normal but does not adversely affect growth in transgenic mice, indicating that it is IGF-I synthesized by the cartilage growth plate that affects chondrocyte division by a paracrine mechanism.[250] In patients with inactivating mutations of the GH receptor or deletion of the gene encoding IGF-I, administration of IGF-I enhances linear growth indicating that this growth factor is able to stimulate cartilage proliferation without the initial differentiating effect of GH but does so to a lesser extent than does GH in the GH deficient subject; thus, sufficient numbers of differentiated prechondrocytes are necessary for optimal IGF-I effect.[251] The GH secretagogue, ghrelin, is also synthesized and secreted by chondrocytes and affects their intracellular metabolism.[252]

Through expression of the GH receptor by osteoblasts, GH stimulates their differentiation, proliferation and function—enhancing synthesis and secretion of osteocalcin, bone-specific alkaline phosphatase, and type I collagen. GH also increases expression of IGF-I by the osteoblast as do estrogen, PTH, cortisol, and calcitriol; IGF-I is essential for GH-induced osteoblast proliferation in vitro; it also decreases expression of the GH receptor, whereas estrogen stimulates its expression.[253] In response to GH, IGFBP-3 and IGFBP-5 are synthesized by (rat) osteoblasts; IGFBP-4 expression is decreased by GH in rat and human osteoblasts. The IGFBPs may augment or restrict activity of IGF-I and IGF-II; thus, IGFBP-5 binds to bone cells, matrix, and hydroxyapatite and enhances the actions of IGF-I on bone. Expression of the GH receptor by the osteoblast is up-regulated by IGFBP inhibition of IGF-I activity. Acting through the osteoblast, GH increases osteoclast proliferation and activity; human osteoclasts express receptors for IGF-I, which also enhances osteoclast formation and activation.

In children with GH deficiency and adults with childhood-onset or adult-onset GH deficiency, BMC and areal and volumetric BMDs are decreased and increase when GH is administered.[253] Administration of

GH to the GH deficient subject is followed by increase in serum and urine levels of markers of bone formation and resorption (osteocalcin, bone-specific alkaline phosphatase, PICP, ICTP, PYR, DPD, and NTX) with maximal values achieved 3 to 6 months after beginning treatment. There is a biphasic response of bone mass during GH treatment; for approximately the first 6 months of GH administration BMD declines as bone resorption exceeds formation; BMD increases steadily to positive values over the next 6 to 12 months. In subjects with GH receptor deficiency or IGF-I gene deletion, BMC and BMD are decreased relative to control subjects but volumetric BMD is not, suggesting that bone size but not bone mineral acquisition is impaired by isolated IGF-I deficiency. Nevertheless, administration of IGF-I to subjects with deletion of *IGF1* enhances osteoblast function as documented by increased serum concentrations of osteocalcin and bone specific alkaline phosphatase, BMC, and areal and volumetric BMDs. In acromegalic patients there is increased bone turnover, and variably increased lumbar spine and femoral neck BMD and iliac crest cortical and trabecular bone mass.

Thyroid hormone receptors (TRα, TRβ) are expressed in the reserve and proliferative zones of the growth cartilage. Triiodothyronine, acting primarily through TRα, enables the differentiation of resting chondrocytes and their entrance into the proliferative phase; but there, thyroid hormone inhibits further chondrocyte proliferation and promotes differentiation to terminal hypertrophic chondrocytes and secretion of collagen type X. They do so in part by disrupting the reciprocal interaction of Ihh and PTHrP thereby accelerating chondrocyte maturation, effects mediated by FGFR3 and the STAT signaling pathway and by down-regulation of IGF-I expression in chondrocytes.[254] Thyroid hormone is essential also for vascular invasion of the growth plate's hypertrophic zone and induction of metaphyseal trabecular bone formation. Thyroid hormones are necessary for fusion of the epiphyseal cartilage plate, although fusion may occur in the absence of thyroid hormone through estrogenic action. Through osteoblast-expressed receptors for thyroid hormone, triiodothyronine increases osteoblast production of osteocalcin, bone-specific alkaline phosphatase, and IGF-I. Thyroid hormones increase the rate of bone remodeling by expanding the number of osteoclasts and sites of bone resorption and the amount of bone resorptive surface; urinary calcium excretion is increased by thyroid hormones; in excess, thyroid hormones lead to net bone loss.

Estrogen and androgens promote chondrocyte maturation.[245] Although many of the effects of androgens are mediated by their conversion to estrogens (discussed later), nuclear androgen receptors are expressed by chondrocytes, and nonaromatizable androgens stimulate chondrocyte proliferation and long bone growth. Estrogens acting through ERα and ERβ expressed in chondrocytes exert a biphasic effect on chondrocyte proliferation, increasing its rate at low doses and reducing it at higher doses; by decreasing chondrocyte proliferation and accelerating the rates of chondrocyte maturation, senescence, and apoptosis, estrogens lead to epiphyseal fusion.[255] Complete maturation and fusion of the growth plate are mediated primarily by estrogens as evidenced by the failure of growth plate fusion in young adult males with inactivating mutations of the genes encoding aromatase (the enzyme that converts androgens to estrogens) or ERα, despite adult levels of testosterone. Chondrocytes may also be capable of synthesizing estrogens from androgens as aromatase activity has been found in growth plate chondrocytes.[245] This observation suggests that locally produced as well as systemic estrogens may contribute to chondrocyte maturation and growth plate fusion. Sex hormones play major roles in the accretion of bone mineral in both females and males as the bulk of adult bone calcium stores are deposited during puberty when the peak rate of accrual of total body BMC occurs in boys and girls 0.7 years after attainment of peak height velocity (PHV) and 0.4 to 0.5 years after peak accrual of lean body mass (a surrogate measurement of muscle mass).[234,256] After controlling for size, total body and femoral neck peak BMC velocity and BMC accrual over 2 years around the PHV are greater in males than females; there is no gender effect on accrual of BMC of the lumbar spine, however. Both androgens (in part by conversion to estrogen) and estrogens markedly influence rates of bone formation and resorption, although it is the effect of estrogen that predominates as evidenced by (1) the marked osteopenia of adult males with androgen sufficiency but estrogen deficiency related to loss-of-function mutations in the genes encoding aromatase and ERα, (2) the beneficial effects of estrogen but not of testosterone on BMD in males with aromatase deficiency, (3) the very close association of BMD and serum levels of bioavailable estrogen in elderly men, and (4) the significant correlation in adult men treated with testosterone between changes in BMD and increases in serum concentrations of estradiol but not of testosterone.[255] Nevertheless, the osteopenia of adult (46XY) females with complete androgen insensitivity due to loss-of-function mutations of the X-linked androgen receptor despite elevated serum testosterone and (endogenous or exogenous) estradiol concentrations and the fragile bone structure of the (*Tfm*) mouse counterpart of this disorder indicates that androgens, too, increase bone mineralization. Furthermore, nonaromatizable dihydrotestosterone has a direct anabolic effect on bone, as it stimulates the proliferation and maturation of osteoblasts, increases the production of procollagen I(α1), and prevents bone loss in orchidectomized rats.

Estrogens increase bone mass primarily by suppressing bone resorption; they do so through inhibition of osteoclastogenesis and down-regulation of osteoblast production of osteoclast activating factors such as IL-6 (and its receptor), TNFα, and M-CSF, increasing production of osteoprotegerin, and accelerating apoptosis of mature osteoclasts.[257] Estrogens also prolong the life span of osteoblasts and osteocytes. During adolescence in the female not only does the rate of bone deposition increase, but that of bone resorption declines. There is maturation-related increase in BMC and areal and volumetric BMD and in metacarpal length, width, and cortical thickness due, in part, to decline in width of the marrow cavity. Data suggest that the pubertal increase in production of GH and IGF-I mediates, in part, longitudinal and periosteal skeletal growth and mineral acquisition during puberty. Estrogen may decrease endosteal bone resorption through inhibition of IL-6 generation, thereby

contributing to increase in cortical bone mass. Estrogens likely account for part of the pubertal growth spurt of girls and boys acting both indirectly by increasing the secretion of GH and the systemic and local production of IGF-I and directly on the chondrocyte.

The nuclear glucocorticoid receptor is expressed in chondrocytes in the proliferative and hypertrophic zones; cortisol exerts an inhibitory effect on chondrocyte proliferation, hypertrophy, synthesis of cartilage matrix, and maturation, but also delays senescence of the growth plate thereby permitting catch-up growth when excess glucocorticoid exposure is temporary.[258,259] Glucocorticoids act in part by depressing expression of the genes encoding the GH receptor, IGF-I, and IGF1R in growth plate chondrocytes and by regulating synthesis of IGFBPs and thereby indirectly function of IGF-I. Paradoxically, glucocorticoids also increase expression of *SOX9* and the earliest phase of chondrocyte differentiation. Glucocorticoids suppress osteoblastogenesis and accelerate the rate of apoptosis of osteoblasts and osteocytes, in part by suppressing expression of *BMP2* and *RUNX2*, thus depressing the rate of bone formation.[257] Glucocorticoids transiently accelerate osteoclastogenesis by promoting osteoblast synthesis of RANKL and depressing expression of *TNFRSF11B* (encoding OPG).[187] In excess, glucocorticoids decrease trabecular bone and osteoid volumes contributing to bone weakness and collapse.

Transcripts of C-type natriuretic peptide (CNP, encoded by *NPPC*) and its receptor (encoded by *NPR2*) are expressed by chondrocytes; these peptides stimulate the growth of proliferative and hypertrophic chondrocytes, enhance osteoblast function, and induce endochondral ossification.[260] CNP increase the thickness of the growth plate by enlarging chondrocyte size, signaling through the MAPK pathway; it does not affect differentiation of chondrocytes.[261] Plasma concentrations of the amino-terminal pro-C-type natriuretic peptide are positively related to growth velocity in normal children and adolescents.[262] Biallelic loss-of-function mutations in *NPR2* have been identified in patients with acromesomelic dysplasia–Maroteaux type (OMIM ID: 602875).[263] In this disorder, there is shortening and deformation of the forearms, forelegs, and vertebrae resulting in severely compromised adult stature. Increased expression of *NPPC* has been associated with an overgrowth phenotype.[261] In an experimental mouse model of achondroplasia due to a gain-of-function mutation in *Fgfr3*, increase in serum levels of CNP can promote substantial growth.[261]

After genetic influences, the factor to which bone mass is most closely related is weight. Obese children, adolescents, and adults have higher BMC and BMD values than do slimmer subjects—levels that are directly related to both lean body mass (i.e., muscle) and to fat mass.[264,265] Chondroblasts, osteoblasts, and adipocytes arise from a common mesenchymal stem cell and can be interconverted depending on which transcription factor is expressed in the stem cell (e.g., PPARγ promotes adipogenesis); consequently, the fat cell synthesizes and secretes a number of adipokines that affect bone development. Among these products is leptin (encoded by *LEP*), a 16-kDa protein with anorexigenic properties that acts within the ventromedial hypothalamic nucleus to depress appetite, increase the rate of energy utilization, enable fertility by enhancing gonadotropin secretion, and regulate thyrotropin secretion; leptin also decreases bone mineralization.[177,228] Within the central nervous system, leptin is linked to osteoblasts through the sympathetic nervous system; mediated by the β_2-adrenergic receptor expressed on the osteoblast cell membrane, leptin-stimulated increase in sympathetic input both inhibits osteoblast proliferation, hence decreasing bone formation, and increases osteoblast expression of *RANKL*, thereby favoring osteoclastogenesis. The neurotransmitter serotonin—synthesized by neurons in the nuclei of the dorsal and ventral raphe of the brainstem and transported by their axons to the ventromedial hypothalamic nucleus—there stimulates the local expression of genes whose products increase appetite such as proopiomelanocortin and the melanocortin-4-receptor that oppose the anorexigenic effects of leptin; serotonin also decreases sympathetic tone, thus antagonizing the skeletal effects of leptin and increasing bone formation in the periphery. It has been suggested that acting on the serotonin synthesizing neurons of the dorsal and ventral raphe, leptin inhibits serotonin production (or release) and thereby depresses both the accrual of bone mass and appetite.[177,228] The dual central actions of leptin on appetite and bone accrual may thus link the processes of energy metabolism and bone accretion. Another association between bone and energy metabolism is the relationship between osteocalcin and insulin; undercarboxylated osteocalcin stimulates insulin release from the pancreatic β-cell and facilitates insulin sensitivity in muscle, fat, and liver; reciprocally, insulin increases osteoblast synthesis of undercarboxylated osteocalcin.[228] Osteocalcin also stimulates Leydig cell synthesis of testosterone, acting through its GPCR and the cyclic AMP response element binding protein to increase steroidogenesis, a complementary physiologic effect to that of luteinizing hormone.[227] Adiponectin (OMIM ID: 605441), a 28-kDa product of the white adipocyte whose plasma values are inversely related to visceral fat mass, modulates osteoclastogenesis by inducing osteoblast expression of RANKL and inhibiting that of its antagonist, osteoprotegerin.[266] Experimentally, loss-of-function mutations in the gene encoding adiponectin are associated with increase in bone mass.[265] Resistin (OMIM ID: 605565) stimulates both osteoblastogenesis and osteoclastogenesis.[265] MEPE and ASARM peptides influence energy metabolism and fat mass.[54] *Phex* deficient HYP mice are hyperglycemic and hypoinsulinemic, and the rate of gluconeogenesis is increased in HYP osteoblasts. Further, acidic ASARM peptides enhance decarboxylation of osteocalcin.[54]

Assessment of Bone Mass and Strength

Bone stress is determined by the three-dimensional size (volume) of the bone, its mineral content, and its material properties such as elasticity. Bone mineralization may be directly assessed by bone biopsy and histomorphometric analysis of bone formation and resorption.[267,268] Undecalcified transiliac biopsies permit limited assessment of bone modeling (changes in bone size, shape, mass) but detailed analysis of remodeling (bone renewal) as the iliac

crest biopsy is primarily composed of trabecular bone with a circumscribed amount of cortical bone. During bone modeling, osteoblasts and osteoclasts are active on opposite bone surfaces across from one another. Thus, the bone surface may change position, size, or mass during the modeling process. Usually modeling is associated with gain in bone mass as the rate of osteoblastic deposition of bone is more rapid than is the rate of osteoclastic resorption. During bone remodeling, osteoclastic resorption of bone is followed by osteoblastic replacement of the reabsorbed bone at the same surface with a net change of zero in bone mineral at the remodeling site under normal circumstances. Histomorphometry enables quantitation of structural parameters of bone size and amount (cortical width, trabecular number, and thickness), static bone formation (thickness and surface of osteoid or unmineralized bone matrix, osteoblast surface), dynamic bone formation after labeling with a fluorochrome such as tetracycline (mineral apposition and bone formation rates), and static resorption (osteoclast number and appearance and extent of eroded surfaces). Iliac trabecular thickness but not trabecular number increases substantially between 2 and 20 years of age, whereas remodeling activity peaks in young children, declines, and then increases again during puberty.[267] Noninvasive bone biopsy is now achievable with the use of high-resolution peripheral quantitative computed tomography (HRpQCT) employing a voxyl size of 82 μm that permits construction of microfinite element (μFE) models of bone strength and enabling quantitation of both cortical and trabecular bone dimensions (discussed later).[269,270] Micro-magnetic resonance imaging (μMRI) is another noninvasive technique that allows "virtual bone biopsy."[271]

Noninvasive methods of assessment of skeletal mineralization include bone x-rays (of limited value), radiographic absorptiometry or photodensitometry, single photon or single x-ray absorptiometry, dual photon or dual energy x-ray absorptiometry (DEXA), spinal and peripheral quantitative computed tomography (pQCT), quantitative ultrasonography (QUS), high-resolution quantitative MRI, quantitative μMRI, and magnetic resonance microscopy.[233] DEXA is the most frequently employed method for quantifying axial (skull, spine) and peripheral (appendicular) bone mass and bone area as well as body composition because of its relatively low radiation dosage (5 μSv), ease of use and applicability for infants, rapidity, accuracy, precision, and reproducibility under controlled circumstances.[233,272] The ratios of attenuation of x-rays of two energies (70 kV, 140 kV) traversing the same pathway through the patient reflect the density and mass of the tissue through which the x-rays have crossed; computer analysis of these captured energies then reconstructs the boundaries, density, and mass of the tissue. Because of the variability between instruments and analytic software programs (infant, pediatric, adult) employed for DEXA, the report of the DEXA scan should include not only the recorded data but also the type of DEXA instrument and the software version employed for analysis. Because relatively low BMDs in children make it more difficult to distinguish clearly bone edges, specific infant and pediatric software must be used to address this problem.

DEXA does not measure true BMD, the mass within a volume of uniform composition that is expressed as grams of hydroxyapatite/cm^3 (g/cm^3); rather DEXA measures the two-dimensional areal or surface mass of mineral within a region of bone of nonuniform composition (cortex, trabeculae, osteoid, marrow); it is expressed as grams of hydroxyapatite/cm^2 (g/cm^2). Because DEXA does not take into account the depth of a bone, it underestimates BMD in small children and overestimates it in large subjects.[273] In children and adolescents, bone size (volume) increases with growth and maturation; the larger the three-dimensional structure of bone, the greater is the recorded areal BMD, even though the actual or volumetric (v) BMD may not change substantially. Therefore, calculated or apparent (v) BMDs (BMAD) (g/cm^3) data have been generated in an attempt to correct this problem. Volumetric BMD increases as the cortex thickens, the number and width of trabeculae per unit volume rises, and the amount of hydroxyapatite per unit of trabecular volume accrues. Although during childhood and adolescence areal BMD of the femoral shaft increases with age, its vBMD remains relatively constant. On the other hand, vBMD of the lumbar spine increases in late puberty and early adulthood because of increasing thickness of trabeculae that is not gender specific but is greater in blacks than in whites after puberty.[274] Cross-sectional areas of cortical and trabecular bone increase with age with males achieving greater increase in periosteal apposition than do females during puberty. Cortical cross-sectional area is similar in white and black subjects.[275] Included in measurement of whole body areal BMD is the skull; this structure characteristically has twice the areal BMD of that of the rest of the skeleton and may comprise as much as 20% to 50% of the total BMD in young children; whole body areal BMD correlates better with height when the skull is excluded.[276] Consequently, there are reference data for DEXA whole body BMC and BMD with inclusion or exclusion of the skull.[239,277] The influence of the skull on BMC is illustrated by the observations that in non-black 10-year-old boys, the 50th percentile for whole body BMC including the skull is 1109 g; excluding the skull the BMC of this cohort is 804 g; in non-black males at age 17 years the 50th percentile for whole body BMC including the skull is 2532 g; without the skull the 50th percentile BMC is 2055 g. Inasmuch as DEXA BMC and BMD values increase with height in both boys and girls, DEXA-derived bone mass and density data should be adjusted for height (height age) when interpreting study results in children and adolescents (and very short and very tall adults as well).[278,279]

Whole or total body BMC/BMD, lumbar spine BMC/BMD, and femoral BMD are the most commonly measured indices of bone mass in childhood by DEXA and recorded as g/cm^2. Data are often reported as a Z score, the number of standard deviations about the mean of peers matched for chronologic age, gender, and stage of pubertal development. (In adults, the DEXA T score is commonly reported; the T score is the number of standard deviations about the mean of

maximal or peak bone mass recorded in healthy young adults aged 20 to 29 years. The T score should *not* be utilized in children and adolescents.) In neonates and infants, it is recommended that whole body BMC be the primary measurement when assessing bone mineralization.[280] In neonates with appropriate weight for gestational age (AGA), whole body BMC by DEXA doubles between 32 and 40 weeks and increases 3.5-fold between birth weights of 1000 and 4000 g; small for gestational age (SGA) neonates have lower whole body BMC than do AGA neonates of comparable gestational age but they are similar to those of AGA infants with the same birth weights (Table 8-7).[281,282] In young adults (16 to 19 years) born prematurely with birth weights < 1.5 kg, total body BMC is less than that of subjects born at term with normal birth weights but appropriate for their smaller stature.[283] Areal BMD of the lumbar spine (L2 to L4) is low in prematurely born infants but "catches up" to that of full-term infants by 2 years of age.[284]

Whole body BMC by DEXA increases approximately threefold between 7 and 17 years of age and is greater in males than females and in black relative to non-black youth (Tables 8-8A and 8-8B).[239,277,285] Whole body BMC is greater in adult males than females because of the larger size of male bones. Lumbar vertebral areal BMD doubles between 5 and 17 years of age in both boys and girls (Tables 8-9A and 8-9B).[239,277] The BMD of the femoral neck increases 1.5-fold between 7 and 17 years of age in both genders.[239] The BMC of the distal one-third radius approximately doubles and its BMC increases 1.5-fold between 7 and 17 years.[239,270] At all skeletal sites, BMC and BMD assessed by DEXA are higher in males than females and in black relative to non-black children and adolescents.[239] In females, the rate of maximal increase in whole body BMC occurs in the year of menarche and follows the year of peak height velocity (Figure 8-16).[234,286] In girls with menarche before 12 years, there is greater peak BMD (at age 18 to 19 years) than in females with menarche after 14 years. BMD is greater in children with premature adrenarche than in preadrenarchal peers, but appropriate for the tall stature of the adrenarchal subjects.[278] In adult males with a history of delayed puberty, there is lower lumbar spine BMD than in those with pubertal onset at 11 to 12 years. DEXA measurements of bone mineralization are affected by the composition of soft tissues that surround the axial skeleton; variations in fat about the bone may significantly influence the recorded DEXA measurements, thus limiting the use of DEXA

in extremely thin or obese children.[287] Generally, BMC, areal BMD, or BMAD below −2 SDs for age and gender are considered abnormally low. However, DEXA measurements must always be interpreted in relationship to the patient's clinical findings.[273]

QCT measures volumetric BMD of both trabecular and cortical bone at any site but has been commonly applied to the lumbar spine.[274] However, the radiation dose delivered to the spine by this method is high (~30 μSv). During childhood, lumbar spine vBMD measured by QCT is similar in black and white youth; during puberty black males and females gain twice the vBMD recorded in whites with no gender difference. Although BMD values of the lumbar spine acquired by DEXA and QCT are reasonably well related, osteopenia is reported in children far more often by DEXA than by QCT, unless DEXA measurements take into account body height and bone size.[287] Peripheral (p) QCT enables quantitation of bone mineralization in distal or proximal radial, femoral, or tibial sites (regions of both cortical and trabecular bone); the delivered radiation dose (10 μSv) is low. Peripheral QCT may be determined in the non-dominant radius two thirds of the distance between its proximal and distal ends and (ultra) distally at a point that is 4% of forearm length with a reference line being drawn through the most distal aspect of the cartilage growth plate when it is open or through the middle of the ulnar border of the articular cartilage when the growth plate is closed.[288] pQCT permits measurement of total and cortical bone area, cortical thickness, BMC (mg/mm), cortical and trabecular vBMD, periosteal and endosteal circumferences, and marrow area (Table 8-10).

High-resolution pQCT (HRpQCT) measurements are obtained at the ultradistal radius in the interval between 1 and 10 mm above the proximal limit of the epiphyseal growth plate of the nondominant wrist (the site in which the majority of adolescent fractures occur) and deliver a local absorbed radiation dose of 0.065 cGy and a total radiation exposure of < 0.01 mSv.[270] HRpQCT enables quantitative measurement of cortical and trabecular bone including cortical bone vBMD, cortical bone area, cortical bone thickness (Ct.Th [μm]), periosteal and endosteal (endocortical) circumferences (μm), cortical pore volume (cortical areas of inverse density) and the "cortical porosity index" (cortical pore volume/cortical bone volume ratio), trabecular bone vBMD, trabecular

bone vBMD/total bone volume ratio (BV/TV [%]), trabecular number (Tb.N [mm^{-1}]), trabecular thickness (Tb.Th [μm]), and trabecular spacing (Tb.SP [μm]) (Table 8-11). Determination of the "cortical porosity index" affords an estimate of strength of the distal wrist. HRpQCT also permits construction of microfinite element (μFE) models of bone strength enabling calculation of strain energies and loads supported by cortical and trabecular bone and "failure loads."[270,289] Utilizing μFE models, graphic representations of the architecture of the cortex and trabeculae can be constructed. Figure 8-17 (see the website for the full color image) depicts visually three-dimensional reconstructions of cortical and trabecular bone as derived by HRpQCT examinations.[270] In boys, cortical bone vBMD, Ct.Th, BV/TV, and Tb.Th increase in late puberty. In girls, cortical bone vBMD and Ct.Th decline in midpuberty and then increase. Total bone strength increases in males and female through puberty. The percentage of load borne by cortical bone decreases and the cortical bone porosity index increases in midpuberty, coincident with the point of peak incidence of adolescent radial fractures.[270]

Quantitative ultrasonography (QUS) measures the speed of a longitudinal sound (SOS) wave as it is propagated along a bone.[233] The rate of movement of sound through bone is dependent on its microstructural and macrostructural characteristics, mineral density, and elasticity and is thought to be a measure of bone strength. It is an attractive method for assessment of bone because it does not utilize radiation, is low in cost, and the measuring equipment is portable. Transmitter and receiver ultrasound transducers placed on either side of the examination site (os calcis, patella, tibia, radius, phalanges) quantitate transmission velocity or signal attenuation and convert these observations to SOS. In a study of 1085 children and adolescents, SOS increased steeply at the tibia and radius during the first 5 years of life, more slowly between 6 and 11 years of age, and then again more rapidly during pubertal development.[290] In 3044 healthy subjects ages 2 to 21 years, phalangeal QUS SOS and bone transmission time (BTT) increased over time and with advancing adolescent development and were related to gender, age, height, and weight.[291] QUS SOS is higher in postmenarchal than in premenarchal girls; adiposity (BMI) and serum leptin levels are inversely related to SOS in pubertal girls.[292] The overlap of QUS data between various ages makes interpretation of a single SOS measurement problematic;

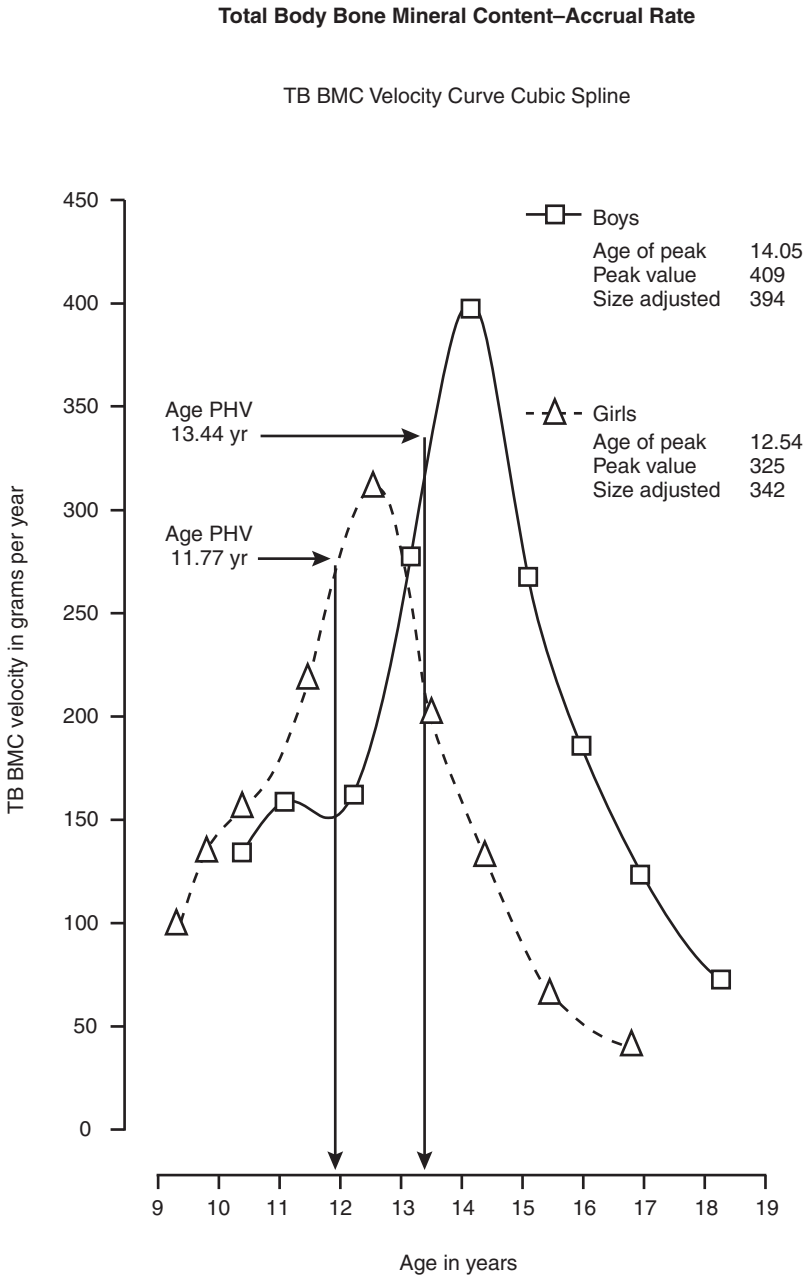

FIGURE 8-16 ■ During adolescence the peak rate of accrual of total body bone mineral content (BMC) occurs in boys and girls 0.7 years after attainment of peak height velocity (PHV). (Reproduced from Bailey, D. A., McKay, H. A., Mirwald, R. L., et al. (1999). A six-year longitudinal study of the relationship of physical activity to bone mineral accrual in growing children: the University of Saskatchewan bone mineral accrual study. *J Bone Miner Res, 14,* 1672-1679, with permission.)

serial assessment may be useful. Thus, in a cohort of 29 preterm infants, tibial SOS values declined over time in neonates whose gestational ages were less than 29 weeks, suggesting progressive loss of bone strength in this population and consistent with the development of osteopenia of prematurity.[293] Although there is marginal correlation between vBMD determined by pQCT and SOS measurements in children and adolescents, QUS may complement but is unlikely to replace assessment of mineralization by radiographic methods at this time.

Magnetic resonance imaging of the skeleton may also be utilized to assess bone geometry and estimate bone strength.[294] Bone high-resolution magnetic resonance imaging (hrMRI) of the wrist and tibia measures cortical and trabecular bone structure including trabecular number (mm^{-1}), thickness (mm), bone fraction (%), and separation (mm).[295] Further, micro MRI can be employed to measure whole bone and trabecular bone stiffness (an indicator of whole bone mechanical competence, quality, and strength) and to obtain virtual bone biopsies.[271,296]

MINERAL HOMEOSTASIS DURING THE LIFE CYCLE

During the first trimester of pregnancy, maternal serum concentrations of total calcium decline and remain low through gestation, whereas serum concentrations of Ca^{2+}_e remain relatively constant.[297] PTH values decline to 10% to 30% of the nonpregnant range in the first trimester of pregnancy and then rise to mid nonpregnant levels in the latter half of gestation. The secretion of PTHrP by the placenta, amnion, decidua, umbilical cord, breast, and fetal parathyroid glands increases several-fold beginning early in the first trimester, and maternal levels rise throughout gestation. Maternal calcitonin values also increase during gestation. Serum concentrations of calcidiol do not change, but maternal levels of calcitriol, synthesized primarily by the maternal kidney under the influence of PTHrP but also in part by the placenta, decidua, and fetal kidneys, increase more than twofold, enabling increased calcium absorption by the maternal small intestine. The rate of maternal bone resorption increases through gestation, whereas the rate of bone formation declines during the first trimester and then increases in the third trimester (see Table 8-5).[212,298] During a normal 40-week gestation, maternal whole body BMD does not change; cortical BMD increases (arms +2.8%, legs +1.8%), whereas trabecular BMD declines (vertebrae −4.5%, pelvis −3.2%); these affects are reversible after completion of pregnancy.[297]

Compiled and adapted from Ackerman, K. E., Nazem, T., Chapko, D., et al. (2011). Bone microarchitecture is impaired in adolescent amenorrheic athletes compared with eumenorrheic athletes and nonathletic controls. J Clin Endocrinol Metab, 96, *3123–3133; Chevalley, T., Bonjour, J. P., van Rietbergen, B., et al. (2011). Fractures during childhood and adolescence in healthy boys: relation with bone mass, microstructure, and strength.* J Clin Endocrinol Metab, 96, *3134–3142.*

Thus, early in gestation the pregnant woman meets fetal demand for calcium by increasing the rate of resorption of stored bone calcium, whereas the calcium requirement of the more mature fetus is met by a substantially increased rate of maternal intestinal calcium absorption.

During lactation, the nursing mother daily transfers to her suckling infant 280 to 400 mg of calcium mobilized from her skeleton in response to PTHrP secreted primarily by the breast.[297] Calcium concentrations are low in colostrum, approximately 25 mg/dL in breast milk during the first 6 months of lactation and 21 mg/dL during months 6 to 12 of nursing.[299] Maternal total calcium, calcitriol, and calcitonin values are normal, whereas $Ca^{2+}{}_e$, phosphate, and PTHrP levels increase during lactation. Urinary levels of markers of bone resorption and serum values of markers of bone formation are both elevated during lactation, implying rapid turnover of maternal bone mineral during nursing. Maternal bone mineralization declines 3% to 10% during lactation only to reaccrue rapidly after weaning.[300] It has been recommended that pregnant and lactating women receive 600 IU of vitamin D and 1300 mg of calcium daily and that their neonates and infants receive 400 IU of vitamin D daily whether breast or formula fed (see Table 8-3).

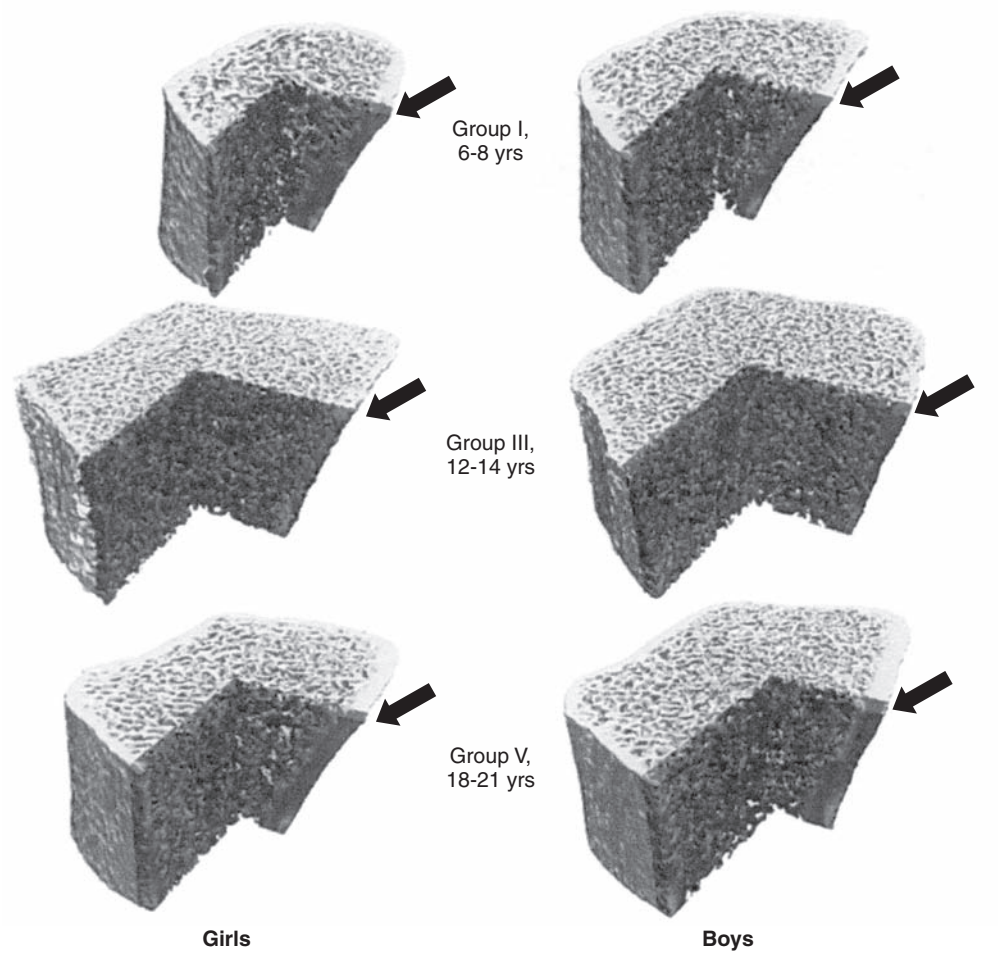

FIGURE 8-17 ■ Three-dimensional (3D) reconstructions of cortical and trabecular bone of ultradistal radius. Arrows point to cortical bone. (Reproduced from Kirmani, S., Christen, D., van Lenthe, G. H., et al. (2009). Bone structure at the distal radius during adolescent growth. *J Bone Miner Res, 24*, 1033–1042, with permission.)

During gestation, the fetus accrues 30 to 35 g of calcium beginning late in the first trimester with development of primary ossification centers in the long bones and vertebrae between the eighth and twelfth weeks of pregnancy; approximately 80% of calcium accretion occurs in the third trimester.[150,301] At 28 weeks' gestation calcium is deposited into the fetal skeleton at the rate of 100 mg/day, whereas at 35 weeks calcium is deposited at the rate of 250 mg/day.[298,302] At birth, whole body bone mineral content (BMC) is positively related to gestational age, body length, and most closely to body weight, as are lumbar spine (L1-L4) BMC and BMD.[302,303] The fetal skeleton serves two roles: (1) it is a metabolically important source of calcium mobilized by fetal PTH and PTHrP acting through PTH1R when the supply of calcium from the mother is limited; (2) it provides a rigid structural and protective framework for fetal soft tissues. From at least 15 weeks' gestation, serum concentrations of total calcium and particularly Ca^{2+}_e are substantially higher in the human fetus than in the mother (1.4:1), the physiologic significance of which is unknown. Fetal serum calcium levels are established independently of and are not directly related to maternal calcium concentrations. Additionally, fetal serum concentrations of magnesium and phosphate are greater than maternal values. The parathyroid glands are essential for maintenance of normal fetal calcium concentrations. By the tenth week of gestation, they secrete PTH and possibly PTHrP as well, and both peptides function additively to maintain fetal serum calcium levels. PTH does not stimulate placental calcium transport, but it is secreted by the fetal parathyroid gland in response to hypocalcemia, and fetal mice in which the expression of PTH has been ablated (e.g., *Hoxa3* null mice) are hypocalcemic and skeleton mineralization is impaired.[96,301] Fetal PTH increases fetal renal tubular and bone mineral reabsorption. Maternal hypercalcemia suppresses and maternal hypocalcemia stimulates secretion of fetal PTH. Both amino and mid-molecule fragments of PTHrP (e.g., $PTHrP^{1\text{-}86}$, $PTHrP^{67\text{-}86}$) produced by the fetal parathyroid gland, placenta, amnion, chorion, and umbilical cord maintain high fetal serum calcium concentrations

by stimulating active maternal-to-fetal transport of calcium across the placental syncytiotrophoblast against a concentration gradient. The CaSR is expressed in the human placenta in the first trimester and is involved in placental calcium transport.[304] Calcium selective ion channels (TPRV5, TPRV6) located at the apical surface of synctiotrophoblast cells facilitate maternal-fetal transplacental transfer of calcium. Ca^{2+} enters the syncytiotrophoblast through a calcium channel and exits via a Ca^{2+}-ATPase channel (encoded by *ATP2B1* or related gene whose expression is up-regulated by calcitriol). The effect of PTHrP on placental calcium transport is mediated in part by receptors that recognize mid-molecule or carboxyl terminal fragments of PTHrP, as in fetal mice in which *Pth1r* has been ablated placental calcium transport remains active while fetal serum calcium levels are low. In fetal mice in which the expression of *Pthlh* has been lost, serum calcium levels are lower than control values and maintained by fetal PTH at values comparable to those of the mother; in Pth1r null fetal mice placental calcium transfer is decreased, and chondrocyte maturation and bone development are abnormal.[301] Serum concentrations of PTHrP are high in the human fetus (term cord blood 2 to 5 pmol/L) and increase still further when fetal plasma calcium values decline; PTH levels are less than those in maternal serum. In utero, calcitonin concentrations are elevated in response to the increased serum calcium levels of the fetus, but this peptide does not have a major impact on fetal calcium homeostasis.[301]

Fetal serum calcitriol concentrations are a bit lower than those of the mother. Experimentally, fetal serum calcium values and mineralization of the fetal skeleton are normal in the presence of maternal vitamin D deficiency or an inactive VDR and in the VDR-null fetal mouse, if the mother ingests a diet enriched with calcium and phosphate, indicating that the fetus does not have an absolute requirement for calcitriol or the VDR for normal mineral metabolism.[301,305] In humans, the fetal cartilaginous skeleton is present by the eighth week of gestation; primary ossification centers appear in the long bones and vertebrae by the twelfth week and secondary centers at the femoral ends are noted by the thirty-fourth week.[150] Fetal PTHrP secreted by juxta-articular cells of the long bone regulates the orderly rate of chondrocyte maturation, whereas fetal PTH maintains serum calcium and phosphate values appropriate for bone mineralization. Magnesium is actively transported across the placenta. In utero fetal magnesium concentrations exceed maternal values and are inversely related to gestational age, reflecting the third trimester decline in maternal magnesium concentrations.

Calcium levels in cord blood correlate with gestational age and exceed maternal values by 1 to 2 mg/dL as a result of the active placental calcium pump. When the neonate is abruptly removed from the transplacental infusion of maternal calcium, total calcium and Ca^{2+}_e concentrations decline rapidly in the first 6 to 12 hours after delivery to nadir values (from 12 to 9 mg/dL and 1.45 to l.20 mmol/L, respectively) by 24 to 72 hours of age.[301,306] Calcium levels are a bit lower and PTH values higher in neonates delivered by cesarean section than in those delivered vaginally. After birth, PTHrP values decline rapidly; thus, in order to maintain mineral homeostasis, the neonate becomes dependent on endogenous PTH, exogenous vitamin D, ingested and absorbed calcium, renal tubular resorption of calcium, and bone calcium stores for its calcium needs. In response to the fall in Ca^{2+}_e values, serum levels of PTH begin to increase on the first day of life followed by rise in calcitriol concentrations and slow decline (after an initial postnatal rise) in calcitonin values.[307] For the first 2 to 4 weeks after birth, there is increased efficiency of intestinal calcium absorption by passive means that are independent of vitamin D, perhaps due to the lactose content of milk which affects paracellular transport of Ca^{2+}.[301] Later in the neonatal period, vitamin D–dependent intestinal calcium absorption increases. Renal tubular handling of calcium and the response to PTH matures during the first several weeks of life. Bone calcium accretion continues at the rate of 150 mg/kg/day for several months after birth, a vitamin D–dependent process. Due to both decreased glomerular filtration and increased tubular reabsorption, serum concentrations of phosphate are maximum in the neonate. Serum phosphate concentrations increase after delivery from cord values of 3.8 to 8.1 mg/dL to levels that range between 4.5 and 9 mg/dL during the first week of life and then stabilize at values between 4.5 and 6.7 mg/dL through the first year of life. In preterm or acutely ill neonates, the fall in calcium values is often exaggerated and more prolonged, and bone mineralization is frequently impaired in very preterm newborns and infants. Maternal hypercalcemia suppresses and maternal hypocalcemia stimulates secretion of fetal PTH, effects that may carry over to the neonate for several days. Serum magnesium concentrations are quite stable in infants and children ranging between 1.5 to 2.2 mg/dL through four months of age and between 1.7 to 2.3 mg/dL through 5 years of age. Human breast milk contains on average: calcium 28 mg/dL, phosphate 13 mg/dL, and vitamin D15-50 IU/L.[299] Cow milk formulas contain approximately 40 to 60 mg/dL calcium, 30 to 40 mg/dL phosphate, and 30 to 40 IU/dL vitamin D. The bioavailability of calcium in prepared formulas depends on its source and the formula's content and source of protein, fat, and carbohydrates. Infants fed formulas that contain palm olein absorb less calcium than those receiving a formula fortified with another form of fat or human breast milk, and these infants have lower total body bone mineral content.[308] Phytate (inositol hexaphosphate) present in soy formulas and infant cereals chelates calcium, and oxalate, a constituent of spinach, precipitates calcium thereby reducing intestinal absorption of this mineral, a difficulty overcome by increasing dietary calcium content.

During childhood and adolescence serum concentrations of total calcium (8.8 to 10.8 mg/dL depending on the analytic laboratory) and magnesium (1.7 to

2.2 mg/dL) remain relatively constant.[307] Serum phosphate levels are higher in children (4.5 to 6.2 mg/dL) than in adults (2.5 to 4.5 mg/dL) and attain maximum values several months before the peak height velocity of adolescence is achieved; the rise has been attributed to augmentation of the renal tubular reabsorption of phosphate due to the combined effects of the increased secretion of growth hormone, IGF-I, and sex hormones, factors that contribute to the pubertal growth spurt. Total serum alkaline phosphatase activity is also higher in children than in adults and increases transiently during the pubertal growth spurt. Levels of bone-specific alkaline phosphatase increase between 12 and 9 months before peak height velocity, reach maximum levels at Tanner male genital stage 3, and are directly related to the secretion of testosterone in boys. In females, serum bone-specific alkaline phosphatase activity peaks at Tanner stage 3 breast development and correlates with serum osteocalcin concentrations. Serum concentrations of PTH fluctuate very little during adolescence, whereas levels of calcitriol rise transiently.

QUESTIONS

1. In response to changes in the extracellular concentration of ionized calcium, what does the calcium sensing receptor do?
   a. Stimulates synthesis of parathyroid hormone
   b. Transduces its intracellular signal through activation of tyrosine kinase
   c. Impairs production of calcitriol (1,25-dihydroxyvitamin D3)
   d. Decreases renal tubular reabsorption of filtered calcium
   e. Inhibits the secretion of calcitonin

Answer: d

2. Which of the following describes α-Klotho?
   a. A coreceptor for parathyroid hormone and parathyroid hormone related protein (PTH/PTHrP)
   b. Essential for the regulation of renal tubular reabsorption of phosphate
   c. Necessary for the nuclear action of vitamin D
   d. A member of the intracellular adenylyl cyclase signal transduction pathway
   e. Critical for the differentiation and specificity of bone alkaline phosphatase

Answer: b

3. Which of the following describes parathyroid hormone related protein (PTHrP)?
   a. Its secretion is regulated by the serum ionized calcium concentration.
   b. It accelerates chondrocyte differentiation.
   c. It regulates placental transport of calcium.
   d. It increases the rate of cartilage ossification.
   e. It suppresses breast development in utero.

Answer: c

4. Which of the following describes calcitriol (1,25-dihydroxyvitamin D3)?
   a. Is inactivated in the kidney by hydroxylation at carbon 24
   b. Maintains a spatially fixed three-dimensional configuration
   c. Down-regulates the expression of epithelial calcium channels in the intestinal tract and kidney
   d. Suppresses osteoblast differentiation and proliferation
   e. Inhibits paracellular transport of calcium by the renal tubule

Answer: a

5. SOX9 encodes a transcription factor that does which of the following?
   a. Represses testicular differentiation
   b. Enhances osteoclast function
   c. Modulates PTH/PTHrP intracellular signal transduction
   d. Activates cellular apoptotic pathways
   e. Regulates the synthesis of cartilage matrix components

Answer: e

6. How does the WNT/β-catenin signal transduction pathway function?
   a. Enhances vitamin D synthesis
   b. Suppresses calcitonin secretion
   c. Decreases osteoclast secretion of acid
   d. Mediates osteoblast differentiation and function
   e. Modifies the fragmentation of parathyroid hormone (PTH)

Answer: d

7. What is the role of osteoprotegerin?
   a. Antagonizes function of the ligand of the receptor activator of nuclear factor κB (NFκB-ligand)
   b. Enhances osteoclastogenesis
   c. Suppresses osteoblastogenesis
   d. Moderates synthesis of parathyroid hormone related protein (PTHrP)
   e. Accelerates degradation of collagen type I

Answer: a

CHAPTER 9

Neonatal Diabetes Mellitus

Mark A. Sperling, MD

CHAPTER OUTLINE

DEFINITION

Neonatal diabetes mellitus (NDM) was strictly defined as severe hyperglycemia occurring in the first month of life, lasting at least 2 weeks, and requiring insulin therapy to control blood glucose.[1] These strict criteria have been progressively loosened, initially to include onset in the first 6 months of life, when autoimmune type 1 diabetes mellitus (T1DM) is highly unlikely, thereby implicating a genetic cause for pancreatic malformation, or faulty insulin synthesis and secretion. Increasingly, it has become recognized that, depending on the degree of expression and the inherent capacity of the genetic mutation to disrupt normal insulin output, several of the genetic forms can initially present with symptoms up to 9 months to 1 year, or even later.[2-4] Indeed, pedigree analyses conclusively demonstrate that the same defect that causes permanent or transient NDM can be present in parents or other first-degree relatives and be diagnosed as T1DM, monogenic diabetes of youth (MODY), or type 2 diabetes mellitus (T2DM) as subsequently detailed.[5,6] Herein lies the importance of understanding the genetic basis of NDM, for although considered rare, with a reported incidence varying from approximately 1 in 100,000 to 1 in 400,000 live births,[7] these entities have taught us much about the genetic pathways involved in the formation of the exocrine and endocrine pancreas.[8,9] For example, it has been shown that the specific combination of three transcription factors, *Ngn3*, *Pdx1* and *Mafa*, known to be implicated in the determination of cell lineage during pancreas formation, can reprogram adult mouse exocrine pancreatic cells into cells that closely resemble pancreatic β cells.[10] Such information is essential for the ultimate ability to generate β cells and whole islets as potential therapies for T1DM.[11] Equally important is the demonstration that activating mutations in the pore-forming $K_{ir6.2}$ and its regulatory subunit SUR1 of the K_{ATP}-regulated potassium channel, which keep the channel open and hence limit or preclude insulin secretion resulting in NDM (Figure 9-1), can be overcome by high-dose sulfonylurea therapy, which restores endogenous insulin secretion in response to feeding.[12] Due to the restoration of endogenous insulin secretion together with an incretin effect in response to feeding as opposed to intravenous glucose, this oral treatment provides better metabolic control than multiple daily injections of insulin or insulin pumps and with a better quality of life.[7,12] These findings emphasize the benefits of research for understanding pathophysiology and choosing appropriate treatment. Indeed, for those whose NDM is caused by mutations in the K_{ATP} channel that respond to sulfonylureas, these treatments border on the miraculous.

INCIDENCE

Early estimates placed the incidence at approximately 1 in 500,000,[1] and most authorities still cite figures in the 1 in 200,000 to1 in 400,000 range.[13] As increased awareness has led to these entities being recognized more frequently, the reported incidence has risen considerably. In populations with high rates of consanguinity, it has been reported that 1 in 21,000 births is associated with NDM.[14] A large representative database for pediatric diabetes reported that the incidence of NDM

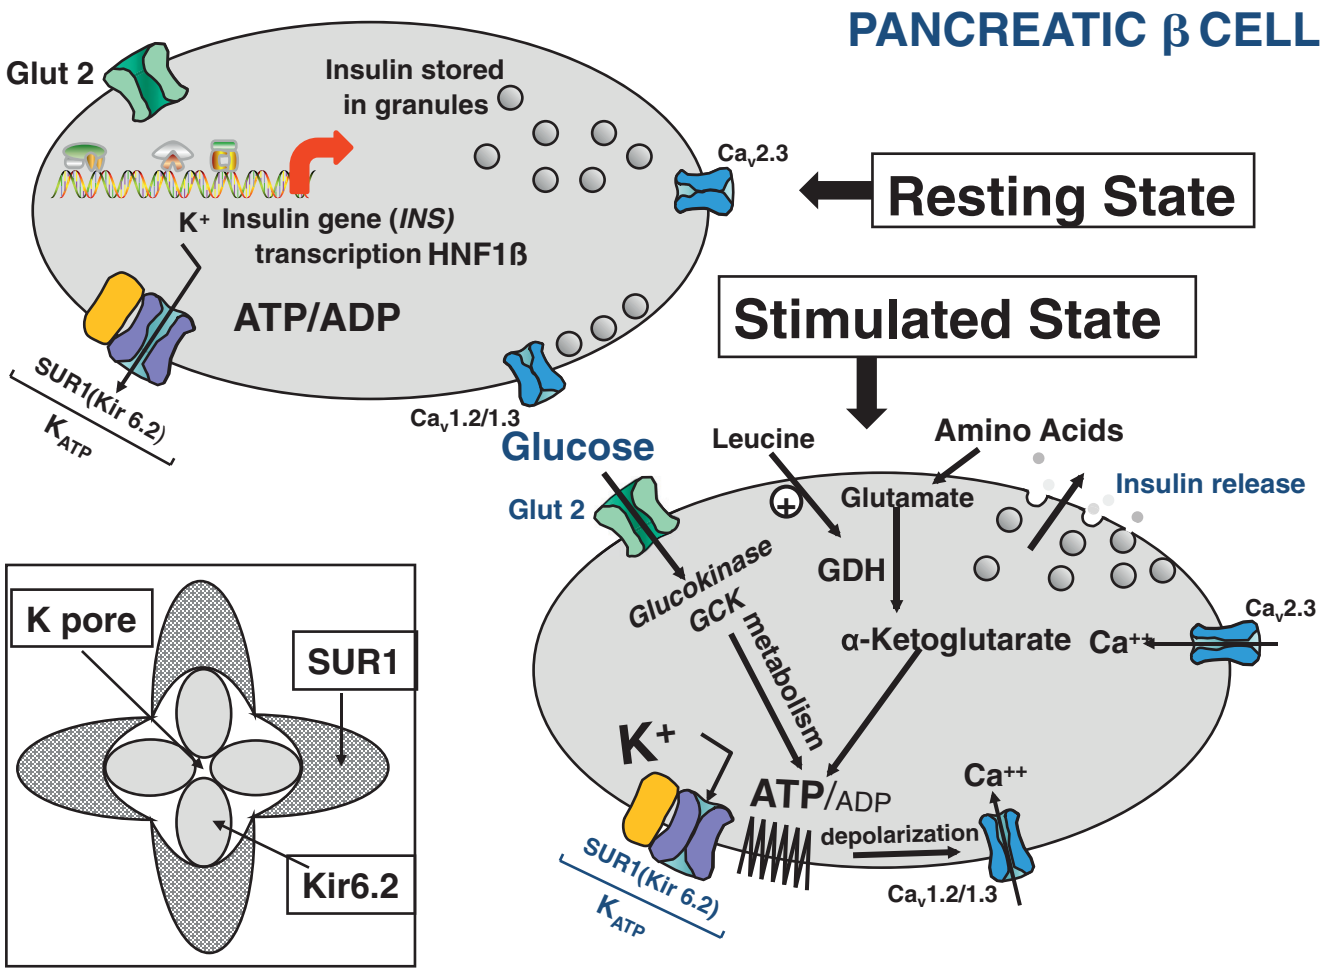

FIGURE 9-1 ■ This is a schematic representation of the role of K_{ATP} channels in nutrient regulation of insulin secretion. In the resting (nonfed) state, depicted in the upper left panel, insulin synthesis and storage are regulated by transcription from the insulin gene (INS) and by transcription factors such as hepatic nuclear factor 1β (HNF1β); mutations in INS or HNF1β as well as other genes can cause transient or permanent neonatal diabetes mellitus (NDM).The K_{ATP} channel is composed of four subunits of the inward rectifying potassium channel 6.2 (Kir 6.2) encoded by the KCNJ11 gene on chromosome #11) and four regulatory subunits of sulfonylurea receptor 1 (SUR1), encoded by the ABCC8 gene, also located on chromosome #11 (inset lower left). In the fasting nonfed state, the K_{ATP} channel remains open. However, in the stimulated (fed) state (panel lower right) glucose concentration increases and enters the β cell in a concentration-dependent, but insulin-independent manor via the Glut 2 glucose transporter encoded by the gene SLCA2A. Glucokinase (GCK) phosphorylates glucose to G6P and its metabolism generates ATP. The resultant change in ATP:ADP causes closure of the K_{ATP} channel, accumulation of intracellular potassium, membrane depolarization leading to opening of voltage-gated calcium channels and secretion of stored insulin, as depicted in the lower right panel. Metabolism of amino acids such as glutamate also generates ATP, which stimulates insulin secretion as described for glucose. The amino acid leucine acts as an allosteric stimulus to glutamate dehydrogenase (GDH), which enables metabolism and generation of ATP. Activating mutations of the KATP channel maintain it in an open state to varying degrees, in spite of ATP generation, therefore preventing insulin secretion, which leads to diabetes mellitus, including NDM. Inactivating mutations in KATP genes prevent normal channel opening, maintaining varying degrees of channel closure, and hence constant insulin secretion that causes HI (see Chapter 21). ATP, adenosine triphosphate; ADP, adenosine diphosphate; Ca++ -, calcium; GDH, glutamate dehydrogenase; K_{ATP}, ATP-regulated potassium channel; INS, insulin gene; HNF1β, hepatic nuclear factor1β; SUR1, sulfonylurea receptor1, K+, potassium; Kir6.2, potassium inward rectifying channel family6 subtype2; GCK, glucokinase, Glut2, glucose transporter 2. *(This image can be viewed in full color online at ExpertConsult)*

represented approximately 1 case in 89,000 live births in Germany, and a similar incidence occurred in Italy.[15,16] However, in three other European countries, the incidence was reported to be 1 in 260,000 live births.[17] In the SEARCH for Diabetes in Youth Study involving 15,829 subjects aged < 20 years diagnosed with diabetes during the years 2001-2008, 39 were diagnosed before the age of 6 months.[18] Among these 39 subjects with onset < 6 months of age, 35 had permanent neonatal diabetes and an additional 3 had transient NDM leaving 1 subject whose status remained unknown.[18] Hence, the total prevalence was approximately 0.246% or approximately 1 in 4000 of all children diagnosed with diabetes in that study during that time frame. The majority were classified by their primary care providers as having T1DM and treated with insulin; only seven underwent mutational analysis for three of the most common genes (*KCNJ11*, *ABCC8*, and the insulin gene *INS*) and five of these seven had mutations in one of these three genes.[18]

CLINICAL PRESENTATION

Typically, infants affected with NDM present in the first days to weeks of life with intrauterine growth retardation, reflecting the in utero deficiency of insulin and emphasizing the role of insulin as a determinant of fetal growth.[19] Their small size and low birth weight markedly contrasts with the large birth weight and size of infants with inactivating mutations in the same genes that lead to hyperinsulinemic hypoglycemia (see Chapter 21). A disproportionate number are born prematurely at < 37 weeks' gestation.[20] Hyperglycemia leads to osmotic diuresis and avid feeding from breast or bottle despite which the infants fail to thrive. Delay in diagnosis from not considering the possibility of diabetes mellitus in a newborn may lead to severe dehydration and life-threatening diabetic ketoacidosis. Some have congenital malformations including macroglossia and umbilical hernia, reminiscent of Beckwith-Wiedemann syndrome; these usually represent inheritance of genes with disordered methylation as a result of uniparental (paternal) disomy, paternal inherited duplications, or maternal hypomethylation of a differentially methylated region (DMR) at chromosome 6q24 (Figure 9-2).[20] Some of these infants have dysmorphic facies as well as renal tract anomalies such as hydronephrosis and vesicoureteral reflux, a variety of cardiac anomalies, hypothyroidism, and hand-finger anomalies.[20] A coarse facial appearance together with epilepsy and later manifestations of developmental delay constitute the *d*evelopmental delay, *e*pilepsy, *n*eonatal *d*iabetes (DEND) syndrome associated with severe mutations of the KCNJ11 gene.[12] However, clinical manifestations involving organs other than the pancreas may be part of the syndrome of a variety of genetic mutations associated with NDM as listed in Figure 9-3.

CLASSIFICATION

The entities of NDM are conveniently divided into transient and permanent, which together make up approximately 90% of the genetically recognized types of NDM; a third category constituting approximately 10% of known entities is associated with mutations that affect organs other than the pancreas and hence present as syndromes whose spectrum of clinical and radiologic features provide clues to the cause (see Figure 9-3). Transient NDM is so named because hyperglycemia is transient, and in the most common form, named TNDM1, it resolves at a median age of 3 months, although rarely it has taken up to 48 months for resolution.[20] Generally, those that do not remit by the end of the first 6 months to 1 year are considered to have permanent neonatal diabetes. Transient neonatal diabetes predominantly involves disturbances in the imprinted genes *pl*eomorphic *a*denoma *g*ene-*l*ike 1 (PLAGL-1) also known as *z*inc

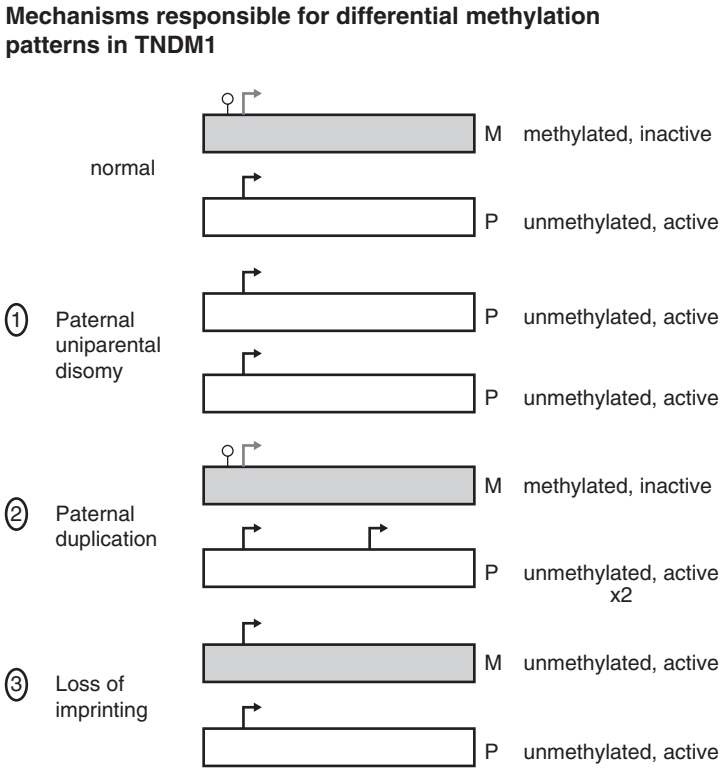

FIGURE 9-2 ■ Transient neonatal diabetes mellitus type 1 is caused by differential expression of PLAGL1 and HYMAI, genes on chromosome 6q24 that result from differential expression of the maternal and paternal alleles. Normally the maternal allele remains methylated and inactive, whereas the paternal allele is unmethylated and active. The differential expression of these genes can occur by one of three mechanisms: (1) paternal uniparental disomy, where both genes are of paternal origin; (2) paternal duplication, so that two active paternal genes are expressed; (3) loss of imprinting, also referred to as "relaxation of imprinting," on the maternal genes on 6q24 as illustrated here. See text for details.

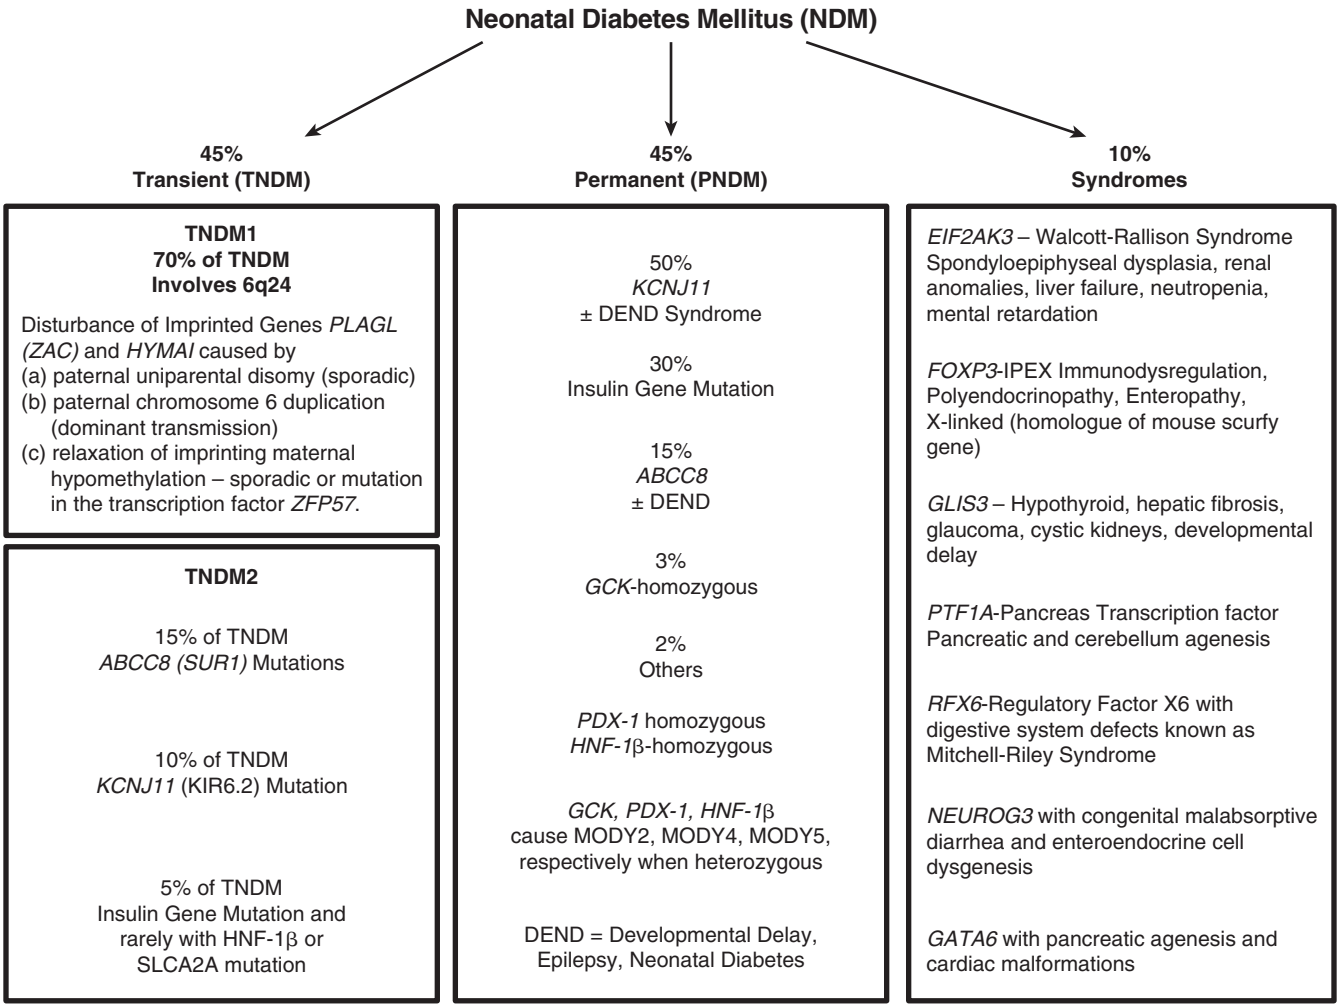

FIGURE 9-3 ■ Classification of neonatal diabetes mellitus. (Modified from Mccarthy, M. I., & Hattersley, A. T. (2008). Learning from molecular genetics: novel insights arising from the definition of genes for monogenic and type 2 diabetes. *Diabetes, 57*, 2889–2898.)

finger gene regulating *a*poptosis and the *c*ell cycle (ZAC) and *hy*datidiform *m*ole-*a*ssociated and *i*mprinted transcript (HYMAI) on the differentially methylated region (DMR) of chromosome 6q24. This entity has been named transient neonatal diabetes mellitus type 1 (TNDM1) and comprises the majority, estimated at some 70% of all forms of TNDM. A second form of TNDM, named TNDM2 to distinguish it from the defects in the 6q24 region, includes mutations in the ATP-regulated potassium channel involving predominantly mutations in ABCC8 (SUR1) and KCNJ11 (KIR6.2), with a small minority being due to recessive insulin gene mutations, mutations in the transcription factor HNF1β, and mutations in SLCA2A, the gene encoding the GLUT2 transporter, that together account for ~30% of TNDM (see Figure 9-3).

Transient Neonatal Diabetes Mellitus (TNDM)

TNDM1

TNDM1 is caused by the overexpression of the paternal PLAGL-1, which is a proapoptotic zinc finger protein, and HYMAI gene, encoding an untranslated mRNA, which arise as a result of uniparental disomy (UPD), duplication of chromosome region 6q24, or relaxation of imprinting of the maternal methylated genes on chromosome 6 (see Figures 9-2 and 9-3). It is important to emphasize that these chromosomal changes cause altered expression of genes, rather than representing mutations. For example, PLAGL-1 (ZAC) has antiproliferative properties and is thought to function as a tumor growth suppressor expressed only on the paternal allele[21]; overexpression in fetal life is believed to lead to underdevelopment of the pancreas. Although the precise mechanisms by which overexpression of PLAGL-1 lead to TNDM1 are not known, overexpression of ZAC in a clonal pancreatic beta cell line impairs glucose-stimulated insulin translation and secretion.[22] A transgenic mouse model expressing the human TNDM1 locus (6q24) is characterized by impaired glucose homeostasis with hyperglycemia in the neonatal period and impaired glucose tolerance with reduced insulin responses to IV glucose as adults.[23] The pancreata of these animals display reduced expression of endocrine differentiation factors, notably Pdx-1, Ngn3, and Pax6. There is also a reduction in the number of insulin staining cells and

reduced insulin content or insulin secretion despite normal or elevated beta cell mass at all postnatal periods.[23,24] Thus, this model recapitulates TNDM1 and suggests that altered expression of ZAC/HYMAI cause impaired development of the endocrine pancreas as well as impaired beta cell function.[23,24] This mouse model also demonstrates resolution of abnormal insulin secretion with restoration of normal glucose tolerance during the "juvenile" phase of mouse development between 1.5 and 2 months of life, during which there is an approximate doubling of beta cell number that compensates for the reduced insulin synthesis and secretion of each cell. Also, as in humans, the compensatory increase in beta cell mass is not sustained resulting in a mild diabetes mellitus characterized by normal fasting glucose but hyperglycemia after glucose challenge.[23,24] Overall, despite the recapitulation of the key features of the human disease, the mouse model displays milder features.[23,24] One possible reason for this milder phenotype in mice is that pancreatic expression of the mouse ortholog Zac-1 declines drastically during gestation and early postnatal growth in mice, whereas expression of the ZAC gene in human pancreas declines between the second trimester and adult life.[25] More important, ZAC was specifically expressed only in the islets of the human fetus, whereas Zac-1 was predominantly expressed in mesenchyme of the mouse embryo which may explain the milder features in the mouse model of TNDM1.[25]

In patients with TNDM1 due to hypomethylation of the maternal DMR of chromosome 6q24, there may be hypomethylation of other maternally imprinted loci (HIL) throughout the genome.[26] In cases that display a more generalized hypomethylation of imprinted loci (HIL), the majority have a mutation in the transcription factor zinc finger protein 57 (ZFP57).[27] HIL also occurs in the Beckwith-Wiedemann syndrome and this likely explains the macroglossia, umbilical hernia, and several congenital abnormalities described in TNDM1.[28] In a large multinational cohort involving 163 patients with TNDM1,[20] the authors describe intrauterine growth retardation with a mean birth weight of 2001 ± 417 g (mean ± SD) and adjusted Z score for birth weight of −2.5. The mean age of presentation was 8±12 days with a median of 4 days and a mode of 1 day. Mean gestation was 37.8 ± 2.4 weeks and prematurity was significantly more common than in the general population.[20] Remission occurred at a mean age of 4.5 ± 5.8 months with a median at 3 months. Age at presentation was positively correlated to gestational age, but age at remission was negatively correlated with adjusted birth weight. Thus, the higher the birth weight, the earlier the remission and vice versa. This would be consistent with the effects of insulin on intrauterine growth, so that the larger infants would have the milder defect and therefore tend to enter remission sooner. Congenital anomalies were significantly more frequent in patients with UPD of chromosome 6 or hypomethylation of multiple imprinted loci. Hypomethylation defects were overrepresented in patients born after assisted conception. Thus, babies with TNDM1 generally present with diabetes mellitus within the first days of life, are small, and may have been born prematurely. The presence of congenital anomaly suggests UPD or multiple HIL, and among the latter, almost one in seven conceived with assisted reproductive techniques. Macroglossia is present in about 50%, umbilical hernia in ~25%, and facial dysmorphism in about 20%. Cardiac and renal anomalies (~9%), hand abnormalities (~8%), and hypothyroidism (~4%) also may be present.[20] Remission, when it occurs, is usually around 3 months and about half of these patients will revert to varying degrees of hyperglycemia in the teen years or later.[20] An unusual manifestation is hypoglycemia with hyperinsulinemia, following remission of diabetes in patients with 6q24 methylation defects, most often parental unidisomy.[29] Modern molecular techniques permit diagnosis to be established, and these may influence treatment.

Ideally, these patients should be treated with an insulin pump using insulin diluted to 1:10 with appropriate diluent in order to provide the lower required amounts (0.2 to 1 u/kg/day).[30] Patients with TNDM1 are sensitive to insulin and respond with rapid and remarkable catch-up growth after several weeks of the treatment. Progressive reduction of the insulin dose required to control blood glucose while avoiding hypoglycemia heralds the onset of remission.

TNDM-2

Transient neonatal diabetes mellitus type 2 is a convenient way to classify conditions associated with a neonatal form of diabetes mellitus that remits during infancy and may recur later in life, but is due to mutations in genes regulating insulin secretion rather than expression of imprinted genes.[31,32] The majority of these entities are due to activating mutations in the ABCC8 and KCNJ11 genes, which, respectively, code for the SUR_1 and Kir6.2 subunits of the K_{ATP} channel (see Figure 9-1).[31,32] Recessive, loss of function mutations in the insulin gene itself may occasionally be responsible for TNDM2[33]; the autosomal dominant insulin gene mutations are associated with permanent NDM.[2,31,32] There are rare reports of HNF1β[34] and SLC2A2 mutations[35] also associated with TNDM.

The normal state of the K_{ATP} channel is to remain open; insulin secretion occurs when the channel closes in response to an increase in ATP generated from the metabolism of glucose or amino acids, thereby changing the ATP:ADP ratio. Closure of the channel with intracellular retention of the K+ causes depolarization of the plasma membrane, opening of voltage-gated calcium channels, influx of calcium, and secretion of insulin. Activating mutations in ABCC8 or KCNJ11 alter the ability of the channel to respond to the change in the ATP:ADP, so that the channel remains open to some extent, efflux of K+ from the β cell continues, permitting the cell membrane to remain hyperpolarized and therefore resulting in decreased insulin secretion. These same mechanisms also are responsible for the most common form of permanent neonatal diabetes mellitus as subsequently discussed.[31,32] It remains unclear how or why remission occurs, but it has been shown in vitro that mutations causing TNDM have a less pronounced effect on channel function compared with mutations that cause

PNDM.[36] The ability of ATP to close the channel in vitro correlates with the severity of neonatal diabetes mellitus, including the severe permanent form associated with the DEND syndrome, which demonstrates the greatest resistance to closure by ATP in vitro.[36,37] Both resistance to closure due to activating mutations, or resistance to opening of the channel due to inactivating mutations, segregate with certain mutations as illustrated in Figure 9-4, adapted from reference 36. As shown in the figure, near the fulcrum of this spectrum, those with minor defects may be prone to either develop milder type 2 diabetes, or be resistant to the development of diabetes by virtue of enhanced insulin secretion (see Figure 9-4).

In comparison to TNDM1, patients with TNDM2 generally have greater birth weight, present or are diagnosed with diabetes mellitus later, remit later, and recur earlier (Table 9-1). Family members of patients with these forms of TNDM2 may have diabetes that was diagnosed in adulthood as T1DM, T2DM, or MODY and yet harbor the same heterozygous mutations as the proband with NDM.[4-6] This reflects the variable penetrance of these genes or upstream factors that may modify the expression of the gene in different individuals. Confirming the presence of an ABCC8 or KCNJ11 mutation in a case of NDM is important for management because most of these K_{ATP} channel mutations respond to sulfonylurea treatment both at the time of initial diagnosis or later at the time of relapse.[12,31] During their remission phase, these patients do not require therapy.

A few patients have been reported with recessive loss of function mutation in the *INS* gene in patients with TNDM.[33] These patients appear to enter remission at a median age of 12 weeks; insulin is required before remission and after relapse, which has occasionally been reported.

Patients with mutations in the transcription factor hepatocyte nuclear factor 1 beta (HNF1β) are known to have diabetes associated with renal cysts with onset at a median of 20 years. However, two reported patients had neonatal diabetes: one was diagnosed at age 15 days and required insulin, initially intermittently and then permanently; a second patient diagnosed at the age of 17 days

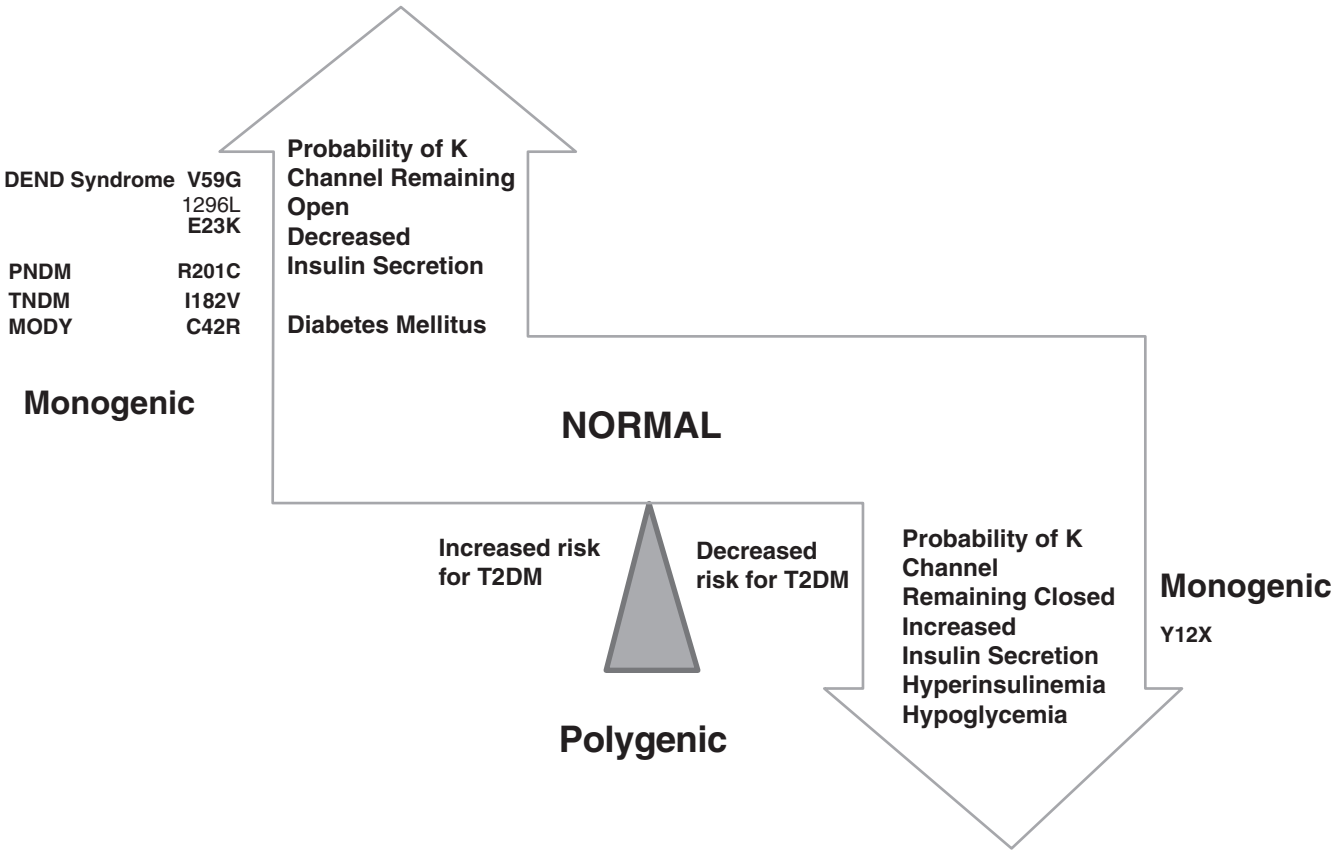

FIGURE 9-4 ■ This is a schematic representation of the relationship between K_{ATP} channel activity and insulin secretion. Activating mutations of KCNJ 11 gene maintain the channel in an open state and hence limit insulin secretion. With progressively increasing probability of the potassium channel remaining open, the severity of the diabetes increases from a mild increased risk for T2DM, to monogenic diabetes of youth (MODY), transient neonatal diabetes mellitus (TNDM), permanent neonatal diabetes mellitus (PNDM), and in the most severe state the DEND syndrome (*d*evelopmental delay, *e*pilepsy, *n*eonatal *d*iabetes) as illustrated on the left. By contrast, mutations that increase the probability that the channel remains closed also increase the likelihood of persistent insulin secretion and lead to hyperinsulinemia and hypoglycemia as illustrated on the panel on the right; in milder forms they may decrease the risk for T2DM by maintaining a higher insulin secretion. Common genetic defects are illustrated in each as examples. (Modified from Ashcroft FM [2005]. ATP-sensitive potassium channelopathies: focus on insulin secretion. J Clin Invest 115:2047-2058. Figure 6.)

TABLE 9-1 **Comparison of Clinical Characteristics of Patients with K_{ATP} Channel Mutations to Patients with 6q24 TNDM (data given in median [range])**

Characteristic	ABCC8 and KCNJ11 (n = 25)	6q24* (n = 23)	P-Value
Age at diagnosis (weeks)	4 (0-16)	0 (0-4)	< 0.001
Age at remission (weeks)	35 (2-208)	13 (5-60)	< 0.001
Age at relapse (years)	4.7 (3-15)	16 (4-25)	0.073
Birth weight (g)	2570 (1360-3570)	1950 (1600-2670)	<0.001
Percentile birth weight	12 (< 1st-89th)	<1st (< 1st-21st)	< 0.001

From Flanagan, S. (2013). Transient neonatal diabetes. Diapedia, *Rev. 21. Retrieved from www.diapedia.org/other-types-of-diabetes-mellitus/41040851198/transient-neonatal-diabetes.*

had remission 2 weeks after diagnosis but relapsed at the age of 8 years.[34] There have also been a few cases reported of mutations in the SLC2A2 gene, which encodes the glucose transporter GLUT2 (glucose transporter type 2).[35] Recessive inactivating mutations in this gene cause the Fanconi-Bickel syndrome, characterized by glucosuria, galactosuria, aminoaciduria, proteinuria, and phosphaturia as well as rickets, poor growth, and short stature with associated glucose and galactose intolerance and enlarged livers. Transient neonatal diabetes has been reported in these patients to occur in association with the classic Fanconi-Bickel syndrome.[35]

PERMANENT NEONATAL DIABETES MELLITUS (PNDM)

K_{ATP} and Insulin Gene Mutations

Almost half of newborns with NDM never enter a remission and therefore are considered to have PNDM (see Figure 9-3). Excluding the syndromic entities, mutations in three genes account for approximately 95% of affected patients with NDM; almost two thirds are mutations in the K_{ATP} channel genes, KCNJ11 coding for the pore-forming protein $K_{IR6.2}$ (50%) and ABCC8 coding for the sulfonylurea receptor protein SUR1 (15%; see Figures 9-1 and 9-3). Finally in this group, approximately 30% have autosomal dominant insulin mutations or rarely autosomal recessive insulin mutations. The remaining 5% of patients with nonsyndromic PNDM have homozygous mutations in factors that, when heterozygous, cause forms of monogenic diabetes of youth (MODY; see Figure 9-3).

Until the discovery of the genes responsible for the K_{ATP} channel, patients with PNDM were considered to have insulin-dependent diabetes mellitus; now it is known that the majority of patients with K_{ATP} mutations causing PNDM respond to oral therapy with sulfonylurea.[12,32] Patients with PNDM due to mutations in the K_{ATP} genes or the insulin gene usually present at 2 to 3 months of life, and sometimes later, and may be in severe DKA by the time of the diagnosis. Activating mutations in the $K_{IR6.2}$ subunit of the K_{ATP} channel were first reported in 2004,[37] being found in 10 out of 29 subjects with permanent NDM. Whereas the insulin secretory response to intravenous glucagon and glucose was absent, patients did respond with insulin secretion to intravenous tolbutamide, clearly hinting at possible therapy by the administration of sulfonylurea and confirmed by a landmark study published 2 years later.[12] Expression of the mutated $K_{IR6.2}$ subunit together with a normal SUR1 subunit in Xenopus laevis oocytes revealed that the ability to enable channel closure by ATP was greatly impaired. This provided a means to correlate the degree of in vitro abnormality with the clinical severity of the diabetes.[36-38] The affected patients predominantly had de novo mutations, with only 20% of the mutations inherited from a parent. It also was noted that 4 out of 10 of the patients had severe developmental delay, muscle weakness, and epilepsy, as well as dysmorphic facial features, which was termed the DEND syndrome. The degree of muscle weakness was ameliorated by treatment with sulfonylurea, raising the possibility that the developmental delay and epilepsy may also be ameliorated, or perhaps prevented, by early recognition and treatment with sulfonylurea.[32,37-39] Subsequently it was demonstrated in mice that transgenic expression of an activating mutation in Kir6.2 in mouse pancreatic β cells recapitulates neonatal diabetes[40] and that the muscle dysfunction caused by a human K_{ATP} channel mutation is neuronal and not muscular in origin.[41] K_{ATP} channels exist in other tissues and are known to modulate electric activity and neurotransmitter release at brain synapses in various regions of the brain.[36] Moreover, K_{ATP} channels in the ventromedial hypothalamic nucleus may be involved in the counter-regulatory response to hypoglycemia[42]; in the arcuate nucleus neurons, K_{ATP} channels may be involved in appetite regulation.[42,43]

A spectrum of clinical disturbances occurs with different mutations ranging from the DEND syndrome, to relapsing diabetes,[36,44,45] permanent diabetes appearing initially in childhood or later in adults.[44-46] Mutations in adjacent locations may cause either neonatal diabetes or hyperinsulinism because they increase or decrease the open state of the channel.[44-48] Likewise, mutations in the ABCC8 gene encoding SUR1 cause transient or permanent NDM, or permanent diabetes diagnosed beyond the newborn period in children, or in adults, and mutations at a similar site in the gene can result in either hyperinsulinism or neonatal diabetes.[5,49-52]

Insulin gene mutations as a cause of PNDM were first reported in 2007 and are now known to be the second most common mutations responsible for these entities.[53-55] Inheritance was autosomal dominant in the familial cases, but the majority had de novo mutations. The mutations occurred in a critical region of the preproinsulin molecule,

predicting misfolding and hence loss of normal trafficking of the proinsulin in the insulin secretory pathway. This misfolding was also proposed to induce the unfolded protein response, with degradation in the endoplasmic reticulum, leading to severe ER stress and apoptosis of the beta cells, processes known to occur in mouse models of dominant insulin gene mutations.[53] Clinically, the age at diagnosis averaged 13 weeks compared with 5 weeks for KCNJ11 and 7 weeks for ABCC8 mutations. Gestational age at birth was within the normal range of 36W to 41W, and mean birth weight was also normal at 2846 Gm. Thus, these abnormalities appear to disturb intrauterine growth less than in the 6q24 and severe K_{ATP} channel mutations. These dominant or de novo mutations are not usually associated with TNDM or remission,[53] whereas recessive mutations of the insulin gene can result in a remitting type of NDM as described earlier.[33] The initial suggestion of ER stress as a mechanism has been largely confirmed and the spectrum of disorders in the insulin gene extends to a MODY phenotype or onset in adulthood.[54-59]

Other Genetic Forms of PNDM

Three factors involved in islet regulation of insulin secretion, via an enzymatic gatekeeper function (Glucokinase-GCK), the islet formation transcription factor PDX-1, sometimes also known as IPF-1, and the transcription factor HNF1β, cause a monogenic form of diabetes respectively known as MODY2, MODY4, and MODY5 when in the heterozygous state and can cause PNDM when in the homozygous state (see Figure 9-3).

GCK

Glucokinase has been called the "glucose sensor" of the beta cell. It phosphorylates glucose to glucose-6-phosphate, permitting entry into the glycolytic pathway for metabolism and generation of ATP, which triggers insulin secretion (see Figure 9-1). GCK is also known as hexokinase IV or hexokinase D and is most active in the physiologic range of glucose at 4 to 10 mmol/L (72 to 180 mg/dL) with a K_m of ~8 mmol /L (144 mg/dL). The glucose-stimulated insulin release (GSIR) threshold occurs when glucose phosphorylating capacity reaches 30% of maximum, which generally occurs under normal circumstances at a glucose concentration of ~90 mg/dL and is maximum at glucose concentrations of 300 mg/dL or higher but not reaching more than ~80% of full (100%) glucose phosphorylating capacity.

Activating mutations of GCK exert these effects at lower glucose concentrations and hence cause hyperinsulinemic hypoglycemia (see Chapter 21). Inactivating heterozygous mutations in GCK cause a mild diabetes because the glucose phosphorylating capacity is shifted to the right, so that the 30% phosphorylating capacity needed for the GSIR occurs when glucose concentrations are ~120 mg/dL rather than 90 mg/dL and reach only a peak of 50% to 60% of the 100% phosphorylating capacity. This is enough to clear all glucose after a meal, but with periods of hyperglycemia before this occurs. In children, GCK inactivating mutations causing MODY2 are the most common form of MODY, often presenting as incidental findings discovered during blood tests for other causes and often with a positive family history for diabetes. A second common presentation of MODY2 is as "gestational diabetes" in an otherwise healthy young mother and which may persist as a mild diabetes postpartum.

Homozygous inactivating mutations in GCK were reported in two patients in 2001,[60] and the same authors reported an additional three cases in 2003.[61] The affected subjects were homozygous for the mutation or were compound heterozygous for two different mutations, being a splice site in one and a missense mutation in the other. Each of these five initial subjects was characterized by intrauterine growth retardation, permanent neonatal diabetes from day 1 of life, and hyperglycemia in parents, which was an important diagnostic clue. Apart from some other novel single case reports,[62,63] an additional four novel cases of permanent NDM due to homozygous mutations in GCK were reported in 2011.[64] Overall, these mutations are rare in NDM; in one large cohort of 54 cases of NDM, GCK mutations were found in only one case of European ancestry,[65] and the same was true for a study comparing the etiologies of PNDM in an Arab versus European population.[66]

PDX-1

PDX-1, which stands for pancreatic duodenal homeobox-1 and is also known as insulin promoter factor-1 (IPF-1), is a critical transcription factor that defines the pancreatic progenitor cell as it differentiates from the endodermal epithelium. Exocrine-duct lineage is then specified by the transcription factor PTF1 (pancreas transcription factor-1), which defines the exocrine and duct cells. However, in the presence of Ngn3, the progenitor cell differentiates into a series of endocrine pancreatic cells under the influence of other transcription factors including Pax4 and Pax6, as well as Beta2. Thus, PDX-1 is critical for the formation of both the exocrine and endocrine pancreas and hence homozygous mutations will lead to an absence of pancreas formation with manifestations of neonatal diabetes and pancreatic exocrine insufficiency. The parents may be heterozygous carriers and therefore known to have a form of diabetes known as MODY4. The first report of pancreatic agenesis attributed to homozygous deletion of a gene in the PDX-1 (IPF1) gene was reported in 1997,[67] the second case was reported in 2003,[68] and the third case was reported in 2009[69]; each was characterized by pancreatic agenesis with manifestations of both exocrine and endocrine abnormalities. In a more recent study in a large cohort of patients with permanent neonatal diabetes but without known abnormal development or clinical exocrine insufficiency of the pancreas, the possibility of PDX-1 mutations was investigated in 103 patients in whom K_{ATP} and INS mutations had been excluded. In this group, 3 additional cases of mutations in PDX1 were identified, but these patients did not have evidence of exocrine pancreatic insufficiency either clinically or biochemically. Thus, it is possible to have PNDM due to a mutation in PDX1 without necessarily having pancreatic hypoplasia or agenesis.[70] In this regard it is important to note that neonatal diabetes may be associated with

pancreatic as well as cerebellar agenesis as a result of mutations in the PTF1A gene (pancreas transcription factor 1A)[71] and that the Ngn3 gene can be associated with neonatal diabetes and congenital malabsorptive diarrhea consistent with the role of this gene in pancreas development as briefly described earlier.[72] Other genes that have been implicated in pancreatic agenesis include EIF2AK3, HNF-1B, RFX6, and GATA6, which may be associated with pancreatic agenesis and other lesions including heart defects.[73] As a diagnostic clue, if pancreatic imaging shows the absence or hypoplasia of a pancreas, the diagnostic search can be restricted to a series of genes as outlined.[74]

HNF1β

As previously noted, mutations in HNF1β can cause neonatal diabetes mellitus and neonatal polycystic dysplastic kidneys with either permanent or transient neonatal diabetes.[34]

Syndromic Neonatal Diabetes Mellitus

The syndromes associated with NDM constitute no more than 10% of all forms of NDM and hence are each rare (see Figure 9-3). But they are of interest in identifying the spectrum of genetic disorders that can result in abnormal pancreas formation, malfunction, or destruction. In a sense, even the most common forms of PNDM caused by K_{ATP} mutations may have a syndromic component as in the DEND syndrome, but this is not integral to the condition, whereas in the syndromic forms of NDM, associated features define and distinguish the entities and point to the likely etiology.

Wollcott-Rallison Syndrome: Mutations in EIF2AK3

This rare condition is actually the most common genetic cause of permanent neonatal diabetes mellitus in consanguineous families,[66,75] and it may present as isolated non-autoimmune neonatal diabetes mellitus diagnosed at 3 weeks of age or later. Typically, skeletal dysplasia and growth retardation are recognized in the first year or two of life; other manifestations include episodes of liver failure, renal dysfunction and evidence of pancreatic exocrine insufficiency, neutropenia with recurrent infections, hypothyroidism, and mental retardation.[76] The basis for this condition are mutations in the gene encoding *e*ukaryotic translation *i*nitiation *f*actor α-kinase 3 also known as PKR-like endoplasmic reticulum kinase (PERK), which participates in the unfolded protein response in the ER. Environmental factors and modification by other genes may influence the spectrum of clinical severity. Skeletal dysplasia with bone fractures and episodes of liver failure plus neonatal diabetes mellitus are pathognomonic of this entity; a review in 2010 indicated that fewer than 60 cases had been reported worldwide[76]; two novel mutations were subsequently reported.[77] The prognosis is poor for affected patients. Treatment of the diabetes mellitus by pump therapy is recommended; parents should have genetic counseling for risks of recurrence, as this is an autosomal recessive condition.

IPEX-FOXP3

The term *IPEX* is an acronym for *i*mmune dysregulation, *p*olyendocrinopathy, *e*nteropathy, *x*-linked and is due to dysfunction of T regulatory cells caused by mutations in the FOX P 3 gene, which normally is a transcriptional regulator for CD4 regulatory T cells, so that mutations result in the multiorgan autoimmunity. The clinical characteristics are early onset, insulin-dependent diabetes mellitus, or enteritis; eczema and elevated serum Ig E also occur early. Later manifestations include primary hypothyroidism, nephritis, hepatitis, enteritis, and alopecia. Bone marrow stem cell transplant offers potential for cure, but it depends on the availability of a suitable donor.[78,79] Scurfy mice serve as a model for this condition in humans.[80]

GLIS 3

GLIS 3 is a member of the GLI-similar zinc finger protein family, which can function both as a repressor and activator of transcription and is specifically involved in the development of pancreatic beta cells, the thyroid, eye, liver, and kidney. An autosomal recessive syndrome, characterized by neonatal diabetes mellitus, IUGR, congenital hypothyroidism, hepatic fibrosis with cholestasis, polycystic kidneys, and congenital glaucoma, it was first described in 2003,[81] and the responsible mutation in the GLIS 3 gene was identified in 2006.[82] As noted, this gene is expressed in the early developmental stages of the thyroid, eye, liver, kidney, and the pancreas, particularly in beta cells. Thus, mutations in GLIS 3 may have a role in other developmental anomalies and possibly in T1DM or T2DM. Novel mutations associated with the classical findings of NDM and hypothyroidism, plus bilateral sensorineural deafness, osteopenia, and pancreatic exocrine insufficiency, enlarge the clinical spectrum as reported.[83] In animal studies, it appears that GLIS 3 expression is required for pancreatic beta cell function and maintenance of beta cell mass in the adult, so that impaired function could lead to diabetes mellitus.[84,85] Genome-wide association studies identify GLIS 3 as a locus that affects risk for T1 DM,[86] and variants of GLIS 3 have been implicated in the predisposition to T2 DM.[87]

PTF1A

The gene PTF1A encodes pancreatic transcription factor 1α known to be involved in pancreatic development. Mutations in this gene were identified in two families with neonatal diabetes mellitus associated with pancreatic agenesis as well as cerebellar agenesis, implicating this factor in normal cerebellar development as well as pancreatic development, findings confirmed in knockout models of this gene in mice.[71]

Rfx6

In mice, it was shown that absence of the transcription factor Rfx 6 prevents the formation of any pancreatic endocrine cells except for pancreatic polypeptide producing

cells; mutations in the human ortholog RFX6 gene caused an autosomal recessive form of neonatal diabetes mellitus.[88] In humans, the syndrome of neonatal diabetes mellitus, intestinal atresia, and hepatobiliary abnormalities had been known as the Mitchell-Riley syndrome.[89] Clinically, patients are characterized by severe IUGR, fluctuation in glucose concentrations, stabilizing as persistent hyperglycemia and requiring insulin for stabilization, cholestatic jaundice and anatomic findings of intestinal atresia, agenesis of the gall bladder, and abnormal formation of the pancreas. Those who survive this critical neonatal period as the result of surgical and medical interventions can continue with a favorable prognosis for subsequent life apart from the likelihood of mental retardation.[90]

Neurog-3

Neurogenin 3 is a critical transcription factor for the differentiation of islet endocrine cell types from the pancreatic endoderm. Mice lacking this factor are devoid of intestinal pancreatic endocrine cells and develop diabetes mellitus as newborns. In humans, homozygous mutations in Neurog-3 cause malabsorptive diarrhea and early onset diabetes mellitus.[72,91]

GATA6

Both GATA4 and GATA6 are critical factors with differential contributions for normal pancreatic organogenesis; double Gata 4 and Gata 6 knockout mice do not develop a pancreas and hence have diabetes.[92-94] In humans, heterozygous inactivating mutations in GATA6 were found to be the most common cause of pancreatic agenesis occurring in 15 of 27 subjects with pancreatic agenesis.[95] These patients required both insulin plus pancreatic enzyme replacement.[95] In a follow-up study,[96] the same investigators sought GATA 6 mutations in 171 subjects with NDM of unknown etiology, having already identified other mutations, including 15 with GATA6 mutations, in 624 subjects out of a cohort totaling 795. In the new cohort of 171 remaining subjects, an additional 9 new cases of GATA 6 mutations were identified for a total of 24 affected out of the original cohort of 795 subjects (3%). In these 9 new cases, 2 had neonatal diabetes mellitus but did not require pancreatic enzyme replacement, and 1 had transient neonatal diabetes mellitus. In addition, four parents were found to have GATA 6 mutations, but the diabetes was diagnosed between the ages of 12 and 46 years. Several of the 9 new subjects had subclinical pancreatic enzyme deficiency. Except for one of the parents, subjects with GATA 6 mutations had extra pancreatic features, congenital heart malformations being found in 83%. Thus, these GATA 6 mutations can cause permanent neonatal diabetes mellitus or occasionally transient neonatal diabetes mellitus, as well as adult-onset diabetes with gradations in exocrine pancreatic insufficiency from complete agenesis, subclinical, or no deficiency at all; the majority manifest congenital heart defects.[96] In evaluating a patient with neonatal diabetes mellitus, pancreatic imaging is useful, because finding pancreatic hypoplasia, or aplasia, limits the possible genetic causes to GATA 6[96] as well as EIF2 AK3, PTF 1A, HN1B, PDX 1, and RFX 6.[74]

DIAGNOSIS AND TREATMENT OF NEONATAL DIABETES MELLITUS

Neonatal diabetes mellitus should be considered in babies who display IUGR in utero or at birth, and who fail to thrive despite apparent lusty suck, adequate intake, and copious urine output. A positive family history of diabetes mellitus in one or both parents, or in prior siblings, points to a likely genetic cause; most cases represent de novo mutations. The diagnosis is established by confirmation of hyperglycemia and glycosuria, both readily available in hospitals or medical clinics. Recognition of diabetes mellitus within the first week of life likely represents TNDM1, due to the differential expression of imprinted genes on chromosome 6q24, particularly if congenital defects such as macroglossia and umbilical hernia are present. Somewhat later recognition should also include consideration of defects in the K_{ATP} channel, involving KCNJ11 and ABCC8 genes as well as the INS gene; β-cell antibodies need not be determined unless features such as those found in the IPEX syndrome are present. Pancreatic antibody testing should be performed after age 6 months, however.

A molecular diagnosis should be sought; confirmation of methylation defects will raise the possibility of remission; K_{ATP} channel defects also may remit, but if confirmed, a trial of transition to oral sulfonylurea therapy may be feasible. Ascertainment of four genes, methylation defects on 6q24, KCNJ11, ABCC8, and INS, will identify the majority of the 90% of identifiable genes responsible for NDM in the first 6 months of life; defects in GCK, HNF1β, PDX-1, and SLCA2A are the result of autosomal recessive inheritance so that both parents likely have some form of diabetes mellitus (see Figure 9-3). Pending establishment of the molecular defect, patients should be treated with insulin; pumps delivering insulin should be used if available because they offer the ability to deliver small amounts via insulin diluted in appropriate diluent. Trial and error determine the amount to be given to achieve reasonable glycemic control to avoid both hyperglycemia and hypoglycemia; a starting dose of 0.5 units per kilogram per day increasing or decreasing by 0.1 unit per kilogram per day and distributed over 24 hours is a reasonable starting approach. The temptation to start these patients on sulfonylurea pending the establishment of the molecular diagnosis should be avoided; based on available data, only approximately 20% of those diagnosed in the first week of life have a high probability of responding to treatment with sulfonylurea.[97] Current methodology permits molecular diagnosis to be completed relatively quickly with results available in 1 to 2 weeks and it can be performed at established regional centers in the UK, United States, and elsewhere. Some of these centers offer molecular diagnostics to be performed without charge as a result of funding from various national agencies. In the absence of a molecular diagnosis, a trial of sulfonylurea may aggravate the hyperglycemia and lead to diabetic ketoacidosis in the patients who do not respond. Hence, we strongly urge that when a diagnosis of NDM is established in a newborn, treatment should be started with insulin and a sample sent for molecular diagnosis, the results of which will be informative regarding likely response to sulfonylurea.[31]

Presentation later than the first 2 to 4 weeks but within the first 6 months of birth is likely to yield a molecular

diagnosis in about two thirds of all patients[2]; clinical features such as specific patterns of congenital defects may offer clues to the diagnosis and prognosis as discussed earlier for syndromic NDM (see Figure 9-3).

AVAILABLE RESOURCES

The following resources offer advice in diagnostic and therapeutic services and may also perform the molecular diagnosis free of charge as part of their mandate funded by national governmental agencies:

- www.kovlerdiabetescenter.org/registry Chicago (United States)
- www.mody.no Norway
- www.genetests.org CLIA certified laboratories performing the tests

TRANSITION TO ORAL THERAPY

Once the diagnosis of a mutation in the K_{ATP} channel likely to respond to sulfonylurea is established, transition to oral treatment from insulin treatment is best accomplished on an inpatient basis using tablets or suspensions of glyburide prepared in a hospital pharmacy to facilitate the swallowing of the medication. The starting dose is 0.4 milligram per kilogram per day in two divided doses. Table 9-2 outlines the sequential steps to be taken in transitioning the patient and is based on recommendations from NDM centers in both the UK and the United States.

FUTURE DIRECTIONS

The discovery of the genes responsible for various forms of NDM has been spectacular in its impact on the

TABLE 9-2 **Inpatient Transition to Oral Sulfonylurea**

Day	Glucose Monitoring	Insulin Adjustments	Glyburide Dosing
Prep	Monitor capillary blood glucose (BG) before meals, 2 hours post meals, bedtime, and 2 a.m. Monitor ketones any time BG is > 300 mg/dL (> 16 mmol/L). Have a plan for hypoglycemia.	Maintain usual insulin regimen either via pump or customary basal-bolus injections. Reduce basal insulin by 50%. (If pump is being used, can be done just before day 1 breakfast; if long-acting insulin is being used, may be reduced on previous evening.)	The experience of previous cases with the same mutation will help inform expected response. Tablets (easily halved) available: 1.25, 2.5, or 5 mg For infants, tablets can be crushed and suspended in water/formula at the bedside or by any pharmacy.
1	If BG before dinner dose is: > 126 mg/dL (7 mmol/L) → < 126 mg/dL (7 mmol/L) →	Administer rapid-acting bolus insulin as needed based on capillary BG: Give usual bolus insulin dose Give 50% of usual insulin dose	0.1 mg/kg before breakfast and dinner (total of 0.2 mg/kg/day), depending on BG: Give 0.1 mg/kg dose at dinner Dinner dose may be skipped
2-7	If BG before SU dose is: > 126 mg/dL (7 mmol/L) → < 126 mg/dL (7 mmol/L) →	Continue decreasing insulin as tolerated: Continue bolus dosing from previous day Decrease insulin bolus by 50%	Each day dose will increase by 0.2 mg/kg/day (0.1 mg/kg/dose) depending on BGs: Increase dose by 0.1 mg/kg/dose May continue dose from previous day
Last	On final day and after discharge continue checking BG at least 4-6 times per day to monitor response. Relative hypoglycemia may necessitate lowering of glyburide dose in following weeks-months.	In most SU-responsive cases, insulin can be discontinued within 5-7 days, although mild hyperglycemia may still occur. Treat with rapid-acting bolus insulin as needed, as well as low-dose basal insulin in some cases. It may be possible to discontinue insulin in the following weeks-months.	By the end of 5-7 day admission, the patient will either have clearly responded on a lower dose or will be on at least 1 mg/kg/day. The dose may continue to be increased after discharge if needed, with some patients requiring up to 2-2.5 mg/kg/day (which may be lowered eventually in the following weeks-months).
Notes	If expected response is uncertain, C-peptide levels pre and 90-120 minutes post breakfast (no insulin given) may be done on day 1 and a later day after the glyburide dose is at least 1 mg/kg/day (usually day 5). If levels pre SU are nearly undetectable but show a significant increment on glyburide, consider increasing dose as high as 2-2.5 mg/kg/day.	BG ranges and insulin adjustments are only a guideline; the physician should be guided by clinical judgment. If there is any indication that glyburide is helping to control BG levels overall, it is often better to decrease the insulin aggressively so as to avoid hypoglycemia. If little/no insulin is given with meals, corrections for high BGs (per usual sensitivity/correction scale) may be given post mealtime or at any time.	Patients with neurodevelopmental disability or those who are older at the time of transition may experience less responsiveness and require higher doses of glyburide. In such cases, the possible benefit of continuing a high dose for the long term should be carefully considered even if the patient still requires insulin.

Data from Pearson, E. R., Flechtner, I., Njolstad, P. R., et al. (2006). Switching from insulin to oral sulfonylureas in patients with diabetes due to Kir6.2 mutations. N Engl J Med, 355, *467-77. diagnosis and treatment of affected patients and its relevance to understanding the global burden of diabetes mellitus. The same genetic defects that cause NDM have been found in parents or unrelated individuals considered to have T2DM or classic T1DM non-autoimmune. Thus, these discoveries have informed potential mechanisms by which insulin secretion is impaired at the level of pancreas formation and development, insulin synthesis, and insulin secretion. In addition, this offers the possibility to overcome the defect through the pharmacogenetics of the K_{ATP} channel in which activating mutations can be overcome by sulfonylurea treatment. However, the cause in at least a third of patients with NDM in the first 6 to 9 months of life is still not known and, as yet, a genetic mutation has not been identified. Whole genome or exome sequencing[98] may reveal the basis for these undefined syndromes in the near future.

QUESTIONS

1. Neonatal diabetes, hypothyroidism, and glaucoma occur in which of the following conditions?
   a. DEND syndrome
   b. Relaxation of imprinting due to mutation in ZFP57
   c. GLIS3 mutation
   d. All of the above
   e. None of the above

Answer: c

2. FOXP3 mutation is responsible for which of the following conditions?
   a. Pancreatic and cerebellum agenesis
   b. Immunodysregulation, polyendocrinopathy, and enteropathy
   c. Digestive system defects known as Mitchell-Riley syndrome
   d. Transient diabetes mellitus
   e. None of the above

Answer: b

3. A man fathers three children, all of whom develop TNDM, by three different mothers. What is the most likely mechanism?
   a. TNDM due to homozygous mutation in KCNJ11
   b. TNDM due to homozygous mutation in ABCC8
   c. Duplication of the paternal 6q24 region
   d. Relaxation of imprinting due to maternal hypomethylation of 6q24
   e. A freakish chance occurrence

Answer: c

4. Prenatal assessment via ultrasound indicates a baby with severe IUGR. At full-term birth, the baby weighs 1800 grams, has very little subcutaneous fat, and constantly cries for "the bottle" but passes copious amounts of urine so that nurses assume the baby is well hydrated. Persistent failure to thrive leads to the discovery of severe hyperglycemia. How would you advise the parents regarding this presentation?
   a. It is typical for the DEND syndrome.
   b. It is neonatal diabetes mellitus, which should respond to sulfonylureas tablets and the baby will not require insulin shots.
   c. It is TNDM for which molecular diagnosis is not necessary, as this baby's condition will most likely remit in several weeks though it may recur later in life.
   d. It is most likely TNDM1, which responds to surgical correction.
   e. None of the above

Answer: e

5. TNDM can occur in all *except* which of the following conditions?
   a. PTF1A
   b. HNF1β
   c. SLCA2A
   d. KCNJ11
   e. Recessive INS

Answer: a

ENDOCRINE DISORDERS IN CHILDREN AND ADOLESCENTS

CHAPTER 10

Disorders of Growth Hormone/ Insulin-Like Growth Factor Secretion and Action

Philippe F. Backeljauw, MD • Mehul Tulsidas Dattani, MD • Pinchas Cohen, MD • Ron G. Rosenfeld, MD

CHAPTER OUTLINE

NORMAL GROWTH

Normal growth is one of the fundamental characteristics of childhood and adolescence. As multifactorial and complex as the process of growth is, children normally grow in a remarkably predictable manner. Deviation from a normal pattern of growth can be the first manifestation of a wide variety of disease processes, including endocrine and nonendocrine disorders, and may involve virtually any organ system of the body. Frequent and accurate assessment of growth is, therefore, of primary importance to physicians and nurses caring for children.

Measurement

Correct assessment of statural growth requires optimizing accuracy in height determinations.[1-3] When feasible, measurement of supine length is employed in children younger than 2 years of age, and that of standing height is done in older children. Between 2 and 3 years of age, measurement of both length and height can be helpful to assess growth velocity more accurately whereas taking into account the measurement technique. In this age range the supine length averages about 1 cm greater than the standing height. However, the inherent inaccuracies involved in measuring length in infants are often obscured by their rapid skeletal growth characteristic of this age. For measurement of supine length, it is best to employ a firm box with an inflexible board (against which the head lies) and a movable footboard on which the feet are placed perpendicular to the plane of the supine infant. Alternatively, in many offices a counter-mounted or portable infantometer is used to assess infants' and toddlers' growth. To achieve reliable and accurate measurements, the technique used is of great importance. Optimally, the child needs to be relaxed—with the legs fully extended and the head positioned in the "Frankfurt plane" (meaning

the line connecting the outer canthus of the eye and the external auditory meatus is perpendicular to the long axis of the trunk). Repeating the length measurement three times and using the mean is another way to improve reliability.

When children are old enough to stand erect (and physically capable of doing so), it is best to employ a wall-mounted "Harpenden" stadiometer similar to that designed by Tanner and Whitehouse for the British Harpenden Growth Study. Freestanding stadiometers are also available but require frequent recalibration. The traditional measuring device of a flexible arm/bar mounted to a weight balance is notoriously unreliable and cannot be counted on to provide accurate serial measurements.

As with length measurements in infants, positioning of the child is critical. The patient should be fully erect, with the head in the Frankfurt plane. The back of the head, thoracic spine, and buttocks should be touching the vertical axis of the stadiometer; the heels are put together with the toes slightly separated. Every effort should be made to correct discrepancies related to lordosis (neck and lower back) or scoliosis. Ideally, serial measurements should be made at the same time of day because diurnal variation in standing height has been observed, leading to measurements in children and adolescents being up to 0.8 cm shorter at the end of the day compared with measurements obtained in the morning; this phenomenon is likely due to development of fatigue of the spine musculature throughout the day.[4]

It is critical that height determinations be performed by an individual with proper training, rather than (as is often the case) by an inexperienced member of the staff. We recommend that heights also be measured in triplicate, that variation be no more than 0.3 cm, and that the mean height be recorded. For determination of height velocity, it is obviously best to have the same individual performing the determinations. Even when every effort is made to maximize the precision of height determinations, a minimum interval of 3 months is necessary for accurate height velocity computation. Six months worth of data are preferable, although it is of note that seasonal variation in height velocity has been reported.[5]

Growth Charts

Evaluation of a child's height must be done in the context of normal standards. Such standards can be either cross-sectional or longitudinal. Most American pediatric endocrine clinics continue to use the cross-sectional data provided by the National Center for Health Statistics (NCHS), which were originally introduced in 1977 and have been updated.[6-8] Epidemiologic limitations in these growth charts have been noted, however. The data included in the original infant charts, for example, were derived from a private study of a group of subjects who were primarily white, formula-fed, middle-class infants from southwestern Ohio. Data employed for older children came from national health examination surveys conducted from 1963 to 1974.

The NCHS (now a part of the Centers for Disease Control and Prevention) has provided a set of new growth charts, representing revisions of the previous charts, and has introduced new charts for body mass index[9] (Figures 10-1 through 10-8). Interestingly, the new charts show little change in average height since the late 1980s, despite the common perception that today's children are taller than peers from 10 to 25 years ago. This is in contrast to other countries, in particular, The Netherlands, where mean height continued to rise in spite of the population being the tallest in the world. In many current and formerly developing countries, the population, which was typically shorter than in the Western world, is becoming taller.

Classic percentile-based growth charts are invaluable for plotting growth of children relative to the 3rd or 5th, 10th, 25th, 50th, 75th, 90th, and 95th or 97th percentiles of normal American children. There are, however, two major limitations of these charts. First, they do not satisfactorily define the growth rates of children below the 3rd or above the 97th percentile—the very children for whom it is most critical to accurately describe the degree to which their growth deviates from the normal growth percentiles. The NCHS data can be used to compute standard deviation (SD) scores (or Z scores), which are more helpful because a short child can be described as having a growth rate of (for example) 2 or 2.5 SD from normal. Because these SDs are defined by cross-sectional data, however, SD scores during childhood are not directly comparable with SD scores during adolescence—when great variation in growth rates can be normally observed. Second, cross-sectional data are of greater value during infancy and childhood than in adolescence—when differences in the timing of puberty can introduce considerable variability into normal growth rates. To address this issue, Tanner and colleagues[10] have developed longitudinal growth charts that accommodate the timing of puberty. These charts are of greatest value in assessing growth during adolescence and puberty and are probably superior for plotting sequential growth data on any given child.

The data from cross-sectional and longitudinal growth studies have been employed to develop height velocity standards[10] (Figures 10-9 and 10-10). It is important to emphasize that carefully documented height velocity data are invaluable in assessing the child with abnormalities of growth. Although considerable variability exists in the normal height velocity observed in children of different ages, between the age of 2 years and the onset of puberty children normally grow with remarkable fidelity relative to the normal growth curves. The physician should note any "crossing" of height percentiles during this age period, and abnormal height velocities always warrant further evaluation.

Disease-related growth curves have been developed for a number of clinical conditions associated with growth failure, such as Turner syndrome,[11] achondroplasia,[12] and Down syndrome.[13] Such growth profiles are invaluable for tracking the growth of children with these clinical conditions. Deviation of growth from the appropriate disease-related growth curve suggests the possibility of a second underlying condition.

Body Proportions

Many growth disorders, leading to either short stature or tall stature, are associated with disproportionate growth. Some of the more common disorders leading to disproportionality include the many forms of osteochondrodysplasia and rickets. Survivors of childhood cancer who received spinal irradiation are also at increased risk for disproportionate growth.[14] To allow documentation of such disproportionate growth, the following measurements can be made:

- Occipitofrontal head circumference
- Lower body segment: distance from top of pubic symphysis to the floor
- Upper body segment: sitting height (height of stool should be subtracted from standing height)
- Arm span: measurement of the length from one end of a patient's arms (measured at the fingertip) to the other with the arms raised parallel to the ground at shoulder height

Published standards exist for these body proportion measurements, which must be evaluated relative to the patient's age.[15] The upper segment-to-lower segment ratio, for example, ranges from 1.7 in the neonate to slightly below 1 in the adult. Ethnic differences also exist: black children and adolescents have shorter sitting height and longer length of the lower extremities (about one inch for each, corrected for age and sex).[16]

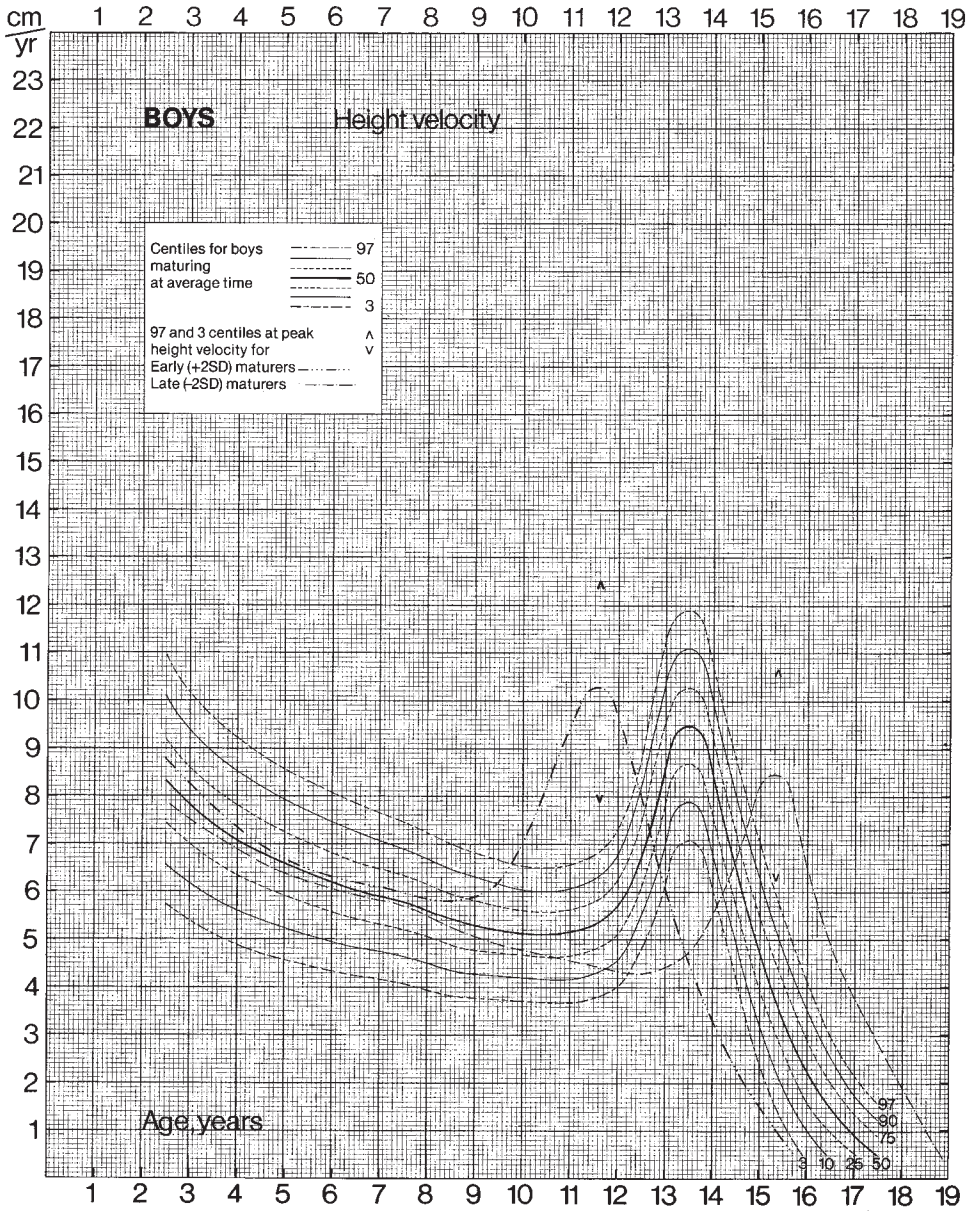

FIGURE 10-9 ■ Height velocity chart for males from 0 to 19 years. (From Tanner, J. M., & Davies, S. W. D. (1985). Clinical longitudinal standards for height and height velocity for North American children. *J Pediatr, 107*, 312.)

Skeletal Maturation

The degree to which a child's skeleton has matured over time gives the physician a window into the true physical developmental age of that child. The growth potential inherent in the tubular bones of the body can be assessed by evaluation of the progression of ossification within the epiphyses. The ossification centers of the skeleton appear and progress in a predictable sequence in normal children, and skeletal maturation can therefore be compared with normal age-related standards. This forms the basis of "bone age" or "skeletal age." It is not clear what factors determine this normal maturational pattern, but it is certain that genetic factors and multiple hormones—including thyroxine (T4), growth hormone (GH), and sex steroids—are involved in this process.

Studies in patients with mutations of the gene for the estrogen receptor[17] or for aromatase enzyme[18] have demonstrated that it is estrogen that is primarily responsible for ultimate epiphyseal fusion, although it seems unlikely that estrogen is alone responsible for all skeletal maturation. Beyond the neonatal period, and especially after age 2 years, a radiograph of the left hand and wrist is commonly used to determine "bone age"—which can be related to the published standards of Greulich and Pyle.[19] Although the authors recommend a bone-by-bone assessment approach to arrive at a mean bone age for the patient, most endocrinologists determine the bone age by finding the standard radiograph that best matches their patient's using a subjective comparative approach. This technique creates significant variability in bone age reading between different interpreters. An alternative method for assessing bone age from

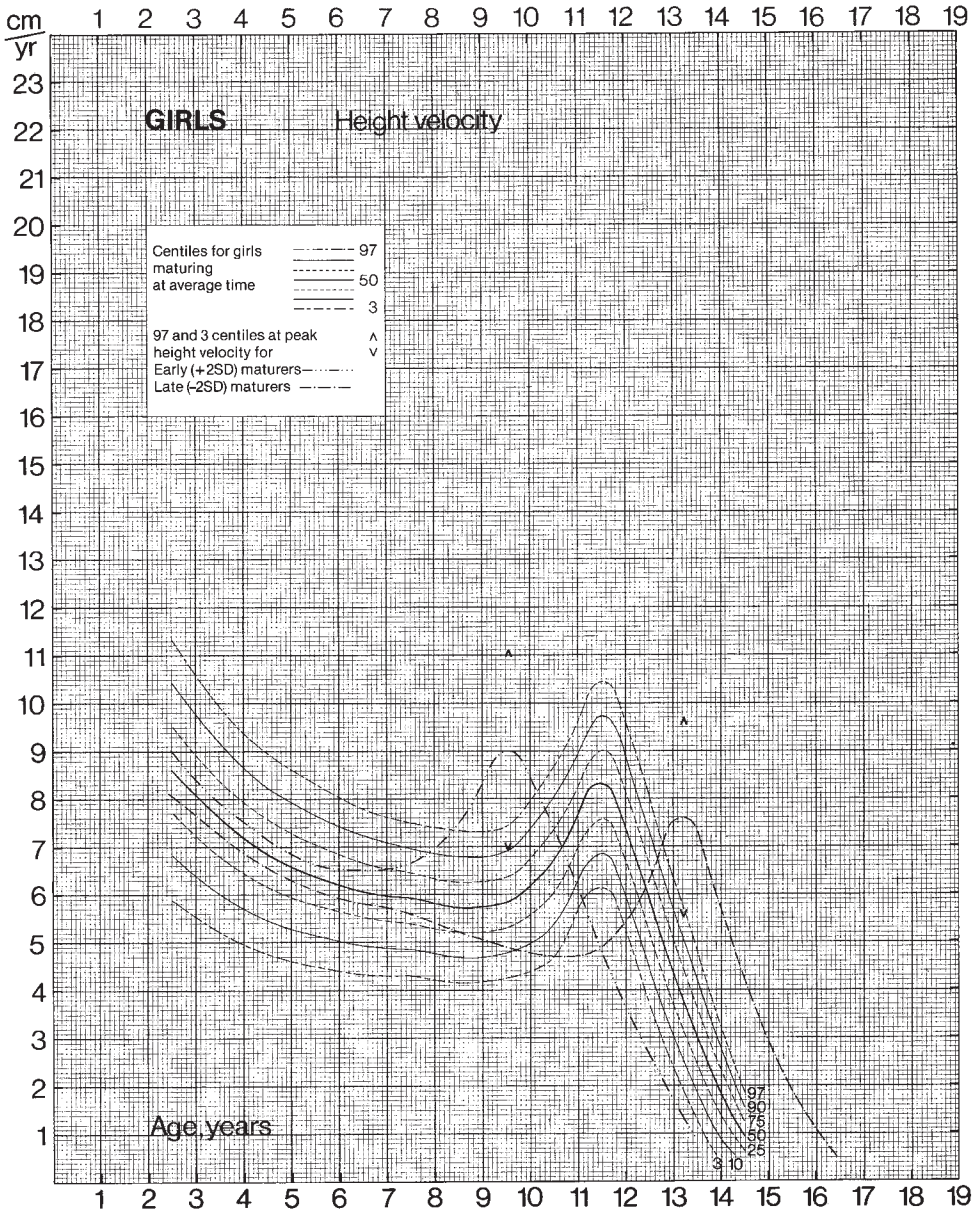

FIGURE 10-10 ■ **Height velocity chart for females from 0 to 19 years.** (From Tanner, J. M., & Davies, S. W. D. (1985). Clinical longitudinal standards for height and height velocity for North American children. *J Pediatr, 107,* 312.)

radiographs of the left hand, involving a scoring system for each individual bone, has been developed by Tanner and Whitehouse and their colleagues.[20] The left hand obviously represents a compromise, because radiographs of the entire skeleton would be tedious, expensive, and necessitate excessive radiation exposure. It is important to note, however, that the hand obviously does not contribute to the height of an individual and that accurate evaluation of growth potential might necessitate radiographs of the legs and spine.

A number of important caveats concerning bone age determination must be considered. Experience in reading bone age films is essential, and clinical studies involving bone age generally benefit from having a single reader who does all interpretations. Second, the normal rate of skeletal maturation differs between males and females (and ethnic variability exists). The standards of Greulich and Pyle are divided by sex, but they were developed in American white children. Finally, the Greulich-Pyle and the Tanner-Whitehouse standards were developed using normal children.[21] They are not necessarily applicable to children with skeletal dysplasia, endocrine abnormalities, or a variety of other causes of growth retardation.

Prediction of Adult Height

The extent of skeletal maturation observed in a patient can be used to predict the patient's height potential. The estimated adult height potential may be interpreted in function of the parental target height. Predictions of adult height are based on the observation that the more delayed the bone age (relative to the chronologic age),

the greater the length of time before epiphyseal fusion prevents further growth. The classic method for height prediction, based on Greulich and Pyle's *Radiographic Atlas of Skeletal Development*,[19] was developed by Bayley and Pinneau[22] and relies on the patient's bone age and height (Table 10-1).

Additional refinements were introduced by Tanner and colleagues[20,23] with a system that employs height, bone age, and chronologic age; and by Roche and associates,[24] who employ the combination of height, bone age, chronologic age, midparental height, and weight. All of these systems are by nature empirical and should never be used as absolute predictors. The more advanced the bone age, the greater the accuracy of the adult height prediction, but this is natural because a more advanced bone age places a patient closer to final height.

All of these methods of predicting adult height are based on data from normal children. None of these systems has been demonstrated to be accurate in children with growth abnormalities. For this type of precision, it would be necessary to develop disease-specific (e.g., Turner syndrome, Noonan syndrome, specific types of skeletal dysplasia) atlases of skeletal maturation. Retrospective analyses indicate that bone age–based adult height predictions slightly underpredict female but often overpredict male children's eventual height. Predictions are also notoriously inaccurate in children born small for gestational age.

Parental Target Height

Because genetic factors are of great importance as determinants of growth and height potential, it is always worthwhile to assess a patient's stature relative to that of siblings and parents. The parental target height can be readily ascertained by calculating the mean parental height and adding or subtracting 6.5 cm for male or female children, respectively. The standard deviation for this calculated parental target height is about 2.5 cm and the range within which it is likely to occur at least 95% of the time is approximately 7.5 to10 cm. As with predicted adult heights, calculated target heights should be taken as approximations.

Nevertheless, when a child's growth pattern clearly deviates from that of parents or siblings, one must seriously consider the possibility of an underlying pathologic process. It is important, when possible, to measure the heights of parents and siblings rather than accepting their own statural claims (mothers often overestimate the height of fathers). In addition, one should recall that it is not always possible to know the heights of the true biologic parents (or, sometimes, who the real biologic parents actually are). Finally, short parents are not an excuse to avoid working up a child who is clearly short because this may represent a treatable genetic disorder within the growth hormone signaling cascade.

ENDOCRINE REGULATION OF GROWTH

The Pituitary

The pituitary gland lies in the sella turcica, the hypophyseal fossa of the sphenoid bone, which is located in the center of the cranial base. The concept of the pituitary as a "master gland" controlling the endocrine activities of the body has become outdated and has been replaced by an appreciation of the importance of the brain, particularly of the hypothalamus, in regulating hormonal production and secretion. Nevertheless, the pituitary gland remains central to our understanding of the regulation of growth, metabolism and homeostasis, response to stress, lactation, and reproduction.

Embryologically, the pituitary gland is formed from two distinct sources.[25,26] Rathke's pouch, a diverticulum of the primitive oral cavity (stomodeal ectoderm), gives rise to the adenohypophysis. The neurohypophysis originates in the neural ectoderm of the floor of the forebrain, which also develops into the third ventricle. The adenohypophysis normally constitutes 80% of the weight of the pituitary and consists of the pars distalis (also known as the pars anterior or anterior lobe), the pars intermedia (also known as the intermediate lobe), and the pars tuberalis (also known as the pars infundibularis or pars proximalis).

Much of our knowledge of normal hypothalamopituitary development is derived from animal, particularly rodent, models. In the mouse, a thickening of the ectoderm in the midline of the anterior neural ridge, forming the hypophyseal placode, heralds the onset of pituitary development at 7.5-days postcoitum (dpc). The formation of a rudimentary Rathke's pouch follows at 9 dpc, with formation of a definitive pouch by 12 dpc and, subsequently, the anterior pituitary consisting of five different cell types secreting six different hormones (Figure 10-11). The developing Rathke's pouch is initially associated with the presumptive hypothalamic territories, and later with the developing diencephalon.

In humans, the pars distalis is the largest portion of the adenohypophysis and houses the great majority of hormone-producing cells. The pars intermedia is, typically, poorly developed and consists of several cystic cavities lined by a single layer of cuboidal epithelium. Pars distalis and intermedia are separated by a cleft, a vestigial structure of Rathke's pouch from which it develops. This structure may often develop as a cyst (Rathke's cleft cyst). In humans, in contrast to the mouse, pars intermedia is rudimentary as it largely disappears during embryogenesis. The pars tuberalis represents an upward extension of the pars distalis onto the pituitary stalk and may contain a limited number of gonadotropin-producing cells. The posterior pituitary (neurohypophysis) consists of the infundibular stem or hypophyseal stalk, the median eminence of the tuber cinereum, and the infundibular process (posterior lobe, neural lobe). The posterior pituitary contains the terminal axonal projections of magnocellular neurons from the paraventricular and supraoptic nuclei of the hypothalamus. These produce oxytocin, required during lactation and parturition, and vasopressin, required for osmotic regulation—as detailed in Chapter 11. It has no known function in the regulation of growth and will not be discussed further in this chapter.

Rathke's pouch, the origin of the adenohypophysis, can be identified in the 3-mm embryo during the third week of pregnancy in humans. Rathke's pouch then begins to

develop, resulting in a complete pouch disconnected from the oral ectoderm by the end of the sixth gestational week. GH-producing cells can be identified by 9 weeks of gestation.[27] It is at about this time that the vascular connections between the anterior lobe of the pituitary and the hypothalamus develop,[28,29] although it has been demonstrated that hormonal production by the pituitary can occur in the absence of connections with the hypothalamus. Somatotropic cells in the pituitary are thus frequently demonstrable in the anencephalic newborn. Nevertheless, it appears likely that the initiation of development of the anterior pituitary is dependent on responsiveness of the oral ectoderm to inducing factors from the ventral diencephalon[30-34] (Figure 10-12).

Maintained apposition and interactions between the oral ectoderm and neuroectoderm is critical for normal anterior pituitary development.[35-38]

Experimental manipulation of embryos from several species as well as Rathke's pouch explant experiments in rodents have shown that signals from the diencephalon are essential not only for the induction and maintenance of Rathke's pouch, but also for the regionalization within the pouch that allows the emergence of the different endocrine cell types. During gestation, proliferating progenitor cells are enriched around the pouch lumen, and they appear to delaminate as they exit the cell cycle and differentiate. During late mouse gestation and the postnatal period, anterior lobe progenitors reenter the cell cycle and expand the populations of specialized, hormone-producing cells. At birth, all cell types are present, and their localization appears stratified based on cell type. Current models of cell specification in the anterior lobe suggest that opposing gradients of FGF and BMP signaling pattern the progenitor cells within Rathke's pouch before they move on to the anterior lobe where they differentiate. Explant studies in the mouse have demonstrated that if Rathke's pouch is removed from the oral ectoderm on embryonic days 12 to 13 and incubated in appropriate culture medium, differentiation of each of the pituitary cell types continues, indicating that by that point organogenesis of the anterior pituitary is no longer dependent on hypothalamic signals—although such signals may remain critically involved in pituitary hormone production. These and other studies have revealed that normal pituitary development is dependent on a complex cascade of transcription factors and signaling molecules that are expressed in a spatiotemporal manner.

Signaling molecules implicated in pituitary development are either intrinsic emanating from the oral ectoderm such as sonic hedgehog (Shh) or extrinsic from the neuroectoderm such as Nkx2.1, fibroblast growth factors (Fgfs eg Fgf8), and bone morphogenetic factors (Bmps eg. Bmp4) (Figure 10-13). These molecules may activate or repress transcription factors such as Hesx1, Lhx3, and Lhx4. They may also act as morphogens creating the appropriate environment for cell differentiation, thus playing a critical role in cell fate. Such signaling molecules include members of the Shh family, Fgfs, transforming growth factors (Tgfs)/Bmps, Wingless/Wnts, and molecules in the Notch pathway, to mention a few.

One study has challenged the current dogma of pituitary cell specification, using simple yet elegant experiments.[40] The authors showed that, in mice, the pattern of cell specification that results in the rostral location of gonadotropes, the caudal location for somatotropes, and a more intermediate location for corticotropes and thyrotropes does not appear to be the result of an ordered cell cycle exit, as previously predicted. All anterior lobe cell types appear to begin the differentiation process concurrently (E11.5-E14.5), rather than in a temporally discrete manner.

To date, not many pituitary phenotypes have been reported in association with mutations in these signaling molecules. Importantly, the Wnt signaling pathway has recently been implicated in pituitary tumorigenesis. A number of microarray studies have identified altered

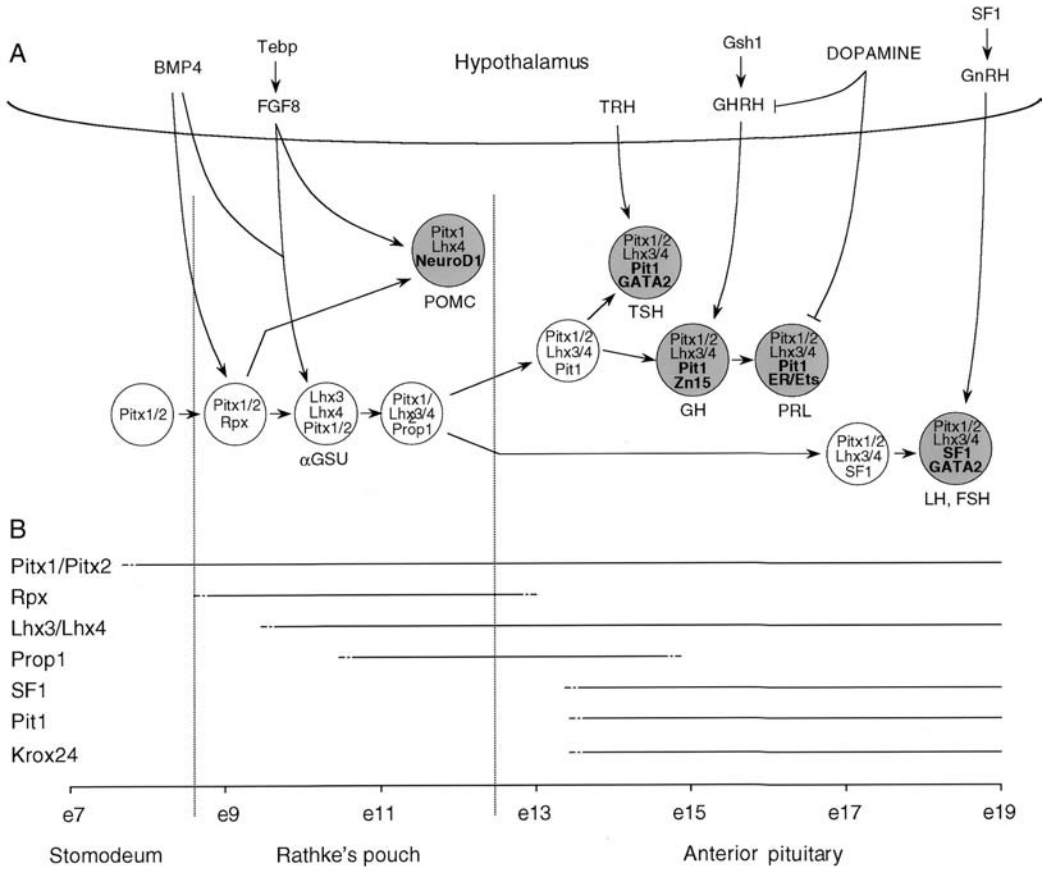

FIGURE 10-12 ■ Development of pituitary cell lineages. **A,** Schematic representation of pituitary cell precursors showing the expression of prevalent transcription factors at each stage of development. Terminally differentiated cells are shown as larger and shaded circles together with the hormones produced (lineage-specific transcription factors are highlighted in bold in these cells). The interaction with transcription factors and signaling molecules in the hypothalamus is also noted. Transcription factors are represented in lowercase (except for SFI and GATA2), whereas signaling molecules appear in uppercase. **B,** Schema showing the timing of the appearance and disappearance of pituitary transcription factors during mouse embryogenesis. BMP4, bone morphogenic protein 4; e, embryonic day; ER, estrogen receptor; FGF8, fibroblast growth factor 8; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin–releasing hormone; αGSU, α-glycoprotein subunit; LH, luteinizing hormone; POMC, pro-opiomelanocortin; PRL, prolactin; SFI, steroidogenic factor I; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone. expression of Wnt inhibitors in pituitary tumors, and there is clear evidence that the Wnt/β catenin pathway is involved in the pathogenesis of craniopharyngioma, a rare tumor in the hypothalamo-pituitary region.[41,42]

Multiple pituitary-specific transcription factors are involved in the determination of pituitary cell lineages and cell-specific expression of anterior pituitary hormones.[30-34,37,38,43] To date, several homeodomain transcription factors have been shown to be involved in human anterior pituitary development and differentiation. Defects in each have now been associated with various combinations of pituitary hormone deficiencies (see Figure 10-12 and Table 10-2). Because additional gene defects have been implicated in abnormal murine hypothalamo-pituitary development, it seems likely that the number of human genetic defects will expand.

In the human adult, the mean pituitary size is 13 by 9 by 6 mm.[44] Mean weight is 600 mg, with a range of 400 to 900 mg. Pituitary weight is slightly greater in women than in men and typically increases during puberty and pregnancy.[45] In the newborn, pituitary weight averages about 100 mg. Infrequently, the craniopharyngeal canal (marking the embryonic migration of Rathke's pouch) remains patent and may contain small nests of adenohypophyseal cells—giving rise to a pharyngeal hypophysis that may be capable of hormone synthesis.[46]

Normally, however, the pituitary resides in the sella turcica immediately above and partially surrounded by the sphenoid bone. The volume of the sella turcica provides a good measure of pituitary size, which may be reduced in the child with pituitary hypoplasia.[47] It is important, however, to recognize that considerable variation in pituitary size occurs normally. The pituitary is covered superiorly by the diaphragma sellae, and the optic chiasm is directly above the diaphragma. The anatomic proximity between the optic chiasm and the pituitary is important because hypoplasia of the optic chiasm may occur together with hypothalamic/pituitary dysfunction, as in the condition of septo-optic dysplasia and because pituitary tumors may in turn impact on the optic chiasm

leading to visual impairment.[48] The patient with congenital blindness or nystagmus should be initially evaluated and then subsequently monitored carefully for hypopituitarism as this can evolve. In addition, suprasellar growth of a pituitary tumor may initially manifest with visual complaints or evidence of progressive impairment of peripheral vision.

The existence of a portal circulatory system within the pituitary is critical to normal pituitary function[28,29] (Figure 10-14). The blood supply of the pituitary derives from the superior and inferior hypophyseal arteries, branches of the internal carotid. The anterior and posterior branches of the superior hypophyseal artery may terminate within the infundibulum and the proximal portion of the pituitary stalk. Hypothalamic peptides, produced in neurons that terminate in the infundibulum, enter the primary plexus of the hypophyseal portal circulation and are transported by means of the hypophyseal portal veins to the capillaries of the anterior pituitary. This portal system thus provides a means of communication between the neurons of the hypothalamus and the hormone-producing cells of the anterior pituitary. The blood supply of the neurohypophysis is separate, deriving from the inferior hypophyseal artery. Regulation of the posterior lobe of the pituitary does not involve the hypophyseal portal circulation but, rather, is mediated through direct neural connections.

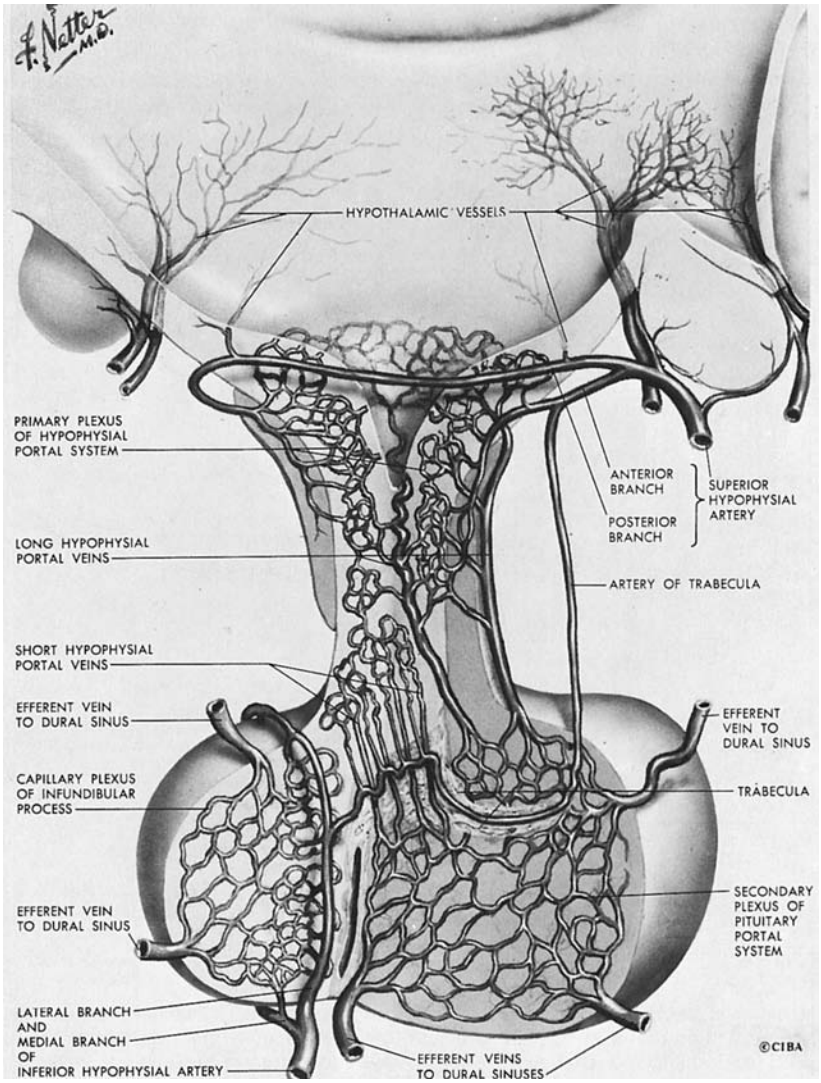

FIGURE 10-14 ■ Illustration of the main components of the hypothalamic-pituitary portal system. (NetterImages.com #4613, © Elsevier, Inc.) *See the accompanying website to view a color version of this illustration.*

The definitive Rathke's pouch comprises proliferative progenitors that will gradually relocate ventrally, away from the lumen as they differentiate. A proliferative zone containing progenitors is maintained in the embryo in a periluminal area and was found to persist in the adult. The exact nature of progenitor cells in the pituitary gland, however, remains unknown. Research has focused on the biology of these progenitor and putative stem cells within the pituitary gland.[49,50] Several reports have suggested that the pituitary stem cells take the form of a *SOX2*+ cell population, *GFRa2*+ cells, a side population of cells, *Nestin*+ cell population, or folliculostellate cells.[51] It has been hypothesized that there are two critical roles of stem cells: one is to establish the pituitary gland during development and the other is to maintain the mature pituitary gland in response to physiologic challenges and normal cell turnover. The hypothesis of two different populations of stem cells, one involved in embryogenesis and one involved in maintenance function after birth, remains highly controversial. Members of the Sox family of transcription factors are likely involved in the earliest steps of pituitary stem cell proliferation and the earliest transitions to differentiation. The transcription factor PROP1 and the NOTCH signaling pathway may then regulate the transition to differentiation. Identification of the stem cell niche is important for several reasons, and it has been proposed that the niche may be the marginal zone around the lumen of Rathke's pouch, between the anterior and intermediate lobes of mouse pituitary, because cells in this region are able to give birth to all five pituitary hormone cell lineages.

Stem cells have been shown to play a role in tumorigenesis in some tissues, and their role in pituitary hyperplasia, pituitary adenomas, and tumors is an important area for future investigation. The ability to cultivate and grow stem cells in a pituitary predifferentiation state might also be helpful for the long-term treatment of pituitary deficiencies. Indeed, a seminal study has resulted in the efficient self-formation of a three-dimensional anterior pituitary tissue in an aggregate culture of mouse embryonic stem (ES) cells.[52] ES cells were stimulated to

differentiate into non-neural head ectoderm and hypothalamic neuroectoderm in adjacent layers within the aggregate and treated with agonists of sonic hedgehog signaling. This resulted in increased expression of the Rathke's pouch marker Lhx3 followed by self-organization of Rathke's pouch–like three-dimensional structures at the interface of these two epithelia. The resulting 3D structures had a central cavity, and the resemblance to Rathke's pouch was striking, as was the topographic location between the neuroepithelium and the rostral headlike ectoderm. The juxtaposition of the two tissues, mimicking the spatial organization in embryonic development, was indeed critical as Rathke's pouch–like vesicles did not develop when neuroepithelium tissue was not present. Various endocrine cells were subsequently produced and these cells were able to respond to trophic hormones. For example, adrenocorticotropic hormone (ACTH)–expressing cells developed from the vesicle like structures, and activation of Wnt signaling led to expression of Pit1, growth hormone (GH), and prolactin. Luteinizing hormone (LH)/follicle-stimulating hormone (FSH)/thyroid-stimulating hormone (TSH) expression was also achieved, albeit after more intense manipulation of the culture conditions. When ES-derived cell aggregates were implanted under the kidney capsule in hypophysectomized mice, corticosterone was produced. These studies may therefore reflect the first step toward stem cell treatment.

Terminally differentiated secreting cells are not distributed randomly in a patchwork-like fashion throughout the pituitary gland. Instead, it is starting to emerge that these cells organize themselves in same-cell type networks. This was first shown by Bonnefont and colleagues when GH cells in murine pituitary slices were visualized using high-resolution imaging.[53] The connectivity between the cells of this network is important to deliver coordinated secretory pulses of hormones to their target tissues. Additionally, the two least abundant pituitary cell types, corticotropes and gonadotropes, are also organized in homotypic cell networks, as are pituitary lactotropes.[54,55] This distribution of cells into networks facilitates the coordinated physiologic response to stimuli.

Growth Hormone

Chemistry

Human GH is produced from somatotrope cells within the anterior pituitary as a single-chain nonglycosylated 191-amino-acid 22-kd protein (Figure 10-15)[56,57] that comprises a core of four helices in a parallel/antiparallel orientation with two disulfide bonds between cysteines 53 to 165 and 182 to 189.[58] The 217aa GH-precursor is transported in the lumen of the endoplasmic reticulum (ER) via a mechanism that involves the recognition of the signal peptide (first 26 aa). Following its cleavage, the mature protein is transported to the Golgi apparatus and secretory vesicles; the presence of zinc ions facilitates the formation of soluble GH dimer complexes within the secretory granules, as well as the storage and secretion of GH aggregates.[59]GH is homologous with several other

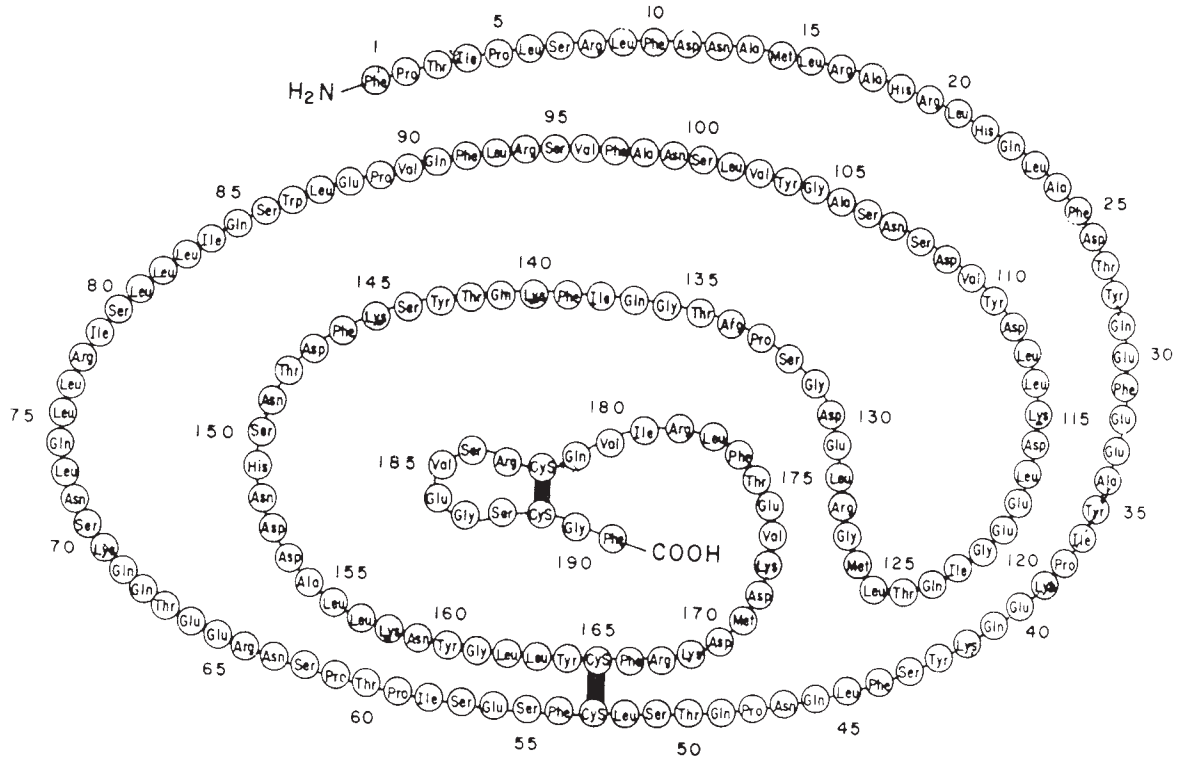

FIGURE 10-15 ■ Covalent structure of human growth hormone. (From Chawla, R. K., Parks, J. S., & Rudman, D. (1983). Structural variants of human growth hormone: biochemical, genetic and clinical aspects. *Annu Rev Med, 34*, 519.)

proteins produced by the pituitary or placenta, including prolactin, chorionic somatomammotropin (CS, placental lactogen), and a 22-kd GH variant (hGH-V) secreted only by the placenta.[60] The latter differs from pituitary GH by 13 amino acids. The genes for these proteins have probably descended from a common ancestral gene, even though the genes are now located on different chromosomes (chromosome 6 for prolactin and chromosome 17 for GH).[61]

The genes for GH, prolactin, and placental lactogen share a common structural organization—with four introns separating five exons. *GH1* is located on the long arm of chromosome 17 (17q22-24) within a cluster of five homologous genes encompassing a distance of about 65kb—*CSHP* (chorionic somatomammotropin pseudogene), *CSH-1* (chorionic somatomammotropin gene), *GH-2*, and *CSH-2*.[62] Expression of *GH1* is regulated by the highly polymorphic proximal promoter and a locus control region (LCR) 15-32kb upstream of the gene that confers the pituitary-specific and high-level expression of GH.[63] Normally, the majority of GH (75%) produced by the pituitary is of the mature 22-kd form. Alternative splicing of the second exon results in deletion of amino acids 32 through 46, yielding a 20-kd form that normally accounts for less than 10% of pituitary GH.[61,64,65] The remainder of pituitary GH includes desamidated and N-acetylated forms, as well as various GH oligomers. A 17.5-kDa variant that results from complete skipping of exon 3 and lacks amino acids 32-71 is much less abundant (1% to 5%).

Secretion

The pulsatile pattern characteristic of GH secretion largely reflects the interplay of multiple regulators, including two hypothalamic regulatory peptides: GH-releasing hormone (GHRH)[66,67] and somatostatin (somatotropin release–inhibiting factor [SRIF]).[68] The amino terminus of the 44-amino-acid protein GHRH is required for stimulation of GH secretion. GHRH activity is species specific, presumably reflecting the specificity of binding to a G protein–coupled receptor on the pituitary somatotropes.

Regulation of GH production by GHRH is largely transcriptionally mediated and is dependent on stimulation of adenylate cyclase and increases in intracellular cyclic adenosine monophosphate (AMP) concentrations. The GHRH receptor is a member of the G protein–coupled receptor family B (also called the secretin family) and has partial sequence identity with receptors for vasoactive intestinal polypeptide, secretin, calcitonin, and parathyroid hormone.[69] Solid tumors secreting GHRH are a rare cause of GH excess. GHRH has previously been approved in the United States for treatment of growth hormone deficiency but has been withdrawn from the market for therapeutic purposes. It can still be used as a diagnostic agent—if available, especially for the identification of adult growth hormone deficiency, and then it is frequently used in combination with arginine as part of a stimulation testing protocol.

The actions of the 14-amino-acid protein somatostatin appear to be related to the timing and amplitude of pulsatile GH secretion, rather than to GH synthesis. The binding of somatostatin to its specific receptor results in an inhibition of adenylate cyclase activity and a reduction in intracellular calcium concentrations.[68] Treatment of cultured somatotropic cells with GHRH and somatostatin has indicated a dominant effect of somatostatin, with a reduction of intracellular calcium concentrations and an inhibition of GH secretion. The pulsatile secretion of GH observed in vivo is believed to result from a simultaneous reduction in hypothalamic somatostatin release and increase in GHRH activity.[70] Conversely, a trough of GH secretion occurs when somatostatin release is increased in the presence of diminished GHRH activity. Somatostatin analogs are used therapeutically for the treatment of acromegaly, underscoring its role as a GH secretion inhibitor.

The regulation, on a neuronal basis, of this reciprocal secretion of GHRH and somatostatin is imperfectly understood. Multiple neurotransmitters and neuropeptides are involved in regulation of release of these hypothalamic factors, including serotonin, histamine, norepinephrine, dopamine, acetylcholine, gamma-aminobutyric acid (GABA), thyroid-releasing hormone, vasoactive intestinal peptide, gastrin, neurotensin, substance P, calcitonin, neuropeptide Y, vasopressin, corticotrophin releasing hormone,[71] and galanin.[72] These factors are clearly implicated in the alterations of GH secretion observed in a wide variety of physiologic states (such as stress, sleep, hemorrhage, fasting, hypoglycemia, and exercise) and form the basis for a number of GH-stimulatory tests employed in the evaluation of GH secretory capacity/reserve.

GH secretion is also impacted by a variety of nonpeptide hormones, including androgens,[73,74] estrogens,[75] thyroxine,[76] and glucocorticoids.[77,78] The precise mechanisms by which these hormones regulate GH secretion are complex, potentially involving actions at the hypothalamic and pituitary levels. Practically speaking, hypothyroidism and glucocorticoid excess may each blunt spontaneous and provocative GH secretion (and therefore should be corrected prior to GH testing). Sex steroids, at the onset of puberty or administered pharmacologically, appear to be responsible for the rise in GH secretion characteristic of puberty.[79]

Synthetic hexapeptides capable of stimulating GH secretion have been developed[80] and termed *GH-releasing peptides* (GHRPs). These peptides, later recognized as analogs of the gastric hormone ghrelin, are capable of directly stimulating GH release and enhancing the GH response to GHRH.[81] These agents have the potential advantage of oral administration, and in the patient with an intact pituitary they may be capable of greatly enhancing GH secretion. When these agents were administered chronically to elderly patients and to some GH-deficient children, the amplitudes of GH pulses were significantly increased. Ghrelin-mimetic ligands were used to characterize a common receptor termed the *GH secretagogue receptor* (GHS-R) for the GH-releasing substances. The GHS-R is distinct from the GHRH receptor.[82]

Subsequently, the GHS-R gene was cloned and shown to encode a unique G protein–coupled receptor with a deduced protein sequence that was 96% identical

in human and rat. Three receptor isotypes were isolated from human genomic libraries. The receptor is strongly expressed in the hypothalamus. Specific binding sites for GH releasing peptides have also been identified in other regions of the central nervous system (CNS) and peripheral endocrine and nonendocrine tissues in both humans and other organisms. Ghrelin is a 28-amino-acid peptide that has been identified as the endogenous ligand for the growth hormone secretagogue receptor (GHS-R).[83] It is expressed predominantly in the stomach, but smaller amounts are also produced within the bowel, pancreas, kidney, the immune system, placenta, pituitary, testis, ovary, and hypothalamus. Ghrelin is a unique gene product that requires octanoylation for normal function. Intravenous, intracerebroventricular, and intraperitoneal administration of ghrelin in animal models stimulates food intake and obesity[84] and raises plasma GH concentrations[85]—and to a lesser extent prolactin and adrenocorticotropic hormone (ACTH) concentrations. Additionally, it influences endocrine pancreatic function and glucose metabolism, gonadal function, and behavior. It also controls gastric motility and acid secretion and has cardiovascular and antiproliferative effects. Both ghrelin and GH-releasing peptides release GH synergistically with GHRH, but the efficacy of these compounds as growth-promoting agents is poor. Mutations in the ghrelin receptor have been identified as a possible cause of idiopathic short stature (ISS) and GH deficiency.[86] However, it is important to note that mouse models with targeted deletion of the receptor (*ghsr* $^{-/-}$) have a near normal phenotype.[87]

This suggests that ghrelin is an important stimulus for nutrient allocation for growth and metabolism and that it may represent a key component of the GH regulatory system. A second peptide encoded by the same gene as ghrelin has been identified and termed *obestatin*. This appears to regulate weight but not GH secretion.[88,89]

In addition to the complex regulatory processes described previously, the synthesis and secretion of GH are also regulated by feedback by the insulin-like growth factor (IGF) peptides.[90-95] IGF receptors have been identified in the pituitary.[96-98] Inhibition by IGF-1 of GH secretion has been demonstrated in multiple systems.[99] In addition, inhibition of spontaneous GH secretion has been demonstrated in humans treated with subcutaneous injections of recombinant IGF-1.[100,101] GH can be identified in fetal serum by the end of the first trimester. Serum concentrations are lower in term infants than in premature infants, perhaps reflecting feedback by the higher serum levels of IGF peptides characteristic of the later stages of gestation.[102] However, at birth, GH concentration in normal newborns is of the order of 40 ng/mL, declining gradually in the initial weeks of life to levels less than 10 ng/mL.

Twenty-four hour GH secretion peaks during adolescence,[79] undoubtedly contributing to the very high serum concentrations of IGF-1 characteristic of puberty. GH secretion begins to decline by late adolescence and continues to fall throughout adult life. Indeed, puberty may be considered with some justification a period of "acromegaly," whereas aging (with its characteristic decrease of GH secretion) has been termed the *somatopause*.[75,103,104]

Twenty-four-hour GH production rates for normal men range from 0.25 to 0.52 mg/m^2.[78,105] However, a wide variety of physiologic conditions (in addition to aging) affect GH secretion. These include stage of sleep,[106,107] nutritional status,[108] acute fasting, exercise,[109] stress,[109] and sex steroids.[73,74] Ho and associates[75] have reported that serum estradiol concentrations are the dominant factor affecting GH secretion. Neither age nor sex influenced the integrated serum concentrations of GH when the effects of estradiol were removed from analysis. The effects of testosterone on serum IGF-1 concentrations may be at least in part independent of GH because individuals with mutations of the GH receptor (GHR) still experience a rise in serum IGF-1 during puberty.[110]

The pulsatile nature of GH secretion is readily demonstrable by frequent serum sampling, especially when coupled with sensitive assays for GH.[108] Such assays demonstrate that under normal conditions serum GH concentrations are less than 0.2 ng/mL between bursts of GH secretion. It is consequently impractical to assess GH secretion by random serum sampling. Maximal GH secretion occurs during the night, especially at the onset of the first slow-wave sleep (stages III and IV). Rapid-eye-movement (REM) sleep is, on the other hand, associated with low GH secretion.

Normal young men generally experience 12 GH secretory bursts per 24 hours. Obesity is characterized by decreased GH secretion, reflected by a decreased number of GH secretory bursts.[111] Fasting increases the number and amplitude of GH secretory bursts, presumably reflecting decreased somatostatin secretion and possibly increased ghrelin secretion. The impact of the pulsatile secretory nature of GH secretion on its biologic actions remains uncertain.

GH Receptor/GH-Binding Protein

The GH receptor is synthesized as a 638-amino-acid peptide, which is later processed into a mature receptor of 620 amino acids with a predicted molecular weight of 70 kDa before glycosylation. The extracellular hormone-binding domain contains 246 amino acids, followed by a single membrane-spanning domain, and a cytoplasmic domain of 350 amino acids. In humans, the circulating GH-binding protein (GHBP) appears to derive from proteolytic cleavage of the extracellular domain of the receptor.

The gene for the human GHR has been localized to chromosome 5p13.1-p12, where it spans more than 87 kb.[112,113] In the mouse[114,115] and rat,[116] on the other hand, multiple transcripts for the GHR have been identified. The larger (3.4 to 4.8 kb) transcript codes for the intact receptor, whereas the 1.2- to 1.9-kb transcript codes for the soluble GHBP. The coding and 3′ untranslated regions of the human GHR are encoded by the nine exons, numbered 2 through 10.[117] Exon 2 corresponds to the secretion signal peptide, whereas exons 3 through 7 encode the extracellular domain. Exon 8 encodes the transmembrane domain. Exons 9 and 10 encode, respectively, the intracellular domain and the 3′ untranslated region. Two genomic *GHR* isoforms that exist

only in humans have arisen from ancestral homologous recombination. They differ in the retention or deletion of exon 3. Exon 3 of the GHR has been shown to be deleted in a substantial number of normal individuals. This delta-3 GHR polymorphism has been shown by some but not all investigators to determine responsiveness to GH and to be associated with birth size and postnatal growth.[118-120]

The GHR has been found to be highly homologous with the prolactin receptor and to share sequence homology with many of the receptors for interleukins, as well as receptors for erythropoietin, leptin, granulocyte-macrophage colony-stimulating factor, and interferon.[117] The GHR is a member of the class 1 hematopoietic cytokine family. A complex of the GH and the GHBP molecule has been shown to be more effective as an agonist of GH action than GH alone—indicating a physiologic and possible therapeutic role for the GHBP.[121] Examination of the crystal structure of the GH-GHR complex revealed that the complex consisted of one molecule of GH bound to two GHR molecules, indicating a GH-induced receptor dimerization—which is necessary in GH action.[58] Interestingly, as noted previously, a genetically engineered fusion complex of GH and the GHR has been shown to have a significantly improved efficacy and a dramatically longer half-life compared to growth hormone alone when tested in rodent models.[121]

The GHR, like its family group member EPO-R, is preformed as a dimer and is transported in a nonligand bound state to the cell surface.[122,123] GH then binds in a sequential manner to the GHR dimer where the first GHR binds to the stronger site 1 of the GH molecule followed by the second GHR binding to the weaker site 2. Binding of GH results in a conformational change whereby rotation of the GHRs results in repositioning of the intracellular domains and of Box1-associated Janus Kinase 2 (JAK2), a major GHR-associated tyrosine kinase. As a result, JAK2 is auto-phosphorylated and activated, leading in turn to cross phosphorylation of distal tyrosine residues of GHR that enables SH2 (*Src* homology 2) domain molecules to dock to these sites.[124,125] The GHR itself appears to have no intrinsic kinase activity. It is likely that co-localization of two JAK2 molecules by the dimerized GHR results in transphosphorylation of one JAK2 by the other, leading to JAK2 activation. Stat5a and Stat5b molecules contain SH2 domains and bind to these phosphorylated tyrosine sites. In turn they then become phosphorylated. Phosphorylated Stat5 molecules (homo- and hetero-) dimerize and translocate to the nucleus where they bind DNA, as dimers or as tetramers, and activate target genes.[126,127]

GH can activate both Stat5a and Stat5b, and they have both overlapping and distinct functions.[128-135] Gene inactivation mouse models have shown that deletion of *Stat5b*, but not of other Stat genes, even though GH also activates Stat1 and Stat3, affects growth, and that Stat5b is of greater importance for stimulation of growth than Stat5a. *Stat5b* null mice have severe postnatal growth retardation especially in males, although this is not as severe as in *Ghr* null mice. They have increased GH secretion; reduced hepatic IGF1-, IGF-binding protein (IGFBP)3-, and acid labile subunit (ALS)-expression; and increased obesity.[135] *Stat5a* null mice have normal growth but impaired mammary gland formation and lactogenesis, reflecting impaired signaling of prolactin.[130] *Stat5a/b* double null mice are more severely affected than the single null mice and display more severe growth retardation, although *Ghr* null mice are still more severely affected.[136,137] *Stat5a/b* double null mice also have a severe combined immunodeficiency, with reduced CD8 T cell number and a failure of hematopoietic stem cells to develop lymphoid lineages.[138] Transgenic Stat5 expression results in expansion of CD8 cells and lymphomagenesis[139] and also in increased proliferation and differentiation in mammary cells,[140] suggesting a critical role for Stat5 in cell proliferation, particularly in immune cells. Stat5b is phosphorylated upon stimulation by a pulse of GH, and after this rapid activation it becomes temporarily refractive to further or continuous stimulation.[141,142] GH secretion is more continuous in females and, indeed, in female rodents, Stat5b is phosphorylated to a lesser extent although phosphorylation still occurs. This gender-specific signaling plays an important role in the regulation of gender-specific proteins, especially CYP450 enzymes,[143,144] which play a role in hepatic metabolism of steroids and foreign compounds. The *Stat5b* null male mice are resistant to GH pulses,[145]and their hepatic male-specific genes are decreased to female levels, whereas female predominant genes are expressed at higher levels than in WT males. Hepatic nucleic factors (HNFs), especially HNF3, 4α, and 6, interact with Stat5b to induce these Stat5b-dependent gender-specific gene expression patterns.[134,144,146]

Phosphorylated Stat5a and Stat5b bind Stat5 response elements (Stat5 RE) as dimers or tetramers, but their binding is enhanced by the interaction of coactivators binding to adjacent DNA binding sites. Stat5 RE are located in the second and third intron of the human *IGF1* gene and 73 kb upstream of the initiation site, although the effectiveness of the distant site is much less.[147,148] Activation of JAK-STAT signaling occurs rapidly, within minutes after GH stimulation, but is transient due to the tight control of the termination of signaling. This negative regulation of signaling occurs at several levels: GHR internalization, suppressors of cytokine signaling (SOCS), protein tyrosine phosphatases (PTPs), and protein inhibitors of activated stats (PIAS). The inhibition of GH signaling by several members of the GH-inducible suppressors of the cytokine signaling (SOCS) family has been demonstrated. The SOCS family of proteins comprises cytokine inducible-Src homology 2 protein (CIS) and SOCS 1-7. GH, PRL, and many other cytokines can induce CIS, SOCS1, -2, and -3. SOCS family proteins inhibit JAK-STAT signaling by inhibiting JAK proteins, binding positive regulators of signaling or docking sites, and promoting GHR ubiquitination. The role of the several family members has become clearer from phenotypes associated with their overexpression. Mice overexpressing CIS have mild growth retardation and have also altered T-cell function and impaired mammary gland development, whereas *Socs2* null mice show gigantism similar to bovine GH overexpessing mice (30% to 40% overgrowth), are hyperresponsive to GH, and have increased extrahepatic IGF-1 production.[149]

By contrast, complete inhibition of GH activation of the signal transducer STAT5 and STAT5-dependent transcriptional activity is seen when cellular overexpression of SOCS family members is induced. SOCS also inhibit the GHR-dependent tyrosine phosphorylation of JAK2. Endotoxin and proinflammatory cytokines such as interleukin-1b (IL-1b) and tumor necrosis factor-α (TNFα) induce a state of GH resistance.

All of these agents can also induce SOCS proteins.[150] SOCS-3 induced by IL-1b and TNFα or by endotoxin in vivo may play a role in the GH resistance induced by sepsis.[151] Critically ill patients with septic shock who had been treated with GH were shown to have increased mortality, possibly related to the induction of GH resistance in specific tissues as a consequence of sepsis.[146] Thus, the role of SOCS proteins as intracellular GH signaling antagonists appears to be important in a variety of pathophysiologic states.

PTPs dephosphorylate activated phosphorylated proteins in cytokine signaling pathways but also insulin signaling pathways. Several PTPs—such as PTP-1, PTP-H1 and PTP-B1, and TC-PTP—attenuate GH signaling, and PTP-1B is involved in fasting-induced GH insensitivity.[153,154] PTPN11 mainly functions in RAS-MAPK signaling, and abnormalities result not only in Noonan syndrome but also in associated mild GH resistance.[155]

Other GH-activated pathways include mitogen-activated protein kinases (MAPKs), extracellular signal-regulated kinase (ERK)-1 and ERK2, the insulin-signaling pathway (by means of insulin receptor substrate [IRS]-1 and IRS-2), and protein kinase C (PKC).[156,157] How all of these pathways interact to mediate the various anabolic and metabolic actions of GH remains to be elucidated (Figure 10-16).

The main GH binding protein (GHBP) is the soluble extracellular domain of the GHR with an apparent molecular weight of approximately 55 kDa and has an identical affinity for GH as GHR.[112] It binds to GH with high specificity and affinity, but with relatively low capacity.[158-160] It increases its half-life in the circulation and may serve a function in the transportation of GH to target tissues and subsequent binding to the receptor. Although in rodents GHBP arises through alternative splicing, human GHBP arises from proteolytic cleavage of the cell membrane anchored GHR, for example, by TNF α converting enzyme (TACE).[161] GHBP is, like GHR, present in many tissues, but GHBP in the circulation is mostly derived from the liver. Although GHR and GHBP are regulated by and are very sensitive to GH, and GHR and GHBP often change in parallel,[162-164] measurement of plasma GHBP has not been shown to reflect GHR and GH responsiveness.[165] Initial assays for GHBP involved incubation of serum with 125-I-GH and separation of bound from free radioligand by gel filtration, high-pressure liquid chromatography, or dextran-coated charcoal. Carlsson and colleagues[166] developed a ligand-mediated immunofunctional assay (LIFA) that measures GHBP capable of binding GH. Assays of serum concentrations of GHBP have been instrumental in identifying patients with GH insensitivity (GHI) caused by genetic abnormalities of the GHR.[167,168] Patients with

GHI from nonreceptor abnormalities, abnormalities of the intracellular portion of the GHR, or inability of the receptor to dimerize may, however, have normal serum concentrations of GHBP.[169]

GH Actions

According to the somatomedin hypothesis, the anabolic actions of GH are mediated through the IGF peptides.[170-175] Although this hypothesis is at least in part true, it appears that GH is capable of stimulating a variety of effects that are independent of IGF activity. Indeed, the effects of GH and IGF are on occasion contradictory—as evident in the "diabetogenic" actions of GH[175,176] and the glucose-lowering activity of IGFs. Green and colleagues[177] attempted to resolve some of these differences in a "dual-effector" model in which GH stimulates precursor cells, such as prechondrocytes, to differentiate.

When differentiated cells or neighboring cells then secrete IGFs, these peptides act as mitogens and stimulate clonal expansion. This hypothesis is based on the ability of IGF peptides to work not only as classic endocrine factors that are transported through the blood but as paracrine or autocrine growth factors. GH also stimulates a variety of metabolic effects, some of which appear to occur independently of IGF production—such as lipolysis,[178] amino acid transport in diaphragm[179] and heart,[180] and production of

specific hepatic proteins. Thus, there are multiple sites of GH action—and frequently it is not entirely clear which of these actions are mediated through the IGF system and which might represent IGF-independent effects of GH.[181] The sites of action of GH include the following:

- *Epiphysis:* Stimulation of epiphyseal growth.
- *Bone:* Stimulation of osteoclast differentiation and activity, stimulation of osteoblast activity, and increase of bone mass by endochondral bone formation. Lupu and coworkers[182] have shown that mice with a complete knockout of IGF-I (making them substantially smaller than wild-type mice) become even smaller when mated into a GH receptor knockout strain, indicating a direct IGF-independent effect of GH on growth.
- *Adipose tissue:* Acute insulin-like effects, followed by increased lipolysis, inhibition of lipoprotein lipase, stimulation of hormone sensitive lipase, decreased glucose transport, and decreased lipogenesis.[183]
- *Muscle:* Increased amino acid transport, increased nitrogen retention, increased lean tissue, and increased energy expenditure.[183]

The concept of IGF-independent actions of GH is supported by in vivo studies, in which IGF-1 cannot duplicate all of the effects of GH (such as nitrogen retention and insulin resistance). The effects of GH in normal human aging[184] and in catabolic conditions[185] are subjects of active investigation.

Insulin-Like Growth Factors

Historical Background

The insulin-like growth factors (or somatomedins) constitute a family of peptides that are at least in part GH dependent and that are believed to mediate many of the anabolic and mitogenic actions of GH. Although they were originally identified in 1957 by their ability to stimulate [35S] sulfate incorporation into rat cartilage,[173] it has been established over the ensuing 45 years that they are involved in diverse metabolic activities (Figure 10-17).

In 1957, Salmon and Daughaday[173] first demonstrated that the inability of serum from hypophysectomized rats to stimulate [35S] sulfate incorporation into rat chondrocyte proteoglycans could not be restored by in vitro addition of GH. However, [35S] sulfate incorporation could be restored by the addition of serum from hypophysectomized rats that had been treated with GH, thereby demonstrating the existence of a GH-dependent "sulfation factor."

Concurrent investigations on insulin activity in rat muscle and adipose tissue indicated that only a small component of the insulin-like activity of normal serum could be blocked by the addition of anti-insulin antibodies. The remaining activity was termed *nonsuppressible insulin-like activity* (NSILA) and was subsequently demonstrated to contain two soluble 7-kd forms named *NSILA-I* and *NSILA-II*.[186,187]

A third converging line of investigation arose from studies by Dulak and Temin[188] of the mitogenic nature of bovine serum. Serum-free conditioned media from fetal Buffalo rat liver cells (BRL-3A) were found to support the growth of cultured cells. The mitogenic factor in the medium was termed *multiplication-stimulating activity* (MSA) and was found to share metabolic and mitogenic activities with sulfation factor and NSILA.

In 1972, the restrictive labels of sulfation factor and NSILA were replaced by the term *somatomedin* (SM).[189] In recognition of the broad metabolic and mitogenic actions of these factors, the following criteria were established: concentration in serum must be GH dependent, must possess insulin-like activity in extraskeletal tissues, must promote the incorporation of sulfate into cartilage, and must stimulate DNA synthesis and cell multiplication.

Purification efforts yielded two legitimate somatomedin peptides: a basic peptide (SM-C) and a neutral peptide (SM-A).[190,191] In 1978, Rinderknecht and Humbel[192,193]

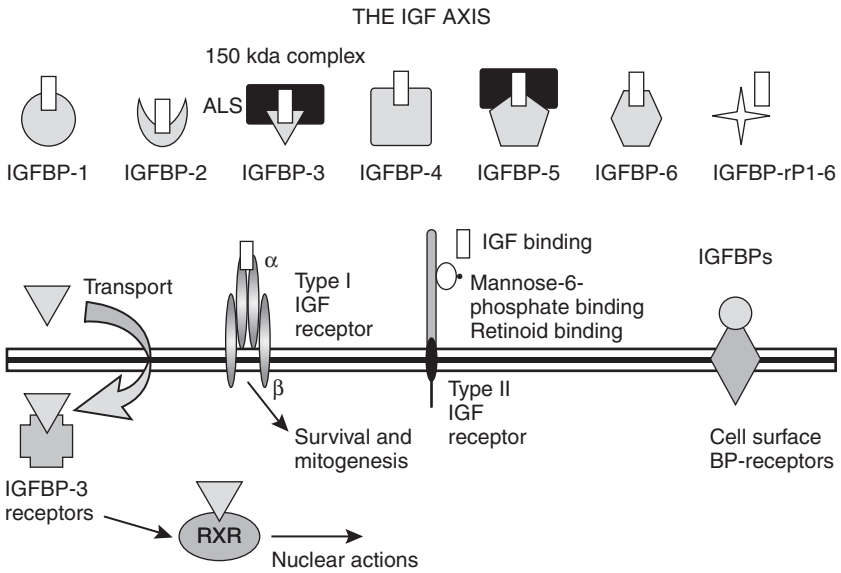

FIGURE 10-17 ■ The insulin-like growth factor (IGF) axis. BP, binding protein; RXR, retinoid X receptor.

isolated two active somatomedins from human plasma that demonstrated a striking structural resemblance to proinsulin. Accordingly, these two peptides were renamed *insulin-like growth factors* (IGFs).

IGF Structure and Molecular Biology

IGF-1, a basic peptide of 70 amino acids, correlates with SM-C—whereas IGF-2 is a slightly acidic peptide of 67 amino acids (Figure 10-18). The two peptides are structurally related, sharing 45 of 73 possible amino acid positions. They have approximately 50% amino acid homology to insulin.[174,192,193] Like insulin, both IGFs have A and B chains connected by disulfide bonds. The connecting (C peptide) region is 12 amino acids long for IGF-1 and 8 amino acids long for IGF-2 and bears no homology with the C-peptide region of proinsulin. IGF-1 and IGF-2 also differ from proinsulin in possessing carboxyl-terminal extensions (D peptides) of 8 and 6 amino acids, respectively. It is clear that this structural homology explains the ability of both IGFs to bind to the insulin receptor and for insulin to bind to the type 1 IGF receptor. On the other hand, structural differences explain the failure of insulin to bind to the IGF-binding proteins.

Two different forms of IGF-1 precursor molecules have been identified.[174] The first 134 amino acids of each are identical, comprising the signal peptide (48 amino acids), the mature IGF-1 molecule (70 amino acids), and the first 16 amino acids of the E domain of the precursor. IGF-1A has an additional 19 amino acids (total 153 residues), whereas IGF-1B has an additional 61 amino acids (total 195 residues).

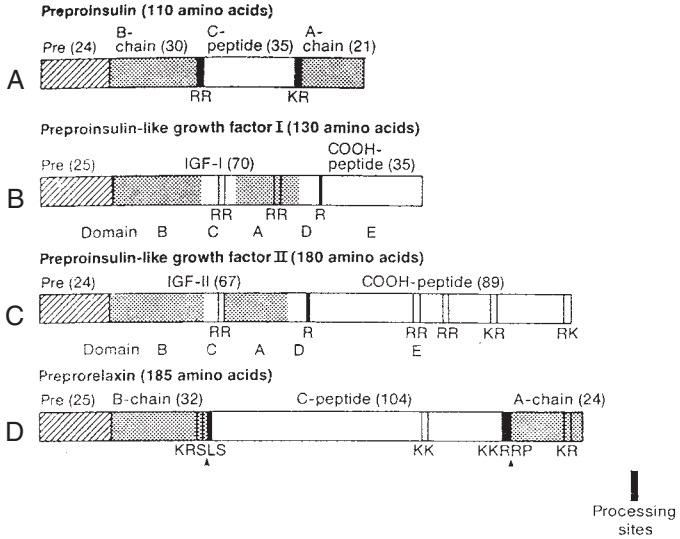

FIGURE 10-18 ■ Schematic representations of the structures of precursors to human insulin, insulin-like growth factor I (IGF-I), IGF-2, and relaxin. *Stippled segments* indicate the homologous B- and A-chain regions. Proteolytic processing sites are indicated by the following amino acid code: K, lysine; L, leucine; P, proline; R, arginines; S, serine. (From Bell, G. I., Merryweather, J. P., Sanchez-Pescado, R., et al (1984). Sequence of cDNA clone encoding human preproinsulin-like growth factor II. *Nature, 310,* 775, MacMillan Magazines Limited.)

Alternative splicing of the IGF-1 gene presumably generates the two alternative messenger RNAs (mRNAs). The primary IGF-2 translation product in human, rat, and mouse contains 180 amino acids—including a 24-residue signal peptide, the 67-amino-acid mature IGF-2 sequence, and a carboxyl-terminal E-peptide of 89 amino acids.

Control of IGF gene expression appears to be complex, perhaps explaining variability in tissue expression as well as differential expression in the embryo, fetus, child, and adult.[174,194-196] IGF-1 and IGF-2 are encoded by single large genes, spanning approximately 95 and 35 kb of genomic DNA, respectively. The human IGF-1 gene contains at least six exons. Exons 1 and 2 encode alternative signal peptides, probably each containing several transcription start sites. Exons 3 and 4 encode the remaining signal peptide, the remainder of the mature IGF-1 molecule, and part of the trailer peptide. Exons 5 and 6 encode alternatively used segments of the trailer peptide (resulting in the IGF-1A and IGF-1B forms), as well as 39 untranslated sequences, with multiple different polyadenylation sites. The human IGF-1 gene is located on the long arm of chromosome 12.[197,198]

The human IGF-2 gene is located on the short arm of chromosome 11,[197-199] adjacent to the insulin gene, and spans 35 kb of genomic DNA—containing nine exons. Exons 1 through 6 encode 59 untranslated RNA, including multiple promoter sites. Exon 7 encodes the signal peptide and most of the mature protein, whereas exon 8 encodes the carboxyl-terminal portion of the protein plus the trailer peptide (whose coding is completed in exon 9). The result is that multiple mRNA species exist for both IGF-1 and IGF-2. This permits remarkable complexity in the regulation of gene expression, allowing for tissue-specific expression of specific transcripts as well as ontogenic and hormonal regulation.

Assay Methodologies for the IGF Peptides

Since their first identification in 1957, the IGF peptides have proven to be remarkably difficult to permit accurate measurement. Bioassay methods were often influenced by a variety of other serum factors capable of mimicking or inhibiting IGF action. More important, virtually all assays were influenced by the presence of IGF-binding proteins (IGFBPs)—which have been found in all biologic fluids tested to date.

Bioassay methods included stimulation of [35S] sulfate incorporation, using various modifications of the original method described by Salmon and Daughaday.[173,200,201] A wide variety of several bioassays included stimulation of DNA synthesis,[202] RNA synthesis, protein synthesis,[203] glucose uptake,[204] and others. In general, however, such assays were cumbersome, subject to interference by IGFBPs, and unable to distinguish between IGF-1 and IGF-2. When SM-C (and later, IGF-1 and IGF-2) were purified, it became possible to radiolabel the pure proteins and employ them in a variety of radioreceptor assays[205,206] and competitive protein-binding assays.[207,208] It was not until the development of specific antibodies that it became possible to accurately distinguish between IGF-1 and IGF-2 and measure each peptide

accurately.[209-212] Current frequently used assays for IGF-I are primarily "double antibody sandwich assays" such as ELISA and have a reasonable accuracy and reproducibility.[213]

Nevertheless, the issue of IGFBPs must be dealt with in any IGF assay.[214] Powell and coworkers,[215] for example, have demonstrated that the discrepant results found in uremic sera assayed for IGF by bioassay, radioreceptor assay, and radioimmunoassay can be entirely attributed to the interference of IGFBPs. Even antibodies with high affinity and specificity will still exhibit interference by IGFBPs. This is particularly true in conditions in which there is a relatively high IGFBP/IGF peptide ratio, or at the clinical extremes of the assay—that is, GH deficiency (GHD) or acromegaly.

In general, the most effective and reliable way to deal with IGFBPs is their separation from IGF peptides by sizing chromatography under acidic conditions.[216] IGF-1 and IGF-2, each with a molecular weight of approximately 7 kd, can be readily separated from the IGFBPs—whose molecular weights range from 25 to 45 kd (glycosylated form of IGFBP-3). This is, however, a labor-intensive procedure and has been occasionally replaced by the more rapid acid ethanol extraction.[217] Although this method may be reasonably effective for most serum samples, it is problematic in conditions of high IGFBP/IGF peptide ratios—such as conditioned media from cell lines and sera from newborns, GHD, and uremia.

Alternative methodologies include the use of antibodies generated against synthetic peptides, such as the C-peptide region of IGF-1 or IGF-2. In general, such antibodies have high specificity but relatively low affinity. Nevertheless, the radiolabeled peptide does not bind to endogenous IGFBPs—offering an important advantage. An alternative approach, developed by Blum and colleagues,[218] has been the use of an antibody with high specificity for IGF-2—which permits the addition of excess unlabeled IGF-1 to saturate endogenous IGFBPs. Bang and coworkers[219] have bypassed the interference of IGFBPs by employing truncated IGF-1, which has decreased the affinity for IGFBPs, as a radioligand. Another way to perform more accurate IGF assays with minimal interference by IGFBPs is through the use of the so-called sandwich assay.[209] Such an assay (either an enzyme-linked immunosorbent assay or an immunoradiometric assay) does not employ a radiolabeled IGF molecule, as compared to the conventional radioimmunoassay.[210] However, at present, the state-of-the-art method for measuring IGFs is liquid chromatography followed by tandem mass spectrometry (LC/MS-MS).[220-222]

Serum Levels of IGF Peptides

In human fetal serum, IGF-1 levels are relatively low and are positively correlated with gestational age (Figure 10-19).[223,224] A correlation between fetal cord serum IGF-1 levels with birth weight has been reported by some groups,[223-225] although others have reported no correlation.[226] IGF-1 levels in human newborn serum are generally 30% to 50% of adult levels. There is a slow, gradual rise in serum concentrations during childhood, with attainment of adult levels at the onset of sexual maturation.[227]

During the process of puberty, IGF-1 concentrations rise to be two to three times the concentrations seen in adults.[228] Thus, concentrations during adolescence correlate better with Tanner stage (bone age) than with chronologic age. Girls with gonadal dysgenesis show no adolescent increase in serum IGF-1, clearly establishing the association of the pubertal rise in IGF-1 with the production of sex steroids.[229-231] It has been suggested that the pubertal rise in sex steroids stimulates IGF-1 production indirectly by first leading to a rise in GH secretion. It is of note, however, that patients with GH insensitivity (GHI) resulting from GHR mutations show a pubertal rise in serum IGF-1, which could not have been produced by GH action inducing IGF-1, thereby implicating a direct effect of sex steroids on IGF-1.[232] After adolescence, or at least after 20 to 30 years of age, serum IGF-1 concentrations demonstrate a gradual and

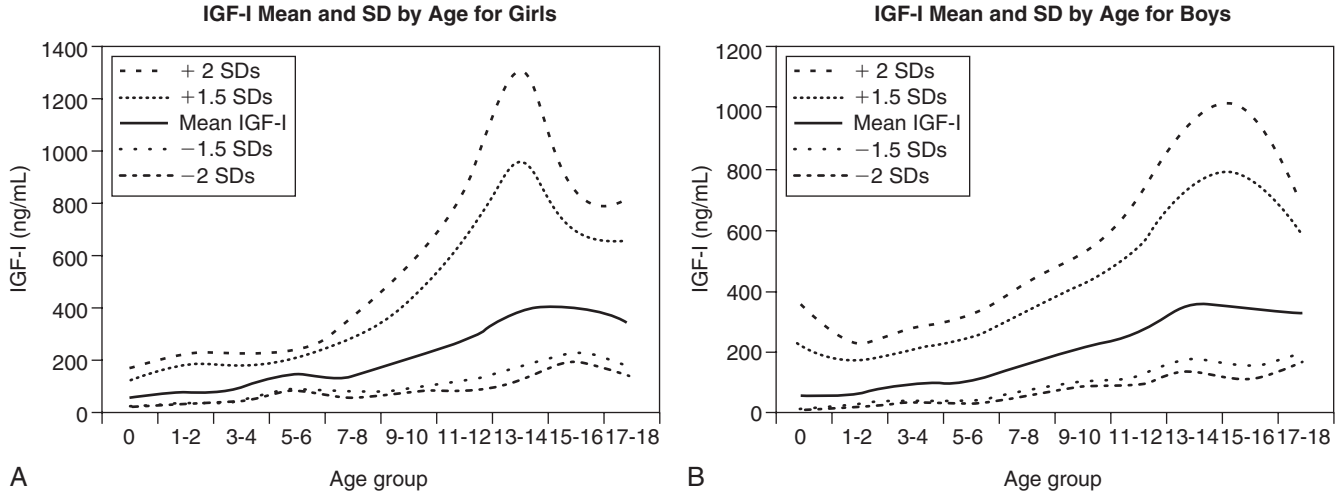

FIGURE 10-19 ■ Serum insulin-like growth factor I (IGF-I) values by age for females (**A**) and males (**B**). SD, standard deviation.

progressive age-associated decline.[184,233] It has been suggested that this decline may contribute to the negative nitrogen balance, decrease in body musculature, and osteoporosis characteristic of aging.[184] This provocative hypothesis remains unproven at this time, although it has generated considerable interest in the potential use of GH or IGF-1 therapy in normal aging.

Human newborn levels of IGF-2 are generally 50% of adult levels. By 1 year of age, however, adult concentrations are attained with little if any subsequent decline—even out to the seventh or eighth decade of life. It is of interest that this pattern of IGF-2 concentrations is distinctly different from that in the rat or mouse (in which serum IGF-2 levels are highest in the fetus and rapidly decline postnatally to essentially undetectable levels in the adult).[234,235]

Measurement of IGF Levels in Growth Disorders

The GH dependency of the IGFs was established by the initial report from Salmon and Daughaday.[173] Following the development of sensitive and specific radioimmunoassays that could distinguish between IGF-1 and IGF-2, the relationship of serum IGF levels to GH status has been established.[213] Measurement of each IGF peptide offers its own particular advantages. IGF-1 concentrations are far more GH dependent than are IGF-2 concentrations and are useful in identifying changes in GH secretory patterns. Serum IGF-1 concentrations, however, are greatly influenced by chronologic age, degree of sexual maturation, and nutritional status. As a result, construction of age-defined normative values is critical. IGF-1 levels in normal children younger than 5 years of age may be so low that extensive overlap exists between the normal range and values in GH-deficient children.

Ranke and coworkers [232] performed GH stimulation tests in 400 children with heights below the 5th percentile and assessed the value of IGF-I as a surrogate of the diagnosis of GHD. The children subsequently diagnosed as GH deficient on the basis of standard provocative tests had very low levels of IGF-I. However, significant overlap of serum IGF-1 levels existed between GH-deficient patients and children with other forms of short stature and normal provocative GH levels. It was only in children with bone ages greater than 12 years that serum IGF-1 levels permitted complete discrimination between GHD and normal short children.

Similarly, Rose and colleagues[236] found that in children with low provocative GH or overnight GH concentrations serum IGF-1 concentrations were lower but not dramatically lower compared to children with normal GH levels. Rosenfeld and associates[213] evaluated the efficacy of IGF-1 and IGF-2 radioimmunoassays in 68 children with GHD, 197 children of normal stature, and 44 normal short children. Eighteen percent of the GH-deficient children had serum IGF-1 levels within the normal range for age, whereas 32% of normal short children had low IGF-1 concentrations. Low IGF-2 levels were found in 52% of GH-deficient children but also in 35% of normal short children. The use of combined IGF-1/IGF-2 assays provided better discrimination, however, but pediatric endocrinologists do not commonly practice this method.

The observation that many "normal but short" children have low serum concentrations of IGF-1 or IGF-2 (or both) calls into question the criteria by which the diagnosis of GHD is currently made. Given that provocative GH testing is both arbitrary and nonphysiologic and that inherent variability in GH radioimmunoassays exists, it is not surprising that the correlation between IGF-1 levels and provocative GH levels is imperfect. These points are further supported by observations with radioimmunoassays for IGFBP-3.

IGF Receptors

In the early 1970s, it became apparent that the IGFs could bind (although generally with low affinity) to insulin receptors, thus providing an explanation for their insulin-like activity.[237] Shortly thereafter, Megyesi and associates[238] identified distinct receptors for insulin and IGF in rat hepatic membranes. Specificity studies, employing radiolabeled IGF preparations, demonstrated that at least two classes of IGF receptors existed. Insulin, at high concentrations, could compete for occupancy of one form of IGF receptor but had essentially no affinity for the second form of receptor.

The development of methodologies for structural characterization of these receptors enabled the clear discrimination of two receptor forms[239-242] (see Figure 10-17). The type 1 IGF receptor is closely related to the insulin receptor. Both are heterotetramers composed of two membrane-spanning alpha subunits of apparent molecular weight of 130 kd and two intracellular beta subunits of apparent molecular weight of 90 kd. The alpha subunits contain the binding sites for IGF-1 and are linked by disulfide bonds. The beta subunits contain a transmembrane domain, an adenosine triphosphate (ATP)-binding site, and a tyrosine kinase domain, which constitutes the presumed signal transduction mechanism for the receptor. Whereas each alpha-beta heterodimer appears capable of binding one molecule of ligand, it appears that 1 mole of the full heterotetrameric receptor binds only 1 mole of ligand.

Although the type 1 IGF receptor has been commonly referred to as the "IGF-1 receptor," studies indicate that the receptor is capable of binding IGF-1 and IGF-2 with high affinity—and both IGF peptides appear capable of activating tyrosine kinase by binding to this receptor. Affinity of the type 1 receptor for insulin is generally 100-fold less, thereby providing a mechanism for the relatively weak mitogenic effect commonly observed with insulin. Ullrich and coworkers[243] deduced the complete primary structure of the human type 1 IGF receptor from cDNA cloned from a human placental library. The mature peptide constitutes 1,337 amino acids, with a predicted molecular mass of 152 kd.

The translated alpha-beta heterodimer is subsequently cleaved at an Arg-Lys-Arg-Arg sequence at positions 707 to 710. As is the case with the insulin receptor, the beta subunit has the expected hydrophobic transmembrane domain and the intracellular tyrosine kinase domain and ATP binding site. Although it appears reasonable to presume

that insulin and IGF-1 receptors have both evolved from a common ancestor protein, they are encoded by genes on separate chromosomes (chromosome 15 q26.3 for the type 1 IGF receptor and chromosome 19 for the insulin receptor).

IGF-1 acts primarily through IGF1R but can bind with lower affinity to the highly homologous insulin receptor and to IGF1R/IR heterodimers. Vice versa, insulin is able to signal through the IGF1R.[244,245] Signs of such alternative signaling can become apparent in pathologic states of IGF-1 or insulin secretion.

The type 1 IGF receptor mediates IGF actions on all cell types, and these actions are diverse and tissue specific. In general, it is believed that all of the effects of IGF receptor activation are mediated by tyrosine kinase activation and phosphorylation of substrates—which activate specific cellular pathways, leading to various biologic actions. Among these effects is induction of cell growth through activation of the cell cycle machinery, maintenance of cell survival (prevention of apoptosis) mediated by effects on the bcl family members, and induction of cellular differentiation, which occurs by as yet incompletely characterized mechanisms.

The substrates, which are phosphorylated by the IGF receptor, include the members of the insulin receptor substrate family (particularly IRS-1 and IRS-2) because both of the knockout mice models for these genes result in poor growth (as well as insulin resistance).[246] Other IRS molecules may have a negative feedback role in regulating IGF action.[247] In addition, several other signaling molecules respond to IGF receptor activation. Blockade of the IGF-I receptor has been proposed as a cancer therapy, and clinical studies show promise in early trials.[248]

It is of particular note that a prototypic molecule for the IGF-1/insulin receptor in nematodes (termed Daf2) is related to longevity, such that mutations of this gene extend the life expectancy of these organisms. This extension of life expectancy in nematodes has also been shown for other components of the GH-IGF system, as well as being demonstrated in several other species including flies and mice.[249] It is unclear, however, what relevance the IGF-1/insulin receptor has for human longevity. Data have suggested that genetic alterations in the human IGF1R that result in altered IGF signaling confer an increase in proclivity for human longevity, suggesting a role of this pathway in modulating human life span.[250] The type 2 IGF receptor, however, bears no structural homology with either the insulin or the type 1 IGF receptors. On sodium dodecyl sulfate–polyacrylamide gel electrophoresis, the type 2 IGF-R has been demonstrated to migrate at an apparent molecular weight of 220 kd under nonreducing conditions and 250 kd after reduction—indicating that it is a monomeric protein.

The cloned human type 2 receptor has a predicted molecular mass of 271 kd and is characterized by a lengthy extracellular domain containing 15 repeat sequences of 147 residues each,[251] followed by a 23-residue transmembrane domain and a small cytoplasmic domain consisting of only 164 residues. The receptor does not contain an intrinsic tyrosine kinase domain or any other recognizable signal transduction mechanism. Surprisingly, the type 2 IGF receptor has been found to be identical to the cation-independent mannose-6-phosphate (CIM6P) receptor—a protein involved in the intracellular lysosomal targeting of a variety of acid hydrolases and other mannosylated proteins.[252,253] The majority of these receptors are located on intracellular membranes, where they are in equilibrium with receptors on the plasma membrane.[254]

Why this receptor binds IGF-2 and mannose-6-phosphate–containing lysosomal enzymes remains unresolved. Unlike the type 1 IGF receptor, which binds both IGF peptides with high affinity and insulin with 100-fold lower affinity, the type 2 receptor only binds IGF-2 with high affinity. IGF-1 binds with substantially lower affinity, and insulin not at all.[254] One mole of IGF-2 binds per mole of receptor. The binding sites for IGF-2 and mannose-6-phosphate appear to reside in different portions of the receptor. Nevertheless, the two classes of ligand do show some reciprocal inhibitory effects on receptor binding—suggesting a potential effect of IGF-2 on the sorting of lysosomal enzymes.

Most studies have indicated that the classic mitogenic and metabolic actions of IGF-1 and IGF-2 are mediated through the type 1 IGF receptor, with its tyrosine kinase signal transduction mechanism. Conover and coworkers[255] and Furlanetto and associates[256] have demonstrated that monoclonal antibodies directed against the IGF-1 binding site on the type 1 IGF receptor inhibit the ability of IGF-1 and IGF-2 to stimulate thymidine incorporation and cell replication. Similarly, several groups have shown that polyclonal antibodies capable of blocking IGF-2 binding to the type 2 IGF/mannose-6-phosphate receptor do not block IGF-2 actions.[257-259]

More direct evidence for the role of the type 1 IGF receptor in mediating classic IGF actions of IGF-2 comes from the use of IGF-2 analogues as probes of receptor function. IGF-2 analogs with decreased affinity for the type 1 receptor but preserved affinity for the type 2 receptor were markedly less potent than IGF-2 in stimulating DNA synthesis.[260] In further support of the concept that the type 2 IGF receptor does not mediate the mitogenic actions of IGF-2, it has been shown that the mannose-6-phosphate receptor in hepatic tissues from chicken[261] or frogs[262] does not bind IGF-2. Presumably, IGF-2 mitogenic actions in these species are mediated solely through the type 1 IGF receptor.

Nevertheless, a number of observations are consistent with the possibility of an IGF-2 action mediated via the type 2 IGF receptor. Rogers and Hammerman[263] have suggested that the type 2 receptor is involved in production of inositol triphosphate and diacylglycerol in proximal tubule preparations and canine kidney membranes. Tally and coworkers[264] have reported that IGF-2 stimulates the growth of a subclone of the K562 human erythroleukemia cell line, an action not duplicated by either IGF-1 or insulin. Minniti and coworkers[265] reported that IGF-2 appears capable of acting as an autocrine growth factor and cell motility factor for human rhabdomyosarcoma cells, actions apparently mediated through the type 2 receptor. It has been suggested that IGF-2 can activate a calcium-permeable cation channel by means of the type 2 IGF receptor,

perhaps through coupling to a pertussis toxin–sensitive guanine nucleotide–binding protein (Gi protein).[266]

It now appears that the type 2 IGF receptor binds several other molecules in addition to IGF-2. The ability of this receptor to bind mannose-6-phosphate–containing enzymes (such as cathepsin and urokinase) is well recognized and may be important in its ability to remove these enzymes from the cellular environment, thus modulating tissue remodeling.[267] In addition, reports indicate that the type 2 IGF receptor binds retinoic acid and may mediate some of the growth inhibitory effects of retinoids.[268] Knocking out the gene for type 2 IGF receptor results in excessive growth, as subsequently detailed. It appears that this receptor acts as a growth inhibitory component of the IGF system responding to and mediating multiple antimitogenic systems.[269]

The occasional observation of seemingly anomalous competitive binding results[270] has led to the suggestion that variant or atypical insulin and IGF receptors might exist.[271] One possible explanation for such findings is the existence of hybrid receptors composed of 1 alpha-beta dimer of the insulin receptor and 1 alpha-beta dimer of the type 1 IGF receptor.[272] Ligand-dependent formation of hybrid IGF/insulin receptors has been reported by Treadway and associates,[273] and studies with monoclonal antibodies specific for the insulin or type 1 IGF receptor have suggested that such receptors may develop spontaneously in cells with abundant native receptors.[274] The physiologic significance of such hybrid receptors, however, is entirely speculative.

IGF-Binding Protein Superfamily

Although insulin and the IGFs share significant structural homology, and despite the structural-functional similarity of the insulin and type 1 IGF receptors, the IGFs differ from insulin in one important respect. In contrast to insulin, the IGFs circulate in plasma complexed to a family of binding proteins.[275-277] These carrier proteins extend the serum half-life of the IGF peptides, transport the IGFs to target cells, and modulate the interaction of the IGFs with their surface membrane receptors.

The existence of IGFBPs was initially inferred from chromatographic studies of size distribution of IGF peptides in serum,[278] but the complexity of the interactions among the IGFs, IGFBPs, and IGF receptors has been fully appreciated only recently. The identification and characterization of IGFBPs in body fluids and in conditioned media from cultured cells have been facilitated by the development of a number of biochemical and assay techniques, including gel chromatography, radioreceptor assays, affinity cross-linking, Western ligand blotting,[279] immunoblotting, and specific radioimmunoassay and ELISA assays. It has been the study of the molecular biology of the IGFBPs that has provided the most information concerning their structural interrelationship, however.

Six distinct human and rodent IGFBPs have been cloned and sequenced.[276,277,280] Their structural characteristics are summarized in Figure 10-20. The determination of the primary amino acid sequences from the cloned cDNAs of the IGFBPs has revealed important structural relationships among the IGFBPs. Probably the most impressive similarity in structure is the conservation of the number and placement of the cysteine residues. The total number of cysteines varies from 16 to 20, and each of the IGFBPs has cysteine-rich regions at the amino and carboxyl termini of the protein. Conservation of the spatial order of the cysteines presumably indicates that the secondary structure of the IGFBPs, which is dependent on disulfide bonding, must also be well maintained. Disulfide bonding establishes the IGF-binding site of each IGFBP. Reduction of the binding proteins results in loss of IGF binding.

Analysis of the amino acid sequences of the IGFBPs also reveals the presence of an arginine-glycine-aspartic acid (RGD) positioned near the carboxyl terminus of

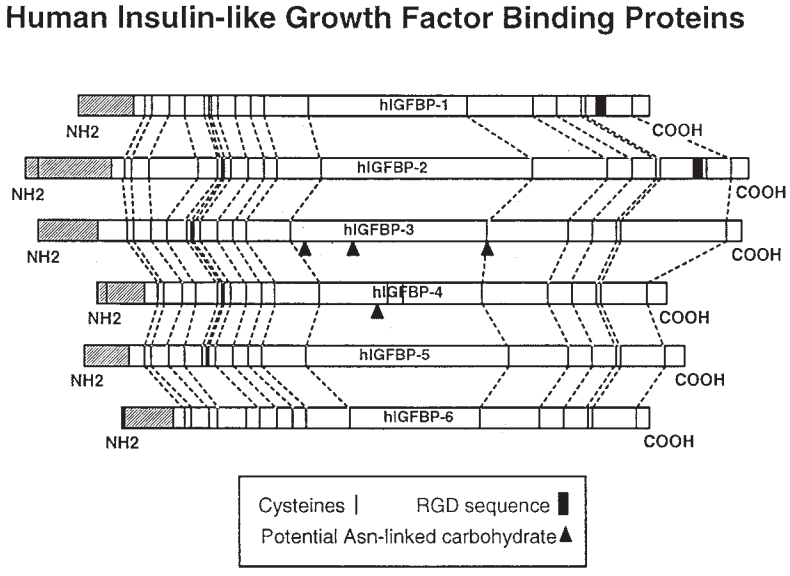

FIGURE 10-20 ■ Schematic representation of the insulin-like growth factor (IGF)–binding proteins. (Adapted from Lamson, G., Giudice, L., & Rosenfeld, R. G. (1991). Insulin-like growth factor binding protein and molecular relationship. *Growth Factors, 5,* 19.)

IGFBP-1 and IGFBP-2.[281] This sequence has been demonstrated to be the minimum required in many extracellular matrix proteins for their binding by membrane receptors of the integrin protein family. It has been suggested that IGFBPs may associate with the cell surface through such amino acid sequences. On the other hand, IGFBP-3 (which lacks an RGD sequence) also appears capable of specific binding to cell membrane receptors.[282,283] Membrane proteins capable of specifically binding IGFBP-3 have been proposed.[284]

Under most conditions, the IGFBPs appear to inhibit IGF action—presumably by competing with IGF receptors for IGF peptides.[285] This conclusion is supported by the observation that IGF analogues with decreased affinity for IGFBPs generally appear to have increased biologic potency.[286-288] In many studies involving transfection of the hIGFBP-3 gene into cells, expression of IGFBP-3 resulted in an inhibition of cell growth even in the absence of added IGF—suggesting a direct inhibitory role of the binding protein.[289] Under specific conditions, however, several of the IGFBPs apparently are capable of enhancing IGF action—perhaps by facilitating IGF delivery to target receptors.[290]

Of interest is the discovery of several groups of cysteine-rich proteins that contain domains strikingly similar to the amino-terminal domain of the IGFBPs. This has led to the proposal of an IGFBP superfamily,[291] which includes the family of six high-affinity IGFBPs—as well as a number of families of IGFBP-related proteins (IGFBP-rPs). Three of the IGFBP-rPs (Mac25/IGFBP-rP1; connective tissue growth factor, CTGF/IGFBP-rP2; NovH/IGFBP-rP3) have been shown to bind IGFs, although with considerably lower affinity than in the case of IGFBPs. Like the IGFBPs, the IGFBP-rPs are modular proteins—and the highly preserved aminoterminal domain appears to represent the consequence of exon shuffling of an ancestral gene. It is not clear what role, if any, the IGFBP-rPs play in normal IGF physiology. However, it is likely that they can influence cell growth by IGF-independent (and perhaps IGF-dependent) mechanisms.

Evidence indicates that IGFBPs are essentially bioactive molecules that in addition to binding IGF have a variety of IGF-independent functions. These clearly include growth inhibition in some cell types,[292] growth stimulation in other tissues,[293] direct induction of apoptosis,[294] and modulation of the effects of other non-IGF growth factors. These effects of IGFBPs are mediated, undoubtedly, by binding to their own receptors. These IGFBP-signaling pathways are being unraveled and involve the interaction of IGFBPs with nuclear retinoid receptors as well as with other molecules on the cell surface and in the cytoplasm.[295] Because IGFBP-3 is regulated by GH, it is intriguing that in vivo IGFBP-3 enhances IGF-I action when given to hypophysectomized rats (rather than inhibiting it).[296] The mechanisms involved in this effect have not been elucidated but may explain the limited effects of IGF-1 therapy on the growth of Laron patients (discussed later in the chapter).

Analysis of IGFBPs is further complicated by the presence of IGFBP proteases, capable of various levels of IGFBP degradation.[297,298] Initially reported in the serum of pregnant women,[297,298] proteases for IGFBP-3, -4, and -5 have already been demonstrated in a variety of biologic fluids—including serum, seminal plasma,[67] cerebrospinal fluid,[299] and urine.[300] Proteolysis of IGFBPs complicates their assay by both Western ligand blotting and radioimmunoassay methodologies and must be taken into consideration when concentrations of the various IGFBPs in biologic fluids are reported.[301] The physiologic significance of limited proteolysis of IGFBPs remains to be determined, although evidence suggests that protease activity results in decreased affinity of the IGFBP for IGF peptides.

The relative amounts of each of the IGFBPs vary among biologic fluids. IGFBP-1 is the major IGFBP in human amniotic fluid.[302] IGFBP-2 is prominent in cerebrospinal fluid[303] and seminal plasma.[304] IGFBP-3 is the major IGFBP in normal human serum and demonstrates clear GH dependence.[305] Among the IGFBPs, IGFBP-3 and IGFBP-5 are unique in that they normally circulates in adult serum as part of a ternary complex consisting of IGFBP-3 or IGFBP-5, an IGF peptide, and an acid-labile subunit.[306]

Specific immunoassays have been developed for the IGFBPs, including IGFBP-1,[302,307,308] IGFBP-2,[309] and IGFBP-3.[301,310,311] Currently, measurement of IGFBP-3 appears to have the greatest potential clinical value because this IGFBP appears to be directly GH dependent (Figure 10-21). Blum and associates[45] have suggested that radioimmunoassay determination of serum concentrations of IGFBP-3 might be more specific (but less sensitive) than IGF-1 assays in the diagnosis of GHD because normal concentrations of IGF-1 are so low in young children and many "normal" short children have low concentrations of IGF-1. Because IGFBP-3 determinations reflect not only IGF-1 levels but IGF-2 concentrations, their age dependency is not nearly as striking as that of IGF-1. Even in young children, normal concentrations are at least above 500 ng/mL. The use of IGFBP assays in the evaluation of IGF deficiency and GHD is discussed later in this chapter.

Targeted Disruption of Components of the IGF System

The critical role of the IGF system in fetal and postnatal growth was demonstrated in a series of elegant gene knockout studies in mice.[312] Unlike GH and GHR knockouts,[213] which are near normal size at birth, Igf1 null mice have a birth weight 60% of normal.[110] Postnatal growth is abnormal, and the surviving mice are only 30% of normal size by 2 months of age. A similar prenatal and postnatal growth phenotype has been observed in a reported human case of an IGF-1 gene deletion.[313]

Igf2 null mice (or heterozygous mice carrying a paternally derived mutated Igf2 gene) also have birth weights 60% of normal and remain about 60% of normal size throughout life.[314] When the gene for the IGF-1 receptor is knocked out (Igf1r null mice), the mice are severely growth retarded with a birth weight only 45% of normal

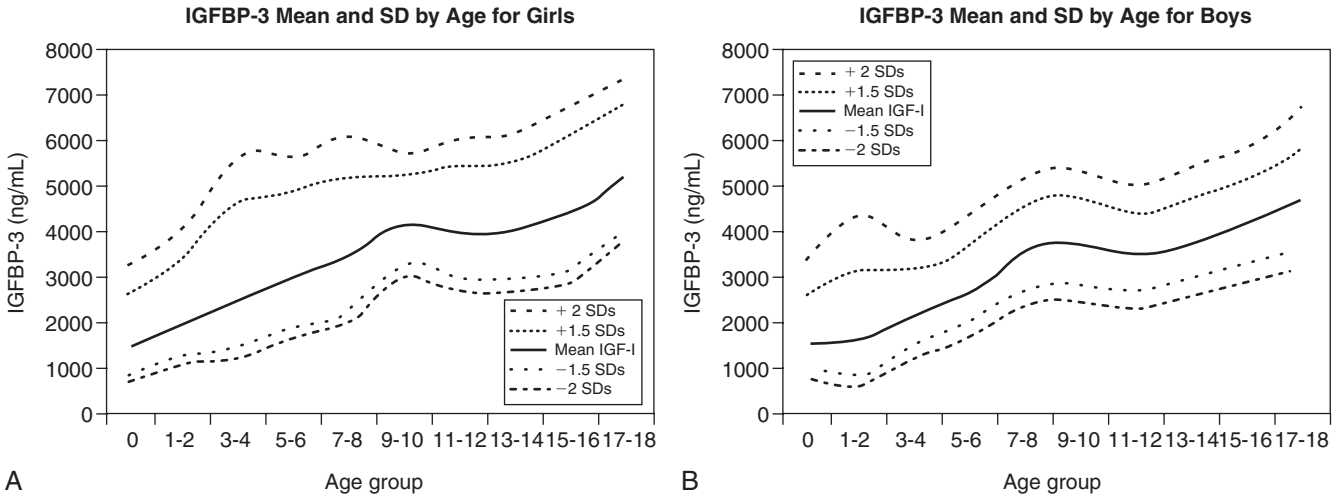

FIGURE 10-21 ■ Insulin-like growth factor–binding protein 3 (IGFBP-3) values by age for females (**A**) and males (**B**). SD, standard deviation.

and die soon after birth—apparently of respiratory failure.[315] The addition of an Igf1 knockout to the Igf1r knockout does not change the growth characteristics significantly, consistent with the hypothesis that IGF-1 is signaling exclusively (at least from the perspective of growth) through the IGF-1 receptor. On the other hand, the combination of Igf2 and Igf1r knockouts results in further growth retardation (birth weight 30% of normal)—indicating that IGF-2 is signaling through the IGF-1 receptor and a second receptor (probably the insulin receptor).

The relationship between GH and IGF-1 in controlling postnatal growth was analyzed in mouse mutants lacking GHR, IGF-1, or both.[182] This demonstrated that GH and IGF-1 promote postnatal growth by independent and common functions because the growth retardation of double GHR/IGF-1 null mice is more severe than that observed with either class of single mutant. In fact, the body weight of these double-mutant mice is only approximately 17% of normal—indicating IGF-independent GH actions. Thus, the growth control pathway in which the components of the GH/IGF-1 signaling systems participate constitutes the major determinant of body size.

The Igf2 gene has been shown to be maternally imprinted in mice and humans (only the paternal gene is expressed). On the other hand, the gene for the IGF-2 receptor (Igf2r) is paternally imprinted (although only in mice).[316] The phenotypes of Igf2r null mice or of heterozygous mice inheriting a mutated maternal gene are indistinguishable and demonstrate overgrowth, with birth weights 140% of normal. Because this receptor normally degrades IGF-2, increased growth reflects excess IGF-2 acting through the IGF-1 receptor. As mentioned previously, mice with deletions in GH and GH-receptor-related genes (as well as IGF-1R and downstream signaling genes) display increased life span and reduced oxidative stress. The human counterparts of these mutations in mice are now known to occur in humans and are discussed in detail later.

Other Growth Factors

The FGF Family of Peptides and Receptors

Fibroblast growth factors (FGFs) constitute an expanding family of peptide cytokine growth factors, which are important in the physiologic regulation of many tissues. In the early 2000s, a large amount of data from both animal and human studies confirmed that these pluripotent FGFs are involved in angiogenesis, wound healing, and proliferation and differentiation of a wide variety of cells and tissues.[317] Initially, it was suggested that FGFs may be specific for cells of stromal lineage. However, it appears that many other cell types respond to FGFs; their multifunctional nature includes both morphologic and endocrine/autocrine/paracrine effects, and they have a mitogenic role as well. There are 22 different members of the FGF family identified in humans so far.[318] FGF1 through FGF10 are all structurally related and bind to one of four fibroblast growth factor receptors (FGFRs). This group includes the better characterized FGF1 (acidic FGF oraFGF), FGF2 (basic FGF or bFGF), and keratinocyte growth factor (KGF or FGF-7).[318] In addition to these FGFs, FGF11 to FGF14 are also known as FGF homologous factors 1 to 4 (FHF1 to FHF4). Although these peptides are structurally homologous to the other FGFs, they do not bind to the FGFRs, which results in their different intracellular function. FGF15 is only found in mice and is the orthologue of human FGF19—both play a role in the intestinal-to-liver signaling of bile acid regulation.[319] FGF16 to FGF23 have been discovered and studied more recently, and some of these peptides appear to have more systemic endocrine-like effects.

The FGFs mediate their actions by binding to one of four receptors[320] (FGFR1, FGFR2, FGFR3, and FGFR4), which have distinct tissue distributions.[321] FGFRs have three extracellular domains, one transmembrane domain, and an intracellular tyrosine kinase domain. Alternative FGFR mRNA splicing leads to several FGFR variants on the cell surface, which determines both specific

ligand-receptor interaction and function for the different FGFs. For the most part, FGFs appear to be autocrine-paracrine growth factors that participate in organ growth and differentiation (as well as in carcinogenesis) but not in somatic growth. In contrast, FGF23, a phosphatonin, is a crucial factor—in an endocrine manner—in the pathophysiology of hypophosphatemic disorders leading to osteomalacia and rickets.[322] Another exception to this rule is the observation that several genetic forms of skeletal dysplasia (achondroplasia, hypochondroplasia, thanatophoric dysplasia) are caused by activating mutations in the FGFR3 gene, suggesting that normal FGFR3 signaling is essential to the normal growth of long bones.[323,324] A human mutation in the FGFR2 gene causes craniosynostosis, a condition characterized by abnormal closure of the bones in the skull, and FGFR2 appears to be a major regulator of bone formation during embryologic development.[325] Other craniosynostosis syndromes have now been associated with mutations that enhance FGFR2 function, and mutations leading to diminished FGFR2 function have also been documented, including distinct forms of perinatal lethal skeletal dysplasia.[326] These clinical conditions in humans together with targeted disruptions of several murine FGF and FGFR genes underscore the importance of the FGFs on a multitude of developmental systems and processes, including, but not limited to, angiogenesis, neurogenesis, limb development, and many other functions.

The EGF System

Epidermal growth factors (EGFs) and their receptors are ubiquitous in many tissues and participate in developmental processes in mice, such as precocious eyelid opening and tooth eruption. EGF itself it the best studied polypeptide in the larger family of EGF proteins, which further include transforming growth factor alpha (TGF-α), epiregulin, neuregulin, and betacellulin among several other proteins. The mitogenic actions of EGF have been extensively explored in cell culture systems, and the receptor for EGF (EGFR) was characterized as a prototype model for signal transduction involving tyrosine kinases. EGFR, a transmembrane glycoprotein, is one of four members of the erbB family of tyrosine kinase receptors.

The extensive in vitro data indicate multiple cellular functions of EGF. EGF has been identified in most body fluids of several mammalian species. EGF-EGFR interaction promotes cellular proliferation, differentiation, and survival. However, neither EGF antibody administration to newborn animals nor gene targeting of EGF has caused major deleterious effects—as might have been expected from the in vitro studies.[327]

The EGF family of growth factors appears to be important in mammalian development and function, although the precise roles and significance are not entirely clear. Members of the EGF family may have a role in embryogenesis and fetal growth because receptors have been identified in fetal tissues. It has been proposed that abnormal EGF-EGF receptor interactions may be instrumental in the development of cancer, but it appears that they are not involved in somatic growth. It has long been documented that EGFR is overexpressed in a number of tumor cell lines. This may worsen tumor prognosis and patient survival, because EGFR may affect the tumors' resistance to chemo- and radiation therapies. For this reason, newer anticancer therapies have been developed to interfere with EGFR signaling, either by blocking ligand-EGFR binding (monoclonal antibodies) or by inhibiting the intracellular signal transduction cascade (such as with small molecule inhibitors). These treatments have allowed tumor arrest and even regression, as well as strengthened the effect of standard anticancer treatment modalities.[328]

Other Growth-Promoting Peptides

An ever-growing number of growth factors are being recognized, and multiple hormones and peptides are being characterized as having growth-promoting activities in certain cell types. In general, these molecules appear to lack somatic growth-promoting effects but play important autocrine-paracrine and endocrine roles. Notable among these molecules are groups of growth factors that have tissue-specific effects. Endothelin, platelet-derived growth factor (PDGF), and vascular-epithelial growth factor (VEGF) all regulate angiogenesis and other vascular processes in addition to modulating the function of numerous cultured cells. A variety of hematopoietic growth factors—such as the granulocyte and macrophage colony-stimulating factors (GCSF, MCSF), erythropoietin, and thrombopoietin—promote the growth of the different lineages of the hematopoietic cells.

The growth of various cells of the immune system is stimulated by an array of cytokines, including interleukins (ILs) and interferons (IFNs). Up to 35 different human interleukins, small cell-signaling molecules that organize communication between immune system cells, have been described, each with a variety of target receptors. Their functions are highly variable and involve differentiation of immune response and modulation of inflammation, proliferation of myeloid progenitor cells, and they serve a regulatory role in the differentiation and proliferation of multiple other cell types (osteoclasts, keratinocytes, etc.). ILs are being used in cancer immunotherapy and immunomodulation of transplant patients.[329] About 10 different IFNs have been identified in mammals; 7 of these are believed to be important in humans. Based on which receptor they signal through, the IFNs are further subdivided in three major subclasses (IFNs types I to III). The major function of IFNs relates to (1) their antiviral effect and (2) their tumor fighting ability (most often for hematologic malignancies). This is attributed to their antiproliferative, apoptotic, and antiangiogenic action, as well as their ability to modulate immune responsiveness.[330] In 2012, more than 10 pharmaceutical formulations of IFNs were available for variable therapeutic usage.

The complex array of cells that constitute the nervous system is under the regulatory influence of specific growth factors, such as nerve growth factor (NGF), the neurotrophins, and brain- and glial-derived neurotrophic factors (BDNF, GDNF). Other growth factors that have been attributed to specific tissues (e.g., hepatocyte growth factor [HGF]) are being recognized as

having a general growth-promoting effect in numerous tissues, and additional organ-specific growth regulatory processes have been described in the gastrointestinal tract and kidneys.

Growth Inhibitory Peptides

Of particular interest is a class of cytokines that can negatively modulate cellular growth. Transforming growth factor-beta (TGF-β) is a protein that comes in at least three isoforms and is part of the superfamily of proteins known as the transforming growth factor beta superfamily. Other members include inhibin, activin, and anti-Mullerian hormone. TGF-β mediates cellular growth and malignant transformation and can function as a growth inhibitory substance with the potential of arresting the growth of both normal and neoplastic cells. Abnormal TGF-β signaling also appears to play a role in disorders such as Marfan syndrome (possibly through abnormal TGF-β sequestration) and Loeys-Dietz syndrome (TGF-β receptor mutation). Tumor necrosis factors (TNFs) and other compounds have been reported to have similar effects to TGF-β.

All these molecules may regulate the entry of cells into programmed cell death (apoptosis). The growth inhibitory processes of TGF- β and other cytokines may prove to be of great importance in the development of cancer treatments. A family of genes/proteins, of which the most important is p53, is also critical to growth and tumor suppression.[331] These genes/proteins that function as tumor suppressors may also be involved in fetal growth.

Sex Steroids

Whereas androgens and estrogens do not contribute substantially to normal growth before the onset of puberty, the rise in serum sex steroid concentrations during adolescence is an important part of the pubertal growth spurt. States of androgen or estrogen excess before epiphyseal fusion are invariably characterized by rapid linear growth and skeletal maturation. Thus, just as growth deceleration requires further evaluation, growth acceleration can be just as abnormal and may be a sign of increased sex steroid production or action, as observed in precocious puberty and with the virilizing effects of congenital adrenal hyperplasia.

A GH-replete state is obligatory for a normal growth response to sex steroids. Children with GHD do not have a normal growth response to either endogenous or exogenous androgens. Although androgens work at least in part by enhancing GH secretion, they must also have a direct effect on IGF-1 production—as observed with the rise in serum IGF-1 concentrations and pubertal growth spurt characteristic of children with mutations of the GHR.[110]

Androgens and estrogens have been shown to increase skeletal maturation. Advancement of skeletal age and epiphyseal fusion appear to be estrogen-mediated, as indicated by the report of tall stature with open epiphyses in a patient with a mutation of the estrogen receptor.[17] Similar findings are noted in those with inactivating mutations of the gene regulating the aromatase enzyme that normally converts androgens to estrogens.[332] Whichever the mechanism, however, clinical states of androgen or estrogen excess are characterized by disproportionate skeletal maturation and premature epiphyseal fusion. Interestingly, a condition of aromatase excess has been described, resulting from mutations in the promoter region of the gene and leading to early epiphysial closure and gynecomastia.[333]

Thyroid Hormone

Thyroid hormone is also a major contributor to postnatal growth, although, like GH, it is of relatively little importance to growth of the fetus. Hypothyroidism occurring postnatally can, however, result in profound growth failure and virtual arrest of skeletal maturation. In addition to a direct effect on epiphyseal cartilage, thyroid hormone appears to have a permissive effect on GH secretion. Patients with hypothyroidism have decreased spontaneous GH secretion and have a blunted response to GH provocative tests. Treatment with thyroid hormone results in rapid "catch-up" growth, which is typically accompanied by marked skeletal maturation—potentially resulting in overly rapid epiphyseal fusion and compromise of adult height.

GROWTH RETARDATION

Systems for classification of growth disorders are problematic because diagnostic categories have not always been sharply defined and frequently overlap. Genetic short stature, for example, may often be associated with constitutional delay of growth and maturation—and both disorders fall under the umbrella of idiopathic short stature (ISS). Because diagnostic criteria for GHD have been problematic, overlap has frequently existed among genetic short stature, constitutional delay, and the vague category of "partial" GHD. In addition, the cause of growth failure in intrauterine growth retardation (IUGR) and various syndromes associated with poor growth has generally remained obscure.

Box 10-1 represents an effort at classification of growth retardation. Growth disorders have been subdivided into primary growth abnormalities, in which the defect(s) appears to be intrinsic to the growth plate, genetic short stature, and secondary growth disorders (i.e., growth failure resulting from chronic disease or endocrine disorders). The category of "IGF deficiency (IGFD)" has become accepted as an overall category encompassing disorders that can result from various causes of GH deficiency (sometimes called secondary IGFD) or GH insensitivity (sometimes referred to as primary IGFD). The category of "IGF deficiency" takes on special meaning in light of recommendations for reevaluation of the diagnosis of GHD and primary IGFD.

Primary Growth Abnormalities

Osteochondrodysplasias

The osteochondrodysplasias represent a heterogeneous group of disorders characterized by intrinsic abnormalities of cartilage or bone.[334] The conditions share the following

BOX 10-1 Classification of Growth Retardation

I. Primary Growth Abnormalities

A. Osteochondrodysplasias
B. Chromosomal abnormalities

II. Secondary Growth Disorders

A. Malnutrition
B. Chronic disease
C. Intrauterine growth retardation
D. Endocrine disorders
- Hypothyroidism
- Cushing syndrome
- Pseudohypoparathyroidism
- Vitamin D deficient or resistant rickets

III. IGF Deficiency

A. Secondary IGFD
- GH deficiency due to hypothalamic dysfunction
- GH deficiency due to pituitary GH deficiency

B. Primary IGFD (GH insensitivity)
- Primary GH insensitivity-GH receptor defects
- Secondary GH insensitivity (Stat-5b)-GHR signal transduction defects
- Primary defects of IGF synthesis
- Primary defects of IGF transport/clearance (ALS)

C. IGF resistance
- Defects of the IGF-1 receptor
- Postreceptor defects

IV. Idiopathic Short Stature (ISS)

A. Constitutional delay of growth and puberty with normal height prediction
B. ISS with delayed bone age and tempo of puberty
C. ISS with normal bone age and tempo of puberty
D. ISS with a familial component
E. ISS without a familial component

GH, growth hormone; IGF, insulin-like growth factor.

BOX 10-2 Classification of Osteochondrodysplasias[876]

- Defects of tubular (and flat) bones or axial skeleton
- Achondroplasia group
  - Achondrogenesis
  - Spondylodysplastic group (perinatally lethal)
  - Metatropic dysplasia group
  - Short rib dysplasia group (with/without polydactyly)
  - Atelosteogenesis/diastrophic dysplasia group
  - Kniest-Stickler dysplasia group
  - Spondyloepiphyseal dysplasia group
  - Other spondyloepi(meta)physeal dysplasias
  - Dysostosis multiplex group
  - Spondylometaphyseal dysplasias
  - Epiphyseal dysplasias
  - Chondrodysplasia punctata (stippled epiphyses) group
  - Metaphyseal dysplasias
  - Brachrachia (short spine dysplasia)
  - Mesomelic dysplasias
  - Acromelic/acromesomelic dysplasias
  - Dysplasias with significant (but not exclusive) membranous bone involvement
  - Bent bone dysplasia group
  - Multiple dislocations with dysplasias
  - Osteodysplastic primordial dwarfism group
  - Dysplasias with increased bone density
  - Dysplasias with defective mineralization
  - Dysplasias with increased bone density
  - Disorganized development of cartilaginous and fibrous components of the skeleton
  - Idiopathic osteolyses

features: genetic transmission; abnormalities in the size or shape of bones of the limbs, spine, or skull; and radiologic abnormalities of the bones (generally). More than 100 osteochondrodysplastic conditions have been identified, based on physical features and radiologic characteristics. The ongoing characterization of biochemical and molecular abnormalities in these conditions will undoubtedly lead to an increase in the number of these disorders.

An international classification for the osteochondrodysplasias was developed.[335] Box 10-2 provides a brief summary of this classification. Of note, the category of dysostoses has been dropped from the classification—which now focuses on developmental disorders of chondro-osseous tissues. Diagnosis of osteochondrodysplasias can be problematic and often relies on careful radiologic evaluation. Although progress has been made in identifying the underlying molecular and biochemical defects in many of these conditions, clinical and radiologic evaluation remains central to the diagnosis at this time. Frequently, the clinical features are obvious—and the diagnosis can then be made at birth (or even prenatally) by ultrasound.

The family history is obviously critical. However, many cases represent fresh mutations—as is generally the case in the classic autosomal-dominant achondroplasia and hypochondroplasia. Careful measurement of body proportions is necessary, including arm span, sitting height, upper/lower body segments, and head circumference. Clinical and radiologic evaluation should be used to determine whether involvement is of the long bones, skull, or vertebrae—and whether abnormalities are primarily at the epiphyses, metaphyses, or diaphyses. Two of the more common forms (achondroplasia and hypochondroplasia) of the more than 100 defined osteochondrodysplasias are discussed in the following sections.

Achondroplasia. This is the most common of the osteochondrodysplasias, with a frequency of approximately 1:26,000 births. Although transmitted as an autosomal-dominant disorder, 90% of cases apparently represent new mutations. Studies have indicated that achondroplasia is caused by a mutation of the gene for fibroblast growth factor receptor 3 (FGFR3), located on the short arm of chromosome 4.[336] The overwhelming majority of cases identified represent mutations at a "hot spot" at nucleotide 1138 of FGFR3, and because these mutations create new recognition sites for restriction enzymes, it is easy to test for the mutation.

Infants homozygous for this condition have severe disease, typically dying in infancy of respiratory insufficiency

resulting from the small thorax. Short stature may not be evident until after 2 years of age, although the deviation from the normal growth curve is progressive. Mean adult height in males and females is 131 and 124 cm, respectively. Growth curves for achondroplasia have been developed and are of great value in following patients.[12]

With increasing age, the diagnosis of achondroplasia becomes easier because in addition to short stature these patients have other abnormalities of the skeleton—including megalocephaly, low nasal bridge, lumbar lordosis, short trident hand, and rhizomelia (shortness of the proximal legs and arms). Radiologic abnormalities include small cuboid-shaped vertebral bodies with short pedicles and progressive narrowing of the lumbar interpedicular distance. The iliac wings are small, with narrow sciatic notches. The small foramen magnum may lead to hydrocephalus, and spinal cord or root compression may result from kyphosis, stenosis of the spinal canal, or disk lesions. Acanthosis nigricans may be present.[337]

Hypochondroplasia. Hypochondroplasia has been described as a "milder form" of achondroplasia. However, although the two disorders are both transmitted as autosomal-dominant traits due to mutations in the same gene (*FGFR3*), they have not been reported to occur in the same family. Hypochondroplasia, however, has been shown to result from a different mutation (Asn540Lys) of the FGFR3 gene. The facial features characteristic of achondroplasia are absent, and the short stature and rhizomelia are less pronounced.

Adult heights are typically in the 120- to 150-cm range. As in the case of achondroplasia, short stature may not be evident until after 2 years of age—but stature then deviates progressively from normal. Outward bowing of the legs accompanied by genu varum is frequently observed. Lumbar interpedicular distances diminish between L1 and L5, and as with achondroplasia there may be flaring of the pelvis and narrow sciatic notches.

Chromosomal Abnormalities

Abnormalities of the autosomes and sex chromosomes may be characterized by growth retardation. In general, these disorders are also associated with somatic abnormalities and mental retardation—as in deletion of chromosome 5 or trisomy 18 or 13. Such abnormalities, however, may be subtle—and, for example, the diagnosis of Turner syndrome must be considered in any girl with unexplained short stature. In many cases, the precise cause of growth failure in these chromosomal abnormalities is unclear because the genetic defects do not appear to affect known components of the GH-IGF system. It is presumed, then, that the chromosomal defect influences normal cell proliferation and tissue growth or development or indirectly affects the responsiveness to IGF or to other growth factors yet to be identified.

Down Syndrome. Trisomy 21, or Down syndrome, is probably the most common chromosomal disorder associated with growth retardation, affecting approximately 1 in 600 live births. On average, newborns with Down syndrome have birth weights 500 g below normal and are 2 to 3 cm shorter. Growth failure continues postnatally and is typically associated with delayed skeletal maturation and a poor delayed pubertal growth spurt. Adult heights range from 135 to 170 cm in males and 127 to 158 cm in females.[338] The cause of growth failure in Down syndrome and in other autosomal defects is unknown. Attempts to find underlying hormonal explanations for growth retardation have been unsuccessful, even though hypothyroidism is more common than normal in Down syndrome and should be excluded. It is likely that growth failure in such conditions reflects a generalized biochemical abnormality of the epiphyseal growth plate.

Turner Syndrome. Short stature is the single most common feature of Turner syndrome, occurring more frequently than delayed puberty, cubitus valgus, and webbing of the neck.[339-341] Reviews of large series of Turner syndrome individuals have indicated that short stature occurs in 95% to 100% of girls with a 45,X karyotype. Ranke and colleagues identified several distinct phases of growth in girls with Turner syndrome,[342] including mild IUGR, with mean birth weights and heights of 2,800 g and 48.3 cm, respectively; normal height gain from birth until 3 years of age; progressive decline in height velocity from 3 years of age until approximately 14 years of age, resulting in a gradual and progressive deviation from normal height percentiles; and a prolonged adolescent growth phase characterized by a partial return toward normal height, followed by delayed epiphyseal fusion.

More recent detailed analyses of longitudinal and cross-sectional growth data from several centers have indicated that growth in girls with Turner syndrome is frequently abnormal in infancy and early childhood and that most cases of Turner syndrome diagnosed before adult life have fallen off the normal growth curve by 2 to 3 years of age.[343,344] Investigations of Turner syndrome from the United States and Europe have indicated mean adult heights ranging from 142 to 146.8 cm (lower in Asia). Parental height can influence final height significantly. (see Chapter 16).

The cause of growth failure in Turner syndrome is multifactorial, although the loss of one copy of the homeobox gene—SHOX (short stature homeobox-containing gene)—is the major contributor.[345] The SHOX gene covers a 40-kb region of the pseudoautosomal region of the X chromosome, escapes X inactivation, and is highly expressed in osteogenic tissue. Haploinsufficiency for SHOX has been implicated in the short stature of Turner syndrome, as well as several other somatic features. In addition, SHOX mutations appear responsible for the mesomelic growth retardation and Madelung deformity characteristic of Leri-Weil dyschondrosteosis—and complete absence of SHOX is associated with Langer mesomelic dysplasia. Girls with Turner syndrome are more likely to manifest autoimmune hypothyroidism and inflammatory bowel disease, both of which can also impact on growth.

The majority of patients have normal GH concentrations during childhood. Reports of low GH concentrations in adolescents with Turner syndrome are likely ascribable to low serum concentrations of sex steroids.[346] Nevertheless, GH therapy is capable of accelerating

short-term growth and increasing adult height in both Turner syndrome and SHOX haplo-insufficiency.[230,347-349] Indeed, early initiation of GH therapy at appropriate dosages appears to enable most girls with Turner syndrome to attain heights within the normal adult range.[348,349] Turner syndrome is described in greater detail in Chapter 16. The point is worth repeating, however, that the diagnosis of Turner syndrome should be considered in any phenotypic female with unexplained growth failure.

18q Deletions. Deletion of the long arm of chromosome 18 has an estimated prevalence of 1 in 40,000 live births. In one review of 50 cases, 64% of children (mean age 5.8 years) had heights greater than 2 SD below the mean.[350] Fifteen percent had serum IGF-1 concentrations below 2 SD, and 9% had IGFBP-3 concentrations below 2 SD. Seventy-two percent of children had reduced GH responses to provocative testing, although such testing was not always rigorous.

Intrauterine Growth Retardation

Despite the critical importance of the endocrine system in postnatal growth, normal intrauterine growth is largely independent of fetal pituitary hormones.[351,352] Athyreotic and agonadal infants are of normal length and weight at birth. Based on the normal size of anencephalic fetuses, it has been proposed that even the pituitary is unnecessary for fetal growth.[353,354] Careful documentation of birth size of rats with congenital GHD[355] and of human newborns with mutations of the GH or GHR gene[110] has indicated, however, that fetal pituitary-derived GH makes a small but statistically significant contribution to birth size.

These observations should not be interpreted to mean that the IGF axis is irrelevant in fetal growth. Gene knockout studies have shown that elimination of paracrine/autocrine production of IGF-1 has a major impact on fetal and postnatal growth.[356] A human with an IGF-1 gene deletion had the same growth characteristics as observed in the murine IGF-1 knockout, namely IUGR and postnatal growth failure that was unresponsive to GH administration.[357] Similarly, several reports of IGF-1 receptor defects associated with IUGR and postnatal growth retardation have appeared, and a family with bioinactive IGF-1 has also been reported.[351,352]

Thus, although the fetus may be largely GH independent, the production and activity of IGF-1 are clearly critical for normal intrauterine (as well as postnatal) growth. Human cord lymphocytes have been demonstrated to have increased numbers of IGF receptors[358] and mRNAs because IGF-1 and IGF-2 are abundant in fetal tissues.[359,360] Similarly, the IGFBPs are identifiable in serum and other biologic fluids, although it is of note that the relative serum concentrations of various IGFBPs are different in the fetus and newborn than in the older child or adult.[361] In particular, serum concentrations of IGFBP-3 and acid-labile subunit (ALS)—which together comprise the major serum carriers of IGF peptides in the adult—are much lower in the fetus and newborn.

IUGR is defined on the basis of a birth weight or birth length more than 2 SD below the mean for gestational age. Although the majority of such infants show good catch-up growth during the first few years of life, approximately 15% of such children fail to have sufficient catch-up growth to bring them into the normal height range by 4 years of age.[351,352,362] Whereas several studies have demonstrated that infants with IUGR tend to have low serum concentrations of IGF-1 and IGFBP-3 at birth,[361] it is not entirely clear whether failure of catch-up growth represents the effects of subtle persistent abnormalities of the GH-IGF axis. Barker and colleagues have proposed that in the process of adapting to a limited supply of nutrients in utero IUGR fetuses permanently alter their physiology and metabolism, a reprogramming process that results in physiologic consequences in later life—such as increased risk of coronary artery disease, stroke, hypertension, and type 2 diabetes mellitus.[363,364]

IUGR can arise from intrinsic abnormalities in the fetus, placental insufficiency, or maternal disorders (Box 10-3). Although it is understandable why uterine constraint or twin pregnancies might result in limited fetal growth, the biochemical and cellular basis for abnormal fetal growth in most cases of IUGR is unclear.

BOX 10-3 Etiology of Intrauterine Growth Retardation

Intrinsic Fetal Abnormalities

- Chromosomal disorders
- Syndromes associated with primary growth failure
  - Russell-Silver syndrome
  - Seckel syndrome
  - Noonan syndrome
  - Progeria
  - Cockayne syndrome
  - Bloom syndrome
  - Prader-Willi syndrome
  - Rubinstein-Taybi syndrome
- Congenital infections
- Congenital anomalies
- Primary abnormalities of insulin-like growth factor axis

Placental Abnormalities

- Abnormal implantation of the placenta
- Placental vascular insufficiency; infarction
- Vascular malformations

Maternal Disorders

- Malnutrition
- Constraints on uterine growth
- Vascular disorders
  - Hypertension
  - Toxemia
  - Severe diabetes mellitus
- Uterine malformations
- Drug ingestion
  - Tobacco
  - Alcohol
  - Narcotics

Adapted from Underwood, L. E., & Van Wyk, J. J. (1992). Normal and aberrant growth. In J. D. Wilson, & D. W. Foster (Eds.), Williams textbook of endocrinology *(8th ed.) (p.1110). Philadelphia: WB Saunders.*

It has been proposed that such cases result from reduced cell number or cell size, but the mechanisms for such abnormalities remain to be elucidated. Intrinsic fetal endocrine abnormalities are unlikely explanations for IUGR in most cases.

Congenital thyroid or GH deficiencies are typically characterized by near-normal birth size. Recently recognized human mutations in IGF-1 and IGF-1 receptors are associated with IUGR, but serum IGF-1 concentrations in IUGR children are highly variable—indicating that there is a large clinical diversity in this condition. Infants with IUGR frequently exhibit poor postnatal growth, particularly when the abnormalities are intrinsic to the fetus. Such conditions have frequently been categorized as "primordial growth failure."

Russell-Silver Syndrome (RSS). This condition was independently described by Russell,[365] and later by Silver and associates, in the early 1950s. Although this syndrome probably represents a heterogeneous group of patients, the "common" findings include IUGR, postnatal growth failure, congenital hemihypertrophy, and small triangular facies. Because no genetic or biochemical basis for this disorder has been identified until recently, Russell-Silver syndrome was often used improperly as a designation for IUGR of unknown cause. Other common nonspecific findings include clinodactyly, precocious puberty, delayed closure of the fontanelles, and delayed bone age. A genetic basis to RSS has now been described. Maternal uniparental disomy for chromosome 7 (mUPD7) is found in 5% to 10% of patients with RSS. More commonly, epigenetic changes in the form of DNA hypomethylation at the telomeric imprinting control region (ICR1) on chromosome 11p15, involving the *H19* and *IGF2* genes, have been identified in up to 60% of cases of RSS. These changes result in relaxation of imprinting and biallelic expression of *H19* and down-regulation of *IGF-2*.[366] Attempts to relate genotype to phenotype suggest that prominent forehead, relative macrocephaly, body asymmetry, and a low body mass index (BMI) were significantly associated with ICR hypomethylation.[367] Bruce and colleagues[368] identified hypomethylation of H19 ICR in 62% of a cohort of RSS patients and found that these patients manifested a more severe phenotype than those with maternal UPD7. Additionally, the degree of hypomethylation correlated with the phenotype; the most severe degree of hypomethylation was associated with the asymmetry, skeletal, and urogenital abnormalities. In another study by Binder and coworkers, patients with hypomethylation of 11p15, but not other causes of RSS or SGA, showed increased IGF-1- and IGFBP-3 concentrations, suggesting that there may be counterregulation by IGF-1 or resistance to some actions of IGF-1.[369]

Maternally inherited mutations in *CDKN1C* (also known as *P57KIP2*) have been implicated in the etiology of IMAGe syndrome, characterized by IUGR, metaphyseal dysplasia, adrenal hypoplasia congenita, and genital abnormalities. *CDKN1C* is an imprinted gene that is maternally expressed, and the protein inhibits cell cycle progression. Loss of function alterations in the gene have previously been associated with Beckwith-Wiedemann syndrome. In contrast, mutations associated with IMAGe syndrome cause gain in function.[370]

Seckel Syndrome. Although originally described by Mann and Russell in 1959,[371] this condition is most commonly termed *Seckel syndrome* or *Seckel birdheaded dwarfism*.[372] A genetically heterogeneous autosomal-recessive condition, this syndrome is caused by mutations in *ATR*, *RBBP8*, *CENPJ*, *CEP152*, and *CEP63*, Seckel syndrome is characterized by IUGR and severe postnatal growth failure combined with microcephaly, prominent nose, and micrognathia. Final height is typically 91.4 to 106.7 cm, with moderate to severe mental retardation.

Noonan Syndrome. Although this condition shares certain phenotypic features with Turner syndrome, the two disorders are clearly distinct.[373] In Noonan syndrome, several genes have been implicated—including KRAS (Kirsten rat sarcoma 2 viral oncogene homolog), *SOS1 (Son of Sevenless 1)*, *RAF1*, *NRAS*, and *BRAF* —but the majority of cases are caused by PTP11 (protein tyrosine phosphatase nonreceptor type 11) mutations. Both males and females may be affected, explaining the misleading names "Turner-like syndrome" and "male Turner syndrome." As in Turner syndrome, patients typically have webbing of the neck, a low posterior hairline, ptosis, cubitus valgus, and malformed ears.

Cardiac abnormalities are, however, primarily right-sided (pulmonary valve)—rather than the left-sided lesions (aorta, aortic valve) characteristic of Turner syndrome. Microphallus and cryptorchidism are common, and puberty is frequently delayed or incomplete. There is an increased risk of malignancies such as leukemia. Mental retardation is observed in approximately 25% to 50% of patients. In a manner similar to Turner syndrome, Noonan syndrome responds to GH therapy—and this treatment has been approved by the U.S. Food and Drug Administration (FDA).

Progeria. The senile appearance characteristic of progeria (Hutchinson-Gilford syndrome) typically appears by 2 years of age.[374] There is a progressive loss of subcutaneous fat, accompanied by alopecia, hypoplasia of the nails, joint limitation, and early onset of atherosclerosis—typically followed by angina, myocardial infarction, hypertension, and congestive heart failure. Skeletal hypoplasia results in severe growth retardation, which typically becomes evident by 6 to 18 months of age. The molecular basis of this syndrome, as well as that of the Cockayne syndrome, is described at www.ncbi.nlm.nih.gov/omim.

Cockayne Syndrome. Cockayne syndrome, like progeria, is characterized by a premature senile appearance.[375] Patients also have retinal degeneration, photosensitivity of the skin, and impaired hearing. Growth failure typically appears at 2 to 4 years of age. Transmission is as an autosomal-recessive disorder.

Microcephalic Osteodysplastic Primordial Dwarfism. This is characterized by severe growth failure, microcephaly,

facial dwarfism, and skeletal abnormalities. The condition is genetically heterogeneous and mutations in genes, including *NU4ATAC*, encoding a small nuclear RNA (snRNA) component of the U12-dependent (minor) spliceosome, and PCNT, encoding pericentrin, have been identified in a proportion of cases.

Prader-Willi Syndrome. Growth failure may be evident at birth but is generally more impressive postnatally. The neonatal period is characterized by hypotonia, and in the male by cryptorchidism and microphallus. With advancing age, hyperphagia and obesity become prominent. Hypogonadism may persist into adult life. The cause of growth failure is unclear. Low serum GH concentrations may reflect the impact of obesity and are not necessarily etiologic. On the other hand, low GH secretion and hypogonadism may reflect subtle defects of hypothalamic-pituitary function—and these patients respond well to GH therapy.[376-378] Blunted cortisol responses to CRH have been reported in some patients.[379] Patients with Prader-Willi syndrome have been found to have deletions of the paternal short arm of chromosome 15, or uniparental disomy of the maternal imprinted region of chromosome 15—a situation equivalent to paternal deletion of that region.

Other Genetic Causes of Short Stature

A variety of other syndromes may be associated with moderate-profound growth failure. These include Bloom syndrome, de Lange syndrome, leprechaunism (mutations of the insulin receptor gene), Ellis-van Creveld syndrome, Aarskog syndrome, Rubinstein-Taybi syndrome, Mulibrey nanism (Perheentupa syndrome), Dubowitz syndrome, and Johanson-Blizzard syndrome. The syndromes discussed in this section are described in greater detail in Online Mendelian Inheritance in Man (OMIM), a National Institutes of Health–supported regularly updated website that publishes information on genetic conditions (www.ncbi.nim.nih.gov/omim).

Placental insufficiency and maternal factors may also contribute to poor fetal growth. Whereas such infants have a better growth potential than do cases of "primordial growth failure," postnatal growth is not always normal. Maternal nutrition is an important contributor to fetal growth, impacting not only the size of the fetus but growth during the first year of life.[380] Fetal growth retardation may also result from alcohol consumption during pregnancy,[381-383] as well as from use of cocaine,[384,385] marijuana,[385] and tobacco.[386] The mechanisms for such drug-induced fetal growth retardation are unclear but probably include uterine vasoconstriction and vascular insufficiency, as well as placental abruption and premature rupture of membranes. Although maternal tobacco use is statistically a major contributor to reduced fetal size, it is unlikely by itself to result in severe IUGR, although it has been shown to impact on the GH-IGF-1 axis.[387]

The implications of IUGR may extend beyond decreased fetal size. In a retrospective study of 47 children evaluated before puberty for growth failure secondary to IUGR, 23 boys had an adult height of 162 cm and 24 girls an adult height of only 148 cm[388] in the United States and Europe. Being SGA and failing to catch up are indications for GH therapy. More recent studies have indicated that small-for-gestational-age infants have an increased risk of hypertension, maturity-onset diabetes mellitus, and cardiovascular disease.[389] It remains unclear, however, whether IUGR is causally related to these disorders or is a symptom of an underlying inborn metabolic disorder.

Regulation of skeletal growth involves multiple factors, including hormones and growth factors, nutrition, general health, and a wide variety of other environmental factors. Even when evaluating hereditary aspects of skeletal growth, it is clear that control of growth in childhood (as well as final height) is polygenic by nature. Numerous genome-wide association studies have been done in an attempt to explain the genetic basis of growth, but to date they explain only 2.9% to 3.7% of the variance in adult height. Nevertheless, a direct impact of familial height on an individual subject's growth is normally evident, and evaluation of a child's growth pattern must be placed in the context of familial growth and stature. As described previously, formulas have been developed for determination of a person's target height based on parental heights—and growth curves that relate a child's height to parental height are available.[390] As a general rule, a child who is growing at a rate that is clearly inconsistent with that of siblings or parents warrants further evaluation.

Many organic diseases characterized by growth retardation are genetically transmitted. This list includes many endocrine causes, such as GHI resulting from mutations of the GHR gene, GH-1 gene mutations and deletions, mutations of the *PROP1* and POU1F1 gene, pseudohypoparathyroidism, and familial thyroid hormone deficiency. Many other nonendocrine diseases characterized by short stature may be genetically transmitted, such as osteochondrodysplasias, dysmorphic syndromes associated with IUGR, diabetes mellitus, metabolic disorders, renal disease, thalassemia, and others. Identifying short stature as genetically transmitted thus does not by itself relieve the physician of responsibility for determining the underlying cause of growth failure.

Secondary Growth Disorders

Malnutrition

Given the worldwide presence of undernutrition, it is not surprising that inadequate caloric or protein intake represents by far the most common cause of growth failure.[391] Marasmus refers to cases with a global deficiency of calories, although often accompanied by protein insufficiency. Kwashiorkor, on the other hand, refers to inadequate protein intake—although it may also be characterized by caloric undernutrition. Frequently, the two conditions overlap.

The impaired growth characteristic of protein-energy malnutrition is frequently characterized by elevated basal or stimulated serum GH concentrations.[392] In generalized malnutrition (marasmus), however, GH concentrations may be normal or even low.[393] In both

conditions, nevertheless, serum IGF-1 concentrations are typically reduced.[394,395] Malnutrition may, consequently, be considered a form of GHI in cases in which serum IGF-1 concentrations are reduced in the presence of normal or elevated GH levels. It has been suggested that elevated serum GH concentrations represent an adaptive response whereby protein is spared by the lipolytic and anti-insulin actions of GH. Reduced serum IGF-1 concentrations may represent a mechanism by which precious calories are shifted from use in growth to survival requirements of the organism. These adaptive mechanisms may be further enacted by changes in serum IGFBPs during periods of malnutrition.[396]

Inadequate caloric or protein intake may also complicate many chronic diseases characterized by growth failure. Anorexia is a common feature of renal failure and inflammatory bowel disease but may also be associated with cyanotic heart disease, congestive heart failure, central nervous system (CNS) disease, and other illnesses. Some of these conditions may, furthermore, be characterized by deficiencies of specific dietary components—such as zinc, iron, and various vitamins necessary for normal growth and development.

Undernutrition may also be voluntary, as is the case with dieting and food fads.[397] Caloric restriction is especially common in girls (such as among gymnasts and ballet dancers) during adolescence, when it may be associated with anxiety concerning obesity. Anorexia nervosa and bulimia represent extremes of "voluntary" caloric deprivation and are commonly associated with impaired growth if undernutrition occurs before epiphyseal fusion. Even later in adolescence, these conditions may be characterized by delayed puberty or menarche and a variety of metabolic alterations.

Chronic Diseases

Malabsorption. Intestinal disorders associated with inadequate absorption of calories or protein are typically associated with growth failure for many of the reasons cited previously.[398-401] It is not uncommon for growth retardation to predate many of the other manifestations of malabsorption or chronic inflammatory bowel disease. Accordingly, such conditions—especially gluten-induced enteropathy (celiac disease) and regional enteritis (Crohn disease)—must be in the differential diagnosis of unexplained growth failure. Serum concentrations of IGF-1 may be reduced,[402] reflecting the malnutrition. It is therefore all the more critical to discriminate these conditions from GHD or related disorders.

Documentation of malabsorption requires demonstration of fecal wasting of calories, especially fecal fat. The diagnosis of celiac disease ultimately requires a biopsy of the small intestine and demonstration of the characteristic flattening of the mucosa. Normalization of jejunal mucosa after gluten withdrawal and reappearance of abnormalities on gluten challenge are necessary to confirm the diagnosis. The use of antigliadin autoantibodies has been disappointing in the diagnosis of celiac disease because of its low specificity, but tissue transglutaminase antibodies are very useful.

On the other hand, whereas some have recommended jejunal biopsy to rule out celiac disease in all cases of unexplained growth failure during the first 5 years of life, this aggressive an approach is not usually necessary.[403] Generally, an alternative would be to reserve biopsies for children with a history of diarrhea or steatorrhea in the first 2 years of life, abnormal D-xylose absorption tests, and positive transglutaminase antibodies.[404] The growth failure characteristic of Crohn's disease probably represents a combination of malabsorption, anorexia, chronic inflammation, inadequacy of trace minerals, and use of glucocorticoids.[405] As stated previously, growth retardation may precede other clinical manifestations such as fever, abdominal pain, and diarrhea. An elevated erythrocyte sedimentation rate is a useful clue, although diagnosis ultimately requires endoscopy and biopsy.

Cardiovascular Disease. Cyanotic heart disease and congestive heart failure may be associated with growth failure.[406,407] Because cardiac defects are usually congenital, many infants have syndromes associated with dysmorphic features and IUGR. Postnatal growth failure is usually attributable to hypoxia and the increased energy demands of a failing heart. These conditions are often accompanied by feeding difficulties that exacerbate the poor growth.

Corrective surgery often results in restoration of normal growth, frequently with a phase of "catch-up" growth. Unfortunately, surgery must on occasion be delayed until the infant has reached an appropriate size—resulting in the conundrum that surgery corrects growth failure but cannot be performed because the infant is too small. In these situations, meticulous attention to caloric support and alleviation of hypoxia and heart failure is necessary to maximize growth before surgery.

Renal Disease. A wide variety of clinical conditions that affect renal function can result in significant growth retardation.[408,409] Uremia, Fanconi syndrome, and renal tubular acidosis can all lead to growth failure before other clinical manifestations become evident. It is probable that renal disease leads to growth retardation through multiple mechanisms, including decreased caloric intake, loss of electrolytes necessary for normal growth, metabolic acidosis, protein wasting, inadequate formation of 1,25-dihydroxycholecalciferol, insulin resistance, chronic anemia, and compromised cardiac function.

Although earlier studies suggested a decrease in serum IGF concentrations in uremia, it is now evident that these erroneous determinations reflected inadequate separation of IGF peptides from IGFBPs before assay.[215] Serum IGF-1 and IGF-2 concentrations are in general within normal limits, but increases in serum IGFBPs (especially IGFBP-1) may lead to inhibition of IGF action. The use of chronic glucocorticoid therapy in the treatment of a variety of nephritic and nephrotic conditions can exacerbate the growth retardation characteristic of renal disease.

The age at onset of renal dysfunction is a factor in the resultant growth failure. Impairment of renal function at an early age typically results in a greater degree of growth

failure, probably owing at least in part to the cumulative effects of growth retardation over many years. Subsequent correction of renal failure does not always allow for full catch-up growth. In a study in which renal transplantation was performed before 15 years of age (with a mean age at onset of hemodialysis of 10.6 years and at initial transplantation of 11.8 years), height SD scores did not significantly improve.[410] In patients with renal disorders, approximately 75% of subjects had adult heights below the third percentile.

Although GH or IGF deficiency does not cause the growth failure of renal disease, GH therapy has proven useful in accelerating skeletal growth. It is likely that such treatment increases the molar ratio of IGF peptides to IGFBPs, potentially overriding the inhibitory actions of IGFBPs.

Hematologic Disorders. Chronic anemias, such as sickle cell disease, are characterized by growth failure.[411-413] In these disorders, the causes of growth retardation probably include impaired oxygen delivery to tissues, increased work of the cardiovascular system, energy demands of increased hematopoiesis, and impaired nutrition. Thalassemia, in addition to the consequences of chronic anemia, can also be characterized by endocrine deficiencies resulting from chronic transfusions and accompanying hemosiderosis.[414,415] Despite vigorous efforts to maintain hemoglobin near normal and to employ chelation therapy, growth failure has remained a common feature of thalassemia—especially in adolescents. It is likely that impaired IGF-1 synthesis,[416,417] hypothyroidism, gonadal failure, and hypogonadotropic hypogonadism—combined with chronic anemia—all contribute to growth failure.

Diabetes Mellitus. Growth failure can be observed in children whose diabetes is under chronically poor control.[94] The so-called Mauriac syndrome[418] describes children with diabetes mellitus, severe growth failure, and hepatomegaly resulting from excess hepatic glycogen deposition. This type of striking growth retardation is unusual in diabetes, and in general growth failure is modest. As with other chronic diseases, growth retardation probably represents a combination of pathophysiologic processes—such as calorie wasting from hyperglycemia or malabsorption secondary to celiac sprue, chronic acidosis, increased glucocorticoid production, hypothyroidism, and delayed puberty. Modern treatment modalities, when available and applied, have markedly reduced the prevalence of delayed puberty and poor growth in children with diabetes mellitus.

Because IGFBP-1 is normally suppressed by insulin, chronic hypoinsulinemia results in elevated serum IGFBP-1 concentrations—which may inhibit IGF action. In addition, insulin regulates the expression of the GHR—and hypoinsulinemia commonly leads to low IGF-1 levels through this mechanism.[419] Nevertheless, the correlation between glycemic control and skeletal growth is surprisingly unreliable—and many children with apparently marginal control appear to grow well.[420] One can only surmise that such patients are able to attain normal intracellular nutrition despite seeming hypoinsulinemia. It is likely, however, that progress in improving glycemic control in diabetes will improve growth in these children.

Inborn Errors of Metabolism. Inborn errors of protein, carbohydrate, and lipid metabolism are often accompanied by growth failure—which can be pronounced. Glycogen storage disease, the mucopolysaccharidoses, glycoproteinoses, and mucolipidoses may all be characterized by poor growth. Many inborn metabolic disorders are also associated with significant skeletal dysplasia.

Pulmonary Disease. Cystic fibrosis is the classic example of growth failure associated with pulmonary disease, although poor growth undoubtedly represents the combined effects of pulmonary and pancreatic dysfunction.[238] The Cystic Fibrosis Foundation reports that 18% of patients with cystic fibrosis fall below the 5th percentile in height, and 23% fall below the 5th percentile in weight. In addition, the appearance of diabetes, the use of steroids, and the presence of frequent infections all contribute to the poor growth cystic fibrosis. Any condition associated with chronic hypoxemia may result in growth retardation. In children with chronic asthma, the long-term use of glucocorticoids undoubtedly contributes significantly to growth failure. Children with asthma often have associated growth delay with catch-up during puberty.

Chronic Infection. In many developing countries, chronic infestation with intestinal and systemic parasites (such as schistosomiasis, hookworm, and roundworm) contributes to nutritional debilitation and growth failure.[421]

Endocrine Disorders

Hypothyroidism. Many of the clinical features characteristic of adult myxedema are lacking in pediatric patients with acquired hypothyroidism. The most common and prominent manifestation of chronic acquired hypothyroidism is growth failure, which may be profound.[422] Postnatal growth retardation may also be observed in the infant with congenital hypothyroidism, but the development of newborn screening programs for hypothyroidism have generally resulted in prompt diagnosis and treatment of such patients. In acquired hypothyroidism, growth retardation may take several years to become clinically evident. However, once present growth failure is typically severe and progressive.

Rivkees and associates[422] have reported a mean 4.2-year delay between documentation of growth deceleration and the diagnosis of hypothyroidism. At diagnosis, girls were 4.04 ± 0.5 SD and boys 3.15 ± 0.4S D below the mean heights for age, respectively. (This is one of several situations in which the diagnosis of short stature is more delayed in girls than in boys.) Although chronic hypothyroidism is generally characterized by delayed puberty, precocious puberty and even premature menarche can occur in hypothyroid children—an entity called Van Wyk–Grumbach syndrome. However, in males with this clinical presentation, the testes may be enlarged with relatively minimal virilization, possibly due

to a predominant effect on the FSH receptor. In some females with severe primary hypothyroidism, large recurrent ovarian cysts may manifest.[423] Skeletal age is usually markedly delayed in both sexes. High serum TSH (with prepubertal LH concentrations) is consistent with Van Wyk–Grumbach syndrome, in which the high TSH may act directly on the FSH receptor to mediate the precocious puberty.

Confirmation of the diagnosis of primary hypothyroidism is usually straightforward. Serum concentrations of T4 are reduced, and TSH concentrations are elevated. The presence of antithyroid antibodies is consistent with a diagnosis of Hashimoto thyroiditis, the most common cause of acquired hypothyroidism in the United States. Isolated secondary and tertiary hypothyroidism, caused by TSH and TRH deficiency (respectively), are very rare causes of acquired hypothyroidism. Mutations in the genes encoding TSHβ or the TRH receptor have been identified in a proportion of cases.

Replacement therapy with levothyroxine is associated with a period of rapid catch-up growth. Despite this gratifying response, however, accelerated growth often does not result in restoration of full growth potential—largely because of the rapid increase in skeletal age during the first 18 months of treatment, often with rapid progression through puberty. In the study of Rivkees and associates,[422] children treated at an initial mean chronologic age of 11 years had adult heights approximately 2 SD below the means for sex. These final heights were significantly lower than midparental heights or initial predicted adult heights based on data of Bayley and Pinneau. The deficit in adult stature correlated significantly with the duration of hypothyroidism before initiation of treatment. Accordingly, it may be appropriate to use lower than usual replacement dosages of levothyroxine or to consider delaying puberty and epiphyseal fusion pharmacologically.

Cushing Syndrome. Glucocorticoid excess has a profound effect on skeletal growth[423,424] whether the cause of Cushing syndrome is hypersecretion of ACTH, a primary adrenal tumor, or glucocorticoid therapy. It is assumed that the effects of glucocorticoids are directly at the epiphysis because GH secretion is typically normal and serum concentrations of IGF peptides and IGFBPs are not generally affected. This is supported by the observation that treatment with GH cannot completely overcome the growth inhibiting effects of excess glucocorticoids. The "toxic" actions of glucocorticoids on the epiphysis often persist at least in part after termination of chronic glucocorticoid excess, and patients frequently do not attain their target heights.[425]

The longer the duration and the greater the intensity of glucocorticoid excess, the less likely the patient will experience complete catch-up growth. It is therefore important to limit exposure to excess glucocorticoids as much as the underlying condition being treated will allow. This may in part be accomplished by the use of alternate-day steroid therapy. The characteristic signs of Cushing syndrome (such as truncal obesity, decreased muscle mass, striae, easy bruising, thin skin, hypertension, and osteoporosis) are well known. Adrenal tumors secreting large amounts of glucocorticoids frequently also produce excess androgens, which may mask the growth inhibitory effects of glucocorticoids, but also advance epiphyseal fusion.

It is also important to note that Cushing syndrome in children may be lacking many of the clinical signs and symptoms associated with the disorder in adults and may present exclusively with growth arrest. On the other hand, Cushing syndrome is an unlikely diagnosis in children presenting with obesity because exogenous obesity is associated with normal or even accelerated skeletal growth—whereas in Cushing syndrome growth deceleration is generally evident by the time other signs appear.

Pseudohypoparathyroidism. This condition is discussed in more detail elsewhere, but it is included here because at time of presentation growth failure is a frequent feature.[426] In its classic form, this condition combines growth failure and characteristic dysmorphic features with hypocalcemia and hyperphosphatemia secondary to end organ resistance to parathyroid hormone (PTH). Children with pseudohypoparathyroidism are short and truncally obese, with short metacarpals, subcutaneous calcifications, round facies, and mental retardation. Resistance to TSH with ensuing mild hypothyroidism may compound the suboptimal growth.

Rickets. Hypovitaminosis D is historically a major cause of abnormal skeletal growth and short stature. Often it is associated with other causes of growth failure, such as malnutrition, prematurity, malabsorption, hepatic disease, and chronic renal failure. When vitamin D deficiency occurs by itself, typically when infants have poor exposure to sunlight and are not being nutritionally supplemented with vitamin D, the characteristic skeletal manifestations of rickets are evident: frontal bossing, craniotabes, rachitic rosary, and bowing of the legs.

Vitamin D–Resistant (Hypophosphatemic) Rickets. This condition results from decreased renal tubular reabsorption of phosphate. Clinical features are generally more severe in males and include short stature and prominent bowing of the legs, but other rachitic signs may be present.[427] The metabolic and skeletal abnormalities cannot be overcome by vitamin D therapy alone, thus the name "vitamin D–resistant rickets." Treatment requires oral phosphate replacement, but such therapy often results in poor calcium absorption from the intestine. The addition of vitamin D, especially 1,25 (OH)2 VitD (calcitriol), to oral phosphate increases intestinal phosphate absorption and prevents hypocalcemia. Preliminary studies with GH therapy have indicated (at least in the short term) an enhancement of skeletal growth.

IGF Deficiency. Thyroid hormone and IGF-1 appear to be the major mediators of skeletal growth. Studies involving targeted disruption of genes for various components of the IGF system have established the critical role of the IGF axis in prenatal and postnatal growth.[428] Given the critical role of the IGFs in both intrauterine and postnatal growth, in 1996 Rosenfeld proposed that a critical factor in the diagnostic evaluation for a child with

growth failure was the identification of "IGF deficiency." Deficiency of IGF-1 could result from hypothalamic dysfunction, pituitary GHD, or primary or secondary GHI. It is not always possible to completely discriminate between hypothalamic and pituitary dysfunction because both organs may be involved in the same pathologic process. In addition, embryonic development of the hypothalamus and pituitary appears to be codependent.[30-34]

A number of factors produced in the developing ventral diencephalon function as molecular signals for initial formation and development of Rathke's pouch. Subsequent differentiation of each of the various anterior pituitary cell types appears to be primarily regulated by a strict temporal and spatial pattern of pituitary transcription factors.

It thus becomes somewhat of a semantic issue as to whether to label some of the molecular defects "hypothalamic" or "pituitary." Nevertheless, some arbitrary classification decisions have been made. Table 10-3 presents our current classification of molecular defects of the GH-IGF axis, and sites of established and hypothetical defects are shown in Figure 10-22. Interestingly, many of the "hypothetical" molecular defects proposed in 1996 have subsequently been identified, such as abnormalities of GH signal transduction, IGF synthesis, IGF transport and IGF receptors. Figure 10-23 provides a "decision tree" for investigation of genetic defects in patients with IGF deficiency. Significant developments are likely in our understanding of these defects so that this classification will require updating and modification.

Hypothalamic Dysfunction. Hypothalamic dysfunction can arise from congenital malformations of the brain or hypothalamus, trauma, infections, sarcoid, tumors, or cranial irradiation. Anencephaly results in a pituitary gland that is small or abnormally formed and frequently ectopic. Holoprosencephaly, resulting from abnormal midline development of the embryonic brain, is also typically associated with hypothalamic insufficiency.[429,430] The clinical spectrum of holoprosencephaly can range from cyclopia to hypertelorism, accompanied by absence of the philtrum or nasal septum and midline clefts of the palate or lip. In these situations, the classic endocrine feature is diabetes insipidus, often accompanied by GH, TSH and ACTH deficiencies.

Debate continues as to whether the incidence of GHD is increased in cases of simple clefts of the lip or palate

TABLE 10-3 **Established Genetic Defects of the GH-IGF Axis Resulting in IGF Deficiency**

Mutant Gene	Inheritance	Phenotype
HPA		Developmental abnormalities
HESX1	AR	Septo-optic dysplasia; variable involvement of pituitary hormones
PROP1	AR	GH, PRL, TSH, LH, FSH deficiencies; variable ACTH deficiency
POU1F1 (Pit1)	AR, AD	GH, PRL deficiency; variable degree of TSH deficiency
RIEG	AD	Rieger syndrome
LHX3	AR	GH, TSH, LH, FSH, prolactin deficiencies
LHX4	AD	GH, TSH, ACTH deficiencies
SOX3	XL	GH deficiency, mental retardation
GLI2	AD	Holoprosencephaly, hypopituitarism
GLI3	AD	Pallister-Hall syndrome, hypopituitarism
Isolated GHD		
GHRHR	AR	IGHD, type IB form of IGHD
GHS-R	AD	GHD and ISS
GH1	AR	Type IA form of IGHD
	AR	Type IB form IGHD
	AD	Type II form of IGHD
	X-linked	Type III form of IGHD; hypogammaglobulinemia
	AD	Bioinactive GH molecule
GHI		
GHR		
Extracellular domain	AR, AD	IGF-I deficiency; decreased or normal GHBP
Transmembrane	AR	IGF-I deficiency; normal or increased GHBP
Intracellular domain	AD	IGF-I deficiency; normal or increased GHBP
IGF		
IGF1 (see also Box 10-4)	AR	IGF-I deficiency; IUGR and postnatal growth failure
STAT 5 b (see also Table 10-5)	AR	IGF-I deficiency, variable immune defect, hyperprolactinemia, chronic pulmonary infections, recurrent eczema
ALS (see also Table 10-6)	AR	IGF-I deficiency; variable postnatal growth failure, delayed puberty

HPA, hypothalamic pituitary; ACTH, adrenocorticotropic hormone (corticotropin); AD, autosomal dominant; AR, autosomal recessive; FSH, follicle-stimulating hormone; GH, growth hormone; GHBP, GH-binding protein; GHRHR, GH-releasing hormone receptor; IGF, insulin-like growth factor; IGHD, isolated GHD; IUGR, intrauterine growth retardation; LH, luteinizing hormone; PRL, prolactin; TSH, thyroid-stimulating hormone; and ALS, acid labile subunit.

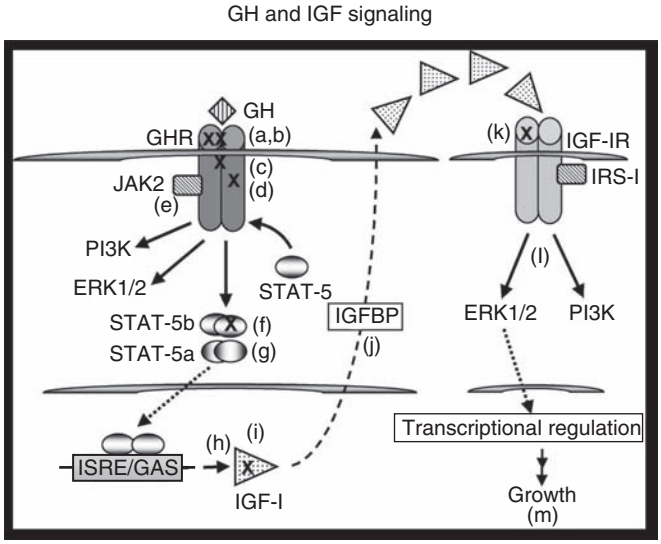

FIGURE 10-22 ■ Schematic diagram of the GH–IGF axis, showing identified and theoretical defects: (*a*) defects of the extracellular domain of the GHR, affecting binding of GH; (*b*) defects in GHR dimerization; (*c*) defects of the transmembrane domain of the GHR; (*d*) defects of the intracellular domain of the GHR; (*e*) defects of JAK2 (theoretical at this time); (*f*) defects of STAT5b; (*g*) defects of STAT5a (theoretical at this time); (*h*) defects of transcriptional regulation of IGF-I (theoretical at this time); (*i*) defects of the IGF-I gene; (*j*) defects of IGFBPs, affecting IGF availability (theoretical at this time); (*k*) defects of the IGF receptor; (*l*) defects of IGF receptor signal transduction (theoretical at this time); and (*m*) defects at the epiphyseal growth plate, potentially affecting IGF action. GH, growth hormone; GHR, growth hormone receptor; JAK2, janus-family tyrosine kinase 2; PI3K, phosphatidylinositol-3 kinase; ERK, extracellular signal-regulated kinase; STAT, signal transducer and activator of transcription; ISRE, interferon-stimulated response element; GAS, interferon-gamma-activated sequences; IGF, insulin-like growth factor; IGFBP, IGF binding proteins; IGF-IR, IGF-I receptor; and IRS, insulin receptor substrate. (Used with permission from Rosenfeld, R. G., & Hwa, V. (2004). New molecular mechanisms of GH resistance. *Eur J Endocrinol, 151*, S11–S15.)

alone.[431,432] Clearly, children with clefts who are growing abnormally certainly require further evaluation, and both GHD and combined pituitary hormone deficiencies (CPHD) are more frequent in this cohort. Septo-optic dysplasia (SOD) is a rare congenital heterogeneous anomaly with a prevalence ranging from 6.3 to 10.9 per 100,000.[433,434] The condition is defined by presence of any two of three features: midline forebrain defects such as absence of the septum pellucidum or corpus callosum, optic nerve hypoplasia (ONH) and hypopituitarism due to hypothalamo-pituitary maldevelopment.[48,435] De Morsier, in 1956, described the postmortem findings of optic nerve hypoplasia (ONH) and agenesis of the septum pellucidum and coined the term "septo-optic dysplasia," also known as De Morsier's syndrome. Approximately 30% of patients with SOD manifest the complete clinical triad, 62% of patients have some degree of hypopituitarism, and 60% have an absent septum pellucidum.[436,437] The condition is equally prevalent in males and females. ONH may be unilateral or bilateral and may be the first presenting feature, with the later onset of endocrine dysfunction. Bilateral ONH is more common (88% as compared with 12% unilateral cases). Additionally, there appears to be little correlation between the size of the optic nerve and its visual function. Neuroradiologic abnormalities are present in from 75% to 80% of patients with ONH.[438,439] Pituitary hypoplasia may manifest as endocrine deficits varying from isolated GH deficiency to panhypopituitarism. There has been some suggestion that abnormalities of the septum pellucidum and hypothalamo-pituitary axis on neuroimaging can predict the severity of endocrine dysfunction.[439] A decrease in growth rate due to GH deficiency is the most common feature, with hypoglycemia and polyuria and polydipsia being less common. Either sexual precocity or failure to develop in puberty may occur. Abnormal hypothalamic neuroanatomy or function and diabetes insipidus may be features. The endocrinopathy may be evolving with a progressive loss of endocrine function over time. The most common endocrinopathy is GH deficiency followed by TSH and ACTH deficiency. Gonadotropin secretion may be retained in the face of other pituitary hormone deficiencies.[440] Neurologic deficit is common, but not invariably so, and in one study it was documented in 15 of 24 children with a severe degree of optic nerve hypoplasia. The deficit ranged from global retardation to focal deficits such as epilepsy or hemiparesis. Other neuroanatomic abnormalities include cavum septum pellucidum, cerebellar hypoplasia, schizencephaly, and aplasia of the fornix. An association between SOD and other congenital anomalies such as digital abnormalities is not uncommon.[441]

The etiology of SOD has remained largely unknown until recently. Both genetic and environmental factors have been implicated in the etiology of the condition.[442,443] Environmental agents such as viral infections, vascular or degenerative changes, and exposure to alcohol or drugs have been implicated in the etiology of SOD. The condition presents more commonly in children born to younger mothers and clusters in geographic areas with a high frequency of teenage pregnancies.[433,443] As forebrain and pituitary development occur as early as 3 to 6 weeks gestation in the human embryo, and are closely linked, any insult at this critical stage of development could account for the features of SOD. First indications of a genetic etiology came from the targeted mutagenesis of the transcription factor Hesx1 in mice. Hesx1 is a paired-like homeodomain transcriptional repressor that is expressed in the prospective cephalic region earlier during gastrulation. Later, it can be found throughout the prosencephalon—but it is restricted ultimately to Rathke's pouch. Its expression is switched off at E13.5 in the mouse.[444,445] The phenotype of these mice included a reduction in the prospective forebrain tissue, absence of developing optic vesicles, markedly decreased head size, and severe microphthalmia reminiscent of the syndrome of SOD in humans. Other abnormalities included absence of the optic cups, the olfactory placodes and Rathke's pouch, reduced telencephalic vesicles, hypothalamic abnormalities, and aberrant morphogenesis of Rathke's pouch. In 5% of null mutants, the phenotype was characterized by complete lack of the pituitary gland. In the majority of mutant mice, they were characterized by formation of multiple oral ectodermal invaginations and hence multiple pituitary glands. In the light of the phenotype demonstrated in *Hesx1* null mutant mice, the human homologue of the gene was screened for mutations in patients with

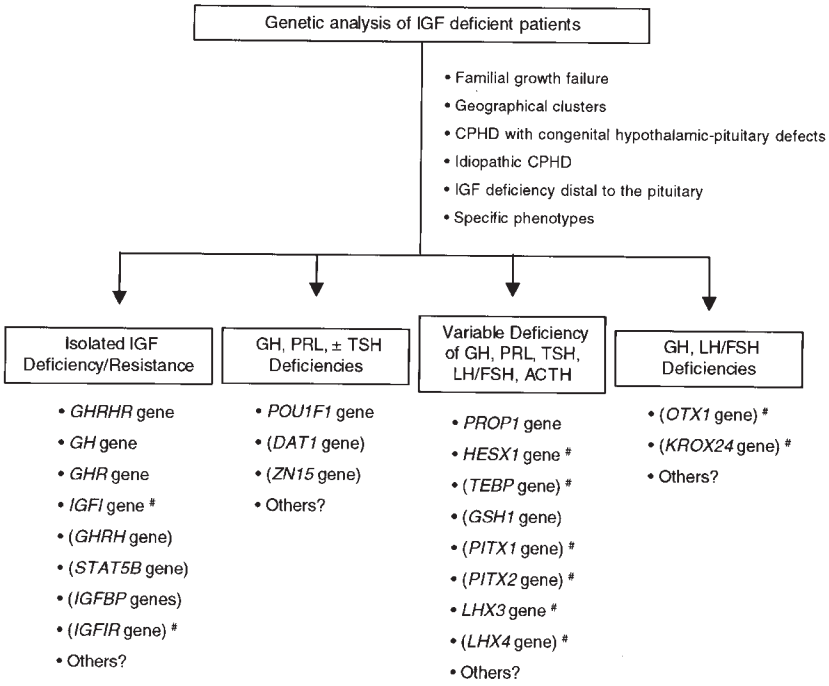

FIGURE 10-23 ■ Decision tree for investigation of genetic defects in patients with insulin-like growth factor (IGF) deficiency. Hypothetical genetic defects are presented in parentheses. Abnormalities in other organs and structures besides the hypothalamus-pituitary-IGF axis are expected to occur as a result of these genetic defects. ACTH, adrenocorticotropic hormone; CPHD, combined pituitary hormone deficiencies; FSH, follicle-stimulating hormone; GH, growth hormone; GHR, growth hormone receptor; GHRHR, GH-releasing hormone receptor; IGFIR,IGF-1 receptor; LH, luteinizing hormone; PRL, prolactin; STAT5, signal transducer and activator of transcription 5; TSH, thyroid-stimulating hormone. (From Lopez-Bermejo, A., Buckway, C. K., & Rosenfeld, R. G. (2000). Genetic defects of the growth hormone–insulin-like growth factor axis. *Trends Endocrinol, 11*, 43.)

SOD. A homozygous missense mutation (Arg160Cys) was found in the homeobox of *HESX1* in two siblings within a highly consanguineous family in which the affected siblings presented with optic nerve hypoplasia, absence of the corpus callosum, and hypoplasia of the anterior pituitary gland with panhypopituitarism.[361] The parents were heterozygous for the mutation and phenotypically normal. Screening of extended members of the family revealed another nine phenotypically normal heterozygotes within this highly consanguineous pedigree, consistent with an autosomal recessive inheritance. The mutation led to a complete loss of DNA binding. Subsequently, *HESX1* mutations have been identified in association with isolated growth hormone deficiency (IGHD) or combined pituitary hormone deficiency (CPHD), in addition to SOD. These patients exhibit variable magnetic resonance imaging (MRI) abnormalities ranging from a structurally normal pituitary to a more severe radiologic phenotype characterized by anterior pituitary hypoplasia or aplasia, an undescended or ectopic posterior pituitary, optic nerve hypoplasia, and agenesis of the corpus callosum.[446] Mutations in *HESX1* can result in hypopituitarism without midline defects or optic nerve anomalies, as the pituitary is believed to be more sensitive to Hesx1 dosage than the developing brain.[447] In addition to recessive mutations, dominant mutations in *HESX1* have been described. Haplotype analysis using markers that closely flanked *HESX1* revealed that such heterozygous *HESX1* mutations are associated with a dominant inheritance that is incompletely penetrant, although a de novo heterozygous insertion mutation has also been described. The phenotypes associated with heterozygous mutations are, on the whole, milder, classically characterized by isolated GHD with an ectopic/undescended posterior pituitary. The overall frequency of *HESX1* mutations in SOD has, however, been low, suggesting that mutations in other known or unknown genes may contribute to this complex disorder.[448,449]

Mutations in orthodenticle homeobox 2 (OTX2) have been identified in patients with SOD. Otx2 is a transcription factor whose role in hypothalamo-pituitary development remains largely unclear. Expression in mice is restricted to developing neural and sensory structures such as the brain, eyes, nose, and ears. Studies show that *Otx2* is expressed in the ventral diencephalon (VD) by E10.5 where it may affect *Fgf8* or *Bmp* induction of RP formation.[450] Its expression at the same time in RP suggests an intrinsic role in RP development as well, which is consistent with its proposed ability to activate *Hesx1* expression. By E12.5, *Otx2* mRNA expression is undetectable in RP (however, it is still detectable in the VD), although the protein persists through to E14.5. By E16.5, Otx2/*Otx2* is absent from both RP and the VD. Homozygous-null mutant mice, which die midgestation, exhibit severe malformations of the forebrain structures as well as the eyes due to impaired gastrulation. Heterozygous mice present with variable eye phenotypes ranging from normal to severe (anophthalmia/microphthalmia) and brain structural abnormalities (holoprosencephaly or anencephaly). Its potential role in pituitary development

was suggested in a report looking at *Prop1*-mutant mice.[450] In these animals, *Otx2* expression in RP persists through to E16.5, which is 4 days after peak expression of *Prop1*. This suggested that *Prop1* may regulate genetic expression of factors that may suppress *Otx2* expression and implies a role for *Otx2* in murine pituitary development. Further evidence of a role in hypothalamo-pituitary development was shown in GnRH-neuron-*Otx2* knockout mice that exhibited gonadotropic hypogonadism.[451] These data are consistent with human *OTX2* phenotypes, which can encompass highly variable hypopituitary phenotypes (ranging from isolated growth hormone deficiency to panhypopituitarism) and hypogonadotrophic hypogonadism, both of which are most commonly detected in association with severe eye abnormalities including anophthalmia or microphthalmia. To date, *OTX2* mutations, of which 20 have been described, account for 2% to 3% of severe eye abnormalities. Two complete deletions and 12 heterozygous intragenic mutations (of which 6 have been shown to be associated with functional compromise) have been associated with severe ocular and CNS phenotypes including developmental delay and seizures. The association of deletions of 14q22-23 (which also includes the candidate genes *BMP4*, *RTN1*, *SIX6*, *SIX1*, and *SIX4*) with anophthalmia, hypopituitarism, and ear abnormalities[452] originally led to the investigation of the role of OTX2 in hypothalamo-pituitary development. Subsequently, mutations were identified in association with eye defects (e.g., bilateral anophthalmia), CNS defects such as developmental delay and seizures, and variable hypopituitarism associated with a small anterior pituitary gland, an ectopic/undescended posterior pituitary, and an absent infundibulum.[453-455] Because Otx2 appears to regulate the expression of *Hesx1*, it is possible that mutations in the protein compromise the development of the forebrain and ventral diencephalon, in addition to any direct effect within RP.

The sonic hedgehog (SHH) signaling pathway has been implicated in more complex disorders of pituitary development. Mutations within SHH are associated with holoprosencephaly.[456] Three members of the Gli gene family of transcription factors have been implicated in the mediation of SHH signals, and heterozygous loss-of-function mutations within *GLI2* have been identified in patients with holoprosencephaly.[457] Phenotypic penetrance was variable, with the disorder transmitted through a parent carrying the mutation but showing no obvious phenotype in one family. In all affected individuals with *GLI2* mutations, pituitary gland function was abnormal, accompanied by variable craniofacial abnormalities. Other features included postaxial polydactyly, single nares, single central incisor, and partial agenesis of the corpus callosum. Mutations in *GLI2* have been associated with hypopituitarism in the absence of any midline defects.[458]

SOX2 and SOX3 are members of the SOX (SRY-related high mobility group [HMG] box) family of transcription factors and are early markers of progenitor cells; their expression is down-regulated as cells differentiate. Strong *SOX2* expression is detected within RP in human embryos (4.5 to 9 weeks of development), which is maintained throughout anterior pituitary development as well as in the overlying diencephalon. However, there is no *SOX2* expression in the infundibulum or posterior pituitary. Initially *SOX2* mutations had been associated with bilateral anophthalmia, severe microphthalmia, learning difficulties, esophageal atresia, and genital abnormalities. However, further phenotypic characterization has revealed the presence of anterior pituitary hypoplasia, hypogonadotrophic hypogonadism, and variable GHD, often with accompanying phenotypes such as hippocampal abnormalities, corpus callosum agenesis, esophageal atresia, hypothalamic hamartoma, and sensorineural hearing loss.[459,460] Although in the majority of patients the MRI reveals a small anterior pituitary, in occasional cases, the pituitary is enlarged and remains so for years.[461]

The definitive Rathke's pouch comprises proliferative progenitors that will gradually relocate ventrally, away from the lumen as they differentiate. A proliferative zone containing progenitors is maintained in the embryo in a periluminal area and was found to persist in the adult.[49] During pituitary development, SOX2 is expressed in the early ectoderm and maintained throughout the pouch. Its expression is down-regulated as endocrine cell differentiation proceeds. Expression is maintained in the prospective progenitor proliferative zone, around the Rathke's pouch lumen, during embryogenesis but also in the mature gland.[49] It is also expressed in the VD.

Normal hypothalamo-pituitary development is critically dependent on the dosage of SOX3; over- or underdosage can lead to hypopituitarism or infundibular hypoplasia. *Sox3* null mutant mice have a variable phenotype showing poor growth, craniofacial defects, and variable endocrine deficits. In humans, *SOX3* duplications or mutations are associated with variable phenotypes including either IGHD or panhypopituitarism. There is variable developmental delay, and MRI usually reveals a small anterior pituitary, an ectopic/undescended posterior pituitary, and dysgenesis of the corpus callosum.[462,463] A *SOX3* variant that leads to a deletion within a polyalanine tract has been associated with hypopituitarism in a heterozygous female patient; the variant has been shown to be associated with a gain in function as opposed to the previously described polyalanine expansions that led to loss of function.[464]

Molecular Defects of GHRH or the GHRH Receptor. No cases of mutations of the GHRH gene in humans have been identified,[465] a somewhat surprising observation, and the GHRH gene must still be considered a candidate gene for familial forms of isolated GHD. Abnormalities of the gene for the GHRH receptor (GHRHR), on the other hand, have been found in number of pedigrees.[466-469] The GHRH receptor consists of a 423-amino-acid peptide, which contains an N-terminal extracellular domain, seven transmembrane domains, and an intracellular C-terminal domain. *GHRHR* is a 13-exon gene located on chromosome 7p14, and its expression requires the presence of the pituitary-specific transcription factor 1 (Pou1F1). The implication of growth-hormone-releasing hormone receptor in the etiology of isolated growth hormone deficiency stemmed from observations in a spontaneously occurring dwarf mouse model (termed the "*little* mouse") that has a homozygous missense mutation (Asp60Gly) in

the extracellular domain of the receptor gene. Although the development of the anterior pituitary is not affected in the *little* mouse, it shows severe anterior pituitary hypoplasia, with an almost 10-fold decrease in the number of somatotrophs and pituitary growth hormone content. In 1996, Wajnrajch and colleagues reported on two patients of a consanguineous pedigree who had severe isolated growth hormone deficiency resulting from a homozygous mutation in the *GHRHR* that caused premature termination of translation (Glu72X, where X represents a stop codon after amino acid 72); this would result in a truncated protein without transmembrane and intracellular domains.[466] An apparently identical mutation has been identified in a family from Sri Lanka[468] and in 17 members of an inbred kindred in Sindh (Pakistan).[467] Since then, homozygous or compound heterozygous mutations have been reported in *GHRHR* (missense, nonsense, splice site, deletions or regulatory mutations), leading to type IB isolated growth hormone deficiency. The largest kindred with a mutation of GHRHR has been identified in Brazil.[469] A donor splice mutation in position 1 of exon 1 results in a severely truncated GHRHR protein.

Missense mutations seem to predominantly affect ligand binding, but not cell surface expression of the receptor[470] whereas nonsense and splice site mutations result in truncated, nonfunctioning receptor products.

GHRHR mutations are identified in about 10% of patients with familial recessive isolated growth hormone deficiency,[471] and in about 3% of a selected cohort of patients with isolated growth hormone deficiency.[472] Patients are of consanguineous pedigrees or from certain ethnic backgrounds, such as from the Indian subcontinent and Brazil. Nevertheless, compound heterozygous *GHRHR* mutations have been described in patients from nonconsanguineous families. Children with mutations in *GHRHR* have severe growth hormone deficiency and short stature, but midfacial hypoplasia, neonatal hypoglycemia, and microphallus, as found in those with recessive *GH1* mutations, are rare. The anterior pituitary may rarely be normal; in the majority, it is hypoplastic. The posterior pituitary and the pituitary stalk are within the normal range.

Trauma of the Brain or Hypothalamus. Traumatic brain injury (TBI) has been recognized as a cause of acquired hypopituitarism in a number of adult studies. Data on pediatric patients are still sporadic, but there is a growing awareness that hypopituitarism after TBI is underdiagnosed with possible negative effects on growth and development.[473] Although the pituitary gland is protected within the sella turcica, the rich vascular network of the hypothalamus and pituitary and the structure of the pituitary stalk make it vulnerable to the effects of traumatic brain injury. The hypothalamus and pituitary have a complex vascular supply consisting of long hypophyseal vessels and a rich network of portal capillaries that surround the pituitary and infundibulum. The pathophysiology of hypopituitarism related to TBI is not clearly defined, but it is thought that it is the result of direct trauma or of vascular injury resulting in ischemia and infarction.[474,475] This is supported by the anatomic findings of autopsies following head trauma, which include anterior lobe necrosis, pituitary fibrosis, hemorrhage, infarction, or necrosis of the pituitary stalk.[476]

It is of note that the peripheral layer of anterior pituitary cells, under the capsule, receives arterial blood from the capsule and not from the system of portal veins, and this may explain why these cells and those in a small area adjacent to the posterior lobe are the only surviving cells in cases of pure anterior lobe necrosis.[477] Somatotrope cells are located in the wings of the pituitary gland, their vascular supply comes from portal vessels, and they are vulnerable to the disruption of blood supply after head injury. On the other hand, ACTH and TSH secreting cells are located in the medial portion of the pituitary and receive blood supply from portal vessels and the anterior pituitary artery. This may explain why GHD is the most common deficiency seen after TBI.[478] Hormone deficiencies may be identified in the first days to weeks post trauma (acute phase) or may develop over time (late effect). As there is overlap between the symptoms and signs of hypopituitarism and those of neurologic-psychological sequelae of TBI, it is possible that late evolving or partial deficiencies can remain undiagnosed for a long period (in different studies the time to diagnosis ranges from 1 to 40 years).

In the acute phase alterations in endocrine function may reflect an adaptive response to acute illness. The clinically significant alterations involve mainly the regulation of fluid and electrolyte balance (diabetes insipidus, syndrome of inappropriate antidiuretic hormone secretion [SIADH], cerebral salt wasting) and the hypothalamo-pituitary adrenal axis. Most of the pituitary hormone changes observed in the acute phase are transient, and their development cannot predict the development of permanent hypopituitarism.[479] It has been suggested that trauma severity may be the only predictor of permanent hypopituitarism,[480] although not all studies have arrived at this conclusion. It would appear that the majority of patients show a degree of pituitary hormone dysfunction in the first days after TBI (53% to 76%); there is, however, wide variation in the reported hormone responses, which reflects the differences in patient selection and time of testing.[481] All anterior pituitary hormones can be affected. Pituitary hormone deficiencies present in the acute phase are usually transient, but they may persist or appear and evolve over time. In adults, the incidence of permanent hypopituitarism ranges between 23% and 69% depending on the study. The growth hormone axis is the most frequently affected (10% to 33%), followed by the gonadal (8% to 23%), adrenal (5% to 23%), and thyroid (2% to 22%) axes. The prevalence of permanent DI varies between 0% and 6%.[482-485]

There have been only sporadic reports of hypopituitarism following TBI in children, but prospective studies designed to address the problem in the pediatric and adolescent population are in progress. The incidence of hypopituitarism is reported to range from 10% to 60%, and although this is lower in children as compared with adults, it is not uncommon.[486-488] In general, the long-term outcome of TBI seems to be more favorable in children. Growth hormone deficiency appears to be the

main endocrine manifestation, followed by gonadotropin deficiency. GHD can present as growth failure, whereas delayed or arrested puberty and secondary amenorrhea may present in adolescents and in patients in the transition phase. Hypopituitarism may contribute to the lack of energy, fatigability, and reduced bone mineral density that can occur after severe head trauma.[489] In a number of case reports, central precocious puberty has also been described in association with head injury presenting 0.4 to 1.6 years after the event.[490] Patients with hypopituitarism after head injury may have no clinical signs and symptoms suggestive of this disorder, and prompt diagnosis requires a high degree of suspicion. A consensus guideline on the screening of patients post TBI suggests that all patients who had TBI, regardless of its severity, should undergo baseline endocrine evaluation 3 and 12 months after the event or discharge from hospital.[491] For children and adolescents, an algorithm for endocrine assessment and follow-up has also been suggested.[473] However, one study reported that permanent hypopituitarism is uncommon after severe brain injury in young children when stringent clinical criteria for pituitary insufficiency are used. Routine testing of pituitary function, as suggested for adults, may not be necessary in children and will lead to a high number of abnormal test results.

Perinatal trauma to the brain, hypothalamus, pituitary stalk, or anterior pituitary may result in isolated GHD or in multiple deficiencies of the anterior pituitary, as may child abuse.[492,493] Many published series of patients with GHD indicate an increased incidence of birth trauma, such as breech deliveries, extensive use of forceps, prolonged labor, or abrupt delivery.[493] Debate continues as to whether GHD is the consequence of difficult delivery or merely reflects the perinatal consequences of fetal pituitary insufficiency.

Inflammation of the Brain or Hypothalamus. Inflammation of the brain (resulting from bacterial, viral, or fungal infections) may result in hypothalamic/pituitary insufficiency.[494,495] Hypothalamo-pituitary dysfunction has been reported after infectious diseases of the central nervous system (i.e., meningitis or encephalitis), with most cases being reported as isolated case reports. Despite the bias in the selection of cases, one can assume that the incidence of endocrine deficiencies depends on the virulence of the infectious organism, the severity and localization of the disease, and the immune status of the host. In a study of 19 adult patients who were investigated 10 to 56 months following CNS infection, 21% had ACTH deficiency and 11% had gonadotropin deficiency, whereas no GHD or DI was reported.[496] Hypopituitarism has been reported following infection by a variety of agents, including group B streptococcus, *Haemophilus influenza*, and *Mycobacterium tuberculosis*. The hypothalamus or pituitary may also be involved in sarcoidosis.[497] Sarcoidosis is a multisystem granulomatous disease of unknown etiology that clinically affects the central nervous system in 5% to 10% of cases.[498] The effects of sarcoidosis on the hypothalamo-pituitary axis are the result of infiltration by granulomatous tissue: on MR imaging the lesion may infiltrate the hypothalamus and pituitary, enhances with gadolinium, and there is thickening of the pituitary stalk. The most frequently reported endocrine abnormality is diabetes insipidus, reported in 25% to 50% of patients with neurosarcoidosis.[499,500] This is followed by hyperprolactinemia, although anterior pituitary dysfunction with hypogonadism has also been reported.[501] Sarcoidosis of the nervous system has a poor prognosis but long-term remissions have been reported with high-dose intravenous pulse methyl-prednisolone therapy. Hormonal defects of less than 1-year duration may respond to steroid treatment, but longer-standing deficits usually persist.[502]

Hypophysitis is an inflammation of the pituitary gland that can be either primary or secondary resulting from infection, systemic disease, or irritation from adjacent lesions. This inflammatory process mimics, clinically and radiologically, tumors of the pituitary area. There are three histologic types of primary hypophysitis: lymphocytic, granulomatous, and xanthomatous. Lymphocytic hypophysitis is the most common type; it involves the anterior pituitary and may infiltrate the infundibulum and posterior lobe. Lymphocytic hypophysitis occurs mainly in young women and is associated with pregnancy or the presence of autoimmune diseases including Hashimoto's thyroiditis, Graves' disease, type I diabetes, and SLE.[503] There are rare case reports of hypophysitis in children and adolescents, and in most cases diagnosis has been made only after biopsy and histologic examination. In many cases, hypophysitis presented with DI and hypopituitarism and preceded the diagnosis of an intracranial tumor, such as germinoma.[504-506] In other reports, it presented with diabetes insipidus and hypogonadotropic hypogonadism,[507] or in association with common variable immunodeficiency.[508] Once the diagnosis is established, management is generally conservative, unless there are signs of increased intracranial pressure or optic nerve compression.

Langerhans cell histiocytosis (LCH) is characterized by clonal proliferation and an accumulation of abnormal dendritic cells that can affect either a single site or many systems causing multiorgan dysfunction.[509] In children, the median age of diagnosis ranges between 1.8 and 3.4 years.[510,511] LCH infiltrates the hypothalamo-pituitary area in 15% to 35% of patients with subsequent development of at least one pituitary hormone deficiency.[512-514] In a multicenter French national study of 589 pediatric patients with LCH, 145 patients (25%) had pituitary dysfunction. In 60 patients, pituitary involvement was already present at the time of diagnosis and in 20 of them it was the first manifestation of the disease. Patients at high risk of pituitary involvement seem to be those with multisystem disease involving skull and facial bones, mastoid, sinuses, and mucous membranes (i.e. gums, ear, nose, and throat region). Furthermore, compared to patients without pituitary involvement, patients with pituitary involvement have a higher rate of relapse (10% at 5 years versus 4.8% at 5 years) and a higher incidence of neurodegenerative LCH.[515]

Diabetes insipidus is the most frequently reported permanent consequence of LCH and the most common endocrinopathy; almost all patients with pituitary involvement have DI. Diabetes insipidus usually presents

early in the course of the disease, within the first 3 to 5 years, and occasionally may precede the diagnosis of LCH. Children with LCH and DI may also have anterior pituitary hormone deficiencies, with most deficits developing in the 6 years following the diagnosis of DI. The second most common endocrinopathy is growth hormone deficiency, which occurs in 14% of all patients with LCH and in more than 40% of patients who have pituitary involvement.[513,514] In the majority of patients, GHD is associated with DI, with a median interval of 2.9 to 3.5 years between the diagnosis of DI and development of GHD.[516,517] Isolated GHD, or the association of GHD with other anterior pituitary hormone deficiencies, occurs less commonly.

Pituitary MRI findings in patients with LCH include thickening of the pituitary stalk, suggestive of the infiltrative process, enhancing changes in the pituitary gland and hypothalamus, and absence of the bright signal of the posterior pituitary in T1-weighted mages, caused by the loss of the phospholipid rich ADH secretory granules. The latter is an invariable feature of patients who develop DI.[518,519] Although at the time of diagnosis of DI, 75% show a thickened pituitary stalk, only 24% have persistent stalk thickening after 5 years. These changes are variable and do not correlate with treatment or with clinical recovery as DI persists in all cases.[520] The role of MRI in predicting the development of anterior hormone deficiencies is uncertain. It has been reported that patients who will become GHD are more likely to have a smaller anterior pituitary, whereas the size of the stalk and posterior pituitary are not significantly different.

Tumors of the Brain or Hypothalamus. Tumors of the CNS are a major cause of hypothalamic insufficiency.[521] This is especially true for midline brain tumors, such as germinomas, meningiomas, gliomas, colloid cysts of the third ventricle, ependymomas, and gliomas of the optic nerve. Although metastasis from extracranial carcinomas is rarely found in children, hypothalamic insufficiency may result from local extension of craniopharyngeal carcinoma or Hodgkin's disease of the nasopharynx. Pituitary adenomas represent less than 3% of supratentorial tumors in childhood and about 3.5% to 6% of all surgically treated pediatric pituitary tumors. In most cases they are hormonally active, arising from any of the five cell types of the anterior pituitary, and may produce prolactin (prolactinomas, 52%), ACTH leading to Cushing's disease (corticotropinomas 33.3%), GH (somatotropinomas 8%), or, rarely, TSH (thyrotropinomas). Nonfunctioning pituitary adenomas are rare in children (2.7%) compared to adults, where they represent almost 20% of pituitary adenomas. Although the majority of childhood pituitary adenomas are prolactinomas presenting in adolescence, corticotropinomas are the most common tumors in pre pubertal children.[522,523] Pituitary adenomas occur in isolation or may be part of a genetic syndrome such as multiple endocrine neoplasia type 1 (MEN1), McCune-Albright syndrome, or Carney complex. Their pathogenesis is not clear, but there is increasing evidence that dysregulation in hormone receptor signaling, changes in molecules that regulate cell cycle or are important for adhesion to extracellular matrix, as well as changes in growth factors may be implicated.[524] Their clinical presentation results from pituitary hormone hypersecretion or deficiencies, disruption of growth and sexual maturation, and pressure effects. On MRI, pituitary adenomas show slow uptake of gadolinium and appear as hypoenhancing lesions that may displace the pituitary stalk.

Optic Gliomas

Tumors of the optic pathway represent 4% to 6% of all pediatric intracranial tumors and among these the most common are optic gliomas (65%). Most optic gliomas are low-grade lesions with favorable prognosis if treated optimally.[525] Gliomas confined to the optic nerve have a predilection for females (60% to 70%) and are associated with neurofibromatosis type 1 (NF-1) in more than half of cases, whereas 38% are sporadic. Children with sporadic gliomas were more likely to manifest increased intracranial pressure, decreased visual activity and more commonly documented endocrine complications.[526] The most frequent symptoms at presentation are visual defects (diminished vision, optic atrophy, strabismus, nystagmus, proptosis), ataxia and precocious puberty.[527]

Because of their close anatomic relation to the hypothalamus and pituitary, dysregulation of the HP axis is common and is due either to the tumor itself or secondary to treatment. Premature sexual maturation (PSM) is a frequently presenting symptom, whereas the most common defect of postcranial irradiation is GHD.[528]

Cystic Lesions

Cystic lesions in the pituitary area include Rathke's cleft cysts, arachnoidal cysts, and cystic adenomas and craniopharyngiomas. Rathke's cleft cysts are benign cystic remnants of the Rathke's pouch. They are usually small (less than 5 mm), asymptomatic, and are found in almost 20% of routine autopsies.[529] Rathke's cleft cysts consist of well-differentiated columnar or cuboidal epithelial cells, and the content of the cysts varies. Rathke's cleft cysts can grow gradually and become symptomatic, especially if they have suprasellar extension. Symptoms include headache, visual defects, and pituitary dysfunction ranging from increased prolactin to pituitary hormone deficiencies. Differential diagnosis from other cystic lesions in the area is not always easy, as on MRI the cyst fluid shows variable signal intensities and therefore cysts can appear as hypodense or hyperdense. Almost 50% of Rathke's cleft cysts show rim enhancement. Recurrence of the cyst after treatment is rare (2 of 14 patients in one series), and it is recommended that treatment should include both fluid drainage and cyst wall removal in order to avoid relapses.[530]

Arachnoid cysts consist of a collection of CSF-like fluid surrounded by a wall made of arachnoid structures. They are mainly suprasellar, with only rare cases being intrasellar. Suprasellar cysts are usually diagnosed following nonendocrine symptoms such as neurologic deficits, macrocephaly, and visual symptoms. Due to the proximity of the lesion to the hypothalamo-pituitary area, arachnoid cysts may cause central precocious puberty, amenorrhea, and hyperprolactinemia, in addition to thyrotropin,

ACTH, or GH deficiency. Craniopharyngiomas may result in hypothalamic dysfunction and are discussed in greater detail under "Pituitary GH Deficiency."

Irradiation of the Brain or Hypothalamus. Cranial irradiation continues to emerge as an increasing cause of hypothalamic/pituitary dysfunction.[531-534] Irradiation may directly impair hypothalamic and pituitary function, and it is not always easy to discriminate between damage at each of these levels. In addition, thyroidal and gonadal function may also be directly affected if total body irradiation or craniospinal irradiation is administered. The degree of pituitary impairment is related to the dose of radiation received. Low doses typically result in isolated GHD. With higher doses, multiple pituitary hormone deficiencies are observed. Two to 5 years after irradiation, 100% of children receiving more than 3000 cGy over 3 weeks to the hypothalamic-pituitary axis showed subnormal GH responses to insulin-provocative tests.[535]

The degree of pituitary deficiency observed is also directly correlated to the length of time since irradiation. Children who test normally at 1 year post irradiation may still develop pituitary deficiencies at later times. Even when serum GH concentrations after provocative testing are normal, measures of spontaneous GH secretion may indicate impairment. As little as 1800 cGy has been shown to affect spontaneous GH secretion in pubertal children.

Decreased GH secretion may be further complicated by the impact of irradiation on spinal growth, which can result in short stature and skeletal disproportion. Surprisingly, cranial irradiation can also result in precocious puberty, now believed to be the result of inhibition of the normal restraint of puberty imparted by the product of the MKRN3 gene—the gene encoding makorin ring-finger protein 3, which is a paternally expressed, imprinted gene located in the Prader-Willi syndrome critical region (chromosome 15q11-q13).[536] This earlier occurrence of puberty has the consequence that epiphyseal fusion occurs at an earlier age than is ideal from the perspective of maximizing growth. Gonadotropin-releasing hormone (GnRH) analogs may be necessary to delay pubertal progression. The endocrinologist observing the child who has received craniospinal irradiation must weigh these three factors: evolving hypopituitarism, decreased spinal growth potential, and early puberty and premature epiphyseal fusion. Care must be taken to maximize the growth potential of the patient without causing skeletal disproportion and without delaying puberty excessively or allowing growth to terminate too early.

Pituitary GH Deficiency. As discussed previously, many of the disease processes that affect hypothalamic regulation of GH secretion also impact pituitary function. Given current diagnostic limitations, it is not in fact always possible to completely discriminate between hypothalamic and pituitary dysfunction. Furthermore, it is likely that many cases of so-called idiopathic GHD will be found to have a molecular basis for the disorder. Indeed, there has been an explosion of information concerning genes critically involved in pituitary somatotrope differentiation and function (Tables 10-2 and 10-3).

At this time, however, a clear cause for pituitary GHD is often not identified—hence the term *idiopathic*. An incidence of pituitary GHD of 1:60,000 live births was reported from the United Kingdom.[537] A more recent survey of 48,000 Scottish schoolchildren has indicated an incidence as high as 1:4000,[538] whereas the best estimate available in the United States population is at least 1:3480.[539]

It is likely, however, that childhood GHD is an overdiagnosed condition. In particular, the diagnosis of acquired idiopathic isolated GHD should always be suspect. Although one may argue that destructive or inflammatory lesions of the hypothalamus or pituitary may only affect GH secretion, that isolated GHD caused by a mild mutation/deletion of the GHRH receptor gene or GH gene may appear late, or that combined pituitary hormone deficiency (CPHD) may first present with what appears to be isolated GHD, such circumstances appear to be rare. In the absence of anatomic abnormalities evident on imaging studies or biochemical evidence of CPHD, the diagnosis of acquired isolated idiopathic GHD demands careful and thorough documentation.

Genetic Abnormalities Resulting in Combined Pituitary Hormone Deficiency. Septo-optic dysplasia and its relationship to HESX1 was discussed previously. Recessive mutations in *LHX3* have been identified in 13 patients from eight unrelated consanguineous families, in addition to a single patient who was found to be compound heterozygous for two missense mutations within the gene. These patients usually present with a multiple anterior pituitary hormone deficit, with sparing of ACTH in the majority of cases, although patients with ACTH deficiency have also been described.[540] Pituitary morphology is variable between patients with *LHX3* mutations: most patients have a hypoplastic anterior pituitary with a normal posterior pituitary and midline structures[540-542]; conversely, an enlarged anterior pituitary has also been reported in a patient that was not evident in a previous MRI scan performed 10 years earlier.[541] Additionally, a patient with a hypointense lesion in the anterior pituitary consistent with a microadenoma has also been described.[543]

The majority of patients with *LHX3* mutations reported to date have also exhibited a short rigid cervical spine with limited neck rotation and trunk movement. Again, the skeletal phenotypes can vary, and a single patient with normal neck rotation and no other syndromic features has been reported.[542] Analysis of *LHX3* expression during human development shows a pattern of expression in the developing embryonic pituitary highly similar to that observed in the mouse. Expression is detected within Rathke's pouch at 5 weeks of development and later in the anterior and intermediate region of the pituitary, but not in the posterior lobe. Expression of *LHX3* is also observed in specific regions of the spinal cord corresponding to interneuron and motor neuron populations.[544] The underlying mechanism of the vertebral and skeletal defects in patients with *LHX3* mutations is unclear because expression is not detected in the sclerotome or myotome, the tissues giving rise to the vertebrae and skeletal muscle.[544]

More recently, an additional phenotype of sensorineural deafness has been reported in association with homozygous loss of LHX3.[540] The severity of hearing loss is also highly variable and can range from profound to very mild and may be missed in some cases. A direct role may be implicated here because LHX3 is expressed in specific regions of the inner ear in a pattern highly conserved between humans and mice, and it is likely to have a role in cochlea hair cell development.[540]

To date, four separate reports have described six heterozygous mutations within LHX4, with all patients exhibiting GH deficiency and associated short stature on presentation, again with variable additional endocrine deficits and extrapituitary abnormalities. A heterozygous intronic mutation that abolishes normal splicing of LHX4 was initially reported by Machinis and colleagues[545] in a three-generation family segregating in a dominant and fully penetrant manner. The probands presented with short stature and were found to be GH, TSH, and ACTH deficient, with anterior pituitary hypoplasia, an undescended posterior pituitary, and absent pituitary stalk on MRI. Other affected family members presented with short stature associated with IGHD and a normal posterior pituitary. Additional manifestations included a poorly formed sella turcica and pointed cerebellar tonsils. A second, de novo mutation, producing a p.P366T substitution, was associated with a more severe panhypopituitary phenotype. MRI demonstrated a hypoplastic anterior pituitary, an undescended posterior lobe, a poorly developed sella turcica, and a Chiari malformation. In a screen of 253 patients, Pfaeffle and colleagues[546] identified an additional three heterozygous missense mutations—one occurring between the two LIM domains of the protein (p.R84C) and two within the homeodomain (p.L190R, p.A210P). The p.A210P mutation was identified in two female siblings presenting with short stature and GH deficiency; MRI showed that both had a hypoplastic anterior lobe with cystic lesions but a eutopic posterior pituitary. One sister had a more severe hypopituitary phenotype with additional TSH, ACTH, and gonadotropin deficiencies, whereas the other had only partial TSH deficiency. The mutation was inherited from their father who had short stature and low GH but no evidence of other hormone deficiencies. The p.R84C mutation was identified in a single male patient presenting with short stature and was found to be GH and TSH deficient, later developing gonadotropin deficiency with pubertal failure. The p.L190R mutation was associated with GH, TSH, and ACTH deficiency. Patients with both of the latter mutations had a small anterior pituitary and an undescended posterior pituitary on imaging, with no abnormalities in other regions of the brain. More recently, two brothers have been described with a single base insertion in exon 3 (c.293_294insC) resulting in a frameshift after codon 99. Both siblings presented with GH and TSH deficiencies with pituitary hypoplasia and a poorly developed sella turcica. The youngest brother also had a hypoplastic corpus callosum and an undescended posterior pituitary. Their father, who also harbored the mutation, was GH deficient and had experienced delayed puberty.[547]

The gene PROP1 (standing for prophet of Pit1) is involved in the early determination and differentiation of multiple anterior pituitary cell lineages.[548,549] Abnormalities of PROP1 result in CPHD, characterized by variable degrees of deficiency of GH, prolactin, TSH, follicle-stimulating hormone (FSH), luteinizing hormone, and occasionally ACTH.[549-553]

As a result of the identification of Prop1 as the gene underlying the Ames dwarf phenotype, the first mutations in *PROP1* were identified in human patients with hypopituitarism characterized by GH, TSH, and PRL deficiencies in addition to reduced gonadotrophins and failure to enter spontaneous puberty.[551] Subsequently, more than 26 distinct mutations have been identified in more than 180 patients from over 21 different countries, implicating PROP1 mutations as the most common genetic cause of CPHD accounting for approximately 50% of familial cases,[549-553] although the incidence in sporadic cases is much lower.[554,555] All affected individuals exhibit recessive inheritance, and the majority of mutations identified involve the DNA binding homeodomain, which is highly conserved between human and mouse, showing 91% identity at the nucleotide level.[551,556] The mutations in *PROP1* identified to date include nonsense, missense, frameshift, intronic, and deletion mutations. The majority of the mutations are predicted to result in complete loss of function by ablating DNA binding and transcriptional activation, although some missense mutations retain partial activity.[557,558] By far the most common mutation, accounting for 50% to 72% of all familial PROP1 mutations in multiple unrelated families,[549] is a 2-bp deletion within exon 2 resulting in a frameshift at codon 101 and the introduction of a termination codon at position 109 (often referred to as p.S109X). The deletion occurs within three tandem GA repeats, so the 2 bp deleted cannot be defined; consequently this mutation has been referred to as c.296delGA and c.301_302delAG in different reports. This mutation is likely to represent a mutational hot spot within the gene, rather than a common founder mutation, and combined with the incidence of the c.150delA mutation it accounts for more than 90% of all known PROP1 mutations.

Homozygosity for mutations in *PROP1* is typically associated with a deficit of GH, TSH, PRL, and gonadotrophins, although the time of onset and severity of hormone deficiency varies. Most patients present with early-onset GH deficiency and growth retardation; however, normal growth in early childhood has been reported in a patient who attained normal final height without GH replacement therapy.[559,560] Patients may present with gonadotropin deficiency with the evolution of other hormone deficiencies later in life. TSH deficiency is also highly variable and has been reported as the initial presenting symptom in some cases, whereas other patients show delayed onset. Onset of ACTH deficiency is significantly correlated with increasing age, and most patients exhibit normal ACTH and cortisol levels in early life[561-564]; however, patients as young as 6 years have been described with cortisol deficiency emphasizing the necessity for complete and continued clinical assessment of patients with PROP1 mutations.[565,566]

Although PROP1 has been shown to play a critical role in mouse gonadotrope differentiation, the spectrum of human gonadotropin deficiency is extremely variable in patients with *PROP1* mutations, ranging from early hypogonadism with a micropenis and undescended testes and complete lack of pubertal development to spontaneous, albeit often delayed, onset of puberty with subsequent deficiency of gonadotropins, requiring hormone replacement therapy. Variation in the timing and severity of gonadotropin deficiency could mean that hypogonadism in patients with *PROP1* mutations is acquired and late evolving rather than early congenital, consistent with a role for PROP1 in maintenance or terminal differentiation of gonadotropes rather than initial specification. However, a number of individuals with mutations may have congenital gonadotropin deficiency, given the presence of a micropenis and bilaterally undescended testes at birth.

The pituitary morphology in patients with PROP1 mutations is unpredictable; most cases show a hypoplastic or normal-sized anterior pituitary gland on imaging, with a normal pituitary stalk and posterior lobe, although some reports have documented an enlarged anterior gland.[551,561] Longitudinal analyses of anterior pituitary size over time have revealed that several patients with an enlarged anterior gland at initial scanning in childhood show spontaneous regression and involution, so that MRI in older patients often demonstrates anterior pituitary hypoplasia, although the size of the pituitary can wax and wane during this time.[555] The pituitary enlargement consists of a mass lesion interposed between the anterior and posterior lobes, possibly originating from the intermediate lobe[567] or Rathke's pouch remnant in the cleft, although the underlying mechanism for the mass remains unknown. Evidence from the mouse (discussed previously) suggests that PROP1 regulates the migration of progenitor cells from Rathke's pouch into the developing anterior pituitary, and in the absence of functional PROP1, undifferentiated cells are trapped in the periluminal area resulting in enlargement of the anterior pituitary followed by apoptosis.[568] Such a mechanism would be an attractive explanation for the human imaging findings, but, of course, would be difficult to establish and cannot account for the waxing and waning of the mass. Earlier biopsies of such a mass failed to reveal any definitive histopathology, with no cell types identified,[569] and such material is now likely to prove elusive, as these masses no longer require surgical removal in patients with identified *PROP1* mutations.

The evolving nature of hormone insufficiencies in patients with *PROP1* mutations suggests a progressive decline in the anterior pituitary axis, so such patients require regular monitoring for the development of hormone deficits that may not be apparent on initial presentation. The highly variable nature of the phenotype associated with PROP1 mutations, even between siblings within the same family carrying identical mutations, together with the observation of phenotypic differences in Prop1 mutant mice on different genetic backgrounds again implicate unidentified genetic modifiers playing a role in the severity and onset of disease pathogenesis.

POU1F1 is the human homologue of the mouse gene pit1 and encodes a transcription factor involved in activation of GH and prolactin genes, regulation of the TSH-b promoter, and specification, proliferation, and survival of the corresponding cell lineages.[92,570] Mutations within *POU1F1* (PIT1) were first reported in 1992 by four independent groups[571-575] and are generally associated with GH, PRL, and TSH deficiencies with variable anterior pituitary hypoplasia, consistent with the phenotype of Snell and Jackson dwarf mice, which harbor a point mutation and a genetic rearrangement of *Pit1* respectively. Deficiencies of GH and PRL are generally complete and present early in life, whereas TSH deficiency can be highly variable. The majority of cases present with early TSH deficiency; however, in some cases hypothyroidism occurs later in childhood.[571,576] MRI of patients with *POU1F1* mutations demonstrates a small or normal-sized anterior pituitary gland with a normal posterior pituitary and infundibulum, but with no extrapituitary abnormalities. More than 28 mutations in *POU1F1* have been described to date; 23 of these show recessive inheritance, including a complete gene deletion as well as splice site mutations, whereas 5 are dominant mutations, found in more than 60 patients from several countries. Of these, the amino acid substitution p.R271W is the most frequent having been identified in several unrelated patients from a variety of ethnic backgrounds. The R271W substitution results in production of a protein that remains capable of binding to DNA but acts as a dominant negative inhibitor of transcription.[572]

Studies of *POU1F1* in CPHD patient cohorts suggest that the incidence of mutations in cases of sporadic CPHD is quite low (approximately 3% to 6%), whereas the incidence among familial patients with hypopituitarism is much greater (25%).[576] Overall, screening studies suggest that abnormalities of POU1F1 are less common causes of CPHD than are abnormalities of the PROP1 gene.[549,570]

Haploinsufficiency of the homeobox gene RIEG results in Rieger syndrome, an autosomal-dominant disorder that involves abnormal development of the anterior chamber of the eye, teeth, and umbilicus—with an occasional association with GHD.[577,578] The rieg/pitx2 null mouse has been shown to be characterized by multiple pituitary hormone deficiency (MPHD).

Genetic Abnormalities of GH Production or Secretion Resulting in isolated GHD

It has been reported that up to 30% of patients with isolated GHD have an affected parent or sibling. In addition to the abnormalities of the PROP1 and POU1F1 genes described previously, in which abnormalities of GH secretion are associated with decreased secretion of other anterior pituitary hormones, four Mendelian forms of isolated GHD have been reported[579,580] (see Table 10-3).

Isolated GHD IA results from deletions (6.7, 7, 7.6, and 45 kb deletions have been reported) or mutations of the GH1 gene that totally block GH synthesis or secretion.[581-583] Transmission of isolated GHDIA is autosomal recessive, and patients have profound congenital GHD.

Because GH has never been produced by the patient, even in fetal life, patients are immunologically intolerant of GH and typically develop anti-GH antibodies when treated with pituitary-derived or recombinant DNA–derived GH, although development of growth-attenuating antibodies appears to be less frequent with the newer synthetic GH preparations.

When antibodies prevent a patient from responding to GH, GHDIA can be viewed as a form of GHI and the patient is a candidate for IGF-1 therapy. The less severe form of autosomal-recessive GHD (isolated GHDIB) is likely to also be the result of mutations or rearrangements of the GH1 gene, presumably resulting in a GH molecule that retains some function but is perhaps unstable.[584] Additionally, mutations in the GHRHR also lead to GHD1B. To date, however, most patients with presumed isolated GHDIB have not demonstrated an alteration of the GH1 and GHRHR genes and the cause of their GHD remains unclear. These patients generally respond to GH therapy, and development of clinically significant anti-GH antibodies is unusual.

Isolated GHDII is transmitted as an autosomal dominant. Such patients usually have abnormalities of the GH1 gene that function in a dominant negative manner. The most common causes of this disorder appear to be splice site and intronic mutations that inactivate the 5′-splice donor site of intron 3, resulting in skipping of exon 3 with generation of the 17.5-kDa isoform of growth hormone that exerts a dominant-negative effect on the secretion of the 22-kDa molecule. McGuiness and colleagues demonstrated that transgenic mice that overexpress the 17.5-kDa isoform have a defect in the maturation of the growth hormone-containing secretory vesicles and display anterior pituitary hypoplasia.[572] More important, genetically modified mouse strains that express multiple copies of the exon 3-deleted allele had a more severe phenotype, almost undetectable growth hormone levels and profound pituitary hypoplasia, with loss of somatotrophs and macrophage invasion, compared with mice expressing fewer copies of the allele. Unexpectedly, the most severely affected animals also developed deficiencies in TSH, prolactin, and luteinizing hormone. Thus, the activated macrophages possibly accelerate the loss of somatotrophs, and other cell types may be destroyed as a consequence of a "bystander" effect.[585]

At the cellular level, the 17.5-kDa isoform lacks the protein linker domain and a cysteine residue (Cys53) involved in the formation of a disulfide bond between the first two helices of growth hormone and is, therefore, retained in the endoplasmic reticulum. This retention triggers a misfolded protein response and disrupts the secretory pathway and trafficking of growth hormone and other hormones, including adrenocorticotropic hormone (ACTH). The amount of the 17.5-kDa product has to reach a critical threshold to exert its dose-dependent effects, with increasing amounts leading to reduced cell proliferation and apoptosis of somatotrophs.[586-588]

Exon 3 skipping and the generation of the 17-kDa isoform can also result from mutations other than in the conserved consensus splice sites. The first seven bases of exon 3 are crucial for correct *GH1* splicing as they contain an exonic splice enhancer motif (eSe1, which has the sequence GAAGAAG) that strengthens the use of the weak 3′-splice site upstream of exon 3 and suppresses a downstream cryptic splice site.[589] The first mutation in eSe1 was reported by Moseley and colleagues[590] in the fifth nucleotide of exon 3 (e3 + 5A > G); although this mutation results in an amino acid change from glutamate to glycine (Glu33Gly), its mechanism of action has been shown to occur via its effect on splicing. In vitro transient expression assays demonstrated that, in addition to complete exon skipping, the mutation resulted in the activation of the downstream cryptic splice site at nucleotide 45 of the exon (e3 + 45) causing loss of amino acids 32 to 46 of the growth hormone molecule, which leads to the production of a 20-kDa isoform. The 22-kDa isoform represented only 11% of transcripts, whereas the majority comprised the 17.5-kDa (62%) and 20-kDa (27%) products. In fact, mutations in any of the bases of eSe1 lead to either complete or partial skipping of exon 3, resulting in the generation of both the 17.5-kDa and 20-kDa isoforms at various concentrations (35% to 68% and 20% to 37%, respectively). Exon 3 skipping can also result from disruption of sequences in IvS3 downstream of the consensus splice sites that affect intronic splice enhancers or the branching point site. These findings support the notion that the size of intron 3 is important for the integrity of the splicing mechanism.

Missense mutations that affect growth hormone secretion or action can also cause autosomal dominant isolated growth hormone deficiency. Patients with the Arg183His mutation have impaired release of growth hormone as, at the cellular level, the secretory granules that contain the mutant Arg183His protein are not exocytosed as effectively as those containing the wild-type hormone.[591] Other mutations (for example, Pro89leu) can cause more profound and early disturbances in the secretory pathway by alteration of the orientation of the growth hormone helices and an effect on the correct folding of the molecule.[592]

Patients with autosomal dominant isolated growth hormone deficiency have substantial variation in the severity of growth hormone deficiency. They present with low but detectable serum growth hormone levels, variable height deficit, and can show anterior pituitary hypoplasia on MRI (38% to 50%).[593,594] Data on pedigrees with the Arg183His or e3+1G>A mutations highlight the fact that patients with the same mutation can vary considerably in height (≤ –4 SDS to normal) and even attain normal adult height without treatment. Patients with splice site mutations are thought to be more severely affected than those with missense mutations[595]; however, patients with the IvS3+1 or IvS3+2 splice site or the Pro89leu mutations can develop additional pituitary hormone deficiencies, including ACTH, prolactin, TSH, or gonadotropin deficiency.[596,597] This evolving phenotype is unpredictable and dictates the need for lifelong follow-up of affected individuals. Another intriguing observation is that, even in patients with a genetic cause (for example, Glu32Ala), growth hormone deficiency seems to reverse when they are retested at the end of growth, in the transition period before transfer from pediatric to adult services. However, this effect is

temporary, observed in patients tested at the time of transition who should not be discharged from follow-up.[598]

Isolated GHDIII is transmitted in an X-linked manner. Little is known about the etiology of this condition, although rare mutations in *SOX3* can be associated with IGHD with or without learning difficulties.

Congenital Abnormalities of the Pituitary

A number of reports have described the association of "idiopathic" GHD with an ectopic neurohypophysis.[599-601] Magnetic resonance imaging (MRI) findings have been described in several series of patients with idiopathic dwarfism. Abrahams and associates[600] studied 35 patients with idiopathic GHD and found that those with MRI findings could be divided into two groups: 43% had an ectopic neurohypophysis (neurohypophysis located near the median eminence), absent infundibulum, and an absence of the normal posterior pituitary bright spot, and 43% had a small anterior pituitary as an isolated finding or combined with an ectopic neurohypophysis.

All in all, an ectopic neurohypophysis was found in 87% of cases with multiple pituitary hormone deficiencies but in only 10% of cases with isolated GHD. Kuroiwa and coworkers[601] suggested that the ectopic neurohypophysis, typically visualized as a bright spot at the median eminence, might be the consequence of perinatal asphyxia.

In other studies, however, high-resolution MRI findings of one or more of the following have been suggested to be sensitive or specific indicators of hypopituitarism: a small anterior pituitary, attenuated pituitary stalk, and ectopic posterior pituitary. In one study,[602] pituitary abnormalities were found in 80% with isolated GHD and 93% with MPHD. In patients whose peak growth hormone level was less than 3 ng/mL, 90% had MRI findings—compared with 39% of those with growth hormone levels 3 ng/mL or greater. In another study,[603] the stalk was abnormal in 90% of patients with IGHD and was absent in 96% of patients with MPHD. Thus, MRI abnormalities are common in children with isolated GHD and MPHD and are closely associated with the severity of GHD. Patients with structural abnormalities will need lifelong follow-up as adults due to the risk of developing other pituitary hormone deficiencies. Patients with an ectopic posterior pituitary, however, can also show reversal of their growth hormone deficiency on retesting at the time of transition from pediatric to adult services or in adulthood.[604,605]

Tumors Involving the Pituitary. Many of the tumors that affect hypothalamic function also directly impact pituitary secretion of GH.[521] In particular, craniopharyngiomas comprise a major cause of pituitary insufficiency.[606,607] Some consider this tumor a congenital malformation because it is believed to be present at birth, gradually growing over the ensuing years and decades. Craniopharyngiomas are rare epithelial tumors of embryonal origin, derived from remnants of Rathke's pouch.[608] The tumor arises from rests of squamous cells at the junction of the adenohypophysis and neurohypophysis. As it enlarges, it forms a cyst that contains degenerated cells and that may calcify but does not undergo malignant degeneration. In children, craniopharyngiomas represent 5% to 15% of intracranial tumors and are the most common neoplasm of the hypothalamo-pituitary area, accounting for up to 80% of tumors in this location.[609,610] Their incidence in the United States is 1.3 per million per year, and almost 28% affect children younger than 14 years.[611] Data from the UK registry show that there are 15 new cases per year in children under 15 years of age. There is a bimodal peak in incidence: the first peak occurs in children between 5 to 14 years and the second peak in adults older than 50 years. Patients can, however, be diagnosed at any age and have even been reported in the neonatal period.

At presentation, most craniopharyngiomas have a combined intra and suprasellar location (74.2%) and almost half have hypothalamic involvement (51.6%). A smaller percentage is exclusively suprasellar (22.6%) or confined within the sella turcica (6% to 3%). Almost one third invade the floor of the third ventricle and may cause obstructive hydrocephalus.[612,613] In pediatric patients, craniopharyngiomas are predominantly cystic (56.7%), multicystic (16.7%), predominantly solid (13.3%), purely solid (10%), or purely cystic (3.3%). The cystic fluid is viscous and rich in cholesterol and the incidence of calcification is much higher in children (83.3%) compared to adults.[614]

There are two main histologic types: the most common is the adamantinomatous type and consists of epithelial neoplastic cells that resemble those found in lesions of the jaw; the papillary type is much more rare and is found almost exclusively in adults. Although craniopharyngiomas are histologically benign, they can extend from their initial site, develop papillae, and invade vital surrounding tissues including the hypothalamus and optic chiasm. This attachment makes their complete excision difficult, if not impossible, and contributes to tumor recurrence and morbidity.

Craniopharyngiomas are typically sporadic tumors. There have been, however, rare case reports of affected family members suggesting recessive inheritance. Genetic studies of craniopharyngiomas have suggested a role for the Wnt signaling pathway; there is evidence that the activation of beta-catenin may have a role in the pathogenesis of adamantinomatous craniopharyngiomas. Beta-catenin is a cytoplasmic protein important for cell-cell adhesion and association with cadherins. It is also a downstream component of the *Wnt* signaling pathway that regulates many developmental processes such as cell proliferation, axis orientation, and organ development. Sekine and colleagues found mutations in beta-catenin in all adamantinomatous craniopharyngiomas they examined.[615] Although further studies confirmed that it is the adamantinomatous, and not papillary, craniopharyngiomas that have heterozygous missense mutations in beta-catenin, the reported rate was lower (16%, 7 of the 43 examined).[616] Overactivation of the Wnt signaling pathway in the pituitary in a mouse model has led to the development of tumors that are highly reminiscent of craniopharyngioma and offers further hope for possible medical therapy.[41]

Clinical signs and symptoms of craniopharyngiomas can arise at any age, from infancy to adulthood, but most typically occur in mid-childhood. The most common presentation is with symptoms of increased intracranial pressure (up to 75%), such as headaches, vomiting, or oculomotor abnormalities. Impaired vision is common. Visual field defects may result from compression of the optic chiasm, and papilledema or optic atrophy may be observed. Visual and olfactory hallucinations have been reported, as have seizures and dementia.

It is estimated that 70% to 80% of children have evidence of endocrine deficiencies at presentation and that growth failure is observed in 32% to 52% of children prior to diagnosis. Low concentrations of IGF-1 have been reported in 80% of children at time of diagnosis. GH deficiency is the most common hormone deficiency, documented in 75% to 100% of those tested before treatment. It is followed by ACTH (20% to 70%) and TSH (3% to 30%) deficiencies. Compression of the pituitary stalk or damage of hypothalamic dopaminergic neurons results in elevated PRL concentrations, observed in 8% to 20% of children at diagnosis. The incidence of diabetes insipidus at presentation varies between 10% and 29% of patients depending on the study. However, in one study almost half of patients had DI at presentation. The authors suggested that the incidence of DI is either underestimated or may be masked by the simultaneous presence of ACTH deficiency.[617] In adolescence in particular, craniopharyngiomas present with delayed puberty or pubertal arrest: in a series of 56 patients, all adolescents complained of delayed puberty.[617] Rare presentations include precocious puberty[39] and syndrome of inappropriate antidiuretic hormone secretion.

Lateral skull films often demonstrate enlargement or distortion of the sella turcica, frequently accompanied by suprasellar calcification(s). Nevertheless, some children with craniopharyngiomas will have normal plain films (and alternative radiologic techniques are recommended). Computed tomography is a sensitive technique for identification of small amounts of calcification or cystic abnormalities. MRI is probably the most sensitive technique.

Craniopharyngiomas appear as mass lesions in the sellar or suprasellar area that may extend to the hypothalamus and invade the third ventricle. Adamantinomatous craniopharyngiomas are predominantly cystic and the cystic portion of the lesion appears hyperintense in T1 and T2 images. The solid part of the tumor shows areas of high and low signal intensity that represent areas of calcification and hemosiderin deposits. In the majority of cases (58% to 76%), the size of craniopharyngiomas, as estimated by MRI or computed tomography (CT), has been reported to be 2 to 4 cm, whereas it is smaller than 2 cm in 4% to 28% cases and more than 4 cm in 14% to 20%.[610,614]

The management of craniopharyngiomas is complex, controversial, and it is best achieved by a multidisciplinary approach. Aims of the treatment are to relieve acute signs and symptoms of compression (raised intracranial pressure, threatening visual failure), to preserve hypothalamic function, thus reducing later morbidity and mortality, and to provide long-term control and prevent recurrence. What has been evident from different studies is that the extent of surgical resection is probably the most important factor that influences the recurrence of craniopharyngioma.[618] In patients who had surgery only, the 10-year recurrence free survival rate was 83% after total removal, 50.5% after subtotal removal, and 15.6% after partial removal. Tumor recurrence usually occurs in the first 5 years and is relatively rare thereafter. However, even after complete resection confirmed radiologically, relapses occur in up to 15% to 25% of patients. In older series, however, when patients were treated with radical and repeated surgical resections, mortality was high (25% to 50%) and hypothalamic, visual, and cognitive morbidity occurred in the majority (75%), especially in craniopharyngiomas with suprasellar or retro-chiasmatic extension.[612]

Guidelines for the multidisciplinary management of children with craniopharyngioma have been published.[619,620] It is now suggested that patients can be categorized in two risk groups with respect to management and prognosis. The good risk group includes older children with small tumors (2 to 4 cm) and no hypothalamic syndrome or hydrocephalus. Younger children, with larger tumors (> 2 to 4 cm) and hypothalamic syndrome or hydrocephalus are in the poor risk group. Complete radical resection, with or without adjuvant radiotherapy, is suggested for the good risk group, whereas limited surgery and immediate or delayed radiotherapy is the treatment of choice for the poor risk group.

Psychosocial Dwarfism. An extreme form of "failure to thrive" is observed in a condition labeled "psychosocial dwarfism" or "emotional deprivation dwarfism."[621-623] Most cases of failure to thrive can be traced back to a poor home environment and inadequate parenting, with improved weight gain and growth observed on removal of the infant from the dysfunctional home. In 1967, Powell and coworkers[622] described a group of children with dramatic behavioral manifestations beyond those observed in the typical infant with failure to thrive. Behavior was characterized by bizarre eating and drinking habits (such as drinking from toilets), social withdrawal, and primitive speech. GH secretion was abnormally low after provocative testing but returned to normal on removal from the home. Concomitantly, when eating and behavioral habits normalized children experienced a period of catch-up growth.

The neuroendocrinologic mechanisms involved in psychosocial dwarfism remain to be elucidated; however, GH secretion is abnormal, and ACTH and TSH activity may also be reduced—although some patients have been reported to be hypercortisolemic. Even though GH secretion is reduced, treatment with GH is not usually of benefit until the psychosocial situation is improved. It is our experience that whereas failure to thrive is a common cause of poor growth in infancy, the constellation of findings described in psychosocial dwarfism is, fortunately, rare.

GH Neurosecretory Dysfunction. Because of concerns that tests of GH secretion after pharmacologic provocation do not accurately reflect normal GH secretion, it has

been argued that there exists a group of children with "GH neurosecretory dysfunction"—identified by frequent serum sampling over a 12- to 24-hour period or by continuous serum withdrawal over a similar period of time.[624,625] GH neurosecretory dysfunction is characterized by short stature and poor growth, normal provocative serum GH concentrations, reduced 24-hour serum GH concentrations, and low serum IGF-1 concentrations. There appears to be little doubt that some children should be considered GH deficient, even if they pass provocative GH testing, although whether such patients should be identified by 24-hour GH sampling or by measures of the IGF axis remains controversial. This subject is discussed later in the chapter.

Acquired Idiopathic Isolated GHD. In most pediatric endocrine centers, many children receiving GH carry a diagnosis of acquired idiopathic isolated GHD. As stated previously, this diagnosis should always be considered somewhat suspect—although it is clear that some of these patients may actually have undiagnosed gene defects in GH production/secretion or have first manifestations of combined pituitary hormone deficiencies. Tauber and colleagues[626] performed GH stimulation tests on 131 young adults who carried the diagnosis of childhood-onset GHD. Of 10 subjects with organic GHD, 90% had peak GH concentration less than 5 ng/mL. On the other hand, 67% of 121 subjects carrying a diagnosis of idiopathic GHD had a peak GH concentration that was greater than 10 ng/mL and only 17% had a peak concentration that was less than 5 ng/mL.

This study also compared retesting results when subjects were divided into complete GHD (defined by an initial peak), stimulated GH level less than 5 ng/mL, and partial GHD (defined by a peak GH level after two stimulation tests of between 5 and 10 ng/mL or one test below 10 ng/mL and a 24-hour GH level below 2.5 ng/mL). Subjects with partial GHD were twice as likely to have normal GH responses on retesting than were those with complete GHD (71% versus 36%, respectively).

In a similar study, Maghnie and coworkers[627] reinvestigated 35 young adults with childhood-onset GHD divided into four groups according to their first pituitary MRI: isolated GHD and normal pituitary volume; isolated GHD and small pituitary volume; isolated GHD or MPHD, together with hypothalamic-pituitary abnormalities on MRI such as pituitary hypoplasia, pituitary stalk agenesis, and posterior pituitary ectopia; and MPHDs secondary to craniopharyngioma. On retesting, all subjects in the first and second groups had normal GH responses to provocative testing, regardless of pituitary size. On the other hand, all subjects in the third and fourth groups had peak GH responses less than 3 ng/mL. These findings and those of a number of similar studies[628] have indicated that the likelihood of sustained GHD is much greater in cases of MPHDs or structural abnormalities of the hypothalamus/pituitary.

Bio-inactive GH. Serum GH exists in multiple molecular forms, representing alternative posttranscriptional or posttranslational processing of the mRNA or protein, respectively. It is conceivable that different molecular forms of GH may have varying potency in stimulating skeletal growth, although this remains to be rigorously demonstrated. It has been suggested that some cases of short stature may be characterized by serum GH forms that have normal immunopotency but reduced biopotency.[629] No completely convincing cases of "bio-inactive GH" had been demonstrated until 1996, when Takahashi and colleagues[630,631] reported two cases that were heterozygous for point mutations in GH1. One patient was characterized by a R77C mutant GH molecule that bound with high affinity to the GHBP but abnormally to the GHR.

The mutant molecule appeared to behave in a dominant negative fashion and could inhibit tyrosine phosphorylation through the GHR. The affected patient had a partial clinical response to GH, and the father (who was heterozygous for the same mutation) was phenotypically normal—thereby raising some questions about the physiologic significance of this mutation. A second patient, with a D112G mutation, produced a GH molecule that apparently inhibits GHR dimerization. This patient, however, was able to respond to exogenous GH by increasing serum IGF-1 and accelerating growth. Although searches will continue for other examples of GH variants with decreased activity, it seems likely that true "bio-inactive GH" is a rare cause of growth failure.

Primary IGFD and GH Insensitivity(GHI). It is important to consider growth in the context of both GH secretion and GH sensitivity, each of which can operate alone or in combination in a variety of patients—including those with ISS (Figure 10-24). GHI describes patients with the phenotype of GHD but with normal or elevated

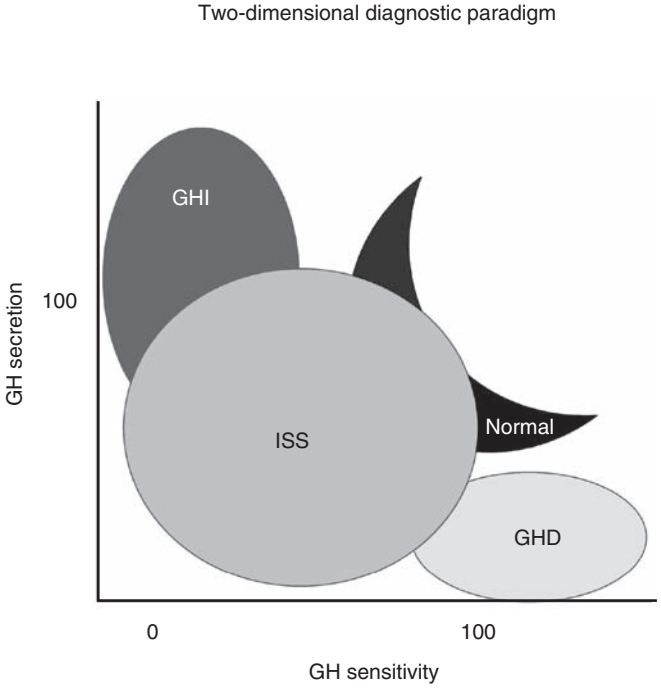

FIGURE 10-24 ■ Dual contributions of GH secretion and action to growth. (From Cohen, P. (2006). Controversy in clinical endocrinology: problems with reclassification of IGF-1 production and action disorders. *J Clin Endocrinol Metab, 91*, 4235–4236.)

BOX 10-4 Proposed Classification of Growth Hormone (GH) Insensitivity[877]

Primary GH Insensitivity (Hereditary Defects)

1. GH receptor defect (may be positive or negative for GH-binding protein)
   - Extracellular mutation (e.g. Laron syndrome)
   - Cytoplasmic mutation
   - Intracellular mutation
2. GH signal transduction defects (distal to cytoplasmic domain of GH receptor)
   - Stat-5b mutations
3. Insulin-like growth factor-1 defects
   - IGF-1 gene deletion
   - IGF-1 transport defect (ALS mutation)
   - IGF-1 receptor defect
4. Bioinactive GH molecule (responds to exogenous GH)

Secondary GH Insensitivity (Acquired Defects)

- Circulating antibodies to GH that inhibit GH action
- Antibodies to the GH receptor
- GH insensitivity caused by malnutrition, liver disease, catabolic states, diabetes mellitus
- Other conditions that cause GH insensitivity

GH insensitivity: Clinical and biochemical features of IGF-1 deficiency and insensitivity to exogenous GH, associated with GH secretion that would not be considered abnormally low.
GH insensitivity syndrome: GH insensitivity associated with the recognizable dysmorphic features described by Laron.
Partial GH insensitivity: GH insensitivity in the absence of dysmorphic features described by Laron.

serum GH concentrations[110,632] (Box 10-4). Primary GHI implies abnormalities of the GHR, including the extracellular GH binding site, the extracellular GHR dimerization site, the transmembrane domain, or the intracellular site; post-receptor abnormalities of GH signal transduction; and primary defects of IGF-1 biosynthesis. The term "Laron syndrome" is commonly applied to these entities. Secondary GHI is an acquired condition and includes circulating antibodies to GH, antibodies to the GHR, malnutrition, and hepatic disease. As Boxes 10-1 and 10-4 and Table 10-3 show, a growing number of genes have been identified in the distal portion of the GH-IGF axis, and defects of each one have specific phenotypic and biochemical characteristics (Table 10-4). Additionally, different mutations of the same gene may result in significant variability in the phenotype. This has led to the concept of a continuum of GH insensitivity, ranging from severe (with heights as low as −10 SD and undetectable serum IGF-I concentrations) to quite mild (heights and serum IGF-I concentrations at the lower part of the normal range). Details concerning each of the molecular defects involved in GHI, IGFD, and IGF resistance are available at www.growthgenetics.com.

The initial report of what proved to be a defect of the GH receptor, by Laron and colleagues, described "three siblings with hypoglycemia and other clinical and laboratory signs of growth hormone deficiency, but with abnormally high concentrations of immunoreactive serum growth hormone.[632] To date, several hundred such cases have been identified worldwide.[110] The majority of reported cases come from the Mediterranean region or from Ecuador (in presumed descendants of Spanish "conversos": that is, Jews who converted to Christianity during the Inquisition).[632] Such patients have been demonstrated to be unresponsive to exogenous GH in terms of growth, metabolic changes, and alterations in serum concentrations of IGF-1 and IGFBP-3.[633]

Cellular unresponsiveness to GH was demonstrated in vitro by the failure of GH to stimulate erythroid progenitor cells from the peripheral blood of patients.[634] Direct evidence of receptor failure was provided by the demonstration that hepatic microsomes obtained by liver biopsy failed to bind radiolabeled GH.[635] Absence of detectable GHBP activity in the sera of patients with this familial form of GHI was subsequently demonstrated by the reduced ability of serum to bind radiolabeled GH.[167,168]

This latter observation was rapidly followed by the purification, cloning, and sequencing of the serum GHBP and the demonstration that it was in essence identical to the extracellular domain of the GHR.[112] Initial studies of the GHR gene in Israeli patients indicated that some contained gene deletions.[636] A wide variety of point mutations (missense, nonsense, and abnormal splicing) were identified subsequently.[110,637-639] The majority of reported point mutations are in the extracellular domain of the GHR, although there are some at the extracellular domain that did not affect GH binding but prevented dimerization of the receptor[640]; such cases may be characterized by normal or even increased serum concentrations of GHBP because the GHBP binding site is intact. There are, additionally, reports of patients with separate amino acid substitutions in the intracellular domain of the GHR.[641]

Woods and associates[642] reported two cousins with severe GHI resulting from a mutation in the 59-splice donor site of intron 8, resulting in a truncated GHR lacking the transmembrane and intracellular domains and leading to increased concentrations of serum GHBP—presumably owing to accelerated release from the cell membrane. A similar defect has been described in a Druse girl with a mutation of the 39-acceptor site of intron 7.[643] Defects directly affecting the intracellular domain have been reported to result in dominantly inherited GHI. In one, a girl and her mother (both with short stature and biochemical evidence of GHI) were found to be heterozygous for a single G-to-C transversion in the 39-splice acceptor site of intron 8—resulting in a truncated GHR 1–277 lacking most of the intracellular domain.[644]

A second report described high serum GHBP concentrations in two Japanese siblings and their mother, who were characterized by partial GHI. The patients and their mother had a point mutation that disrupted the 59-splice donor site of intron 9, causing skipping of exon 9 and the appearance of a premature stop codon in exon 10—resulting in the same GHR 1–277 molecule described by Ayling and associates.[644] Experiments under in vitro conditions showed that the Japanese mutation

From David, A., Hwa, V., Metherell, L., et al. (2011). Evidence for a continuum of genetic, phenotypic, and biochemical abnormalities in children with growth hormone insensitivity. Endocr Rev*, 32, 472–497, Table 2.*

results in a GHR molecule that behaves in a dominant negative manner—inhibiting GH-induced tyrosine phosphorylation of STAT5.

The clinical features of GHI due to GHR deficiency (GHRD) are identical to those of other forms of severe IGF deficiency, such as congenital GHD.[110] Basal serum GH concentrations are typically elevated in children but may be normal in adults (Figure 10-25). Most patients have decreased serum GHBP concentrations, at least as measured by functional assays. A normal (or even elevated) serum GHBP concentration does not, however, exclude the diagnosis of GHRD because mutations at the GHR dimerization site have been already described, as well as mutations of the transmembrane or intracellular domain of the receptor. Serum IGF-1, IGF-2, and IGFBP-3 concentrations are profoundly reduced in classic GHI (Figure 10-26)—but partial clinical and biochemical phenotypes have been described, typically related to milder mutations of the GHR gene and resulting in only a modest reduction in binding activity or receptor action.

Unlike the cases with "classic" GHR defects, as described in Israel and Ecuador, such cases may have heights and serum IGF-I concentrations that border on the lower limits of normal, again supporting the concept of a continuum of GHI defects.[639] Molecular defects that have been associated with milder phenotypes include an intronic base change resulting in activation of a pseudoexon sequence and insertion of 36 amino acids into the extracellular domain of the GHR,[645,646] some compound heterozygous mutations,[647] and some unequivocal dominant negative mutations.[648,649] Given that the GHR must dimerize to elicit a signal, molecular defects involving the intracellular domain of the GHR are particularly likely to result in such dominant negative expression.[649]

Sequencing of the *GHR* gene should not be limited, consequently, to coding exons, as intronic defects and splice site defects may result in GH insensitivity, often with atypical phenotypes and milder clinical expression. By the same token, it has become clear that not all mutations result in physiologically and clinically significant defects and that functional studies of mutations should be performed before attributing a phenotype to a specific mutation.

GHR Signaling Defects. Although some cases of primary IGFD with normal serum GHBP have proven to have defects of the transmembrane or intracellular domain of the GH receptor, patients have been reported with similar clinical and biochemical phenotypes but with normal sequencing of the GH receptor gene. Until recently, such cases (even when characterized by apparently abnormal activation of the STAT or MAPK pathways) have had no demonstrable molecular basis. Kofoed and colleagues,[650] however, reported a 16-year-old girl with a height of –7.5 SD and markedly low serum concentrations of IGF-I, IGFBP-3, and ALS despite normal serum concentrations of GHBP and a normal GHR gene sequence.

The patient, born to consanguineous parents, proved to be homozygous for a point mutation resulting in a substitution of proline for alanine at position 630 of the STAT5b gene—with resulting marked decrease in phosphorylation of tyrosine, a critical step in the pathway to STAT activation of IGF-I gene transcription. Subsequent investigations indicated that the mutant STAT5b

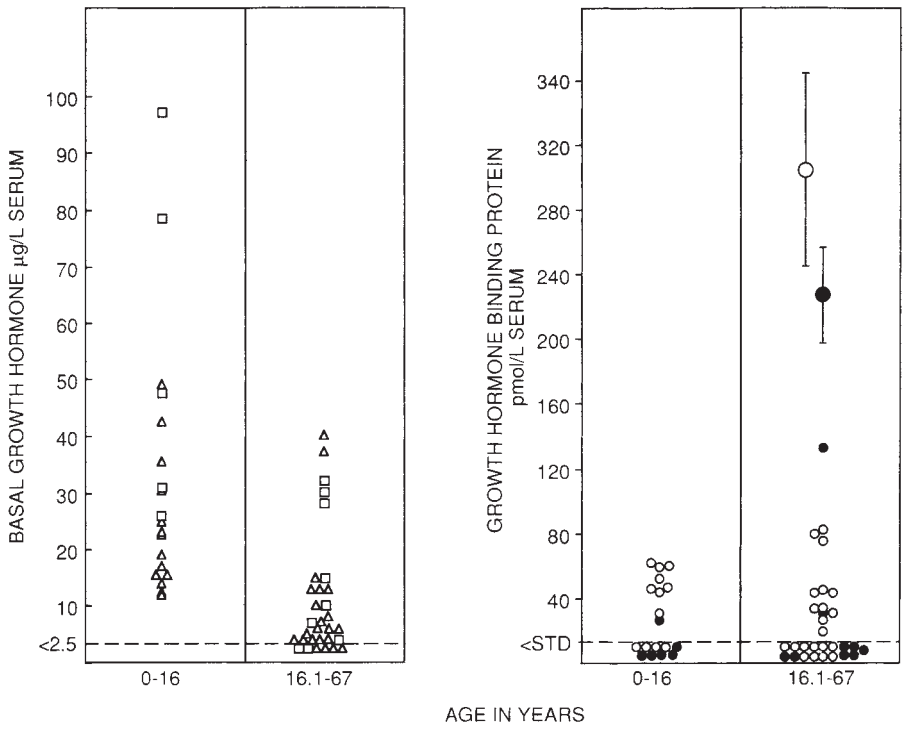

FIGURE 10-25 ■ Growth hormone and growth hormone-binding protein concentrations in sera of patients from Ecuador with GH receptor deficiency. (From Rosenfeld, R. G., Rosenbloom, A. L., & Guevara-Aguirre, J. (1994). Growth hormone [GH] insensitivity due to primary GH receptor deficiency. *Endocr Rev*, *15*, 369.)

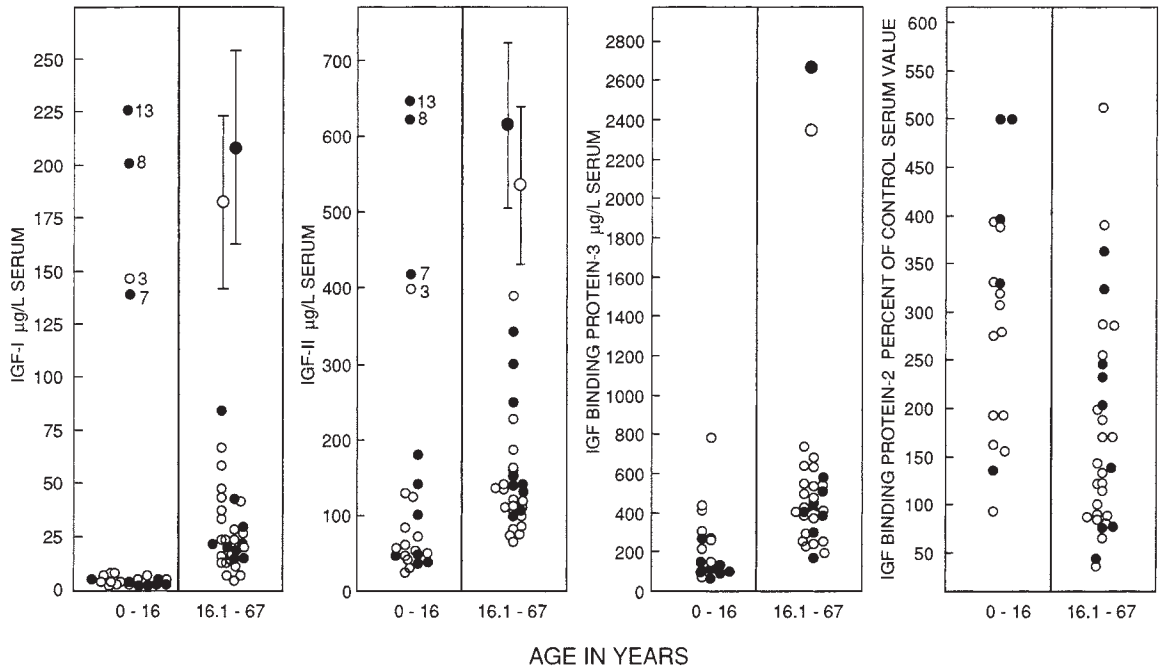

FIGURE 10-26 ■ Serum concentrations of insulin-like growth factor-1 (IGF-1), IGF-binding protein-3, and IGF-binding protein-2 in patients from Ecuador with growth hormone receptor deficiency. (From Rosenfeld, R. G., Rosenbloom, A. L., & Guevara-Aguirre, J. (1994). Growth hormone [GH] insensitivity due to primary GH receptor deficiency. *Endocr Rev*, *15*, 369.)

could not function as a signal transducer or transcription factor, presumably because of an inability to dock with phosphotyrosines on GH-activated receptors as well as an inability to form a stable interaction with DNA. The A630P STAT5b was shown to be characterized by aberrant folding and diminished solubility, resulting in aggregation and formation of cytoplasmic inclusion bodies.

A second case of severe primary IGFD and GH insensitivity resulting from a novel mutation of STAT5b has

been reported. The patient was shown to be homozygous for a single nucleotide insertion in exon 10 of the STAT5b gene, leading to early protein termination. Because STAT5b is involved in the signaling pathway for multiple cytokines, it is of note that both patients had evidence of immune dysfunction and recurrent pulmonary infections. The growth and clinical characteristics of these two patients strongly support the hypothesis that STAT5b mediates the overwhelming majority, if not all, of GH's effects on IGF-I gene transcription. To date, no convincing mutations of the genes for JAK2 or MAPK have been implicated in primary IGFD and GH insensitivity. It is possible that severe mutations of JAK2 (involved in signaling for multiple growth factors and cytokines) are incompatible with life.

Table 10-5 provides details on all of the cases of homozygous *STAT5b* defects reported to date. A total of 10 cases, involving 7 different mutations, have been described. Size at birth was generally within normal limits, as observed with *GHR* defects, but postnatal growth was severely impaired, with heights ranging from −3 to −9.9 SD. The biochemical data were consistent with GHI, with generally elevated serum GH concentrations and low serum IGF-I, IGFBP-3, and ALS concentrations. Serum prolactin levels, when measured, were elevated. Unlike defects of *GHR*, however, clinical evidence of immune compromise was evident in all but one patient, often accompanied by severe and life-threatening pulmonary disease. Given that STAT5b is involved in the signaling of multiple cytokines, this combination of growth failure, GHI, and immunodeficiency is not surprising.[651]

ALS Mutations. Markedly reduced serum concentrations of IGF-I and IGFBP-3 have also been observed in cases involving mutations of the ALS gene.[652,653] Of note is that even though serum concentrations of IGF-I and IGFBP-3 were as low as in patients with mutations of the GHR or STAT5b genes, growth was only modestly affected (Table 10-6). Indeed, the index case actually attained an adult height within the normal range. Whether the relatively normal growth reflects the greater importance of locally produced IGF-I or reflects altered kinetics of serum IGF-I in the face of reduced concentrations of binding proteins remains uncertain.

At least 16 different mutations have been identified to date, involving a minimum of 21 cases. Classical cases were either homozygous or compound heterozygotes, consistent with an autosomal recessive transmission. Heights ranged from −0.5 to −4.2 SD, but even this modest growth failure could reflect some degree of ascertainment bias. The possibility of heterozygous expression of *IGFALS* mutations has also been considered.[654] Analysis of heights within individual families has suggested that having two affected alleles results in about 2 standard deviations of height loss compared to wild-type relatives, whereas having one affected allele results in a loss of almost 1 SD of height. Given the remarkably low serum concentrations of both IGF-I and IGFBP-3 in these patients, however, the degree of growth failure is actually modest, especially when compared with other molecular defects of the GH-IGF axis.

IGF1 Gene Defects. Growth failure associated with a primary defect of IGF-1 synthesis has also been reported[357] (Table 10-7). The first case was a 15-year-old boy who had many of the growth characteristics predicted from mouse knockout models,[356,428,655] including intrauterine and postnatal growth failure. Additional features were mental retardation and sensorineural deafness. These features serve to distinguish IGF1 defects from GHI resulting from disorders of the GHR and STAT5b genes, where intrauterine growth is normal, as are head growth and intellectual function. These phenotypic features serve to underscore the observation that, although IGF-I is critical for both intrauterine and postnatal growth, GH, itself, has little role in prenatal growth and development. The patient was shown to be homozygous for deletions of exons 4 and 5 of the human IGF-1 gene, with both parents being heterozygous carriers and perhaps mildly affected. Although unresponsive to GH therapy, the patient was able to accelerate growth velocity on treatment with IGF-1. Of note is that the patient with IGF-1 gene deletion had in addition to severe growth failure and mental retardation substantial insulin resistance, and that IGF-1 therapy resulted in a marked improvement of insulin sensitivity, reduction of serum insulin, and overall improvement in various aspects of carbohydrate metabolism.[656]

Two cases of homozygous mutations have been reported where missense mutations (V44M[657] and R36Q)[658] resulted in an immunologically active, but bioinactive IGF-I molecule. Both patients had prenatal and postnatal growth attenuation, microcephaly, and one of the two had sensorineural deafness. Bioinactivity in these cases reflects a decrease in the affinity of the altered IGF-I for the IGF-I receptor.

IGF-I deficiency resulting from a homozygous T. A transversion in exon 6 has also been reported.[659] Although the phenotype of this case resembles those of the cases described earlier, this defect, which affects the E domain of the IGF-I precursor, may prove to be a polymorphism.

IGF1 Receptor Mutations. Cases of IGF-1 receptor mutations have also been described (Table 10-8).[660,661] In knockout models created in mice, homozygous mutations of the IGF-I receptor result in profound growth failure and neonatal mortality. Heterozygous mutations are phenotypically similar to wild-type mice.

More than a dozen patients with IUGR and postnatal growth failure associated with defects of the IGF1R have been reported.[661] Clinical findings have included microcephaly and mild mental retardation. The combination of prenatal and postnatal growth failure, in association, at times, with microcephaly and developmental delay, is similar (although milder) to the observations noted in molecular defects of *IGF1*, again emphasizing the importance of IGF-I and its receptor in both intrauterine and childhood growth. In general, serum IGF-I and IGFBP-3 concentrations were normal to elevated, possibly reflecting decreased IGF-I feedback on GH production. Functional studies typically demonstrate decreased affinity for IGF-I and decreased downstream phosphorylation in response to IGF-I stimulation. Other mechanisms whereby mutations of IGF1R result in IGF-I resistance

From David, A., Hwa, V., Metherell, L., et al. (2011). Evidence for a continuum of genetic, phenotypic, and biochemical abnormalities in children with growth hormone insensitivity. Endocr Rev, 32, *472–497, Table 9.*

include defects that result in degradation of IGF1R mRNA through the nonsense-mediated mRNA decay pathway[662] and defective pro-receptor processing and plasma membrane localization.[663]

The first reported case of *IGF1R* defect was a compound heterozygote (*p.*R108Q; *p.*K115N).[664] Only one additional compound heterozygote has been reported, with both defects in exon 3 (*p.* E121K; *p.*E234K).[665] In the latter case, two siblings were affected and the growth defect was more severe than that generally described in heterozygous cases. All other reported cases have been simple heterozygotes. The absence of homozygous cases may reflect the observation in mice that *IGF1R* knockouts were generally lethal.

In leprechaunism, a syndrome of growth failure and insulin receptor dysfunction, there is variable IGF-I insensitivity. The profound abnormality of the insulin receptor suggests that heterodimeric insulin- and IGF-I receptor combinations could possible lead to failed activation of the IGF-I signaling cascade. As the IGF-I receptor gene resides at 15q26.3, deletions of the distal long arm of chromosome 15 or ring chromosome 15 may lead to hemizygosity for the IGF-I receptor. Although such patients may have intrauterine growth retardation and striking postnatal growth failure, lack of a biologic response to IGF-I has not been conclusively demonstrated. Whether growth failure in such patients is due to altered levels of IGF-I receptor or represents the net effect of the loss of other genes located on 15q remains to be determined.[660]

Clinical Features. Cases of IGF-1 deficiency resulting from hypothalamic dysfunction, decreased pituitary GH secretion, or GHI share a common phenotype, although specific features characteristic of each molecular disorder may help distinguish the various etiologies (Table10-4). The striking clinical similarity among patients with GHD caused by a GH gene deletion and patients with GHI secondary to mutations of the GHR gene emphasizes the role of IGF-1 in mediating most, but not all, of the anabolic and growth-promoting actions of GH. This point is further supported by the ability of IGF-1 therapy to partially normalize growth in children with mutations of the GHR gene. Children with less severe IGF deficiency will generally have milder clinical characteristics. If GH or IGF deficiency is acquired, clinical signs and symptoms will obviously appear at a later age (Box 10-5).

As stated previously, birth size is remarkably normal even in severe forms of congenital GHD or GHI due to defects of *GHR*, *STAT5b* or *IGFALS*. Birth length and weight are typically within 10% of normal, and severe IUGR is not part of the classic phenotype. Neonatal signs can exist, however, including hypoglycemia and prolonged jaundice.[666] When GHD is combined with ACTH and TSH deficiency, hypoglycemia may be severe. On the other hand, when GHD is combined with gonadotropin deficiency, microphallus, cryptorchidism, and hypoplasia of the scrotum may be observed.[667] GHD (or GHI) must therefore be considered in the differential diagnosis of neonatal hypoglycemia or microphallus/cryptorchidism.

BOX 10-5 Clinical Features of Growth Hormone Insensitivity

Growth and Development

- Birth weight: near-normal
- Birth length: may be slightly decreased
- Postnatal growth: severe growth failure
- Bone age: delayed, but may be advanced relative to height age
- Genitalia: micropenis in childhood; normal for body size in adults
- Puberty: delayed 3 to 7 years
- Sexual function and fertility: normal

Craniofacies

- Hair: sparse before the age of 7 years
- Forehead: prominent; frontal bossing
- Skull: normal head circumference; craniofacial disproportion due to small facies
- Facies: small
- Nasal bridge: hypoplastic
- Orbits: shallow
- Dentition: delayed eruption
- Sclerae: blue
- Voice: high-pitched

Musculoskeletal/Metabolic/Miscellaneous

- Hypoglycemia: in infants and children; fasting symptoms in some adults
- Walking and motor milestones: delayed
- Hips: dysplasia; avascular necrosis of femoral head
- Elbow: limited extensibility
- Skin: thin, prematurely aged
- Osteopenia

When intrauterine growth retardation is noted, in addition to postnatal growth failure, the possibility of GHI resulting from molecular defects of *IGF1* or *IGF1R* should be considered. This is particularly true if any of the following additional signs are observed: microcephaly, developmental delay, or sensorineural deafness.

Postnatal growth is strikingly abnormal in severe congenital IGF deficiency (Figure 10-27). Although earlier reports suggested that growth in such cases was relatively normal during the first 6 months of life, more recent surveys of GHD and GHI have indicated that growth failure may be observed during the first months of life. By 6 to 12 months of age, the child is clearly growing at an abnormally slow rate and has usually deviated away from the normal growth curve. It is important to emphasize that the single most important clinical manifestation of IGF deficiency is growth failure, and careful documentation of growth rates is critical to making the correct diagnosis. Deviation away from the normal growth curve should always be a cause of concern, and between the ages of 2 years and the onset of puberty growth deceleration (or acceleration) is always pathologic.

Skeletal proportions tend to be relatively normal, although they often correlate better with bone age than with chronologic age. Skeletal age is delayed, often to

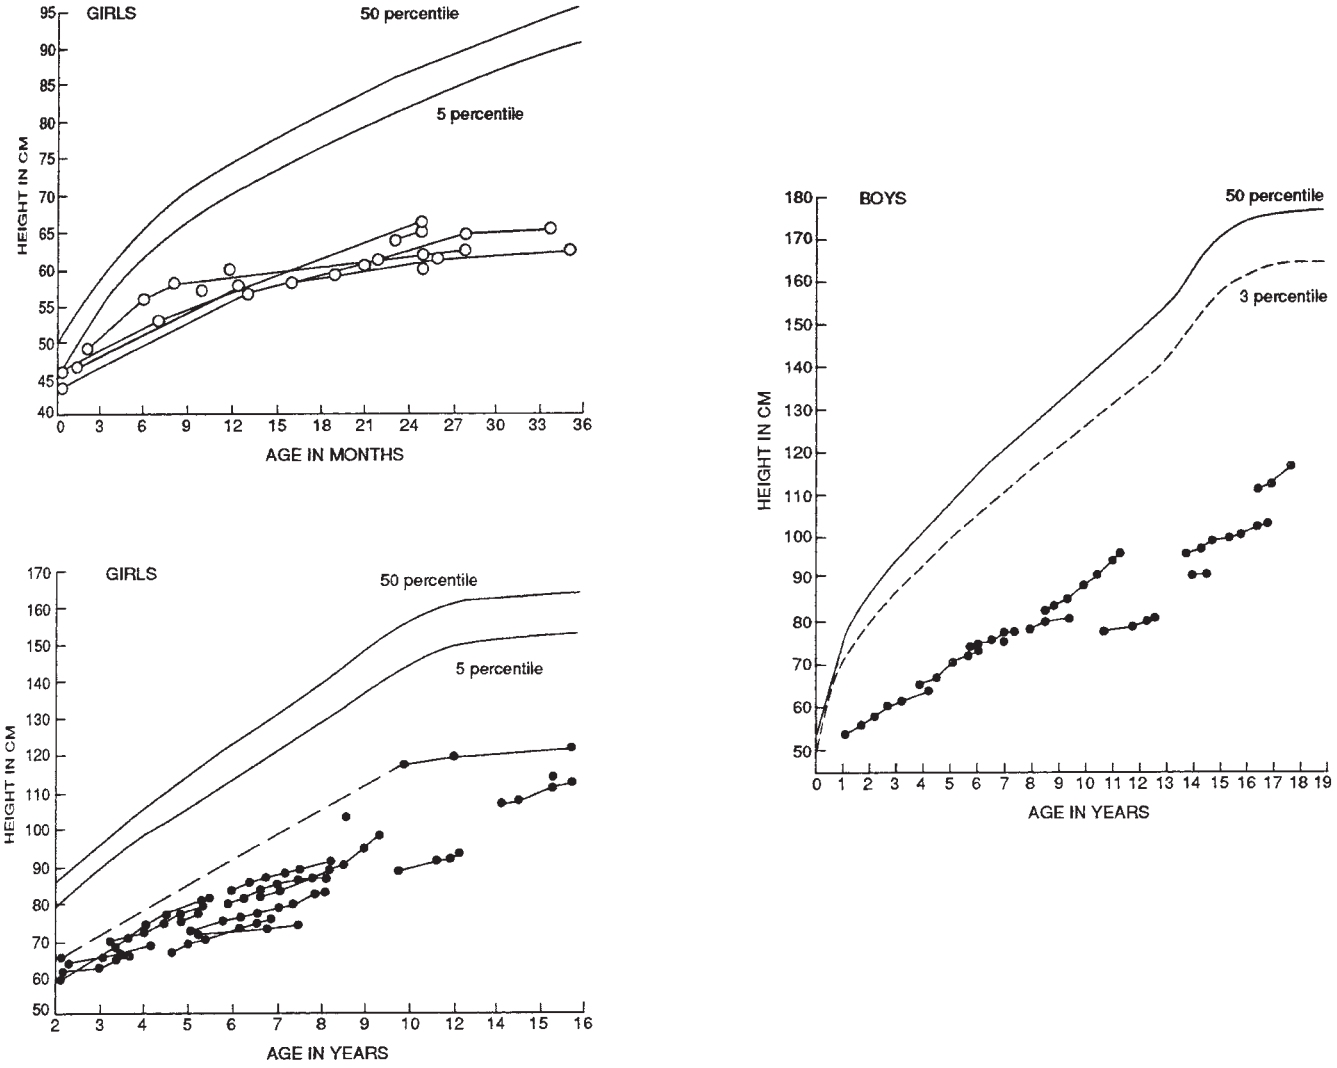

FIGURE 10-27 ■ Height measurements for children from Ecuador with growth hormone receptor deficiency. (From Rosenfeld, R. G., Rosenbloom, A. L., & Guevara-Aguirre, J. (1994). Growth hormone [GH] insensitivity due to primary GH receptor deficiency. *Endocr Rev, 15,* 369.)

less than 60% of the chronologic age. In acquired GHD, as from a tumor of the CNS that presents as symptoms resulting from increased intracranial pressure, the skeletal age may approximate the chronologic age and should therefore not be considered a requirement for the diagnosis of GHD. Weight/height ratios tend to be increased, and fat distribution is often "infantile" in pattern.

Musculature is poor, especially in infancy, which may result in significant delays in gross motor development—leading to the erroneous impression of mental retardation. Facial bone growth is particularly retarded, and the nasal bridge may appear underdeveloped (Figure 10-28). Fontanelle closure is often delayed, but the overall growth of the skull is normal—leading to cephalofacial disproportion and the appearance of hydrocephalus. The voice remains infantile, owing to hypoplasia of the larynx. Hair growth is sparse and the hair itself is thin, especially during the early years of life. Nail growth is also frequently slow. Even with normal gonadotropin production, the penis is small and puberty is generally delayed.

Diagnosis of IGF Deficiency. The proper means of establishing a diagnosis of GHD continues to be highly controversial.[314] With the availability of highly specific assays for the IGF peptides and binding proteins, and with increasing understanding of the GH-IGF axis, we believe that evaluation of patients with growth failure should rest on a combination of careful auxologic assessment and appropriate measures of the GH-IGF system. Establishment of deficiency of IGF peptides and concomitant alterations in serum concentrations of IGFBPs then necessitates a thorough evaluation of hypothalamic-pituitary-IGF function.

The foundation for the diagnosis of IGF deficiency must be auxology, with careful documentation of serial heights and determination of height velocity. In the absence of other evidence of pituitary dysfunction, it is generally unnecessary to perform tests of GH secretion. Thus, even in children below the 5th percentile in height (which obviously applies to 5% of the population), documentation of a normal height velocity

FIGURE 10-28 ■ Facial appearance of patients from Ecuador with growth hormone receptor deficiency. (From Rosenfeld, R. G., Rosenbloom, A. L., & Guevara-Aguirre, J. (1994). Growth hormone [GH] insensitivity due to primary GH receptor deficiency. *Endocr Rev, 15*, 369. Photography by Arlan L. Rosenbloom, MD.)

makes the diagnosis of IGF deficiency and GHD highly unlikely.

Assessment of pituitary GH production is problematic because GH secretion is pulsatile throughout the day and night, with the most consistent surges occurring at times of slow-wave electroencephalographic rhythms during phases 3 and 4 of sleep. Regulation of GH secretion is complex, involving two hypothalamic proteins (GHRH and somatostatin) as well as multiple other peptides and neurotransmitters. Spontaneous GH secretion varies significantly with gender, age, and pubertal status—all of which must be factored into any evaluation of GH production.

Between normally occurring pulses of GH secretion, serum GH concentrations are normally low—below the limits of sensitivity of most conventional assays. Accordingly, measurement of random serum GH concentrations is virtually useless in establishing a diagnosis of GHD. Measurement of GH "reserve" has therefore relied on the use of physiologic or pharmacologic stimuli, and these "provocative tests" have been the basis for diagnosing GHD since the 1980s.[314,668]

"Physiologic" stimuli have included fasting, sleep,[669] and exercise,[670,671] whereas pharmacologic stimuli have included levodopa,[672] clonidine,[673] glucagon,[674] propranolol, arginine,[675] and insulin[676,677] (Table 10-9). Stimulation tests have often been divided into "screening tests" (exercise, fasting, levodopa, clonidine)—characterized by ease of administration, low toxicity, low risk, and low specificity—and "definitive tests" (arginine, insulin, glucagon). To improve specificity, provocative tests are customarily combined or given sequentially.[678-680] It has been generally accepted that a child must "fail" provocative tests with at least two separate stimuli to be considered as having GHD. Standard provocative GH tests are summarized in Table 10-9.

Although provocative GH testing has been the foundation for the diagnosis of GHD since GH radioimmunoassays first became available, its use as a determiner of GH status has come under criticism for a number of reasons.[314,681] These issues, as follows, have been summarized in a consensus report on the diagnosis of childhood GHD.[667]

Provocative GH Testing Is Nonphysiologic. None of the standard pharmacologic provocative tests satisfactorily mimics the normal secretory pattern of pituitary GH. Even when naturally occurring regulatory peptides are used for stimulation, their dosage, route of administration, and interactions with other regulatory factors are artificial. In addition, because most endocrine centers use several different stimulation tests, there is no validated means of resolving conflicting data from two or more provocative tests.[682] In a report of 6373 GH stimulation tests performed on 3233 short French children, 11 different pharmacologic tests were employed, 62 of the possible 66 pairs were employed at least once, and the most frequent combination of tests was used in only 12.7% of the patients.[683]

TABLE 10-9 **Growth Hormone Stimulation Tests***

Stimulus	Dosage	Samples (Min)	Comments/Side Effects
Levodopa (PO)	< 15 kg: 125mg 15-30 kg: 250 mg > 30 kg: 500 mg	0, 60, 90	Nausea
Clonidine (PO)	0.15 mg/m^2	0, 30, 60, 90	Tiredness, postural hypotension
Arginine HCl (IV)	0.5 g/kg (max 30 g) 10% arginine HCl in 0.9% NaCl over 30 min	0, 15, 30, 45, 60	
Insulin (IV)	0.05-0.1 IU/kg	0, 15, 30, 45, 60, 75, 90, 120	Hypoglycemia; requires supervision†
Glucagon (IM)	0.03 mg/kg (max 1 mg)	0, 30, 60, 90, 120, 150, 180	Nausea

*Tests should be performed after an overnight fast. Some authorities generally recommend that prepubertal children be "primed" with sex steroids (e.g., Premarin, 5 mg PO, the night before and the morning of the test, or ethinyl estradiol, 50 to 100 μg/day for 3 consecutive days before testing; or depot testosterone, 100 mg 3 days before testing). Patients should be euthyroid at time of testing.

†Insulin-induced hypoglycemia is a potential risk of this procedure, which is designed to lower the blood glucose by at least 50%. Documentation of appropriate lowering of blood glucose is recommended. If there is growth hormone deficiency, the lower dosage of insulin may be advisable, especially in infants. $D_{50}W$ solutions and glucagon should be available.

Arbitrary Definitions of "Subnormal" Response to Provocative Tests. Endocrine centers vary in their definition of a "normal" response to stimulation tests. Whereas early reports generally employed a cutoff level of 5 ng/mL, this was gradually increased to 7 ng/mL. With the availability of recombinant DNA–derived hGH, this level was increased to 10 ng/mL—although no data exist for validating any of these arbitrary cutoff levels. The lack of objective confirmation of any defined normal response can be seen in the use of language such as "lack of adequate endogenous growth hormone secretion"[684] and "inadequate secretion of normal endogenous growth hormone."[684] As reported by Guyda, many of the newer GH assays measure GH concentrations twofold to threefold lower than older assays and yet there has been no systematic reevaluation of the "normal" GH cutoff level.[670]

Age Dependency and Use of Sex Steroids. Serum GH concentrations typically rise during puberty, manifested as an increase in pulse-amplitude but not pulse frequency.[79,685] Immediately before puberty and during the earliest phases of puberty, GH secretion may normally be so low as to blur the distinction between GHD and constitutional delay of growth and maturation.[79,685] There are multiple reports of children who "failed" provocative testing before the onset of puberty but proved to have "normal" GH secretion after puberty or after administration of exogenous sex steroids.[686-689] A study of provocative GH testing in children of normal stature has clearly demonstrated the inherent problems with provocative GH testing and the need for standardization of sex steroid administration during stimulation tests.[690]

When exercise and arginine/insulin stimulation tests were administered to these normal children, the lower limit of normal (2 SD) for peak serum GH concentration in prepubertal children was only 1.9 ng/mL—whereas in children of Tanner stage 5 puberty this level was 9.3 ng/mL. When estrogen was administered before provocative testing, the lower 95% confidence limit for the normal serum GH range rose to 7.2 ng/mL. All in all, when estrogen was not administered 61% of the normal prepubertal children failed to raise their serum GH concentration above 7 ng/mL after three provocative tests. These children could have been erroneously labeled as having GHD.

GH Assays of Limited Accuracy. Several studies have demonstrated as much as threefold variability in the measurement of serum GH concentrations by established laboratories.[691,692] This is explained at least in part by the existence of several molecular forms of GH in serum and by the use of monoclonal versus polyclonal antibodies. The inevitable result has been that children labeled as having GHD by one assay would be considered normal by another.

A highly sensitive immunofunctional GH assay has been developed that measures concentrations of GH capable of binding to GHBP. It is not clear, however, that such assays necessarily have any advantages over standard radioimmunoassays for routine GH measurements.[693] When arginine/levodopa or arginine/insulin stimulation tests were used, approximately 50% of normal children had peak GH concentrations less than 7 ng/mL and 30% were less than 5 ng/mL whether GH was measured by immunofunctional assay or enzyme-linked immunosorbent assay.

Expense, Discomfort, and Risks of Provocative GH Testing. Provocative testing typically requires multiple timed blood samples and frequently necessitates parenteral administration of drugs. The resulting discomfort to the patient and expense are self-evident. In addition, insulin administration carries the risk of hypoglycemia and seizures and should be performed by experienced medical personnel under appropriate supervision. Death has been reported from insulin-induced hypoglycemia and from its overly vigorous correction with parenteral glucose.[694]

Poor Reproducibility of Provocative Tests. The reproducibility of provocative GH tests has never been adequately demonstrated, even when GH concentrations are determined with the same assay.[694] An alternative approach is the measurement of spontaneous GH secretion. This can be done either by multiple sampling (every 5 to

30 minutes) over a 12- to 24-hour period or by continuous blood withdrawal over 12 to 24 hours.[78,624,695,696] The former method allows one to evaluate and characterize GH pulsatility, whereas the latter only permits determination of mean GH concentration. Either approach, however, is subject to many of the same criticisms as provocative GH testing. The potential expense and discomfort of such testing are obvious. Furthermore, although it has been claimed that this technique is more reproducible than are provocative GH tests, variability remains problematic.[418,420,697,698] The ability of such tests to discriminate between GHD and normal short children is also an issue. Rose and colleagues[699] reported that spontaneous GH determinations identified only 57% of children with GHD, defined by provocative testing. In this report, no case of "neurosecretory dysfunction" could be identified in the group of normal short children. Similarly, Lanes and coworkers[700] reported that one fourth of normally growing children had decreased overnight GH concentrations.

Given the problems with GH testing in general, it is not surprising that provocative tests and 24-hour GH profiles do not correlate perfectly. It is in fact likely that 12- to 24-hour GH profiles can correctly identify the majority of children with GHD and may be superior in sensitivity and specificity to provocative GH testing. With the advent of more routine treatment of ISS with GH, GH testing is no longer the controversial topic it once was—and many experts recognize that a large overlap exists between GHD and ISS as they are commonly defined.

"Neurosecretory dysfunction" probably does exist in children who have had cranial irradiation and likely does describe a subgroup of children with GHD and IGF deficiency. However, the expense and discomfort of frequent overnight or 24-hour sampling combined with many of the problems intrinsic to GH determinations preclude this form of testing for GH deficiency from being the test of choice in establishing the diagnosis of GHD.

The measurement of GH concentrations in urine has provided an alternative means of assessing "integrated" GH secretion (or at least excretion).[701-703] This technique requires anti-GH antibodies of high affinity because urinary GH concentrations are normally low. It also requires timed urine collections. Adequate age- and sex-related standards have not yet been fully developed, and the diagnostic use of urinary GH determinations remains to be adequately evaluated.

Whereas some have interpreted these difficulties in measuring GH as a reason to stop performing GH testing altogether, we strongly recommend continuing use of this testing modality that is nevertheless critical to differentiating GHD from ISS, and secondary from primary IGFD. These conditions are vastly different in a variety of ways. Rather, we believe that the results of the GH testing should not serve as an absolute determinant of the decision to treat with GH (or other drugs, including IGF-I). A complementary approach to the diagnosis of GHD is the use of IGF-related assays.[209,210,213,236] GHD then becomes part of the differential diagnosis of IGF deficiency, which includes hypothalamic dysfunction, pituitary insufficiency, and GHI.

With the development of sensitive and specific assays for IGFs, as well as for the IGFBPs, it has become apparent that these peptides can reflect the GH status of the patient. Furthermore, they have the advantage that they normally circulate in serum at high concentrations—and thus assay sensitivity is less of an issue. Serum levels of these peptides remain relatively constant during the day, and provocative testing or multiple sampling is not necessary. It is important, however, to recognize the following potential limitations of assays for IGF-1.

- The IGFBPs potentially interfere with radioimmunoassays, radioreceptor assays, and bioassays.[215-217] These binding proteins must be completely removed, as with acid gel chromatography (which is labor intensive)[215-217] or blocked by the addition of excess IGF-2 (which requires a high-affinity antibody with a high degree of specificity for IGF-1).[218] An alternative approach is to employ a radiolabeled IGF-1 analog with reduced affinity for IGFBPs.[219]
- Serum IGF-1 concentrations are highly age dependent.[211,227,228] They are lowest in young children (< 5 years of age), the age at which one most wishes to have a simple diagnostic test.
- Serum IGF-1 concentrations may be reduced in a variety of conditions other than GHD. These include primary and secondary forms of GHI. Malnutrition or any cause of diminished insulin concentration (such as poor food intake, dieting, type 1 diabetes) and malabsorption (such as with celiac sprue) will result in low circulating IGF-1 levels. Patients whose weights are less than the 25th percentile for age are likely to have low IGF-1 levels in the range of classic GH deficiency, but their primary problem is malnutrition and not GH deficiency.
- Serum concentrations of IGF-1 (and IGFBP-3) are frequently normal in adult-onset GHD and in children with GHD resulting from brain tumors or cranial irradiation.

Even when these caveats are considered, the correlation between serum IGF-1 concentrations and provocative or spontaneous GH measurements is imperfect. Juul and coworkers[704] have reported that in children younger than 10 years of age, IGF-1 levels were below 2 SD in only 8 of 15 children with a diagnosis of GHD based on provocative testing (53.3% sensitivity) and were normal in 47 of 48 children with a normal GH response (97.9% specificity).

In one study, 18% of patients with abnormally low provocative GH concentrations had IGF-1 concentrations in the normal range but only 4% of "GHD" patients had normal serum concentrations of IGF-1 and IGF-2. Serum levels of IGF-1 and IGF-2 were reduced in only 0.5% of normal children and in 11% of normal short children.[213] The development of specific immunoassays for IGFBP-3, normally the major serum carrier of IGF peptides, has provided a supplementary means of establishing a diagnosis of IGF deficiency and GHD (Figures 10-21 and 10-29).[301,310,311] Because molar concentrations of IGFBP-3 correlate with the sum of the molar concentrations of IGF-1 and IGF-2, IGFBP-3 determinations offer the following advantages over assays of IGF peptides and other IGFBPs.

- IGFBP-3 immunoassays are technically simple and do not require any separation of the binding protein from IGF peptides.

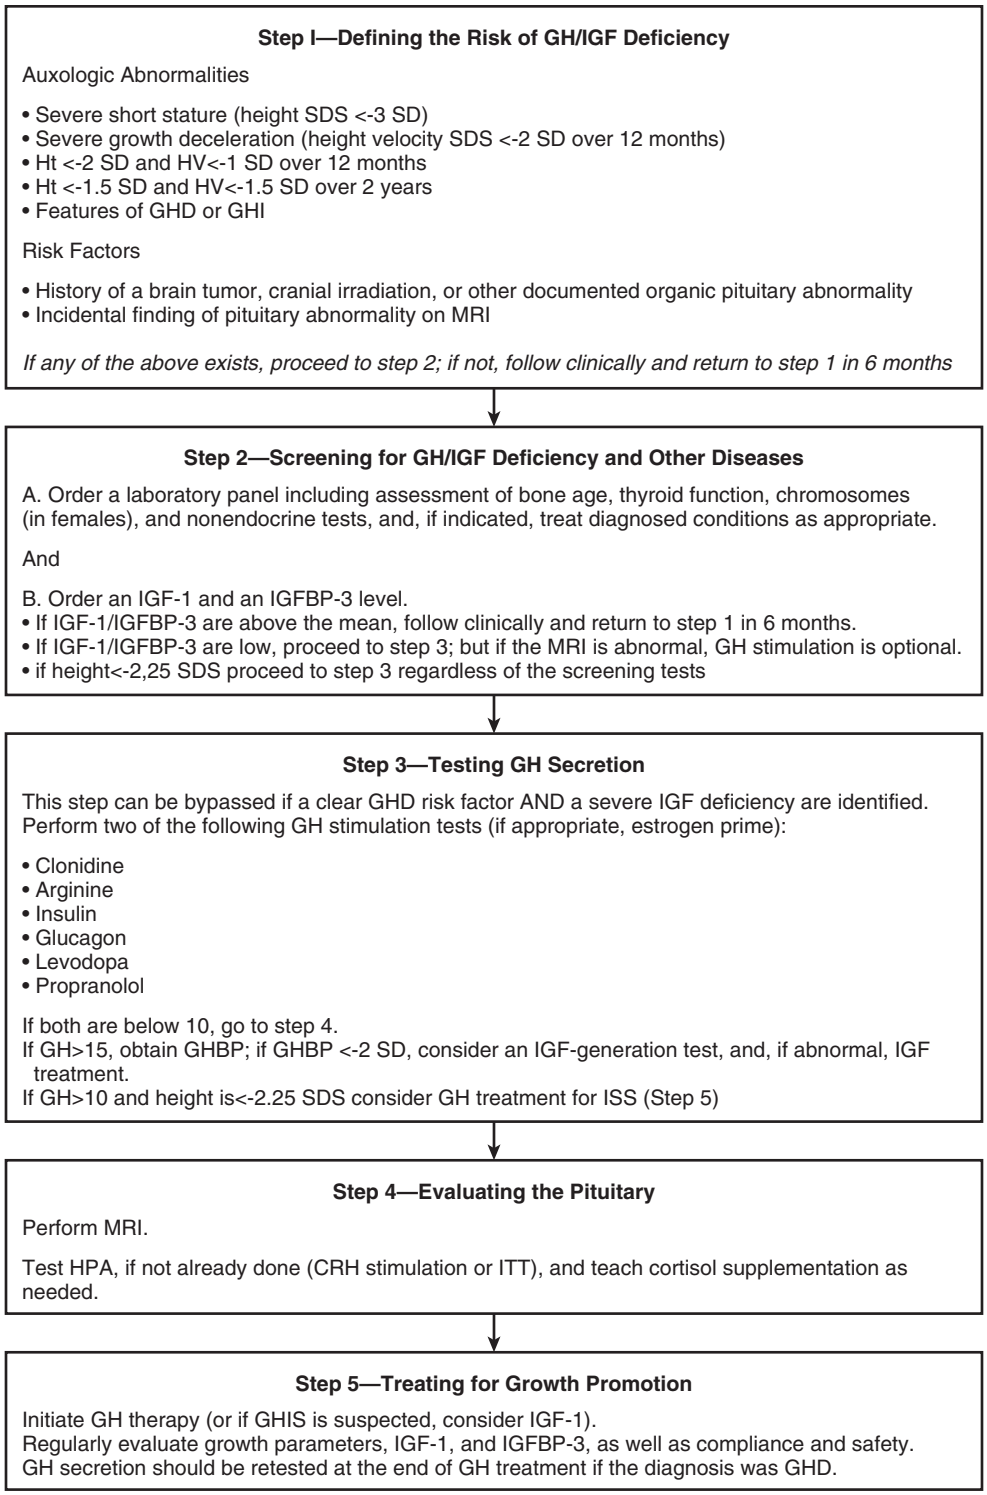

FIGURE 10-29 ■ Algorithm of biochemical evaluation of growth failure. CRH, corticotropin-releasing hormone; GH, growth hormone; GHBP, GH-binding protein; HPA, hypothalamic-pituitary axis; HV, height velocity; IGF, insulin-like growth factor; IGFBP-3, IGF-binding protein-3; ITT, insulin tolerance test; MRI, magnetic resonance imaging; SD, standard deviation; and SDS, standard deviation score.

- Normal serum concentrations of IGFBP-3 are quite high, typically in the 1- to 5-mg/mL range, and thus assay sensitivity is not an issue.
- Although age dependency exists, serum IGFBP-3 concentrations vary with age to a lesser degree than is the case for IGF-1. Even in infants, serum IGFBP-3 concentrations are normally sufficiently high to allow discrimination of pathologically low values from the normal range.
- Serum IGFBP-3 concentrations are less nutritionally dependent than concentrations of IGF-1, reflecting the "stabilizing" effect of IGF-2 concentrations.
- IGFBP-3 concentrations are clearly GH dependent.

The utility of IGFBP-3 assays in the diagnosis of GHD was evaluated by Blum and colleagues,[311] who found that serum IGFBP-3 concentrations were below the 5th percentile for age in 128 of 132 (97%) of children diagnosed as having GHD by conventional criteria (height < 3rd percentile, height velocity < 10th percentile, and peak serum GH < 10 ng/mL). At the same time, 124 of 130 (95%) of non-GHD short children had normal IGFBP-3 concentrations.

It is likely that Blum's patients largely consisted of children with severe GHD because this degree of correlation between provocative GH testing and serum IGFBP-3 concentrations has not been consistently identified. For example, Hasegawa and associates[705] reported that the sensitivity of the IGFBP-3 radioimmunoassay in complete GHD (peak GH < 5 ng/mL) was 93% but was only 43% in cases of partial GHD (peak GH 5 to 10 ng/mL). Smith and coworkers[706] found that 100% of children with severe GHD (peak GH < 1 ng/mL) and low serum IGF-1 also had decreased serum IGFBP-3. Four of 8 children with GHD and normal serum IGF-1 levels had reduced IGFBP-3 concentrations, and 10 of 23 (43%) of normal short children had decreased serum IGFBP-3. The addition of a radioimmunoassay for IGFBP-2 further enhanced the ability of IGF axis measures to identify children who had GHD by conventional criteria.

The correlation between IGF-axis determinations and measures of spontaneous GH secretion nevertheless remains imperfect. Even in healthy normal children the correlation between 24-hour GH secretion and serum IGF-1 and IGFBP-3 concentrations is modest ($r = 0.78$ and $r = 0.62$, respectively).[706] In the Smith study,[707] 18% of patients were found to have discordant measures of IGFBP-3 and provocative GH response. It is impossible at this time to resolve conflicts between assays of the IGF axis and measurements of GH secretion because there is no way to definitively diagnose GHD. Experience in patients with GHRD, however, has provided further evidence in support of the utility of IGF-related determinations.[110,708,709]

Although such patients may have normal or elevated serum GH concentrations, mutations or deletions of the GHR gene render them unresponsive to GH—and such patients may be considered "functionally GH deficient." In the experience in Ecuador, of approximately 70 documented cases of GHR gene mutations, all patients were found to have markedly reduced serum concentrations of both IGF-I and IGFBP-3. Even so, IGF-1 and IGFBP-3 correlated significantly with height. Measures of serum concentrations of IGF-1 and IGFBP-3 have been used in other studies of GHI to establish diagnostic criteria.

Ultimately, the diagnosis of GHD (or IGF deficiency) should be made on the basis of combined clinical and laboratory criteria. Short children who have well-documented normal height velocities do not generally require evaluation of GH secretion, and normal (> 25%) serum IGF-1 and IGFBP-3 concentrations can be reassuring. Children with Turner syndrome and short stature that is consistent with the expected growth pattern for this syndrome should not be required to undergo GH testing to qualify for GH therapy because such treatment is not predicated on abnormal GH secretion.

On the other hand, the child with documented growth deceleration requires further evaluation—even if tests of GH secretion appear normal. Documentation of decreased serum IGF-1 or IGFBP-3 concentrations would then constitute a diagnosis of IGF deficiency, and the diagnoses of GHD and GHI would need to be considered. The child with a history of cranial irradiation, decreased height velocity, and reduced serum concentrations of IGF-1 and IGFBP-3 should be considered to have GHD—even in the presence of normal provocative tests.

This approach still requires measurements of GH secretion. Such determinations are critical to distinguishing between GHD and GHI as causes of IGF deficiency. Documentation of abnormal pituitary GH secretion alerts the physician to the possibility of intracranial tumors and to the potential for other pituitary hormone deficiencies. Evaluation for GHD allows for concomitant assessment of ACTH secretion, and TSH and gonadotropin determinations can be added where appropriate. Ultimately, however, one must conclude that the single most important parameter in assessment of children with growth failure is careful clinical evaluation—including accurate serial measurements of height and determinations of height velocity.

The possibility of hypothalamic-pituitary dysfunction should always be considered in children with documented growth deceleration, particularly in the presence of a known intracranial pathologic process (e.g., tumors, irradiation, malformations, infection, trauma, blindness, nystagmus). Similarly, the neonate with hypoglycemia or microphallus warrants evaluation of pituitary function—and patients with documented TSH, ACTH, ADH, or gonadotropin deficiency are candidates for GHD. For children with proportional short stature and documented growth deceleration, assessment of serum concentrations of IGF-1 and IGFBP-3 is clearly warranted—and based on those results the possibilities of hypothalamic dysfunction, pituitary insufficiency, and GHI can be investigated.

Recommendations by the Growth Hormone Research Society (GRS) for the diagnosis of GHD recognize that there is no "gold standard" for the diagnosis of GHD and suggest that in a child with slow growth whose history and auxology suggest GHD, testing for GH/IGF-1 deficiency requires the measurement of IGF-1 and IGFBP-3 levels as well as GH provocation tests (after hypothyroidism has been excluded). In suspected isolated GHD, two GH provocation tests (sequential or on separate days) are required. In those with a defined CNS pathologic process, history of irradiation, MPHD, or genetic defect, one GH test will suffice. In addition, an evaluation of other pituitary function is required. In patients who have had cranial irradiation or malformations of the hypothalamic-pituitary unit, GHD may evolve over years and its diagnosis may require repeat testing of the GH-IGF axis.

It is recognized, however, that some patients with auxology suggestive of GHD may have IGF-1 or IGFBP-3 levels below the normal range on repeated tests but GH responses in provocation tests above the cutoff level.

These children are not classically GH deficient but may have an abnormality of the GH/IGF axis, and after the exclusion of systemic disorders affecting the synthesis or action of IGF-I could be considered for GH treatment. An MRI (or computed tomographic scan) of the brain with particular attention to the hypothalamic-pituitary region should be carried out in any child diagnosed as having GHD. These GRS recommendations underscore the importance of good clinical judgment rather than specific tests as the key to the diagnosis of GHD.

Testing in the Neonate. The diagnosis of GHD in a newborn is particularly challenging and important. The presence of a micropenis in a male newborn should always be addressed by an evaluation of the GH axis. A GH level should always be measured in the presence of neonatal hypoglycemia in the absence of a metabolic disorder. A GH level in a polyclonal radioimmunoassay of less than 20 mg/L would suggest GHD in the newborn. The use of standard GH stimulation tests is not recommended in newborns, with the exception of the glucagon test (which is safe). In the newborn, although normative data are not available for stimulated serum GH, a cutoff value of 25 ng/mL is probably appropriate and certainly stimulated values under 20 ng/mL should raise suspicion.

An MRI is essential when the diagnosis is suspected, and results may be available sooner than with serum assays. An IGFBP-3 level is of great value to the diagnosis of GHD in infancy, but IGF-1 levels are rarely helpful.[711] In fact, serum IGFBP-3 should be performed as the test of choice in suspected neonatal GHD. Figure 10-29 provides an algorithm for the biochemical evaluation of growth failure. The diagnosis of IGF or GHD should be considered in any child who meets one or more of the criteria listed in Box 10-6.

A child should be considered a candidate for GH therapy if he or she meets one of these criteria, supported by biochemical evidence of GHD based on sex-steroid–primed provocative tests or evidence of IGF deficiency based on measurement of IGF-1 and IGFBP-3 concentrations. Such cases need to also have MRI of the hypothalamus-pituitary and assessment of other pituitary hormone deficiencies. It is understood that this approach will result in GH treatment of some children with "idiopathic isolated" GHD or IGF deficiency and that such cases require careful monitoring of both pituitary status and responsiveness to GH treatment. The latter can be assessed relative to recently developed predictive models,[710] and the diagnosis of GHD should be reconsidered in the child with idiopathic isolated GHD, a normal MRI, and a subnormal clinical response to GH.

BOX 10-6 Key History and Physical Examination Findings That May Indicate GH Deficiency

- In the neonate; hypoglycemia, prolonged jaundice, microphallus, or traumatic delivery
- Cranial irradiation
- Head trauma or central nervous system infection
- Consanguinity or an affected family member
- Craniofacial midline abnormalities
- Severe short stature (< − 3 SD)
- Height (< − 2 SD) and a height velocity below over 1 year (< − 1 SD)
- A decrease in height SD of more than 0.5 over in children > 2 years of age
- A height velocity below − 2 SD over 1 year
- A height velocity more than 1.5 SD below the mean sustained over 2 years
- Signs indicative of an intracranial lesion
- Signs of multiple pituitary hormone deficiency
- Neonatal symptoms and signs of growth hormone deficiency

SD, standard deviation.
